- Prophylactic, elective neck dissection for the N0 melanoma of neck has failed to demonstrate an overall survival benefit and is no longer advocated. Instead, the procedure has been replaced by sentinel lymph node mapping and biopsy, which is a minimally invasive, cost-effective, and efficient means to screen patients for regional disease. This screening modality identifies the 10% to 20% of patients with occult nodal metastasis, who then may benefit from therapeutic lymph node dissection and adjuvant therapy.
- High dose interferon-α 2b remains the only FDA adjuvant treatment approved by the U.S. Food and Drug Administration for stage III disease. It is reserved for patients at high risk for tumor recurrence, including individuals with regional metastasis or a primary lesion more than 4 mm in thickness.
- Hypofractionated radiation therapy is also an adjuvant treatment for high-risk patients with extracapsular spread or multiple node involvement. Additional roles for this modality are palliative care and, on rare occasions, as the primary treatment for extensive lentigo maligna melanomas in patients who are not candidates for surgery.

Although the overall trend in the United States demonstrates both a stabilization of cancer incidence and a decrease in cancer death rates, the incidence of cutaneous melanoma continues to rise dramatically on an annual basis.[1,2] The diagnosis is growing in men faster than any other malignancy; for women, the increase in incidence is second only to that for lung cancer.[3] Overall, cutaneous melanoma remains the sixth leading cause of cancer among men and the seventh cause among women. The current annual budget for melanoma treatment in the United States exceeds $740 million.[4]

Fortunately, the management of cutaneous melanoma is also one of fastest-evolving fields in cancer, with promising research taking place at both the molecular and clinical levels. Greater understanding of melanoma biology prompted major changes in the staging classification system set forth by the American Joint Committee on Cancer (AJCC).[5] Given its association with sun exposure, melanoma is considered a preventable disease. Decreases in incidence and mortality ultimately hinge upon increases in education, prevention, and early diagnosis, as well as improved treatment for advanced disease.

Epidemiology

Despite a decline in overall cancer trends, the incidence of invasive cutaneous melanoma continues to rise dramatically, with an estimated 62,480 new cases anticipated in 2008.[1] Over the past 50 years, the annual percentage change in invasive melanoma incidence has steadily increased by 4.3% each year. The lifetime risk for development of invasive melanoma has climbed at an epidemic rate, rising from 1 in 1500 individuals born in 1935 to 1 in 250 born in 1980.[6] This trend is expected to continue at a startling rate, with a current estimation that 1 in 41 men and 1 in 61 women will have invasive carcinoma during their lifetimes.

Melanoma is the most lethal form of skin cancer, accounting for 8110 American deaths in 2007, 8420 deaths in 2008, and an expected 8650 deaths in 2009.[1,2] These estimates average to approximately one American dying from melanoma every hour. Over the past 50 years, the annual percentage change in mortality rate has increased at a steady rate of 1.8% per year. Melanoma accounts for the second highest increase in mortality rate, especially for men older than 65 years. However, it should not be viewed as a cancer limited to the elderly because 1 in 4 patients are diagnosed before age 40, and it is the third most common cancer among women ages 20 to 39.[4,6,7] Consequently, melanoma represents one of the leading cancer causes of lost potential life years, ranking second only to leukemia.

Approximately 25% of all cutaneous melanomas arise in the head and neck region,[8] with more than 9000 cases diagnosed annually. The majority involve the cheek, scalp, and neck. A slight male preponderance is consistently reported,[9-11] and the median age at diagnosis is 55 years.[7] However, juvenile cases account for 1.66% of head and neck melanoma cases, and patients as young as 4 years are diagnosed with these lesions.[12,13]

Etiology and Risk Factors

Numerous environmental and genetic risk factors have been implicated in the development of cutaneous melanoma.[14] They are summarized in Box 82-1.

Risk Factors

Sun exposure is considered the leading cause of melanoma.[15,16] Patients who experienced peeling or blistering sunburns, even during childhood, are at particular risk.[17] Associated factors include blond or red hair, green or blue eyes, and fair skin consistent with Fitzpatrick skin types I through III.[18] Adults with more than 100 clinically normal-appearing nevi, children with more than 50 clinically normal-appearing nevi, and any patients with atypical or dysplastic nevi are also at risk.

A prior history of melanoma poses a greater risk; 5% to 10% of individuals diagnosed with melanoma experience a second primary melanoma.[16] This increased risk remains lifelong, and the melanoma can occur anywhere on the skin. For this reason, long-term follow-up with a thorough total body examination is critical.

Box 82-1

Risk Factors Associated with Cutaneous Melanoma

Environmental/Sun Exposure

Inability to tan
Fair complexion/inability to tan
Blue/green eyes
Blonde/red hair
Freckling
History of blistering/peeling sunburns
Immunosuppression
Teenage outdoor summer jobs
Tanning booth exposure

Genetic/Past Medical History

CDKN2A (p16) mutation
Family history of melanoma
History of prior melanoma
Actinic keratoses
Nonmelanoma skin cancer
Xeroderma pigmentosa
Atypical (dysplastic) nevus
Giant congenital melanocytic nevus

Genetics

A genetic component has been implicated in the pathogenesis of melanoma[19]; 10% to 15% of patients with melanoma report a positive family history.[20] The most common chromosomal mutation associated with melanoma involves CDKN2A, which is also known as p16.[21] However, the mutation accounts for only a small percentage (0.2%) of melanoma cases observed.[22]

B-K mole syndrome is a hereditary form of cutaneous melanoma in which members acquire large, irregular, and dysplastic nevi, often in sun-protected regions of the body, such as the scalp and trunk.[23] A familial association of melanoma among individuals with atypical nevi has also been coined *familial atypical multiple mole-melanoma (FAMMM) syndrome*.[24] Today, the term "*atypical mole syndrome*" is applied to familial cases of melanoma. The syndrome is inherited in an autosomally dominant fashion.[25,26] The 10-year melanoma risk in this setting is reported to be 10.7%, compared with 0.62% in control patients.[27,28] Fitzpatrick and Ortonne[18] and Greene and associates[29] approximated a 56% cumulative risk from age 20 to 59 years, which predicts that 100% of patients with atypical mole syndrome would have melanoma by age 76.

Xeroderma pigmentosa is a rare hereditary disorder also associated with melanoma; it is inherited in an autosomally recessive fashion.[30] The fibroblasts in patients with this disease have a reduced or no ability to repair DNA that has been damaged by ultraviolet light.[31] Consequently, multiple primary cutaneous malignancies, including melanoma, basal cell carcinoma, and squamous cell carcinoma, develop. Individuals are usually diagnosed with their first cancer prior to age 10. Unfortunately for patients with xeroderma pigmentosa, the relentless development of skin cancers—as well as other cancers—ultimately leads to death at an early age.

Congenital Nevi

Congenital melanocytic nevi (CMN) are present at birth or appear within the first 6 months of life[32]; an estimated 1% to 6% of children are born with CMN. The nevi are classified by size: small CMN measure less than1.5 mm in diameter and account for the majority of lesions; medium-sized CMN measure between 1.5 and 19.9 mm in

diameter; and large CMN, which are also called giant congenital nevi, measure 20 mm or more. This large size can have significant cosmetic and psychosocial implications.[28]

The risk of melanoma development in small- and medium-sized CMN is similar to that in any other nevi. Melanoma development usually occurs after childhood and arises from the dermoepidermal junction, which makes early detection and intervention feasible. Routine prophylactic removal of small and medium CMN is rarely indicated in the absence of signs or symptoms indicative of malignant progression.

Conversely, giant CMN carry an increased risk for melanoma, with an estimated 5% to 20% of patients with these lesions eventually experiencing cancer.[33,34] Seventy percent of these individuals are diagnosed before age 10 years.[35] Melanoma in the setting of giant CMN originates deep within the epidermis, thus potentially delaying the diagnosis and treatment.

Melanoma Classification

Several histologic subtypes of melanoma are recognized within the head and neck region. It is important to note that if data are corrected for other prognostic variables, such as tumor thickness and ulceration, melanoma subtype does not generally influence prognosis.[36]

In general, superficial spreading melanoma is the most common type of cutaneous melanoma, accounting for approximately 70% of all cases. It commonly arises in the setting of a preexisting nevus, with a diagnosis rendered during the fourth or fifth decade. Characteristic features include color variation and border asymmetry. Nodular melanoma is the second most common subtype on the skin, accounting for 15% to 30% of cases. This lesion typically appears as a blue-black or blue-red nodule. For this reason, a nodular melanoma must be differentiated from hemangioma, blue nevus, pyogenic granuloma, and pigmented basal cell carcinoma.

Lentigo maligna (LM) represents intraepidermal or in situ melanoma. Histologically, it is often seen in the background of chronic sun damage. LM is the precursor to invasive lentigo malignant melanoma (LMM). The exact percentage of LMs that progress to invasive LMM remains unknown[37]; however, it is speculated that, if patients live long enough, all LMs will eventually progress to cancer. LM/LMM is most often found in the head and neck region. Traditionally, the subtype has been associated with older individuals, but the frequency in younger patients is increasing. The LM/LMM pattern warrants special comment, because this subtype is characterized by asymmetric, subclinical, and often extensive involvement of margins with atypical junctional melanocytic hyperplasia. Therefore, management with adequate wide margins can be challenging from both a functional and cosmetic standpoint. Additionally, amelanotic melanoma and invasive desmoplastic melanoma (see later) often arise within LM/LMM.

Desmoplastic-Neurotropic Melanoma

Desmoplastic melanoma (DM) describes a subtype composed of spindle cells, abundant collagen, and features resembling fibromas.[38] Some lesions demonstrate a propensity for perineural and endoneural infiltration, which prompted further subclassification of a desmoplastic neurotropic melanoma (DNM) variant.[39]

DM/DNM subtypes are rare, accounting for approximately 1% of all cutaneous melanomas.[40] However, up to 75% of the lesions manifest in the head and neck region, often in the setting of LM/LMM. The clinical presentation and biologic behavior of these tumors are distinct from those of other cutaneous melanomas. Although amelanotic cases account for only 4% to 5% of cutaneous melanomas, up to 73% of DM/DNMs are amelanotic.[40,41] As demonstrated in Figure 82-1, the neoplasms often lack the typical ABCD criteria for melanoma (described later), and they can have a difficult histologic pattern that requires interpretation by an experienced pathologist. Overall, the atypical and challenging appearance of DM/DNM is thought to result in a delay in diagnosis. This fact provides one explanation for the reason that patients with DM/DNM present with thicker, more aggressive tumors.

DM/DNM is known to be locally aggressive and highly infiltrative, often leading to cranial nerve and skull base involvement. Local recurrence has been reported in up to 50% of cases.[40] Explanations for this high rate include the association with neurotropism and the failure to recognize and adequately clear peripheral atypical junctional melanocytic hyperplasia margins. Although DM/DNM demonstrates greater tumor thickness at the time of diagnosis, the 12.5% rate of regional lymph node metastasis is lower than that for other melanoma subtypes.[39]

Figure 82-1. Desmoplastic melanoma of the nose. Note the amelanotic appearance and the absence of typical ABCD findings associated with other melanoma subtypes.

Mucosal Melanoma

Mucosal melanoma is recognized as a distinct subtype from its cutaneous counterpart. The most common site for mucosal melanoma is the head and neck, with 40% to 50% of cases arising in this location.[42] However, less than 2% of all head and neck melanomas are mucosal in origin. Of the 84,836 melanoma cases registered in the National Cancer Database from 1985 to 1994, only 1074 (1.3%) were of the mucosal melanoma variant.[43]

Although small case numbers limit research to anecdotal reports, several common trends have been noted throughout the literature. The peak age for mucosal melanoma is during the sixth to seventh decade, which is approximately 10 to 15 years later than that for cutaneous melanoma.[42,44-47] A slight male preponderance has also been reported.[45,47,49] Ethnic differences have been observed; approximately 8.8% of mucosal melanoma cases afflict blacks and Hispanics, a considerable percentage given that less than 3% of all other melanoma variants are diagnosed among this group.[48] The relative frequency is also exceedingly high in Japan, where mucosal melanoma accounts for 7.5% of all melanoma cases.[50]

Within the head and neck region, the most common site of origin is the nasal cavity, where the anterior nasal septum is most often involved, followed by the inferior and middle turbinates.[46,49,51,52] The second most common site is the oral cavity, where a predilection for the hard palate and maxillary alveolar gingivae has been found. A review of five major mucosal melanoma series by Batsakis and colleagues[51] found laryngeal primary tumors to account for less than 4% of all cases. Within the larynx, the supraglottis was the most common site of origin.

The presenting signs and symptoms of mucosal melanoma directly correlate with the anatomic site of origin. The majority of patients with nasal cavity primary tumors present with nasal obstruction and epistaxis.[49,51,52] Proptosis, diplopia, pain, and facial deformity are less common and indicate advanced disease. When present, the most common sign of an oral cavity tumor is a mass lesion.[52] However, oral cavity mucosal melanoma is often asymptomatic, going undiagnosed until a neck mass develops from metastasis.[44,49]

Many of the prognostic markers for cutaneous melanoma do not have correlates in mucosal sites.[42] Consequently, the cutaneous melanoma staging system set forth by the AJCC (see later) may be less applicable to mucosal melanoma. Most patients with mucosal melanoma present with localized disease, and in only 18.7% is regional spread detected at the time of diagnosis. The high percentage of patients with stage I disease is deceiving, because local recurrence is the major reason for treatment failure.[51] Fifty percent of patients have local recurrence,

usually within 9 to 12 months of diagnosis, and the overall 5-year survival rate is a dismal 10% to 20%.[45-47,51] Rich submucosal vasculature and lymphatics are thought to account for the aggressive behavior of mucosal melanoma.[51]

Unknown Primary

Approximately 2% to 8% of cases of melanoma involve unknown primary sites.[43,48,53] In two thirds of the cases, the patients present with regional metastasis in the absence of an identifiable primary lesion or history of melanoma; the remaining third of unknown primary cases involve distant metastasis to sites such as the subcutaneous tissues, lung, and brain.[48,53-55] Several theories have been proposed to explain melanoma of unknown primary origin. The identification of melanocytes and nevus cells within the lymph node capsule and visceral organ epithelium lends credence to the belief that unknown primary cases result from melanoma arising de novo at regional and distant sites.[43,56] Another clinical scenario is that the primary melanoma lesion undergoes complete spontaneous regression.[56,57]

The diagnosis of melanoma of unknown origin necessitates a search for the primary site with a total body skin and mucosal evaluation. A history of a previous skin biopsy or a skin lesion that spontaneously disappeared may be helpful. All pathology slides from previously excised lesions should be re-reviewed. The metastatic workup is identical to that for known primary cases (see later). After adjustment of data for tumor stage, melanomas of unknown primary origin share an overall prognosis equivalent to their counterparts with known primary sites.[43,53-55]

Diagnostic Workup

History

The majority of melanoma lesions are first detected by the patient or his/her significant other.[58,59] Less than one fourth of lesions are diagnosed during routine office physical examination, and these latter lesions tend to be thinner.[59] Overall, 80% of newly diagnosed melanomas are limited to localized, stage I/II disease.[2]

The earliest signs of melanoma are a change in color, size, or shape of a lesion, and pruritus is the earliest symptom. Later signs and symptoms, which are usually associated with a more advanced lesion, include bleeding, ulceration, and tenderness. Patients should be questioned about a personal and family history of melanoma. Information about previous skin biopsies, sun exposure, history of blistering sunburns, use of tanning booths, chronic sun exposure, and occupation should be obtained. Schwartz and colleagues[59] investigated characteristics of 1515 patients with melanoma and found that 81% elicited a history of at least one sunburn.

Physical Examination

All patients presenting with a suspicious lesion warrant full evaluation of the skin and nodal basins by a physician who is well versed in cutaneous cancers. Thorough evaluation is imperative because up to 8% of newly diagnosed patients have multiple primary cutaneous melanomas.[16,60-62]

The differential diagnosis for cutaneous melanoma is broad and includes seborrheic keratosis, hemangioma, blue nevus, Spitz nevus, pyogenic granuloma, pigmented basal cell carcinoma, and cutaneous squamous cell carcinoma. The American Cancer Society has published the ABCD checklist to educate both patients and physicians about the early detection of melanoma.[63] Under these guidelines, concerning signs for melanoma are as follows:

*A*symmetry in appearance

*B*order irregularity, such as scalloped, poorly circumscribed, or ill-defined margins

*C*olor variation within a lesion, such as shades of black, red, white, or blue

*D*iameter of more than 6 mm

Although the ABCD checklist is helpful for the identification of melanoma, it does not detect every case.[64,65] It is important to realize that a subset of cancers (e.g., amelanotic, desmoplastic, and nodular melanoma) lack the common features of the ABCD list. In one series, 88% patients with melanoma (615 of 696) recalled change in their pigmented lesions prior to melanoma diagnosis.[66] Owing to the significance of change, a proposal has been set forth to add "*E*volving changes" to the traditional ABCD warning signs.[63] Clinicians are hopeful that the new, more comprehensive ABCDE criteria will lead to even further detection of melanoma at an earlier stage.[66] Another useful screening tool is the "ugly duckling sign,"[67] whereby any pigmented lesion that appears significantly and singularly different from other surrounding lesions should be viewed with a high index of suspicion, even if the lesion lacks the traditional ABCD criteria.

Biopsy

Any pigmented lesion that demonstrates an ABCD warning sign, has undergone change, or appears different from surrounding nevi on the body necessitates histologic evaluation. The biopsy of a potential melanoma should be considered a two-step process. The first step involves biopsy not only for tissue diagnosis but also to evaluate important prognostic factors such as tumor depth, ulceration, mitotic rate, angiolymphatic invasion, and perineural spread. Ideally, a complete excisional biopsy with a narrow, 1- to 2-mm, clinical margin of surrounding skin is performed. For lesions that are not amenable to excisional biopsy because of large size or anatomic location, punch biopsy or incisional biopsy through the thickest portion of the neoplasm is recommended. Superficial shave biopsy and find-needle aspiration are discouraged, because neither procedure allows the thickness of the tumor, which dictates further diagnostic workup and treatment, to be determined. It is important to realize that punch and incisional biopsies are subject to sampling error. If a diagnosis of melanoma in this setting is not rendered, a second biopsy may be necessary.

The pathology results from this biopsy then serve as the guide for the second step, which entails wide local excision (WLE) utilizing a 0.5- to 2-cm margin of normal surrounding skin, with or without sentinel lymph node [mapping and] biopsy (SLNB). The role of SLNB ultimately depends on the final microstaging of the primary lesion and is detailed later. Although obtaining wider margins at the time of the initial biopsy seems efficient and cost effective, it is highly discouraged because clinical accuracy is uncertain and removal of significant amounts of skin surrounding the lesion may compromise the ability to accurately stage regional lymph node basins by means of lymphoscintigraphy and SLNB techniques.[68] Instead, biopsy with narrow margins in a two-step fashion is advocated.

Metastatic Workup

In an attempt to standardize staging workup for melanoma, a panel of the National Comprehensive Cancer Network (NCCN) has published guidelines.[69] The metastatic workup performed at our institution, which accords with these guidelines, is summarized in Table 82-1.

Patients presenting with localized stage I disease simply require a thorough history and physical examination. Many physicians advocate a screening chest radiograph, because the lung is the most common site for distant metastasis.[68] Although a chest radiograph is an inexpensive, noninvasive means of metastatic evaluation, the rate of detection of occult pulmonary metastasis on chest radiograph in an asymptomatic patient with stage I or II disease is exceedingly low (0.1%).[70,71] The high false-positive rate, 15%, necessitates additional and costly evaluations. Evidence supporting the use of other screening modalities, such as computed tomography (CT),[72,73] liver-spleen scans, magnetic resonance imaging, and bone scans for patients with limited stage I and II disease is also lacking.[74,75] For this reason, the National Comprehensive Cancer Network panel unanimously agreed that a search for visceral metastases, with either a chest radiograph or blood analysis, is not warranted for a patient with in situ or thin, stage IA lesions. A baseline chest radiograph is considered optional for thicker stage IB and II lesions. Imaging studies (CT, magnetic resonance imaging, positron emission tomography) may be obtained in this setting if there are specific concerning signs or symptoms.[69] Screening serum lactate dehy-

drogenase (LDH) measurement carries a 15% false-positive rate, does not correlate with sentinel lymph node (SLN) status, and has not been helpful in detecting occult disease in asymptomatic patients.[76] For this reason, our institution recommends LDH measurement only when the history or physical examination reveals jaundice, abdominal pain, or other specific findings that raise concern about distant metastasis.[77]

Patients with clinically or radiographically suspicious lymph nodes, satellite lesions, or *in-transit metastasis* (defined as intralymphatic tumor dissemination between the primacy lesion and draining nodal basin) are considered to have stage III disease and are at higher risk for distant metastasis. Fine-needle aspiration is an accurate and cost-effective means of confirming metastatic melanoma within lymph nodes.[78] Additional imaging studies should be ordered according to the patient's history and physical findings. A list of symptoms that warrant a focused investigation of systemic metastasis is summarized in Box 82-2.[79] Overall, the yield of screening CT in patients with stage III melanoma has been low[77,80-82]; however, many physicians obtain the studies to serve as a baseline for future comparison.

Patients with known stage IV disseminated melanoma require a complete evaluation for systemic metastasis. LDH measurements and chest radiography or chest CT are recommended. CT of the abdomen and pelvis, magnetic resonance imaging of the head, and a positron emission tomography scan (whole body) should also be considered. In this setting, workup is often dictated by clinical trial protocols. Unfortunately, greater survival has not been demonstrated for patients who are asymptomatic when diagnosed with their distant, stage IV disease than for their symptomatic counterparts[76]; however, this thorough evaluation may lead to a better quality of life.

Prognostic Factors and Tumor Staging

As a result of a greater understanding of the biology of cutaneous melanoma, the AJCC introduced a revised staging system in 2001.[5,83]

Box 82-2

Review of Systems for Melanoma and Metastasis

Skin/Lymphatics
Change (i.e., size, shape, color)
Lesion or persistent pruritus
Enlarged lymph nodes
Mass/nodules
Nonhealing/bleeding skin lesions
Easy bruising
New pigmented skin lesions

Constitutional
Weight loss
Malaise
Decreased appetite
Weakness
Fatigue
Fever

Respiratory
Cough
Hemoptysis
Pneumonia
Pleurisy
Chest pain
Dyspnea

Hepatic
Abdominal pain
Right upper quadrant pain
Back (scapula) pain on inspiration
Jaundice

Neurologic/Psychiatric
Headache
Memory disturbance
Depression
Focal central nervous system symptoms
Visual disturbances
Balance problems
Blackouts
Seizures
Numbness
Local weakness
Paralysis
Mood swings

Gastrointestinal
Cramping
Abdominal pain
Bleeding
Nausea
Anorexia
Vomiting
Constipation

Musculoskeletal
Bone pain (e.g., rib, spine, hip)

The goal of modifying the classification system was twofold. The main objective was to develop categories based on the most important independent prognostic markers for melanoma. Doing so may make it easier to identify cohorts of patients who have similar survival rates, thereby leading to increased homogeneity in future clinical trials. To achieve this goal, reliable prognostic markers recognized throughout the literature were studied among a cohort of 17,600 patients with melanoma from 13 major cancer institutions.[83] This investigation marks the largest analysis of its kind to date. The second goal was to provide physicians with a practical classification system that mirrors clinical practice.

Summary of Revisions

The current AJCC staging system for cutaneous melanoma remains founded upon the traditional tumor, node, metastasis (TNM) classification system (Tables 82-2 and 82-3). Stage I and stage II represent localized disease, stage III is regional disease, and stage IV is reserved for distant metastatic disease. The most important predictors for survival now serve as criteria for the definition of melanoma stage and are summarized in Box 82-3. Major revisions of the staging system are highlighted in Box 82-4.

T Classification: Localized Disease

Multivariate analysis of 13,581 patients with localized disease identified tumor thickness and ulceration as the most important predictors of outcome. Overall, tumor thickness was the most powerful prognostic indicator for this subgroup. The 1997 staging system had employed the empirically based Breslow depth of 0.75 mm to differentiate T1 from T2 lesions.[84] The revised staging system now uses even-integer cut-points of 1.0, 2.0, and 4.0 mm to delineate T stage. These new cut-points represent the best statistical fit in the correlation of tumor thickness and survival.

In the previous staging system, histologic level of invasion, as represented by the Clark scale (Fig. 82-2), was also used in the definition of T classification. However, the analysis by Balch and associates[83] found the histologic level of invasion to be prognostic only for thin T1 lesions. For tumors 1 mm or thinner without ulceration, invasion to Clark level II or III is considered T1a, whereas invasion into the reticular dermis (level IV or V) is considered T1b. With the exception of T1 lesions, Clark level of invasion is no longer used in staging melanoma.

Tumor ulceration was the second most important prognostic indicator for patients with localized disease. Ulceration is not a visible crater on gross examination but, rather, a histologic diagnosis in which intact epidermis overlying the melanoma is absent. Survival rates were found to be significantly lower for all patients with ulcerated lesions than for their counterparts without ulceration. In fact, the survival of patients with ulcerated tumors mirrored that of patients with nonulcerated tumors in the next highest T categories; for this reason, ulceration warrants classification of a tumor to a higher stage. The prognostic significance of ulceration[85] and the correlation between ulceration and mitotic rate have been reported.[86,87] Although mitotic rate was not evaluated during the revision of the AJCC staging system, it may become an important prognostic marker in the future.

Nodal Classification: Regional Disease

Similar multivariate analysis was performed in more than 1000 patients with melanoma diagnosed with lymph node metastasis. The following three prognostic factors met statistical significance, at $P < .0001$: (1) number of metastatic lymph nodes, (2) tumor burden as represented by microscopic versus macroscopic disease, and (3) primary tumor ulceration. The gross diameter of metastatic nodes was previously used in N classification but is no longer incorporated into the staging system owing to a lack of compelling evidence supporting its predictive value.[72,88]

Overall, the most important predictive marker for patients with nodal metastasis was the number of positive lymph nodes.[83] The greatest difference in 5-year survival rates was used to subclassify the N category. Patients with one metastatic node are now categorized as having N1 disease, patients with two or three metastatic nodes as having N2, and patients with four or more nodes as having N3.

The second most important prognostic indicator for patients with regional metastasis was tumor burden. Patients identified as having microscopic nodal disease, through either SLNB or elective lymphadenectomy, were found to have a significantly better survival than individuals diagnosed with macroscopic disease on the basis of clinical or radiographic examination.[83] This difference was so compelling that microscopic versus macroscopic nodal disease is now subclassified

Table 82-2

TNM Classification for Melanoma

T Classification	Thickness (mm)	Ulceration Status
T1	≤ 1.0 mm	a: without ulceration and level II/III b: with ulceration or level IV/V
T2	1.01-2.0 mm	a: without ulceration b: with ulceration
T3	2.01-4.0 mm	a: without ulceration b: with ulceration
T4	> 4.0 mm	a: without ulceration b: with ulceration
N Classification	**No. of Metastatic Nodes**	**Nodal Metastatic Mass**
N1	1 node	a: micrometastasis* b: macrometastasis†
N2	2-3 nodes	a: micrometastasis* b: macrometastasis† c: in-transit metastasis(es) satellite(s) without metastatic nodes
N3	4 or more metastatic nodes, or matted nodes, or in-transit metastasis(es)/ satellite(s) with metastatic node(s)	
M Classification	**Site**	**Serum Lactate Dehydrogenase Level**
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases Any distant metastasis	Normal Elevated

*Micrometastases are diagnosed after sentinel or elective lymphadenectomy.
†Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.

*Clinical staging involves microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.
†Pathologic staging consists of microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Patients with pathologic stage 0 or stage 1A lesions are the exception; they do not require pathologic evaluation of their lymph nodes.
‡There are no stage III subgroups for clinical staging.

Box 82-3

Summary of the Most Important Predictors of Survival that Serve as Criteria for the 2001 American Joint Committee on Cancer Cutaneous Melanoma Staging System

Stage I and II Localized Disease
Tumor thickness
Tumor ulceration
Histologic level of invasion for T1 lesions only

Stage III Regional Disease
Number of metastatic lymph nodes
Tumor burden (microscopic vs macroscopic nodal disease)
Primary tumor ulceration

Stage IV Distant Disease
Anatomic site
Elevated lactate dehydrogenase

Box 82-4

Revisions to the American Joint Committee on Cancer Staging System

1. *Tumor thickness (Breslow depth measured in mm)* and *ulceration* are now utilized in T classification. Clark's histologic level of invasion is now applicable only in the staging of thin (≤1 mm) T1 lesions.
2. The *number of metastatic lymph nodes*, as opposed to the gross size of the metastatic node, defines the N category.
3. The technique of *sentinel lymph node mapping and biopsy (SLNB)* is now incorporated into the staging system. Delineation of *occult (microscopic/subclinical)* nodal metastasis versus clinically/radiographically apparent (*macroscopic*) nodal metastasis is outlined within the N category.
4. Both *anatomic site* of distant metastasis and *elevated lactate dehydrogenase level* are utilized in the M classification.
5. *Ulceration of the primary lesions* raises the stage level of the case.
6. Primary lesions with surrounding *satellite metastasis* or *in-transit metastasis* are defined as stage III regional disease irrespective of nodal status.

From Schmalbach CE, Johnson TM, Bradford CR. The management of head and neck melanoma. *Curr Probl Surg.* 2006;43:797.

within the N category. In addition, the AJCC Melanoma Committee strongly recommends staging with SLNB for patients with T2N0M0, T3N0M0, and T4N0M0 disease before entry into clinical trials.[5] The identification of occult nodal disease enables accurate pathologic staging and greater homogeneity among cohorts under clinical investigation.

Ulceration continued to remain an important prognostic indicator, even in the presence of nodal metastasis. In fact, ulceration was found to be the only feature of the primary tumor indicative of outcome. After adjustment of data for regional metastasis, tumor thickness was no longer a prognostic marker ($P = .16$).

A fourth criterion now used in the definition of stage III regional disease is intralymphatic metastasis. The presence of satellite metastasis surrounding a primary lesion and in-transit metastasis identified between the primary melanoma and lymph node have been identified as poor prognostic indicators.[72,89] Both findings portend a prognosis similar to that for nodal metastasis. Under the new staging system, satellite metastasis and in-transit metastasis are classified as N2c disease, in the absence of nodal disease (N0). If synchronous nodal metastasis is found in a patient with satellite or in-transit metastasis, prognosis is extremely poor. Patients with these findings are automatically classified a having N3 disease, irrespective of the number of synchronous positive lymph nodes.

Overall 5- and 10-year survival rates for patients with metastatic nodal disease were 49% and 37%, respectively.[83] However, the range in survival for patients with stage III disease was significant, ranging from 13% for those with ulcerated primary lesion and macroscopic disease identified in four lymph nodes to 69% for patients with non-ulcerated primary tumor and microscopic disease confined to one lymph node. This finding confirms previous studies demonstrating that patients with stage III disease are a heterogeneous group.[88,90] In addi-

tion, it highlights the critical impact on survival afforded by the early diagnosis of regional metastasis.

M Stage: Distant Metastasis

Prognostic factors for disseminated stage IV disease were studied among 1158 patients; the most significant difference was found to be anatomic site of metastasis. Patients with distant metastasis to the skin, subcutaneous tissue, or distant lymph nodes (M1a) had a slightly higher survival rate than patients with lung metastasis (M1b). Patients with metastasis involving other visceral organs (M1c) had the worst prognosis. Previous studies have also identified elevated serum LDH as a marker of poor prognosis.[91-94] For this reason, any patient with elevated serum LDH and distant metastasis, regardless of site, is classified as having M1c disease. Additional studies correlated male gender, more than one metastatic site, Karnofsky performance status less than 80, and limited disease-free survival with a poor prognosis.[91,95] Overall, survival for patients with distant metastasis is extremely grave, measured in months as opposed to years. The median survival time following the diagnosis of disseminated disease is only 6 to 8 months, with a dismal 5-year survival rate of 6%.[91,95] For this reason, stage IV melanoma is not subclassified under the AJCC staging system.

Anatomic Site

Although anatomic site is not used within the formal staging system, prognostic differences have been reported for melanoma.[7,96] A review of 6300 cutaneous melanomas treated at the Duke Medical Center identified the worst 10-year survival rate among primary tumors of the head and neck (54%), compared with those of the trunk (61%), lower extremity (71%), and upper extremity (76%).[96] A 50% tumor recurrence rate has been reported for head and neck cutaneous melanomas.[97,98] This aggressive behavior is likely due to (1) thicker melanoma lesions in the head and neck region than in other sites and (2) inadequate removal of atypical junctional melanocytic hyperplasia at tumor margins, which leads to a higher rate of local recurrence.

Surgical Management of the Primary Tumor

Wide Local Excision and Surgical Margins

The standard of care for primary melanoma is complete surgical excision. However, the extent of surgical margins remains an unanswered question despite numerous retrospective studies, clinical trials, and meta-analyses. Historically, WLE included an extensive, 5-cm surrounding margin of normal tissue, a recommendation based on a 1907 autopsy report of a patient with advanced melanoma.[99] The use of 5-cm surgical margins was routine practice until the 1970s, when Breslow and Macht[100] challenged the concept by successfully treating 35 patients with thin melanomas through the use of narrower margins.

Two prospective, randomized trials investigating surgical margins for cutaneous melanoma have since followed. The World Health Organization (WHO) sponsored an international trial in which 612 patients with *thin* melanomas (2 mm) were randomly assigned to surgical excision with either 1-cm margins or margins larger than 3 cm.[101] At a mean follow-up of 8 years, disease-free survival and overall survival were reported to be equivalent in the two groups. For this reason, the researchers in this study concluded that wide excision did not influence survival for patients with thin melanomas. For patients with melanomas less than1 mm in thickness, they advocated "narrow," 1-cm margins to the muscular fascia plane.

Within the WHO trial, a subset of 245 patients had tumors measuring 1.1 to 2.0 mm in thickness. Although a difference in disease-free survival and overall survival was not observed with respect to margins, a local recurrence rate of 3.3% was reported among patients undergoing "narrow" excision. This finding prompted the Intergroup Melanoma Surgical Trial, which prospectively randomly assigned 740 patients with *intermediate-thickness* (1- to 4-mm) melanomas to WLE with either 2-cm or 4-cm margins.[102] Local recurrence rates and 10-year survival were reported to be equivalent in the two groups. This finding led to the recommendation of a 2-cm surgical margin for patients with intermediate-thickness melanomas—those measuring 1.1 to 4.0 mm in.

The latest prospective clinical trial, conducted by the United Kingdom Melanoma Study Group, randomly assigned 900 patients with localized cutaneous melanomas 2 mm or more in thickness to excision with 1-cm or 3-cm margins.[103] A statistically significant difference was not identified between the two groups when local, regional, and distant recurrences were compared; overall mortality rates were identical in the two groups. However, when all recurrences (local, in-transit, and nodal) were pooled together, the 1-cm margin group had a statistically higher recurrence rate. This is the first clinical trial comparing tumor margins to report a statistically significant difference in tumor recurrence. From a practical standpoint; however, it is the 1-cm versus 2-cm margin that is debated more often in this clinical setting.[104]

To date, there is no prospective randomized trial to address the optimal surgical margin for *thick* (> 4 mm) melanomas. A retrospective study of 278 thick melanomas found that surgical margins greater than 2 cm did not lead to a difference in rates of local recurrence rate, disease-free survival, or overall survival from rates for surgical margins of

Table 82-4

Recommended Surgical Margins for Excision of Primary Cutaneous Melanoma

Tumor Thickness (mm)	Surgical Margin (cm)
In situ	0.5
<1.0	1.0
1.01-2.0	1.0-2.0
>2.0	2.0

2 cm.[104] Within this study, 16% of the tumors involved head and neck subsites.

The primary goal of melanoma excision is to eliminate local recurrence secondary to persistent disease. The rate of local recurrence from narrow-margin excisions is admittedly low; however, the consequences are potentially fatal. It is estimated that 100% achievement of ideal margins would lead to a reduction in melanoma-related mortality and a 0.4-year increase in life expectancy for patients with melanoma.[105] Although this difference appears small at first glance, it equates to an estimated 11 additional years of life expectancy for patients who would have experienced local recurrence after excision with a 1-cm surgical margin but who instead experienced a disease-free state after excision with a wider surgical margin.

Current guidelines for surgical margins are based on primary tumor thickness (Table 82-4). It is important to realize that these recommendations serve only as guidelines; choices for each case of melanoma must be individualized. The depth of excision includes full-thickness skin and underlying subcutaneous tissue. Resection of fascia, perichondrium, and periosteum is required only in the setting of direct tumor invasion or if the surgical plane was violated during a previous biopsy.[106]

LMM warrants special comment, because it has a propensity for wide subclinical spread, which often results in pathologically positive margins.[107] Johnson and coworkers[108] and Anderson and colleagues[36] have reported on the use of the "square" procedure in the treatment of LM and LMM. This staged procedure entails complete excision of the peripheral margin with permanent-section histologic evaluation of 100% of the peripheral margins surrounding the entire tumor.

Closure and Reconstruction

With the use of judicious undermining, the majority of surgical sites can be closed primarily. Larger defects may require reconstruction with a split-thickness skin graft, a full-thickness skin graft, a local advancement flap, a regional flap, or free tissue transfer. The method of reconstruction depends on anatomic location, skin color and texture, depth of defect, and patient and surgeon preference. Initially surgeons were reluctant to use grafts at excision sites for fear that surveillance within the surgical bed would be hindered and future diagnosis of recurrence delayed. However, the method of closure has not been shown to affect survival.[109] After "clear" margins have been confirmed, surgeons are encouraged to close surgical defects using the technique that they believe will yield the best cosmetic result.

Melanoma of the Ear

Originally, melanoma involving the ear was thought to carry a worse prognosis than that in other head and neck sites.[98,110,111] This increased risk was attributed to rich lymphatics, complex anatomic subdivisions of the auricle, and a paucity of subcutaneous tissue between the thin auricular skin and underlying perichondrium.[112] Consequently, full-thickness excision or total auriculectomy was often advocated.

After accounting for tumor thickness, later studies demonstrated that melanoma of the ear carries the same prognosis as that in other sites.[68,113] In addition, outcome differences were not observed between auricular subsites.[112] Retrospective reviews did not demonstrate a difference in local recurrence based on the extent of surgical excision, even when perichondrium was preserved.[113] Today, the same prognostic indicators and surgical principles of obtaining wide, clear margins for treatment of cutaneous melanoma can be safely applied to the auricular region.

Surgical Management of Regional Lymph Nodes

Therapeutic Lymph Node Dissection

The most common sites for metastasis of head and neck cutaneous melanoma are the cervical and parotid lymph node basins.[114-116] The treatment of choice for regional disease remains a therapeutic lymph node dissection (TLND), which includes draining nodal basins as well as all intervening lymphatics between the primary tumor and the site of regional disease.

The location of the primary tumor dictates the type of TLND and the need for a superficial parotidectomy. Melanomas of the anterolateral scalp, temple, lateral forehead, lateral cheek, and ear, arising anterior to an imaginary coronal plane through the external auditory canals, drain via the parotid nodal basin to the jugular lymph node chain.[117] For this reason, a superficial parotidectomy and modified radical neck dissection are both recommended. In the absence of gross tumor involvement or disruption from open biopsy or previous surgical dissection, concerted efforts should be made to preserve the spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle.[117] If the melanoma arises in a more inferior location (e.g., the chin or neck), a superficial parotidectomy is not warranted. Melanomas located on the scalp and occiput—posterior to the imaginary coronal plane through the external auditory canals—can drain to postauricular, suboccipital, and posterior triangle lymph nodes. These nodal basins are not addressed during routine modified radical neck dissection and necessitate a posterolateral neck dissection that includes levels II through V as well as the preceding nodes.[118]

Elective Lymph Node Dissection

One of the most controversial historic debates about melanoma surrounded the treatment of regional nodal basins in the absence of clinical metastasis (prophylactic treatment of the N0 neck).[114,116] Opponents of elective lymph node dissection (ELND) contend that melanoma metastasis is unpredictable. In Fisher's[9] retrospective review of 1444 head and neck patients with melanoma, 16% had distant metastasis in the absence of regional disease. This potential for hematogenous melanoma spread to bypass regional nodal basins theoretically limits the utility of an ELND. Opponents further argue that all four prospective, randomized trials detailed here failed to demonstrate an overall survival benefit for patients undergoing ELND in the absence of regional metastasis.[119-124]

The WHO Melanoma Group conducted the first prospective, randomized trial (Trial No.1) between 1967 and 1974, in which 535 patients with stage I and II melanoma of the extremity were enrolled.[123] A survival difference was not found between patients who underwent WLE and observation, with TLND reserved for the development of gross nodal metastasis, and patients who underwent WLE and ELND. Similarly, surgeons at the Mayo Clinic randomly assigned 171 patients with stage I disease to (1) WLE and observation, (2) WLE and delayed (30 to 60 days) ELND, or (3) WLE with concomitant ELND.[122] ELND was not found to provide a survival benefit over observation.

Although both prospective trials represent pioneering research in a challenging area, Balch[114] criticized both study designs. At the time of the studies, the prognostic significance of tumor thickness and ulceration was unknown. Later analysis of WHO Melanoma Group Trial No. 1 found significant discrepancy in the distribution of tumor thickness between the two treatment arms. Furthermore, 52% of lesions in the ELND group were ulceration compared with only 19% in the

observation group.[114] Subsequent reanalysis of these data with respect to tumor thickness and ulceration identified a subset of patients with a 22% better 10-year survival in the setting of ELND. The accuracy of clinical staging within the trial was also questioned because several institutions reported a 30% rate of occult nodal metastasis. This rate is quite high in comparison with rates reported in the literature, which range from 10% to 20%. Lastly, Balch[114] argued that the failure to detect a survival benefit with ELND was not surprising, given that both trials included patients with an overall low risk for regional metastasis at the time of diagnosis. Approximately 85% of patients enrolled in WHO Melanoma Group Trial No. 1 were women with extremity melanomas, which are recognized to have a lower rate of metastasis than melanomas at other sites. In addition, the Mayo Clinic study excluded patients with head and neck and midline trunk melanomas.

In order to address these concerns, the Intergroup Melanoma Surgical Trial was initiated.[119] This prospective, multi-institutional study involved 740 patients with intermediate tumor thickness (1 to 4 mm) melanomas of the trunk, extremity, or head and neck region. Patients were once again randomly assigned to undergo either WLE and observation or WLE and ELND. Cox regression analysis of the results identified ulceration, site, tumor thickness, and age as independent markers for survival. Overall 5-year survival rates were not found to differ in the two treatment groups. However, a significant survival benefit was found in patients 60 years of age and younger who underwent ELND, especially if their tumors were nonulcerated or measured 1 to 2 mm in thickness. Although this subgroup analysis is criticized for the shortcomings of a retrospective review and the failure to randomize by age, patients were prospectively randomized according to tumor thickness and ulceration.

The fourth prospective trial, initiated in 1982 by the WHO Melanoma Group (Trial No. 14), attempted to study patients truly at high risk for occult nodal metastasis.[121] It enrolled 240 patients with trunk melanomas measuring 1.5 mm or more in thickness. A survival difference was not observed between patients randomly assigned to observation and those who underwent ELND. In a multivariate analysis that included sex, age, tumor thickness, and treatment, only sex and tumor thickness were found to have a significant impact on survival. The study did identify a statistically significant 5-year survival difference between patients in whom micrometastasis identified during ELND (47%) and patients in the observation arm who underwent TLND only after the development of gross nodal disease (27%). For this reason, the WHO Melanoma Group advocated early detection of nodal metastasis using procedures such as SLNB (see later).

Statistical power remains one of the greatest challenges in investigating the survival benefits of ELND and early detection of nodal disease in melanoma patients presenting with localized disease in clinical trials conducted to date.[125] Only 20% of patients with melanoma presenting with localized disease actually have occult nodal metastasis. It is this 20% who would potentially benefit from early removal of nodal basins. Adjuvant melanoma therapy imparts a survival benefit in 25% to 50% of cases. If a similar survival benefit is applied to the ELND group, 25% to 50% of the 20% of patients with occult disease should benefit. In other words, only 5% to 10% of patients undergoing ELND are expected to experience a survival advantage. Detecting this small difference requires an extremely large clinical trial with enrollment numbering in the thousands. McMasters and colleagues[125] point out that the Intergroup Melanoma Surgical Trial, WHO trial, and Mayo Clinic study lacked adequate statistical power to detect this small survival benefit. For this reason, these researchers concluded that the 4% survival benefit observed in the ELND group of the Intergroup Melanoma Surgical Trial study is clinically significant, despite the fact that statistical significance was not reached.

In summary, numerous prospective, randomized trials failed to demonstrate an overall survival benefit for patients undergoing ELND.[110,119,121,123,125,126] Therefore, routine ELND is no longer advocated for melanoma. Instead, the procedure has been replaced by SLNB.

Sentinel Lymph Node Biopsy

Sentinel lymph node mapping and biopsy represents a minimally invasive, cost-effective, and efficient means of screening patients for regional metastasis.[127] Nodal status is currently recognized as the most important prognostic factor for patients with melanoma.[5] Ten percent to 20% of such patients have occult microscopic nodal disease. In an attempt to identify this small group of patients who need TLND while sparing the remaining 80% of patients without regional disease the morbidity associated with a neck dissection, Morton and colleagues[126] introduced SLNB for the evaluation of patients with trunk and extremity cutaneous melanoma. The investigators demonstrated that the status of the SLN accurately represented the status of the entire nodal basin from which it was obtained. SLNB is considered the best staging modality for regional disease, with the highest sensitivity and specificity of any modality currently available. In a multivariate model using data from 910 patients with melanoma, Peak and associates[128] identified an association between SLN positivity and increasing Breslow depth, younger age, higher mitotic rate, angiolymphatic invasion, and location on the trunk/lower extremities. The indications for SLNB are summarized in Box 82-5. Patients who have metastatic disease or who have undergone previous surgical disruption of the lymphatics or resection with wide margins are not deemed candidates for this screening.

Box 82-5

University of Michigan Indications for Consideration of Melanoma Sentinel Lymph Node Mapping and Biopsy

Breslow depth = 1 mm
Breslow depth = 1 mm in setting of adverse prognostic variables, including the following:
- Tumor extension to deep margin
- Ulceration
- Extensive regression to 1.0 mm
- Young age
- High mitotic rate[86]
- Clark level IV

The SLN technique introduced by Morton and others has since evolved to include preoperative lymphoscintigraphy.[129] Approximately 2 to 4 hours before surgery, patients undergo intradermal injection of a radioactive colloid into the four quadrants surrounding the primary melanoma tumor. Lymphoscintigraphy is then performed. This nuclear medicine scan enables the surgeon to determine the number, location, and laterality of nodal basins at risk for metastatic disease (Fig. 82-3). It is particularly helpful in the setting of midline head and neck melanomas, for which there is a risk of bilateral lymphatic drainage.

Once the patient is under anesthesia, intraoperative lymphatic mapping with isosulfan blue dye (Lymphazurin 1%; Covidien, Mansfield, MA) or methylene blue dye is performed.[126] Approximately 1 mL of dye is injected into the intradermal layer surrounding the primary melanoma lesion (Fig. 82-4). The primary tumor and draining lymphatics are in close proximity within the head and neck region. Therefore, WLE of the primary tumor is performed first to reduce radioactive "shine-through," which would render the intraoperative gamma probe useless for the identification of SLNs (Fig. 82-5) *Shine-through* refers to radioactive counts attributable to the primary site injection rather than sentinel lymph nodes.

Following WLE of the primary melanoma, the surgeon uses handheld gamma probe to identify the site(s) of sentinel lymph node(s). The procedure of identifying and removing sentinel lymph nodes continues until the gamma counts per minute (cpm) in the lymph node basin are equal or less than 10% of the "hottest" sentinel lymph node removed. We advocate this 10% rule because our data suggest that for surgeons using radioactive colloid who routinely terminate the procedure after identifying only the hottest node, or when the cpm values for nodes drop below one-half to one-third the cpm of the hottest node, the false-negative rates are higher.[130] The SLNs are removed with the use of 1- to 3-cm incisions overlying the areas of increased radioactivity. A preauricular incision is recommended for SLNB in the parotid region.

Figure 82-3. Preoperative lymphoscintigraphy is performed about 3 hours prior to sentinel lymph node biopsy. Approximately 2 µCi of technetium Tc 99m sulfur colloid is injected intradermally into the four quadrants surrounding the primary melanoma lesion located midline on the posterior occiput. The right posterior occiput primary lesion with an overlying shield to limit "shine-through" is denoted by the *small arrow*. The *larger arrow* points to two draining sentinel lymph nodes observed in the right posterior triangle of the neck.

Figure 82-4. After the administration of anesthesia, intraoperative lymphatic mapping is performed with the use of approximately 1 mL of isosulfan blue dye (Lymphazurin 1%; Covidien, Mansfield, MA) injected into the intradermal layer surrounding the primary melanoma.

SLNs are then identified through the use of a combination of the gamma probe and visual cues from the blue dye (see Fig. 82-5). Each SLN is individually dissected from surrounding tissue.

At our institution, all SLNs are sent for histologic evaluation using permanent sections. Frozen sections are less reliable, carrying a false-negative rate between 5% and 10%.[131] The evaluation involves serial sectioning (5-µm thick sections) and staining with hematoxylin and eosin. Special melanoma immunohistochemical staining for S-100 protein and melan-A (MART-1 [melanoma antigen recognized by T cells]) are performed for all SLNs with negative response to hematoxylin and eosin staining. This panel was chosen after pathologic evaluation of 99 positive SLNs from 72 patients treated at our institution.[132] The sensitivities for S-100, melan-A, and HMB-45 monoclonal antibody were found to be 97%, 96%, and 75%, respectively. In addition, HMB-45 stained a smaller percentage of cells (25% to 75%), with weaker intensity compared with S-100 and melan-A; for this reason, we no longer routinely stain for HMB-45.

Patients with a positive SLN result are returned to the operating room within 2 weeks of diagnosis for definitive TLND; patients with

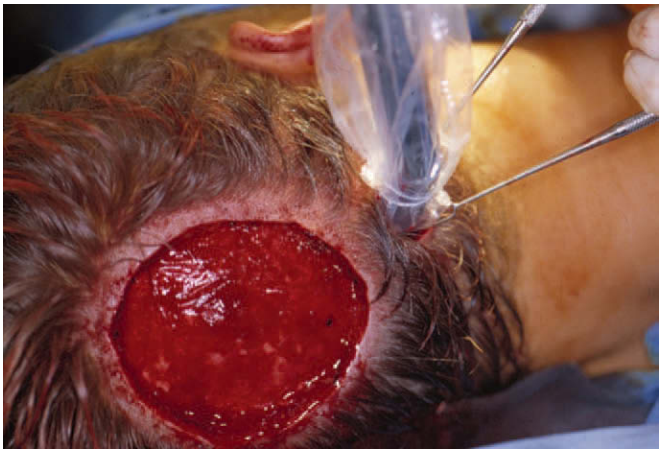

Figure 82-5. Wide local excision of the primary melanoma is performed prior to sentinel lymph node biopsy; otherwise, the close proximity of the primary lesion to the draining nodal basins within the head and neck region would cause significant radioactive "shine-through" and difficulty with localization of the sentinel lymph node. Each sentinel lymph node is then identified through the use of a combination of the gamma probe, which detects radioactive activity from the technetium Tc 99m sulfur colloid, and visual cues from the isosul-

a negative result are followed clinically. An alternative to this two-stage technique is immediate TLND on the basis of frozen-section evaluation of the SLNs. However, it is important to realize that the reliability of frozen sections for melanoma analysis has been questioned,[133] and permanent sections remain the "gold standard."

The pathologist plays an extremely critical role in the success of SLNB. Occult lymphatic metastasis from cutaneous melanoma can be difficult to detect and warrants rigorous pathologic analysis, including serial sectioning, special immunohistochemical study when indicated, and interpretation by an experienced pathologist. Wagner and associates[134] reported the mean tumor volume in SLNs positive for metastatic melanoma to be only 4.7 mm^3. Joseph and colleagues[66] reported the identification of only 73% of metastatic SLNs with the use of standard hematoxylin and eosin staining alone. In our study, 20 of the 97 positive SLNs (21%) tested negative on initial hematoxylin and eosin staining.[132] This high false-negative rate highlights the importance of immunohistochemical staining for accurate diagnosis of occult nodal disease.

The histologic analysis of SLNs is more thorough, complete, and practical than the traditional evaluation of the entire lymphadenectomy specimen, because the technique provides the pathologist with a limited number of nodes to evaluate thoroughly.[135] SLNB is particularly helpful in the diagnosis of occult DM/DNM. For this subtype, a focused histopathologic evaluation is of particular importance because the microscopic features are quite variable, often lack resemblance to the primary tumor, are limited to a paucity of tumor cells, and demonstrate inconsistencies on HMB-45 and melan-A staining.[136]

SLNB is a team effort involving experienced surgeons, nuclear medicine staff, and pathologists. The experience and technical skill of the surgeon is vital. Morton and associates[127] previously suggested a 30-case learning curve. However, long-term follow-up of their international Multicenter Selective Lymphadenectomy Trial (MSLT-1) found the 30-case learning curve to be too shallow. Analysis of the first 25 cases performed at the 10 highest-volume centers in the trial revealed a nodal basin recurrence rate of 10.3%.[131] This false-negative rate dropped to 5.2% after 25 additional cases. The researchers now conclude that a 55-case learning curve is required in order to achieve at least 95% accuracy with SLNB.

An experienced nuclear medicine staff is also necessary, because inappropriate administration of the radioactive tracer can also lead to "shine-through." Communication between the surgeon and the nuclear medicine team is helpful not only for the interpretation of the lympho-

scintigram but also to ensure that the appropriate lesion is mapped, because patients with melanoma often present with multiple pigmented lesions.

A multivariate analysis involving patients with stage I and II melanoma by Gershenwald and coworkers[137] found the pathologic status (positive or negative for metastasis) of the SLN to be the most important prognostic factor for both recurrence and overall survival. For patients with stage III melanoma, survival was better in those with occult microscopic disease than in those with palpable macroscopic disease.[5] This survival difference was so compelling that the AJCC has now incorporated SLNB into the revised staging system for cutaneous melanoma.

Although SLNB has a defined role in the evaluation of cutaneous melanoma of the trunk and extremities, several questions have been posed with respect to its application in the head and neck region.[127] The complexity of the head and neck lymphatic system has caused concern about the reliability of the SLNB to accurately reflect the status of the entire nodal basin. The interlacing network of cervical lymphatic vessels is often deemed to be watershed in nature. The complexity of this lymphatic system was demonstrated by O'Brien and colleagues,[138] who reported a 34% discordance between the clinical prediction of lymphatic drainage and lymphoscintigraphy findings in 97 cases of head and neck cutaneous melanoma. The popularity of SLNB in the head and neck region has also been limited by concern surrounding damage to vital structures such as the facial nerve,[139] technical difficulties,[139] and the necessity for nuclear medicine staff as well as pathologists who specialize in SLNB technique.

Our experience in staging 80 cases of head and neck cutaneous melanoma demonstrated that the complexity of the head and neck anatomy does not preclude the use of SLNB for the staging of cutaneous melanoma.[140] SLNB in the head and neck region accurately predicted the status of the nodal basin. Fourteen of 80 patients (17.5%) had a positive sentinel lymph node. Of 66 (4.5%) patients with negative SLNB results, only 3 experienced regional recurrence. The 17.5% positivity rate of SLNs and the 4.5% false-negative rate both mirror the results that SLNB achieved in other anatomic sites, such as the trunk and extremities.[135,141] Similar success in the application of SLNB for head and neck cutaneous melanoma has been reported by others,[142,143] and the technique has been applied successfully in pediatric head and neck cases.[13]

Approximately 25% to 30% of head and neck cutaneous melanomas drain to lymph nodes within the parotid bed.[138,140] Potential injury to the facial nerve from SLN biopsy has led some surgeons to advocate superficial parotidectomy over the mapping procedure.[139] In our retrospective analysis, staging with SNLB was successful in 28 of 30 (93.3%) patients whose tumors were draining to the parotid nodal basin.[140] One patient required a superficial parotidectomy owing to the location of the SLN deep to the facial nerve, and a second patient experienced significant bleeding from surrounding parotid tissue, which could have put the facial nerve at increased risk. A total of 39 nodes from the parotid basins of these 28 patients were removed without facial nerve injury. Continuous facial nerve monitoring for SLNB within the parotid nodal basin can be helpful when the biopsy is performed within the parotid bed.

Concern has also been expressed that SLNB causes inflammation and fibrosis that could place the facial nerve at increased risk when reoperation is required to definitively treat the parotid basin in the setting of a pathologically positive SLN.[139] In our experience, all patients with a positive parotid SLN underwent superficial parotidectomy as a subsequent procedure without facial nerve injury. Our findings are consistent with those of other reports demonstrating that SLNB can reliably and safely be performed within the parotid nodal basin.[144,145]

Other researchers have suggested that SLNB increases the risk of *in-transit metastasis* (ITM), which is defined as intralymphatic tumor dissemination within cutaneous or subcutaneous tissue located between the primary lesion and draining nodal basin.[146-150] It is theorized that ITM develops when melanoma cells detach from the primary lesion and become lodged in the dermal plexus of lymphatics prior to reaching the lymph nodes. ITM presents a therapeutic challenge and carries a poor prognosis, as indicated by the changes to the AJCC staging system previously described.[5] Original reports citing increased ITM following SLNB must by viewed with caution, because the studies often entailed pooled data from small cohorts and failed to control for important prognostic factors such as tumor thickness and ulceration.[61,148] A later prospective review comparing 4412 patients undergoing WLE alone, WLE with SLNB, or ELND identified a correlation between ITM and increasing Breslow depth, Clark level, and T stage.[61] A statistically significant difference between ITM and tumor recurrence was not found among the treatment groups, once adjustment of data was made for T stage, age, sex, tumor thickness, and site. Additional studies have concluded that it is the tumor biology, rather than the surgical procedure (SLNB; ELND), which dictates melanoma metastatic behavior.[148,151] Finally, a correlation between ITM and SLNB was not reported with MSLT-1, thus negating this concern.[131]

The impact of SLNB on overall survival remains to be determined. The answer will hopefully be provided through the multi-institutional Sunbelt Melanoma Trial, which is a prospective, randomized clinical trial that utilizes SLN staging to determine the need for adjuvant therapy.[152] While we await these results, McMasters and colleagues[153] outline the following four compelling reasons to use of SLNB for accurate regional staging of cutaneous melanoma.

1. The SLNB technique provides important prognostic information to the physician, patient, and family members in guiding subsequent treatment options.

2. SLNB helps identify patients with nodal metastasis, who then may benefit from early TLND.

3. SLNB identifies patients who are candidates for adjuvant treatment such as interferon-α 2b.

4. SLNB provides the most accurate means of regional staging. In doing so, the technique enables the identification of a homogeneous population of patients for enrollment into clinical trials. Regional metastasis is recognized as the most important prognostic factor in melanoma. Without accurate pathologic staging, stratification is impossible, and result of clinical trials will remain inconsistent and difficult to interpret.

The fifth and final analysis of MSLT-I will provide additional insight into the potential therapeutic benefit of SLNB.[131] Publication of the MSLT-I interim analysis is exciting in that it is the first randomized, prospective trial to demonstrate that SLNB accurately identifies occult nodal metastasis that would lead to advanced, palpable nodal disease if left in situ. The researchers argue that there is no reason not to perform SLNB because a zero mortality rate was reported, and the complication rate for SLNB (10%) was significantly lower than that for TLND (37%). Morton and colleagues[131] concluded that SLNB should be considered the standard of care for regional staging of primary cutaneous melanoma—the key term being "staging." At present SLNB is a diagnostic tool for regional staging, not a therapeutic modality. Although it is not 100% accurate, SLNB is the most reliable means for regional staging. It is more sensitive and specific than CT, magnetic resonance imaging, positron emission tomography, ELND, and clinical examination.[154] McMasters astutely points out that we do not expect a survival benefit from any other cancer staging test, and therefore we should not ask the same of SLNB.

Future Investigations

SLNB research endeavors hold exciting and great promise for the future. In an effort to further investigate the therapeutic potential of SLNB, research efforts have focused on identifying markers of both the primary lesion and SLN, which are predictive of tumor-containing non-SLNs.[155-157] Absence of these markers would then allow identification of the subset of patients with positive SLNB results, in whom further treatment with a formal TLND may not be warranted. Unfortunately, current studies have not identified a consistent and 100%

accurate marker. For this reason, the MSLT-II trial, currently under way, is designed to investigate the indications for TLND following a positive SLNB result. Specifically, it will determine whether immediate TLND provides a survival benefit over diligent postoperative, ultrasonographic monitoring of the draining nodal basins.[131]

Molecular staging of melanoma is also gaining increased interest. Reverse transcriptase–polymerase chain reaction (RT-PCR) analysis of SLNs for melanoma-associated genes such as MART-1, tyrosinase, microphthalmia-associated transcription factor (MIFT), and tyrosinase-related protein 2 (TRP-2) has proved helpful in identifying a subset of patients who have occult nodal disease at a submicroscopic level, which cannot be detected with traditional immunohistochemical staining.[84,158,159] In one study, in 30% (49 of 162) of patients in whom results of immunohistochemical staining of SLNs were negative, at least one melanoma marker was identified with RT-PCR.[160] This subset of patients experienced a higher rate of tumor recurrence. Currently, RT-PCR lacks specificity. The reason for the high false-positive rate may be the inability of RT-PCR to differentiate melanoma cells from occult benign nevus cells.[16] Through future research efforts, molecular staging may prove helpful in the identification of a subset of high-risk patients with melanoma in whom nodal or distant metastases develop despite presentation with a thin primary tumor. This information has the potential to change the manner in which these individuals are counseled both with respect to adjuvant therapy and follow-up surveillance.[65]

Surgical Management of Distant Metastasis

Patients with stage IV melanoma involving distant sites have an exceedingly grave prognosis. Surgical treatment has a limited role in the setting of disseminated disease. It has successfully been used as a means of palliative treatment in patients suffering from brain, lung, gastrointestinal, subcutaneous soft tissue, and distant lymph node metastasis.[161] Success of surgery in the palliative setting depends heavily on appropriate patient selection; it should be considered only if clearly identifiable and specific symptoms are associated with a metastatic lesion. Other considerations are surgical morbidity, expected quality of life, expected survival, and, most important, the patient's wishes.[162] It is imperative that the patient and his or her family understand that the goal of surgery is palliative in nature.

Several prognostic markers have been identified in patients with disseminated stage IV melanoma.[162,163] These markers are reflected in the AJCC staging system previously described above and should serve as a guide for the consideration of surgical resection of distant tumors. Patients with metastatic disease limited to one or two isolated sites experience a better prognosis as than patients who have multiple metastatic lesions. A short disease-free interval is associated with an overall poor prognosis. Patients in whom distant metastasis develops within a year of initial diagnosis have a poor prognosis, even when complete resection of the metastatic lesion is achieved.[162] Lastly, the anatomic site of the metastatic lesion is of importance. Patients with metastatic spread to nonvisceral sites (e.g., distant subcutaneous tissues, lymph nodes) have a better prognosis than those with visceral metastasis. Within the group of patients suffering from visceral metastasis, individuals with pulmonary lesions experience better survival than those with lesions at other visceral sites.

Radiation Therapy

Melanoma has traditionally been classified as a radioresistant tumor.[8,164] Although adjuvant irradiation has not been shown to have an impact on survival,[165] researchers at the MD Anderson Cancer Center completed a phase II clinical trial supporting the efficacy of hypofractionated radiation as an adjuvant to surgery for patients with head and neck cutaneous melanoma at high risk for local/regional recurrence.[166-168] Local/regional control was achieved in 88% of patients, which is an improvement over the historic control rates of 50% to 70%.[10,169] Late complications of irradiation were rare (3 of 174 patients) and included moderate neck fibrosis, mild ipsilateral hearing loss, and transient exposure of external auditory canal cartilage. Local/regional control is important, because recurrence can significantly affect quality of life by causing pain, wound breakdown, and socially debilitating cosmetic disfigurement.[170,171] However, no overall survival benefit has been demonstrated.

Ultimately the survival benefit achieved with adjuvant radiation therapy will be determined through the prospective, randomized phase III clinical trial (E3697) currently being conducted by the Radiation Therapy Oncology Group.[170] Until this trial is completed, most authorities advocate the use of adjuvant irradiation for patients demonstrating adverse prognostic markers such as neurotropism, extracapsular spread, multiple node involvement (>4), or recurrence.[172-174] These patients are often eligible to receive adjuvant interferon-α 2b (see later), which is thought to act as a radiosensitizer. Therefore, it is common practice to delay radiation therapy until the 4-week induction phase of interferon therapy is complete.[175]

On very rare occasions, primary irradiation can be used to treat extensive LM or LMM in an elderly patient who is not deemed a surgical candidate.[176] Radiation therapy can also be administered as palliative treatment in patients suffering from systemic stage IV disease, especially in the setting of brain metastasis, bone metastasis, spinal cord compression, or isolated, symptomatic visceral metastasis.[2]

Chemotherapy

Melanoma is a relatively chemoresistant tumor.[177-179] A small subset of patients is thought to benefit from chemotherapy; however, a regimen shown definitively to have an impact on survival has not emerged. The main role of chemotherapy remains as palliative treatment in the setting of disseminated stage IV disease.

Dacarbazine (DTIC) is currently the only chemotherapeutic agent approved for the treatment of advanced stage IV melanoma. Response rates following DTIC administration are modest at best, ranging from 10% to 20%.[8,87,180-182] This prognosis has not changed over the past 20 years, despite dedicated research efforts using a host of chemotherapeutic agent regimens.[178] Overall, less than 5% of individuals with stage IV melanoma experience a complete response with DTIC therapy.

Immunotherapy

Classically, immunotherapy is divided into two categories. Specific immunotherapeutic agents up-regulate the antibody and cytotoxic T-cell immune responses specifically to the patient's tumor or to known melanoma antigens; the majority of melanoma vaccines fall into this category. By contrast, nonspecific immunotherapeutic agents such as interferon, interleukin, and microbacterial products stimulate the host's immune system without targeting melanoma tumor antigens. These agents are often administered in concert with specific immunotherapeutic agents in an attempt to augment the immune system.[175,182]

Interferon

Despite myriad clinical trials involving adjuvant regimens, high-dose interferon-α 2b remains the only adjuvant treatment approved by the U.S. Food and Drug Administration (FDA) for stage III melanoma. It functions as a biologic response modifier; the mechanism of action includes direct antiproliferative effects, immune stimulation through the enhancement of natural killer cells, increased histocompatibility antigen expression on melanoma cells, macrophage phagocytosis, and enhanced T-cell–mediated cytotoxicity.[107,183] Although all three types of interferon (α, β, and γ) demonstrate antitumor activity,[183] Interferon-α 2b is the only treatment that is currently approved for the adjuvant treatment of patients with melanoma at high risk for recurrence after surgery.

Three large clinical trials involving adjuvant interferon-α 2b have been conducted by the Eastern Cooperative Oncology Group (ECOG).[184-186] In brief, ECOG trial E1684 was the first study to demonstrate the efficacy of interferon-α 2b.[184] The regimen consisted of high-dose interferon (20 million units/m^2/day) administered intravenously, 5 days a week, for 4 weeks. Maintenance treatment followed, consisting of 48 weeks of subcutaneous interferon-α 2b (10 MU/m^2/day) administered 3 days a week. The prolonged disease-free survival rate and overall survival rate in the interferon-α 2b arm of E1684 ultimately led to FDA approval of the adjuvant therapy.

Although the follow-up trial E1690 did not confirm the efficacy of high-dose interferon-α 2b,[185] the results require careful interpreta-

tion.[153] Unlike in E1684, patients enrolled in E1690 did not require pathologic staging with ELND or SLNB, nor were they stratified according to ulceration. In addition, a disproportionate number of individuals from the observation arm crossed over into the interferon-α 2b arm to receive salvage therapy for recurrent disease. Any therapeutic benefit provided to this subgroup by interferon-α 2b went unrecognized, because the crossover patients remained in the observation arm for the purposes of statistical analysis.

The latest and largest of the three studies, ECOG 1694,[186] once again confirmed the efficacy of high-dose interferon-α 2b. In fact, the difference between rates of relapse-free and overall survival observed in the high-dose interferon-α 2b control arm in the GMK ganglioside vaccine treatment arm was so compelling that the Data Safety Monitoring Committee terminated the trial early.

With close follow-up, dose modification, and pharmacologic intervention, the majority of patients with melanoma are able to tolerate the 1-year course of interferon-α 2b.[153,175,185,186] Almost all individuals experience flulike symptoms (fevers, chills, malaise) during the initial treatment course. Severe and intolerable chronic fatigue occurs in 20% to 30% of patients, and an additional 2% to 10% experience neurologic and psychiatric side effects, including depression, anxiety, suicidal ideation, and difficulty with cognition. Myelosuppression, thyroid dysfunction, and elevated liver enzyme values require close monitoring. Contraindications include a history of myocardial infarction or dysrhythmia, liver disease, central nervous system disorders, and severe psychiatric illness.[175] Approximately 50% of patients require a dose reduction or delay as a result of these side effects. The majority of patients with melanoma are willing to accept these side effects, given the potential benefit of interferon-α 2b.[187]

Although clinical trials continue to investigate alternative dosages and schedules,[188,189] high-dose interferon-α 2b remains the only proven adjuvant treatment for melanoma, with relapse-free survival prolonged by approximately 10%.[190] It remains the standard of care for adjuvant therapy against which all interventions must be compared, ideally in the setting of prospective, randomized trials.[191] Every patient with regional lymph node metastasis or a primary tumor thickness greater than 4 mm should be informed of the option to receive postoperative interferon-α 2b. To enable the patient to make an educated decision, the surgeon must have an objective discussion about the side effects of interferon-α 2b and the opportunities to enroll in other clinical trials.

Interleukin-2 and Other Cytokines

Interleukin-2 (IL-2) is another form of immunotherapy that is used in the primary treatment of disseminated stage IV disease. Unlike interferon, IL-2 lacks direct antitumor activity and in vitro activity.[107] However, in vivo, IL-2 stimulates the host's immune system by activating effector cells such as natural killer cells, monocytes, cytotoxic T cells, and helper T cells. It also induces cytokines such as interferon-γ and tumor necrosis factor-α.[107,192]

Rosenberg and colleagues,[193] of the Surgery Branch of the National Cancer Institute, successfully used high-dose IL-2 to treat 134 patients with melanoma. An overall response was observed in 17% of patients; 10% experienced a partial response, and an additional 7% had complete regression. The therapeutic benefit was substantial, lasting between 2 and 8 years.

The side effects of IL-2 are significant and potentially lethal. Acute toxic effects include myocardial infarction, arrhythmia, respiratory distress, hypotension, capillary leak syndrome, nephrotoxicity, hepatic toxicity, and sepsis.[192,194] Others are anemia, thrombocytopenia, nausea, emesis, diarrhea, myalgia/arthralgia, skin erythema, and pruritus. Only patients who demonstrate excellent cardiopulmonary health and performance status should be considered for clinical trials involving IL-2.

Subsequent efforts to enhance the response to IL-2 by altering the schedule and dose and by combining it with other therapeutic agents (e.g., lymphokine-activated killer cells) have not proved beneficial.[107,182,192,194] In addition to IL-2, other cytokines have been studied alone and in combination with various chemotherapeutic agents, including IL-1, IL-4, IL-6, and tumor necrosis factor-α.[192] Significant therapeutic benefit has not been demonstrated for any.

Future Immunotherapy Investigations

Significant advances in the field of melanoma research have been achieved in recent years.[175,182,183,195,196] Intense efforts in the areas of melanoma vaccination, gene therapy, and HLA immunoprinting will likely play important roles in future research endeavors. Until therapeutic efficacy achieves that of interferon-α 2b, all other adjuvant agents should be administered to high-risk patients only in the setting of well-designed clinical trials. Given the heterogeneous melanoma patient population, myriad immunotherapy regimens, and the limited survival of high-risk patients with melanoma, multi-institutional studies with accurate clinical staging will be imperative.

Follow-Up and Surveillance

The primary goals of melanoma follow-up are the early detection of local/regional tumor recurrence, the early identification of second primary tumors (including melanoma and other skin cancers), continuing patient education, and psychological support.[197] Each follow-up visit should include an inquiry into new or changing skin lesions. A review of systems (see Box 82-2) as they relate to distant metastasis should be performed.[79] A thorough examination of the skin and mucosa is required, with particular attention paid to the original melanoma site and associated draining nodal basins. Each follow-up visit should be viewed as an opportunity to reducate patients about the ABCD melanoma warning signs and the importance of monthly skin self-examination. Education about sun exposure—including using sunscreen, avoiding peak sunlight hours, seeking shade, wearing protective clothing, and the potential risks of tanning booths—should be emphasized.

CHAPTER EIGHTY-THREE

Malignancies of the Paranasal Sinus

Ernest A. Weymuller, Jr.

Greg E. Davis

Key Points

- Malignant paranasal sinus tumors are rare and have relatively poor survival outcomes, often related to advanced stage at diagnosis.
- Symptoms suggesting sinus malignancy include nasal obstruction, pain, epistaxis, swelling, nasal discharge, epiphora, palate lesion, diplopia, cheek numbness, decreased vision, neck mass, proptosis, and trismus.
- Treatment for sinonasal malignant tumors varies widely according to histologic type, tumor location, and institutional experience.
- Advancements in imaging, experience with image-guided endoscopic surgery, and new chemoradiation therapy regimens have significantly altered attitudes regarding the optimal approach to sinus malignancy.
- Understanding the complex three-dimensional anatomy of the sinuses and surrounding structures is a crucial component of therapeutic decision-making.

In the first decade of the 21st century it is difficult to describe the "standard of care" for any malignant process. The rapid evolution of imaging combined with the emergence of effective nonsurgical treatment modalities and the expansion of image-guided surgical technology has created a dynamic therapeutic environment. Management of paranasal sinus malignancy exemplifies this situation, and treatment selection is additionally influenced by the proximity of the sinuses to the eyes and the brain, which limits the opportunity to achieve "clear surgical margins" for the majority of these tumors. Consideration of post-treatment quality of life has clearly influenced treatment selection in the past and is driving current management toward combined therapy and aggressive endoscopic debulking to achieve organ preservation while also preserving the probability of cure.

We present traditional topics in paranasal sinus malignancies and also discuss some of the emerging modalities, including endoscopic resection, concomitant chemoradiation therapy, and image-modulated radiation therapy. Benign lesions in the paranasal sinus and tumors of the nasopharynx are discussed elsewhere in this book.

Recognition of malignant lesions in the paranasal sinuses creates a challenge for patients and practitioners, given that the area is neither visible nor palpable and sinus malignancy initially mimics a benign process. The diagnosis usually becomes apparent only after the lesion has reached an advanced stage, thus explaining the relatively poor prognosis. The otolaryngologist has a unique obligation to be aware of these disorders and to understand the management of these complex tumors.

This chapter first reviews material common to all sinus tumors: anatomy, symptoms, physical findings, diagnostic assessment, and surgical options. Although these lesions are rare, numerous histologic subtypes must be discussed individually because management varies significantly among them (Fig. 83-1).

Epidemiology and Survival

Malignant lesions within the sinuses are uncommon, accounting for less than 1% of all neoplasms, with a frequency of 0.1 to 0.3 per 100,000 during the first decade of life that rises to 7 per 100,000 by the eighth decade of life.[1] Several histologic subtypes have been described. In one of the most widely cited papers on the incidence of malignant sinonasal lesions, Jackson and colleagues[2] reviewed 115 patients between 1957 and 1974 and reported on the histologic distribution of their tumors (Table 83-1). These rates are similar to those in a review by Sisson and associates[3] in 1989. In 2007, the Memorial Sloan-Kettering Cancer Center published their experience with paranasal sinus malignancies; the histologic prevalence remains similar to that described by Jackson 30 years earlier (see Table 83-1).[4] The most common lesions reported were squamous cell carcinomas, with a frequency of less than 1 per 200,000 per year.

A large retrospective review of 220 patients with nasal and paranasal sinus malignancies showed a 5-year survival rate of 40%.[1] The National Cancer Institute created the Survival, Epidemiology, and End Result (SEER) database in 1973. This database enables accurate estimates for cancer incidence and mortality in the United States. In 2006, Davies and Welch[5] used this database to compile recent incidence and mortality rates for head and neck cancer. The data suggest that mortality for sinus malignancies decreased by 11% between 1990 and 2001.

Numerous environmental agents are considered to have a causal relationship with carcinoma of the paranasal sinuses. The following are all associated with squamous cell carcinoma: aflatoxin, found in certain

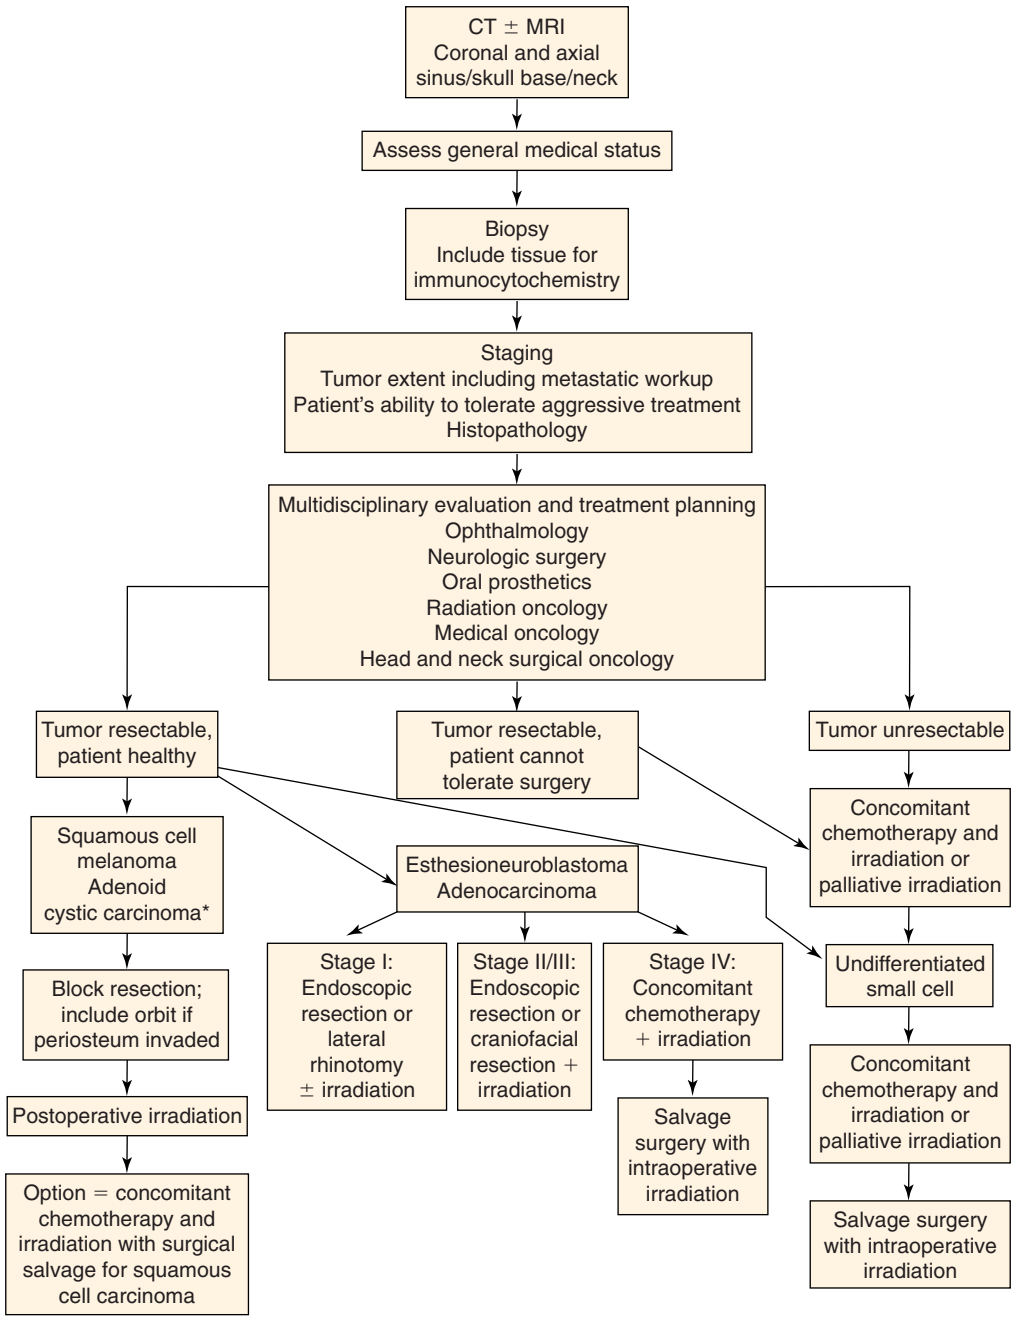

Figure 83-1. Evaluation and management of suspected paranasal sinus cancer. *Neutron irradiation is an option for adenoid cystic carcinoma. CT, computed tomography; MRI, magnetic resonance imaging.

foods and dust; chromium, nickel, mustard gas, polycyclic hydrocarbons, and other organic chemicals, usually from manufacturing processes; and mesothorium (Thorotrast), a radiopaque dye used as a contrast medium within the antrum. Wood dust has a particular association with adenocarcinoma of the ethmoid sinus. Tobacco smoke, salted or smoked foods, woodworking, heavy metal exposure, and hydrocarbon refining have all been linked with a higher incidence of these malignancies. There is a 2:1 male to female preponderance, likely due to the higher rates of male workers in the occupations listed. Additionally, human papillomavirus, including subtypes 6, 11, and 18, has been identified in inverted papilloma and associated squamous cell carcinoma.[6]

Anatomy

Assessment and management of this group of tumors demands an intense personal effort to understand the complex anatomy of the sinuses and skull base. Such knowledge is best obtained through anatomic dissection and repeated review of the anatomy of the human skull. It may be helpful to have a skull available in the operating room for inspection during complex resections, especially those that approach or traverse the skull base.

Pertinent to this discussion are the structures contiguous to each of the sinuses, because they define the extent of disease and determine the design of therapy. It is important to realize that all of the sinuses have venous communications with intracranial veins, which provide an avenue for intracranial spread.

Maxillary Antrum

As noted by Ohngren,[7] the most prognostically significant structures are above and behind the maxillary antrum. Superior to this structure are the orbit and the ethmoid sinus. The posterior boundary includes the pterygoid plates, the pterygoid space, and the infratemporal fossa.

Table 83-1

Rates of Malignant Tumors

	Number Reported (%)	
Histology	Jackson et al (1977)[2]	Hoppe et al (2007)[4]
Squamous cell carcinoma	61 (55)	42 (49)
Undifferentiated carcinoma	11 (10)	4 (5)
Adenoid cystic carcinoma	8 (7)	11 (13)
Adenocarcinoma	7 (6)	6 (7)
Melanoma	7 (6)	
Olfactory neuroblastoma	5 (4)	7 (8)
Fibrosarcoma	3 (3)	9 (11)
Papillary adenocarcinoma	2 (2)	
Transitional cell carcinoma	2 (2)	
Plasmacytoma	2 (2)	
Hemangiopericytoma	1 (1)	
Lymphoma	1 (1)	
Carcinosarcoma	1 (1)	
Chondrosarcoma	1 (1)	
Neuroendocrine	n/a	2 (3)

The other boundary areas are more easily resected en bloc and thus are less worrisome when involved. Anteriorly lies the canine fossa, inferiorly the alveolus, and medially the nasal cavity.

Ethmoid Sinus

As with the antrum, the least worrisome directions of spread from the ethmoid sinus are inferior into the antrum and medial into the nasal cavity. Of much greater concern is superior spread, in which the fovea ethmoidalis and the cribriform plate provide little barrier to intracranial spread. Evidence of intracranial spread requires consideration of an anterior craniofacial resection. The lateral wall consists of the thin bone of the lamina papyracea, which also provides little resistance to neoplastic invasion.

Sphenoid Sinus

Located in the center of the head, the sphenoid sinus is immediately adjacent to very complex and vital structures. For this reason, complete resection of a malignant tumor involving the sphenoid sinus is usually not possible. The optic nerve and the pituitary gland are superior to this sinus, and the internal carotid artery and the cavernous sinus sit laterally. The bone of the lateral wall is usually less than 0.5 mm thick and not uncommonly is dehiscent. Anterior to the sinus are posterior ethmoidal cells, and inferiorly are the vidian nerve, the clivus, and the nasopharynx.

Frontal Sinus

The sinus least frequently involved by malignant tumors, the frontal sinus, is bounded anteriorly by the soft tissues of the scalp, inferiorly by the dense frontal beak of the frontal bone, the ethmoidal cells, and the orbit, and posteriorly by the anterior cranial fossa.

Lymphatics

Ohngren[7] emphasized the importance of precise understanding of the lymphatic drainage of the nose and paranasal sinuses as a prerequisite to adequate therapy. He contested the established dictum that these tumors do not often metastasize. He held that they do metastasize but that clinical evidence of early metastasis is absent because the primary drainage is to the lateral and retropharyngeal nodes. He believed that the relative success of his therapy hinged on electrocoagulation and irradiation of the rich lymphatic channels passing from the nose and paranasal sinuses posteriorly to the retropharynx which remains an important therapeutic concept.

Symptoms

In the review of 115 patients by Jackson and colleagues,[2] the symptoms associated with malignancy were nasal obstruction (61%), localized pain (43%), epistaxis (40%), swelling (29%), nasal discharge (26%), epiphora (19%), palate lesion (10%), diplopia (8%), cheek numbness (8%), decreased vision (8%), neck mass (4%), proptosis (3%), and trismus (2%). As the disease becomes more advanced, the tumor infiltrates adjacent structures, giving rise to these symptoms as follows:

Diplopia or vision loss is most often a manifestation of tumor mass compressing or invading the orbit and may also result from direct involvement of the optic or oculomotor nerves at the orbital apex or the cavernous sinus.

Epiphora is caused by obstruction or infiltration of the lacrimal duct situated in the anteromedial aspect of the maxilla.

Facial swelling and malocclusion result from bone destruction and advancement of the tumor into the soft tissues of the face or mouth.

Trismus signals far-advanced tumor invading the muscles of mastication, most commonly the pterygoid muscles.

Neck mass; palpable metastatic adenopathy in the jugular chain is another sign of advanced disease.

Hearing loss usually results from nasopharyngeal extension of the tumor that obstructs the eustachian tube. This finding is important because nasopharyngeal extension of disease usually precludes a clear resection margin in this area.

Facial numbness is a manifestation of tumor invasion of portions of the trigeminal nerve.

Physical Findings

Until the tumor has infiltrated a cranial nerve or facial bones or has grown sufficiently to obstruct a sinus ostium, it silently advances in size and extent. Discovering an asymptomatic sinus tumor at an early stage is truly a rare and fortuitous event. The most common physical features are as follows:

Nasal, facial, or intraoral mass. The intranasal mass is often necrotic, but polypoid mucosa may obscure underlying tumor tissue in the nose. Facial swelling results when an antral tumor erodes into the soft tissues of the cheek. Widening of the upper alveolar ridge or development of loose, nonvital teeth may be the earliest sign of inferior bony invasion. A palatal mass and ulceration are evidence of more advanced disease.

Proptosis. Mild protrusion of the eye may be consistent with tumor compression of the periorbita without frank invasion, but often it reflects intraorbital tumor and implies advanced disease.

Cranial nerve deficits. The commonly involved cranial nerves are II, III, IV, V1, V2, and VI. Involvement of cranial nerves is a manifestation of advanced disease and indicates a poor prognosis.[8]

Diagnostic Assessment

The selection of diagnostic studies should be guided by thorough history-taking and head and neck examination, including a careful assessment of cranial nerve function. Once a working diagnosis of neoplasm has been inferred from the history and physical findings, subsequent studies are directed toward establishing the extent of the lesion and its histology.

Imaging Studies

Computed Tomography

Computed tomography (CT) is the initial imaging modality of choice for paranasal sinus disease. CT is superior to magnetic resonance imaging (MRI) for detection of bony involvement. CT scanning is also particularly helpful for evaluation of tumor involvement of the retro-orbital and orbital apex region, where there should be a "central low density region of fat surrounding the optic nerve with a radial arrangement of the extraocular muscles."[9] Loss of this plane implies advanced disease because the veins in this area extend directly to the cavernous sinus. CT is also valuable in assessing infiltration of the nasopharynx, where normal anatomy consists of a very thin layer of mucosa over the medial pterygoid plate. Thickening in this region implies tumor infiltration.[9] When evaluation of intracranial extension is necessary, contrast-enhanced CT may improve the definition of tumor from adjacent brain.

Magnetic Resonance Imaging

The impact of MRI on the preoperative assessment of tumor extent has been dramatic. The combination of CT to evaluate changes in the bony architecture of the cranial and facial structures with MRI to define soft tissue extent of disease has introduced a new era in staging and planning treatment for sinus neoplasms. The particular benefit of MRI is its ability to differentiate tissue density and predict with excellent accuracy the difference between tumor and retained secretions in the sinuses. By using T1 and T2 weighting with gadolinium dye enhancement, the experienced neuroradiologist is able to accurately determine the extent of the tumor.

Angiography

Angiography may be appropriate, especially if the lesion demonstrates enhancement during the initial contrast CT study or if it approximates the carotid system. This modality can also be helpful in the evaluation of unusual tumors involving the sphenoid sinus and skull base. In the instance of vascular tumors involving the sinuses, angiography is essential for assessment of tumor extent and delineation of feeding vessels and as an approach for embolization when it is deemed necessary and safe.

Positron Emission Tomography

Positron emission tomography is of little utility in assessing local tumor extent, but it can play a role in evaluating for the presence of metastatic disease before extensive oncologic surgery with or without concomitant chemoradiotherapy, in which a pretreatment positron emission tomography study provides the optimal baseline for post-treatment decision-making.

Biopsy

Often a paranasal sinus tumor presents a surface that lends itself to biopsy at the time of initial clinical presentation. In this instance a biopsy specimen obtained with use of local anesthesia and a biting forceps advances the diagnostic evaluation. Infiltration of epinephrine with a local anesthetic may decrease bleeding. Tumors contained within the sinus cavities are ideally sampled transnasally because transcutaneous or transmucosal approaches may breach the margins of a subsequent en bloc resection. One must be mindful of the possibility of a vascular tumor or an encephalocele during biopsy of unilateral nasal masses. Usually palpation of the tumor with an instrument demonstrates its solid nature. If the mass is soft or cystic, the patient should be asked to perform a Valsalva maneuver while the mass is being observed. Expansion of the mass implies an intracranial connection or a major venous connection. If doubt still exists, it is best to perform aspiration with a fine-gauge spinal needle before the biopsy. If the needle aspirate consists of cerebrospinal fluid or blood, CT, MRI, and, possibly, angiography should be considered before a biopsy is performed.

If none of the preceding methods achieves satisfactory material for histologic examination, the tumor must be approached directly. A surgical procedure appropriate to the lesion must be selected (such as frontal trephination, transseptal sphenoidotomy, intranasal antrostomy, or external ethmoidectomy). Performance of biopsy through a standard endoscopic sinus surgical approach is also appropriate when feasible. The operation should be designed to minimize disruption of later en bloc resection. Biopsy may be the only surgical procedure carried out during the patient's treatment. In that case, wide drainage of the sinus should be carried out at the time of biopsy to allow for the discharge of necrotic debris that results from subsequent therapy.

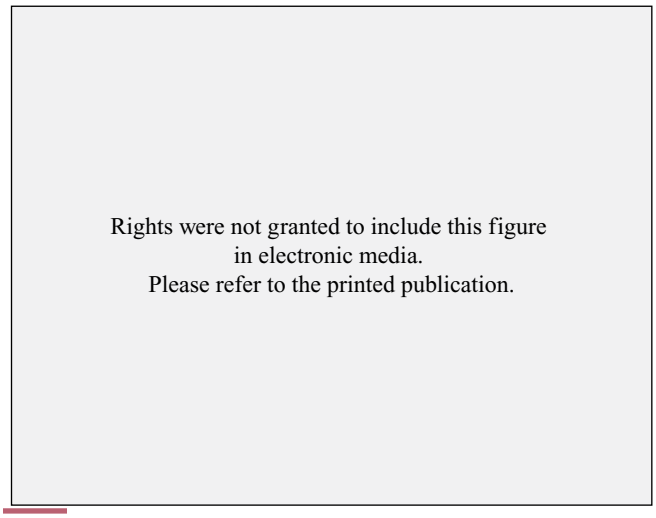

Figure 83-2. Anatomic reference for the surgical options available for treatment of malignancies of the paranasal sinuses.

Surgical Options

Extirpation of paranasal sinus tumors is a challenging exercise in surgical planning, which may be considered in three phases. First, one must assess the bony and soft tissue structures to be included for en bloc resection. Second, the approach must be designed to provide adequate exposure while preserving functional tissue and cosmetic integrity whenever possible. Third, the repair should be planned to use prosthetics or soft tissue techniques to the best advantage. See Figure 83-2 for anatomic reference.

Classic "Open" Procedures

External Ethmoidectomy

INDICATIONS. The most limited operation to be discussed, external ethmoidectomy, is appropriate for removal of small tumors of the ethmoidal region and as an approach to biopsy and drainage of tumors of the sphenoethmoid region and the medial orbit (Fig. 83-3).

BONY EXCISION. The limits of bony resection are the medial orbital wall and the ethmoidal labyrinth.

SURGICAL APPROACH. The surgical approach is through an incision on the lateral wall of the nose.

BENEFITS. The external ethmoidectomy approach allows excellent cosmesis and preservation of functional tissue.

LIMITATIONS. External ethmoidectomy will not provide en bloc excision for any but the most limited tumors (middle turbinate). There

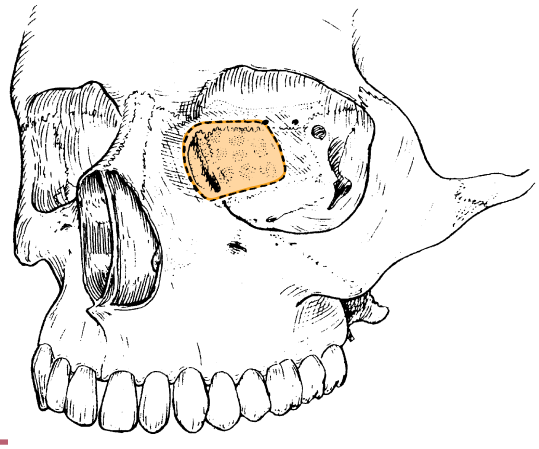

Figure 83-3. External ethmoidectomy.

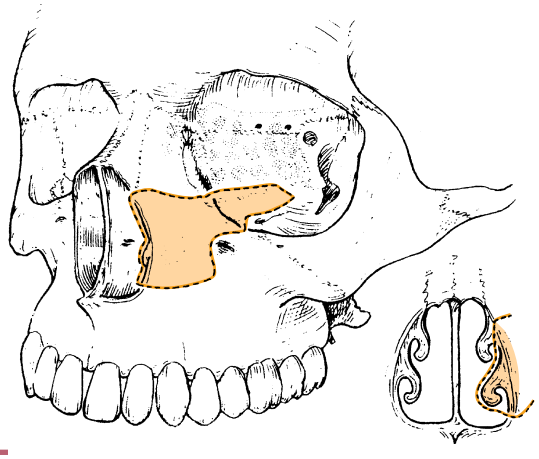

Figure 83-4. Inferior medial maxillectomy.

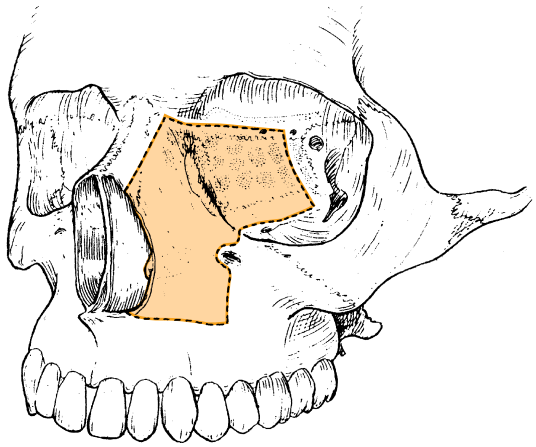

Figure 83-5. Medial maxillectomy.

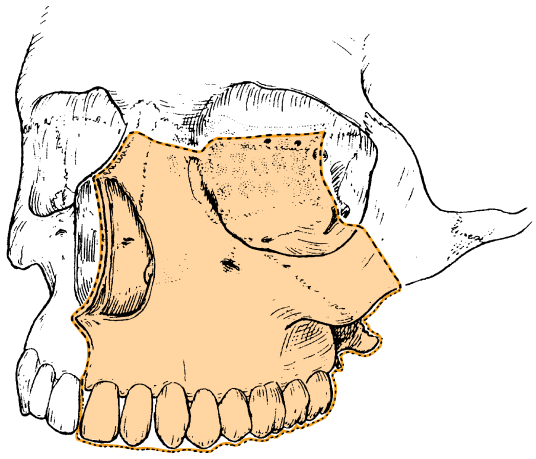

Figure 83-6. Radical maxillectomy.

is a tendency for fistula formation from the skin to the nasal cavity when this area is irradiated.

Inferior Medial Maxillectomy

INDICATIONS. Inferior medial maxillectomy is designed for resection of the medial wall of the antrum and the inferior turbinate. It is most often used for management of an inverted papilloma (Fig. 83-4).

BONY EXCISION. The margins extend laterally to the infraorbital foramen, inferiorly to the floor of the nose, superiorly to the lacrimal fossa and the middle meatus, and posteriorly to the dorsal end of the inferior turbinate.

SURGICAL APPROACH. A lateral rhinotomy incision is frequently used; the same bony excision may be achieved through a sublabial approach, although an en bloc resection may be more difficult with the latter approach.

BENEFITS. Inferior medial maxillectomy allows adequate exposure and resection for limited tumors while preserving functional tissue and providing a very acceptable cosmetic result.

LIMITATIONS. Inferior medial maxillectomy provides en bloc removal of a limited area.

Medial Maxillectomy

INDICATIONS. Medial maxillectomy may be used for larger benign or intermediate tumors involving the entire lateral nasal wall but without extension to the orbit, anterior cranial fossa, lateral maxilla, or alveolus (Fig. 83-5).

BONY EXCISION. The block removed contains the lateral nasal wall, including all turbinate tissue, and the contents of the ethmoid and maxillary sinuses.

SURGICAL APPROACH. An extended lateral rhinotomy incision provides excellent exposure. In some instances the same procedure may be accomplished by combining an ethmoidectomy incision with a sublabial incision.

BENEFITS. An en bloc resection may be accomplished with little resulting cosmetic deformity.

LIMITATIONS. Postoperative epiphora due to division of the nasolacrimal duct is not uncommon. The posterior and superior margins of resection should be monitored by means of a frozen section when indicated. Removal of all turbinate tissue results in an abnormal nasal cavity, which may require long-term management of crusting.

Radical Maxillectomy

INDICATIONS. Radical maxillectomy is the standard operation for advanced carcinoma of the maxilla (Fig. 83-6). Considerable debate exists regarding the proper application of this procedure, because the amount of tissue to be removed depends on a careful assessment of the extent of tumor involvement. Another uncertainty relates to the establishment of proper indications for removal of the orbital contents in combination with radical maxillectomy.

BONY EXCISION. Complete radical maxillectomy involves removal of the maxilla along with the nasal bone, the ethmoid sinus, and, in some instances, the pterygoid plates.

SURGICAL APPROACH. The Weber-Ferguson incision is used with extensions around the eyelids to preserve those soft tissues. A skin or dermis graft is used to line the defect.[10] A preformed obturator can be of great assistance in the immediate postoperative period because it acts as a support for packing and provides immediate dental function.

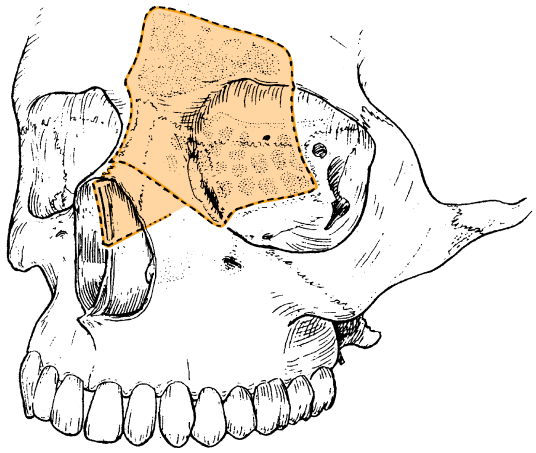

Figure 83-7. Craniofacial frontoethmoidectomy.

BENEFITS. Radical maxillectomy is adequate treatment for malignant tumors confined to the maxilla and those with extension to the facial soft tissues, lateral palate, or anterior orbit but without invasion of the eye, ethmoidal roof, posterior orbit, or pterygoid region. Historically, when the procedure was supplemented by irradiation, a cure rate approximating 30% was expected.[2] However, in the update by Sisson and associates[3] on their experience, patients who received multimodality therapy consisting of surgery, irradiation, and chemotherapy achieved a 5-year survival rate of 49%.[3]

There is little debate regarding the indications for resecting the orbital contents in patients with advanced paranasal sinus carcinoma.[10a] As indicated by Ketcham and Van Buren,[8] the decision to excise the orbital contents was made on the basis of achieving an en bloc resection of the tumor. However, those researchers implied that as imaging became more precise, more selective resection might be possible. Perry and colleagues[11] emphasized the impact of CT on surgical planning and documented that selective preservation of the orbital contents is appropriate and achieves adequate local control in properly selected cases.[11] This finding was consistent with the experience of Weymuller and coworkers,[12] who also could not demonstrate better local control or survival when the orbital contents were included in maxillectomy procedures. This position was later further supported by the experience of Larson and associates.[13]

LIMITATIONS. Even when orbital exenteration is included, a maxillectomy fails to provide an adequate resection when the tumor has escaped superiorly (ethmoidal roof) or posteriorly (orbital apex, pterygoid region). When these areas are demonstrably involved, one must decide whether to undertake craniofacial resection or use a regimen as described by Sakai and colleagues[14] that relies on chemotherapy, curettage, and irradiation.

Craniofacial Frontoethmoidectomy

INDICATIONS. Craniofacial frontoethmoidectomy is specifically designed to provide en bloc resection for tumors of the ethmoidal and frontal regions (Fig. 83-7). By including exposure of the anterior cranial fossa, the procedure makes possible complete resection of the ethmoid and frontal sinuses, and dural resection may be included when necessary. As previously noted, one or more margins of these extensive resections are often limited by proximity to the eye or brain, resulting in surgical margins that are "microscopically positive" for tumor.

BONY EXCISION. Resection may include the anterior cranium (including the frontal sinus), the floor of the anterior cranial fossa, the ethmoid labyrinth (and the eye when necessary), and the nasal septum. If the tumor crosses the midline, the procedure may be performed bilaterally.

SURGICAL APPROACH. The craniofacial frontoethmoidectomy approach described by Kaplan and associates[15] allows excellent exposure with preservation of the supraorbital rim to decrease the cosmetic impact of the procedure. Although removal of the eye is unpleasant to consider, Ketcham and Van Buren[8] have documented an improved survival when orbital resection is combined with craniofacial resection (57%, vs. 26% without exenteration).

BENEFITS. Craniofacial exposure provides direct visualization of the cribriform plate and the fovea ethmoidalis and the potential for en bloc removal. It also offers wide exposure to allow effective repair of dural tears, thus decreasing the chance of a postoperative cerebrospinal fluid leak and intracranial infection.

An international collaboration reviewing 188 patients published a report in 2005. The reported mortality associated with craniofacial resection was 4.5%, and the complication rate was 33%.[16] Surgical margins, histologic type, and intracranial extension were independent predictors of survival. Shah and associates[17] reported their experience with 71 patients, which showed an overall 5-year survival of 56% and a median survival of 4.2 years. Like the international group, Shah and associates[17] showed that intracranial involvement predicted significantly worse survival.

LIMITATIONS. If the tumor extends to the sphenoid sinus, the cavernous sinus, or transdurally, en bloc resection cannot be achieved.

Extended Craniofacial Resection

INDICATIONS. A single definitive extended craniofacial resection cannot be described (Fig. 83-8). Extensive tumors involving the anterior skull base, including certain tumors with involvement of the pterygoid plates, can be approached surgically, with the resection to include any and all of the structures outlined below. Each operation is individually tailored according to the extent and nature of the tumor to be excised.[18,19]

BONY EXCISION. The posterior line of resection is defined by the foramen ovale, the foramen rotundum, and the internal carotid artery. The excision may extend through the sphenoid sinus and up to the contralateral optic nerve. The remaining margins are those of the craniofacial frontoethmoidectomy and the radical maxillectomy.

SURGICAL APPROACH. A team consisting of a neurosurgeon and a head and neck surgeon should perform the extended craniofacial resection. A combination of coronal and anterior or lateral facial incisions is used for exposure. The closure is improved by inclusion of a split-galea flap or free tissue transfer to cover the dura.

BENEFITS. Thorough exposure and complete excision of otherwise unresectable tumors are the main benefits of extended craniofacial resection.

LIMITATIONS. In discussing the limitations of the craniofacial approach, Ketcham and Van Buren[8] cited clear-cut pterygoid plate erosion and cranial nerve invasion as indicators of unresectability. Even though this operation has extended the limit of surgical resection and in so doing has resulted in occasional cures, we must reiterate that it does not provide clear resection margins at the orbital apex, the nasopharynx, or the deep pterygoid space. Local control depends on the addition of aggressive adjuvant therapy.

Supplemental Management in Extended Craniofacial Resection

The boundary between resectability and unresectability for advanced skull base malignancy is ill defined. For reasons of palliation or for attempted cure, it is not uncommon for extended craniofacial resection to be performed for the resection of all grossly resectable tumors, with the understanding that at the most central margins of the resection there is a high probability of residual microscopic disease. In this setting, consideration of supplemental therapy is appropriate and it has a modest track record of success. In particular, using the surgical exposure as an opportunity to deliver localized supplemental irradiation is now a well-accepted technique. Intraoperative radiotherapy of the skull base has been documented as a technique to improve local control rates.[20,21]

Our unreported institutional experience with intraoperative iodine seed implantation at the University of Washington has been reviewed. Local regional control appears acceptable for tumors with indolent biologic behavior (such as adenoid cystic carcinoma). For patients with undifferentiated carcinoma and squamous cell carcinoma, the anticipated benefit for long-term survival is poor. Additionally, our experience has highlighted the risk of intracranial infection when radioactive seed implantation is used after previous irradiation. For this

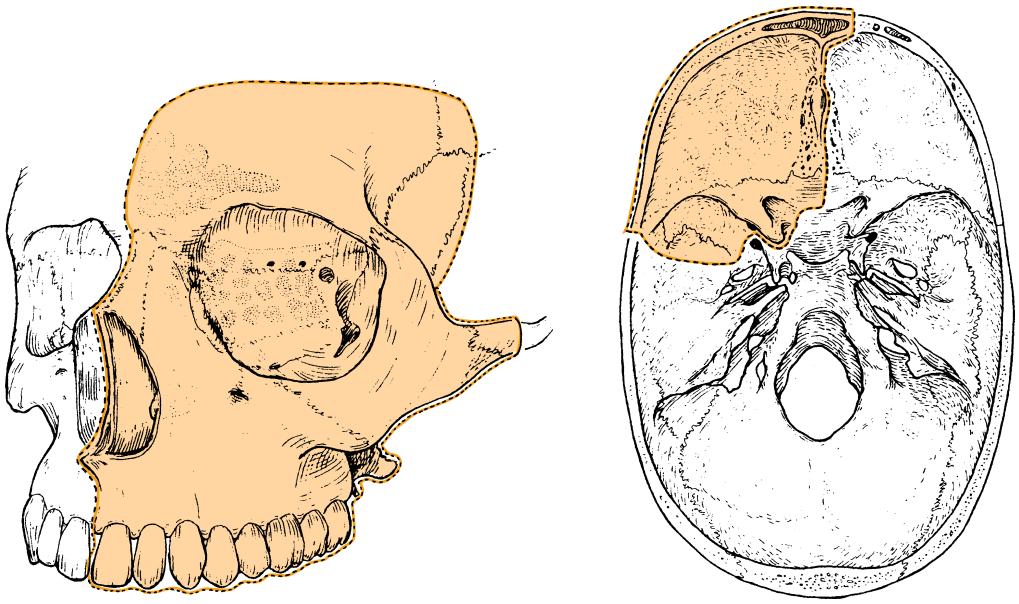

Figure 83-8. Craniofacial resection.

reason, our current posture is that whenever radioactive seeds are used as a supplement to previous irradiation, the skull base should be reconstructed with free tissue transfer to establish a highly vascularized and relatively thick separation between the airway and the intracranial contents.[22] Vikram and Mishra[23] offer support for this technique. Depending on the size of the defect, the radial forearm and rectus abdominis musculocutaneous flaps are best suited for this purpose because they are easily accessible, they provide the necessary soft tissue bulk to seal the defect, and they have sufficient pedicle length to reach recipient vessels in the neck from the skull base.

Minimally Invasive Approaches

Advancements in imaging combined with extensive experience with image-guided endoscopic surgery and new chemoradiotherapy regimens have significantly altered attitudes regarding the optimal approach to sinus malignancy. Multiple authorities have now published institutional series to document the value of endoscopic approaches. Common to all publications is a philosophy that includes endoscopic resection as one (but not the only) option to be considered in the management of individual patients. Small, purely endonasal tumors can be effectively managed endoscopically. Lesions that involve the perimeter of the sinonasal region (orbit and cranium) require consideration of combining endoscopic with the various open procedures described previously. In our experience, a surgical procedure that begins with endoscopic resection to define the truly involved areas, in combination with a flexible plan for a combined open approach (as dictated by the endoscopic findings), results in the least invasive and most accurate tumor resection. A similar surgical philosophy is reflected in a number of articles by others.[24-29]

Walch and colleagues[30] have utilized endoscopic sinus surgery, in combination with stereotactic radiosurgery, in the management of several cases of olfactory neuroblastoma. Stammberger and associates[31] also published a report on 43 destructive and invasive paranasal sinus lesions that were resected via an endoscopic approach and stated that "outcome is at least equal to standard external approaches." Kabil and coworkers[32] have also described a supraorbital endoscopic approach, although to date this has been limited to benign skull base tumors.

Intermediate Neoplasms

Inverted Papillomas

Inverted papilloma usually manifests as a polypoid unilateral nasal mass. On occasion these lesions may be found in association with allergic nasal polyps, accounting for the need in routine polypectomy to always submit labeled, separate specimens from each side of the nose. The histology consists of infolded epithelium that may be squamous, transitional, or respiratory. The incidence of frank malignant change approximates 10%.[33]

Even when not malignant, inverted papillomas must be treated with respect, because incomplete excision is likely to result in recurrence.[34] A lateral rhinotomy incision combined with medial maxillectomy to allow adequate margins is the classic approach. However, experience with endoscopic sinus surgery supports a less invasive approach. In carefully selected cases, inverted papilloma may be removed endoscopically. For example Sautter and associates[35] published a retrospective review of their experience at Cleveland Clinic Foundation of 68 patients with inverted papilloma.[35] These researchers reported the following recurrence rates: 22% in the endoscopically resected group, 39% in the open resection group, and 50% in "limited open cases."

Intermediate Neoplasms

Epithelial Malignancy

Staging

Staging is appropriately discussed only in the context of squamous cell tumors because the other lesions are so uncommon that they do not warrant such attention (or such confusion). As Harrison[36] has suggested, the staging system should allow differentiation between distinct stages of disease progression.

In 1933, Ohngren[7] emphasized the ominous importance of tumor spread in a posterior or superior direction. "*Ohngren's line*," described as an imaginary line extending from the medial canthus to the angle of the jaw, gives a rough estimate of the dividing line between tumors that may be resected with a good prognosis or a poor prognosis (Fig. 83-9). Ohngren[7] developed a staging system based on personal experience that included topography (tumor location and extent), histology (three grades), and cervical metastases (presence or absence). Tumors located below Ohngren's line involved fewer critical structures and were associated with a better survival rate than lesions arising above the line, which were more likely to involve important structures such as the orbit, optic nerve, and carotid artery. That the system was effective is borne out by this researcher's statistics, which clearly show a difference in rates of 3-year "freedom from symptoms" between groups I (82%), II (63%), and III (25%).

Other systems have been proposed by experienced surgeons. Each represents a personal variation of the generally accepted schemes, but they differ from one another sufficiently to make direct comparison of

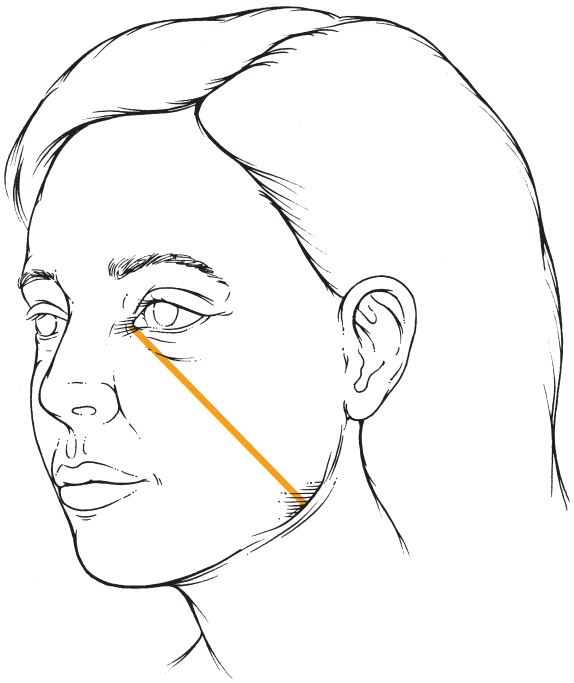

Figure 83-9. Ohngren's line—an imaginary line extending from the medial canthus to the angle of the jaw—gives a rough estimate of the dividing line between tumors that may be resected with a good prognosis (below the line) and with a poor prognosis (above the line). *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

results impossible, thus negating one of the primary goals of any staging system. The interested reader is referred to the article by Harrison[36] for further discussion and references.

According to the American Joint Committee on Cancer, staging of nasal cavity and paranasal sinus carcinomas is not as well established as for other head and neck tumors. For cancer of the maxillary sinus, the nasal cavity, and the ethmoid sinus, the Committee has designated staging by TNM classification (Box 83-1).[37] This system is well accepted, although an adjustment based on Harrison's[36] criticism of it should be seriously considered. In particular, he argued that orbital apex involvement and pterygoid muscle involvement should be placed in the T4 category. The 6th edition of the American Joint Committee on Cancer's staging manual does differentiate between resectable lesions (T4a) and unresectable lesions (T4b) of the maxillary sinus.[37]

Management

Definitive treatment has included surgery, irradiation, and electrocoagulation in varying combinations. Adjunctive chemotherapy has been introduced, but its impact on outcome is still uncertain.

Maxillary Sinus Tumors

Early (T1 and T2) lesions may be treated by surgical resection (maxillectomy) or irradiation. Although Wang[38] did not recommend definitive irradiation, he did report curing all of four patients with T2 maxillary sinus tumors with that modality alone. Bryce[10] has also stated that irradiation alone (5500 rad) is an effective way to manage early tumors but that 25% to 30% of patients will die of local recurrence.

The majority of patients have advanced (T3 or T4) disease when first seen, which most authorities agree requires combined therapy for optimal control.[10,14,38] Considerable variation exists within each reporting institution regarding the application of surgery and irradiation. All series are retrospective and present a mixture of patient populations, usually receiving the following types of management: surgery for cure, surgery with preoperative or postoperative irradiation, and irradiation with surgical salvage. This collection of retrospective data leaves one in a muddle, although some trends are becoming apparent.

Surgery Alone

Surgery alone is generally accepted as adequate management for tumors isolated to the antral mucosa. As stated previously, most investigators agree that T3 and T4 lesions require combined therapy. Terz and coworkers[39] have taken a more aggressive surgical posture and have reported dramatic improvement in survival for patients with T3 and T4 lesions when craniofacial resection was performed. According to these researchers, craniofacial resection achieved a remarkable 3-year disease-free survival of 72% (15 of 22 patients) among patients who had T3 or T4 tumors. The numbers are even more surprising when one realizes that irradiation was not used. However, reporting separately on patients from the same institution and the same time period, Amendola and colleagues[40] compared the outcome of 19 patients who underwent "radical craniofacial surgery" with that of 20 patients treated with megavoltage irradiation and a Caldwell-Luc procedure.[40] Their reported 3-year survival for the group undergoing radical craniofacial surgery was 37%, whereas that for the irradiated group was 50%. Were the surgical patients reported on by Terz and coworkers[39] identical to those reported on by Amendola and colleagues?[40] If so, how do we resolve the dichotomy of the reporting, and in what light should we hold any retrospective report concerning an uncommon disorder that is typically managed on an individual basis?

Surgical management should include consideration of immediate rehabilitation. This is usually best achieved with prosthetics that allow immediate restoration of function and yet are removable to allow inspection of the maxillary cavity. Preformed palatal plates may be used to support transoral packing in the postoperative period and may later be modified to occlude the oronasal defect. If one has access to a talented prosthetics department, the aftermath of a craniofacial-orbital resection can be reasonably well camouflaged.

Traditionally, reconstruction of maxillary sinus defects has been performed with skin graft and prosthetics. With the advent of free tissue transfer, more acceptable cosmetic reconstruction including rehabilitation of the bony hard palate for dental rehabilitation is now achievable. The fibula osteocutaneous flap has been shown to be a reliable method of midface reconstruction for lower maxillary defects. It allows for closure of the palate as well as placement of osseointegrated dental implants or implant-borne prosthetics.[41] However, this approach is of limited use when the orbitozygomatic support is the objective. In these instances, the scapula osteocutaneous flap is preferable. This flap has the advantage of better rotation of the soft tissue component around the bone, which allows for reconstruction of the orbital floor, palate, and zygoma.[42] Iliac crest osteomyocutaneous flaps can be used when additional soft tissue bulk and bone are required. Clearly one of the major potential risks is "covering recurrent disease"; however, because disease recurrence at this site, whether observed or not, is sometimes untreatable, this may be a moot point.

Combined Irradiation and Surgery

With T3 tumors, there is little survival difference between preoperative irradiation and postoperative irradiation. Postoperative irradiation often controls microscopically positive resection margins. With the more advanced lesions, especially those for which resectability is questionable, preoperative irradiation appears to be the procedure of choice. A planned preoperative dose of 5500 rad has been used successfully, followed by radical resection.[10] For patients in whom no tumor is found at operation, the 5-year survival is 77%; for those in whom tumor is found, 5-year survival is 23%; overall survival is 50%. For operable lesions (meaning those not extending to the nasopharynx, skull base, or pterygoid fossa), Wang[38] favored radical surgery to remove tumor bulk and establish drainage followed by irradiation using 5000 to 5500 cGy in 6 weeks.

Radiotherapy

Wang[38] took special care to shield the eye and the frontal lobe and reported a recurrence rate of 76% for 34 patients treated with irradiation alone.[38] In contrast, Ellingwood and Million[43] intentionally irradiated the orbit to include the probable routes of tumor extension within the irradiation field. Their cure rate of 71% suggested a successful regimen. However, all patients treated with this regimen lost vision in

Box 83-1

Staging of Paranasal Sinus Malignancies According to the American Joint Committee on Cancer

TNM Definitions

Maxillary Sinus

Primary Tumor (T)

- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma in situ
- T1: Tumor limited to maxillary sinus mucosa with no erosion or destruction of bone
- T2: Tumor causing bone erosion or destruction including extension into the hard palate and/or the middle of the nasal meatus, except extension to the posterior wall of maxillary sinus and pterygoid plates
- T3: Tumor invades any of the following: bone of the posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa, ethmoid sinuses
- T4a: Tumor invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
- T4b: Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V_2), nasopharynx, or clivus

Nasal Cavity and Ethmoid Sinus

Primary Tumor (T)

- TX: Primary tumor cannot be assessed
- T0: No evidence of primary tumor
- Tis: Carcinoma in situ
- T1: Tumor restricted to any one subsite, with or without bony invasion
- T2: Tumor invading 2 subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
- T3: Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
- T4a: Tumor invades any of the following: anterior orbital contents, skin of nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
- T4b: Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than (V_2), nasopharynx, or clivus

Regional Lymph Nodes (N)

- NX: Regional lymph nodes cannot be assessed
- N0: No regional lymph node metastasis
- N1: Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
- N2: Metastasis in a single ipsilateral lymph node, >3 cm but ≤6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension
  - N2a: Metastasis in a single ipsilateral lymph node >3 cm but ≤6 cm in greatest dimension
  - N2b: Metastasis in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension
  - N2c: Metastasis in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension
- N3: Metastasis in a lymph node >6 cm in greatest dimension

In clinical evaluation, the actual size of the nodal mass should be measured, and allowance should be made for intervening soft tissues. Most masses >3 cm in diameter are not single nodes but confluent nodes or tumors in soft tissues of the neck. There are 3 stages of clinically positive nodes: N1, N2, and N3. The use of subgroups a, b, and c is not required but is recommended. Midline nodes are considered homolateral nodes.

Distant Metastasis (M)

- MX: Distant metastasis cannot be assessed
- M0: No distant metastasis
- M1: Distant metastasis

the treated eye. Amendola and colleagues[40] also documented a 3-year absolute survival of 55% for the use of an average of 6600 cGy for lesions that were primarily T4. The fields were angled posteriorly to avoid the contralateral optic nerve. No complications of irradiation were mentioned in this article, and the authors stressed the improved quality of life in patients undergoing irradiation for cure compared with those undergoing craniofacial resection.

Difficulties in the use of standard radiation therapy for paranasal sinus tumors arise from the fact that in air-filled spaces such as the sinuses, the range of particles and thus the dosimetry are subject to considerable uncertainty.[44] Treatment with conventional photon-beam technique using an anterior field and one or two wedged lateral fields either may cause significant morbidity to the eye and optic nerves or may result in significant under-dosing of portions of the posterior

ethmoid and maxillary sinuses. Improvements using conformal radiotherapy and intensity-modulated radiation therapy have allowed for more precise treatment of paranasal sinus tumors with sparing of binocular vision by improving the tumor-dose homogeneity while reducing the dose to the optic nerves and lenses.[45] These techniques allow for the treatment of tumors with large volumes and complex shapes in critical proximity to organs at risk, such as the eye and optic nerves. Although these techniques have yet to provide a therapeutic advantage (improved survival) over standard radiotherapy, they have the potential of offering better protection of adjacent normal structures.

Chemoradiotherapy

Perhaps the most significant variation from traditional management was reported by Sakai and colleagues.[14] They accumulated more than 780 patients from 1957 to 1983 at Kobe and Osaka Universities in Japan. Their cumulative experience demonstrated impressive results for their latest reported regimen, which consisted of 5000 cGy, continuous intra-arterial 5-fluorouracil infusion, tumor reduction (via the Caldwell-Luc procedure), and immunotherapy. In the years covered by this experience they observed an increase in 5-year survival from 20% (282 patients treated with 7000 cGy and maxillectomy, 1957-1966) to 54% (134 patients treated with the current regimen, 1976-1979). They simultaneously saw a substantial decrease in functional disability encountered by their patients.

An analogous regimen was reported from Rotterdam, Holland, with similarly encouraging results in a series of 60 patients (2-year survival, 76%; 5-year survival, 65%).[46] Several smaller studies have also demonstrated clinical benefit to the use of combined chemotherapy and radiation therapy. Using doses of 6920 cGy and adjuvant chemotherapy in responders, Fitzek and colleagues[47] demonstrated a local control rate of 88% in 19 patients with advanced neuroendocrine carcinoma of the sinonasal tract.Use of split-course concomitant infusion cisplatin chemotherapy with hyperfractionated radiotherapy in 21 patients with locally advanced nasopharyngeal and paranasal sinus tumors resulted in a local control rate of 94% without an increase in normal tissue injury.[48] In 33 patients with maxillary sinus carcinoma, 5-year survival rates of 86% for T3 lesions and 67% for T4 lesions were achieved by Nibu and associates,[49] who used 3000 to 4000 cGy of preoperative radiotherapy with concomitant intra-arterial infusion of 5-fluorouracil and cisplatin followed by 3000 to 4000 cGy of postoperative radiotherapy. Dramatic response with combined chemotherapy and irradiation appears to be possible even in the presence of bulky or unresectable disease, with acceptable complication rates and less morbidity than associated with craniofacial resection and conventional radiotherapy. Further study is necessary to refine this evolving therapeutic technique, because small single-institution studies have limited ability to draw definitive conclusions regarding these approaches.

Inoperable Neoplasms

Irradiation may be used to determine operability in tumors that initially appear inoperable. In this situation, Wang[38] delivered 6000 cGy in 6 weeks, with surgery to follow.He encouraged aggressive surgery if the response to irradiation appeared to make the lesion operable. If margins were subsequently positive, a further boost of local irradiation was considered. Interestingly, Wang[38] had better results in this group of patients with more advanced tumors (survival of 58% or 11 of 19 patients) than he did in those with smaller lesions, in which he favored surgery to be followed by irradiation (survival of 36%, or 5 of 14 patients). The rationale for treating patients with "curative" doses of irradiation when their lesions are initially inoperable is borne out by the number of long-term survivors seen in this group of patients.[38] This result is probably a manifestation of the heterogeneous nature of the "inoperable" patients; some are inoperable by virtue of tumor extent, whereas others either are medically unsuitable for surgery or have refused it outright.

Lee and coworkers[50] documented the potential value of intra-arterial infusion chemotherapy (5-fluorouracil) and simultaneous irradiation for initially inoperable tumors. They achieved an absolute 2-year survival of 50% in this group, which had a very poor prognosis. Survival dropped to 28% at 5 years. Unfortunately, optic nerve damage was fairly prevalent and caused bilateral blindness in two patients. The utilization of selective chemotherapy and irradiation for advanced tumors of this area has tremendous appeal when contrasted to the defects created by surgical ablation of lesions in the axial region of the skull.

Ethmoid, Sphenoid, and Frontal Sinus Tumors

Ethmoid, sphenoid, and frontal sinus tumors are especially likely to manifest at advanced stages. Tumor extension to the structures of the skull base can be expected at initial presentation in 50% of patients with these lesions.[43]

Assessment and management of ethmoidal carcinoma should be performed with a specific staging system in mind. The four-stage system introduced by Dulguerov and colleagues[1] has been modified and updated by the American Joint Committee on Cancer (see Box 83-1). This system is useful because it distinguishes tumors originating in the nasal cavity from those originating in the sinuses.[1,37] Management for esthesioneuroblastoma and adenocarcinoma is generally similar, based on craniofacial resection and postoperative irradiation when surgically feasible. The addition of chemotherapy to the management of advanced esthesioneuroblastoma (T3 and T4) is now well established, particularly in light of the experience of Spaulding and associates[51] at the University of Virginia.

In 2005 a large multi-institutional study, The International Collaborative Study, examined outcomes related to craniofacial surgery for malignant sinus tumors.[51a] This review of 334 patients revealed an overall 5-year survival rate of 48%, with craniofacial resection and multimodality therapy in a selection of these patients. Free surgical margins, intracranial extension, and histologic findings were independent predictors of survival. Suarez and colleagues showed similar findings in their review of 100 patients who underwent craniofacial resection for malignant sinus tumors.[51b] They showed 40% overall 5-year survival. Interestingly, positive surgical margins, orbital periosteum involvement, dura involvement, and frontal sinus invasion were not associated with increased mortality. Only tumor histology, brain involvement, deep orbit involvement, sphenoid sinus involvement, and previous treatment predicted decreased survival.

Ketcham and Van Buren's[8] argument for craniofacial resection in patients with malignancy extending to or primarily arising from the ethmoid sinus was presented and discussed earlier. En bloc tumor resection, improved assessment of disease extent, and better cosmesis provided the rationale for applying this technique. These researchers obtained a 5-year survival of 41% in a particularly challenging group of patients, many of whom were referred with advanced disease after failure of previous treatment. They also reported lower survival with preservation of the orbital contents (26%) than with orbital resection (57%). Further documentation of the techniques and applicability of craniofacial resection and its significant impact on improved local control and survival can be found in studies reported by Shah and associates,[17] Biller and coworkers,[52] and Panje and colleagues.[53]

Ellingwood and Million[43] stressed the importance of properly designed fields to include the whole orbit (when necessary) and skull base. Using primary irradiation, they achieved a 5-year actuarial survival of 59% and a 5-year survival with no evidence of disease of 50%. The incidence of major complications in this series was substantial; blindness occurred in every eye treated with irradiation of the whole orbit.

Primary carcinoma of the frontal sinus is a very uncommon entity. According to a review article by Brownson and Ogura,[54] the survival rate is 1 of 33 patients. One would anticipate improvement of these statistics as craniofacial resection and appropriately designed irradiation fields are used.

Involvement of Cervical Lymph Nodes

Involvement of cervical nodes occurs in about 25% to 35% of paranasal sinus tumors.[55] Most authorities agree that palpable cervical lymph nodes indicate a very poor prognosis.[12] In contrast, the experience of Shidnia[56] suggests that if neck disease is discovered at an early stage, it can be successfully managed with neck dissection. These researchers advise inclusion of the ipsilateral neck and preauricular area in the initial field of irradiation for T3 and T4 tumors.

Adenocarcinoma

Adenocarcinomas have an epidemiologic association with woodworking, furniture making, and leatherwork. They are more commonly found in the upper nasal cavity and ethmoid sinus and are usually lethal by virtue of local progression. In light of its propensity for aggressive local progression, adenocarcinoma should be treated in a surgically aggressive fashion with en bloc resection when possible.

In contrast to adenoid cystic carcinomas, adenocarcinomas have a relatively low incidence of distant metastasis, but the long-range survival is equally poor. There is a range of histologic differentiation. Patients with the poorly differentiated form have a 5-year survival no better than 20%,[33] whereas that for patients with well-differentiated papillary tumors is better.[54]

Adenoid Cystic Carcinoma

Adenoid cystic carcinomas occur with about the same frequency as adenocarcinomas but most commonly involve the antrum. They have a variable histologic pattern, and substantial biopsy tissue may be necessary before an accurate diagnosis can be established. Also part of the histologic picture is the propensity of these lesions for invasion along nerve sheath structures. Adenoid cystic carcinomas are more likely to express distant metastases than regional metastasis, although the most likely cause of death is relentless local progression at the skull base. Initially high cure rates (5-year survival of 75%) decrease as time goes on, with the Armed Forces Institute of Pathology Registry reporting a 15-year survival of 25%.[33]

More recently, the group at the M.D. Anderson Cancer Center reviewed 105 patients with adenoid cystic carcinoma of the paranasal sinuses and showed an overall 5-year survival rate of 70%.[56a] Orbital and infratemporal fossa involvement did not appear to affect survival.

Management relies on surgical resection, with irradiation added if the margins are in question.[38] Bryce[10] recommended using only one major modality (surgery or irradiation) at a time because the 5-year survival is good and late recurrence is virtually a certainty. This posture is based on a desire to hold a potentially effective treatment modality in reserve. One wonders whether this approach is treating the physician or the patient, because we do not know whether combined treatment decreases the recurrence rate or increases the disease-free interval. A contrasting opinion was offered by Horree,[57] who has recommended "three-modality therapy," including regional infusion with 5-fluorouracil, maxillary resection, and then irradiation. Neoplasms representing the entire spectrum of salivary gland malignancy have been reported to occur in the paranasal sinuses but are not discussed here.

Analysis of experience gained in the few centers that provide neutron irradiation has demonstrated improved local control in the management of salivary gland neoplasms. When confronted with an adenoid cystic carcinoma, and particularly one that is otherwise untreatable, the use of neutron beam irradiation should be seriously considered.[58,59]

Complications

The incidence of complications increases significantly when surgery breaches the intracranial space and also when high doses of irradiation are delivered to the orbit or intracranial contents. Major complications of surgery of paranasal sinus tumors are decreased by the use of perioperative antibiotics and by careful attention to dural closure, including the use of pericranial flaps. The most significant complications are meningitis, brain abscess, cerebrospinal fluid leak, and postoperative wound hemorrhage.

Cataracts are the most common complication of sinus radiotherapy. Other irradiation-induced lesions include osteoradionecrosis, keratitis, optic neuritis, and hypopituitarism. Injury to the optic nerve is made more likely with greater fraction size (250 cGy/fraction) and total dose.[38] Conformal radiotherapy and intensity-modulated radiation therapy techniques have reduced the incidence of these complications when treatment portals are in close proximity to the orbit and optic nerve. After high-dose irradiation using fields that include the whole orbit, one can expect loss of vision in 100% of cases.[43]

Therapeutic Decision-Making

Taking into consideration the data reviewed here, we make the following generalizations regarding therapy for advanced disease:

1. Most tumors are at an advanced stage when first recognized and require aggressive multimodality treatment.

2. Survival and local disease control are better when the orbit is included in the therapeutic plan (i.e., exenteration or irradiation).

3. A significant chance of metastasis to the primary (pharyngeal) and secondary (cervical) nodes exists. They should be included in the primary treatment plan.

4. Higher success rates have been reported with primary irradiation, and the associated functional and cosmetic impairment seems to compare favorably with that of surgery.

5. The best regimen may prove to be a combination of chemotherapy, irradiation, and limited surgical débridement. This, of course, requires the availability of sophisticated equipment and a cooperative effort by a multidisciplinary team.

6. The concept of intra-arterial chemotherapy for advanced skull base tumors was advocated by Lee and coworkers[50] and may see continued consideration on the basis of the experience of Robbins and associates,[60] who have pioneered the use of intra-arterial cisplatin with thiosulfate rescue and concomitant radiotherapy.

Sarcomas

Osteogenic sarcomas and chondrosarcomas of the facial skeleton are encountered more commonly in the mandible than in the maxilla. They are usually lethal by virtue of relentless local progression. In that light, the most successful therapy is based on wide en bloc resection, with 5-year survival being in the range of 10% to 20%. Irradiation seems to be an effective adjuvant for both tumors. DeFries and Kornblut[61] reported a survival of 30% with induction chemotherapy, preoperative irradiation, and wide-field ablative surgery. The multi-institutional analysis of outcome from neutron beam irradiation has identified facial sarcoma as a condition in which significant improvement was achieved. Neutron beam irradiation, when available, should be considered especially in the management of surgically unapproachable or unresectable lesions.[62]

Hyams[33] characterized a well-differentiated form and a poorly differentiated form of fibrosarcoma. One must consider the diagnosis of aggressive fibromatosis when evaluating a fibrous tumor in young adults. All tumors in this group require en bloc excision for optimal management.

Hematopoietic and Lymphoid Tumors

The paranasal sinuses are an uncommon primary site for lymphomatous tumors, but any of the multiple subtypes may occur. Because subtyping determines both the therapy and the prognosis, the most important role of the otolaryngologist is to provide adequate tissue in good condition for histologic processing. If a lymphoma is suspected, the pathology department should be notified before the biopsy is performed so that fresh specimens for flow cytometry, as well as permanent fixation, may be properly managed for subtyping and immunohistochemistry analysis.

Treatment is usually with chemotherapy, although irradiation alone is adequate for stage I and stage II Hodgkin's disease.[38]

Malignant Melanoma

Melanomas of the paranasal sinuses are usually advanced at the time of discovery. In addition to symptoms typical of sinus tumors, the patient may note a black nasal discharge and have a pigmented mass within the nose. Nonmalignant melanomas have been reported in up to 10% of cases. Frequently regional or distant metastases exist at the time of initial examination. In the Armed Forces Institute of Pathology series, the 5-year survival was 11% and the 20-year survival was 0.5%, with a mean survival of 2.3 years.[33] Although aggressive surgical removal is

the standard of care, it is obviously not very effective. Irradiation has been considered inadequate, but adjustments in fractionation may provide better results, as suggested by Berthelsen and associates,[63] who achieved local control in three of six patients with nasal melanomas treated with primary irradiation.

The Mayo Clinic reviewed a series of patients in 2008, and the study showed similar poor survival for mucosal melanoma of the paranasal sinuses.[63a] Their experience revealed an overall 5-year survival of 22%.

Paranasal Sinus Neoplasms in Children

Sinus tumors in children are usually benign. The common nasal sinus tumors of children are polyps arising on an allergic basis or in association with cystic fibrosis. The most common neoplasms are fibro-osseous lesions and tumors of dental origin. Mucoceles and hemangiomas are less frequently encountered. Embryonal rhabdomyosarcoma is the predominant paranasal malignancy.

Tumors should be assessed radiographically as discussed earlier. The diagnosis should be established by a transnasal biopsy, and a generous tissue sample should be submitted for pathologic study because special stains and electron microscopy may be necessary.

Most pediatric neoplasms are managed surgically because (1) most lesions are radioinsensitive, (2) irradiation in excess of 3000 rad has a substantial effect on growth of the facial skeleton, and (3) there is a significant risk of radiation-induced malignant transformation or secondary malignancies. Surgery should be designed to respect the developing tooth buds and facial growth centers in the palate, nose, and zygomatic process of the maxilla. The tendency is toward conservative local resection, especially with tumors of dental origin, but some lesions require en bloc resection for a curative effort.

Monostotic fibrous dysplasia is a lesion considered to be a developmental defect of bone. As such, it is most common in children and is more common in the maxilla than in the mandible. According to Schramm,[64] unlike most bony and odontogenic tumors, fibrous dysplasia sometimes requires wide local removal, including partial maxillectomy, to achieve clear margins. Resection causing a major functional or cosmetic deformity (orbital exenteration, mandibulectomy) is not often warranted. Ossifying fibromas and cementomas, in contrast, are well delineated and may be managed by local excision with minimal margins.

Rhabdomyosarcomas are the most common malignant neoplasm of the upper respiratory tract in the pediatric age group (age 15 or younger) in the Armed Forces Institute of Pathology records.[33] The tumor is aggressive, demonstrating rapid progression and dissemination. According to Hyams,[33] the histologic subcategories of juvenile rhabdomyosarcoma (alveolar, botryoid, and embryonal) have no relevance to the neoplasm's clinical behavior or the prognosis, whereas Maurer and colleagues[65] had suggested an unfavorable prognosis for cytologic anaplasia or monomorphous round cell patterns. The best survival is obtained with clear surgical margins supplemented by irradiation and chemotherapy. Maurer and colleagues[65] evaluated results from 157 nonorbital and 54 orbital rhabdomyosarcoma cases. They found patients with parameningeal involvement (as indicated by CT evidence of skull base erosion or cerebrospinal fluid analysis demonstrating pleocytosis as well as elevated protein and decreased glucose values) to have a poor prognosis. This group of patients has benefited by a treatment regimen combining intrathecal chemotherapy and craniospinal irradiation.

A report by Callender and associates[66] spanning 36 years showed that patients younger than 23 years had a 58% 5-year survival, compared with 32% for older patients. When adults and pediatric patients were combined in an analysis of treatment, the researchers found 60% 5-year survival for chemotherapy and irradiation (with or without surgery) compared with 19% for all other single-modality treatments.

Patients with a circumscribed local tumor and no evidence of distant metastases have an excellent prognosis when treated with multidrug chemotherapy and adjuvant irradiation. In most instances radical ablative surgery is not considered necessary to achieve a successful outcome.[65]

Salivary Glands

CHAPTER EIGHTY-FOUR

Physiology of the Salivary Glands

Ravindhra G. Elluru

Key Points

- Importantly, our current understanding of salivary gland physiology is largely derived from the study of nonhuman salivary glands.
- Saliva is a complex mixture of electrolytes and macromolecules secreted from three pairs of major and numerous minor salivary glands.
- The basic unit of the salivary gland consists of an acinus, a secretory duct, and a collecting duct.
- Saliva is formed via active transport processes occurring throughout the secretory unit, and these processes are under the control of complex neuronal and hormonal signals.
- The innervation patterns of the major salivary glands differ considerably, from species to species, subject to subject, and cell type to cell type.
- The neurotransmitter acetylcholine mediates the effects of the parasympathetic nervous system, whereas norepinephrine mediates the effects of the sympathetic nervous system.
- Salivary flow rates are highly variable, stabilizing after the age of 15 years, and therefore should be interpreted in a clinical context.
- Salivary secretion is controlled by a salivary center in the medulla, which is triggered by specific stimuli: (1) the mechanical act of chewing, (2) gustatory, and (3) olfactory.
- Salivary function can be organized into five major categories that serve to maintain oral health and maintain homeostasis: (1) lubrication and protection, (2) buffering and clearance, (3) maintenance of tooth integrity, (4) antibacterial activity, and (5) taste and digestion.
- Dry mouth is a common complaint in the geriatric population and is commonly believed to arise from age-associated intrinsic salivary gland dysfunction.

Throughout the history of science, the salivary glands have been a topic of keen biologic interest and questions regarding their mechanisms of function have spurred numerous research endeavors. As early as 160 AD, Galen described the position of the major and minor salivary glands and their respective ductal openings. In 1543 Vesalius published a more detailed anatomic description of the salivary glands in a monograph entitled *De Humani Corporis Fabrica.* Interestingly, however, before the 17th century the salivary glands were thought to serve only as emunctories, the function of which was to strain excrementitious substances such as the evil spirits of the brain from the blood. Fortunately, the fortitude and dedication of scientists such as Boredu, Ludwig, Langley, Haller, Heidenhain, Mueller, Baylis, Bernard, and Pavlov allowed this notion to be dispelled and the field of salivary gland physiology to be advanced.[1] Recent technologic advances, along with a new generation of scientists, have brought this field even further, expanding our knowledge of the mechanisms of salivary gland function, disease processes that impede normal gland function, and methods by which to restore homeostasis in a diseased gland. Importantly, our current understanding of salivary gland physiology is largely derived from the study of nonhuman salivary glands.

Saliva is a complex mixture of electrolytes and macromolecules secreted from three pairs of major and numerous minor salivary glands. The major salivary glands consist of the parotid, submandibular, and sublingual glands. The minor salivary glands line the mucosa of the lip, tongue, palate, and pharynx. The secretion of saliva is tightly modulated by a multitude of factors including the autonomic nervous system, humoral factors, and disease states. Saliva performs a number of diverse and crucial roles: (1) It provides lubrication that aids in swallowing; (2) it is an emulgent that aids in the digestion of food and enzymatic cleavage; (3) it produces hormones, hormone-like substances, and other metabolically active compounds; (4) it assists excretion of endogenous and exogenous materials such as antibodies, blood-group reactive substances, iodine, and viruses; (5) it mediates taste sensations; and (6) it provides defense against bacterial pathogens. Relative to size, the salivary glands produce a large volume of saliva. The maximal rate of saliva production in humans is about 1 mL/min/g of glandular tissue. The rate of metabolism and blood flow to the salivary glands is also high, proportional to the rate of saliva secreted. To put this in perspective, the flow of blood to a maximally secreting salivary gland is approximately 10 times greater than the flow of blood to an equal mass of actively contracting skeletal muscle.[2] This chapter provides a detailed discussion of the various aspects of salivary gland function and physiology.

Principles of Salivary Gland Secretion

Anatomy of the Secretory Unit

The basic unit of the salivary gland consists of an acinus, a secretory duct, and a collecting duct (Fig. 84-1A and B). In general the area of the acinus and proximal secretory duct is called the *secretory endpiece.* The secretory duct is composed of the intercalated and striated ducts, which are intralobular. The excretory and collecting ducts are

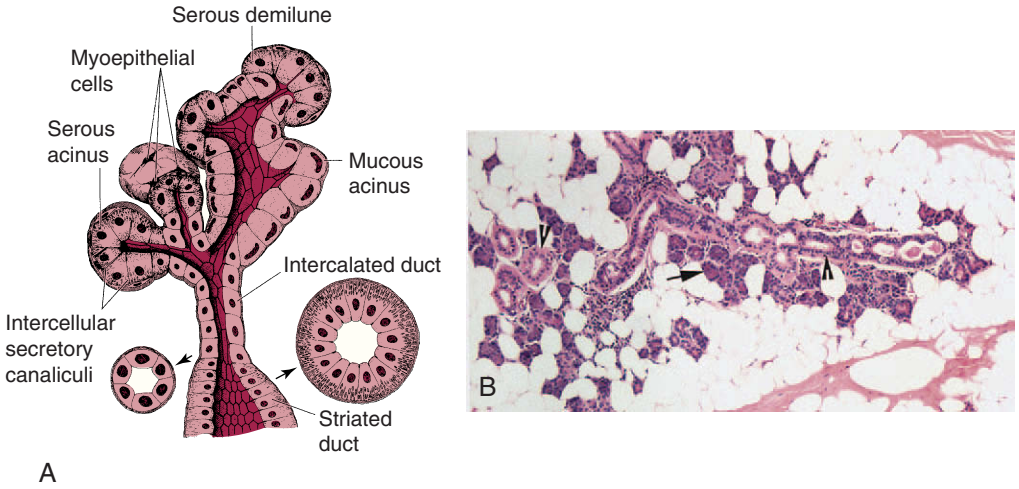

Figure 84-1. **A,** Schematic representation of a normal secretary unit. **B,** Histologic section of a normal salivary gland. Table 84-1

Contribution to Saliva and Relative Viscosities of Saliva by Salivary Glands

Gland	Acinar Type	Viscosity	Percentage of Whole Unstimulated Daily Saliva
Parotid	Serous	Watery	25
Submandibular	Mixed	Semiviscous	71
Sublingual	Mucous	Viscous	3-4
Minors	Mucous	Viscous	Trace

From Mandel ID. Sialochemistry in diseases and clinical situations affecting salivary glands. *Crit Rev Clin Lab Sci.* 1980;12:321.

extralobular. The structural relationships and secretory capabilities of secretory units within different salivary glands differ widely. The parotid and submandibular glands have a single, elongated, large-caliber collecting duct, with only a few major branching interlobular ducts. These interlobular ducts in turn are connected to many intralobular ducts, each of which transports saliva from several acini. In contrast to the parotid and submandibular glands, the secretions of the sublingual gland are discharged through 10 to 12 separate collecting ducts. The minor salivary glands, which are essentially groups of individual secretory units, are distributed throughout the submucosa of the oral cavity and have short convoluted collecting ducts.[2]

The acinus comprises a central lumen surrounded by pyramidal-shaped cells (see Fig. 84-1A and B). These acinar cells are highly polarized and are bounded by a plasma membrane with two distinct domains, a basolateral domain and an apical domain. These two domains are functionally and physically separated by tight junctions that link adjacent cells just below the luminal area. Each acinus is surrounded by a layer of myoepithelial cells, which in turn is delimited by a distinct basement membrane layer. Myoepithelial cells are elongated or star-shaped nonsecreting cells with long-branching processes that surround the acinus and proximal ducts. The observation that myoepithelial cells possess adenosine triphosphate activity, have intercellular gap junctions, and contain myofilaments has led to the hypothesis that these cells have contractile properties and play a role in expelling preformed secretions.[3-5]

Acini are classified as serous, mucous, or mixed (Table 84-1). Serous acini contain pyramidal-shaped cells with round basal nuclei surrounding the lumen. The cytoplasm of the serous cells is densely packed with basophilic secretory granules, poised to discharge their contents into the acinar lumen. The number of these granules varies with the phase of secretory activity, decreasing after a period of secretion and reaccumulating following a period of synthesis. Mucous acini have a larger lumen than serous acini, and the cells surrounding the lumen have a clear cytoplasm, flattened basal nuclei, and numerous droplets of mucigen, which is the precursor of mucin. In mixed salivary glands, acini are composed of both serous and mucinous cells. Mucinous cells are found surrounding the lumen of the acini, whereas serous cells are found near the fundus of the acini forming a caplike structure, called a *serous demilune.*[6]

The acinus is contiguous with the intercalated duct, a hollow structure lined by a single layer of small cuboidal cells (see Fig. 84-1A and B). A layer of myoepithelial cells surrounds these cuboidal cell–lined ducts, similar to acini. The intercalated ducts continue as striated ducts, which are lined by columnar cells and have a brush border composed of microvilli on their luminal surface. Striated ductal cells also have prominent basal striations formed by infoldings of the plasma membrane that enclose columns of rod-shaped mitochondria. The high-energy characteristics of these cells suggest that they are involved with the transport of ions and water. The striated ducts lead into excretory ducts, which are lined by two layers of epithelium, a layer of flat cells surrounding the ductal lumen, and an outer layer of columnar cells.[6,7]

Secretory Process

Saliva consists of a complex mixture of electrolytes and macromolecules. It is now known that saliva is formed via active transport processes occurring throughout the secretory unit and that these processes are under the control of complex neuronal and hormonal signals. The secretory unit consists of two anatomically and functionally distinct regions: the acinus and the secretory duct. The acinus is the site of all fluid generation and most (≈85%) exocrine protein secretion.[7] The fluid component is derived from the local vascular bed in the form of an isotonic solution and secreted into the acinar lumen. This primary secretion traverses the ductal system before emptying into the mouth. In contrast to the water-permeable cells of the acinus, ductal cells are water impermeable. Most of the sodium (Na^+) and chloride (Cl^-) in the primary secretion is reabsorbed in the duct, and a small amount of potassium (K^+) and bicarbonate (HCO_3^-) is secreted. In addition, some proteins are added to the salivary fluid as it traverses the secretory duct.

By the time the saliva enters the mouth, it has generally been rendered hypotonic (≈25 mEq/L NaCl). The electrolyte composition of saliva, however, can be influenced by salivary flow rates. The reabsorption of salivary sodium and chloride is directly related to these rates, with decreased reabsorption and increased salivary concentrations of electrolytes with increasing salivary flow rates. Potassium reabsorption is independent of flow rates.[8,9]

Mechanisms of Primary Fluid Secretion

Fluid transport in salivary glands is thought to be driven osmotically in response to transepithelial salt gradients. These salt gradients are generated by ion transport systems localized to the luminal and basolateral membranes of the acinar cell. On the basis of studies in rabbit and rat salivary glands, three mechanisms for primary fluid secretion by the acini have been proposed. These mechanisms (Fig. 84-2) appear to operate concurrently in the same gland, and possibly in the same acinar cell. The relative importance of each of these mechanisms varies from species to species, gland type to gland type, and possibly from physiologic status to physiologic status.

Fluid secretion in the acini is the result of the combined action of four membrane transport systems: (1) a $Na^+ - K^+ - 2Cl^-$ cotransporter located in the basolateral membrane of the acinar cell; (2) a calcium (Ca^{++})-activated K^+ channel in the basolateral membrane; (3) a calcium-activated Cl^- channel localized to the apical membrane; and (4) an adenosine triphosphatase (ATPase)-driven Na^+/K^+ pump in the basolateral membrane. In the resting or unstimulated state, both K^+ and Cl^- are concentrated in the acinar cell above the electrochemical equilibrium, the former by the Na^+/K^+ ATPase and the latter via the $Na^+ - K^+ - 2Cl^-$ cotransporter.[9,10]

In the first mechanism of saliva secretion (see Fig. 84-2A), stimulation by the autonomic nervous system leads to a rise in intracellular calcium concentration, which results in the opening of the basolateral Ca^{++}-activated K^+ channels and the apical calcium-activated Cl^- channels. This increase in K^+ and Cl^- conductance allows KCl to flow out of the cell, resulting in an accumulation of Cl^- ions and their associated negative electrical charge in the acinar lumen. Sodium in the interstitium then follows Cl^-, due to electrical attraction, by leaking through the tight junctions between the cells into the acinar lumen. The resulting osmotic gradient for NaCl causes a transepithelial movement of water from the interstitium into the acinar lumen. In the continued presence of the agonist, a net transepithelial chloride flux and a concomitant secretion of fluid are sustained due to Cl^- entry via the $Na^+ - K^+ - 2Cl^-$ cotransporter and exit via the apical Cl^- channel. When the stimulus is removed, the intracellular calcium concentrations fall to resting levels, the K^+ and Cl^- channels close, and the cell returns to its resting state. In order for this model to operate continuously, it must satisfy the constraints of mass and charge balance. In other words, in the steady state ion transport must be such that neither mass nor charge is continually accumulated in or depleted from the cell. These constraints, along with the known stoichiometries of the $Na^+ - K^+ - 2Cl^-$ cotransporter ($1Na^+ : K^+ : 2Cl^-$) and the Na^+/K^+ ATPase ($3Na^+ : 2K^+ : 1ATP$), determine the relative fluxes of ions per cycle: Six chloride ions are translocated from the interstitium to the acinar lumen per ATP molecule hydrolyzed by the Na+/K+ ATPase.[9]

Mechanism 2 (see Fig. 84-2B) is similar to mechanism 1, except that in this model a basolateral Cl^-/HCO_3^- exchanger, in parallel with an Na+/H+ exchanger, replaces Na+ – K+ – $2Cl^-$ cotransporter. Decreases in intracellular chloride concentrations resulting from secretagogue-induced KCl loss lead to increased Cl^- entry in exchange for HCO_3^- via the $Cl^-/HCO3^-$ exchanger. The cytoplasmic acidification resulting from this bicarbonate loss is buffered by the Na+/H+ exchanger, which uses the extracellular-to-intracellular sodium gradient generated by the Na^+/K+ ATPase to drive protons out of the cell. The net result is the movement of NaCl into the cell in exchange for H_2CO_3, which in turn is recycled across the basolateral membrane as CO_2 after hydrolysis by carbonic anhydrase. In this model, three chloride ions are translocated from the interstitium to the acinar lumen per ATP molecule hydrolyzed. Sodium and water follow the chloride into the acinar lumen from the interstitium.[9]

In contrast to mechanisms 1 and 2, in which chloride is the secreted anion, mechanism 3 (see Fig. 84-2C) involves apical bicarbonate secretion. In this model, carbon dioxide (CO_2) enters the acinar cell across the basolateral membrane and is converted to HCO_3 plus a proton by carbonic anhydrase. The bicarbonate is lost across the apical membrane via an anion channel, possibly the same channel involved in chloride secretion, and the protein is extruded by the basolateral Na^+/H^+ exchanger. In this model, three bicarbonate ions are secreted per ATP molecular hydrolyzed. Sodium and water follow the secreted bicarbonate ions into the acinar lumen.[9]

Mechanisms of Primary Macromolecule Secretion

The protein subcomponent of saliva is derived primarily from secretory granules of the acinar and ductal cells. Secretory proteins are discharged into the lumen of the secretory unit by a process of exocytosis, wherein fusion of secretory granules with a delimited portion of the plasmalemma of the apical membrane occurs. The membrane fusion is the last of a series of steps required for the transfer of export proteins from their synthesis in the rough endoplasmic reticulum (RER) to the extracellular environment. According to the model by Palade, the secretary process can be divided into six steps: (1) synthesis, (2) segregation, (3) intracellular transport, (4) concentration, (5) intracellular storage, and (6) discharge.[11]

The synthesis of secretory proteins requires the uptake of amino acids by the cell, which is accomplished via an active transport mechanism in the basolateral surface of the cell. Transfer ribonucleic acids (tRNA) then deliver the amino acids to the ribosomes of the RER, where messenger ribonucleic acids (mRNA) are translated into polypeptides. Before transport of these polypeptides from the RER to the Golgi

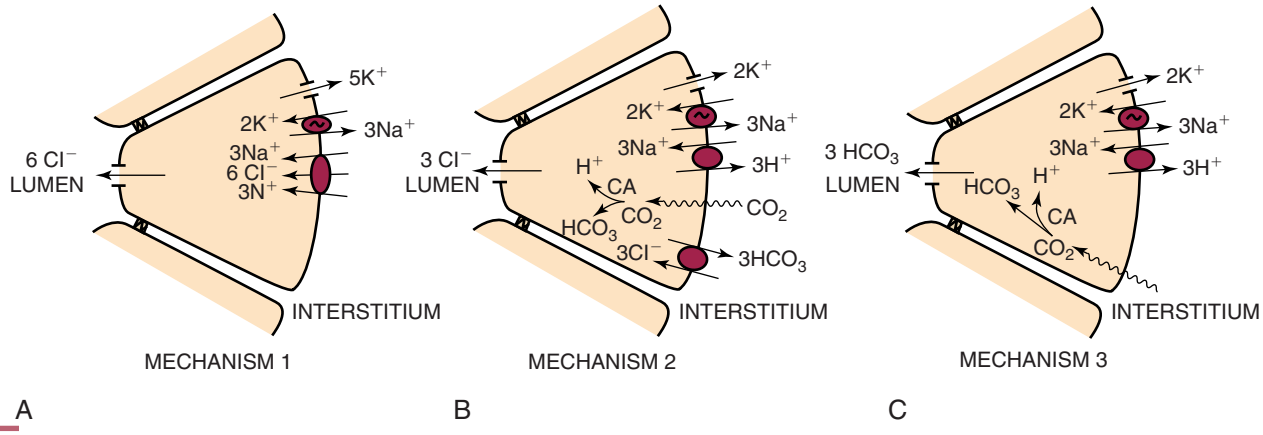

Figure 84-2. Schematic representation of three mechanisms of primary fluid secretion in acinar cells. *(From Turner RJ. Mechanisms of fluid secretion by salivary glands.* Ann N Y Acad Sci. *1993;694:24.)*

apparatus, they undergo some post-translational modifications and are segregated in the cisternal space of the RER. Segregation is regarded as an irreversible step. From the RER, polypeptides are transported to the Golgi apparatus via an ATP-dependent mechanism. In this apparatus, polypeptides undergo further post-translational modifications such as terminal glycosylation and are concentrated. At this step the polypeptides are transferred from a high-permeability membrane to a membrane with characteristics similar to the plasmalemma, forming secretory granules. On appropriate stimulation from the autonomic nervous system (discussed later), the secretory granules discharge their contents into the glandular lumen by the process of exocytosis. The membrane of the secretory granule fuses with the plasmalemma, bringing into continuity the contents of the secretory granule and the extracellular lumen, and at the same time maintaining a diffusion barrier between the interior of the cell and extracellular medium. The mechanism by which the cell recycles the apical membrane is not completely understood but likely involves the process of endocytosis and the selective degradation of endocytic vesicles.[12]

Mechanisms of Ductal Secretion

Ductal secretion is not constant and the underlying mechanisms are only partially understood. Microperfusion studies of excretory ducts have confirmed the ability of ductal cells to modify saliva by reabsorbing sodium and chloride and secreting potassium and bicarbonate to produce the final hypotonic solution.[13] In addition, ductal cells have the ability to secrete some protein into the ductal lumen. In general, when the salivary flow rate is slow, more time is available in which ion transfer can occur across the tubular cells, resulting in greater modification of the secretory fluid. When the flow rate is high, however, the contact period is shortened, diminishing the influence of the tubular cells on solute concentration. The exception to this rule is that conditions that stimulate increased flow rates also stimulate increased bicarbonate secretion.[2,6]

Neuronal Control of Secretion

In general, significant secretion from the human salivary glands occurs only in response to stimulation by the autonomic nervous system or by the action of substances that can mimic the effects of such stimulation.[14] Both sympathetic and parasympathetic nerves innervate the salivary glands, though the effects of the parasympathetic nerves predominate. Nevertheless, it is likely that the two components of the autonomic nervous system have a synergistic effect on salivary gland function. Parasympathetic stimulation is the principal impetus for salivary gland fluid secretion. In addition, parasympathetic stimulation leads to some exocytosis and protein secretion, myoepithelial contraction, and vasodilation. Sympathetic stimulation is a weak mobilizer of salivary fluid, though its effect may be additive to that of the parasympathetic system. On the other hand, sympathetic stimulation causes high levels of protein secretion, myoepithelial contraction, and maintenance of vascular tone. In general, parasympathetic stimulation leads to the output of saliva that has a large volume and low protein content, whereas sympathetic stimulation leads to the secretion of low volumes of saliva with high protein content.[2,6,12]

The innervation patterns of the major salivary glands differ considerably, from species to species, subject to subject, and cell type to cell type. The parasympathetic supply to the parotid gland originates in the inferior salivatory nucleus and travels with the glossopharyngeal nerve, and then with Jacobson's nerve to the otic ganglion, where it synapses. The postganglionic fibers are carried by the auriculotemporal branch of the trigeminal nerve to the parotid gland. The parasympathetic supply to the submandibular gland originates in the superior salivatory nucleus and travels via the nervus intermedius and chorda tympani to the submandibular ganglion. Some of these fibers synapse in the ganglion, whereas others synapse in the gland itself. The sympathetic supply to the parotid and submandibular gland originates from the superior cervical ganglion and follows major arterial blood vessels to reach the various salivary glands. Nerve fibers of the parasympathetic and sympathetic nervous system are distributed in a similar fashion around the acini, intercalated ducts, and striated, though the parasympathetic fibers predominate.[15] Myoepithelial cells are similarly liberally innervated, whereas the collecting ducts are sparsely innervated. In contrast to other organ systems such as skeletal muscles, which contain a well-defined neuronal synapse at the axon-effector organ interface, secretory cells have unmyelinated fibers of the parasympathetic and sympathetic system that lie in close proximity to the effector cell. These axonal fibers can lie either outside (epilemmal fibers) or inside the basement membrane (hypolemmal fibers) of the effector cell.[16] Neurotransmitters released from the axon presumably reach the secretory cell by diffusion. These neurotransmitters, as well as other hormones and regulatory molecules, affect the function of salivary cells in a complex manner that is poorly understood.

Neurotransmitters and Receptors

Cell surface receptors are macromolecular moieties within the cell membrane that bind ligands such as neurotransmitters in the extracellular milieu. Ligand binding activates the receptor, which then transmits a signal across the cell membrane and triggers a biologic response within the target cell (Fig. 84-3). The biologic response can be initiated directly by the receptor or, more commonly, mediated through a second messenger system activated by the receptor-ligand complex. The specific biologic response initiated and the magnitude of the response is a function of the receptor itself and not the ligand with which it binds. Receptors for neurotransmitters are typically located on the basal and lateral surfaces of the secretory cells of the salivary gland.

The neurotransmitter acetylcholine mediates the effects of the parasympathetic nervous system, whereas norepinephrine mediates the effects of the sympathetic nervous system. Adrenergic receptors, receptors for norepinephrine, are divided into two major classes, alpha and beta. Each alpha and beta class is further divided into two subtypes, yielding α_1 and α_2 and β_1 and β_2 receptors (Table 84-2).[17] The best-studied acinar cells, those of the rat parotid gland, appear to have all four subtypes of adrenergic receptors, though in general the functionally important receptors appear to be the α_1 and β_1 subtypes. The β_1 and β_2 receptors are linked to the adenylate cyclase second messenger system, and binding of ligand to this receptor activates adenylate cyclase. Alpha-2 receptors are also linked to the adenylate cyclase system; however, binding of ligand to this receptor leads to the inhibition of adenylate cyclase. Alpha-1 receptors are linked to a yet uncharacterized second messenger system that does not regulate adenylate cyclase but instead modulates calcium influx.[7]

Cholinergic receptors, receptors for acetylcholine, are divided into two categories: muscarinic and nicotinic. Acinar cells contain only muscarinic receptors, specifically the muscarinic receptor M_3 subtype. Binding of acetylcholine to the M_3 receptor leads to activation of the phospholipase C pathway and ultimately intracellular calcium mobilization. Recent evidence suggests the presence of two additional subtypes of muscarinic receptors in the rat submandibular and sublingual gland, M_1 and M_5.[18] The effect of these two receptors on acinar cell

function and the mechanism by which these effects are mediated are unclear at this point. Some of the effects of the M_1 receptor on salivary gland function may be indirect via nitric oxide.[7]

Parasympathetic-mediated nonadrenergic, noncholinergic secretory response and vasodilation are well-known phenomena in salivary glands, and a number of polypeptides including neuropeptide Y (NPY), vasoactive intestinal peptide (VIP), galanin (GAL), substance P (SP), and calcitonin gene-related peptide (CGRP) have been implicated in mediating this pathway.[19] NPY-, VIP-, and GAL-immunoreactive nerve fibers are densely distributed around acini and ducts. CGRP- and SP-immunoreactive fibers are also found around these structures, but to a lesser extent. Interestingly, the density of SP- and CGRP-immunoreactive fibers around the mucous acini was significantly higher than around serous acini. The VIP system is the best studied of these polypeptide neurotransmitters in salivary glands and is similar to what has been described in the gut and pancreas.[8] Currently, the role of these different polypeptide neurotransmitters in salivary gland function is speculative; however, in view of their potential therapeutic roles, intense efforts are under way to better understand them.[19]

Signal Transduction

The formation of a receptor-ligand complex is only the first step toward initiating a biologic response within the target cell. The second step entails transmission of the ligand-receptor binding signal across the cell membrane and activation of a second messenger system. The second messenger system then activates an effector system, bringing about a specific biologic response (see Fig. 84-3).

G Proteins

A family of heterotrimeric guanine nucleotide-binding proteins (G proteins) has a well-defined role in transmitting receptor-ligand signals across the cell membrane by linking the receptor with a second messenger system.[7] G proteins consist of three distinct subunits termed α, β, and γ subunits. The α subunit is the site of guanine nucleotide binding and has generally been considered the subunit that conveys the functional and receptor specificity of the G-protein. When a neurotransmitter binds to a receptor, the affinity of the receptor for a specific G protein increases. Formation of the receptor-G protein complex leads to the replacement of the guanine diphosphate (GDP), which is bound to the α subunit with a guanine triphosphate (GTP), and dissociation of the heterotrimeric G protein into a free α subunit and a free βγ complex. The α subunit is then available to activate a specific second messenger system. The activation continues until the GTP is degraded to GDP by GTPase activity endogenous to the α subunit. The GDP-associated α subunit then reassociates with the βγ complex to generate the inactive heterotrimeric G protein. The two best-studied second messenger systems in the salivary gland are (1) the generation of cyclic adenosine monophosphate following β-adrenergic receptor stimulation leading to protein exocytosis and (2) the formation of 1,4,5-inositol triphosphate (IP_3) after muscarinic acetylcholine receptor stimulation leading to calcium mobilization and fluid secretion. Other more speculative second messenger systems involve nitric oxide, cyclic guanine monophosphate, phospholipids, cytosol pH, and membrane depolarization.

Adenylate Cyclase System

Stimulation of β-adrenergic receptors on acinar cells leads to protein exocytosis. The role of cAMP in protein secretion from acinar cells has been well documented for nearly 30 years, though some of the initial steps in this pathway have only recently been elucidated.[20,21] Binding of norepinephrine to β_1 and β_2 adrenergic receptor leads to activation of the G protein, G_s. Activation of G_s in turn leads to activation of adenylate cyclase, which then converts ATP into cAMP. Increasing concentration of cAMP then leads to the activation of cAMP-dependent protein kinase A. Both type 1 and type 2 cAMP-dependent protein kinase A are thought to be involved in this pathway.[22] Cyclic AMP-dependent protein kinase A phosphorylates several cellular proteins, the most important of which is considered to be a 26-kDa integral membrane protein.[23] As yet, it is unclear how the activation of cAMP and cAMP-dependent protein kinase A leads to protein exocytosis. Also important is that whereas ligand binding to β_1 and β_2 receptors activates the adenylate cyclase system, ligand binding to α_2 receptors inhibits adenylate cyclase via the G protein, G_i.[24]

Phospholipase C System

Researchers have long known that the stimulation of acinar cell muscarinic acetylcholine receptors leads to high levels of fluid secretion and that calcium plays a key role in this process.[7,25] In the past 25 years efforts by several investigators have led to the characterization of the specific mechanisms involved in muscarinic acetylcholine receptor-mediated fluid secretion.[7] Ligand binding to the muscarinic acetylcholine receptor activates a pertussis toxin-insensitive G protein, thought to belong to the G_q family.[26] Activation of this G protein activates the enzyme phospholipase C, which hydrolyzes a minor membrane phospholipid phosphatidylinositol 4,5-bisphosphate. This leads to the formation of two second messenger molecules, inositol triphosphate (IP_3) and diacylglycerol (DAG). Diacylglycerol is capable of activating protein kinase C leading to protein exocytosis, though this is thought to represent a minor pathway for protein secretion in acinar cells.

The other product of hydrolysis, inositol triphosphate, binds to a membrane receptor on intracellular calcium stores, causing the release of calcium into the cytoplasm. These intracellular calcium storage units are derivatives of the endoplasmic reticulum. The IP_3 receptor itself is thought to function as a calcium channel, and on ligand binding it allows calcium to move down a concentration gradient into the cytoplasm. Cytoplasmic calcium concentrations can increase 10-fold within

5 seconds of muscarinic acetylcholine receptor activation and lead to a cascade of events including a sustained influx of extracellular calcium into the cytoplasm and the activation of specific ion transport pathways, leading to fluid secretion. Currently there is little understanding of the cell membrane channels that allow calcium to move into the cytoplasm in response to increased cytoplasmic calcium concentration in nonexcitable cells such as acinar cells.[7]

Flow Rate of Saliva

Salivary flow rates are highly variable, stabilizing after the age of 15 years, and therefore should be interpreted in a clinical context.[27,28] The numbers depicted in this section are averages projected from studies on the general population. The range of normal unstimulated salivary flow is 0.1 mL/min and above, and in the stimulated state, 0.2 mL/min and above. On average the unstimulated flow rate is 0.3 mL/min and the stimulated flow rate is 7 mL/min at maximum. Stimulated saliva is thought to contribute as much as 80% to 90% of the average daily salivary production. This leads to an average daily saliva secretion of around 1000 to 1500 mL or an average flow of 1 mL/minute.[29,30] Salivary flow in the unstimulated state is produced primarily by the submandibular glands (71%) with the parotid and sublingual glands producing 25% and 3% to 4% of the flow, respectively.[30] The minor salivary glands account for trace amounts of saliva. Once stimulated, the relative contributions of the parotid and submandibular glands are reversed and the parotid gland supplies two thirds of the salivary flow.[27,31]

Studies specifically addressing hypofunction of the salivary gland have defined the critical range separating a person with normal gland function from those with salivary gland hypofunction as unstimulated whole salivary flow rates between 0.12 and 0.16 mL/min.[32] The diagnosis of salivary hypofunction is often difficult to make given the wide range of salivary flow rates that are accepted as normal. A more reliable means of diagnosing hypofunction is possible if an individual base record of saliva flow has been established. Salivary gland hypofunction can then be defined as a 50% reduction in the individual base saliva flow rate. About 30% of the population reports some degree of dry mouth. In general, oral-related effects of salivary hypofunction are (1) reduced preparation of food for digestion and taste and (2) an increased susceptibility of oral structures to disease.[33] Although decreased concentrations of salivary mucins and decreased resting salivary flow rates have been associated with increasing age, in general there are no substantial age-related changes in the secretory responsiveness of salivary cells.[34,35] Furthermore, factors endemic to the geriatric population such as polypharmacy, poor nutritional status, and systemic diseases also contribute to salivary gland hypofunction.[36] Presently, the exact role of advancing age on the average daily production of saliva and xerostomia is unknown.

Salivary secretion is controlled by a salivary center in the medulla, which is triggered by specific stimuli: (1) the mechanical act of chewing, (2) gustatory, and (3) olfactory. The stimulation of salivary flow with mastication is thought to be a reflexive response mediated by receptors in the oral mucosa, muscles of mastication, and temporomandibular joint. These receptors stimulate the salivary nucleus, which in turn increases the parasympathetic stimulation to the salivary glands, resulting in increased salivary flow.[37] Interestingly, the increase in salivary flow is thought to be directly proportional to the applied chewing force.[38] Gustatory stimuli are the most potent stimuli to the salivary center, eliciting as much as a 10-fold increase in salivary flow. Acidic tastes lead to the greatest increases in saliva flow, whereas sweet tastes are the least stimulating. Olfaction is the weakest of the salivary center triggers. Furthermore, habituation is thought to occur with repeated presentation of the same food cues, leading to a decrease in stimulation of the saliva center and saliva flow. Dishabituation occurs with presentation of novel food cues.[39-42]

Many other factors also can influence salivary flow. These factors include (1) circadian rhythm; (2) psychic factors such as pain, depression, and anticipation of food; (3) medications; (4) local or systemic diseases; and (5) hormones. Isolating and studying the effect of a specific factor is often difficult because many of these stimuli work in concert to affect salivary flow. Diurnal variation in salivary flow has been reported, with maximal flow rates in the late afternoon and minimal flow rates at night. Decreased salivary output at night may be secondary to a decrease in ambient light and/or arousal state, both of which affect salivary gland function.[43] Medications with anticholinergic properties such as most antidepressants decrease salivary flow. Dehydration can influence salivary gland output, with losses of 8% of body water, resulting in cessation of salivary flow. Decreased salivary output is also noted during the "fight or flight" response, which results from an increased sympathetic response and/or central inhibition of parasympathetic output. The sympathetic nervous system has also been proposed to play a role in the reduction of saliva flow after exercise via constriction of blood vessels that supply the salivary glands.[44]

Salivary flow is not even throughout the mouth secondary to the location of the ducts that empty the parotid and salivary glands. Intraoral flow volume is highest in the mandibular lingual area and lowest in the area of the maxillary incisors and interproximals.[45] These areas of higher and lower volume flow regions have been referred to as "salivary highways and byways." The regional clearance rate of acid produced from bacteria is directly influenced by regional variations in flow within the mouth.[46] Consequently, salivary byways are areas in which acid byproducts may remain in longer contact with oral structures unless mechanical means of cleansing are used. Furthermore, with varying amounts of saliva and salivary constituents coming from different glands, it is suggested that saliva provides different types of protection in different intraoral locations.

Composition of Saliva

Saliva comprises a variety of organic and inorganic compounds (Table 84-3), allowing its varied functional properties. The inorganic component is composed mostly of electrolytes such as sodium, potassium, calcium, magnesium, bicarbonates, phosphates, and nitrogenous products such as urea and ammonia. The organic component includes several classes of proteins such as immunoglobulins, enzymes, and

Table 84-3

Flow Rates and Composition of Saliva in Normal Adults

	Parotid Gland	Submandibular Gland
Stimulated Flow Rate (mL/min/gland)	0.7	0.6
Inorganic Constituents (mEq/L)		
K^+	20	17

mucins. Because the final saliva product is an aggregate of the saliva produced by several glands, each with different secretory characteristics, the composition of whole saliva at any particular time can be highly variable. This variability is further enhanced by the fact that the secretory characteristics of each gland will change with the type of stimulus driving the saliva production. Furthermore, the electrolyte composition of saliva will change depending on flow rates secondary to changes in the amount of inorganic compounds secreted or reabsorbed in the salivary ducts. In general, whole saliva is composed of approximately 99.5% water, has a specific gravity between 1.002 and 1.0012, and a pH that varies between 5.75 and 7.05. The osmolarity of saliva is largely determined by the major ions: sodium, potassium, chloride, and bicarbonate. The pH is largely determined by the carbon dioxide content of saliva because bicarbonate is the principal salivary buffer system. Phosphate serves a minor role in buffering saliva. The electrolyte composition of saliva is relatively independent of plasma concentrations because electrolytes are transported into saliva via an active process. On the other hand, organic compounds passively diffuse into saliva and therefore their concentrations in saliva reflect plasma concentrations.[27]

Inorganic Component

Sodium (Na^+) and potassium (K^+) are the major cations present in saliva (see Table 84-3). The salivary concentration of these ions depends on the type of gland from which it is secreted, as well as the type and amount of stimulation to the gland. In general, the concentration of these electrolytes in the parotid gland is higher than in the submandibular gland. When the salivary flow rate is low, the ratio of Na^+ to K^+ is also low. This ratio increases as the flow rate increases because of decreased reabsorption of Na^+ at higher flow rates. As with Na^+ and K^+, the salivary concentration of Ca^{++} also varies with the type of gland from which it is secreted and salivary flow rates. Salivary calcium concentrations, however, appear to be flow dependent only at high flow rates. In addition, unlike salivary Na^+ and K^+, the concentration of Ca^{++} in saliva from the submandibular gland (3.4 to 4.4 mEq/L) is almost twice that of the parotid gland (1.4 to 2 mEq/L). Calcium is distributed in saliva as a free ion, as well as bound to protein or in complexes with carbonate, phosphate, or lactate. Salivary magnesium concentrations from the parotid and salivary glands are fairly equivalent and represent roughly two thirds of the plasma concentration.[27]

The major salivary cations are chloride, bicarbonate, and phosphate. Salivary concentrations of chloride from the parotid gland and salivary gland are equivalent and lower than that of plasma. Salivary chloride concentrations are flow dependent, decreasing with decreasing flow rates. In the resting state, salivary bicarbonate concentrations can be as low as 5 mEq/L, and with stimulation bicarbonate concentrations may exceed that of plasma (27 mEq/L). Salivary bicarbonate is derived from plasma, as well as from metabolic activity in the gland. Salivary phosphate is present at concentrations appreciably higher than that of serum and serves as one of the minor buffers. About 10% of salivary phosphate is present in the ester form, mainly in phosphoproteins and trace amounts in pyrophosphate.[27]

Minor inorganic components of saliva include iodine and fluoride. The concentration of iodine in saliva is roughly 10 to 15 µg/mL. Salivary fluoride content is approximately similar to that of plasma but is elevated slightly in individuals who drink fluoridated water or use fluoridated toothpaste. In these individuals there is a prolonged release of fluoride into saliva from sparingly soluble deposits on the teeth and soft tissues. These small elevations in salivary fluoride levels are believed to be important in preventing the formation of dental caries.[27]

Organic Components

Proteins or protein-containing moieties comprise the majority of the organic components of saliva. The concentration of protein is higher in stimulated parotid than in stimulated submandibular secretions.[29,30] On average, the protein content of whole saliva is 200 mg/100 mL, which is about 3% of the protein concentration in plasma.[31] Careful analysis of whole saliva, as well as saliva from each of the major salivary glands, has revealed the presence of distinct families of proteins within saliva, each family containing multiple members. The structural variations of individual family members arise by a combination of genetic and posttranslational events. The major salivary components of saliva range in size from small histatins (2 to 4 kDa) to larger mucins (>1000 kDa) (Table 84-4).

Table 84-4

Major Salivary Macromolecules

Protein Family	Molecular Weight (kDa)
Histatins	2-4
Statherins	4-5
Lysozyme	14
Cystatins	14
Proline-rich proteins	10-30
Carbonic anhydrases	42-45
Amylase	55-60
Peroxidase	75-78
Lactoferrin	75-78
Mucin 2 (MG2)	130
Secretory IgA	380
Mucin 1 (MG1)	>1000

From Levine MJ. Salivary macromolecules: a structure/function synopsis. *Ann N Y Acad Sci.* 1993;694:11.

Evaluation of the structural and functional properties of salivary proteins has revealed several important concepts. First, the structural conformation of the protein is essential for its functional properties. For example, the alpha helical conformation of salivary statherins and histatins and the intrapolypeptide disulfide bonds of salivary amylase are essential to the functional properties of these proteins. Disruption of these secondary and tertiary structures abrogates their function. Second, most salivary proteins are multifunctional and overlap in their roles (Table 84-5). This brings up the third concept of functional redundancy, which allows deficiencies in one protein to be compensated for by another protein. In addition, the concept of functional redundancy may explain why there is a high degree of variability in the concentration of individual salivary molecules in the general population. The fourth concept is that salivary proteins can exhibit multiple functions on the basis of the situation. For example, amylase in solution has an antibacterial activity, whereas amylase bound to the tooth surface can promote bacterial adherence and the formation of dental caries. The fifth and final concept is that many salivary proteins form complexes of the same polypeptide (homotypic) or two different polypeptides (heterotypic), via covalent and noncovalent interactions, to become functionally active.[47]

One of the main protein constituents of plasma, albumin, is also present in saliva. Albumin passively diffuses into the glandular secretion from plasma and has been hypothesized to play a similar role in saliva, that of a carrier protein. The concentration of albumin in saliva depends on the salivary flow rate, decreasing in concentration with increasing flow rates. The concentration of albumin in saliva also varies with the overall medical status of the individual, increasing in concentration in the presence of chronic disease states such as immunosuppression, radiation treatment, and diabetes.[48]

The best-studied and quantitatively most prominent salivary enzyme is α-amylase, a glycoprotein with a molecular weight between 62 and 67 kDa. Six isoforms of α-amylase exist, the distribution of which differs between salivary and pancreatic secretions. Alpha-amylase is present in parotid saliva at a 60 to 120 mg/100 mL and in sub-

Table 84-5

Functions of Salivary Molecules

Functional Property	Salivary Molecule
Antibacterial	Amylase, cystatins, histatins, mucins, peroxidases
Antiviral	Cystatins, mucins
Antifungal	Histatins
Buffering	Histatins, carbonic anhydrases
Digestion	Amylases, mucins
Mineralization	Cystatins, histatins, proline-rich proteins, statherins
Lubrication	Mucins, statherins
Tissue coating	Amylase, cystatin, mucins, proline-rich proteins, statherins

Data from Humphrey SP, Williamson RT. A review of saliva: normal composition, flow, and function. *J Prosthet Dent.* 2001;85:162.

mandibular saliva at a concentration of 25 mg/100 mL.[31] The average total daily secretion of amylase is approximately 0.6 g, comprising 10% of the total salivary protein. Alpha-amylase hydrolyzes the α 1:4 glycosidic bond between glucose units in the polysaccharide chain of starch. Hydrolysis can take place anywhere along the polysaccharide chain, except for branching points, and is slow at hydrolyzing terminal glucose units. Therefore the end products of amylase digestion are mainly maltose, oligosaccharides, and some free glucose. The optimal pH for α-amylase activity is in the range of 6 to 8, and chloride is required as a cofactor.[31]

The major salivary glands are regarded as the principal sources of salivary antimicrobial substances such as immunoglobulin-A (IgA), lactoferrin, lysozyme, and peroxidase. Immunoglobulin-A is the predominant immunoglobulin in saliva, being present at a concentration of approximately 20 mg/100 mL, and plays an important role in the local immune system of the salivary gland.[31] Salivary IgA is found predominantly in the dimeric form in which two IgA macromolecules are covalently linked via a J chain. Dimeric IgA is formed by plasma cells in the interstitium of the salivary gland and is transported across the acinar cell into the acinar lumen via an active transport process. Unlike serum IgA, salivary IgA also contains a 70 kDa secretory component that is thought to protect dimeric IgA from digestion by proteolytic enzymes in the saliva. The secretory component is found on the basolateral surface of acinar cells and is thought to play an additional role in transporting the dimeric IgA across the cell into the acinar lumen. The role of IgA as a protective agent against dental plaque formation in humans is controversial.[49] It has been observed that the salivary IgA is increased by both sympathetic and parasympathetic stimulation.[50] Two other immunoglobulins, IgG and IgM, are also present in saliva, though at much lower concentrations.

Lysozyme is an antibacterial enzyme, which attacks components of the cell wall of certain bacteria leading to lysis and death of the bacteria. The effects of lysozyme are potentiated by specific cations in salivary secretions. Lactoferrin is an iron-binding protein, which removes free iron from saliva, depleting the supply needed for bacterial growth. Finally, sialoperoxidase oxidizes salivary thiocyanate to hypothiocyanite using hydrogen peroxide produced by oral bacteria. Hypothiocyanite has potent antibacterial activity.[31]

The major groups of salivary glycoproteins consist of two classes of mucins, mucin 1 and mucin 2, found in submandibular and sublingual saliva, as well as a group of proline-rich-glycoproteins found in parotid saliva. Mucin 1 and mucin 2 are also known after their gene designations, *MUC5B* and *MUC7*, respectively. All of the salivary glycoproteins consist of a polypeptide core with oligosaccharide side-chains. The proportion of the carbohydrate component to the protein component varies between the different groups of glycoproteins. Mucin 1 (MG1) is a high-molecular-weight multi-subunit molecule that is highly glycosylated. Mucin 2 (MG2) is a low-molecular-weight single polypeptide molecule that is glycosylated.[27] Protein-rich polypeptides are low-molecular single polypeptide molecules that are moderately glycosylated. Glycoproteins are thought to have numerous functional roles (see Table 84-5).[31]

Statherin is a small phosphoprotein, which is relatively rich in tyrosine and proline, and has the property of promoting remineralization of the enamel coating of teeth. This role is accomplished by the ability of statherin to prevent the precipitation of calcium phosphates from supersaturated solutions, which also plays a role in inhibiting the formation of salivary gland calculus.[2,27]

Since the discovery of kallikreins in submandibular glands, an increasing number of polypeptides have been either isolated and purified from, or claimed to be present in, the submandibular glands of mammals, primarily mice. Most are androgen dependent and have their secretion mediated primarily by α-adrenergic mechanisms. Nearly all are found in or considered to be synthesized by the granular convoluted tubules/striated duct cells, where they are localized in secretory granules. In addition to their presence in saliva, several of these polypeptides are also found in the blood. The presence of polypeptides in both saliva and blood raises the issue of the endocrine or endocrine-like functions of the submandibular gland. Polypeptides that have been purified from saliva and characterized include epidermal growth factor, nerve growth factor, rennin, and kallikrein.[51]

Epidermal growth factor (EGF) is a 53 amino-acid peptide that stimulates DNA, mRNA, and protein synthesis in many cell types.[51] EGF synthesized and released by the salivary glands has been implicated in a number of biologic processes. It is a potent mitotic stimulator, it enhances keratinization, and it inhibits gastric acid secretion. Studies have confirmed that oral wound healing is significantly delayed after the removal of salivary glands. This delay in oral wound healing is restored by oral administration of EGF.[52] The parotid and submandibular glands appear to be the source of salivary EGF in humans.[53] Patients with risk factors for cancer and those who have head and neck cancer have been shown to have low salivary EGF levels.[54]

The submandibular gland of mice is unique in its capacity to synthesize, store, and secrete large amounts of NGF. The role of NGF in saliva is unknown, despite its high concentration in saliva from the submandibular gland.

Salivary secretion of renin is stimulated by α-adrenergic and cholinergic mechanisms. Plasma angiotensin II concentrations do not have any impact on the release of submandibular gland rennin. The exact physiologic role of salivary rennin is currently unknown. As with salivary rennin, the physiologic role of salivary kallikrein, a serine protease that has been isolated from the submandibular glands of many mammalian species, is unknown.

Functions of Saliva

Salivary function can be organized into five major categories that serve to maintain homeostasis: (1) lubrication and protection, (2) buffering and clearance, (3) maintenance of tooth integrity, (4) antibacterial activity, and (5) taste and digestion.[27] The different components of saliva are multifunctional and have overlapping roles in accomplishing these tasks.

Lubrication and Protection

Saliva is a seromucous substance that coats the structures of the oral cavity and oropharynx, lubricating and creating a protective barrier against irritants such as proteolytic and hydrolytic enzymes produced in plaque, chemical agents, and desiccation. In addition, lubrication of oral structures is essential for such functions as speech, mastication, and swallowing. The subcomponents of saliva with the best lubricating properties are the mucins, the highest concentrations of which are found in saliva secreted from the minor and sublingual salivary glands. Intermediate amounts are found in submandibular gland saliva, and

low amounts in parotid saliva. The low solubility, high viscosity, and adhesiveness of salivary mucins enable these molecules to become concentrated on the oral mucosal lining.[55] Another class of salivary glycoproteins, the proline-rich polypeptides found in parotid saliva, also play a role in lubricating and protecting oral structures.[56] These functions are in part assisted by the fact that the carbohydrate moieties of the mucins and proline-rich polypeptides allow these molecules to bind water and therefore enhance the protective barrier and keep oral structures hydrated.

Buffering and Clearance

Saliva has a slightly alkaline pH and contains several buffer systems, the most important of which is bicarbonate.[27,31,33] Several minor buffer systems are present in saliva as well and include phosphate, urea, and low-molecular-weight histidine-rich proteins. At high flow rates a combination of the increased bicarbonate concentration in saliva and the increased volume of fluid present increases the buffering and clearance capacity of saliva. On the other hand, at low flow rates such as in situations where the salivary glands are not stimulated, the buffering capacity of saliva is at a minimum and is accomplished primarily by buffers such as phosphate and histidine-rich proteins.[27] Clearance of acids and other chemicals occurs by dilution of these substances and then spitting or swallowing the saliva. The buffering and clearance properties of saliva have a known role in the prevention of dental caries.[57]

Maintenance of Tooth Integrity

After tooth eruption, the enamel covering of the tooth undergoes processes of mineralization and demineralization, both of which are influenced by saliva. Demineralization occurs when acids produced by attached bacteria diffuse through plaque and the pellicle into the liquid phase of enamel, between enamel crystals.[27] This results in crystalline dissolution, a breakdown in the enamel coating, and the formation of dental caries. Demineralization is optimized at a pH of 5 to 5.5. Dissolved minerals diffuse out of the tooth structure and into the saliva surrounding the tooth. The buffering capacity of saliva neutralizes acids that accumulate in plaque and thereby inhibit the formation of dental caries. Plaque thickness and the number of bacteria present determine the effectiveness of salivary buffers.

Saliva also plays a role in remineralization, the process of replacing minerals lost from the crystalline matrix of the enamel. Remineralization requires the tooth to be surrounded by fluid supersaturated with minerals such as calcium, phosphorus, magnesium, fluoride, and other trace elements. Saliva has this ability, in large part to its protein subcomponents such as statherin, which stabilizes minerals in solution. Furthermore, proteins such as statherin, mucin, histatin, cystatin, and proline-rich proteins are thought to form a protective pellicle by binding to hydroxyapatite on the surface of the tooth. This protective pellicle also fosters remineralization and limits mineral egress. The remineralization process increases surface hardness, decreases permeability, and decreases the formation of caries.[27]

Antibacterial Activity

Saliva contains both immune-mediated and non–immune-mediated agents that aid in the protection of oral cavity structures. The main immunologic mediator of saliva is IgA and, to a much lesser extent, IgG and IgM. The principal actions of these antibodies are to aggregate bacteria and prevent their adhesion to oral hard and soft tissues. In addition, IgG has the ability to fix complement and cause bacterial lysis, though this represents a minor antibacterial mechanism in saliva.[27]

Nonimmunologic components include various proteins, mucins, and enzymes such as lactoferrin, lysozyme, and peroxidase, all of which are produced by the acinar cells.[27,31] Mucins perform an antibacterial function by modulating the adhesion of microorganisms to oral tissue surfaces. Mucin 1 adsorbs tightly to the tooth and thereby contributes to the enamel pellicle, which protects the tooth from acid. On the other hand, mucin 1 forms heterotypic complexes with other salivary proteins such as amylase, proline-rich proteins, statherin, and histatins. In this manner, mucin 1 allows bacteria to attach to the surface of teeth and provides them with a nutrient source. Mucin 2 also binds to enamel, but in contrast to mucin 1, mucin 2 is easily displaced. Therefore mucin 2 promotes the aggregation and clearance of bacteria.[27] Interestingly, mucin 2 predominates in the saliva of caries-resistant patients, whereas the mucin 1 predominates in caries-susceptible patients.[58]

Lactoferrin is an iron-binding protein found in saliva, whose principal function is that of scavenging free iron in fluids and inflamed areas, to suppress free radical–mediated damage and decrease the availability of the metal to invading microbial and neoplastic cells.[59] Lactoferrin is also thought to have a bactericidal effect that is distinct from its metal chelating properties.[60]

Taste and Digestion

Saliva aids in the mastication and swallowing of food through its lubricating actions. In addition, salivary amylase initiates the digestion of ingested carbohydrates by catalyzing the hydrolysis of the α 1,4 glucosidic bond. Salivary amylase is active only at neutral pH and is inactivated by the pH of gastric juice. However, because of high concentration and activity of amylase in the saliva, a fraction of the ingested starch is digested before the ingested food bolus reaches the stomach. Furthermore, studies suggest that amylase activity may continue for up to 30 minutes in the stomach if protected from the gastric acid within a bolus of food following a large meal. In general, however, most of the digestion of starch results from pancreatic amylase and not salivary amylase.[2,6]

The main role of saliva in taste sensitivity is the solubilization of ingested food particles, transport of taste substances to, and protection of taste receptors. Saliva and its subcomponents may play an additional role in taste perception by neutralizing acids, which would otherwise yield a sour taste, and binding to and neutralizing bitter tasting substances. Salivary constituents such as electrolytes also continuously stimulate the taste receptors altering the threshold of these receptors for substances such as sodium chloride. Finally, saliva bathes and hydrates the taste receptors, preventing them from desiccation, playing a long-term function in maintaining the taste function.[61]

Aging and Salivary Gland Dysfunction

Dry mouth is a common complaint in the geriatric population and is commonly believed to arise from age-associated intrinsic salivary gland dysfunction. Sixty-five percent of patients older than the age of 60 whose presenting complaint is xerostomia have objective evidence of salivary gland hypofunction.[62] However, it is important to keep in mind that extrinsic causes such as polypharmacy and chronic diseases, which are associated with xerostomia, are endemic to the elderly population.[36] A reduction in unstimulated whole saliva is associated with increasing age, when unmedicated healthy subjects older than the age of 80 years are compared with a younger control group (Fig. 84-4).[35] Elderly test

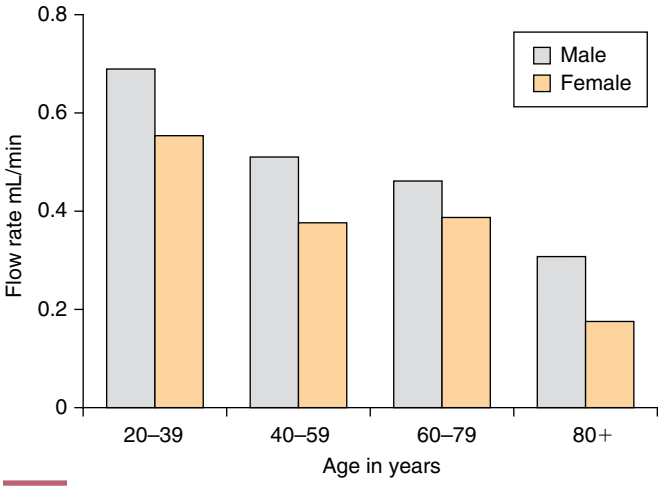

Figure 84-4. Graph demonstrating the age- and gender-specific distribution of unstimulated whole salivary gland secretions. *(From Percival RS, Challacombe SJ, Marsh PD. Flow rates of resting whole and stimulated parotid saliva in relation to age and gender.* J Dent Res. *1994;73:1416.)*

subjects, however, had no impairment in their ability to respond to sialogogues, suggesting that stimulated parotid saliva flow rates are not affected by age.[35] The significance of these findings is somewhat controversial because several other studies in the literature demonstrate a decrease in both unstimulated and stimulated whole saliva with increasing age.[63,64]

All salivary glands undergo structural changes with age. With increasing age, the compact lobular structure and uniform appearance of the ducts and acini are altered. The lobules become more loosely structured, acini assume dissimilar sizes, and intralobular ducts become more prominent. Fibroadipose tissue and acinar atrophy is found in the glands in all ages, but it increases in the elderly. Specific findings in the submandibular gland include a loss of acinar granules with shrinkage of cells, dilation of intralobular and extralobular ducts with a modest hyperplasia of intralobular ducts, oncocytic transformation after 70 years of age, fibrosis around ducts and in septae, an increased glandular adiposity that is independent of general adiposity, and focal obstructive and chronic inflammatory adenitis with intraductal calculi. In general, age-related structural changes in the parotid gland are milder than those in the submandibular gland.[2]

CHAPTER EIGHTY-FIVE

Diagnostic Imaging and Fine-Needle Aspiration of the Salivary Glands

JoAnne Lacey

Key Points

- CT is the modality of choice for patients with inflammatory disorders of the salivary glands.
- MRI is the modality of choice for patients with a palpable lesion or expected neoplasm of the salivary glands.
- US is useful in palpable salivary lesions and has been shown to assist the diagnostic accuracy of FNA.
- Although conventional sialography is the gold standard for evaluating the ductal system in the salivary glands, MR sialography techniques are improving and can provide an alternative, less invasive method for evaluating the ducts.

Although some disorders of the salivary glands can be diagnosed and treated without the use of radiographic studies, imaging of the salivary glands can be useful in the workup of patients with a broad spectrum of salivary pathology. Imaging is used to localize the lesion, define its appearance in order to limit the differential diagnosis, evaluate for staging, and guide fine-needle aspiration for pathologic diagnosis. Various modalities including magnetic resonance imaging (MRI), computed tomography (CT), ultrasound (US), and sialography are used to image and help with the diagnosis of the pathologic processes that occur in the salivary glands. Noninvasive imaging such as MRI, magnetic resonance (MR) sialography, US, and CT have improved to a point that invasive imaging techniques such as conventional sialography are much less frequently employed. Fine-needle aspiration (FNA) of the salivary glands is routinely performed, often under US guidance, for diagnosis and/or presurgical workup of salivary lesions. The role of nuclear medicine imaging in the evaluation of salivary lesions is limited.

Cross-sectional imaging is useful not only for characterization of the major salivary glands and their various pathologies, but also for the evaluation of the surrounding planes and structures revealing possible extension of salivary neoplasms into adjacent spaces, perineural or vascular spread, nonpalpable lesions and lymphadenopathy, or infiltration of the bone marrow. Lesions can also be more clearly defined as extraglandular such as would be seen with a lymph node, schwannoma, developmental cyst, or lipoma.

The clinical presentation of the patient is important in the choice of imaging modality. Patients may present with a painless palpable mass, acute or chronic pain and swelling, or with xerostomia in the setting of collagen vascular disease or radiation therapy. The correct choice of primary imaging modality will assist diagnosis in each instance.

Sialolithiasis (Fig. 85-1) can be seen in any salivary gland but is most commonly associated with the submandibular gland secondary to the more mucinous saliva and the horizontal trajectory of the submandibular duct. Symptoms of acute pain and swelling in the region of a salivary gland would raise suspicion for sialolithiasis, and a CT should be ordered because CT is the modality with the greatest sensitivity for calcification in an obstructive stone.[1]

Neoplasms can occur in any salivary gland tissue. The likelihood of malignancy is largest in the smallest glands. Lesions of the minor salivary glands, for example, have a 50% to 80% chance of being malignant. In the parotid gland, only 20% to 30% of lesions will be malignant, whereas 40% to 60% of submandibular gland lesions will be malignant. In the parotid, therefore, 70% to 80% of lesions will be benign. Of these benign lesions, 80% will be pleomorphic adenomas (Fig. 85-2).[2] Although imaging can give clues as to the pathologic diagnosis (i.e., smooth borders are more likely benign and infiltration of adjacent structures is a sign of malignancy), the role of imaging is primarily to identify the lesion and describe its association with adjacent structures.

Anatomy

It is important to understand the radiographic anatomy of the salivary glands and surrounding structures in order to better interpret the appearance of the various pathologic entities. The three major salivary glands include the parotid glands, submandibular glands, and sublingual glands.

Parotid Glands

The paired parotid glands are the largest of the salivary glands. They are located in the parotid spaces wrapping around the posterior aspects of the mandibular rami bilaterally. Each gland is divided into a superficial lobe and a deep lobe with the posterior facial vein (retromandibular vein) present as the radiographic landmark between the two lobes. The main trunk of the facial nerve exits the skull base at the stylomastoid foramen and pierces the posterior fascial border of the parotid space lateral to the surface of the posterior belly of the digastric

muscle and then courses within the parotid gland lateral to the retromandibular vein. High-resolution MR techniques can show the facial nerve and its relationship to the parotid duct, vascular structures, and, if present, intraparotid tumors.[3] On contrast-enhanced CT or when high-resolution images are not performed, the location of the facial nerve is approximated by the retromandibular vein. Approximately 80% of the parotid lies in the superficial lobe anterior and inferior to the external auditory canal extending down to the angle of the mandible. The deep lobe extends through the stylomandibular tunnel formed anteriorly by the ramus of the mandible and posteriorly by the stylomandibular ligament. The location of a mass in the parotid gland must be defined as superficial, deep, or extraglandular to best plan the surgical approach in order to limit damage to the facial nerve. The parotid duct (Stensen's duct) extends anteriorly from the superficial lobe of the parotid gland around the masseter muscle and anterior to the buccal fat where it proceeds medially to pierce the buccinator muscle. The duct then briefly runs caudally before exiting the papilla at the buccal mucosa opposite the second maxillary molar.

Frommer,[4] in his study of anatomic dissections, found that approximately 21% of parotid glands have an accessory gland. The accessory component is typically located superficial to the masseter muscle just cranial to the main parotid duct (Fig. 85-3). One excretory duct from the accessory parotid gland joins with Stensen's duct. The accessory parotid gland is subject to the same pathologies that affect the parotid gland. The rate of malignancy is estimated to be between 30% and 50%, with mucoepidermoid the most common lesion. Pleomorphic adenoma is the most common benign neoplasm of the accessory parotid gland.

The parotid glands contain many lymph nodes that drain the palatine tonsil, posterior palate, root of the nose, eyelids, frontotemporal scalp, external auditory meatus, and tympanic cavity. This network of nodes drains into the level IIA and IIB nodes of the internal jugular chain and spinal accessory chain.[5]

The parotid gland is interspersed with fat. On CT, the attenuation of the normal gland is lower than muscle and greater than fat. The greater the fat content of the gland, the easier the detection of a parenchymal soft tissue nodule. On MRI, the gland is intermediate to high signal on T1-weighted imaging and low to intermediate on T2-weighted imaging, reflecting its fat content. Flow voids are detectable on T2-weighted imaging due to vessels within the gland. Septations of lower T1 signal are seen in the gland due to interstitial tissues, ducts, and facial nerve branches. The intraparotid facial nerve can be visualized, especially on high-resolution imaging[3,6,7]; the nerve does not normally enhance. Contrast will reveal homogeneous enhancement of the normal parotid glandular tissue (Fig. 85-4).

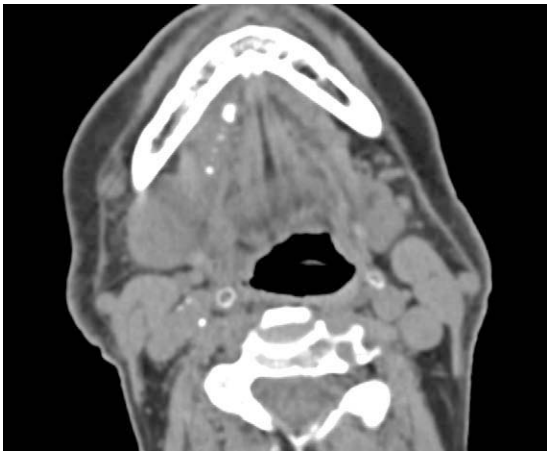

Figure 85-1. Multiple stones within the right submandibular duct (Wharton's duct) with enlargement of the right submandibular gland and periglandular inflammatory fat stranding.

Submandibular Glands

The paired submandibular glands are visible posterior to the angle of the mandible largely within the submandibular space with a small deep portion curling up cranially around the posterior border of the mylohyoid muscle. The submandibular duct (Wharton's duct) exits the deep lobe extending anteriorly and superiorly, medial to the sublingual gland in the sublingual space terminating at the sublingual papilla in the floor of the mouth. The lingual nerve and hypoglossal nerve are closely associated with the duct as it courses anteriorly through the fat-filled sublingual space. The lymphatic drainage from the glands is into the submandibular nodes (level IB).[5]

The parenchyma of the submandibular glands is less fatty than that of the parotid glands. This lends a higher attenuation to the glands on CT and, on MRI, corresponding lower signal on T1-weighted imaging and higher signal on T2-weighted imaging. Again, the use of contrast will reveal homogeneous enhancement, which should be symmetric.

Sublingual Glands

The small, paired sublingual glands are positioned up against the sublingual depressions of the inner surface of the mandible just superior to the mylohyoid muscles bilaterally. Approximately 20 ducts (ducts of Rivinus) drain into the floor of the mouth. The lymphatic drainage

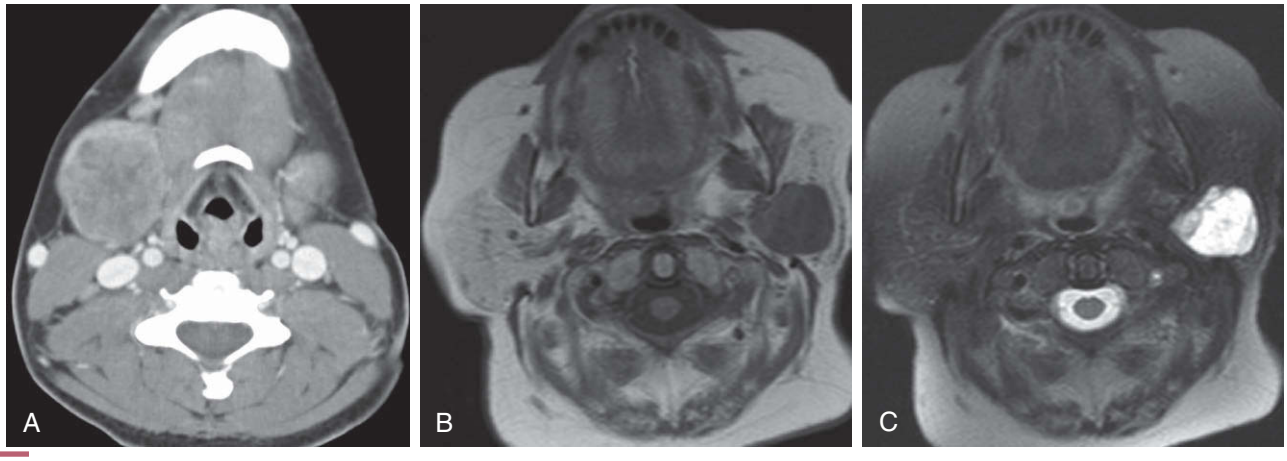

Figure 85-2. **A,** Contrast-enhanced computed tomography showing a large, well-defined, inhomogeneously enhancing right submandibular gland mass that was proven on resection to be a pleomorphic adenoma. **B,** T1-weighted noncontrast magnetic resonance image of a pleomorphic adenoma appearing as a well-defined hypointense mass in the left parotid gland. **C,** On T2-weighted imaging with fat-saturation, the pleomorphic adenoma is hyperintense, a characteristic appearance for this lesion.

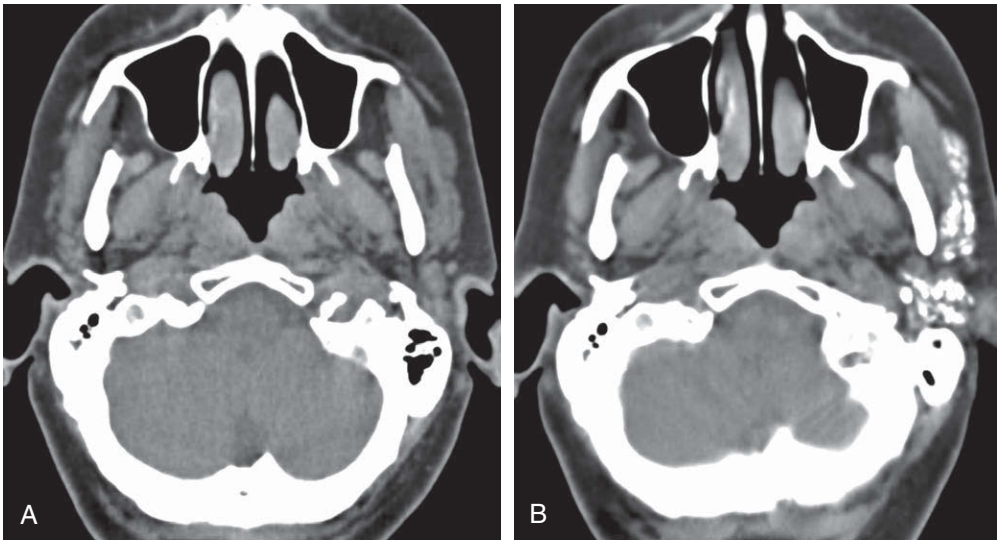

Figure 85-3. Computed tomography sialogram **(A)** before contrast injection and **(B)** after contrast injection showing accessory parotid tissue on the left.

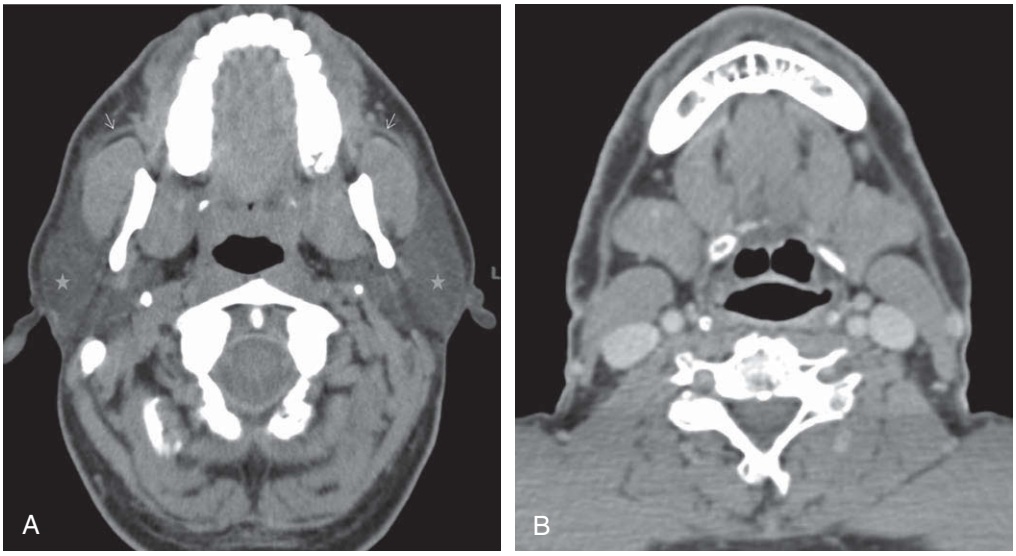

Figure 85-4. **A,** Non–contrast-enhanced computed tomography (CT) with normal parotid glands *(star)* showing the low attenuation consistent with fatty background in this gland. *Arrows* indicate the parotid ducts (Stensen's ducts) bilaterally. **B,** Contrast-enhanced CT with normal submandibular glands.

from the sublingual gland is into the submental and submandibular lymph nodes (levels IA and IB).[5]

Because the sublingual glands are small and closely approximated to the mandible, they are not well visualized on CT when they are normal. The sublingual glands lose volume with increasing age and can be more difficult to differentiate from the surrounding tissues. On MR, the glands are lower on T1WI than the surrounding fat and higher on T2WI.

Minor Salivary Glands

The minor salivary glands are numerous and are present in the deeper submucosal planes of the oral cavity (especially the lip and hard and soft palates), paranasal sinuses, pharynx, external auditory canal, nose, and paranasal sinuses. Though high-resolution MR imaging has been shown to reveal these small glands in the labia,[8] these minor salivary glands are not typically identified on imaging unless they are pathologically enlarged or involved with tumor, of which they are an important tissue of origin.

Magnetic Resonance Imaging

MRI is the modality of choice for the evaluation of salivary neoplasms. Because there is such distinct soft tissue differentiation on MRI, most lesions are identifiable on T1-weighted images, especially in the parotid gland with the fatty background. With the addition of postcontrast imaging on fat-saturated sequences, salivary lesions are easily identified.[9] The adjacent soft tissues are just as well defined, allowing for the assessment of perineal spread, intracranial extension, or marrow invasion. After fat saturation, the previously hyperintense fat on T1-weighted imaging becomes hypointense and the soft tissue mass stands out within the gland. Intravenous gadolinium contrast is helpful to further define salivary lesions and, if present, enhancement along the meninges, within the marrow of the mandible or maxilla or within the foramina of the skull base, all of which would suggest spread of tumor along these routes. Enhancement within the stylomastoid foramen (cranial nerve VII), foramen ovale (cranial nerve V-III), foramen rotundum (cranial nerve V-II), vidian canal (vidian nerve), or the pterygopalatine

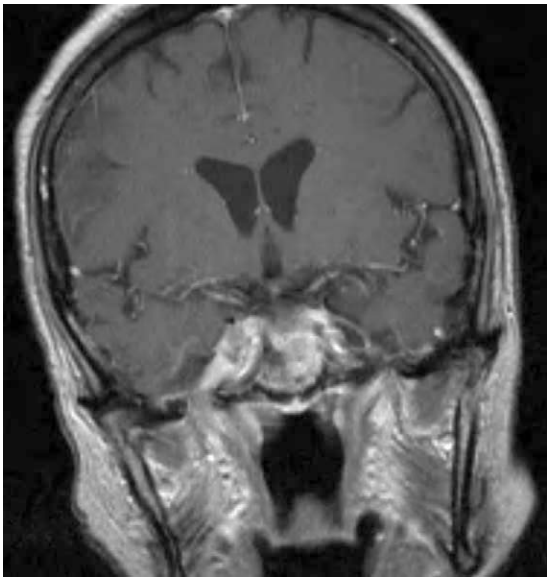

Figure 85-5. T1-weighted postcontrast coronal image showing perineural spread along the mandibular division of the right trigeminal nerve up from the masticator space through foramen ovale into Meckel's cave. This adenoid cystic carcinoma originated in a minor salivary gland of the right maxillary sinus.

fossa suggests perineural spread, and MRI is the best modality to investigate this (Fig. 85-5).

Any tumor imaged by ultrasound (US) with irregular or ill-defined borders or with malignant or suspicious cytology on FNA should be subsequently evaluated by MRI to define the extent of the lesion and possible spread of tumor that might not be identifiable by ultrasound. All sublingual and minor salivary gland tumors should be evaluated by MRI because of the higher rate of malignancy in smaller glands and the risk for perineural spread seen especially with adenoid cystic carcinoma.

Benign lesions are typically well-defined simple or lobulated lesions. Pleomorphic adenomas will have low T1 and high T2 signal intensities similar to water but with solid enhancement best seen on fat-suppressed T1WI after gadolinium. Keep in mind that although pleomorphic adenomas are thought of as benign lesions, malignant degeneration within a pleomorphic adenoma (carcinoma ex pleomorphic adenoma or malignant mixed tumor) may be as high as 25% if left untreated and may, in fact, occur in a patient known to have a previously resected pleomorphic adenoma.[2] For this reason, pleomorphic adenomas are most commonly removed when they are diagnosed.

Warthin's tumor, classified by the World Health Organization as adenolymphoma, is most common in cigarette smokers older than the age of 40 and appears most commonly as a partially cystic lesion arising in the lower portion of the parotid gland at the angle of the mandible (Fig. 85-6). The nature of the lesion results in heterogeneous signal on T2-weighted imaging with bright T2 signal in areas of cyst formation. Nodularity of the cyst wall helps to differentiate it from other cystic lesions. The outer border is well defined and there is no enhancement of the wall. Warthin's tumor is the most likely neoplasm of the salivary glands to be bilateral with up to 10% of patients presenting with bilateral and/or multifocal masses on imaging.[10] Although Warthin's tumors are classically benign, malignant transformation is known to occur, nonetheless, in less than 1% of Warthin's tumors.[11]

Many other cystic lesions affect the salivary glands. AIDS-related parotid cysts can also be bilateral and would have high T2 signal due to their cystic nature (Fig. 85-7). The walls of these cysts are smooth, helping to differentiate them radiographically from cystic Warthin's tumors. A rare first branchial cleft cyst would be seen anterior to the external auditory canal within the parotid tissue. These can become infected with thick enhancing walls and surrounding fat stranding.[2]

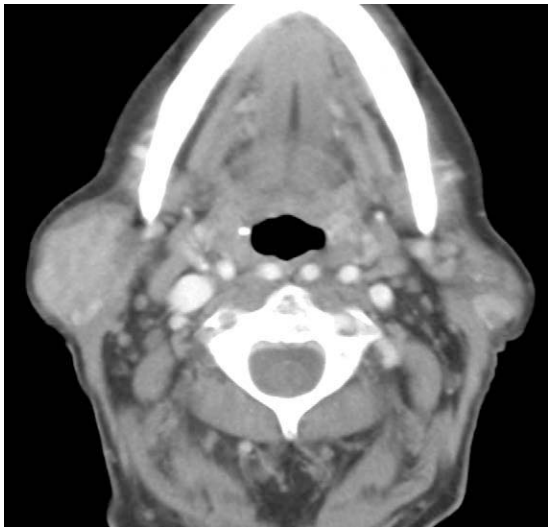

Figure 85-6. Computed tomography showing bilateral Warthin's tumors with solid and cystic components.

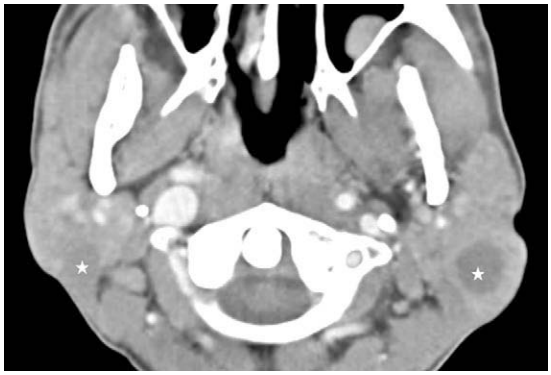

Figure 85-7. Contrast-enhanced computed tomography with bilateral acquired immunodeficiency syndrome (AIDS)-related parotid cysts *(star)* in a patient with human immunodeficiency virus/AIDS.

A ranula is a cystic lesion that arises in the sublingual gland. Two types of ranulae exist. The first, a simple ranula, is an epithelial-lined retention cyst of the sublingual gland. The epithelial border of the simple ranula is intact and the cyst remains above the mylohyoid muscle. If the wall of the simple ranula ruptures and dissects through the mylohyoid muscle into the submandibular space, it forms a mucocele and is referred to as a plunging, or deep, ranula (Fig. 85-8). A ranula of either type will be hyperintense on T2-weighted imaging following fluid on all sequences without enhancement or nodularity in the wall.[10]

Malignant salivary lesions are more likely to be low to intermediate in signal on both T1-weighted imaging and T2-weighted imaging. Most malignant salivary lesions are solitary. Presence of multiple lesions suggests Warthin's tumor, lymphoepithelial cysts, or lymphadenopathy. Lymphadenopathy can be reactive; metastatic, usually from a dermatologic origin (melanoma, basal cell carcinoma, or squamous cell carcinoma); or lymphomatous. Mucoepidermoid carcinoma, the most common salivary malignancy, can look deceptively like a pleomorphic adenoma on all imaging modalities, especially when the lesion is small. It is typically smooth walled, well defined, and may contain calcifications and cysts with mucous material (Fig. 85-9). The mucinous cysts appear as high signal on both T1- and T2-weighted images. The noncystic portions are of low signal on T2-weighted images.[12]

Adenoid cystic carcinoma is the second most common salivary gland malignancy overall and is the most frequent malignant tumor in

the submandibular and sublingual glands. Twenty-two percent of minor salivary gland tumors are adenoid cystic carcinomas. Three pathologic subtypes exist: cribriform, tubular, and solid. The solid lesions have higher cellularity and are correlated with a worse prognosis. These lesions are lower in signal on T2-weighted images. The less cellular lesions of cribriform or tubular subtype are higher in T2 signal intensity on MR imaging[12] (Fig. 85-10). This tumor is well known to spread locally and by perineural invasion. MRI is essential to evaluate the cranial nerves and skull base for this progression. Although the facial nerve is not always well seen on traditional MR sequences, high-resolution MR imaging of the intraglandular facial nerve can be performed, resulting in useful information about a parotid tumor and its relationship to the branches of the facial nerve.[3,6,7,13]

Since MR sialography was first reported in 1996 by Lomas and colleagues,[14] significant advances have been made in sequence development and coil design. These advances have produced high-resolution images of the parotid and submandibular ducts that show obstructions and ductal caliber changes, and they are reproducible.[15,16] These techniques are especially useful in patients with acute sialadenitis in whom conventional sialography is contraindicated. The techniques are also valuable in patients who are allergic to iodinated contrast. Even in cases of radiation-induced xerostomia with intraglandular ductal stenosis[17] and in Sjögren's syndrome, where fine ductal changes are being evaluated, the MR sialogram produced images that aided in the diagnosis when interpreted with the axial T1 and fat-saturated T2.[18]

Advanced MR techniques such as dynamic contrast-enhanced MR imaging, diffusion weighted imaging, and spectroscopy have been studied and show promise in differentiating between benign and malignant lesions.[19-21] These techniques are not in widespread clinical use because they have not typically changed the patient course from imaging, fine-needle aspiration, and extirpation.

Figure 85-8. Hyperintense T2 signal in a plunging ranula in the left sublingual and submandibular spaces.

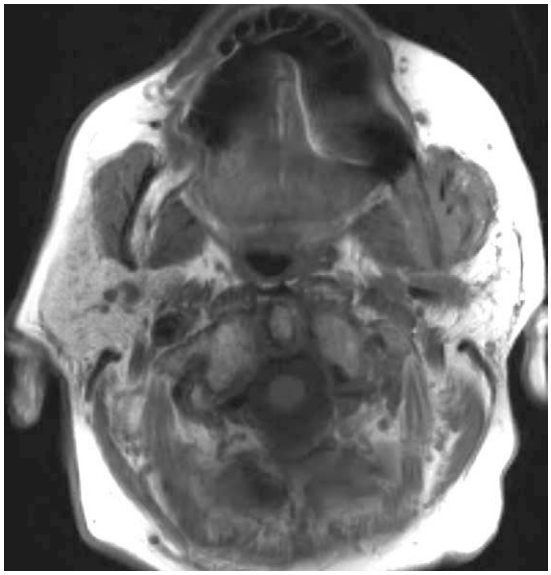

Figure 85-9. T1-weighted precontrast magnetic resonance image revealing a mucoepidermoid tumor of the left parotid gland just posterior to the ramus of the mandible. Note the dark signal in the left mandibular ramus compared with the bright marrow of the right ramus consistent with marrow invasion by tumor.

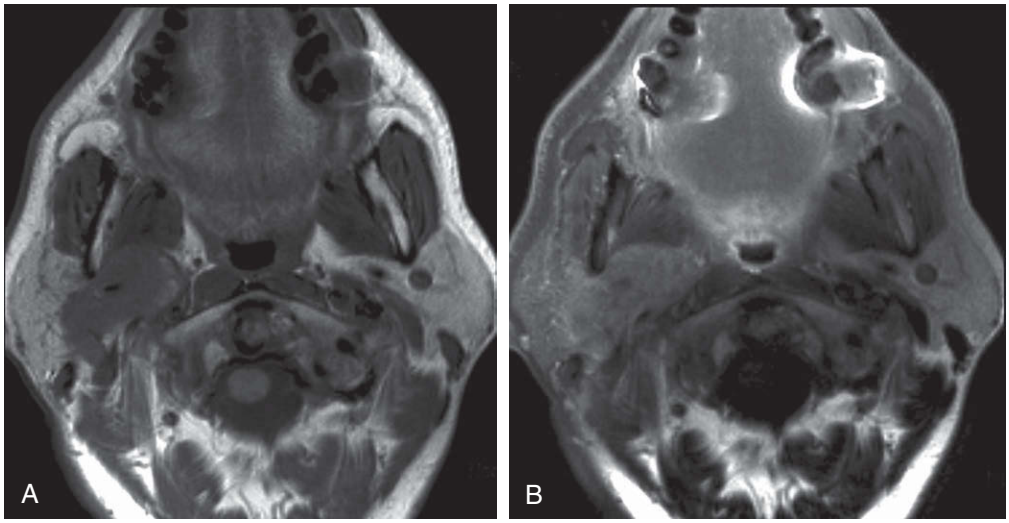

Figure 85-10. **A,** T1-weighted noncontrast magnetic resonance image (MRI) of an adenoid cystic carcinoma in the deep lobe of the right parotid gland. **B,** T1-weighted postcontrast MRI with fat saturation shows enhancement of the mass. Note that the right retromandibular vein is not visualized, raising the concern for involvement of the closely approximated right facial nerve.

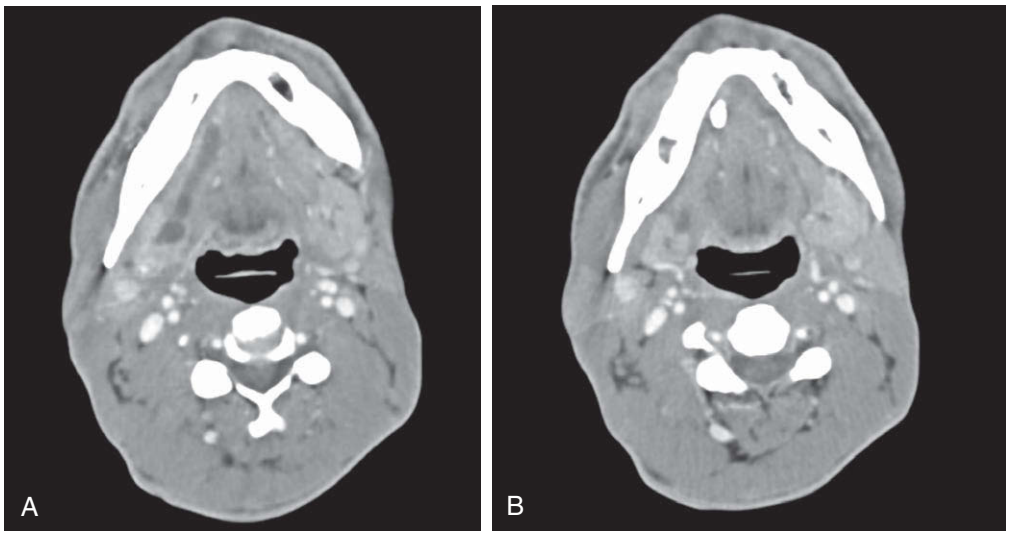

Figure 85-11. **A,** Contrast-enhanced computed tomography showing a dilated right submandibular duct (Wharton's duct). **B,** A few slices cranially in the same patient. A large sialolith is seen near the orifice of the dilated duct, as well as some intraglandular ductal dilatation.

Computed Tomography

As a modality, CT is most useful in the evaluation of calcifications and inflammatory conditions of the salivary glands.[10] The strength of CT is in its ability to show calcification, anatomy, and bony detail. Intravenous iodinated contrast increases the sensitivity of CT for the evaluation of salivary pathology. Spiral CT scans can be reconstructed in the axial, coronal, and sagittal planes to best visualize the anatomy. The fat planes of the neck allow for anatomic placement of a lesion in the correct space limiting the differential diagnosis to the structures occurring in that space. A deep parotid lobe lesion, for example, will be definable as such because it will displace the fat of the parapharyngeal space, as well as the carotid space medially.

Sialolithiasis is a condition in which the precipitation of salts in the saliva forms a stone effectively blocking the flow of saliva from the gland to the oral cavity. Most of the stones (80% to 90%) are associated with the submandibular gland (Fig. 85-11). This is thought to be secondary to the more alkaline pH of the mucinous saliva produced in that gland. The orifice of Wharton's duct is narrow and the duct has a 45% uphill course when the patient is in the erect position. On plain radiographs, 80% of submandibular stones and 60% of parotid stones are radiopaque.[2] Typically, there will be obstructive ductal ectasia with surrounding inflammation in the adjacent fat. The associated gland will be enlarged in the acute state with surrounding inflammation. If there has been chronic obstruction, the gland may be atrophic when compared with the other side.

Ascending infection is a common cause of sialadenitis. Viral infection, most commonly caused by mumps, will cause enlargement and increased density of the affected gland on CT imaging. In acute bacterial infection the gland will be enlarged and more dense than the other side. Inflammatory stranding of the surrounding fat can be seen and abscess could be present, identifiable as a low attenuation area with a thick, irregular, enhancing rim.

Although CT has an overall sensitivity for detecting neoplastic lesions approaching 100%, the distinction between benign and malignant lesions is not always clear on CT. Benign lesions of the salivary glands such as pleomorphic adenoma, Warthin's tumor, and various cystic lesions classically have a well-defined border. These benign lesions, however, can be large and nodular and have hemorrhage, fibrosis, or high protein content that make them inhomogeneous and less well-defined, suggesting a more malignant diagnosis (Fig. 85-12). In contrast, low-grade mucoepidermoid carcinoma and even small adenoid cystic carcinomas can have a pseudocapsule of compressed tissue around them that can make them look more benign. Overall, MR is more sensitive for defining neoplasms and identifying spread to adjacent soft tissues.[10]

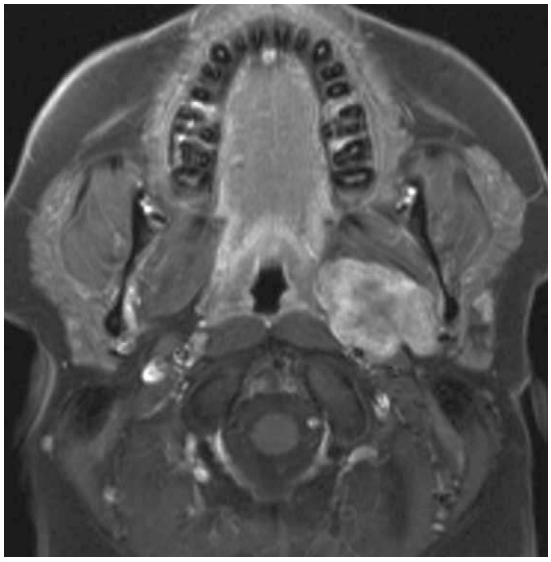

Figure 85-12. T1-weighted postcontrast magnetic resonance image with fat saturation with a pleomorphic adenoma in the deep lobe of the left parotid gland. This pathologically proven benign lesion has deceptively irregular borders, suggesting a more worrisome diagnosis.

Sjögren's syndrome, an autoimmune disease limited to the salivary and/or lacrimal glands, is the result of lymphocyte-mediated destruction of exocrine glands. Serologic markers (SS-A and SS-B antibodies) are elevated in 50% to 70% of patients with active disease. These patients are at higher risk for MALT (mucosa-associated lymphoid tissue) lymphoma. In the early stages of the disease, the gland looks normal on CT. As the disease progresses, the gland becomes enlarged and more dense with eventual development of a honeycomb appearance. Small bilateral cysts may be seen in later stages.[2]

Ultrasound

Ultrasound (US) is typically likely underused in North America in the first-line evaluation of salivary lesions.[9] CT is usually the first choice of imaging for inflammatory diseases, and MRI the first choice of imaging for neoplastic diseased. In experienced hands, however, US may serve the purpose of identifying and characterizing a lesion in the superficial

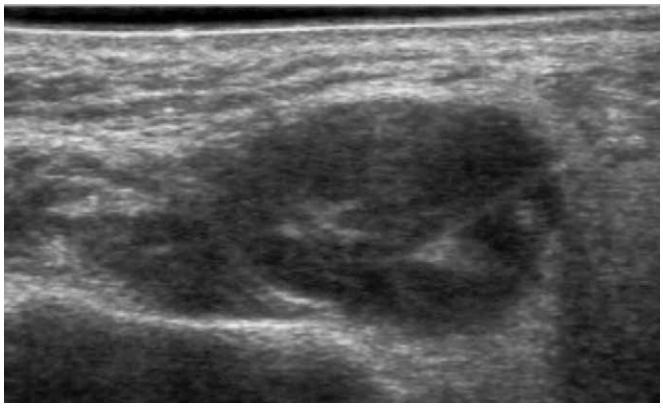

Figure 85-13. Ultrasound-guided fine-needle aspiration of a pleomorphic adenoma of the parotid gland. The needle is identified as the linear structure within the mass.

Figure 85-14. Conventional submandibular sialogram showing a normal ductal appearance.

lobe of the parotid or in the submandibular gland, as well as provide guidance for fine-needle aspiration.[22] The normal appearance of the salivary glands on US is homogeneously hyperechoic to adjacent muscles. The echogenicity of the parotid gland depends on the intraglandular fatty tissue. Higher fat content increases the echogenicity and suppresses the ultrasound waves, limiting the assessment of the deep lobe and even the retromandibular vein and external carotid branches on gray-scale images. Normal, nondilated ducts are not typically on US. Normal intraparotid lymph nodes can be visible with an identifiable fatty hilum. Malignant nodes will be more round, lack a fatty hilum, and will have abnormal peripheral vascularity on Doppler imaging.

Cystic lesions are well defined on US. Cystic neoplasms such as Warthin's tumor or low-grade mucoepidermoid carcinoma are differentiated from developmental or acquired cysts by the thickness and character of the wall of the cyst. Benign pleomorphic adenoma will be homogeneous and hypoechoic with a smooth border, whereas carcinomas will be less well defined and heterogeneous. Malignant lesions will be hypervascular on Doppler imaging. Hypervascularity, however, cannot be the only criterion for malignancy because benign lesions such as hemangiomas can also have increased vascularity. US provides good anatomic detail, and the absence of ionizing radiation in this modality makes it an attractive alternative in the workup of salivary gland lesions, especially in the evaluation of lesions in children, in whom the reduction of diagnostic radiation is crucial.

Fine-Needle Aspiration

Fine-needle aspiration (FNA) has an important role in the diagnostic workup of a salivary gland mass. If definitively positive for malignancy, for example, treatment planning, which often includes surgical resections of varying degrees, is greatly assisted. FNA can be performed without imaging if the lesion is superficial and palpable, though US-guided FNA has been shown to increase the diagnostic accuracy compared with FNA without guidance.[23] US guidance is useful not only for assuring proper needle placement in deeper lesions but also for evaluation of the overall character of the lesion, especially if cross-sectional imaging has not been performed (Fig. 85-13). Aspirates with a 22-gauge needle are usually adequate. Vascular structures are identifiable and therefore avoidable. The facial nerve is not visible on US and therefore the retromandibular vein is used as a landmark because the facial nerve is known to reside just lateral to this readily identifiable structure. Having a cytopathologist present during the procedure to check for adequacy of the specimen is important, especially if the patient is under general anesthesia. Siewert and colleagues[24] reported that the presence of a cytologist increases the likelihood of a diagnostic sample on aspiration without needing a core biopsy. CT guidance for FNA is useful as well, particularly where the lesion is deep, requiring a transbuccal approach.

Early reports raised concerns about the accuracy of cytology and frozen section concurrence with the final histology. The College of American Pathologists Interlaboratory Comparison Program in Nongynecologic Cytology performed a retrospective review of data from 1999 to 2003 including 6249 interpretations of benign and malignant lesions. Their data demonstrate that salivary gland FNA is 73% sensitive and 91% specific for distinguishing between benign and malignant lesions. The overall accuracy of FNA for correctly identifying the correct specific reference interpretation is 48%.[25]

Concerns have been raised regarding the effects of postbiopsy hemorrhage, squamous metaplasia, infarction, and necrosis on the final pathologic diagnosis. A report by Mukunyadzi[26] showed that though these abnormalities were indeed found in the tissues after biopsy, their presence did not alter the final histologic diagnosis. Preoperative FNA combined with intraoperative frozen section resulted in increased diagnostic accuracy than either alone.[27]

Sialography

Conventional sialography is performed to visualize the ducts of the parotid and submandibular glands. It remains the only modality capable of reliably evaluating the fine branches of the intraglandular ductal system (Fig. 85-14). Historically, sialography was useful in the diagnosis of Sjögren's syndrome and differentiating it from chronic sialoadenitis. With modern serum markers for autoimmune disorders, specifically SS-A and SS-B in Sjögren's, sialography is a less important diagnostic aid.[2] Advances in CT and MRI make these cross-sectional modalities superior for evaluation of most salivary lesions, neoplastic and inflammatory.

Conventional sialography is contraindicated in the setting of acute sialadenitis because the procedure may exacerbate the symptoms or cause ascending infection. The procedure is also contraindicated in patients with iodine contrast allergy. Both fat-soluble and water-soluble contrast agents have been used for sialography. Older, fat-soluble contrast agents such as Lipiodol and Pantopaque were reported to cause foreign body reactions following ductal perforation. Ethiodized oil (Ethiodol, 37% bound iodine, Savage Laboratories) is a newer fat-soluble agent that has excellent retention and image resolution with a low reported incidence of foreign body reaction. Water-soluble contrast agents such as diatrizoate meglumine (Sinografin, 38% bound iodine, Squibb) have similar iodine content to ethiodized oil and, if the images are obtained quickly before the contrast mixes with saliva, provide excellent contrast opacification of the ducts with no reported adverse effects with duct perforation. The water-soluble agents such as diatrizoate meglumine are therefore preferable to lipid-soluble contrast agents for silaography.[2]

The papilla for Wharton's duct is located just lateral to the frenulum in the floor of the mouth. The papilla for Stensen's duct is found on the buccal mucosa opposite the second maxillary molar. A blunt-

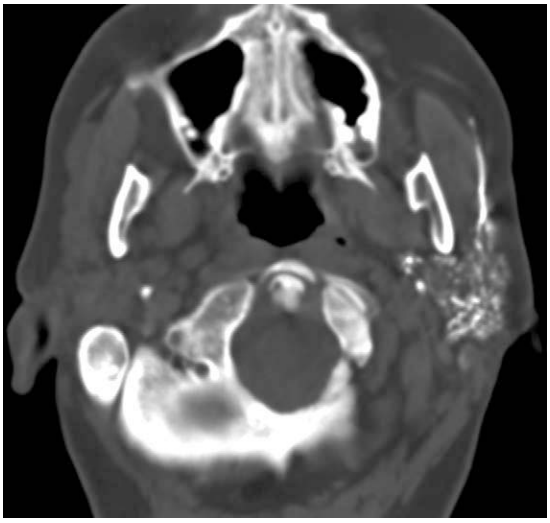

Figure 85-15. Computed tomography sialogram with contrast in a normal left parotid duct and parotid gland.

tipped sialographic cannula with attached tubing is used to access the duct. Some needles have an olive-shaped dilation 1 cm distal to the tip of the needle that, when approximated to the duct orifice, prevents backflow of contrast into the oral cavity. Lacrimal dilators may be necessary to enter the papilla.

Stensen's duct is horizontally oriented, 6 to 7 cm in length, and has a caliber of about 1 to 2 mm. Wharton's duct angles downward and laterally at about a 45-degree angle relative to the sagittal and axial planes and is about 5 cm long with a caliber of 1 to 3 mm. The papilla for Wharton's duct is small and can be more difficult to cannulate and the duct easier to perforate than the parotid duct. The mucosa around the papilla should be dried and the gland massaged to produce saliva. Alternatively, a secretagogue such as lemon juice can be used to produce saliva at the osteum of the duct. Once cannulated, the duct is slowly hand injected with a small volume of contrast under fluoroscopy using approximately 1 mL for Stensen's duct and 0.5 mL for Wharton's duct. Images in the anteroposterior, lateral, and oblique projections are then performed optimizing the visualization of the ductal system. Potential complications of sialography include local pressure or pain, which fades away in minutes and typically completely resolves within 24 hours after the procedure; postsialogram infection; and ductal perforation.

The normal sialographic appearance of the salivary ducts is smooth without filling defects or strictures. The intraglandular branching should be smooth, regular, and without pruning. Postsialogram CT may be helpful to assist localization of abnormalities within the gland (Fig. 85-15).

Nuclear Imaging

The use of nuclear medicine in the evaluation of the salivary glands is limited. It is possible to evaluate physiologic uptake and salivary excretion of intravenously administered technetium 99m pertechnetate. This technique allows for imaging of the parotid and submandibular glands. The sublingual glands and minor salivary glands are too small to evaluate by this method. One instance where nuclear imaging may be useful is in confirming the diagnosis of Warthin's tumors (cystadenoma lymphomatosum) in a patient with surgical contraindications. Pleomorphic adenomas and Warthin's tumors may be difficult to differentiate on CT and MR. Because Warthin's tumors and oncocytomas have increased pertechnetate uptake and pleomorphic adenomas typically have no significant uptake, they can potentially be distinguished with this modality.[9]

The role of F-18 fluorodeoxyglucose positron emission tomography (FDG-PET) imaging in the initial diagnosis of salivary malignancies is limited due to the high false-positive rate. Parotitis, for example, creates a highly FDG-avid environment. Some data in the literature suggest FDG-PET may be useful in the management of patients at staging and in follow-up, but more research is necessary to evaluate the potential of FDG-PET in the monitoring of these patients.[28]

Conclusion

Diagnostic imaging offers valuable tools for helping with the diagnosis, evaluation, and surgical planning of lesions and disorders of the salivary glands. US is useful in defining a palpable lesion and providing guidance for FNA. Inflammatory lesions are best evaluated by CT because the modality has a high sensitivity for calcification and reveals anatomic information crucial to diffuse or deep processes. MRI is the recommended modality to evaluate neoplastic lesions of the salivary glands. Whether the lesion is in the parotid gland or in a minor salivary gland in the sinus, MRI is the modality that will reveal extension of tumor beyond the confines of the gland, as well as complications such as perineural invasion or bone marrow involvement. MR sialography is showing promise to replace conventional sialography, which is contraindicated in patients with acute inflammation or iodine allergy. US-guided FNA is a valuable perioperative procedure to guide patient care.

CHAPTER EIGHTY-SIX

Inflammatory Disorders of the Salivary Glands

Jeremy Rogers

Thomas V. McCaffrey

Key Points

- Sialolithiasis, more frequent in the ducts of the submandibular and sublingual glands, may also contribute to acute infection but more commonly produces chronic salivary gland infection.
- Recurrent parotitis of childhood (RPC) is an uncommon inflammatory condition of the parotid gland characterized by periodic episodes of swelling and pain. The characteristic finding is sialectasis that on conventional sialography appears as numerous scattered punctate pools of contrast.
- Sialolithiasis is the formation of calculi in the ductal system of the salivary glands. The submandibular gland is most commonly affected, with 80% to 90% of stones developing in Wharton's duct.
- Relatively recent treatment alternatives for sialolithiasis are extracorporeal shock wave lithotripsy and the use of sialoendoscopy. Lithotripsy reduces calculi to small fragments that are then flushed out of the duct. Sialoendoscopy involves the use of rigid endoscopes to visualize and remove salivary duct stones.
- The CT evaluation of patients with HIV-associated salivary gland disease demonstrates multiple cysts that appear as low-attenuation, thin-walled masses and diffuse lymphadenopathy.
- The biopsy of labial accessory salivary glands demonstrating salivary gland disease is one of the most consistent features of primary Sjögren's syndrome. The histopathologic lesion is a lymphocytic infiltrate producing a chronic focal sialadenitis.
- Sjögren's syndrome predisposes patients to the development of malignant lymphoproliferative disorders.

Salivary gland infections and inflammations have a wide range of presentations, depending on the etiologic agents involved and the chronicity of the infection. These might range from acute localized infections like bacterial sialadenitis to systemic diseases caused by viruses such as the paramyxovirus or the human immunodeficiency virus (HIV). Noninfectious inflammations such as Sjögren's syndrome may present as a chronic swelling of the salivary glands.

Bacterial Infection of the Salivary Glands

Acute Suppurative Sialadenitis

Acute sialadenitis is a bacterial inflammation of the salivary glands. Although these infections occur in all major salivary glands, the parotid gland is most commonly involved. Frequently associated with medically debilitated and postoperative patients, the incidence of acute sialadenitis is approximately 0.02% of hospital admissions. It occurs between 1 in 1000 and 1 in 2000 operative procedures.[1] Patients undergoing major abdominal and hip repair surgery have been identified as being at increased risk for acute suppurative sialadenitis. The disease is most commonly reported to occur within the first 2 postoperative weeks.[2] Of the medically ill patients affected by sialadenitis, approximately 25% have a malignant lesion and another 50% have a preexisting infection elsewhere than the head and neck. Most affected patients are between 50 and 60 years of age, with an equal incidence among men and women.[3]

Acute infection of the salivary glands is caused by retrograde bacterial contamination of the salivary ducts from the oral cavity. Stasis of salivary flow secondary to dehydration or significant hemorrhage permits retrograde migration of bacteria, producing suppurative infection of the gland parenchyma. The parotid gland is most susceptible to such infections.

In contrast to the mainly serous saliva produced by the parotid gland, the saliva made by the submandibular and sublingual glands is primarily mucoid. Serous saliva, unlike mucinous saliva, is deficient in lysosomes, IgA antibodies, and sialic acid, which have antimicrobial properties. In addition, the saliva from the submandibular and sublingual glands contains high-molecular-weight glycoproteins that competitively inhibit bacterial attachment to the epithelial cells of the salivary ducts.[4] Several predisposing factors might lead to acute sialadenitis. These include diseases such as diabetes mellitus, periodontal disease, hypothyroidism, renal failure, and Sjögren's syndrome. Medications might produce reduced salivary flow through multiple mechanisms (Fig. 86-1).

Mechanical impairment of salivary flow also predisposes to acute infection. Stenosis of the salivary ducts secondary to trauma or a foreign body has been reported to result in acute sialadenitis. Sialolithiasis,

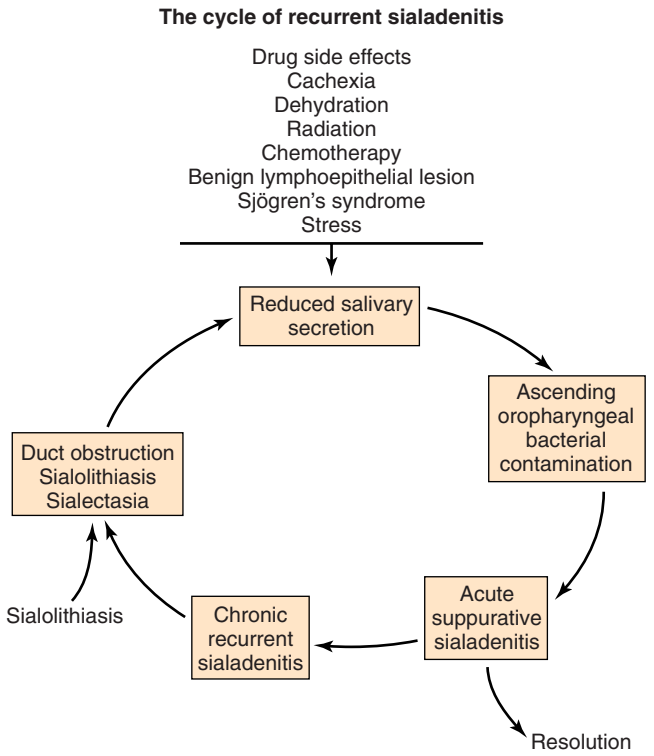

Figure 86-1. Pathophysiology and predisposing factors for the development of acute and chronic suppurative sialadenitis.

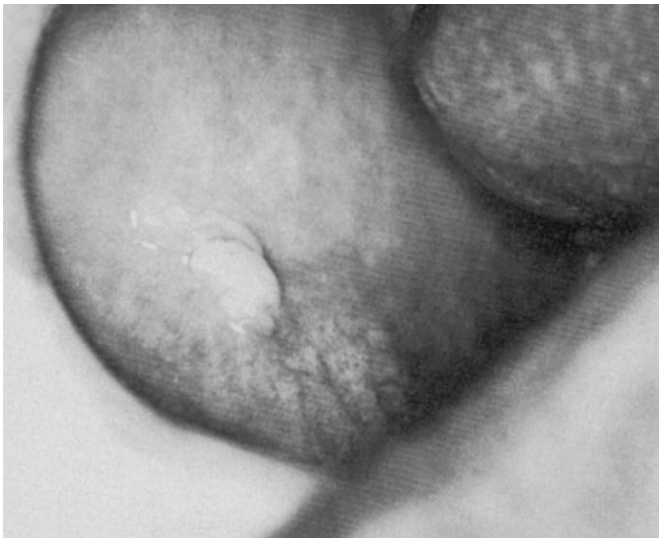

Figure 86-3. A purulent exudate emerging from the orifice of Stensen's duct.

more frequent in the ducts of the submandibular and sublingual glands, may also contribute to acute infection but more commonly produces chronic salivary gland infection.[5] The most commonly cultured organism among hospitalized patients with acute sialadenitis is penicillin-resistant *Staphylococcus aureus,* which is responsible for 50% to 90% of cases. In addition, Streptococcus species including *Streptococcus pyogenes, Streptococcus viridans,* and *Streptococcus pneumoniae,* as well as *Hemophilus influenzae,* can be isolated in community-acquired cases. More recently, the importance of anaerobic and gram-negative bacteria in acute suppurative parotitis has been established. In one study, anaerobic bacteria were isolated from 64% of cases of acute suppurative sialadenitis. The anaerobic bacteria most frequently cultured were *Peptostreptococcus,* bacteroides species, Prevotella species, and fusobacterium. In Southeast Asia, *Burkholderia pseudomallei* is a common cause of parotitis. This apparent shift in microbiology might be the result of improved anaerobic bacterial culture technique rather than a true change in the flora of acute salivary gland infections.[3,6,7]

Acute suppurative sialadenitis presents with local symptoms consisting of rapid onset of pain and swelling over the affected salivary gland (Fig. 86-2). Systemic manifestations include fever, chills, and malaise. Importantly, one should review the medical and surgical history for the previously noted risk factors that would make a patient more susceptible to acute salivary gland infection. On physical examination the patient might demonstrate signs of systemic dehydration with dry mucous membranes. Local findings include tenderness to palpation, with warmth and induration of the overlying skin. Bimanual palpation of the gland results in suppurative discharge from the duct orifice in approximately three fourths of cases (Fig. 86-3).[2] Although typically limited to one gland, multiple glands might be affected, with a reported incidence of bilateral involvement of up to 25% of cases.[8]

The laboratory evaluation will reveal a leukocytosis with neutrophilia. Generally, the serum amylase is normal. Imaging of the affected gland with computed tomography (CT) or ultrasound (US) for abscess formation is indicated in patients who do not respond to medical therapy within 48 to 72 hours. Sialography performed in the acute phases of sialadenitis provides little useful information and is contraindicated because it can exacerbate the existing inflammation. Magnetic resonance imaging (MRI) may be used to evaluate the salivary duct architecture noninvasively; however, its usefulness in acute infection has yet to be established.

Cultures of purulent drainage from the duct orifice should be obtained. Recent reports advocate the use of percutaneous needle aspiration of the involved duct. This technique limits the amount of contamination encountered by means of an intraoral culture.[6,9]

Although the diagnosis of acute parotitis is usually apparent, nonparotid swelling can mimic parotitis. Such conditions include lymphoma, lymphangitis external otitis, Bezold's abscess, cervical adenitis, dental abscesses presenting as buccal or masseteric space abscesses, and infected branchial cleft or sebaceous cysts.[10]

Initial treatment of acute suppurative sialadenitis begins with aggressive medical management. This includes prompt fluid and electrolyte replacement, oral hygiene, reversal of salivary stasis, and antimicrobial therapy. Stimulation of salivary flow is accomplished by the use of sialogogues such as lemon drops and orange juice. Antisialogogic

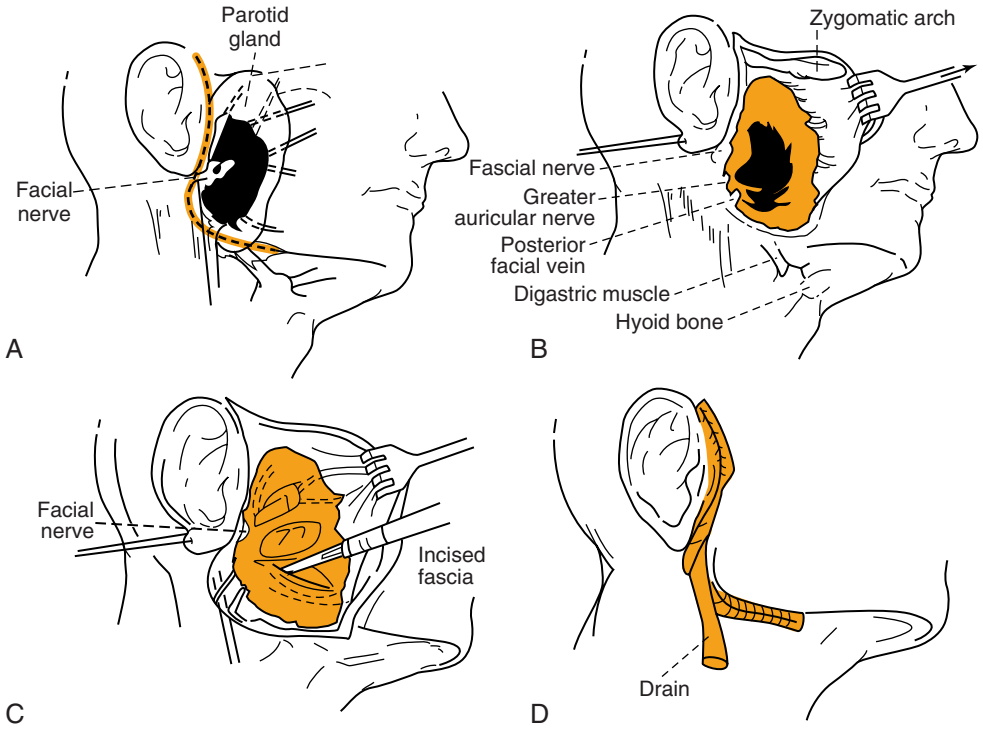

Figure 86-4. Surgical approach to the drainage of an acute parotid gland abscess. **A,** Standard curvilinear incision. **B,** Elevation of an anterior-based facial flap and identification of regional anatomic landmarks. **C,** Abscess drainage by means of incisions in the parotid fascia parallel to facial nerve branches. **D,** Marginal approximation of wound edges and drainage with the central aspect left to heal by secondary intention.

medications should be discontinued. In addition, capable patients should be instructed on regular external and bimanual massage, starting from the distal bed of the gland and working in the direction of duct drainage. Analgesics and local heat application ease the discomfort. If neither saliva nor pus can be expressed from the duct, cannulation and serial dilation may be necessary to establish patency.

Antimicrobial therapy is an essential part of the management of acute salivary gland infections. Antimicrobial therapy is initiated empirically toward gram-positive and anaerobic bacteria. However, the recovery of β-lactamase–producing bacteria in 75% of patients requires the use of augmented penicillin and antistaphylococcal penicillin or a first-generation cephalosporin.[6,11] The use of clindamycin or the addition of metronidazole to the first-line agents to broaden anaerobic coverage has been advocated by some authors.[6] In patients from nursing home environments or cases of nosocomial infection, empiric vancomycin has been advocated given the prevalence of methicillin-resistant *S. aureus*. Aminoglycosides have also been proposed by some in the treatment of critically ill patients. Culture results should be used to further direct antimicrobial treatment. Response to antimicrobial therapy is seen within 48 to 72 hours of initiating treatment and should continue for 1 week after resolution of symptoms.[1]

Rarely, conservative measures fail to eradicate the infection, and surgical drainage of a loculated abscess is necessary. The surgical approach involves elevation of an anterior-based facial flap with abscess drainage by way of radial incisions in the parotid fascia parallel to the facial nerve branches. A drain should be placed, and the wound edges should be loosely approximated, with the central aspect left to heal by secondary intention (Fig. 86-4).

Complications of acute suppurative parotitis are unusual. Suppuration confined to the duct lumen might eventually erode through the epithelium into the interstices of the parenchyma, creating multiple small abscesses that might coalesce into larger collections that can infiltrate a number of potential spaces of the neck. Osteomyelitis of the mandible and temporomandibular joint, thrombophlebitis of the jugular vein, septicemia, respiratory obstruction, and death are potential sequelae of suppurative parotitis. Rupture through the floor of the external auditory canal, spontaneous drainage through the cheek, and extension to the face, neck, and mediastinum have also been reported (Fig. 86-5).[12,13] Facial nerve paralysis, whether complete or incomplete, is uncommon. The etiology of paralysis is unknown but is thought to be due to the virulence of the offending organisms, perineuritis, or acute nerve compression. Because facial nerve paralysis is highly suggestive of parotid malignancy, all patients with paralysis should be followed until the inflammatory process has resolved and facial nerve function returned.[14] Acute suppurative sialadenitis is associated with 20% to 40% reported mortality; however, the prognosis is primarily related to the medical condition of the patient.[2]

Neonatal Suppurative Parotitis

Infections of the salivary glands are uncommon in the neonate. Neonatal suppurative parotitis (NSP) is more common in preterm and male neonates and those with dehydration. *S. aureus* is the most common pathogen, and *Escherichia coli, Pseudomonas aeruginosa*, and group B streptococci have also been implicated in NSP.[15] The oral cavity serves as the portal of entry in most patients.[16] However, transient bacteremia, usually from gram-negative bacteria, may also be responsible.[17]

Clinically, NSP manifests as fever, anorexia, irritability, and failure to gain weight. Erythema of the skin overlying the involved gland might be present. Swelling is usually unilateral initially but often becomes bilateral. The gland might be tender, and the swelling can be firm or fluctuant.

Diagnosis of NSP is made on the basis of clinical findings and Gram's stain, as well as culture of pus from the duct or from fine-needle aspiration (FNA) of the gland. Therapy consists of parenteral antibiotics directed at *S. aureus* and gram-negative bacilli until culture and sensitivity results are available. Drainage procedures should be used only when prompt clinical improvement does not occur or fluctuance of the gland increases.[15]

Recurrent Parotitis of Childhood

Recurrent parotitis of childhood (RPC) is an uncommon inflammatory condition of the parotid gland characterized by periodic episodes of swelling and pain. It can be distinguished from suppurative parotitis by the inability to express pus from the parotid duct. The age of onset

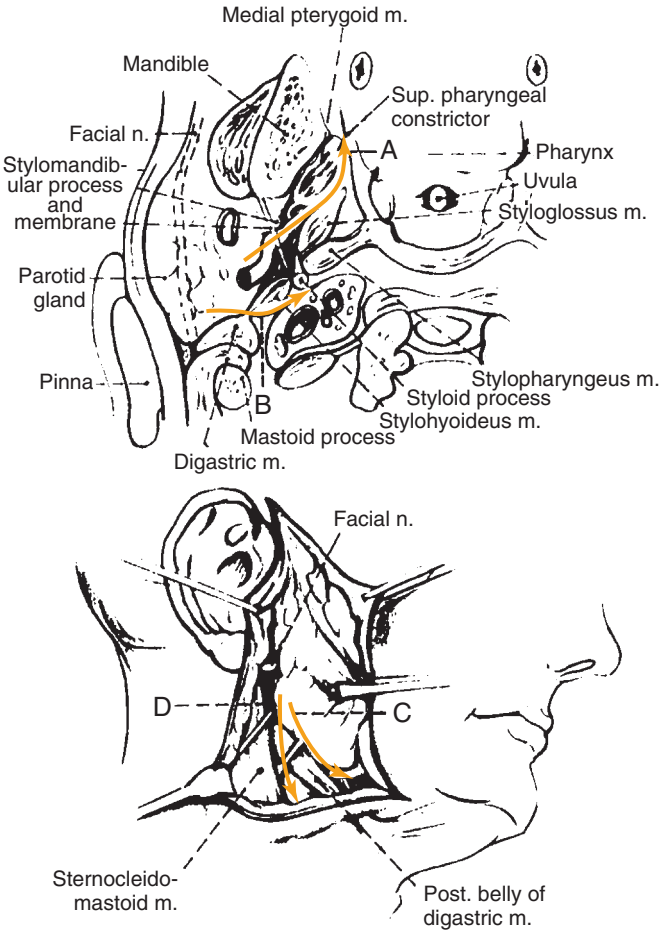

Figure 86-5. Patterns of progression of parotid abscesses. **A,** Prestyloid extension to parapharyngeal space *(arrow)*. **B,** Poststyloid extension to carotid sheath *(arrow)*. **C,** Anteroinferior extension anterior to the posterior digastric belly of the submandibular space *(arrow)*. **D,** Inferior extension posterior to the posterior digastric belly to the carotid triangle *(arrow)*.

ranges from 8 months to 16 years, with a reported peak incidence between the ages of 3 and 6 years.[17,18] Boys are more frequently affected than girls.

The cause of recurrent parotitis of childhood remains unknown, and multiple etiologies have been proposed. Several authors advocate that congenital ectasia of portions of the secondary ductal system predisposes children for bacterial colonization leading to recurrent parotitis.[17] *S. aureus* and *S. viridans* are the most commonly isolated organisms from the parotid ducts of patients. A familial form of RPC has been described with autosomal inheritance.[19] Immunologic abnormalities with isolated IgG3 and IgA deficiencies have been associated with recurrent parotitis. In addition, parotid swelling might be the sole manifestation of juvenile-onset primary Sjögren's syndrome. Several viruses might also play a role in RPC. A history of mumps parotitis often exists. Repeated multiplication of the Epstein-Barr virus in the parotid gland might be responsible for establishing repeated parotid gland inflammation, and RPC has a reported incidence of 20% in HIV-infected children.[20,21]

The histologic appearance of affected parotid glands demonstrates massive periductal lymphocytic infiltration. The intraglandular ducts are dilated and measure approximately 1 to 2 mm in diameter.[20]

Clinically, patients are seen with recurrent episodes of acute or subacute parotid gland swelling along with fever, malaise, and pain frequently after a meal. Episodes of RPC are commonly unilateral, but bilateral involvement has been reported in up to 44% of cases. Afflicted patients tend to experience exacerbations every 3 to 4 months; however, in one series with 53 patients, mean frequency was eight episodes per year. Each might last days to weeks.[17] Diagnosis is usually delayed more than 1 year.

Several imaging modalities may be used to study the ductal system of patients with RPC. The characteristic finding is sialectasis, which on conventional sialography appears as numerous scattered punctate pools of contrast. US of the parotid gland reveals an enlarged gland with multiple small hypoechoic areas. These areas represent both sialectasis of the ducts and the surrounding lymphocytic infiltration. Recently, MR sialography has been reported to be useful in the evaluation of RPC.[20] It is a noninvasive study, not requiring contrast, and may be used during acute episodes.

Treatment consists of adequate hydration, gland massage, local heat, sialagogues, and appropriate intravenous antibiotics. Empiric therapy before culture results should consist of a penicillinase-resistant antistaphylococcal antibiotic. In general, this will lead to rapid resolution of swelling and discomfort. Some authors have advocated prophylactic antibiotics, but this has not been proven effective. Fortunately most cases of recurring parotitis resolve spontaneously near the onset of puberty or in late adolescence, and surgical treatment is rarely required. Of the available options, parotidectomy is curative but carries the risk of facial nerve damage. Ductal ligation and tympanic neurectomy have been reported but with varying results.

Chronic Sialadenitis

Chronic sialadenitis is a localized condition of the salivary gland characterized by repeated episodes of pain and inflammation. The parotid gland is the most frequently affected site.[22] The initial inciting factor is believed to be salivary duct obstruction, with resulting salivary stasis. The most common cause of ductal obstruction is sialolithiasis. Stricture of the salivary duct, extrinsic compression by tumor, stenosis secondary to scar in adjacent tissue, congenital dilation, and foreign body are additional causes of duct obstruction.[23] Salivary stasis from obstruction predisposes patients to episodes of infection and inflammation. Recurrent inflammatory reactions result in progressive acinar destruction with fibrous replacement and sialectasis (Fig. 86-6).

Clinically, patients are seen with a history of recurrent swelling and tenderness of the affected gland associated with eating. Patients frequently report an initial episode of acute suppurative sialadenitis. Asymptomatic intervals might range from a few weeks to months. The physical examination reveals enlargement of the gland, and minimal saliva can be milked from the duct orifice.

Treatment of chronic sialadenitis can be frustrating, and no treatments are consistently successful. Tympanic neurectomy and parotid duct ligation are procedures advocated for chronic parotitis to induce atrophy of the gland, but these have failed to show reliable benefit. Surgical removal of the gland when conservative management has failed to control symptoms has been shown to be safe and effective.[24]

Possible complications of chronic sialadenitis include the development of a benign lymphoepithelial lesion, Kuttner's tumor, and ductal carcinoma.[25-27] A benign lymphoepithelial lesion is characterized by a lymphoreticular infiltrate with acinar atrophy, irregularly placed nuclei, and ductal metaplasia. The metaplasia results in the development of epimyoepithelial islands. Women in the fifth to sixth decade of life are more commonly affected. It has been associated with Sjögren's syndrome and has also been termed Mikulicz's disease. A benign lymphoepithelial lesion typically presents as an asymptomatic mass. FNA may be used for diagnosis and allow for a nonsurgical approach to management.[27] However, patients must be followed because there are reports of the development of malignancy from these lesions.[26]

Kuttner's tumor is a benign inflammatory process similar to a benign lymphoepithelial lesion. However, the lesion occurs almost exclusively in the submandibular gland. Kuttner's tumors are most common in middle-aged adults and present as a painless mass. Histologically, there is a heavy lymphoid infiltrate among discrete tubular structures with regularly aligned nuclei, which differentiates them from a benign lymphoepithelial lesion. Kuttner's tumor might also be followed clinically. Again, careful and routine assessment of patients with chronic sialadenitis is underscored by reports of the development of malignancies including salivary ductal carcinoma.[26]

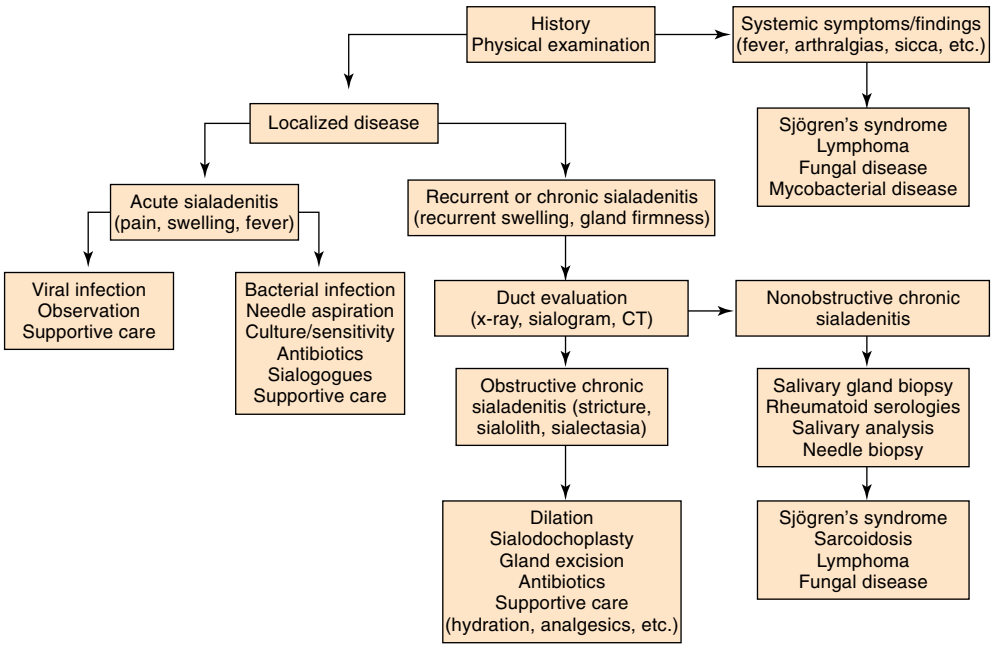

Figure 86-6. A simplified algorithm for the diagnosis and management of chronic salivary gland inflammation.

Sialolithiasis

Sialolithiasis is the formation of calculi in the ductal system of the salivary glands. The submandibular gland is most commonly affected, with 80% to 90% of stones developing in Wharton's duct. Approximately 10% to 20% of calculi form in the parotid (Stensen's) duct and 1% in the sublingual duct.[28] Patients in their fifth to eighth decade of life represent most cases. Sialolithiasis in children is rare; however, if afflicted, children most commonly are seen at 10 years of age.[6] Men tend to develop calculi much more frequently than women.

Salivary stones are composed predominantly of calcium phosphate and carbonate in combination with an organic matrix of glycoproteins and mucopolysaccharides. Small amounts of other salts such as magnesium, potassium, and ammonium are also involved in stone formation.[29]

The exact etiology of sialolithiasis is uncertain. There does not seem to be a relationship between their formation and serum calcium or phosphorous levels.[30] Salivary stasis and ductal inflammation and injury are important factors contributing to stone formation. It is believed that intermittent salivary stasis results in an alteration of the mucoid elements of saliva forming an organic gel. This gel becomes the framework for the deposition of salts, which leads to the development of calculi. The relationship between sialolithiasis and chronic sialadenitis might differ between salivary glands.[28] In the submandibular gland, development of a sialolith might be the primary event that results in stagnation of saliva and inflammation, encouraging bacterial migration and resultant sialadenitis. In contrast, inflammation and ductal injury in the parotid gland from chronic sialadenitis are believed to be the inciting processes for sialolithiasis.

Several factors might account for the propensity of salivary stones to form in the submandibular gland. Wharton's duct is longer, has a larger caliber, and is angulated against gravity as it courses around the mylohyoid muscle, all of which results in slower salivary flow rates. Also, the saliva produced by the gland itself is more viscous and has a higher calcium and phosphorous concentration.[28,31]

In the parotid gland, stones are most commonly located at the hilum or parenchyma. Sialolithiasis in the submandibular gland tends to develop in the duct.[32]

Patients with sialolithiasis are seen with recurrent episodes of postprandial salivary colic with pain and swelling. The patient might also have a history of multiple cases of acute suppurative sialadenitis (Fig. 86-7). On physical examination, bimanual palpation will reveal the presence of a palpable stone in most cases involving the submandibular duct. Parotid stones might be noted at the orifice of Stensen's duct or along the course of the duct.

Figure 86-7. Development of acute suppurative sialadenitis and abscess secondary to submandibular gland sialolithiasis.

Imaging of the salivary glands for sialolithiasis may be accomplished with plain radiographs, conventional and digital sialography, US, CT, and MRI. Plain radiographs that use intraoral or occlusal views might be used to identify radiopaque stones (Fig. 86-8). These stones are much more common in the submandibular gland than in the parotid gland, where up to 80% of stones are radiolucent. However, other calcifications in the area such as phleboliths, arterial atherosclerosis of the lingual artery, or calcified cervical lymphadenopathy make the interpretation of plain radiographs more difficult. US has proven value in the diagnosis of sialolithiasis, with the ability to detect 90% of stones greater than 2 mm.[33] CT scanning with fine cuts is extremely accurate at detecting salivary stones. Digital subtraction sialography, which lessens the interference of surrounding bony structures, has been

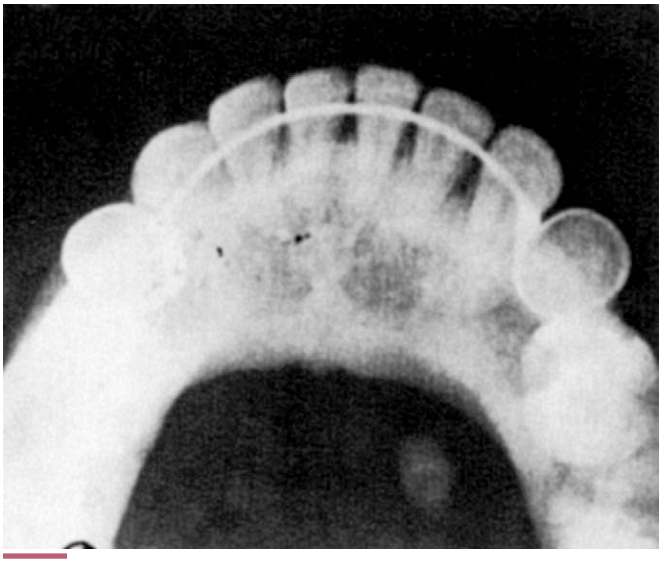

Figure 86-8. An occlusal view radiograph demonstrating an opaque calculus in Wharton's duct.

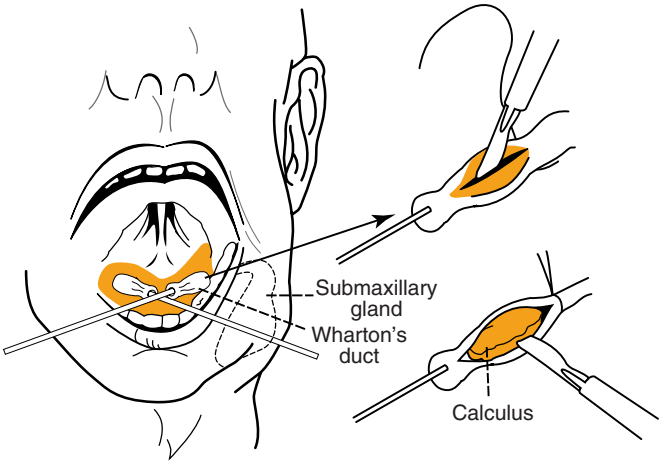

Figure 86-9. Techniques for localization and retrieval of a submandibular duct calculus.

the diagnostic test of choice for sialolithiasis. This can detect radiolucent stones and has a reported sensitivity of 95% to 100%.[27] Several disadvantages are inherent to sialography. It is an invasive technique with the possible side effects of contrast material. Sialography is also contraindicated for stones located in the oral portion of Wharton's duct and in cases of active infection. MR sialography is a relatively new and noninvasive technique being used to evaluate the salivary duct system. Studies indicate that MR sialography of the submandibular duct with evoked salivation has accuracy similar to digital sialography and superior to US.[33] This imaging modality becomes a superior alternative in patients with contraindications to digital sialography. FNA might be indicated in patients with suspected sialolithiasis when no stone is detected and the possibility of malignancy exists. However, pathologic diagnosis in this setting is difficult, and the ductal metaplasia of sialolithiasis secondary to stone formation might be misinterpreted with mucoepidermoid carcinoma.[30]

Initial nonsurgical management of patients with sialolithiasis consists of the use of sialogogues, local heat, hydration, and massaging of the involved gland. If salivary gland infection is suspected, prompt antibiotic coverage should be started.[28]

Surgical intervention for sialolithiasis depends on the anatomic location of the stone. Submandibular stones that are palpable in the mouth and are no more than 2 cm from the duct orifice may be removed using an intraoral approach. This may simply involve milking the stone through the duct opening manually or incising the duct directly over the stone without the need for closure of Wharton's duct after the procedure (Fig. 86-9). Submandibular stones located in a more posterior location will require sialadenectomy,[28] which may be performed through a transcervical or a transoral approach.[34]

The anatomy of Stensen's duct makes the management of parotid stones more difficult. An intraoral approach is limited to parotid calculi that are situated in the segment of Stensen's duct medial to the masseter muscle. In addition, manipulation of the parotid duct is complicated by a high incidence of stricture and frequently requires the use of a temporary stent. The remaining surgical option for parotid stones is a parotidectomy.

Relatively recent treatment alternatives for sialolithiasis are extracorporeal shock wave lithotripsy and the use of sialoendoscopy. Lithotripsy reduces calculi to small fragments that are then flushed out of the duct with spontaneous salivation or the use of a secretagogue.[35] Sialoendoscopy involves the use of rigid endoscopes to visualize and remove salivary duct stones. Several researchers have reported on the efficacy of this technique using a combination of baskets, graspers, and intracorporeal lithotripsy to treat sialolithiasis in both the parotid and submandibular glands.[36-38]

Viral Infections of the Salivary Glands

Viral involvement of the salivary glands most commonly occurs through hematogenous dissemination, although infection by retrograde ductal migration does occur. Viral infection of salivary parenchyma is not always locally symptomatic because transmission from blood to saliva occurs without localizing signs in many systemic viral infections including rabies, hepatitis, influenza, and poliomyelitis.

Mumps

Mumps classically defines an acute nonsuppurative viral parotitis caused by the paramyxovirus. The term "mumps" is derived from the Danish "mompen," which means mumbling (like an old man), and describes the difficulty with speech because of inflammation and trismus.[5] Mumps is the most common cause of nonsuppurative acute sialadenitis, and 85% of cases occur in children younger than the age of 15.[11] The disease is highly contagious and occurs worldwide, with a peak incidence in the spring in temperate climates and with little variation in the tropics.[39]

The paramyxovirus is a ribonucleic acid virus that is endemic in the community and is disseminated by means of airborne droplets from salivary, nasal, and urinary secretions. Interestingly, no known animal reservoir, insect vector, or human carrier has been identified. The disease is maintained by spread from acute cases.[2] Viruses other than paramyxovirus have been implicated as causes of acute viral parotitis: Coxsackie viruses A and B, enteric cytopathic human orphan virus, cytomegalovirus, and lymphocytic choriomeningitis virus.[40]

The virus enters through the upper respiratory tract and has an incubation period of 2 to 3 weeks. During this incubation period, the virus multiplies in the upper respiratory tract epithelium and parotid gland. The virus then localizes to biologically active glandular and central nervous system tissue. Patients will typically experience a viral prodrome consisting of low-grade fever, headache, myalgia, anorexia, arthralgia, and malaise just before parotid gland symptoms. The parotitis is characterized by localized pain and edema of the gland along with otalgia, trismus, and dysphagia. Eating or chewing exacerbates the pain. In 75% of cases, there will be bilateral parotid gland swelling that causes displacement of the pinna.[2] Commonly, the gland on one side will swell first, followed by enlargement of the other gland in 1 to 5 days. The submandibular gland might be affected in rare cases. Physical examination of the involved gland will demonstrate nonpitting edema that is tense and firm. The overlying skin will be stretched with a glazed appearance, but there should be no erythema or warmth.

The diagnosis of viral parotitis is confirmed through viral serology. Complement-fixing soluble (S) antibodies against the nucleoprotein

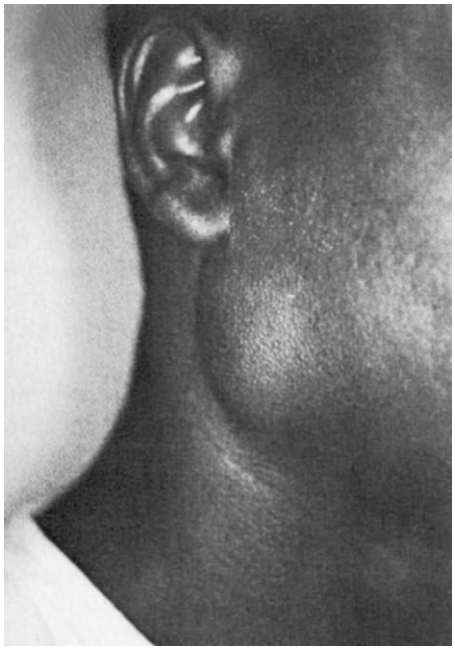

Figure 86-10. Clinical appearance of human immunodeficiency virus–related enlargement of the parotid gland. *(From Debo RF, Davidson M, Petrow CA. Pathologic quiz case 2. core of the virus are the earliest antibodies to appear. Their levels peak at 10 days to 2 weeks and disappear within 8 to 9 months. Therefore these S antibodies are associated with active infection. Complement-fixing viral (V) antibodies against outer surface hemagglutinin appear later than S antibodies but persist at low levels for years. If serology for paramyxovirus is negative, antibody titers for other viral agents that might also result in parotitis may be obtained. A fourfold increase in antibody titer is diagnostic for acute infection.[5] The mumps skin test has no diagnostic value in the setting of acute infection because dermal hypersensitivity does not develop until 3 to 4 weeks after exposure to the virus. A leukocyte count will occasionally be remarkable for leukopenia, and there is also an elevation in the serum salivary-type amylase.

Management of acute viral parotitis involves supportive measures that include bedrest, oral hygiene, hydration, and dietary modifications to minimize glandular secretory activity. Fever will usually subside before the resolution of glandular edema, which requires several weeks. Complications of mumps virus include orchitis, aseptic meningitis, pancreatitis, nephritis, and sensorineural hearing loss.[2]

The prevention of mumps is by means of vaccination with the live attenuated Jerry Lynn vaccine. The vaccine is administered subcutaneously, usually in combination with measles and rubella vaccines after 12 months of age. The antibodies produced persist for at least 5 years. The vaccine is contraindicated in pregnancy, immunocompromised states, allergies to neomycin, and pregnancy.[3]

HIV

HIV is associated with several pathologic processes involving the salivary glands. These include neoplasms such as Kaposi's sarcoma and lymphoma and lymphoproliferative and cystic enlargement of the major salivary glands with accompanying salivary dysfunction (Fig. 86-10). HIV-associated salivary gland disease (HIV-SGD) is a term used to describe this diffuse enlargement of the salivary glands. HIV-SGD may affect patients throughout all stages of the disease and may be the initial manifestation of HIV infection.[41] The parotid gland is the most commonly affected of the salivary glands. Salivary secretions have been shown to contain low concentrations of the virus; however, studies have failed to show infection in the epithelial cells of the salivary gland. No other viruses, such as the cytomegalovirus or Epstein-Barr virus, have been isolated in association with HIV-SGD.

The histologic findings of the salivary glands affected by HIV-SGD are varied. The enlarged intraparotid and periparotid lymph nodes demonstrate a uniform follicular hyperplasia characteristic of the generalized lymphadenopathy associated with HIV infection elsewhere in the body. In addition, there are parotid nodes containing salivary epithelial structures and epithelial-lined cysts in addition to the follicular hyperplasia. In some cases, there is diffuse infiltration of the gland by lymphoid elements with cystic dilation of the salivary ducts. It is believed that the surrounding lymphoid hyperplasia results in incomplete ductal obstruction, leading to the growth of epithelial cysts (Fig. 86-11).[42]

Patients with HIV-SGD report a history of gradual, nontender enlargement of one or more of the salivary glands. The glandular swellings might fluctuate but are generally stable and long standing. Decreased salivary gland function results in xerostomia and sicca symptoms. This sicca symptom complex clinically mimics Sjögren's syndrome and has resulted in the classification of another HIV-related salivary gland pathologic process known as the diffuse infiltrative lymphocytosis syndrome (DILS).[43]

DILS is characterized by the presence of persistent circulating $CD8^+$ lymphocytosis and visceral $CD8^+$ lymphocytic infiltration that occurs predominantly in the salivary glands and lungs. DILS might appear similar to Sjögren's syndrome but can be differentiated by the presence of extraglandular involvement involving the lung, gastrointestinal tract, and kidneys. In addition, autoantibodies present in patients with Sjögren's syndrome will be absent in DILS.

The radiographic evaluation of patients with HIV-SGD involves the use of CT and MRI. On CT, the parotid gland generally demonstrates multiple cysts that appear as low-attenuation, thin-walled masses

and diffuse lymphadenopathy. The MRI will show homogeneous masses of intermediate signal intensity on proton density and T2-weighted images.[41]

Medical treatment of HIV-SGD involves the use of zidovudine, maintenance of good oral hygiene, and the use of sialogogues. Patients with DILS and progressive visceral lymphocytic infiltration may be treated with corticosteroids and immunosuppressive therapy.[44] Some controversy exists regarding HIV-SGD and the need for surgical excision and pathologic examination of an enlarged salivary gland. In general, in patients with documented HIV-SGD, it has been demonstrated that the findings of needle aspiration and CT or MRI are sufficiently typical to provide a presumptive diagnosis, justifying conservative clinical observation.[45]

Granulomatous Infections of the Salivary Glands

Salivary gland involvement frequently arises as a manifestation of a chronic granulomatous disease involving the lymphatic network in and surrounding the parotid gland. Direct infiltration of the adjacent glandular parenchyma occurs in fulminant cases. Manifestations frequently feature asymptomatic gradual enlargement of a nodule within the gland substance, suggesting a neoplasm. Included among these granulomatous diseases are tuberculous and nontuberculous mycobacterial diseases, actinomycosis, cat-scratch disease (CSD), toxoplasmosis, and tularemia.

Tuberculous Mycobacterial Disease

The most common manifestation of *Mycobacterium tuberculosis* infection in the head and neck is cervical lymphadenopathy. The diagnosis of mycobacterial infections has become more frequent secondary to increased immigration from underdeveloped countries and the HIV epidemic. However, primary salivary tuberculosis remains an uncommon entity. The diagnosis of mycobacterial infection of the salivary glands is difficult because the differential diagnosis must include the usual spectrum of inflammatory and neoplastic diseases and lesions unique to the salivary glands.

Tuberculous salivary gland infection is most common in older children and adults. The disease is spread by close person-to-person contact. Primary salivary gland infection by *M. tuberculosis* is believed to evolve from a focus in the tonsils or gingival sulcus ascending to the glands by way of their ducts. This may then spread to the cervical nodes through the lymphatic drainage.[46] This localized, extrapulmonary type of tuberculous infection most frequently affects the parotid gland. Secondary infection of the salivary glands occurs by way of hematogenous or lymphatic spread from the lungs. Mycobacteria are encapsulated in the intraglandular lymph nodes and might be reactivated many years after the acute pulmonary infection. The submandibular gland is the more commonly involved gland after systemic tuberculous infection.[47]

Clinically, tuberculous salivary gland infection presents in two different forms. The first is an acute inflammatory lesion with diffuse glandular edema that may be confused with an acute sialadenitis or abscess. A second chronic tumorous lesion is seen as a discrete slow-growing mass that mimics a neoplasm.[27] Constitutional signs including fever, night sweats, and weight loss might be absent. Involvement of the facial nerve is rare.

The chest x-ray is commonly negative but might show evidence of healed granulomatous disease. The CT images of tuberculous infection in the head and neck are described as having three patterns. The first, early in the course of disease, demonstrates involved lymph nodes with nonspecific homogeneous enhancement. In the second pattern, there is a nodal mass with central lucency and thick rims of enhancement and minimally effaced fascial planes. The third is described as fibrocalcified nodes, usually seen in patients previously treated for tuberculosis.[30]

In the setting of a tuberculous infection, the purified protein derivative (PPD) skin test should be positive. FNA biopsy may be used for diagnosis with a lower risk of producing a draining fistula than incisional biopsy. The FNA sample is analyzed for characteristic cytologic features: granulomatous inflammation and epithelioid histiocytes. In addition, material may be sent for culture and acid-fast smears.[48]

Once diagnosed, *M. tuberculosis* infection may be treated with triple-drug therapy. In cases in which the diagnosis is uncertain or the lesion is resistant to medical therapy, complete surgical excision is both diagnostic and curative.[27]

Nontuberculous Mycobacterial Disease

Nontuberculous mycobacteria (NTM) have become an increasingly important disease of childhood. In fact, more than 92% of mycobacterial cervicofacial infections in children are a result of NTM.[49] The disease mainly affects children younger than 5 years of age, with most cases occurring between 16 and 32 months of age. The specific organisms most commonly classified as NTM are *Myocbacterium kansasii, Myocbacterium scrofulaceum,* and *Myocbacterium avium–intracellulare.* Infection by *Mycobacterium bovis* has decreased dramatically with the institution of milk pasteurization. These organisms are commonly found in soil, water, domestic and wild animals, milk, and other food items.[50] The portal of entry is believed to be through the mouth, and the tonsils have been implicated in particular.

The typical clinical presentation is of a rapidly enlarging and persistent neck mass that has failed to respond to antibiotic therapy in a pediatric patient. The skin becomes adherent to the surrounding tissues and develops a characteristic violaceous discoloration (Fig. 86-12). The infection might progress to fluctuation and the development of a draining sinus. These lesions generally produce few systemic symptoms. Associated cervical lymphadenopathy is more commonly unilateral and located in the high jugular nodes or preauricular areas.[49] The differential diagnosis should include all diseases specific to the salivary glands, as well as other granulomatous diseases, acute bacterial or viral infection, and malignancy. Chest x-ray findings are typically absent. Contrast-enhanced CT images show asymmetric cervical lymphadenopathy with contiguous low-density, necrotic, ring-enhancing masses involving the subcutaneous fat and skin. In addition, inflammatory stranding of the subcutaneous fat characteristic of bacterial inflammation is minimal or absent with NTM infection.[51]

Recently, there have been numerous approaches described to diagnose an NTM infection. FNA biopsy is one method, but it does carry the risk of fistula formation. PPD skin testing might be negative; however, NTM-specific antigens have been developed and are reported to be extremely successful for diagnosis. Newer methods that use polymerase chain reaction techniques to detect mycobacterial RNA in tissue and *Mycobacterium avium* deoxyribonucleic acid in gastric aspirates are still not widely available.[50] Traditional culture of NTM might take up to 6 weeks and is frequently negative.

Figure 86-12. A 4-year-old girl with nontuberculous mycobacterial involvement of periparotid lymph nodes.

Medical treatment of NTM with prolonged courses of antimicrobials, such as clarithromycin, has been advocated but is not well established. The treatment of choice is complete surgical excision of the involved salivary gland and nodes.[49,50]

Other Granulomatous Diseases

Actinomycosis

Actinomycosis is an infectious disease caused by the actinomyces species, a gram-positive, anaerobic, non–acid-fast bacillus. The actinomyces have a branching, filamentous appearance and are similar in appearance and pathogenicity to mycobacteria and fungi. They are a normal commensal organism found in high concentrations in the tonsils and carious teeth. *Actinomycosis israelii* is the most commonly encountered species, with the balance of cases attributable to *Actinomycosis bovis* and *Actinomycosis naeslundii*. The three major clinical infections caused by actinomyces are cervicofacial (55%), abdominopelvic (20%), and pulmonothoracic (15%).[52]

In most cases, poor oral hygiene combined with trauma to the mucosa permits invasion of the organism, leading to a slowly progressive inflammatory reaction. Diabetes, immune suppression, long-term steroid use, and malnutrition have also been implicated as predisposing factors. Isolated salivary gland involvement probably occurs by means of retrograde ductal migration and primarily occurs in the parotid gland.[53] Involvement of the salivary glands also can occur as part of direct spread of an invasive cervicofacial infection.

Patients typically have a painless, indurated enlargement of the involved gland that might suggest a neoplasm. A chronic purulent drainage might occur with granulomatous involvement and spread to adjacent tissue. The periphery of the lesion is densely fibrotic and avascular. The development of multiple draining cutaneous fistulas is quite common.[52] Facial nerve involvement has not been described. A history of recent dental disease and manipulation is common. Constitutional symptoms, malaise, leukocytosis, and lymphadenopathy are typically absent. CT scans typically demonstrate obliteration of the normal tissue planes and extensive soft-tissue destruction.[49]

Anaerobic cultures are obtained for species identification and to confirm the diagnosis; however, the recovery rate in culture is less than 50%.[52] Diagnosis is assisted by needle aspiration of the mass or a fistula swab with smears and stains to examine for the presence of sulfur granules and the organism. Sulfur granules have also been described for nocardiosis, but their identification in the presence of filamentous gram-positive rods is diagnostic for actinomycosis.[54] Biopsy specimens show firm fibrous encasement of multiloculated abscesses containing whitish yellow purulent discharge.

Antimicrobial therapy should consist of a 6-week parenteral course followed by an additional 6 months of oral management to completely eradicate the organism. The antimicrobial of choice remains penicillin because *Actinomyces* species are not known to be resistant to penicillin. Other acceptable alternatives include clindamycin, doxycycline, or erythromycin.[52] Surgical excision is necessary to remove extensive fibrosis and sinus tracts, in cases with a poor response to antibiotics, and for diagnosis. Response to management is generally favorable, with cure rates approaching 90% despite a delayed diagnosis in most instances.[55]

Cat-Scratch Disease

Cat-scratch disease (CSD) is a granulomatous lymphadenitis that most commonly results from cutaneous inoculation caused by scratch trauma from a domestic cat. The causative organism is classified as *Bartonella henselae,* a gram-negative bacillus. Approximately 90% of patients who have CSD report a history of exposure to cats, and 75% of these patients have experienced a cat scratch or bite. Dogs have been implicated in 5% of CSD cases. CSD affects approximately 22,000 persons and results in hospitalization of approximately 2000 persons each year in the United States. The head and neck is the second most common site for CSD after the upper extremity.[56] The reservoir for *B. henselae* has been shown to be kittens. The major vector by which cats themselves are believed to become infected is the cat flea.[57]

The typical history is of a papule or pustule at a scratch or bite site followed in 1 to 2 weeks by the development of lymphadenopathy in the region of inoculation. The nodes will slowly enlarge over a period of 1 to 2 weeks and might not resolve for 2 to 3 months. Erythema and fluctuance of the involved nodes with spontaneous suppuration will occur in a reported 10% to 30% of patients.[57,58] Fever and mild systemic symptoms might occur in up to one third of patients. In the head and neck, this most commonly occurs in the submandibular and cervical areas. However, preauricular adenopathy might be confused with a parotid neoplasm.

The diagnosis of CSD has changed with advances in serologic and molecular biology techniques. These methods have replaced the need for cat-scratch skin testing. Testing for the presence of antibodies to *B. henselae* is now the most commonly used test to confirm the diagnosis.[57] The two methods used for antibody detection are the indirect fluorescent antibody (IFA) and the enzyme immunoassay (EIA). The test with greatest sensitivity is a *Bartonella* polymerase chain reaction (PCR) hybridization assay with an aspirate or biopsy specimen. This test might not be as easily available as the antibody detection techniques.[59] If tissue is removed for diagnosis, histologic examination might demonstrate cat-scratch bacilli with the use of Warthin-Starry silver staining. Lymph node involvement shows reticular cell hyperplasia, granuloma formation, and widening of arteriolar walls. In more advanced stages, stellate areas of necrosis coalesce to form multiple microabscesses. *Bartonella* is a slow-growing organism, and culture requires a 6-week incubation period.

Atypical presentations of CSD in the head and neck have been reported. Parinaud's oculoglandular syndrome is a unilateral granulomatous conjunctivitis associated with a preauricular or submandibular lymph node on the affected side. In addition, a report of diffuse parotid enlargement with facial nerve palsy secondary to CSD has been described.[58] Other atypical presentations include vertebral osteomyelitis encephalitis, granulomatous hepatitis, and optic neuritis. In immunocompromised patients, systemic *B. henselae* infection might result in cutaneous proliferative vascular lesions known as bacillary angiomatosis.

In most cases no active therapy is required. The patient should be reassured that the lymphadenopathy is self-limited and usually will resolve spontaneously in 2 to 4 months. However, in patients who are systemically ill or highly symptomatic, antibiotic therapy is recommended. The β-lactam antibiotics are ineffective in the treatment of CSD. The antibiotics reported to be most effective are rifampin, erythromycin, gentamycin, azithromycin, and ciprofloxacin.[57]

Toxoplasmosis

Toxoplasmosis, an uncommon disease in the United States, is caused by the organism *Toxoplasma gondii*. The usual host for this organism is the domestic cat. Parotid gland disease might involve singular or multiple intraparotid or periparotid lymph nodes. The organism exists in trophozoite, cyst, and oocyst forms, with the latter only existing in the feline vector. Trophozoites and cysts gain entrance to the human host most often through ingestion of infected and undercooked lamb, beef, or chicken, or, less commonly, through cat feces. Digestion of the cyst capsule permits widespread hematogenous dissemination and multiplication of trophozoites in virtually all lymphoreticular organs.

Both disseminated and lymphadenopathic forms of the disease have been described. Immunocompromised individuals are most at risk for the disseminated form of the disease, which features myalgia, lethargy, and anorexia combined with hepatosplenomegaly, pericarditis, and myocarditis. Alternately, the lymphadenopathic variety occurs much more commonly, with most patients being seen with isolated cervical lymphadenopathy.[60]

Definitive diagnosis can only rarely be provided by isolation of the organism. However, there are characteristic histopathologic findings in affected lymph nodes. The lymph node architecture is preserved, with hyperplastic follicles and germinal centers showing abundant mitoses and necrotic nuclear debris. Epithelioid cells with abundant, pale eosinophilic cytoplasm, which occur singly or in groups, are found in cortical and paracortical zones and sinuses.[61] Confirmation of a presumptive histologic diagnosis is made by acute and convalescent serologic testing. Chemotherapy is generally reserved for obviously progressive infections or those involving pregnant or immunocompro-

mised individuals and consists of the combined administration of pyrimethamine and trisulfapyrimidines.

Noninfectious Inflammatory Diseases of the Salivary Glands

Sjögren's Syndrome

Sjögren's syndrome is a chronic autoimmune disorder of the exocrine glands. The disease might be systemic and involve multiple glands; however, the salivary and lacrimal glands are primarily affected. The disease is characterized by a lymphocytic infiltration, with resulting glandular hypofunction leading to dryness of the mouth and eyes.[62]

Sjögren's syndrome might have a variable clinical presentation. When Sjögren's syndrome is confined to the exocrine glands, it is defined as *primary Sjögren's syndrome. Secondary Sjögren's syndrome* refers to patients who have the characteristic signs and symptoms of primary Sjögren's syndrome associated with another autoimmune disease. The disease might even evolve into a malignant lymphoid process. The estimated prevalence of Sjögren's syndrome is believed to be 1% to 3%. The disease is most commonly seen in patients during their fourth to fifth decades of life. More than 90% of patients are women.[63]

The etiology of Sjögren's syndrome is uncertain but is believed to involve an interaction among a patient's genetics, immune system, and environmental exposures. Genetic factors involving the major histocompatibility complex and a certain group of its alleles, such as HLA-B8 and HLA-DR3, are believed to create a predisposition for the development of Sjögren's syndrome.[62] These patients are susceptible to an initial, inciting environmental event. This event is most likely a viral infection that results in an aberrant autoimmune reaction. This autoimmune reaction leads to a dense lymphocytic infiltration of the exocrine glands and the production of multiple autoantibodies. Two distinct autoantibodies found in Sjögren's syndrome are two ribonuclear proteins known as *Ro* (or *SS-A*) and *La* (or *SS-B*). The presence of these antibodies is used to assist in establishing the diagnosis of Sjögren's syndrome.[63]

The predominant clinical presentation of Sjögren's syndrome is dryness of the mouth and eyes. Patients with xerostomia will complain of difficulty chewing and swallowing food. They might also experience difficulty with phonation and with adherence of food to the buccal mucous membranes. Intolerance to acidic and spicy foods is a common complaint. Some patients might be referred by their dentists secondary to multiple dental caries. The most common ocular complaint is a foreign body sensation in the eye, which is commonly described as "gritty" or "sandy." Chronic irritation and destruction of the corneal and conjunctival epithelium results in keratoconjunctivitis sicca.

The physical examination of patients with Sjögren's syndrome will demonstrate dry, sticky oral mucosal surfaces. Multiple dental caries and the absence of pooled saliva in the floor of the mouth may be visualized. The tongue is typically smooth with fissures and atrophy of the filiform papillae occurs. Patients with Sjögren's syndrome will also commonly have an intraoral fungal overgrowth with *Candida albicans.* The examination of the salivary glands results in the expression of scant or cloudy saliva from the ducts. Salivary gland enlargement, most commonly in the parotid glands, occurs in 25% to 66% of patients.[64] This might begin unilaterally, but most patients eventually develop bilateral enlargement, which may be recurrent and episodic or chronic and fixed. Objective evaluation of salivary flow rate can be performed with Lashley cups that fit over the opening of Stensen's duct and collect saliva. Sialography demonstrates sialectasis in 85% to 97% of patients with Sjögren's syndrome.[62]

The ocular findings in patients with Sjögren's syndrome include dilation of the bulbar conjunctival vessels, pericorneal injection, irregularity of the corneal image, and occasionally enlargement of the lacrimal gland. The tear secretion rate may be assessed by means of Schirmer's test. In addition, staining of damaged corneal and conjunctival epithelia by rose bengal dye is reported to be more specific for keratoconjunctivitis sicca.[64]

The systemic nature of Sjögren's syndrome might result in a wide variety of findings other than dryness of the mouth and eyes. Systemic manifestations include generalized malaise, low-grade fever, and myalgia and arthralgia. Dryness of the pharynx and esophagus results in dysphagia, and involvement of the tracheobronchial system might lead to bronchitis or pneumonia. The renal system might be affected, resulting in renal tubular acidosis. Vasculitis is reported to occur in 20% to 30% of patients.[63] Most commonly, the vasculitis manifests itself in the skin in the form of Raynaud's phenomenon and recurrent urticaria-like lesions. Central nervous system involvement is reported to occur in Sjögren's syndrome. The neurologic involvement includes peripheral sensory and motor polyneuropathies that may mimic multiple sclerosis.

Sjögren's syndrome also predisposes patients to the development of malignant lymphoproliferative disorders. The increased risk for lymphoma in patients with Sjögren's syndrome extends even after 2 decades of a benign disease course. Patients with persistent unilateral or bilateral parotid gland enlargement are at higher risk for the development of lymphoma.

In addition to the clinical examination, establishing the presence of an autoimmune process is mandated for the diagnosis of Sjögren's syndrome, which can be done by detecting the presence of autoantibodies and minor salivary gland biopsy. Testing for autoantibodies to the ribonuclear proteins Ro (SS-A) and La (SS-B) is done by use of enzyme-linked immunosorbent assay (ELISA). The biopsy of labial accessory salivary glands demonstrating salivary gland disease is one of the most consistent features of primary Sjögren's syndrome. The biopsy should include several glandular lobes obtained from areas with normal overlying mucosa to exclude nonspecific inflammatory findings.[62] The histopathologic lesion is a lymphocytic infiltrate producing a chronic focal sialadenitis. More specifically, the lesion consists of multiple focal mononuclear aggregates that are adjacent to and replace the normal acini. Several histologic classification methods that score the number of inflammatory foci seen on salivary gland biopsy have been devised.

Several sets of diagnostic criteria, which encompass findings on history, physical examination, and laboratory testing, have been proposed for the diagnosis of Sjögren's syndrome. In general, the diagnosis consists of establishing the presence of keratoconjunctivitis sicca and xerostomia by means of clinical examination and objective testing. This testing should include objective measurements of decreased salivary and tear flow along with a minor salivary gland biopsy. In addition, laboratory evidence suggesting a systemic autoimmune disease, specifically against SS-A and SS-B ribonuclear proteins, is necessary for the diagnosis of Sjögren's syndrome.[63] The presence of another autoimmune disorder, such as rheumatoid arthritis or systemic lupus erythematosus, would mandate a diagnosis of secondary Sjögren's syndrome. Patients who have objective signs of sicca complex but no evidence of an autoimmune process should be evaluated for other causes.

Multiple factors must be considered in the differential diagnosis of patients being evaluated for Sjögren's syndrome. A patient's general state of hydration and the presence of systemic conditions such as diabetes and cystic fibrosis should be assessed. One of the most common causes of xerostomia is medications. Sedatives, antipsychotics, antidepressants, antihistamines, and diuretics are the classes of drugs most often associated with oral dryness. Salivary gland exposure to therapeutic irradiation greater than 4000 cGy will result in severe and permanent secretory hypofunction.[64]

The salivary gland enlargement frequently found in Sjögren's syndrome may also be caused by several other conditions. Unilateral salivary gland enlargement despite an established diagnosis of Sjögren's syndrome should raise the suspicion of tumor.[62] Bacterial infection, chronic sialadenitis, and ductal obstruction are all causes of unilateral salivary gland enlargement. Bilateral salivary gland enlargement might be the result of a viral infection, malnutrition, or granulomatous diseases such as sarcoidosis.

The treatment of Sjögren's syndrome involves symptomatic treatment and prevention of irreversible damage to the teeth and eyes. The management of the oral component of Sjögren's syndrome involves

increasing the secretion rate of remaining salivary glands, using saliva substitutes, treating and preventing dental caries, and eradicating fungal overgrowth.[64] Stimulation of residual salivary gland function might be accomplished by local methods such as chewing sugarless gum or candies. The muscarinic-cholinergic agonist pilocarpine is the most commonly used systemic sialogogue. The drug is administered in 5-mg doses three to four times daily; however, side effects such as sweating, flushing, and increased urination are common. Dental treatment with fluoride is used to prevent and control dental caries. The treatment for keratoconjunctivitis consists of the use of commercially available eye lubricants and eye patching if corneal ulceration develops. The use of systemic corticosteroids or cytotoxic drugs is reserved for the severe extraglandular complications such as glomerulonephritis or necrotizing vasculitis.[62]

Summary

Salivary gland infections manifest differently, depending on the agent and the patient population. The acute suppurative infection is bacterial in origin and has quick onset of signs and symptoms, usually occurring in elderly, debilitated patients. Chronic sialadenitis is characterized by repeated episodes of pain and swelling (usually after an episode of acute sialadenitis) and tends to occur throughout adulthood. Systemic viral infections such as mumps and AIDS can produce localized salivary gland disease in any age group but have different clinical courses. Granulomatous salivary gland infections can occur in children and in elderly patients. They often cause asymptomatic gradual enlargement within a gland nodule, suggesting a neoplasm. The differential diagnoses in salivary gland infections are broad, but with a careful history and physical examination and knowledge of the various etiologic agents that cause disease, the otolaryngologist can make an accurate diagnosis in most cases and recommend appropriate management.

CHAPTER EIGHTY-SEVEN

Benign Neoplasms of the Salivary Glands

Gabriel G. Calzada

Ehab Y. Hanna

Key Points

- The salivary gland neoplasms are uncommon and generally benign.
- Most benign tumors can be easily cured by wide local excision, but pleomorphic adenoma, which is the most common salivary gland tumor, has a propensity for local recurrence. Simple enucleation is discouraged.
- The parotid gland is the most frequently affected major salivary gland, and the palate is the most commonly affected minor salivary gland location.
- Pleomorphic adenomas are the most common neoplasm of salivary glands, comprising 45% to 75% of all tumors in most series. These tumors typically affect patients in their 20s to 50s and there is a female predilection.
- Warthin's tumor is the second most common tumor of the salivary glands and constitutes approximately 14% to 21% of salivary gland neoplasms. The tumor is almost exclusively found in the parotid gland, typically affects males in their 50s to 60s, and often may be bilateral.
- Basal cell adenomas are fairly uncommon benign tumors of the salivary glands and are divided into four major histologic subtypes: tubular, trabecular, solid, and membranous.
- Oncocytomas represent roughly 1% of all salivary gland tumors. They most commonly affect the parotid and occasionally the submandibular gland. Patients are typically in their 50s with a slight female predominance.
- Canalicular adenomas are rare and most commonly affect the minor salivary glands of the oral cavity, especially the upper lip.
- Myoepitheliomas are neoplasms that consist exclusively of myoepithelial cells. These component cells are believed to be one of the two component cells of pleomorphic adenomas.
- The roles of fine-needle aspiration biopsy and high-resolution imaging in the management of patients with salivary neoplasms continue to evolve.
- Deep lobe tumors require a total parotidectomy, with facial nerve preservation. Parapharyngeal tumors are most commonly excised through a cervical-parotid approach and only occasionally in conjunction with a mandibulotomy.

The most common benign neoplasm of the salivary glands is pleomorphic adenoma originating from the parotid gland. Surgical excision is usually all that is required to provide both definitive diagnosis and adequate treatment. Despite this relatively simple algorithm, management of other types of salivary neoplasms is challenging because of their relative infrequency, inconsistent classification, and variable biologic behavior.

Better understanding of the histogenesis of neoplasms of the salivary glands, however, has allowed a more consistent and rational classification of these tumors. Recent advances in molecular biology and tumor genomics have shed some light on the genetic basis of certain types of tumors of the salivary glands.[1] The role of fine-needle aspiration biopsy and high-resolution imaging in the management of patients with salivary neoplasms continues to evolve. This chapter discusses some of the advances made in understanding the etiology and histogenesis of salivary tumors and describes a contemporary approach to the diagnosis and management of patients with benign neoplasms of the salivary glands.

Embryology

Understanding the origin of benign salivary gland tumors requires knowledge of the embryology and ultrastructure of the normal salivary gland. The major salivary glands originate from ectoderm and begin their development during the sixth week of gestation as solid, ridgelike ingrowths of the oral epithelium.[2] These ingrowths continue to develop into tubules that later become the ductal system of the salivary glands. In the major salivary glands both serous and mucous cells are arranged into acini that are drained by a series of ducts. An intercalated duct drains into a striated duct, which empties into an excretory duct. Contractile myoepithelial cells surround the acini and intercalated ducts and help in draining saliva through the ductal system (Fig. 87-1). The parotid gland consists of predominately serous acini. The submandibular gland is composed of a mixture of serous and mucinous acini, whereas sublingual gland and minor salivary glands scattered throughout the upper aerodigestive tract contain predominantly mucinous acini.

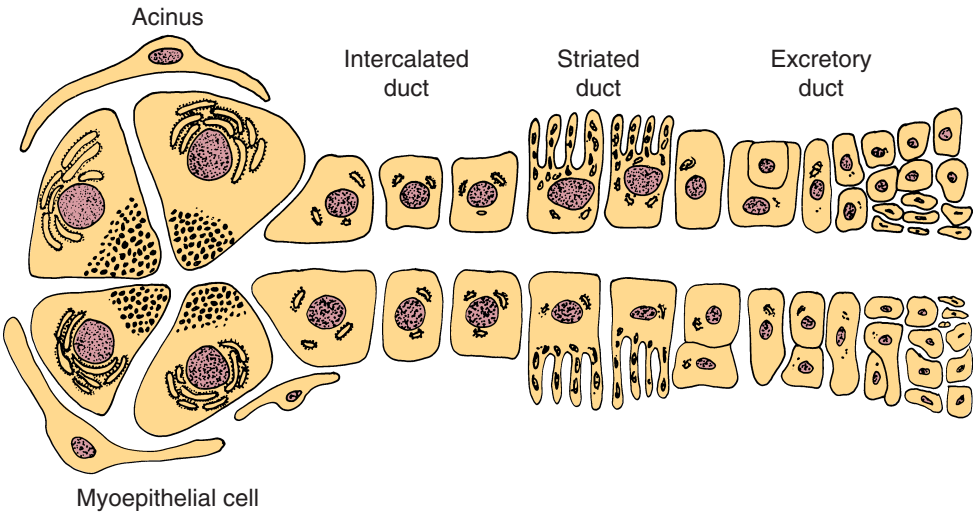

Figure 87-1. Structural elements of the salivary gland unit.

Histogenesis of Salivary Neoplasms

At least two theories of tumorigenesis have been proposed for salivary gland neoplasms.[3] In the multicellular theory, each type of neoplasm is thought to originate from a distinctive cell type within the salivary gland unit. According to this theory, Warthin's and oncocytic tumors are thought to arise from striated ductal cells, acinic cell tumors from acinar cells, and mixed tumors from intercalated duct and myoepithelial cells.[4] This theory is supported by the observation that all differentiated salivary cell types retain the ability to undergo mitosis and regenerate.[5,6] An alternative theory, the bicellular reserve cell theory, assumes that the origin of the various types of salivary neoplasms can be traced to the basal cells of either the excretory or the intercalated duct. According to this theory, either of these two cells can act as a reserve cell with the potential for differentiation into a variety of epithelial cells.[7] Hence despite the seeming heterogeneity of salivary tumors, all of them are thought to arise from one of two pluripotential cell populations. In this model, adenomatoid tumors including pleomorphic adenoma and oncocytic tumors are derived from the reserve cell of the intercalated duct, whereas epidermoid tumors, such as squamous cell carcinoma and mucoepidermoid carcinomas, are derived from the reserve cell of the excretory duct.[8] Some reports provide molecular evidence to support the reserve cell theory of salivary gland tumorigenesis.[9]

Recent efforts to identify biomarkers of salivary neoplasia have focused on methylation patterns. Williams and colleagues[10] investigated methylations status and protein expression of four tumor suppressor genes (*DAPK*, *MGMT*, *RARB2*, and *RASSF1*) in the largest cohort study of benign and malignant salivary neoplasms to date. The authors found benign and malignant salivary tumor differed in the frequency and pattern of gene methylation. They postulate methylation may aid in diagnosis and targeted therapy for salivary neoplasms.[10] Maruya and colleagues analyzed the gene expression profile of 18 primary tumors representing the major benign subtypes using a membrane-based DNA microarray platform. Of the 5000 genes arrayed, S-100 beta, galectin-9 isoform, vimentin, and tyrosine kinase receptor were more highly expressed in adenomas than in carcinomas.[11]

Etiology

The etiology of salivary gland neoplasms, like most other types of tumors, remains unknown. However, there is growing evidence that certain environmental factors such as radiation, viruses, diet, and certain occupational exposures may increase the risk of developing tumors of the salivary glands. In addition to environmental factors, specific genetic abnormalities associated with the development of some types of salivary tumors have recently been well characterized.

Radiation

There is increasing evidence to suggest that exposure to ionizing radiation may increase the risk of developing tumors of the salivary glands. In 1996 the Radiation Epidemiology Branch of the National Cancer Institute published a study on the risk of developing salivary gland tumors among atomic bomb survivors.[12] The study indicated a higher radiation-related risk of developing both benign and malignant salivary gland tumors, as compared with the general population. Dose-response analyses found statistically significant increases in risk with increasing A-bomb dose for both cancer and benign tumors. The risk was higher for malignant tumors, especially mucoepidermoid carcinoma. Among those with benign neoplasms, Warthin's tumor showed the highest dose-response–related risk.

Radiation therapy to the head and neck, especially if it encompassed the salivary glands, may also be a risk factor in the development of salivary gland tumors.[13] A recent study found a 4.5-fold increase in the incidence of salivary gland cancer and a 2.6-fold increase of benign tumors among persons exposed to scalp irradiation compared with matched controls.[14] The mean length of latency period until tumor development was 11 years for malignant tumors and 21.5 years for benign. The study also demonstrated a clear dose response effect for cancer and benign tumors, suggesting that ionizing radiation may play an important role in salivary gland tumorigenesis.

Viral

Although Epstein-Barr virus (EBV) has been consistently associated with lymphoepithelial carcinoma of the salivary gland in the Asian population, there is no evidence of a causal role of EBV in other primary salivary gland neoplasms.[15] Pollock and colleagues[16] failed to demonstrate any positive signal by in situ hybridization for EBV RNA in 42 benign salivary gland neoplasms. Other viruses including human papillomavirus, human herpesvirus-8, and cytomegalovirus do not appear to have any etiologic role in salivary gland neoplasms.[17]

Other Factors

Although tobacco use was not associated with a higher incidence of malignant salivary neoplasms, Warthin's tumor is strongly associated with cigarette smoking.[18] Occupational exposure to silica dust was linked to a 2.5-fold increased risk of cancer of the salivary gland.[19] The risk was also elevated among rubber workers exposed to nitrosamines.[20] Dietary analyses revealed a possible protective effect for a diet high in polyunsaturated fatty acids.[19,21] Similar to breast cancer, women with history of early menarche and nulliparity had an increased risk of cancer of the salivary gland, which may be due to a hormonal effect.[22] Whether these occupational, dietary, or hormonal factors have any association

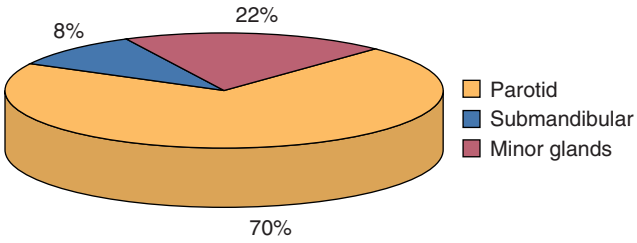

Figure 87-2. The site of origin of salivary neoplasms.

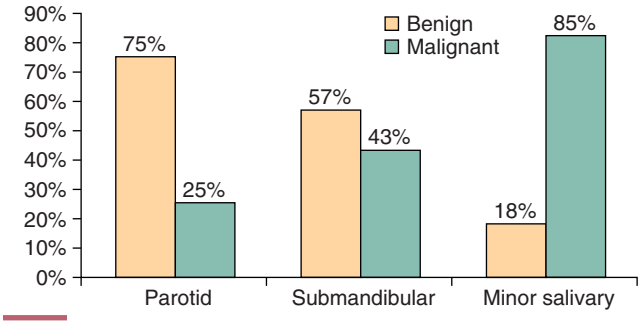

Figure 87-3. The incidence of benign and malignant salivary neoplasms according to the site of origin.

with the risk of developing benign tumors of the salivary glands remains unknown.

Genetic Factors

Recent developments in the field of molecular biology and human genomics have shed light on the genetic basis of developing several types of neoplasms including tumors of salivary gland origin. A study of several types of salivary gland tumors using comparative genomic hybridization found specific genetic alterations in different types of salivary gland tumors and involvement of several chromosomes in the alterations.[23] Genetic aberrations associated with the salivary gland neoplasia include allelic loss and point mutation, structural rearrangement of chromosomal units (most commonly translocations), the absence of one chromosome (monosomy), and the presence of an extra chromosome (polysomy). Any of these genetic aberrations may be the only karyotypic anomaly indicating an early event in tumor initiation, or several genetic alterations may coexist, which are more likely to be associated with tumor progression and more aggressive biologic behavior.[9,24]

Incidence

Salivary gland tumors are relatively rare and constitute 3% to 4% of all head and neck neoplasms. The majority (70%) of salivary gland tumors arise in the parotid gland (Fig. 87-2). Although the majority of minor salivary gland tumors are malignant, three fourths of parotid tumors are benign (Fig. 87-3). Spiro[25] reviewed the Memorial Sloan-Kettering experience with salivary neoplasms over a 35-year period. The distribution of these 2807 patients is shown in Table 87-1. Benign neoplasms constituted 54% (1529 patients) of all tumors. Pleomorphic adenoma (1280 patients) constituted 84% of benign tumors and 45% of all salivary gland neoplasms. Warthin's tumor was the second most benign tumor and comprised 12% (183 patients) of all benign tumors.

Patient Evaluation

Clinical Features

Regardless of whether they are benign or malignant, tumors of the parotid gland usually present as a painless swelling. Benign tumors are usually present for a long duration and have a slow growth rate.

Table 87-1

Distribution of 2807 Salivary Neoplasms

Histology	Number of Patients	Percent
Pleomorphic adenoma	1274	45.4
Warthin's tumor	183	6.5
Benign cyst	29	1.0
Lymphoepithelial lesion	17	0.6
Oncocytoma	20	0.7
Monomorphic adenoma	6	0.2
Mucoepidermoid carcinoma	439	15.7
Adenoid cystic carcinoma	281	10.0
Adenocarcinoma	225	8.0
Malignant mixed tumor	161	5.7
Acinic cell carcinoma	84	3.0
Epidermoid carcinoma	53	1.9
Other (anaplastic)	35	1.3
Total	2807	100

From Spiro RH. Salivary neoplasms: overview of a 35-year experience with 2,807 patients. *Head Neck Surg.* 1986;8:177-84. © 1986 John Wiley & Sons.

However, patients may indicate that they incidentally noticed the appearance of a "recent" lump. The acute onset of a painful swelling of the parotid gland usually indicates an inflammatory process. Acute bacterial parotitis is usually diagnosed in association with sialolithiasis of the parotid gland or in patients who are elderly, malnourished, dehydrated, or immunocompromised. Acute viral parotitis is most commonly due to "mumps"; however, other viral infections may present with acute parotid swelling. Sjögren's syndrome and other forms of autoimmune parotitis usually present with bilateral parotid swelling, although in some patients this may be asymmetric or even unilateral. Obstruction of Stensen's duct with a stone may lead to an acute painful swelling of the parotid gland. Rapid increase in size of a longstanding mass should raise the suspicion of malignant transformation of a preexisting benign tumor, but it may be due to inflammation or cystic degeneration most commonly associated with Warthin's tumor. Patients presenting with a mass in the parotid gland should be asked about a history of cancer of the scalp or facial skin. Metastasis to the parotid gland from skin cancer including melanoma may be diagnosed by a careful examination of these areas for evidence of a skin cancer or a scar of previous excision.

On examination, benign tumors of the parotid gland are usually well defined, nontender, and freely mobile. They are commonly located in the "tail" of the parotid gland but may be present anywhere in the superficial or deep lobe. Tumors may originate entirely from the deep lobe (Fig. 87-4) or extend from the superficial to the deep lobe through the relatively narrow stylomandibular tunnel, giving the appearance of a dumbbell tumor (Fig. 87-5). In either case, the tumor may extend to the parapharyngeal space and displace the oropharyngeal wall medially (Fig. 87-6). The presence of facial nerve paresis or paralysis, pain, fixation of the mass to the overlying skin or underlying structures, and associated cervical adenopathy usually indicate the presence of malignancy. It should be noted, however, that these findings usually indicate

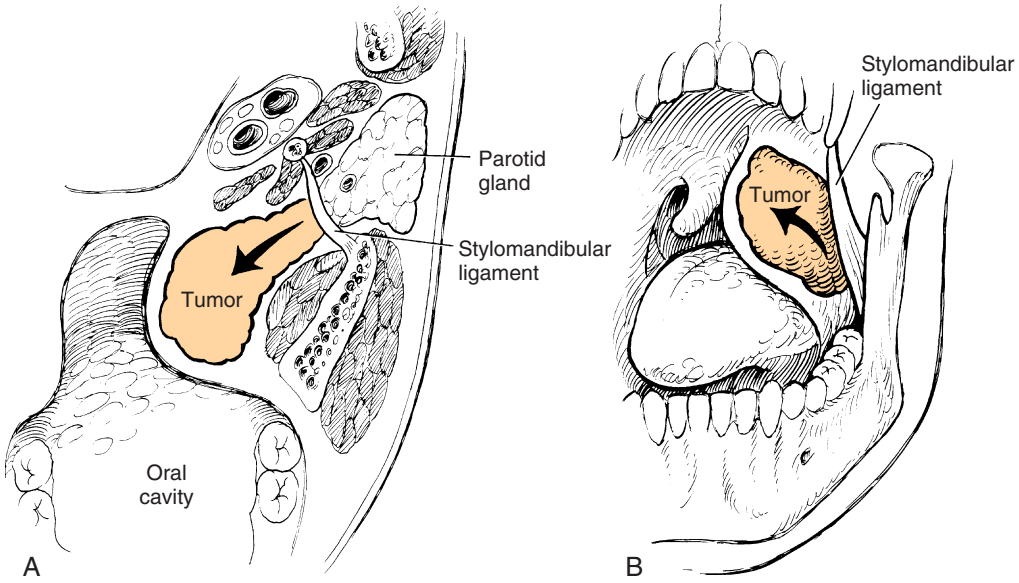

Figure 87-4. **A,** Axial and **B,** coronal diagrams of round tumor passing posterior to stylomandibular ligament to appear as mass in parapharyngeal space. *Arrows* indicate potential routes of tumor spread.

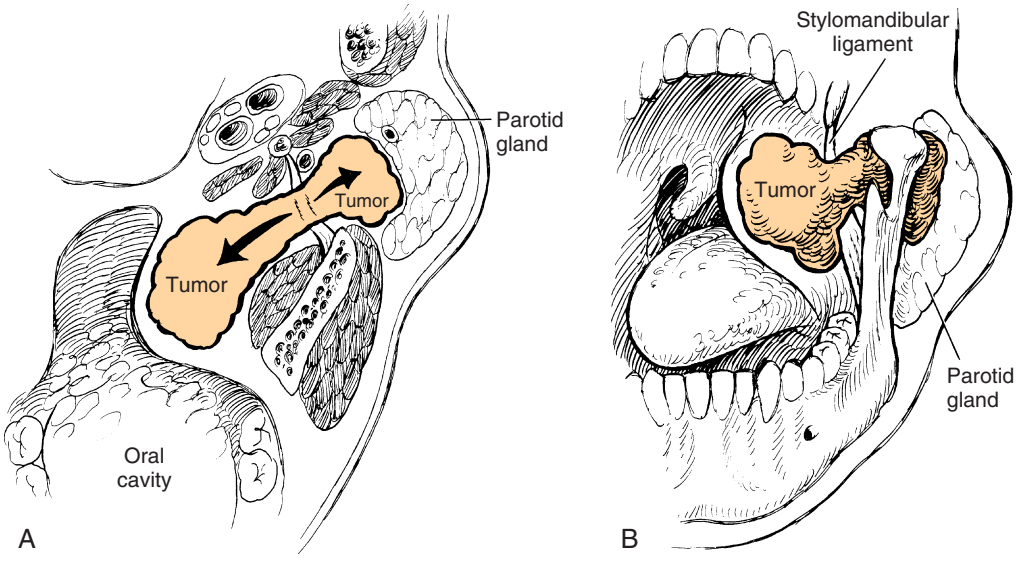

Figure 87-5. **A,** Axial and **B,** coronal diagrams of relationship of dumbbell tumor to stylomandibular ligament. Dumbbell tumor enters parapharyngeal space through stylomandibular membrane between the mandible and the stylomandibular ligament. *Arrows* indicate potential routes of tumor spread.

local or regional extension of the tumor, and the diagnosis of parotid malignancy should not await the development of these signs and symptoms. The possibility of malignancy should be ruled out in patients presenting with any mass in the parotid gland. This will usually require cytologic or histologic evaluation with a fine-needle biopsy, or parotidectomy, respectively.

Benign tumors of the submandibular gland are relatively uncommon and usually present as a painless, mobile mass in the submandibular triangle. Involvement of the overlying skin or fixation to the mandible usually indicates local extension of a malignant tumor. Ipsilateral weakness or numbness of the tongue indicates perineural spread of malignancy along the hypoglossal or lingual nerves, respectively. Weakness of the marginal mandibular branch of the facial nerve also indicates perineural extension of a malignant tumor. Enlargement of the submandibular or upper cervical lymph nodes may be due to reactive lymphadenopathy associated with submandibular sialadenitis, but it usually indicates regional metastasis of malignancy in the submandibular gland.

Benign tumors of the minor salivary glands are rare. Most tumors arising from the minor salivary glands are malignant (see Fig. 87-3). However, similar to the major salivary glands, pleomorphic adenoma is the most frequent benign tumor of the minor salivary glands. The clinical presentation depends on the site of origin, and the most common sites include the palate, parapharyngeal space, and the lacrimal gland.

Fine-Needle Aspiration Biopsy

Fine-needle aspiration biopsy (FNAB) has been widely recognized and well established as an accurate technique in the diagnosis of salivary gland neoplasms. Numerous studies have reported an exceptionally high degree of sensitivity, specificity, and predictive value for FNAB. The overall sensitivity ranges from 85.5% to 99%, and the overall

Figure 87-6. Pleomorphic adenoma of the deep lobe of a parotid gland, causing medial displacement of the palate and tonsil.

specificity ranges from 96.3% to 100%.[26-28] In general, diagnostic accuracy is higher for benign than for malignant salivary gland tumors.[29,30] The accuracy of FNAB, however, depends greatly on the experience of the cytopathologist, as well as the overall volume of patients with salivary neoplasms evaluated in any given institution. The most common source of diagnostic error of FNAB is inadequate sampling.[31] The use of ultrasound-guided FNAB may be of help in cases in which it is difficult to obtain a representative sample, and it enhances the overall diagnostic accuracy of the technique.[32,33] Despite its overall high accuracy, several significant but uncommon areas can lead to diagnostic difficulties, with the potential for clinically important diagnostic errors.[29] The most frequent problems involve variations in the expected cytology of pleomorphic adenoma. Also, there are several benign-malignant "look-alike" pairs of lesions. The first of these is related to small-cell epithelial neoplasms of low nuclear grade; the most frequent problem is between basal cell adenomas and adenoid cystic carcinoma, particularly the solid (anaplastic) type. The next area contrasts mucoepidermoid carcinoma with its cytologic mimic, benign salivary gland duct obstruction. The final difficulty in salivary gland aspiration contrasts large-cell epithelial lesions of low nuclear grade: oncocytic proliferations and acinic cell carcinoma.[34]

In addition to being accurate, FNAB is safe, simple to perform, and relatively inexpensive. However, one essential question is worth asking. Is FNAB really necessary in the evaluation of salivary gland masses? Would it change the course of management on the basis of clinical assessment? In an attempt to answer this question, Heller and colleagues[35] performed a study to determine the impact of FNAB on patient management. One hundred patients underwent FNAB of major salivary gland masses. The physician's initial clinical impression was compared with the FNAB diagnosis and the final diagnosis in each case. Overall, FNAB resulted in a change in the clinical approach to 35% of the patients. Examples of such changes in the planned management included avoiding surgical resection for lymphomas and inflammatory masses and adopting a more conservative approach with benign tumors in elderly and high-surgical-risk patients. FNAB also allows better preoperative counseling of patients regarding the nature of the tumor, the likely extent of resection, management of the facial nerve, and the likelihood of a neck dissection. Such information is not only important in treatment planning but also helps alleviate an already high level of anxiety among patients and their families.

The possibility of tumor seeding is a commonly cited argument against the routine use of FNAB in patients with salivary gland tumors. To address these issues, Mukunyadzi and colleagues[36] recently reviewed 94 resected salivary gland masses for infarction, hemorrhage, and needle track tumor seeding, as well as fibrosis after FNAB. They concluded FNAB with a 25-gauge needle is safe and does not significantly alter the histologic diagnosis because tissue effects did not preclude accurate diagnostic interpretation in any case.[36]

Imaging

The routine use of imaging in patients with small, well-defined masses of the superficial lobe of the parotid gland is probably not warranted because the results of imaging are not likely to change the treatment plan. However, tumors that present with clinical findings suggestive of malignancy, tumors arising from the deep lobe of the parotid gland or the parapharyngeal space, and, tumors of the submandibular and minor salivary gland should be evaluated with high-resolution imaging. In such cases, imaging provides accurate delineation of the location and extent of tumor, its relation to major neurovascular structures, perineural spread, skull base invasion, and intracranial extension.[37]

Computed Tomography and Magnetic Resonance Imaging

In evaluating patients with tumors of the salivary glands, both computed tomography (CT) and magnetic resonance imaging (MRI) provide information that is superior to that provided by other imaging techniques or by physical examination.[38] The normal parotid gland has a high fat content and is easily visualized on both CT and MRI. Therefore both techniques can demonstrate whether a mass in that region is intraglandular or extraglandular. Generally, neither CT nor MRI provides information regarding the specific histologic diagnosis, except rarely.[39] An example of such a rare scenario is with lipoma of the parotid gland (Fig. 87-7). The MRI signal characteristics of parotid masses, however, may be suggestive of certain diagnosis.[40] For example, if a parotid gland mass is bilateral, it is more likely to be Warthin's tumor, especially if it does not enhance. Less likely, it could be lymphoepithelial cyst or necrotic lymph node. A unilateral, nonenhancing mass with a high T2 signal is more likely to be a Warthin's tumor and less likely a necrotic lymph node or first branchial cleft cyst. If the mass is unilateral, shows postcontrast enhancement, has a high T2 signal, and does not invade surrounding tissue planes, it is more likely to be a pleomorphic adenoma (Fig. 87-8). An intermediate to low T2 signal mass, with or without invasion of surrounding tissue planes, is more likely to be a malignant mass such as adenoid cystic or mucoepidermoid carcinoma.[41]

MRI is also superior to CT in demonstrating the internal architecture of salivary gland tumors in a multiplanar fashion and in delineating the interface between tumor and normal salivary gland.[42] In contrast to benign tumors, which invariably have well-defined margins (see Fig. 87-8), malignant tumors may exhibit irregular margins (Fig. 87-9). Extension of the tumor beyond the fascial confines of the gland can be adequately seen on both CT and MRI and should raise the suspicion of malignancy.[43] Bone destruction of the mandible or skull base is best visualized on CT, whereas bone marrow involvement is better demonstrated on MRI. Both studies can adequately evaluate the neck for metastatic adenopathy. CT has the advantage of being less expensive and more available than MRI.

Although parapharyngeal space masses are well visualized by both techniques, they are better delineated with MRI than CT. This is because of the different signal intensity of tumor, fat, and muscle on MRI. The differential diagnosis of parapharyngeal masses includes deep lobe parotid tumors, minor salivary gland tumors, and neurogenic and vascular tumors. Most salivary tumors have low-to-intermediate T1 signal intensities and intermediate-to-high T2 signal intensities. Deep lobe parotid tumors and minor salivary gland tumors of the parapharyngeal space lie in the prestyloid compartment, anterior to the carotid artery, and displace the parapharyngeal fat medially (Figs. 87-10 and 87-11). Deep lobe tumors are connected to the parotid gland at least in one imaging section, whereas minor salivary gland tumors are completely surrounded by fat (see Fig. 87-11). By contrast, neurogenic tumors and glomus tumors lie in the poststyloid compartment, posterior to the carotid artery, which is displaced anteriorly (Fig. 87-12). Neurogenic tumors usually enhance intensely with gadolinium, whereas glomus tumors have characteristic serpiginous flow voids (salt and pepper appearance) on MRI.

Recently, new MR technologies such as dynamic contrast-enhanced MRI, diffusion-weighted MRI, and proton MR spectroscopy have shown promising results in the differentiation between benign and malignant salivary gland tumors.[44] Further research with larger-scale studies on these particular MR methods is necessary.

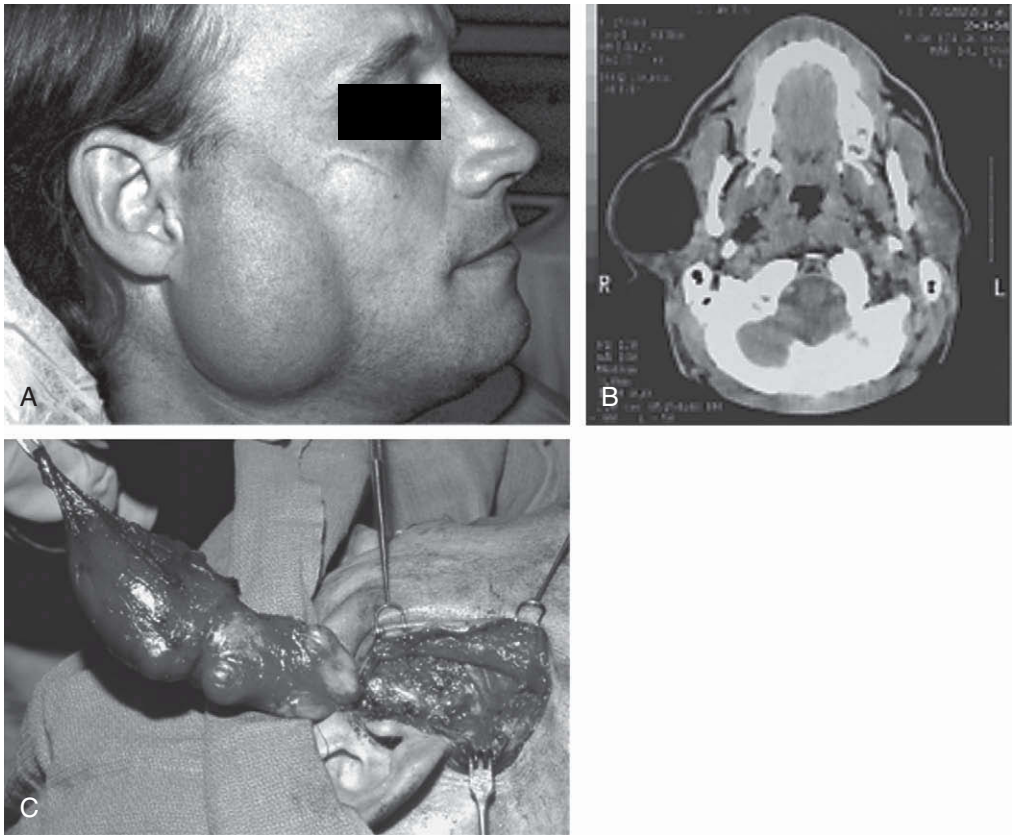

Figure 87-7. A 40-year-old male presented with a large, painless, slow-growing parotid mass. Fine-needle aspiration biopsy was indeterminate. **A,** Lateral view. **B,** An axial computed tomography (CT) with intravenous contrast demonstrating a large, rounded, well-defined mass with smooth borders in the parotid gland. The mass was nonenhancing and had the same density as the subcutaneous fat. These findings were pathognomonic of parotid lipoma. **C,** A superficial parotidectomy was performed, and the diagnosis was confirmed.

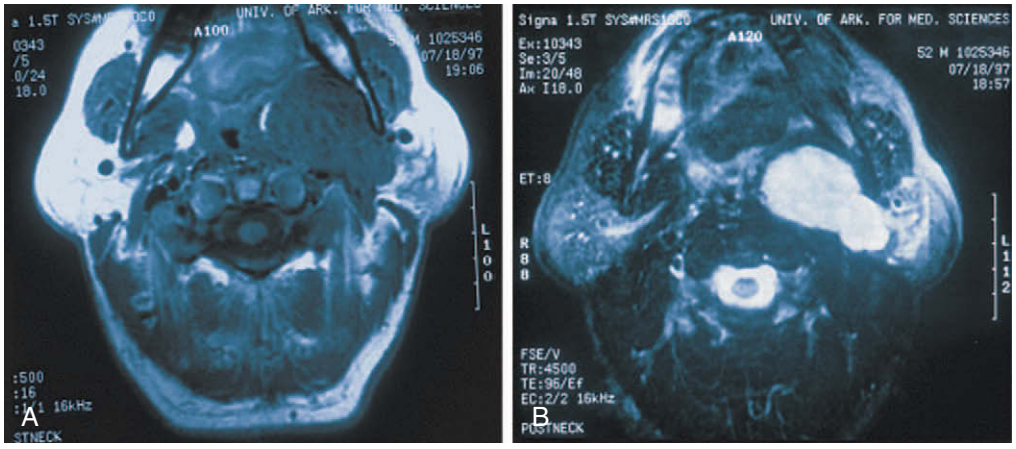

Figure 87-8. Pleomorphic adenoma of the parotid gland. The mass originated from the deep lobe of the gland and extended to the parapharyngeal space through the stylomandibular tunnel, where it was somewhat constricted, giving the appearance of a dumbbell. Note the medial displacement of the oropharynx. The mass has well-defined borders and does not invade surrounding structures. The mass is isointense on T1-weighted magnetic resonance imaging (MRI) **(A)** and has a high signal intensity on T2-weighted MRI **(B).** These signal characteristics are highly suggestive of pleomorphic adenoma.

Ultrasonography

Ultrasonography has the advantage of being inexpensive, noninvasive, simple to perform, and is virtually free of complications. It can be used to differentiate solid from cystic masses in the salivary glands, and most salivary gland diseases can be diagnosed sonographically.[32] Ultrasound guidance may also enhance the accuracy of FNAB in nonpalpable tumors and in masses with a highly heterogeneous architecture.[45]

Color Doppler Sonography

Color Doppler sonography has been recently used to evaluate the vascular anatomy of the salivary glands. It can distinguish between the

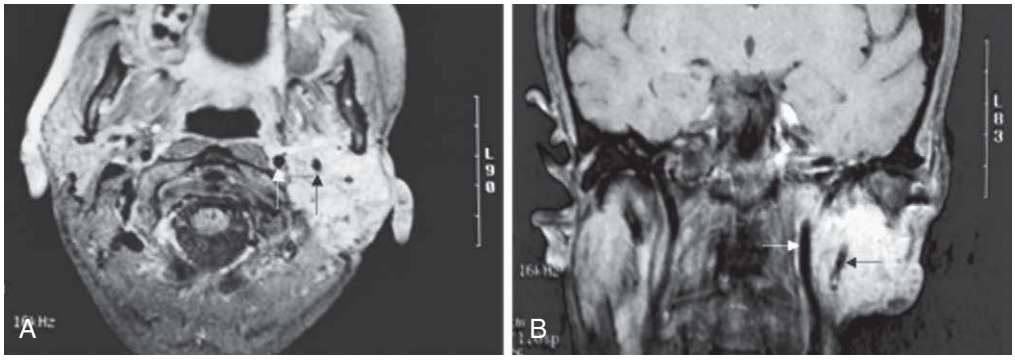

Figure 87-9. T1-weighted magnetic resonance imaging with gadolinium of a patient with mucoepidermoid carcinoma of the parotid shows the tumor to have irregular border and is indistinct from the normal parotid gland. Note complete encasement, rather than displacement of both the internal *(white arrow)* and external carotid arteries *(black arrow)* in both the axial **(A)** and coronal **(B)** images.

Figure 87-10. Large pleomorphic adenoma of the parotid gland. Axial computed tomography with gadolinium. The tumor involves the superficial and deep lobe of the parotid gland and lies anterior to the styloid process (prestyloid) *(white arrowhead)*. The fat of the parapharyngeal space is displaced medially, and the carotid artery displaced posteriorly. The isthmus of tumor between the superficial and deep components passes through the stylomandibular space and is therefore relatively narrow, giving the appearance of a dumbbell *(black arrowheads)*.

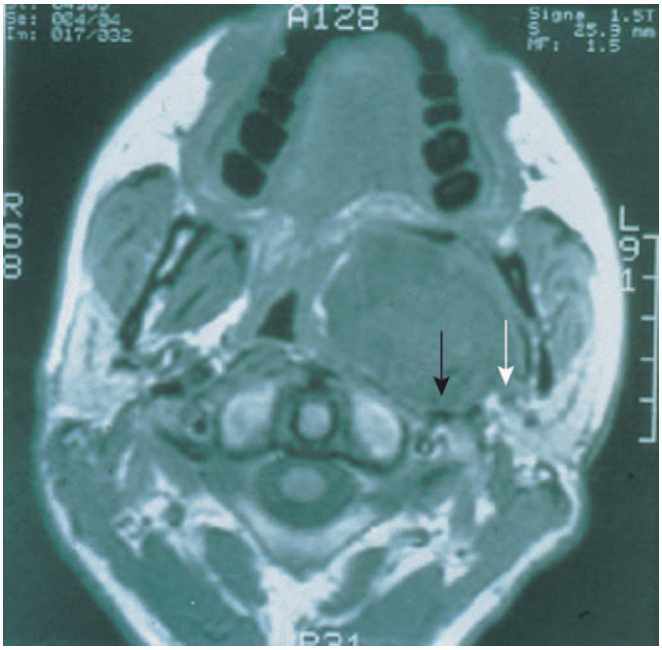

Figure 87-11. In contrast to the dumbbell tumor depicted in Figure 87-10, this pleomorphic adenoma originates entirely from the deep lobe of the parotid gland *(black arrow)* and lies entirely medial to the stylomandibular tunnel. Pleomorphic adenomas originating from the minor salivary glands of the parapharyngeal space have a similar appearance on high-resolution imaging but are not connected to the parotid gland. Regardless of their origin, salivary gland tumors of the parapharyngeal space will occupy the prestyloid compartment and displace the carotid artery posteriorly *(white arrow)*.

physiologic changes that occur during salivary stimulation in normal subjects and the flow alterations that occur in diseased glands.[46]

Positron Emission Tomography

PET scans have not gained wide application in imaging of tumors of the salivary gland for several reasons. First, tumors of the salivary glands have a variable and inconsistent uptake of F-18 fluorodeoxyglucose (FDG), which is the most commonly used radiotracer with PET scans, and therefore FDG PET is unreliable both in tumor detection and in distinguishing benign from malignant salivary tumors.[47] Second, competing techniques such as CT, MRI, and even clinical examination already have a high degree of accuracy. Third, high-resolution studies such as CT and MRI provide anatomic detail required for treatment planning that is unavailable from FDG PET images. Finally, the high cost of FDG PET prohibits its widespread use. Research is ongoing with PET scans. Uchida and colleagues[48] recently proposed combining FDG PET with Tc-99m pertechnetate salivary gland scintigraphy for differentiating various parotid gland tumors in patients with nondiagnostic needle aspiration.

Pleomorphic Adenomas

Pleomorphic adenomas, also known as benign mixed tumors, are the most common neoplasms of the salivary gland. The term *pleomorphic* was chosen to describe these tumors because they possess morphologic diversity with both epithelioid and connective tissue components in various proportions. Although highly debated in the past, most now agree that pleomorphic adenomas originate from an uncommitted reserve cell of the intercalated duct that has the potential to differentiate into epithelial and myoepithelial cells. Pleomorphic adenomas occur most frequently in the major salivary glands but may also arise from the minor salivary glands of the upper respiratory and alimentary tracts.

Pleomorphic adenomas constitute approximately 75% of all benign tumors of the major salivary glands.

In the parotid gland, approximately 90% of pleomorphic adenomas originate superficial to the facial nerve. Occasionally, tumors of the superficial lobe extend to the deep lobe medial to the facial nerve. If they extend to the parapharyngeal space through the stylomandibular "tunnel" bounded by the stylomandibular ligament, they may have a narrow isthmus connecting the superficial and deep components, giving the tumor a dumbbell appearance (see Figs. 87-5 and 87-10). Approximately 10% of pleomorphic adenomas originate entirely from the deep lobe and are usually located deep to the stylomandibular ligament. Therefore they have a more rounded appearance on high-resolution imaging (see Figs. 87-4 and 87-11). Pleomorphic adenomas may also arise from minor salivary gland tissue that naturally occurs in the parapharyngeal space. Regardless of their origin, pleomorphic adenomas of the parapharyngeal space occupy the prestyloid compartment (see Figs. 87-10 and 87-11) and, like other parapharyngeal tumors, may displace the oropharynx medially (see Fig. 87-6). Pleomorphic adenomas of the minor salivary glands most commonly occur in the palate (Fig. 87-13).[49] The second most common site is the upper lip. Despite the abundance of minor salivary glands in the lower lip, pleomorphic adenomas are exceedingly rare in this location. Pleomorphic adenomas are the most common benign tumors of the lacrimal gland (Fig. 87-14).[50-52]

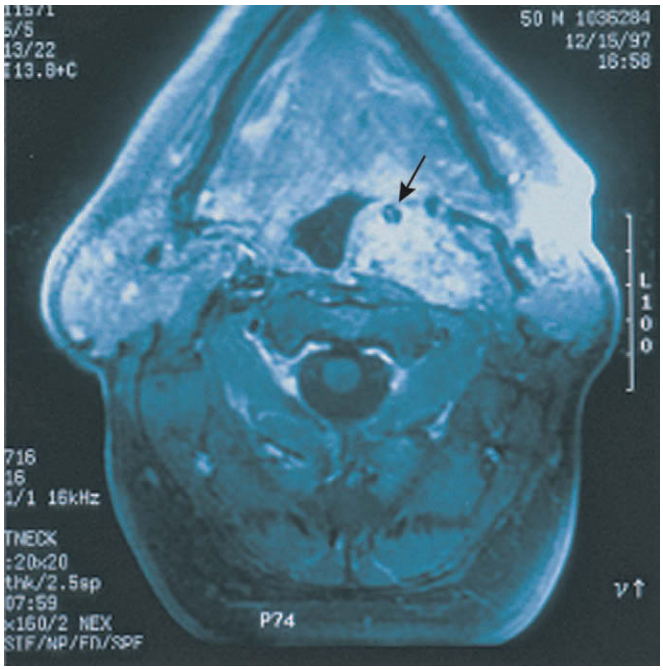

Figure 87-12. On magnetic resonance imaging (MRI), tumors of the poststyloid compartment are usually located behind the carotid artery, displacing it anteriorly *(arrow)*. Glomus tumors have characteristic serpiginous flow voids on MRI, giving a "salt-and-pepper appearance."

Clinically, pleomorphic adenomas are characterized as painless, slow-growing masses. Multiple primary pleomorphic adenomas are extremely rare, although reported.[53] Pathologically, pleomorphic adenomas are solitary, firm, round tumors. The cut surface is characteristically solid and may be hard, rubbery, or soft in consistency with a whitish gray to pale yellow color. Pleomorphic adenomas of the major salivary glands have a capsule, although varying in thickness and completeness, whereas pleomorphic adenomas of the minor salivary glands are usually nonencapsulated.[54] On histologic examination, pleomorphic adenomas consist of epithelial components that may take the form of ducts, nests, cords, or solid sheets of cells and myoepithelial cells that appear plasmacytoid or spindled in a fibrocollagenous, myxochondroid, or chondroid background. Myoepithelium in pleomorphic adenoma is considered to be responsible for the development of the characteristic myxoid or chondroid stroma. Variations in the histologic appearance of this tumor type are common and may include squamous metaplasia, calcification, cartilage-appearing tissue, oxyphilic cells, and a palisading appearance of the underlying stroma. Lipomatous[55] and osseous[56] changes have been occasionally reported in pleomorphic adenoma.

Histopathologic studies have demonstrated that almost all pleomorphic adenomas have focally thin capsules, and one fourth of pleomorphic adenomas demonstrate satellite nodules or pseudopodia.[57] Therefore the recommended treatment is surgical excision with a surrounding cuff of normal tissue to prevent recurrence from failure to address these pseudopod-like extensions of tumor.[58] In patients with tumors of the submandibular gland, the gland is generally removed with careful preservation of the marginal mandibular nerve. Tumors of the parotid gland usually involve removal of the tumor with an adequate margin and facial nerve preservation. Because most of the tumors arise from the superficial lobe, a superficial parotidectomy is often required.

Recurrent pleomorphic adenomas are an uncommon but challenging problem. Frequently, multiple foci of recurrence continue to manifest over several years.[59] This multicentric pattern is characteristic of recurrent pleomorphic adenomas (Fig. 87-15). Currently, no reliable criteria have been established to predict those tumors with a greater tendency to recur. Surgical excision, however, remains the mainstay of treatment for recurrent pleomorphic adenomas. Patients who have undergone previous surgical excision, especially those with previous parotidectomy, are at increased risk for facial nerve injury, as well as recurrence with revision surgery.[60,61] Neutron radiotherapy offers excellent local control rates and survival rates in patients with multiple recurrences who are not surgical candidates even in the presence of gross residual disease.[62]

Malignant transformation of pleomorphic adenoma is rare and occurs most frequently in patients with long-standing tumors. The risk of malignant transformation in pleomorphic adenoma is 1.5% within the first 5 years of diagnosis but increases to 10% if observed for more than 15 years.[63] Cases of benign pleomorphic adenoma metastasizing to cervical lymph nodes have been reported.[64-66]

Figure 87-13. Pleomorphic adenoma of the palate. **A,** Intraoperative view. **B,** Tumor specimen.

Basal Cell Adenomas

Most basal cell adenomas occur in the parotid gland and minor salivary glands of the upper lip. As with other benign neoplasms, they present as a slow-growing, asymptomatic mass. Gross pathologic examination reveals a well-circumscribed, solid tumor with a gray-white to pink-brown cut surface. Parotid basal cell adenomas are characteristically encapsulated, whereas those of minor salivary gland origin may lack a capsule.[67] Histologically, an intact basement membrane helps differentiate basal cell adenomas from pleomorphic adenomas. Four histologic growth patterns have been recognized: solid, trabecular, tubular, and membranous.[68] Basal cell adenomas may be difficult to distinguish from the solid variety of adenoid cystic carcinomas. Cytologic features that help differentiate basal cell adenomas from adenoid cystic carcinomas include lack of true invasion of surrounding tissues, lack of perineural invasion, a vascular stroma, and a peripheral palisading of the outer layer of basaloid cells. The cell-stroma interface is also useful in distinguishing basal cell adenomas from adenoid cystic carcinomas. In basal cell adenomas the collagenous stroma interdigitates with adjacent cells, whereas in those with adenoid cystic carcinomas the two are separated by a sharp, smooth border. Further, the stroma of basal cell adenomas may contain rare spindle cells or capillaries, but the cylinders of adenoid cystic carcinoma are acellular. The treatment of these benign tumors is surgical excision with a cuff of normal surrounding tissue.

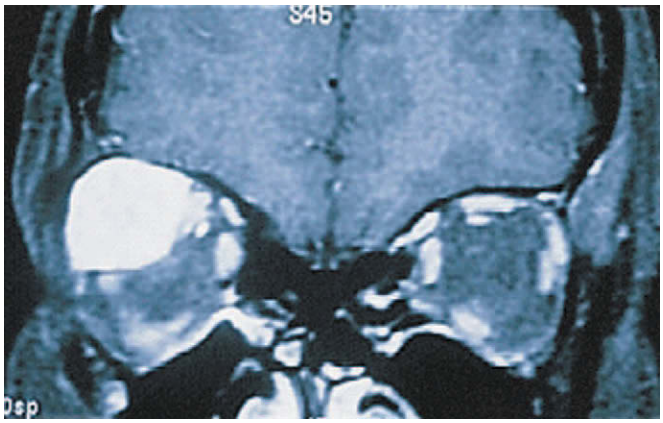

Figure 87-14. Pleomorphic adenoma of the lacrimal gland.

Canalicular Adenomas

Canalicular adenomas are benign neoplasms of predominately oral minor salivary glands, the upper lip being the most common site. They have been reported to account for less than 1% of salivary gland tumors and are rarely reported to be multifocal.[69] The patient presents with complaint of an asymptomatic, slowly enlarging mass. These tumors may be clinically similar to a mucocele or varix and may be multifocal. Histologically, they are characterized by cells arranged in parallel rows forming ductlike structures—hence the term "canalicular." Canalicular adenomas may be distinguished from adenoid cystic carcinomas by their well-circumscribed appearance and lack of perineural or soft tissue invasion. Surgical excision is the treatment of choice for canalicular adenomas.

Papillary Cystadenoma Lymphomatosum—Warthin's Tumors

First described by Aldred Warthin in 1929, Warthin's tumor is the second most common benign salivary gland neoplasm behind pleomor-

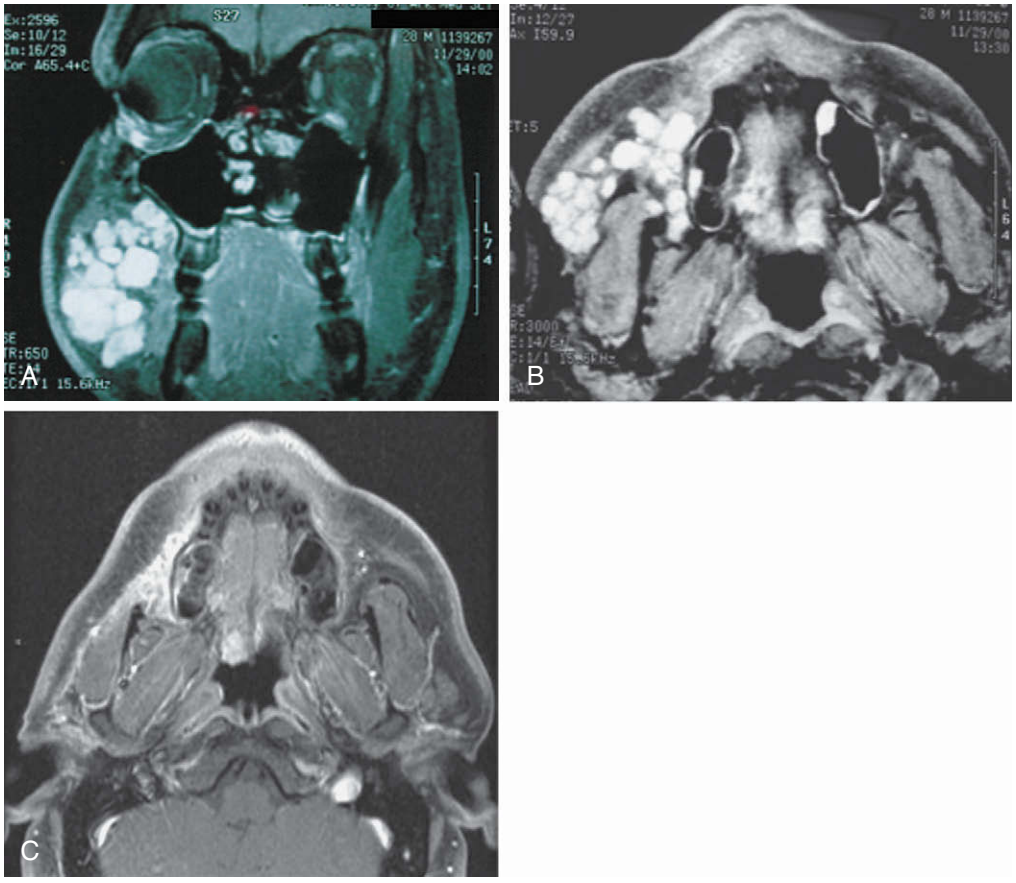

Figure 87-15. Recurrent pleomorphic adenoma of the right parotid gland. Note the multicentric pattern of recurrence in both the coronal **(A)** and axial images. **B,** T1-weighted magnetic resonance (MR) with gadolinium. **C,** The postoperative axial T1-weighted MR with gadolinium shows complete resection of all recurrent tumors.

phic adenoma. Warthin's tumor is also known as papillary cystadenoma lymphomatosum or adenolymphoma. The term "adenolymphoma" is often confused with malignant lymphoma and therefore the use of this term should be discouraged. Papillary cystadenoma lymphomatosum is an accurate descriptive term but is somewhat cumbersome compared with the most favored term of Warthin's tumor. Warthin's tumor accounts for approximately 10% of all parotid tumors and is found almost exclusively in the parotid gland. Warthin's tumor is associated with a higher male preponderance and is more prevalent in whites than in other racial groups. Bilateral Warthin's tumors occur in 10% of cases and may be simultaneous. As previously discussed, Warthin's tumor is associated with cigarette smoking, which may be due to irritation of ductal epithelium by tobacco smoke, which initiates tumorigenesis.[18]

Clinically, patients with Warthin's tumor present with an asymptomatic, slow-growing mass often in the superficial lobe of the parotid gland at the angle of the mandible. However, a few patients will present with swelling, pain, and other inflammatory changes, which may be secondary to an immunologic response of the lymphoid element.

On gross pathologic examination, Warthin's tumors are usually spheric or ovoid masses that are encapsulated with a smooth or lobulated surface. Papillary cysts are commonly found on sectioning and contain mucoid brown fluid. Solid gray tissue encapsulates white nodules of lymphoid tissue. Microscopically, the combination of papillae of eosinophilic epithelia projecting into cystic spaces and lymphoid matrices is a distinct and pathognomonic histologic feature. The typical cystic lining is arranged in two cell layers of even rows. The apical or luminar tall columnar and basal cuboidal cells contain small dark nuclei and abundant granular pink cytoplasm (oncocytes). The granular eosinophilia of oncocytes is due to abundant mitochondria present in the cytoplasm. Treatment of Warthin's tumor is surgical excision, usually a parotidectomy with facial nerve preservation. Inadequate excision or tumor multicentricity may explain tumor recurrence.

Oncocytic Papillary Cystadenoma

Oncocytic papillary cystadenoma is an uncommon tumor type to originate in the parotid gland. Most of these tumors occur in the larynx, although they have been described in the nasopharynx, palate, buccal mucosa, and the accessory tear ducts. These tumors have no gender predilection and usually occur in those aged 50 years or older. Patients usually present with a painless mass. Those with laryngeal lesions may present with hoarseness or cough. The minor salivary glands of the false vocal cords and ventricles are common sites of presentation, but this tumor type also may originate from any site in the laryngeal mucosa. Although they are usually solitary tumors, there have been reports of multiple tumors.

On pathologic examination, oncocytic papillary cystadenomas are smooth round cysts that may be pedunculated. Microscopically, these tumors look like Warthin's tumor, although the lymphoid stroma is absent. Sometimes, these tumors are referred to by some pathologists as "Warthin's tumor without lymphoid matrix." Whether these are true tumors has been debated. They may reflect metaplasia or hyperplasia of preexisting salivary gland ducts, but nonetheless, they are treated with surgical excision.

Oncocytoma

Oncocytoma accounts for less than 1% of all salivary gland tumors. They are usually benign tumors that arise most commonly in the parotid gland. These tumors may also originate in the submandibular, sublingual, and minor salivary glands. The cells of origin, oncocytes, are large epithelial cells with granular eosinophilic cytoplasm secondary to mitochondrial hyperplasia. Oncocytes may be found individually or in groups in otherwise normal major or minor salivary glands. They are also found in the pancreas, respiratory tract, thyroid, parathyroid, pituitary, adrenal glands, and kidney, although the majority of tumors occur in the superficial lobe of the parotid gland.

Most patients are in the fifth to sixth decade of life at the time of diagnosis and the gender distribution is almost equal. Oncocytomas are painless, slowly enlarging tumors that show a predilection for technetium-99m-pertechnetate and thus often enhance on radionucleotide scan.

On gross pathologic examination, oncocytomas of the major salivary glands are well circumscribed and encapsulated. Those originating from minor salivary glands have less well-defined borders and are not encapsulated. The surface is pink to rust in color. Microscopically, the tumor has a granular appearance as a result of the abundant, hyperplastic mitochondria. The concentration of mitochondria differentiates oncocytomas from other tumors. A true oncocytoma contains no lymphoid tissue. The extensive lymphoid component that is typical of a Warthin's tumor is never encountered. Histologically, oncocyte-predominant benign lesions may have a degree of epithelial atypia, squamous metaplasia, or necrosis that may mimic some types of malignant salivary tumors with oncocytic components such as adenoid cystic carcinoma, mucoepidermoid carcinoma, and adenocarcinoma.[70] Metastatic thyroid carcinoma or renal cell carcinoma with a large number of oncocytes should also be differentiated from oncocytoma.

Oncocytomas originating from minor salivary glands tend to grow in an irregular and locally invasive pattern. They are less predictable than those originating in the parotid glands. Those originating from minor salivary glands in the respiratory tract may invade surrounding cartilage or bone. Although histologically benign, they have a destructive potential. Rarely do they demonstrate features indicative of malignancy such as increased mitoses and perineural or vascular invasion. Detection of cellular proliferation using immunohistochemical staining may be helpful in distinguishing a benign oncocytoma from a malignant oncocytoma.[71] Treatment of benign oncocytomas is surgical excision.

Myoepithelioma

Myoepithelioma originates from contractile myoepithelial cells that lie beneath the ductal and acinar epithelium in the salivary glands. These cells also have been identified in sweat glands and mammary glands. They have the ability to contract, and their pumping action helps expel (or discharge) secretions from the salivary glands. Diagnosing myoepitheliomas by fine-needle aspiration is difficult, and immunohistochemistry with CD 10, SMA, and S-100 markers may aid in diagnosis.[72] On gross pathology, myoepitheliomas are well demarcated and the external surface is smooth. The cut surface is homogeneous and white. Microscopically, these tumors have a thin capsule, except when they occur in the palate, wherein they lack encapsulation. The cells are benign appearing with rare mitosis and often assume spindle, polygonal, or plasmacytoid features. Clinically, these tumors are difficult to distinguish from pleomorphic adenomas due to their painless, slow-growing nature. There is no gender predilection, and they occur in the major and minor salivary glands. Histologically, they should be differentiated from plasmacytomas and any tumors with spindle cells including neurilemoma, fibroma, meningioma, and leiomyoma. The majority of these tumors behave in a benign manner, although there have been reports of local aggressiveness. The treatment is surgical excision.

Sialadenoma Papilliferum

Sialadenoma papilliferum is a rare, benign salivary gland tumor named after the skin tumor syringocystadenoma papilliferum, which it resembles on gross pathologic and microscopic examination. This tumor is painless and exhibits slow-to-moderate growth. It originates in the major and minor salivary glands, most commonly in men about 60 years of age. Microscopically, the tumor originates from the superficial extralobular salivary gland ducts. The cell of origin is thought to be the pluripotential myoepithelial cell.

Clinically, the differential diagnosis includes other papillary lesions like squamous papilloma, verrucous hyperplasia, or carcinoma. Usually it can be distinguished from other intraoral minor salivary gland tumors because it is exophytic and not a smooth, mucosa-covered mass. The treatment is surgical excision.

Inverted Ductal Papilloma

Inverted ductal papilloma is an inverted papilloma that originates from the excretory ducts of the minor salivary glands. This tumor is a different entity from the inverted oral papilloma, which is endophytic and does not bear any clinical resemblance to inverted ductal papilloma. The few cases that have been reported occur equally in men

and women. The lesions are raised but not ulcerated. The preoperative differential diagnosis includes salivary gland tumor, fibroma, and lipoma. Treatment should be conservative, but excision should be complete.

Congenital Lesions

Hemangiomas

Congenital vascular lesions are divided into two groups: hemangiomas and vascular malformations. Juvenile hemangiomas are the most common tumors of infancy, occurring in up to 10% of all births.[73] They may be present at birth but commonly appear several days to weeks later. A rapid growth phase occurs around the age of 1 to 6 months, followed by gradual involution over 1 to 12 years. During the growth phase, endothelial cells proliferate rapidly and become flat during involution. Facial infantile hemangiomas occur in two distinct patterns of tissue involvement: a focal type with a tumor-like appearance and a less common diffuse type with a plaquelike appearance. The diffuse lesions are more likely to be complicated by ulceration or airway obstruction and show a strikingly segmental distribution pattern. Focal hemangiomas, in contrast, show a predilection for regions of embryologic fusion.[74] Hemangiomas are more common in the parotid than in the submandibular gland. Hemangiomas of the parotid area are more often seen in female patients and are usually asymptomatic, unilateral, and compressible masses. The overlying skin may be normal or may be involved. It is not uncommon to see other skin lesions present. On gross pathologic examination, this tumor is dark red, lobulated, and nonencapsulated. Microscopically, these tumors are composed of capillaries lined by proliferative endothelial cells. Blood vessels are uniform in size. Mitoses occur frequently but are not indicators of behavior.[75]

Hemangiomas may become extremely large with complications such as bleeding, heart failure, and even death. Treatment initially should consist of steroids administered 2 to 4 mg/kg per day. If the hemangioma is responsive to steroids, the result is usually immediate and often dramatic. Unfortunately, the response rate to steroids is only 40% to 60%. In such patients, interferon may be useful, but it should be reserved for life-threatening situations because of its toxicity and the necessity to continue the drug for prolonged periods. Surgical excision or various types of laser treatments may be performed for select circumstances.[76] Hemangiomas usually involute completely, but they may take years and may result in medical or psychological problems for children.[77]

Vascular and Lymphatic Malformations

Vascular malformations are different from hemangiomas of the parotid gland. These vascular malformations are not true neoplasms and are divided into different categories, which are discussed briefly as follows.

Venous Malformations

Venous malformations are usually noted at the time of birth and continue to grow as the patient gets older. They may become extremely large in size by the time the child is fully grown. Unlike hemangiomas, which grow by cellular proliferation, enlargement of venous malformations is primarily by dilation of the existing vessels and does not represent cellular division.[76] Treatment is usually by surgical excision; however, large venous malformations involving the parotid gland may be difficult to remove. An MRI scan is the best imaging study to determine the extent of disease. Arteriograms are not helpful.

Arteriovenous Malformations

Arteriovenous malformations differ from arteriovenous fistulas in that the malformations are congenital (but may not manifest for several years), whereas the fistulas are acquired, usually as a result of trauma. Arteriovenous malformations involve shunting of blood from the arterial vessels directly into the venous system, causing significant enlargement of the vascular lesion. Generally these should be removed completely in order to stop the progress. They can involve the parotid gland and appear as a parotid mass. An arteriogram is essential to diagnose the presence and extent of the malformation. Surgical resection is desirable.

Lymphatic Malformations

Lymphatic malformations are usually present at birth and gradually grow. They can involve the salivary glands, causing enlargement. In some cases the lymphatic aggregates can be nodular, simulating a mass. Usually very diffuse, they infiltrate locally in the tissue planes of the adjacent structures. Treatment is surgical resection, which can be quite tedious.

Management of Benign Salivary Gland Neoplasms

Management of benign salivary gland tumors has not changed dramatically for years. Management of tumors of the salivary glands requires a detailed understanding of the anatomy and pathologic processes affecting these glands. Benign salivary gland tumors should be excised completely with an adequate margin to avoid local recurrences.[57] Generally tumors in the parotid gland are removed with an adequate cuff of surrounding normal tissue, and the facial nerve is dissected and carefully preserved. The extent of dissection of the facial nerve and the amount of parotid tissue resection depend on the size, location, and histology of the tumor.[78]

Small adenomas located in the tail of the parotid gland may require only dissection of the lower division of the facial nerve with removal of the tumor and the surrounding parotid tissue, avoiding unnecessary dissection of the upper division.

Larger tumors of the superficial lobe, however, usually require a complete superficial parotidectomy. Deep lobe tumors require a total parotidectomy, with facial nerve preservation. Parapharyngeal tumors are most commonly excised through a cervical-parotid approach and only occasionally in conjunction with a mandibulotomy.[79]

A tumor of the submandibular gland requires submandibular gland resection. If the tumor originates from a minor salivary gland, the tumor and a cuff of normal tissue should be excised. Simple enucleation should be discouraged because of the increased risk of recurrence.[58] Pediatric hemangiomas will generally involute but may be resected in special cases. Vascular malformations involving the parotid or submandibular glands may require surgical excision.

Parotidectomy (see Key Indicator Video online)

The patient is placed in the supine position, and the head turned to the opposite side. The standard incision is a modified Blair's incision (Fig. 87-16A). The skin incision is placed in a preauricular crease and extends superiorly to the level of the root of the helix. The incision extends inferiorly around the lobule of ear over the mastoid tip. It then gently curves down along the sternocleidomastoid muscle and then slightly forward in a natural skin crease in the upper neck (see Fig. 87-16A). Alternatively, a "face-lift" incision may be done in selected patients with benign tumors of the lower or mid regions of the parotid gland. The preauricular portion of the incision passes on or just inside the tragal margin. The incision is then carried below the lobule of the ear, turns posteriorly over the mastoid, and then is extended within the hairline (Fig. 87-17A). The face-lift incision is less conspicuous and therefore offers better cosmesis (see Fig. 87-17B).

To expose the parotid gland, skin flaps are elevated in the plane superficial to the parotid fascia in the preauricular region and in the subplatysmal plane in the cervical portion of the incision (see Fig. 87-16B). The greater auricular nerve and the external jugular vein are identified over the sternocleidomastoid muscle and are divided to free the tail of the parotid gland (see Fig. 87-16B). In some cases the greater auricular nerve can be preserved, but whether this preservation has a significant impact on the patients' quality of life is debatable (as will be discussed under Complications).[80,81] The posterior belly of the digastric muscle is exposed proximal to its attachment to the mastoid bone. The fascia between the parotid gland and the cartilaginous external auditory canal is dissected, and the parotid gland is retracted anteriorly. This exposes the tragal pointer. The most common method of identifying the main trunk of the facial nerve is in its course in the region located between the tragal pointer and the attachment of the posterior belly of the digastric muscle to the mastoid bone (see Fig. 87-16C). Unless displaced by tumor, the nerve is usually located approximately

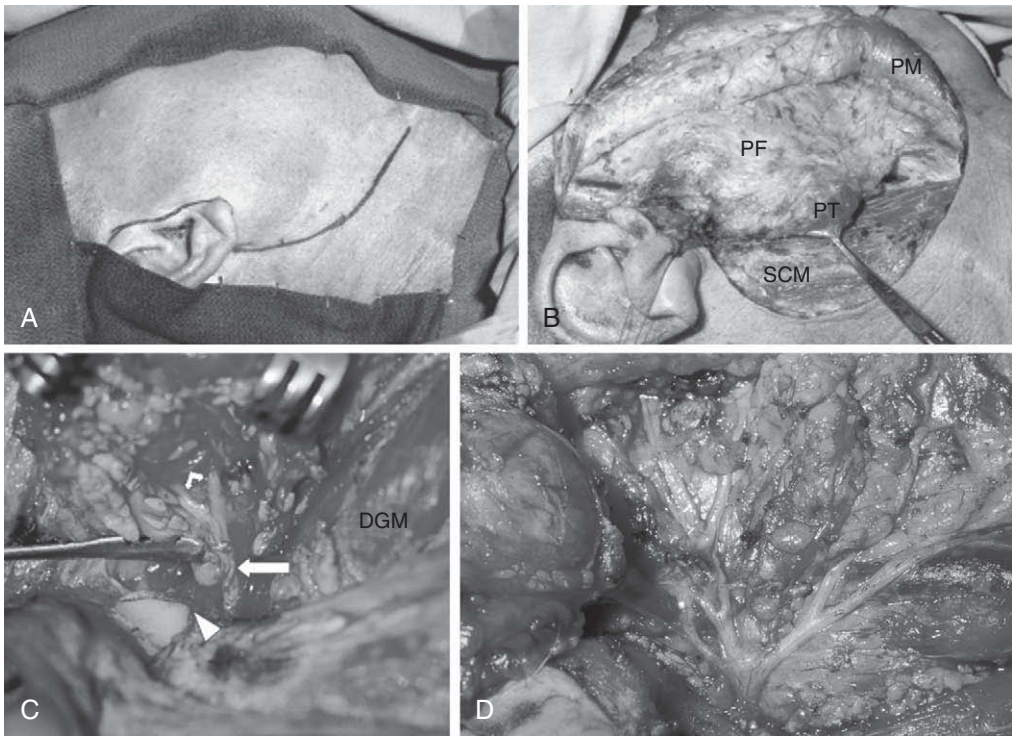

Figure 87-16. Right superficial parotidectomy. **A,** Modified Blair's incision for a right parotidectomy. **B,** Flap elevation and freeing the tail of the parotid gland. **C,** Identification of the main trunk of the facial nerve. The facial nerve is usually identified by dissecting the main trunk *(white arrow)* in the region located between the tragal pointer *(white arrowhead)* and the attachment of the posterior belly of the digastric muscle (DGM) to the mastoid bone. Unless displaced by tumor, the nerve is usually located approximately 1 to 1.5 cm deep and inferior to the tragal pointer. Dissection of the main trunk then proceeds distally until it branches *(double arrow),* and then all branches are sequentially and meticulously dissected. **D,** Complete dissection of all parotid tissue lateral to the facial nerve reveals the main trunk and the complex branching pattern of the facial nerve (pes anserinus). PF, parotid fascia; PM, platysma muscle; PT, parotid tail; SCM, sternocleidomastoid muscle.

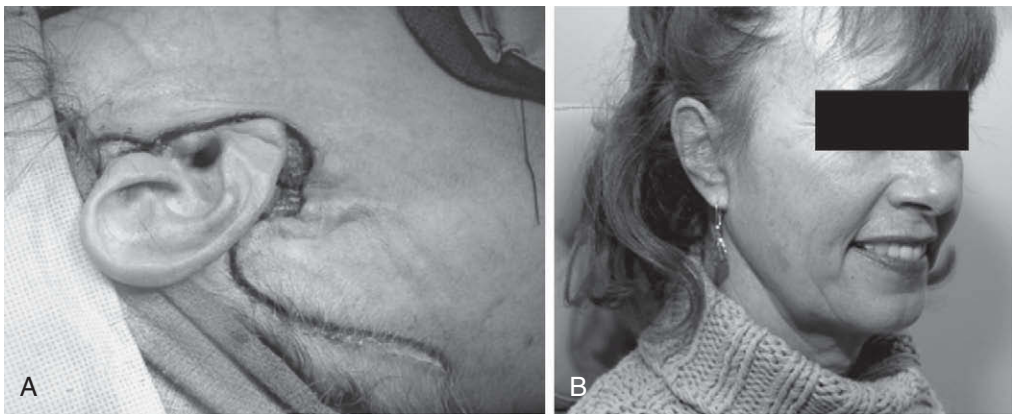

Figure 87-17. Modified "face-lift" incision for parotidectomy. **A,** Unlike the modified Blair's incision, which has a cervical extension (see Fig. 87-16A), the face-lift incision extends posteriorly and inferiorly along the hairline. **B,** The hairline portion of the incision is inconspicuous, making this approach more cosmetically pleasing.

1 to 1.5 cm deep and inferior to the tragal pointer. Another reliable, and perhaps a more constant, landmark to identify the facial nerve is the tympano-mastoid suture line, which could be followed medially to the main trunk of the nerve. The nerve is usually 6 to 8 mm deep to the tympano-mastoid suture line. In certain cases where the tumor is directly overlying the region of the main trunk of the facial nerve, one or more of the peripheral branches of the nerve are identified distally and traced proximally toward the main trunk.[82] The marginal mandibular branch can be identified below the lower border of the mandible, as it crosses superficial to the facial vessels, in the plane immediately underneath the deep cervical fascia. Alternatively, the buccal branch can be identified underneath the parotido-masseteric fascia, coursing parallel to the parotid duct.

Once the facial nerve is identified, the overlying parotid tissue is meticulously elevated from the nerve with a fine clamp and the bridge of tissue between the blades of the clamp carefully divided. If the main trunk of the nerve is identified first, then the overlying parotid tissue is progressively dissected free of the nerve to the first branching of the nerve, usually into an upper and a lower division (see Fig. 87-16C). Subsequent branching of the nerve (pes anserinus) is sequentially dissected in a similar fashion, until the entire superficial lobe of the parotid gland lying lateral to the facial nerve is

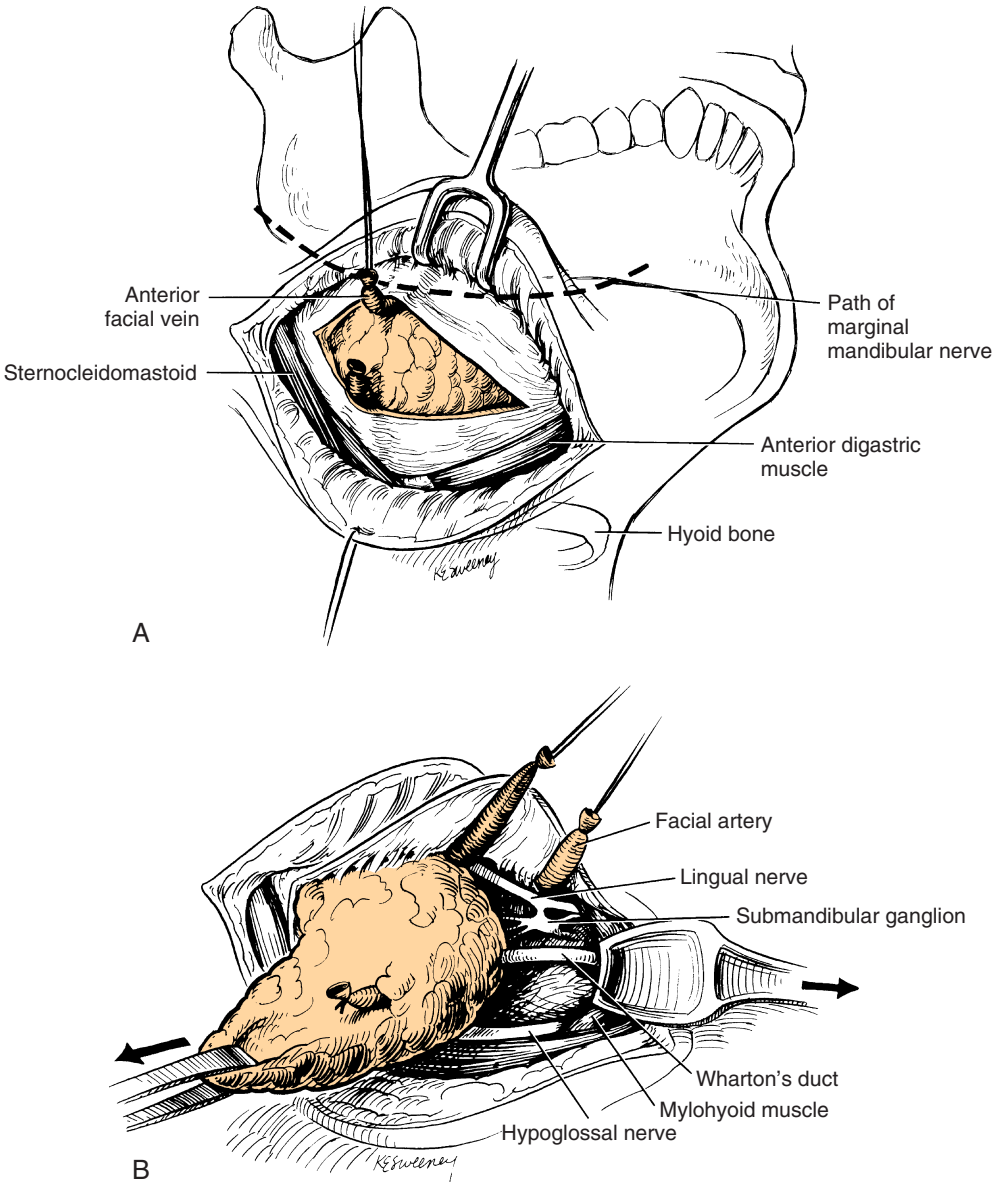

Figure 87-18. Excision of the submandibular salivary gland. **A,** Submandibular incision, made in a natural skin crease 3 to 4 cm inferior to mandible. Marginal mandibular nerve generally lies just superficial to anterior facial vein. **B,** Mylohyoid is retracted anteriorly and the gland posteriorly. This exposes the lingual nerve, submandibular ganglion, and Wharton's duct.

delivered (see Fig. 87-16D). This completes a superficial or lateral parotidectomy.

If a total parotidectomy is indicated, the procedure is extended by meticulous dissection of the main trunk and the branches of the facial nerve from the underlying parotid tissue in a gentle and atraumatic fashion. This allows the salivary tissue lying deep to the facial nerve to be delivered while preserving the nerve and its function.

Submandibular Gland Excision

A curvilinear incision is placed, preferably in a natural skin crease, 3 to 4 cm below the lower border of the mandible, overlying the submandibular gland. The incision is carried down through the subcutaneous fat, and the platysma muscle. Great care should be taken to avoid injury of the marginal mandibular nerve. The nerve lies immediately beneath the deep cervical fascia, and can be identified crossing the anterior facial vein. The vein is doubly ligated and transected well below the nerve, and upward retraction of the superior ligature displaces the nerve superiorly and protects it from injury during further dissection (Fig. 87-18A). Superior dissection proceeds by double ligation and transection of the facial artery, which frees the superior attachment of the gland. Anteriorly the vessels to the mylohyoid muscle are divided, and the gland is mobilized posteriorly, exposing the free edge of the mylohyoid muscle. The free (posterior) edge of the mylohyoid muscle is retracted anteriorly, while gentle posterior traction on the gland is maintained. This exposes the deep portion of the gland and its duct, the submandibular ganglion, and the lingual and hypoglossal nerves (see Fig. 87-18B). These structures lie superficial to the hyoglossus muscle. The contribution of the lingual nerve to the submandibular ganglion is transected, and the Warthin's duct is doubly ligated and divided. This delivers the deep portion of the gland. Care should be taken to avoid injury to the lingual and hypoglossal nerves. Finally the facial artery is divided a second time, and the gland is removed.

Excision of Parapharyngeal Salivary Gland Tumors

Surgical excision of salivary gland tumors within the parapharyngeal space is best done via an external approach.[37,79] The incision is that of a parotidectomy with a cervical extension (Fig. 87-19A). If the tumor involves the deep lobe of the parotid gland, a superficial parotidectomy is done first. If the tumor arises from the minor salivary glands of the

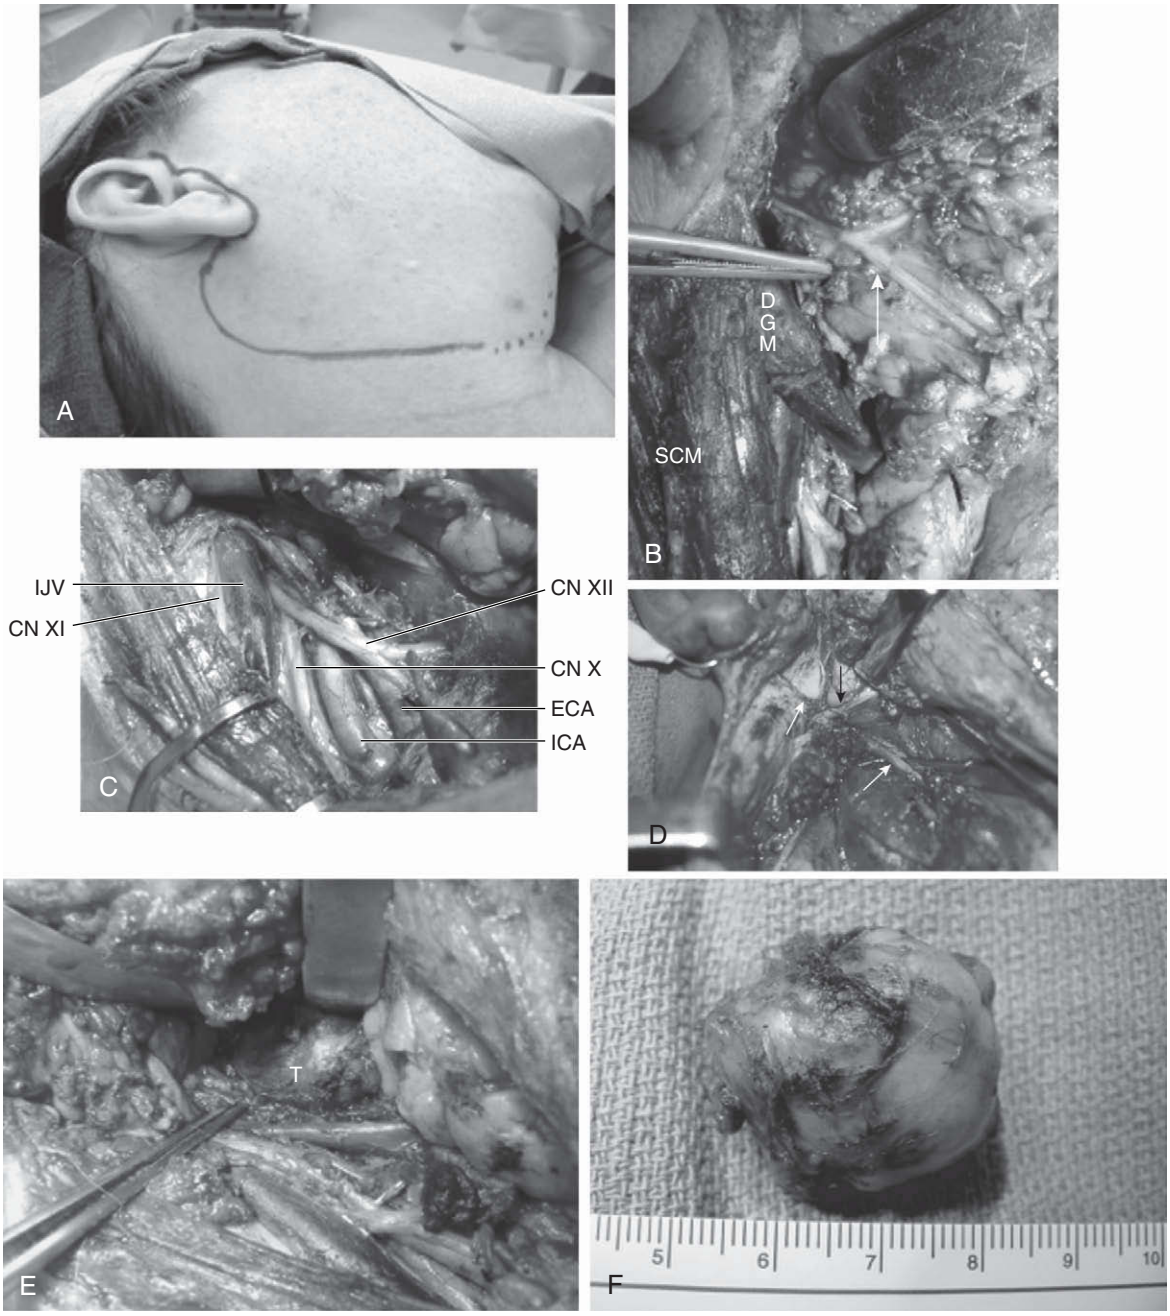

Figure 87-19. Transcervical approach to the right parapharyngeal space. **A,** Incision for transcervical approach to the parapharyngeal space. The incision can be extended to the submandibular region and can also extend as a lip-splitting incision if a mandibulotomy is necessary for added exposure *(dotted line).* **B,** The main trunk of the facial nerve is identified in the same manner as described for superficial parotidectomy. For most benign tumors of the parapharyngeal space, dissection of the facial nerve is limited to the main trunk and the inferior division of the nerve *(arrow).* Dissection of the upper division is occasionally necessary for adequate exposure and tumor resection. **C,** Exposure of the neurovascular structures in the upper cervical region. These include the internal jugular vein (IJV), internal carotid artery (ICA), external carotid artery (ECA), and cranial nerves (CN) X, XI, and XII. **D,** The stylomandibular ligament *(white arrow)* is seen overlying the curved hemostat. The relationship of the main trunk of the facial nerve *(black arrow)* and the tragal "pointer" *(white arrowhead)* is also demonstrated. **E,** Division of the stylomandibular ligament allows further anterior retraction of the mandible, and resection of the styloid process allows more cephalad exposure of the parapharyngeal space. These maneuvers allow wide access to the parapharyngeal space for adequate tumor (T) exposure. **F,** Pleomorphic adenoma of the parapharyngeal space. DGM, digastric muscle; SCM, sternocleidomastoid muscle.

parapharyngeal space, the inferior division of the facial nerve is identified and carefully preserved (see Fig. 87-19B). Next, the sternocleidomastoid is retracted laterally and the upper neck is dissected to expose the internal jugular vein, external and internal carotid arteries, and the last four (IX, X, XI, and XII) cranial nerves (see Fig. 87-19C). The posterior belly of the digastric and the stylohyoid muscle are identified, divided near their mastoid and styloid attachments, respectively, and retracted medially. This allows further superior exposure of the internal carotid artery, internal jugular vein, and adjacent nerves, as well as visualization of the stylomandibular ligament and the styloid process. The stylomandibular ligament is divided (see Fig. 87-19D), which allows further anterior retraction of the mandible and provides a wide opening into the parapharyngeal space (see Fig. 87-19E). The styloid process may be resected for further exposure and to assist delivery of

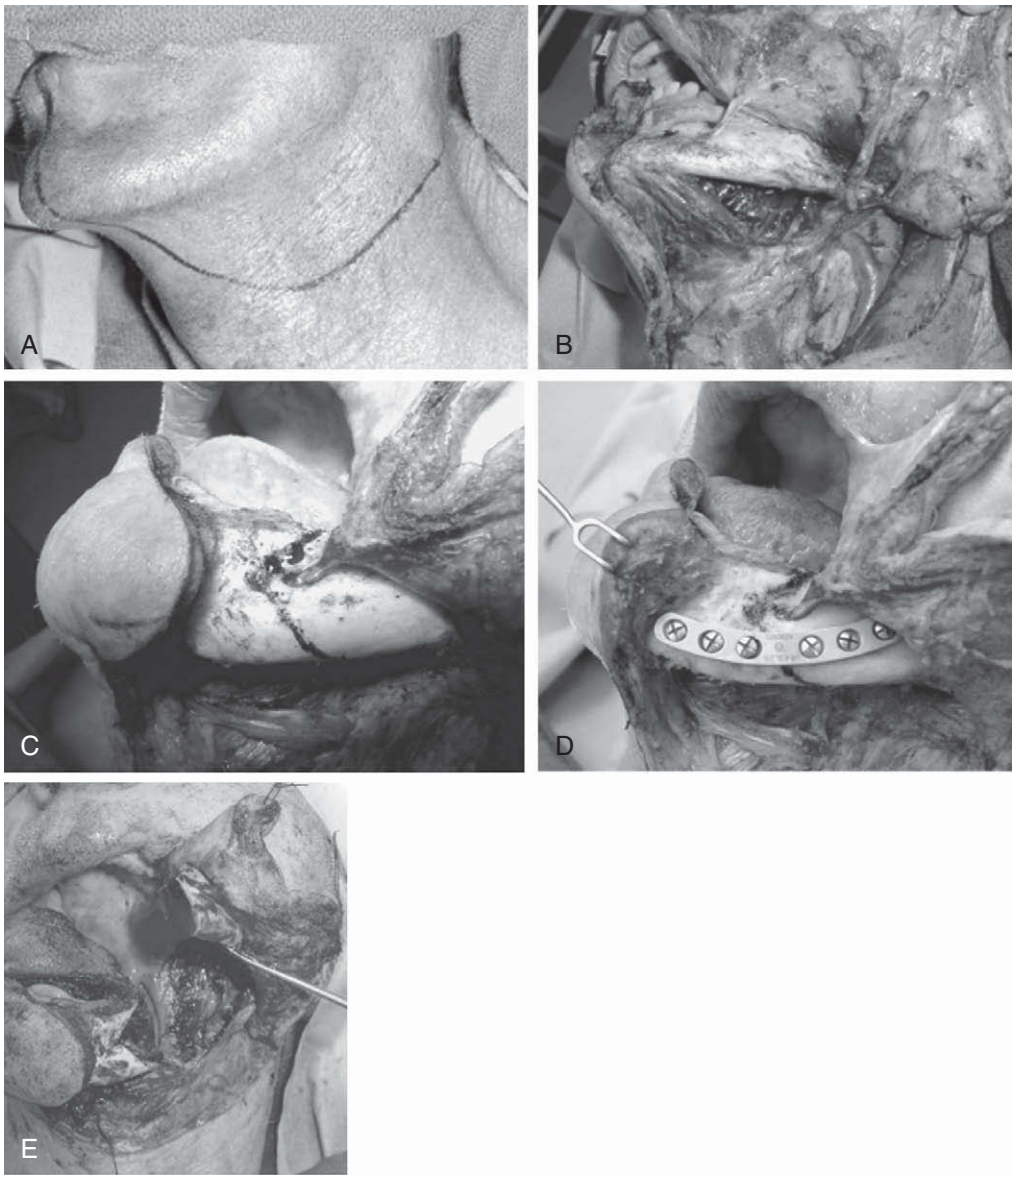

Figure 87-20. Mandibulotomy approach for excision of tumors in the parapharyngeal space. **A,** Lip-splitting incision for mandibulotomy. **B,** Upper cervical dissection and exposure of the mandible with identification and preservation of the mental nerve. **C,** A "Chevron" osteotomy is outlined anterior to the mental foramen. **D,** A metal plate is preregistered and fixed to the mandible before the planned osteotomy to avoid postoperative malocclusion. **E,** After the osteotomy is distracted, dissection is carried along the floor of mouth just lateral to the tongue, providing wider access to the parapharyngeal space.

larger tumors. Through this exposure, the tumor can be easily visualized and safely excised (see Fig. 87-19E and F).

In patients with tumors located in the superior aspect of the parapharyngeal space approaching the eustachian tube and skull base, the addition of a mandibulotomy may be necessary.[37,83] The enhanced exposure offered by the mandibulotomy allows the visualization necessary for resection of the tumor with adequate margins. First, a cervical-parotid approach is performed as described in the previous section. If a mandibulotomy is indicated, a preliminary tracheostomy is performed. Next, the cervical portion of the incision is extended through the chin to split the lower lip in the midline (Fig. 87-20A). After dissection of the upper carotid sheath, the mandible is exposed carefully, identifying and preserving the mental nerve (see Fig. 87-20B). A stair-step or "Chevron" osteotomy is outlined either in the midline (median mandibulotomy) or just anterior to the mental foramen (paramedian mandibulotomy) (see Fig. 87-20C). These types of osteotomies are more mechanically stable than a straight-line osteotomy. In order to obtain normal dental occlusion, a metal plate is preregistered and fixed to the mandible before performing the planned osteotomy (see Fig. 87-20D). The osteotomy is performed using a micro-reciprocating saw in order to minimize bony loss at the osteotomy site. A paralingual incision is then made along the floor of the mouth. The mylohyoid muscle is divided while carefully preserving the hypoglossal and lingual nerves. The tongue is retracted medially, and the parapharyngeal and retropharyngeal spaces are opened widely (see Fig. 87-20E). The tumor can now be excised safely and adequately while protecting the critical neurovascular structures of the parapharyngeal space. Closure involves a water-tight intraoral suture line and rigid fixation of the mandibulotomy. A nasogastric tube is inserted for feeding. Within 7 to 10 days most patients will have their tracheostomy decannulated and be able to resume oral feeding.

Complications

Facial Nerve Paresis or Paralysis

Facial nerve dysfunction may result from traction injury to the facial nerve during dissection. Facial nerve monitoring has helped decrease

the morbidity of a parotidectomy.[84] As long as the anatomic integrity of the nerve is preserved, this type of injury usually results in neuropraxia and, therefore, complete recovery is anticipated. The degree of weakness or paralysis may range from minimal partial weakness of one or more branches of the facial nerve to complete paralysis of all branches of the nerve. Recovery of facial nerve function may be prompt and complete within days or may be delayed for several months. In a study of 256 consecutive patients who underwent parotid surgery at the Cleveland Clinic over a period of 15 years, immediate postoperative facial nerve dysfunction was frequently encountered (46%), but permanent dysfunction was uncommon (4%).[85] The incidence of long-term dysfunction was higher in revision cases and when an extended (total or subtotal) parotidectomy was performed. In order to minimize facial nerve injury, the parotid surgeon should adhere to meticulous dissection and gentle handling of the facial nerve. Excessive traction on the nerve must be avoided, as should overzealous use of the nerve stimulator.

Transection of one or more of the branches of the facial nerve will result in paralysis of the corresponding muscles supplied by the injured nerve. The degree of paralysis may vary and depends on the presence and extent of cross-innervation of the involved muscle groups by the uninjured branches of the facial nerve. Complete transection of the main trunk of the facial nerve results in complete and permanent paralysis of all ipsilateral muscles of facial expression.

If the facial nerve is sacrificed, nerve repair may be done by using either direct neurorrhaphy of the cut edges or a cable graft, depending on the length of the resected segment (see Fig. 87-18). Immediate rehabilitation of the paralyzed face requires diligent eye care to prevent exposure keratitis. This involves liberal use of artificial tears, lubricating ointment, and protection with an appropriate eye dressing and eyewear. A gold weight implant should be used routinely in patients with complete facial paralysis. A temporary tarsorrhaphy may be necessary for patients with lower eyelid ectropion. If the facial nerve is not repaired or grafted, then one or more of the various surgical procedures for static or dynamic rehabilitation of the paralyzed face may be indicated.

Sensory Abnormalities

The greater auricular nerve (GAN) is frequently divided during the operation of parotidectomy. This usually results in sensory deficits in the dermatomal distribution of the GAN, which comprises the lower third of the pinna including the earlobe, as well as the adjacent preauricular and postauricular skin. Although many patients experienced sensory deficits, the overall quality of life was not significantly affected after GAN sacrifice during parotidectomy.[80]

Gustatory Sweating—"Frey's Syndrome"

Patients with Frey's syndrome experience flushing and sweating of the ipsilateral facial skin during mastication (gustatory sweating). The symptoms may vary in severity from barely noticeable to severe and bothersome. The syndrome is a sequela of parotidectomy and may follow other surgical, traumatic, and inflammatory injuries of the parotid and submandibular glands and the cervical and upper thoracic portions of the sympathetic trunk.[86] The true incidence of postoperative Frey's syndrome is unknown, but it is estimated to be between 35% and 60%. The incidence would probably be higher if the syndrome were searched for by directed, symptom-specific questions.[87] The presumed pathophysiology of Frey's syndrome involves aberrant cross-reinnervation between the postganglionic secretomotor parasympathetic fibers to the parotid gland and the postganglionic sympathetic fibers supplying the sweat glands of the skin.

The diagnosis of Frey's syndrome depends largely on the patient's symptoms. An objective method of confirming the diagnosis is the Minor's starch/iodine test. This involves painting the ipsilateral side of the face and neck with iodine solution, which is allowed to dry. Starch powder is then dusted over the painted area. The patient then chews on a sialagogue (e.g., lemon wedge) for several minutes. The appearance of dark blue spots along the face confirms gustatory sweating. This discoloration is the result of the reaction of the dissolved starch with iodine. If the Minor's starch iodine test is used for diagnosis, up to 96% of patients who did not complain of Frey's syndrome after surgery actually had a subclinical manifestation of this complication.[86] This is usually detected within the first year after surgery, but the onset may occasionally be delayed for many years.

If the symptoms are bothersome enough, treatment involves simply applying an antiperspirant over the involved skin. Glycopyrrolate (1%) roll-on lotion is also effective in controlling the symptoms. In cases not responding to these simple measures, surgical interruption of the secretory fibers may be attempted by performing a tympanic neurectomy. Recently, intracutaneous injection of botulinum toxin A has been described as an effective treatment in severe cases of Frey's syndrome.[87,88]

Thick skin flap and partial superficial parotidectomy are the most important techniques to minimize the risk of developing symptomatic Frey's syndrome.[89] The incidence was not altered by the use of sternocleidomastoid muscle flap or other implantation material.[90]

Salivary Fistula

This is an uncommon problem. It usually presents as a clear sialorrhea from the wound or a fluid collection under the skin flaps. In the majority of cases the problem is self-limited. Management includes repeated aspiration, pressure dressing, wound care, and patience. Oral anticholinergics (e.g., glycopyrrolate) may be helpful in temporarily reducing salivary flow until healing is complete.

CHAPTER EIGHTY-EIGHT

Malignant Neoplasms of the Salivary Glands

John B. Sunwoo

James S. Lewis, Jr.

Jonathan McJunkin

Sunitha Sequeira

Key Points

- Salivary gland malignancies are diverse and heterogeneous. Their behavior and resulting clinical management are highly dependent on their histologic type and, often, their grade.
- High-grade histologic types include high-grade mucoepidermoid carcinoma, squamous cell carcinoma, undifferentiated carcinoma, adenocarcinoma not otherwise specified, carcinoma ex-pleomorphic adenoma, and salivary duct carcinoma.
- Treatment is primarily surgical (when resectable) with or without adjuvant postoperative radiation.
- There is controversy regarding when to treat an N0 neck; however, in general, histopathologic type, T stage, and evidence of perineural or bone invasion can guide management.
- Indications for adjuvant postoperative radiation include advanced stage, positive margins, high-grade histologic types, and evidence of local tissue invasion.

Malignant neoplasms of the major and minor salivary glands are rare, comprising approximately 3% of all head and neck malignancies.[1] The estimated incidence is only 0.9 per 100,000 in the United States, but the rate increases with age, peaking at ages 65 to 74 years.[2] Less than 5% of all salivary gland tumors occur in the pediatric age group; however, salivary gland tumors in children are much more likely to be malignant than those of adults.

Of all salivary neoplasms (benign and malignant), the vast majority occurs in the parotid gland and the fewest in the sublingual gland. There is an interesting inverse relationship between the overall incidence of neoplasms by site and the percentage that are malignant (Table 88-1). In a review of 2410 cases of salivary gland tumors,[3] 73% occurred in the parotid, and of those, only 15% were malignant. On the other hand, minor salivary gland tumors constituted only 14% of the total number of cases but 46% were malignant. Likewise, submandibular gland neoplasms constituted 11% of the cases with 37% being malignant; sublingual gland neoplasms constituted only 0.3% with 86% being malignant.

The frequency of the different histologic types of salivary gland malignancy also varies depending on the gland and site. A number of studies have found the most common primary malignancy presenting in the salivary glands to be mucoepidermoid carcinoma.[1,2,4] In one of the largest reviews of salivary gland neoplasms (2807 total), Spiro examined 1278 cases of malignant salivary gland tumors[1] and reported that 34% were mucoepidermoid carcinoma (Table 88-2). The next most common type was adenoid cystic carcinoma (22%), followed by adenocarcinoma (a mixture of tumors which has more recently been subdivided, as described below) (18%), malignant mixed tumor (13%), acinic cell carcinoma (7%), and squamous cell (epidermoid) carcinoma (4%). When considering the types by anatomic site, mucoepidermoid carcinoma was the most frequent malignancy of the parotid, but adenoid cystic carcinoma was the most frequent of the submandibular and minor salivary glands. One exception to the latter was malignant minor salivary gland tumors arising in the nasal cavity and paranasal sinuses, in which case adenocarcinoma was the most common type as opposed to adenoid cystic carcinoma.

This chapter discusses the evaluation of patients with these malignancies, histopathology of the more common types, and currently accepted treatment. Both the rarity of these malignancies and the wide variety of histologic types have made their study challenging. In fact, what is known about their clinical behavior and treatment outcomes is based almost entirely on retrospective studies.

Evaluation of the Patient

Physical Examination

The clinical presentation of malignant salivary gland neoplasms can range from indolent asymptomatic masses to rapidly growing painful masses with progressive facial nerve paralysis. In Spiro's review of 2807 salivary gland tumors, pain was a symptom in only 10% of malignant cases[1] but was more frequently seen with malignant neoplasms than with benign ones. In general, episodic swelling and pain most often indicates salivary gland obstruction and inflammation, whereas constant pain is more worrisome for malignancy. However, sialadenitis can

Table 88-1

Relationship Between Site of Primary Tumor and Frequency of Malignancy

Site	Absolute Numbers	Percentage Frequency	Percentage Malignant
Parotid	1756	72.9	14.7
Submandibular	257	10.7	37
Sublingual	7	0.3	85.7
Minor glands	336	14	46.4
Unknown	54	2.2	—

be secondary to obstruction by a salivary gland neoplasm; thus the latter must be considered in the evaluation of any salivary gland swelling with pain. Approximately 10% of parotid gland malignancies present with associated facial paralysis, and this portends a poor prognosis.[5,6]

Parotid Gland

The parotid glands are the largest of the major salivary glands and are unique in that they are the only salivary glands that contain intraglandular lymph nodes. Both parotid glands can be divided into a superficial "lobe" and a deep "lobe" by the plane in which the branches of the facial nerve course. These lobes are primarily defined for surgical treatment purposes, but anatomically they are also distinguished by the fact that the majority of the intraglandular lymph nodes are in the superficial lobe. The superficial lobe is the portion lateral to the plane of the facial nerve and contains approximately 10 to 20 lymph nodes on average. The deep lobe is medial to the plane of the facial nerve and extends into the parapharyngeal space.

A thorough examination of the parotid gland includes palpation of the gland itself and of the neck, assessment of the overlying skin, bimanual palpation of the buccal space, which includes Stensen's duct, examination of the oropharynx and nasopharynx, and a thorough evaluation of facial nerve function and symmetry. The parapharyngeal space can be divided into a prestyloid (or anterolateral) compartment and a poststyloid (or posterolateral) compartment by a fascial layer extending from the styloid process to the tensor veli palatini. Deep lobe parotid tumors can involve the prestyloid compartment of the parapharyngeal space and present as a submucosal bulging mass in the oropharynx and/or nasopharynx, distorting the soft palate or obstructing the Eustachian tube. If the tumor extends into the poststyloid compartment, there may be cranial nerve (CN) neuropathies, manifesting as a decreased gag reflex (CN IX, X), aspiration (CN IX, X), asymmetric palate elevation (CN X), hoarseness (CN X), dysphagia (CN X), weakness of the trapezius muscle (CN XI), or atrophy/paresis of the tongue (CN XII). If a parotid tumor extends posteromedially into the infratemporal fossa, there may also be associated trismus.

Submandibular Gland

The pair of submandibular glands, located in the submandibular triangle (level Ib) of the neck and extending to the medial aspect of the mandible, represents the second largest of the major salivary glands. These glands are intimately associated with the lingual nerve, hypoglossal nerve, facial artery and vein, and overlying marginal mandibular branch of the facial nerve. They drain into the floor of the mouth via Wharton's duct.

Bimanual (intraoral and external) palpation of any submandibular gland tumor should be performed to assess the extent of the tumor and to determine if there is fixation to adjacent structures such as the mandible or skin. A careful neurologic examination should also be performed to assess nerve involvement. In particular, worrisome signs of malignancy include numbness of the tongue (suggesting lingual nerve involvement), weakness of the tongue (suggesting hypoglossal nerve involvement), or weakness of the lower lip (suggesting facial nerve involvement). Careful examination of the neck is also important because 25% to 28% of submandibular malignancies will have metastases to regional lymph nodes.[1,7]

Sublingual Gland

The pair of sublingual glands is located in the floor of the mouth, one on each side of the frenulum, lateral to Wharton's duct in the submucosal compartment. The drainage of these glands is via Bartholin's ducts, which empty into Wharton's ducts. As with submandibular gland tumors, bimanual palpation of the floor of the mouth is important to assess the extent and possible fixation of sublingual gland tumors to the mandible. Because the sublingual gland is intimately associated with the lingual and hypoglossal nerves, a careful neurologic examination is important as previously stated. Although tumors in this area are usually painless, the vast majority (86%) of sublingual gland tumors are malignant.[1]

Minor Salivary Glands

Minor salivary gland tissue is plentiful with estimates between 500 and 1000 glands along the upper aerodigestive tract. Although they are located in the submucosa throughout the oral cavity, oropharynx, nasal cavities, paranasal sinuses, pharynx, and larynx, the majority of them are located in the oral cavity, with the highest concentration being in the submucosa of the hard palate. As such, the site most frequently involved with minor salivary gland malignancies is the hard palate.[8] Compared with the major salivary glands, minor salivary glands have minimal capsular tissue, making local invasion of tumors into surrounding tissue common. Patients with malignancies of the minor salivary glands most often present with a painless submucosal swelling, but there is frequently fixation of the overlying mucosa and ulceration. Approximately one quarter of patients will complain of local pain,[9] and pain or paresthesia/anesthesia is concerning for nerve invasion. Because minor salivary glands are distributed throughout the mucosalized surfaces of the head and neck, malignancies of these glands may present in diverse ways depending on the location. Symptoms may include nasal airway obstruction, sinusitis, eustachian tube dysfunction, or hoarseness. A thorough head and neck evaluation including fiberoptic examination and cross-sectional imaging should be performed in all cases.

Philadelphia: Mosby; 2002:2074, figure 39-102A and B).*

Radiologic Studies

Magnetic resonance imaging (MRI) is the radiologic modality most often recommended to assess salivary gland neoplasms if there are no contraindications. Benign and malignant neoplasms of the parotid gland are well visualized on T1-weighted images because they are easily distinguished from the fatty parenchyma of the gland, which appears hyperintense. In *general,* benign epithelial neoplasms (such as pleomorphic adenomas) and low-grade malignancies have low T1-weighted and high T2-weighted signal intensities (Fig. 88-1A and B). High-grade carcinomas tend to have low-to-intermediate signal intensities on both T1-weighted and T2-weighted imaging (discussed later). The use of contrast material such as gadolinium and fat saturation of T1-weighted imaging provides additional information regarding the extent of a salivary gland malignancy (Fig. 88-1C and D). This is particularly useful in terms of assessing bone involvement and perineural spread. Bone marrow and cortex appear hypointense on fat-saturated images, and infiltrating tumor tissue appears hyperintense when enhanced with gadolinium. Enlarged foramina at the skull base and the presence of hyperintense enhanced tumor tissue are suggestive of perineural spread.

Some have proposed that T2-weighted imaging is helpful in distinguishing benign from malignant salivary gland neoplasms. Som and Biller[10] examined 35 parotid tumors by MRI and made the following observations. Benign tumors and low-grade malignancies had low T1-weighted and high T2-weighted signal intensities, and they had clearly defined margins. High-grade malignancies, on the other hand, had low T1- and T2-weighted signal intensities and poorly defined margins. Freling and colleagues,[204] however, did not make the same observations. They examined 116 patients with parotid masses, 30 of which were malignant tumors, and found no correlation between malignancy and signal intensity, heterogeneity, or radiographic margins on MRI. Malignant lesions could be discriminated from benign ones only when there was infiltration into adjacent structures. Among the malignant lesions, there was no correlation between tumor grade and MRI features. Thus MRI provides useful information about the extent of the disease, but histopathologic diagnosis is still required to distinguish benign from malignant processes.

Computed tomography (CT) with intravenous contrast is also widely used in evaluating salivary gland masses primarily because of the speed with which images are acquired. CT is particularly useful for evaluating cortical bone erosion from adjacent tumors. CT is much better than MRI in visualizing small salivary duct calculi, and as such, it is particularly helpful in assessing salivary gland masses if sialolithiasis is considered to be a component of the etiology. Highly cellular tumors can be visualized in the parotid gland because the normal parotid tissue has a high fat content, which results in a lower radiodensity on CT imaging compared with neoplasms. However, in general, MRI is superior to CT for providing soft tissue detail and delineating the extent of salivary gland masses.

Biopsy

Pretreatment diagnosis has been made possible by the use of fine-needle aspiration (FNA) biopsies. This diagnostic tool was established in the mid-to-late 1960s[11-16] and has become a mainstay in the workup of salivary gland neoplasms. It is an extremely safe procedure that is well tolerated by patients and is considered to have no significant risk of tumor seeding to surrounding tissue.[17]

Although FNA biopsies of salivary neoplasms have proven to be extremely useful for preoperative planning, the interpretation of these biopsies can be difficult, resulting in diagnostic ambiguity and inaccuracy. A few entities have classic, pathognomonic features on needle aspiration. However, the variety of different tumor types and their widely overlapping histology usually necessitates the acquisition of biopsy or resection tissue for definitive diagnosis. Also, and most importantly, many malignant salivary gland tumors can only be diagnosable as such when the growth pattern (e.g., infiltration beyond the capsule into soft tissue, perineural invasion) is taken into consideration. In these cases, tumors can only be definitively diagnosed as malignant on surgical specimens, which adequately demonstrate the tumor architecture and its relationship to peripheral tissue. This is particularly true for low-grade malignant neoplasms such as polymorphous low-grade adenocarcinoma,[18] myoepithelial carcinoma,[19,20] and basal cell adenocarcinoma,[21] which usually have bland-looking tumor cells and lack necrosis or abundant mitoses. Among tumors of the head and neck, FNA biopsies of major salivary gland tumors are considered to have the highest rate of error.[22] By most reports, the sensitivity of FNA biopsies to diagnose a malignant neoplasm is much lower than the specificity.[22-26] In other words, it is more common to misdiagnose a malignant tumor as benign than the reverse. A 5-year review of data from 6249 participant responses from the College of American Pathologists Interlaboratory Comparison Program in nongynecologic cytology revealed that FNA biopsies had a 68% sensitivity for diagnosing a salivary gland neoplasm as malignant, with an overall false-negative rate of 32%.[27] The greatest number of false-negative diagnoses occurred in cases of lymphoma (false-negative rate = 57%), followed by acinic cell carcinoma (false-negative rate = 49%), low-grade mucoepidermoid carcinoma (false-negative rate = 43%), and adenoid cystic carcinoma (false-negative rate = 33%). In cases of benign neoplasms from the same study, the specificity of FNA biopsies was 91%, with an overall false-positive rate of 8%. The greatest false-positive rate was in cases of monomorphic adenoma (53%), which were most often diagnosed as adenoid cystic carcinoma. Pleomorphic adenomas, when diagnosed as malignant, were most often misinterpreted as adenoid cystic carcinoma, and Warthin's tumors as lymphoma.

Although the utility and ease of FNA biopsies have resulted in a decline in the use of frozen section analysis intraoperatively, there are still several indications for frozen section studies, as reviewed by Seethala and colleagues[28] and Westra.[22] These include assessing the extent of tumor spread to local/regional tissues such as the nerves and lymph nodes, assessing surgical margins, and confirming/establishing the diagnosis in cases where the preoperative FNA biopsy was not diagnostic or was equivocal.

Staging

Clinical staging of salivary gland cancers is important for prognosis and treatment decisions. The 2003 TNM staging classification for major salivary gland cancers established by the American Joint Committee on Cancer (AJCC) is the classification most commonly used in the United States (Tables 88-3A and B). Minor salivary gland carcinomas are staged according to the anatomic site of origin (e.g., oral cavity, sinus, larynx). The staging guidelines are applicable to all forms of carcinoma; any nonepithelial tumor type is excluded.

Table 88-3A

2003 AJCC TNM Staging for Major Salivary Gland Cancer

Primary Tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor is ≤2 cm in greatest dimension without extraparenchymal extension*
T2	Tumor is >2 cm but not >4 cm in greatest dimension without extraparenchymal extension*
T3	Tumor is >4 cm in greatest dimension and/or has extraparenchymal extension*
T4a	Tumor invades skin, mandible, ear canal, and/or facial nerve
T4b	Tumor invades skull base and/or pterygoid plates and/or encases carotid artery
Regional Lymph Nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension
N2b	Metastases in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension
N2c	Metastases in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension
N3	Metastasis in a lymph node, >6 cm in greatest dimension
Distant Metastasis (M)	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

*Extraparenchymal extension is clinical or macroscopic evidence of invasion of soft tissues. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes.
AJCC, American Joint Committee on Cancer.

Histopathology

Because salivary gland malignancies are remarkably diverse and heterogeneous, their behavior and resulting clinical management are highly dependent on their histologic type and, quite often, their grade. Thus knowledge of the types of tumors and their pathologic classification is critical for the clinician in order to provide proper treatment. Table 88-4 lists most of the critical pathology-related issues that the clinician needs to consider. The following section is intended to provide a succinct, but sufficient, discussion of the pathology of these tumors.

First, it is important to consider the normal histology of the glands because most tumors differentiate into the same cell types that are present in the normal gland. Salivary glands contain acini composed of either serous or mucous cells or a mixture of both. Serous cells are rounded or polygonal in shape and characteristically have abundant blue cytoplasmic granules, which are periodic acid–Schiff (PAS) positive. Mucous cells consist almost entirely of lightly basophilic intracytoplasmic mucus. The fluid secreted by the parotid gland is almost exclusively serous, while that from the sublingual gland is almost exclusively mucous and that from the submandibular gland is a mixture of serous and mucous. The ducts have cuboidal to columnar lining cells with abundant eosinophilic cytoplasm. They form tubular structures within the glands (Fig. 88-2). Both the acini and ducts have supportive cells called myoepithelial cells along their periphery. The parotid glands normally contain, on average, 10 to 20 intraglandular lymph nodes, a feature of great importance because many parotid masses represent metastases to these lymph nodes from primary skin or other cancers of the head and neck. These nodes have an otherwise typical appearance to any other nodal tissue in the body. The submandibular (also referred to as submaxillary) and sublingual glands have no intraglandular lymph nodes.

Neoplasms of the salivary gland can be roughly classified on the basis of the type of normal salivary gland cell toward which they differentiate. Neoplasms can differentiate toward the acinar, ductal, or myoepithelial cells. Practically speaking, though, most of them have dual differentiation—specifically, most salivary gland neoplasms have

Table 88-4

Critical Pathologic Features for Assessing Malignant Salivary Gland Tumors

Tumor Type	Unique Pathologic Issue(s)
Mucoepidermoid carcinoma	Grade
Adenoid cystic carcinoma	Grade Dedifferentiation (Y/N)
Carcinoma ex pleomorphic adenoma	Specific histologic type of carcinoma Grade Degree of invasion
Myoepithelial carcinoma	Grade
Basal cell adenocarcinoma	Grade
Adenocarcinoma NOS	Grade
Acinic cell carcinoma	Grade Dedifferentiation (Y/N)
Small cell carcinoma	Primary vs. metastasis
Squamous cell carcinoma	Primary vs. metastasis
Lymphoma	De novo vs. secondary Grade (low vs. high) Necessity of tissue biopsy

some myoepithelial differentiation.[29] Also, most of the benign neoplasms have a malignant counterpart (e.g., pleomorphic adenoma and carcinoma ex pleomorphic adenoma, basal cell adenoma and basal cell adenocarcinoma, myoepithelioma and myoepithelial carcinoma). The number of different malignant epithelial tumors in the World Health Organization (WHO) classification has increased greatly over the past 50 years and now includes 24 entities.[21] Between 21% and 46%[3] of salivary gland tumors are malignant, including 15% to 32% of parotid, 41% to 45% of submandibular, 70% to 90% of sublingual, and 50% of minor salivary gland tumors.[21] It is important to note that the incidence of particular histologic types is dependent on the site. For example, polymorphous low-grade adenocarcinoma virtually never occurs in the major glands.[18,30]

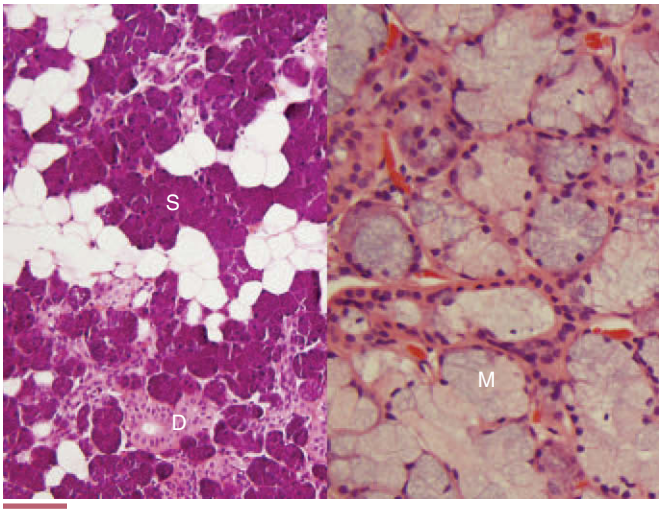

Figure 88-2. Normal major salivary gland histology. Serous acini (left; *S*) have blue-staining cytoplasmic granules; mucinous acini (right; *M*) have pale blue, homogeneous cytoplasm; and ducts (left; *D*) have a two-cell lining and cells with pale pink cytoplasm (400× for both).

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common salivary gland malignancy.[3,31-33] The majority of cases occur in the major salivary glands,[34] but mucoepidermoid carcinoma can also arise from minor salivary glands in the oral cavity, particularly in the hard palate, buccal mucosa, lip, and retromolar trigone.[35] Rarely, they can also arise intraosseously in the mandible and maxilla, but mucoepidermoid carcinomas of this location are considered odontogenic in origin and have a less aggressive clinical behavior.[36,37] Clinically, mucoepidermoid carcinomas are slightly more common in women and have a mean age of approximately 45 years, but they can also occur in children.[31] In fact, they are the most common pediatric salivary gland carcinoma.[38] Patients usually present with a painless, slow-growing mass. Intraoral tumors may mimic a mucocele or vascular lesion clinically by presenting as a blue-red superficial nodule.[3]

Grossly, these tumors are not distinct. They usually have both solid and cystic components, often with mucinous material within the cysts.[39] This is what sometimes imparts a bluish color to them, which can mimic the appearance of a mucocele in the oral cavity. Microscopically, their hallmark is the presence of three cell types: mucous, squamoid (or epidermoid), and intermediate (Fig. 88-3A). The architecture is usually a mixture of cystic (see Fig. 88-3B) and solid elements, the latter with sheets (see Fig. 88-3C), nests, or ductlike structures. The mucous cells have abundant, light blue mucin in their cytoplasm and nuclei displaced to the periphery. The mucin is usually obvious, but, in cases where it is scant, special stains such as PAS, mucicarmine, or Alcian blue can be used to highlight it. The squamoid cells are large with abundant pink cytoplasm, and, although they look somewhat squamous in appearance, true keratinization in mucoepidermoid carcinoma is rare.[40] Intermediate cells typically have more modest amounts of pink or clear cytoplasm. The proportion of cell types varies quite a bit among tumors. Intermediate cells usually predominate and mucous cells usually line cystic spaces. Cytologic atypia varies from minimal to quite prominent.[41-43] Immunohistochemistry is of limited to no utility in the diagnosis.[39]

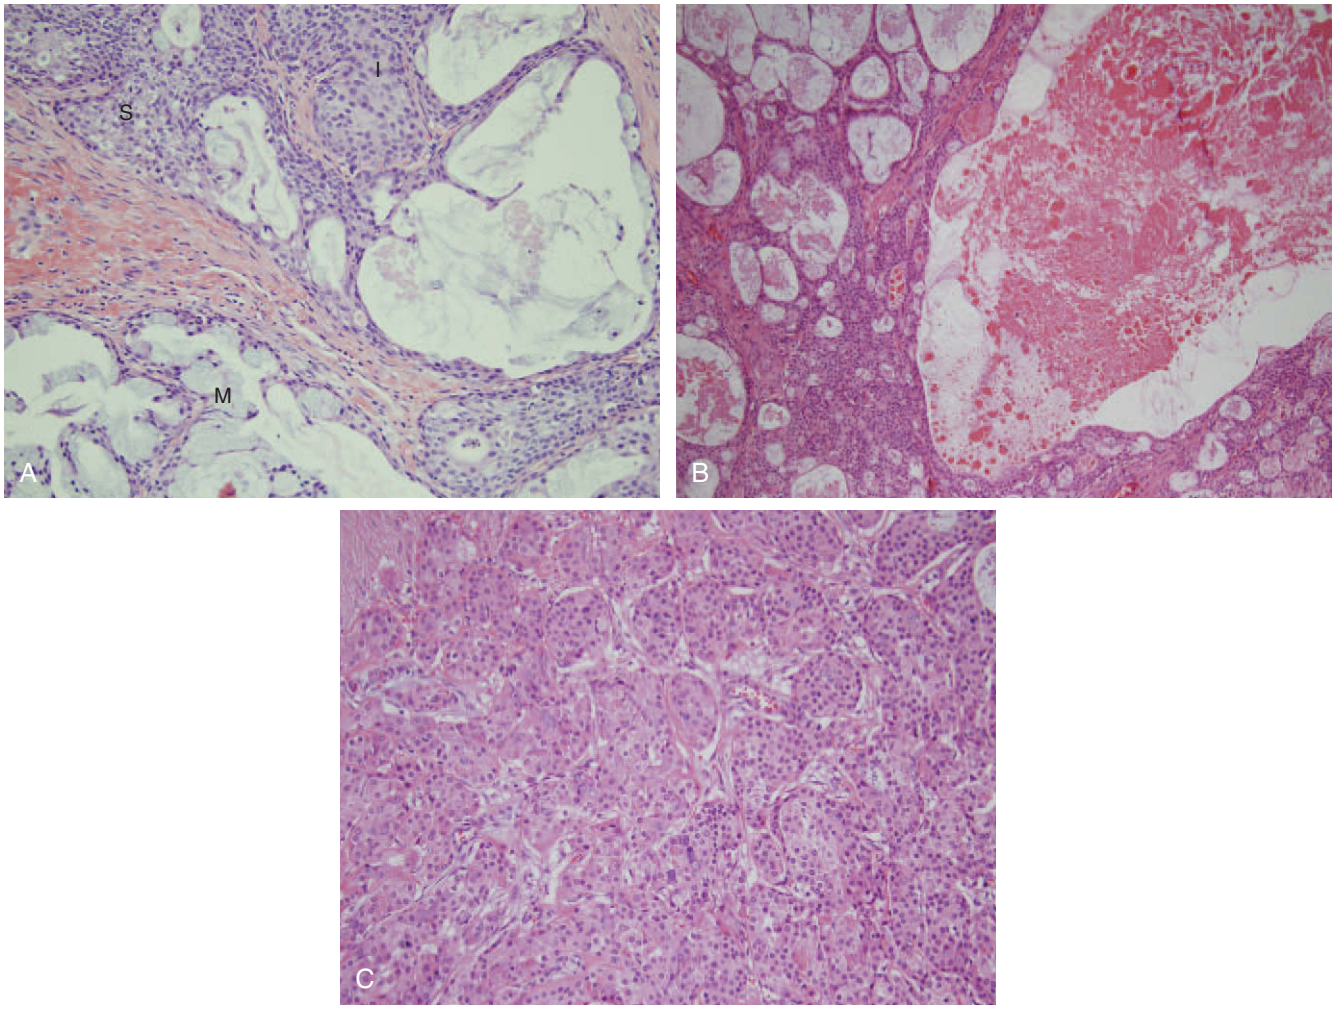

Figure 88-3. Mucoepidermoid carcinoma (MEC). **A,** Different cell types shown in this tumor with abundant intermediate cells *(I),* intermixed mucous cells *(M),* and also squamoid or epidermoid cells *(S)* with slightly more prominent, pink cytoplasm (200×). **B,** Tumor with extensive cystic change (100×). **C,** High-grade MEC with solid sheets of intermediate cells, minimal mucous differentiation, and no cystic change (200×).

FNA yields a mixture of cell types. At a minimum, both glandular and squamoid components must be present to make the diagnosis. The mucous cells have abundant vacuolated cytoplasm, intermediate cells are relatively round and small with little cytoplasm and nuclei with open chromatin, and the squamoid cells have moderate amounts of dense, homogeneous cytoplasm. These typically appear orange on Papanicolaou staining.

The differential diagnosis, particularly in tumors arising along mucosal sites, includes necrotizing sialometaplasia, an uncommon nonneoplastic lesion of the hard palate with reactive changes in minor salivary glands[44] and, more importantly, adenosquamous carcinoma, which is an aggressive variant of squamous cell carcinoma. Adenosquamous carcinomas are high grade, have definitive squamous differentiation usually with keratinization (unlike mucoepidermoid carcinoma), and often have surface mucosal squamous dysplasia, a feature that mucoepidermoid carcinoma does not have.[39]

Grading of mucoepidermoid carcinoma is important and correlates strongly with clinical behavior, although reproducibility and consistency are major issues, and no particular system has been universally accepted.[41-43,45] Clinical staging is as important as histologic grade, so the two should be considered in tandem. In general, low-grade lesions have a prominent cystic component and abundant well-differentiated mucous cells with little cytologic atypia and low mitotic activity. High-grade lesions are more solid with squamoid and intermediate cells predominating. They also have cytologic atypia, mitotic activity, necrosis, and infiltrative growth. A number of different grading schemes (well reviewed by Luna[39]) have been reported over the years. The most used grading system, originally designed by Auclair and colleagues,[41,43] uses a three-tiered score based on a number of histologic features (Table 88-5). The original grading system was initially criticized for a tendency to "under grade" the tumors when others demonstrated that a significant number of low-grade mucoepidermoid carcinomas developed progressive disease. The later modification by Brandwein and colleagues[42] (see Table 88-5) refined the grading system such that none of the tumors classified as low grade in their study went on to have progressive disease. Low-grade mucoepidermoid carcinoma, as strictly defined by their criteria, rarely ever metastasizes or results in death of the patient.[41-43]

In addition to grade, location of the primary tumor is potentially important in predicting clinical behavior. Several studies have shown that low-grade mucoepidermoid carcinomas of the submandibular gland recur and metastasize much more frequently than those of the parotid or minor salivary glands.[40,43] Whether or not this represents truly different biology, it merits the aggressive and thorough resection of any submandibular gland primary malignancy, especially for known mucoepidermoid carcinoma.[42]

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (ACC) is one of the more common,[3,32,33] and certainly more recognizable salivary gland tumors, being notorious for its infiltrative growth and slowly progressive behavior with recurrences and spread over a protracted course of many years.[46] These tumors essentially occur with an even distribution among all salivary gland

Table 88-5

Grading Systems for Mucoepidermoid Carcinoma

Parameter (Auclair et al, 1992)	Point Value
Cystic component <20%	+2
Neural invasion	+2
4+ mitoses/10 HPF	+3
Necrosis	+3
Anaplasia	+4
Grade	**Point Score**
Low (I)	0-4
Intermediate (II)	5-6
High (III)	7 or more
Parameter (Brandwein et al, 2001)	**Point Value**
Cystic component <25%	+2
Tumor front invades in small nests and islands	+2
Pronounced nuclear atypia	+2
Lymphatic and/or vascular invasion	+3
Neural invasion	+3
Necrosis	+3
4+ mitoses/10 HPF	+3
Bony invasion	+3
Grade	**Point Score**
Low (I)	0
Intermediate (II)	2-3
High (III)	4 or more

From Auclair PL, Goode RK, Ellis GL. Mucoepidermoid of intraoral salivary glands. *Cancer.* 1992;69:2021-2030; Brandwein MS, Ivanov K, Wallace DI, et al. Mucoepidermoid carcinoma. A clinicopathologic study of 80 cases with special reference to histological grading. *Am J Surg Pathol.* 2001;25(7):835-845.

sites,[32] although the total number of minor salivary gland cases outnumber those of major salivary glands when all sites are considered together.[47-50] These malignancies occur with an equal incidence in men and women over a wide age range with the peak incidence between 50 and 60 years of age.[47-49,51]

Grossly, ACCs are solid, light tan, firm and well-circumscribed, but unencapsulated, tumors. Microscopically, there are three growth patterns: tubular, cribriform, and solid. The tubular form consists of small tubules sitting in a pink, hyalinized, and hypocellular stroma (Fig. 88-4A). The solid variant has only rounded lobules of tumor cells with no, or almost no, glandlike structures and without a defined architecture (see Fig. 88-4B). The classic and most easily recognized pattern, though, is the cribriform ("Swiss cheese"-appearing) variant. Nests of cells are arranged around glandlike spaces that consist of PAS-positive blue or pink material (see Fig. 88-4C). The central spaces look like glandular lumina but are actually extracellular cavities containing reduplicated basement membrane (or ground substance) material[52,53] and myxoid material that is produced by the tumor cells, rather than true epithelial mucin. The cells in ACC are markedly basaloid in appearance, with little cytoplasm and round-to-oval nuclei that are dark and hyperchromatic without nucleoli (see Fig. 88-4A).[48] They are quite uniform in size and show little mitotic activity, except for the solid type, where mitotic activity can range from barely to extremely prominent. A rim of inconspicuous myoepithelial cells with clear cytoplasm is also usually present.[29,54]

FNA frequently yields characteristic results in ACC. Aspirates have tumor cells with scant cytoplasm and round, regular nuclei in sheets and clusters. These features by themselves are not characteristic and actually are so bland that they might suggest a benign lesion. However, the finding of well-defined, round "cylinders" and/or spheres of acellular stroma accompanying these cells is typical, but not 100% specific, for ACC. The cells often "cling" to these rounded structures (see Fig. 88-4D).

Histologic grading has yielded conflicting results in the literature for predicting prognosis. Clinical stage, on the other hand, holds a great deal of prognostic information and, as such, should be considered as much or more than grade in clinical management.[51] Also, as with mucoepidermoid carcinoma, ACC of the submandibular gland has a much more aggressive clinical course than ACC of other sites.[49,51] The most accurate prognostic information has been garnered when tumors are not only graded by the predominant pattern (tubular, cribriform, or solid) but are more specifically graded as follows: tubular with or without some cribriform areas (grade I), cribriform with no tubular areas and with less than 30% solid areas (grade II), and cribriform with greater than 30% solid areas (grade III).[49,55] A frequent histologic feature of ACC is perineural invasion, which is identified in approximately 70% to 75% of cases.[49,56] Although somewhat inconsistent in the literature, many have correlated this finding with a worse prognosis, particularly when involving a major nerve trunk.[46,57-59]

The diagnosis of ACC is generally straightforward from routine hematoxylin and eosin examination. However, it can be difficult on small biopsies because one may not be able to appreciate the architecture and infiltrative growth. The differential diagnosis includes other salivary gland neoplasms (such as polymorphous low-grade adenocarcinoma or pleomorphic adenoma), basaloid squamous cell carcinoma, or high-grade neuroendocrine carcinoma.[54] Although beyond the scope of this text, immunohistochemistry is not usually necessary but can occasionally be helpful in differentiating among these tumor types.[60,61]

Polymorphous Low-Grade Adenocarcinoma

Polymorphous low-grade adenocarcinoma (PLGA) is a unique, low-grade neoplasm first recognized as a distinct entity in the mid 1980s.[62] PLGAs arise almost exclusively from the minor salivary glands and, in most series, are the second most common minor salivary gland carcinoma.[35,46] The most common site for these neoplasms is the palate,[63] particularly at the junction of the hard and soft palates. Other sites include the upper lip, buccal mucosa, and posterior third of the tongue.[18] There are only rare reports of PLGA arising in major salivary glands.[30] PLGA is twice as common in women and tends to present in the fourth to sixth decades as a slow-growing mass that may have been present for years.[18,63] They are often asymptomatic.[18] On gross examination, they are circumscribed, unencapsulated, pale yellow or tan masses that range from 1 to 3 cm. Microscopically, the architectural features of this tumor are quite variable, as the name would suggest. They are well circumscribed but unencapsulated and may appear as solid nests in lobules, cribriform glandlike structures, or ductlike arrangements. A common appearance within the tumor is concentric whorling of the nests around each other in a single-file arrangement. This has been termed the "eye of the storm" pattern (Fig. 88-5A). Stromal hyalinization with a slate-gray coloration is also characteristic.[18] Tumor cells are quite regular with moderate eosinophilic cytoplasm and characteristic round-to-oval, extremely regular nuclei with open chromatin (see Fig. 88-5B). There is little mitotic activity and no necrosis. The periphery of the tumor shows markedly infiltrative growth and most cases have perineural invasion (see Fig. 88-5C).[18,63,64]

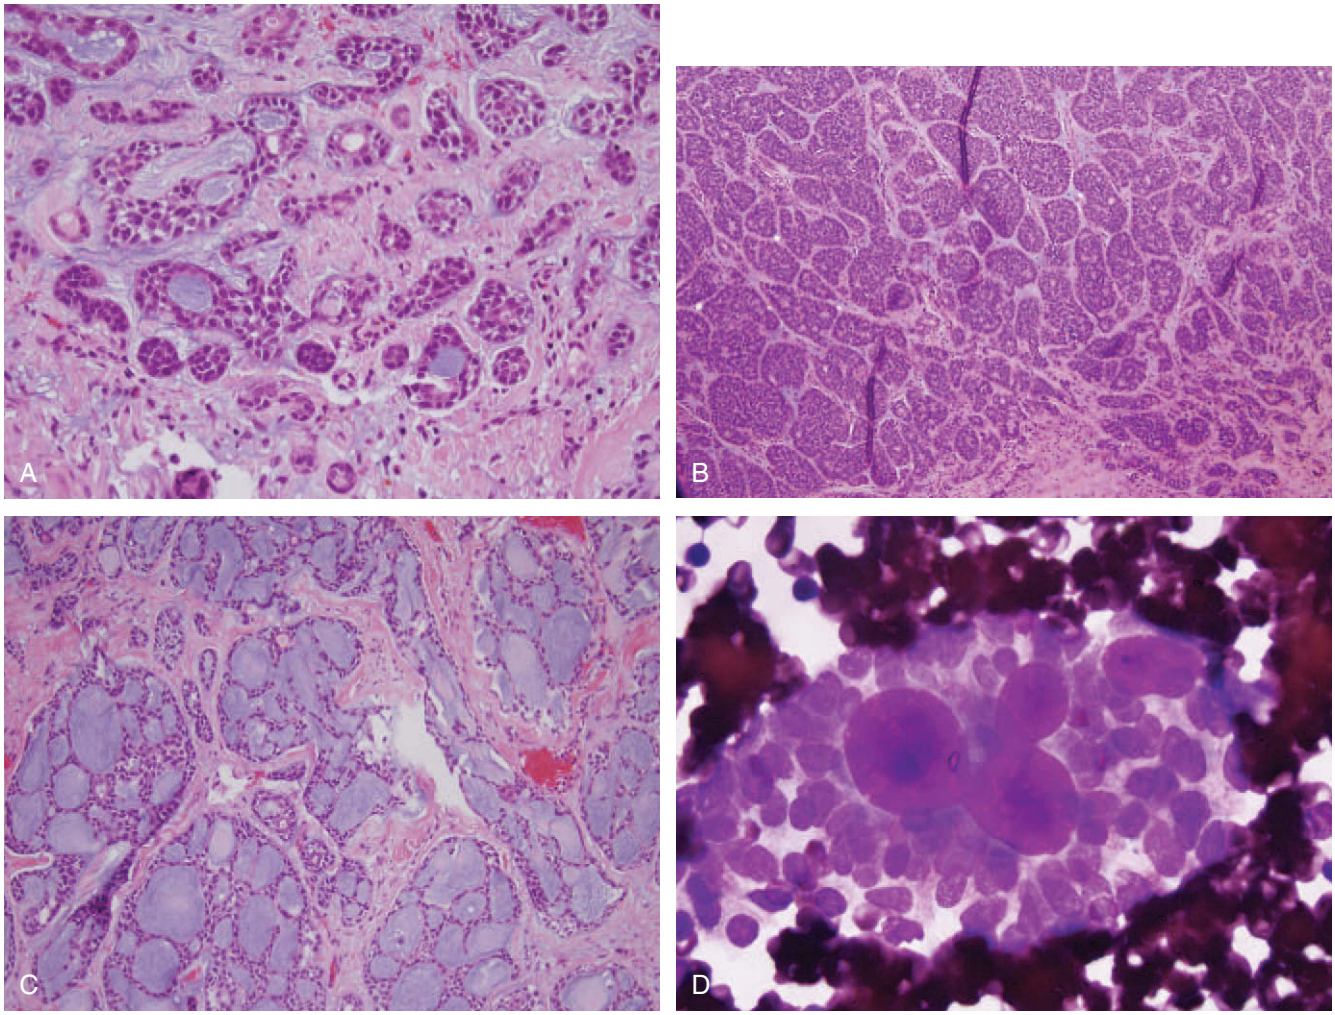

Figure 88-4. Adenoid cystic carcinoma (ACC). **A,** Tubular (grade I) ACC consisting of small tubule-like structures with an epithelial lining of small tumor cells with dark chromatin and with central blue ground substance-type material (400×). **B,** Solid (grade III) ACC with rounded nests of basaloid cells with very little to no ground substance or glandlike formations (100×). **C,** Cribriform (grade II) ACC with basaloid cells arranged around multiple rounded collections of central basophilic material giving a "Swiss-cheese" appearance (200×). **D,** Classic fine-needle aspiration finding of ACC with rounded "cylinders" of basement-membrane/ground substance material (Diff-Quik; 600×).

The differential diagnosis includes pleomorphic adenoma and ACC. The myxochondroid areas of pleomorphic adenoma are not seen in PLGA, and, although minor salivary gland pleomorphic adenomas are unencapsulated, they will not show the infiltrative growth pattern of PLGA and will not have perineural invasion. One particular immunostain that may be useful in difficult cases is worth mentioning here. Curiously, it has been recognized that almost all pleomorphic adenomas will be positive for glial fibrillary acidic protein (GFAP), whereas almost all PLGA are negative.[65-68] ACC is important to differentiate from PLGA. This is done primarily by cytologic features because ACCs have basaloid cells with dark chromatin and little cytoplasm, whereas PLGA cells have moderate eosinophilic cytoplasm and nuclei with open chromatin.

PLGA is a low-grade malignancy, and histologic grading is not applicable. Conservative resection is the treatment of choice. Local recurrence occurs in 10% to 15% of patients.[18,63,69] Because lymph node metastases are distinctly uncommon (literature rates of around 10% or less), neck dissection is only recommended with significant clinical adenopathy or needle-proven metastasis. This likely overestimates the occurrence, however. With strict histologic criteria for PLGA, nodal metastases are extremely rare.[18] Distant metastases are equally as uncommon,[70] and patients have an excellent long-term prognosis.[18,63,69] In fact, few patients have been documented to die from this tumor and only after prolonged periods.[18,63]

Acinic Cell Carcinoma

Acinic cell carcinoma, as the name implies, is a tumor with cells showing differentiation toward cells of the normal salivary gland acini (see Fig. 88-2). However, these tumors also show evidence of ductal and myoepithelial differentiation, an important feature to keep in mind. They are uncommon, comprising 1% to 3% of all tumors and approximately 10% of all malignant ones.[3,32,33,71] More than 90% occur in the parotid,[72,73] with the rest scattered among minor salivary gland sites and rarely the submandibular gland.[71,74] Occurring over a wide age range from children to the elderly, they are relatively evenly distributed in the second through seventh decades[75] with a peak in the third decade.[73] Of note, these tumors are the second most common childhood salivary gland malignancy. They present as a slowly growing mass, which is only occasionally painful and rarely associated with a facial palsy.[71,73]

Grossly, acinic cell carcinoma presents as a single, usually circumscribed, rubbery, solid mass with up to one third showing cystic degeneration.[75] Microscopically, they are highly variable, a feature of these tumors that has always led to angst in the diagnosing pathologist. The four principal histologic patterns are solid/lobular, microcystic, papillary-cystic, and follicular. Small tumors can be easily missed because the acinar cells are so well differentiated that they blend into the surrounding normal gland. Two features are classic, however. The first is the characteristic acinic cell, which has blue cytoplasm with abundant serous-type granules and a small, round, eccentrically placed nucleus (Fig. 88-6A).

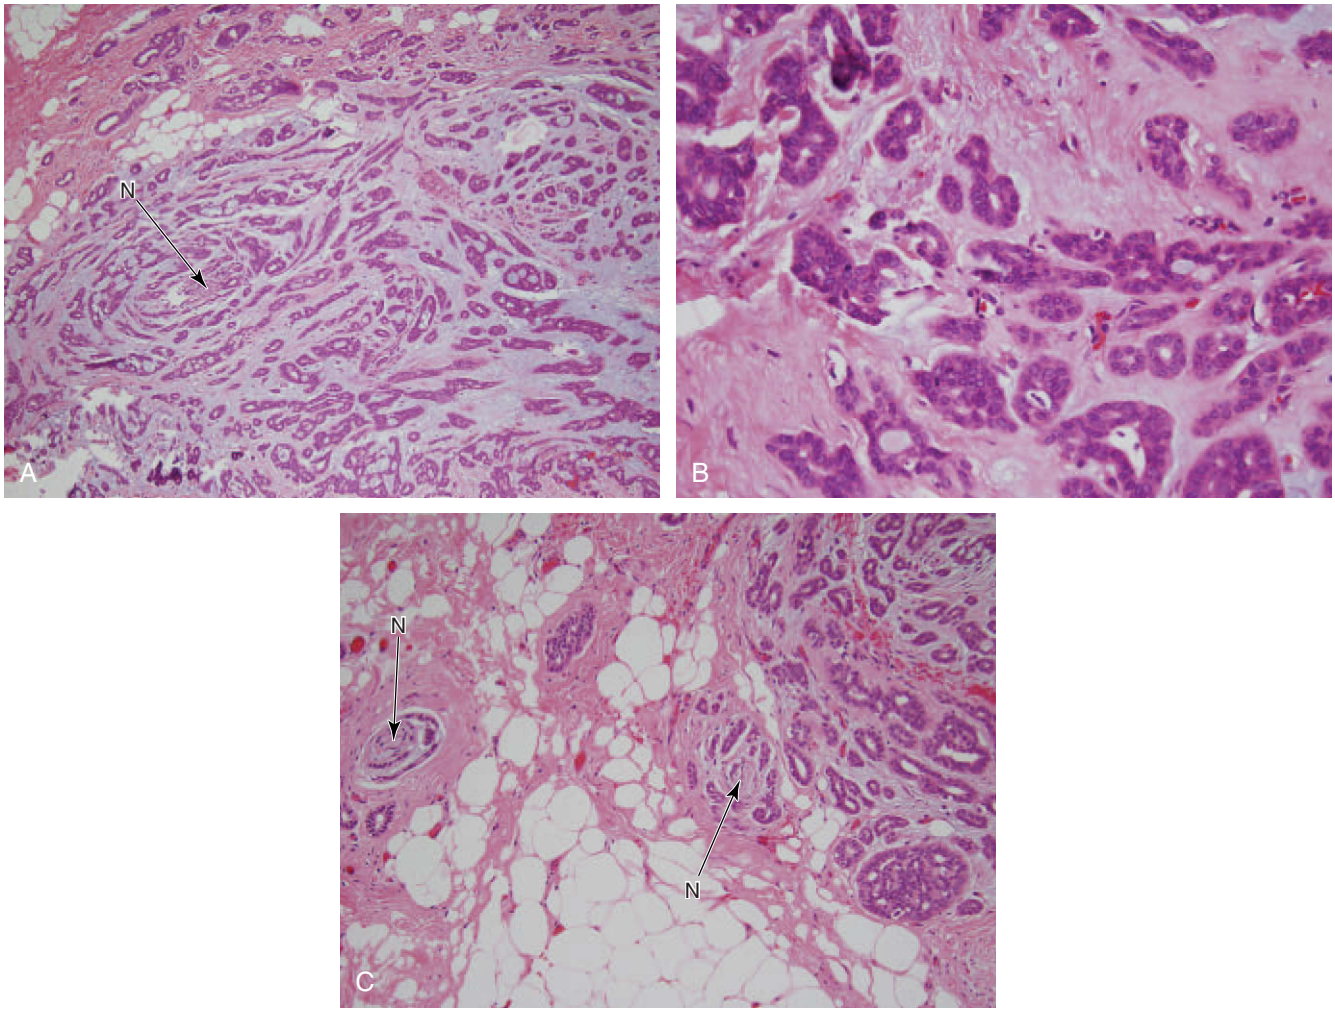

Figure 88-5. Polymorphous low-grade adenocarcinoma (PLGA). **A,** Hard palate PLGA showing an unencapsulated tumor with variable-sized tumor nests, different growth patterns from trabecular to tubular to cribriform, and infiltrating a myxoid and hyalinized stroma and growing around nerves *(N; arrow)* (100×). **B,** PLGA tumor cells with modest pink cytoplasm and oval nuclei with no significant variability in size or shape (400×). **C,** PLGA with infiltration of fat and foci of perineural invasion (200×).

PAS stains will be strongly positive in these cells. A number of other cell types are seen including pink, clear, and vacuolated cells, such that most tumors are a mixture of different cell types (see Fig. 88-6A). The second classic feature is a dense lymphoid infiltrate with germinal centers (see Fig. 88-6B). The periphery of the tumors may or may not be infiltrative but are often "pushing" in nature (see Fig. 88-6C). Although one would assume that lack of an infiltrative border might signal a benign or low-grade lesion, there is no benign equivalent for this lesion (i.e., there is no known benign acinic cell neoplasm). "Dedifferentiation" has been described in a small subset of acinic cell carcinomas. This consists of tumors with areas of classic, "conventional" acinic cell carcinoma and an intermixed undifferentiated carcinoma in sheets with large, pleomorphic cells, brisk mitotic activity, and often necrosis.[76-78]

The differential diagnosis includes normal parotid gland; however, acinic cell carcinoma will not have the exquisitely lobular architecture or the presence of ducts that normal salivary gland tissue will always have. For the pink and clear cell types, tumors such as oncocytic carcinoma or clear cell carcinoma not otherwise specified (NOS) must be considered, and the papillary variant of acinic cell carcinoma must be differentiated from cystadenocarcinoma. The finding of focal cells with blue, serous-type, cytoplasmic granules will confirm the diagnosis of acinic cell carcinoma. Immunohistochemistry has no significant utility in narrowing the differential diagnosis.

FNA biopsy of acinic cell carcinoma is fraught with difficulty because of the resemblance to normal tissue.[27] The diagnosis rests on finding a cellular specimen with sheets and clusters of large acinar cells with abundant granular cytoplasm and central round, regular nuclei. One should not see normal ductal epithelial cells or significant amounts of adipose tissue (both of these latter findings are from normal salivary gland tissue), but there is often a prominent background component of lymphocytes.

Surgical resection with negative margins is the most important therapy. These tumors will recur in approximately one third of cases.[71,73] Although classically regarded as low-grade malignancies, 10% to 15% of these tumors will metastasize locally to regional lymph nodes or distantly to the lung and bones. Acinic cell carcinomas are also notorious for recurrence and spread years beyond the primary presentation and for a protracted clinical course such that survival curves do not flatten out until after a decade.[79] Survival is approximately 80% at 5 years and 70% at 10 years.[71,75,79] Grading of these tumors has not correlated well with behavior, and there is not good agreement on histologic features within the proposed grading systems. Very bland, low-grade-appearing tumors can metastasize almost as frequently as tumors with more aggressive features. However, "dedifferentiation" (where there is a mixture of typical acinic cell carcinoma with a much higher-grade carcinoma) has consistently been associated with a poor outcome.[76-78]

Malignant Mixed Tumors

"Malignant mixed tumor" is the broad term that is used to encompass three different salivary gland malignancies: true malignant mixed tumor

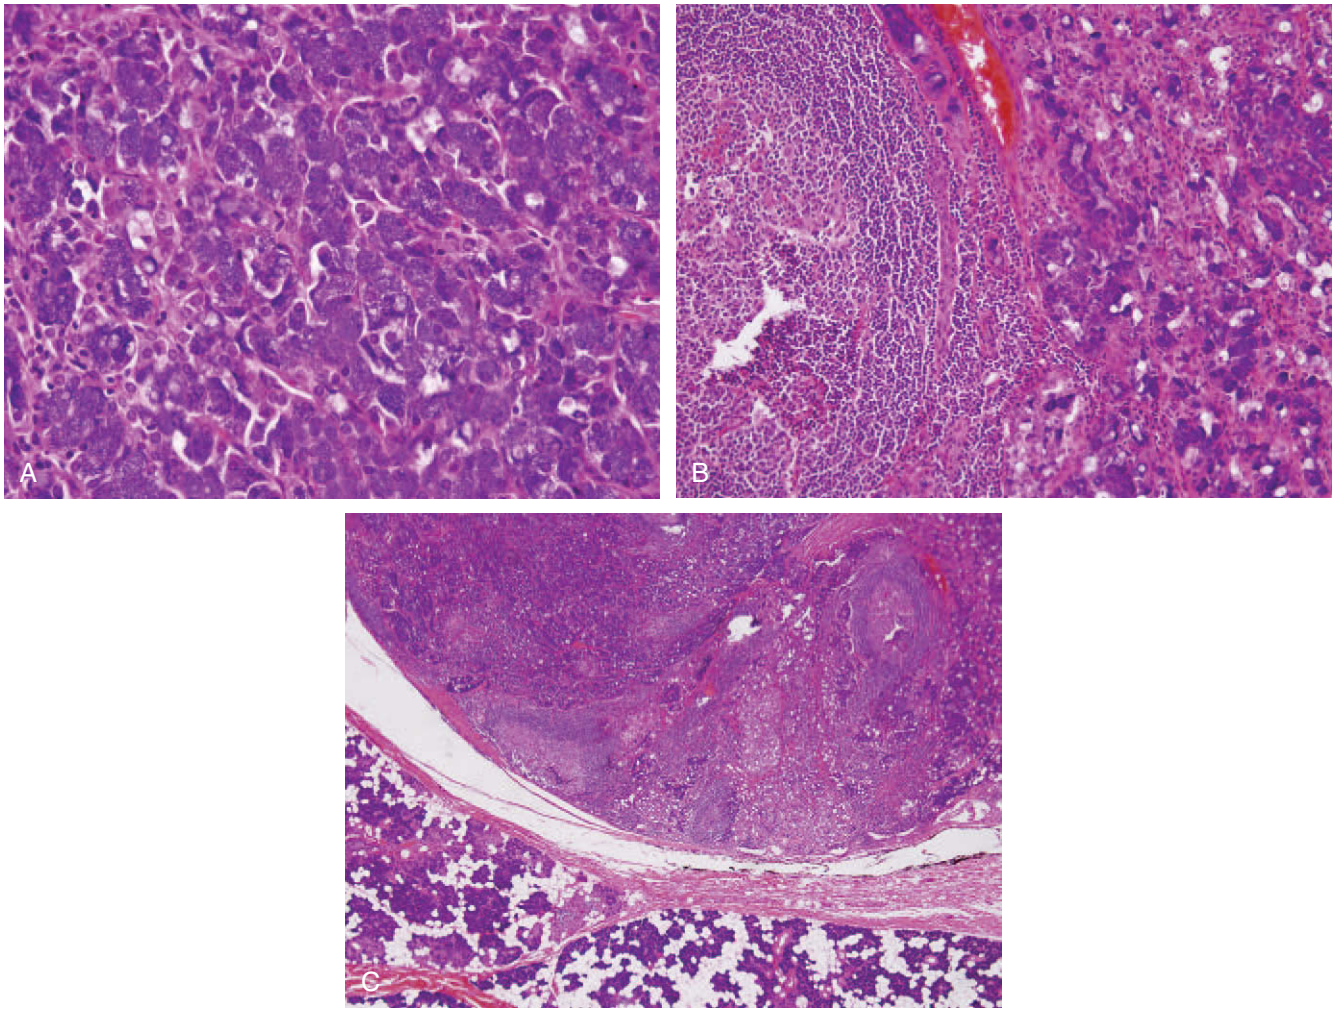

Figure 88-6. Acinic cell carcinoma. **A,** Typical acinic cell carcinoma with round cells having abundant granular, blue cytoplasm (400×). **B,** Dense lymphoid infiltrate (left side) in and around the tumor (200×). **C,** Acinic cell carcinoma with pushing border with adjacent normal salivary gland tissue (100×).

(or carcinosarcoma), carcinoma ex pleomorphic adenoma, and metastasizing mixed tumor. As a group, these account for approximately 3% to 5% of all salivary gland malignancies,[3,32] and carcinoma ex pleomorphic adenoma is by far the most common of these.

True Salivary Gland Malignant Mixed Tumor (or Carcinosarcoma)

True salivary gland malignant mixed tumor (or carcinosarcoma) is a malignant neoplasm that consists of distinct carcinomatous and sarcomatous components. These tumors are rare,[46] comprising approximately 1% of all salivary gland malignancies.[32,35] The mean age of presentation is 58 years. Two thirds of cases arise in the parotid gland, approximately 15% in the submandibular gland, and 15% in the palate.[80-84] Grossly, the findings are not distinct. The mass may be circumscribed or ill defined. It is commonly firm and tan-white with hemorrhage and necrosis and, on occasion, grittiness or calcification. Microscopically, there is an intimate admixture of the two components (carcinoma and sarcoma), but the amounts of each can vary widely. The carcinoma component can have any type of differentiation but typically takes the form of high-grade salivary duct carcinoma or undifferentiated carcinoma (Fig. 88-7A).[80] The sarcomatous component is usually a chondrosarcoma (see Fig. 88-7B) or osteosarcoma,[80] but fibrosarcoma, leiomyosarcoma,[83] or even liposarcoma[85] is possible. Treatment consists of wide local excision combined with radiotherapy. The tumors are aggressive with up to two thirds of patients dying of either local recurrence or, commonly, distant metastasis to the lungs or bone, usually within a period of 30 months.[80]

Carcinoma ex Pleomorphic Adenoma

Carcinoma ex pleomorphic adenoma is defined as a pleomorphic adenoma (or mixed tumor) in which, or with which, a carcinoma is present. It accounts for more than 95% of malignant mixed tumors but is still relatively uncommon. The critical thing to remember is that this term encompasses a heterogeneous group of tumors because the carcinoma component can be of any form, from very low grade to the highest grade types.[86] These tumors are most common in the parotid gland, followed by the submandibular gland, the minor salivary glands, and the sublingual gland.[87] Although there is a wide age range, most patients are in their sixth and seventh decades, approximately 1 decade later than the peak age for pleomorphic adenomas. The classic history is a patient with a longstanding mass that suddenly undergoes rapid growth over a period of several months.[87,88]

Grossly, these tumors can reach up to 25 cm and the average is more than twice that for pleomorphic adenomas.[86] They usually consist of a tan-yellow, firm mass with ill-defined, infiltrative borders, and there may be a component of nodular, translucent blue or gray tumor representing the preexisting pleomorphic adenoma.[88] Microscopically, the proportions of the two components vary quite a bit from tumor to tumor. The pleomorphic adenoma component has typical features with myxoid, blue stromal areas, a variable proliferation of epithelial elements, including ductlike structures and sheets of myoepithelial cells, and chondroid areas reminiscent of cartilage (Fig. 88-8A). This may be replaced by scarring or be overgrown by the malignant component. The malignant component is often distinguished by its collagenous stromal hyalinization (see Fig. 88-8B). It most commonly takes the form of

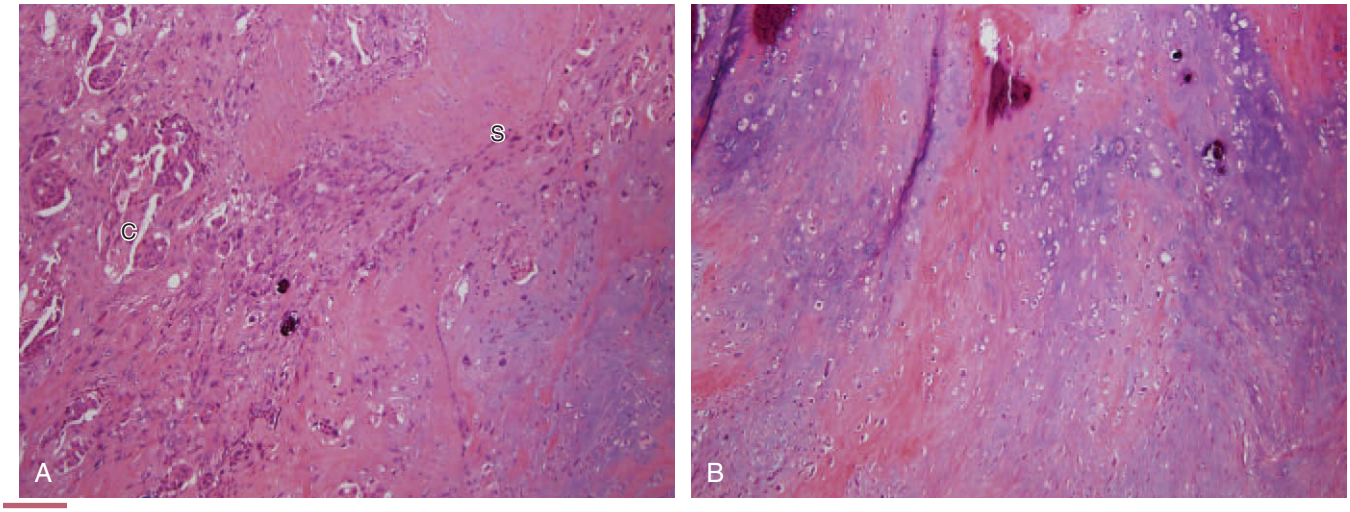

Figure 88-7. True malignant mixed tumor (carcinosarcoma). **A,** Biphasic tumor with a mixture of nests of poorly differentiated carcinoma *(C)* and a malignant spindle cell sarcoma in a myxoid stroma *(S)* (100×). **B,** Other areas of the same tumor show differentiation into chondrosarcoma with cells sitting in lacunae and a more blue, chondroid stroma (100×).

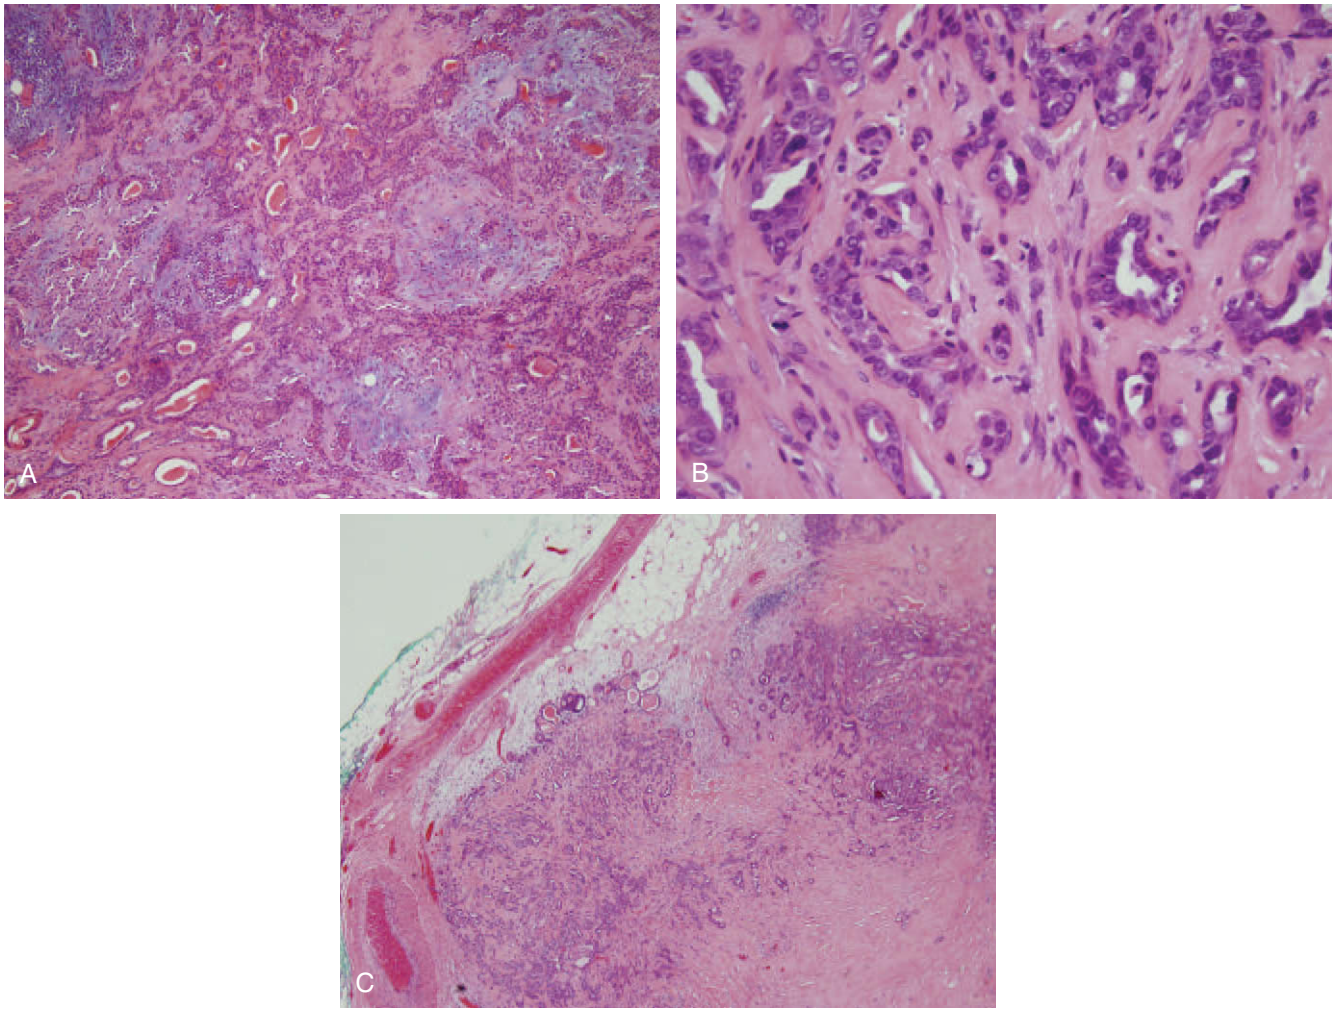

Figure 88-8. Carcinoma ex pleomorphic adenoma. **A,** Areas of otherwise typical pleomorphic adenoma in a carcinoma ex pleomorphic adenoma (200×). **B,** Another area showing nests of tubules of very atypical cells with nuclear pleomorphism, as well as mitotic activity. The cells sit in a hyalinized, pink stroma (400×). **C,** Carcinoma areas of a tumor that approach the periphery of the lesion but do not penetrate beyond it (carcinoma in situ) (40×).

poorly differentiated adenocarcinoma NOS, salivary duct carcinoma, or undifferentiated carcinoma.[88] However, essentially any form of carcinoma can be found. As one can imagine, the prognosis and management are highly dependent on the type of carcinoma.[86]

The extent of invasion is a critical histologic feature for prognostication.[86,88-92] The malignant component should be classified as noninvasive (intracapsular), minimally invasive (≤1.5 mm beyond the capsule), or invasive (>1.5 mm). For those tumors where there is no invasion beyond the capsule/rounded edge of the tumor (so-called carcinoma ex pleomorphic adenoma "in-situ") (see Fig. 88-8C) or where there is less than 1.5 mm invasion beyond it, there is essentially no risk of recurrence or metastasis from a completely resected tumor such that the behavior approaches that of benign pleomorphic adenoma.[92] For invasive tumors, those with high-grade features do poorly, and those that are widely invasive have a survival ranging from 26% to 65% at 5 years and 0% to 38% at 20 years.[86,88,89] Wide resection with lymph node dissection and radiation therapy is the treatment of choice for widely invasive tumors or obvious cervical lymph node metastases.

Metastasizing Mixed Tumor/Pleomorphic Adenoma

This is the least common form of malignant mixed tumor. These are tumors having the exact, bland morphology of a pleomorphic adenoma with a mixture of myoepithelial and ductlike epithelial elements and myxoid and/or chondroid surrounding matrix (see Fig. 88-8A). They show no significant cytologic atypia or mitotic activity, but they metastasize either to local lymph nodes (30%) or to distant sites including bone (50%) and lung (30%).[93-95] Often, there is a prior protracted clinical course with recurrences at the primary site.[96] The mean time between presentation of the primary tumor and detection of metastatic disease is 12 years.[96] Although rare, metastasizing mixed tumor serves as an important reminder to treat pleomorphic adenomas properly at the time of initial therapy.

Salivary Duct Carcinoma

Salivary duct carcinoma is a relatively recently described tumor that was separated from the generic category of salivary adenocarcinoma.[97] It is one of the most aggressive primary salivary gland tumors and has a similar histologic appearance to high-grade ductal carcinoma of the breast.[97-99] It accounts for less than 10% of salivary gland tumors. Males are more commonly affected at a rate of 4:1.[98,100-105] Patients generally present in the sixth decade with a rapidly growing parotid mass; a significant minority have facial nerve involvement and occasional facial skin ulceration.[105] Between 70% and 90% of cases arise in the parotid, with the remaining few occurring in the submandibular gland and oral minor salivary glands.[98,101,104-106] Grossly, these tumors are ill defined, solid and white, with hemorrhage, necrosis, and occasionally cystic areas.[101,105] Infiltration of the surrounding tissue is usually quite obvious. Histologically, most salivary duct carcinomas have a large and prominent ductal carcinoma in-situ component with a cribriform pattern[101] similar to what is seen in breast ductal carcinomas (Fig. 88-9A). This

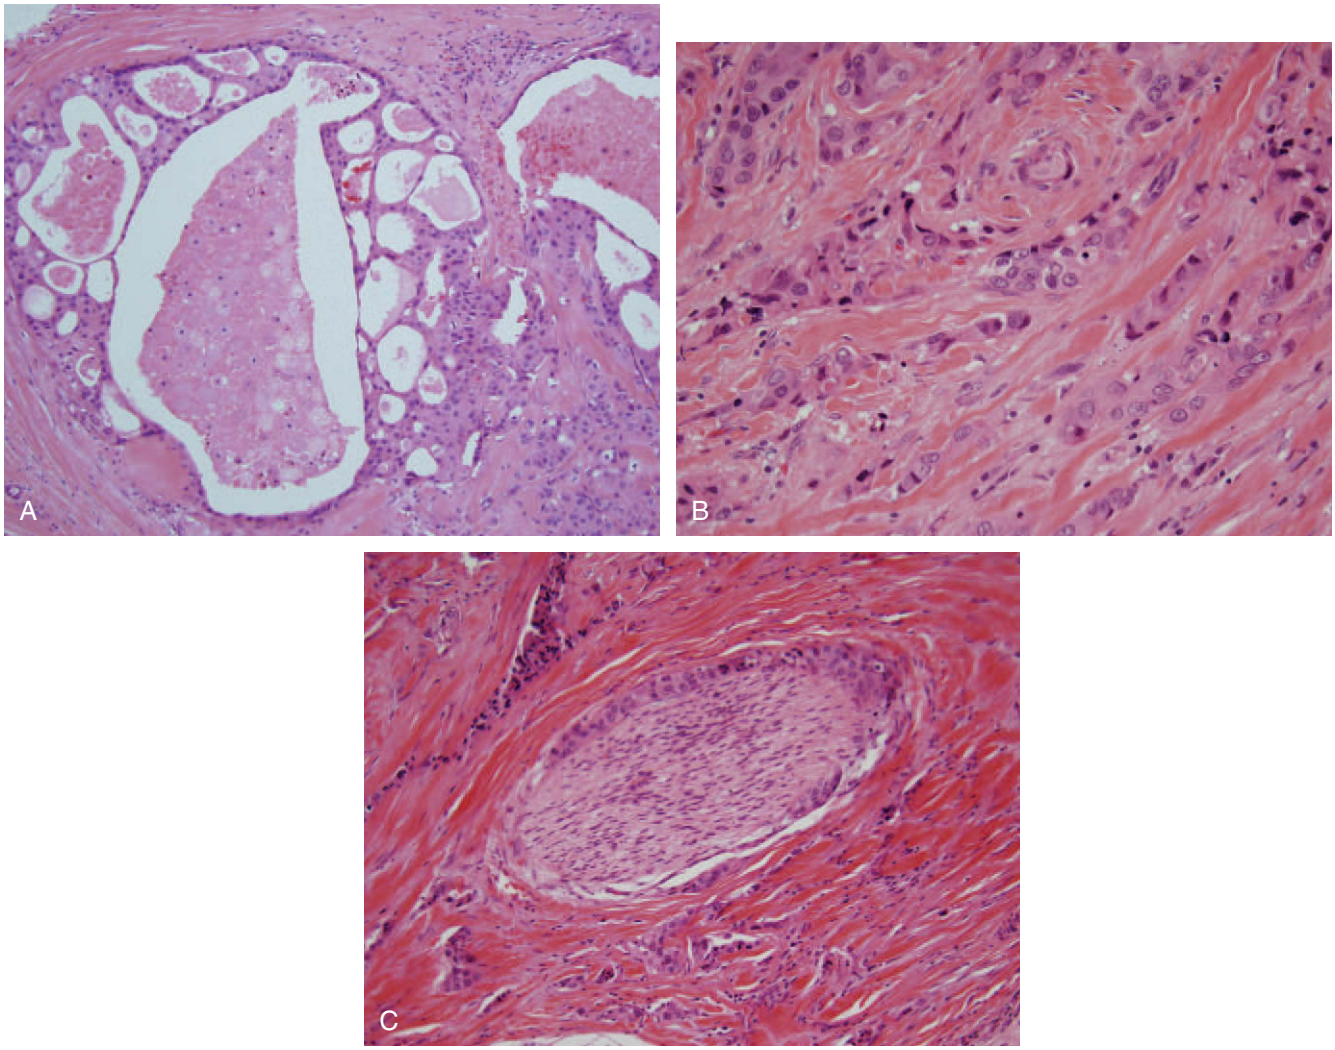

Figure 88-9. Salivary duct carcinoma (SDC). **A,** SDC showing cribriform carcinoma in situ in a large duct with large tumor cells with abundant pink cytoplasm (100×). **B,** Invasive component of SDC showing small nests and single cells with pink cytoplasm and large nuclei with pleomorphism and nucleoli (400×). **C,** Perineural invasion in SDC (200×).

is the classic histologic finding. There is often central comedo-type necrosis. The invasive component consists of small nests, cords, and single large cells with abundant pink cytoplasm and large, round nuclei with vesicular chromatin and prominent nucleoli (see Fig. 88-9B).[101,105] There is marked tissue infiltration with stromal desmoplasia and brisk mitotic activity. Vascular and perineural invasion (see Fig. 88-9C) are common.[101,105,106] Immunohistochemistry is not particularly useful for diagnosis, but salivary duct carcinomas are positive for low- and high-molecular-weight cytokeratins, carcinoembryogenic antigen (CEA), androgen receptors, and, in a significant minority, Her2/neu,[99,107,108] with distinct membrane staining for the latter. A minority of the tumors have actual amplification of the Her2/neu gene. Unlike the histologically similar breast carcinoma, almost all salivary duct carcinomas are negative for estrogen and progesterone receptors.[99] The differential diagnosis includes metastatic breast carcinoma, poorly differentiated squamous cell carcinoma, and mucoepidermoid carcinoma. Intraductal cribriform carcinoma is the most important feature that argues for a diagnosis of primary salivary duct carcinoma and rules out these other possible lesions.

Salivary duct carcinoma is high grade by definition. It is the most aggressive salivary gland carcinoma with 30% to 40% of patients developing local recurrence and between 50% and 75% developing distant metastases and dying of their disease, most within 4 years of diagnosis.[101,104,105] Wide local excision with neck dissection and postoperative radiotherapy is the treatment of choice.

Primary Squamous Cell Carcinoma

Squamous cell carcinomas are only rarely primary in the salivary gland, representing less than 1% of all malignancies in this site.[109] Metastases to intraparotid lymph nodes from primary skin cancers of the head and neck (particularly of the scalp, ear, and face) are much more common, as is direct invasion from adjacent tissues. Most patients are in their sixth through eighth decades, and sometimes there is a history of prior radiation therapy. By definition, the diagnosis of primary squamous cell carcinoma is restricted to the major salivary glands because those arising in the minor salivary glands cannot be distinguished from primary squamous carcinoma of the surrounding mucosa. Of these, 80% to 90% arise in the parotid gland, and 10% to 20% in the submandibular gland.[109,110] These tumors typically are high stage at the time of diagnosis.

Grossly, they appear as a firm, white, infiltrative, and nonencapsulated mass. Microscopically, they are identical to squamous cell carcinomas of the upper aerodigestive tract, although they tend to be better differentiated (most are moderately to well differentiated with abundant keratinization).[109-112] There is usually prominent desmoplasia and perineural invasion, with extension of the tumor into periglandular soft tissue.[109-112]

Primary squamous cell carcinomas are aggressive tumors, with a 5-year survival of approximately 20% to 50%.[112] Histologic tumor grade does not correlate well with behavior. Treatment involves radical surgery, neck dissection, and radiotherapy.

Primary Small Cell Carcinoma

Small cell carcinoma (or high-grade neuroendocrine carcinoma) can occur as a primary tumor in the salivary glands, but this is quite uncommon, representing approximately 2% of salivary gland malignancies.[113,114] The majority occur in major salivary glands, particularly the parotid.[113,114] They present as a painless mass of several months, typically in patients in their sixth and seventh decades, many with associated cervical lymphadenopathy and/or facial nerve palsy.

Grossly, they are not distinct, being poorly circumscribed, infiltrative masses that are white or tan with frequent necrosis.[114] Microscopically, they consist of large sheets or trabeculae of "small blue cells" (having moderate-sized nuclei and minimal cytoplasm). The nuclei characteristically have a punctate, granular ("salt and pepper") chromatin without nucleoli.[113,114] There is nuclear molding where nuclei look pressed against each other due to the minimal amount of cytoplasm (Fig. 88-10A). There is brisk mitotic activity, frequent apoptosis, and often areas of necrosis.

Immunohistochemistry shows staining for neuroendocrine markers such as synaptophysin, chromogranin-A, and CD56 (N-CAM).[113] There is typically punctate or "dotlike" staining for pan-cytokeratin. In addition, specific cytokeratin staining patterns have been described including positive staining for cytokeratin 20 (see Fig. 88-10B) and absence of staining for cytokeratins 34βE12 and 5/6.[61]

The differential diagnosis includes the solid variant of ACC and poorly differentiated squamous cell carcinoma, both of which can be ruled out by neuroendocrine marker staining (synaptophysin, chromogranin-A, neural cell adhesion molecule or N-CAM). Importantly, for both the pathologist and clinician, one must rule out metastases from primary lung small cell carcinoma or skin Merkel's cell carcinoma. Lung primary tumors should be detectable clinically and also would show positive staining for TTF-1 and lack of staining for cytokeratin 20. Metastatic Merkel's cell carcinoma, on the other hand, is virtually indistinguishable from primary salivary small cell carcinoma[113,115,116]; thus clinical findings are critical for these diagnoses.

The prognosis for small cell carcinomas is always relatively poor. However, for primary salivary small cell carcinoma, it may be slightly better than for pulmonary small cell, with reported 5-year survival rates between 13% and 50% and an average across studies of approximately

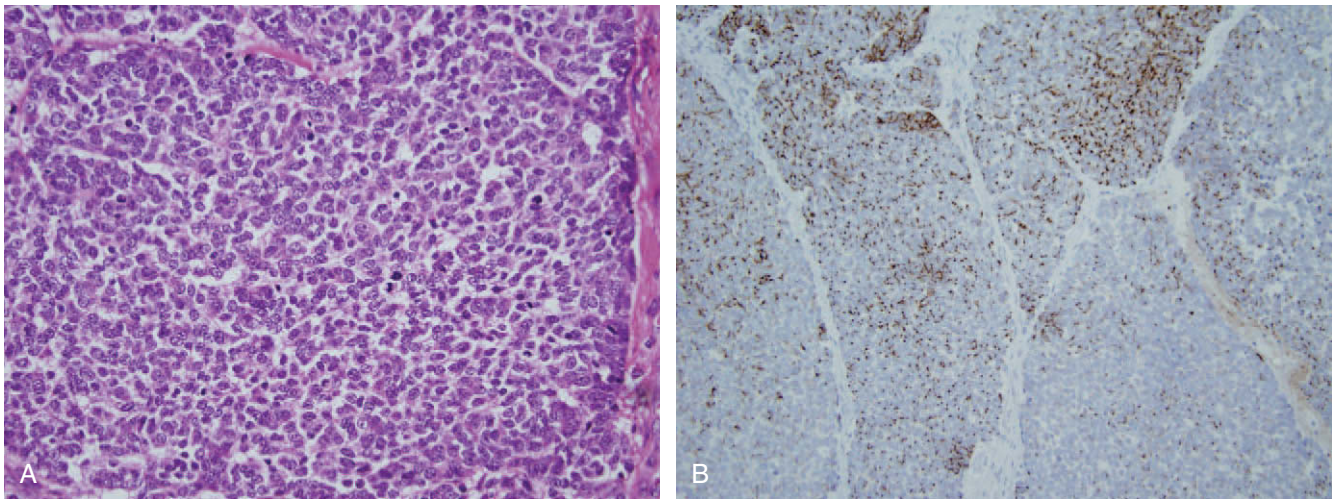

Figure 88-10. Small cell carcinoma. **A,** Typical small cell carcinoma with cells with granular, punctuate chromatin and only small amounts of cytoplasm (400×). **B,** Cytokeratin 20 staining in small cell carcinoma of the salivary gland. Keratin stains in this tumor typically have a dotlike or punctuate staining pattern as is seen here (200×).

30% to 40%.[113,114,117] Lymph node metastases are frequent, as are distant metastases to the liver, lung, brain, and bones.[113]

Other Malignant Tumors

The salivary glands are the primary site of a large number of additional (and heterogeneous) tumors, only a few of which are discussed here. Most of the additional carcinomas are low grade, with relatively frequent local recurrences, but uncommon or rare metastases. These include epithelial-myoepithelial carcinoma,[118] clear cell carcinoma, cystadenocarcinoma, basal cell adenocarcinoma,[119] and myoepithelial carcinoma,[19,20] although the latter is somewhat more aggressive.

Epithelial-myoepithelial carcinomas are low-grade tumors that account for approximately 0.5% to 1% of salivary gland neoplasms. They occur in older patients, predominantly in the parotid gland (80%), and rarely in the larynx or paranasal sinuses. Microscopically, they are usually well demarcated and partially encapsulated, but there is invasion of tumor into adjacent parenchyma. The classic appearance is of duct structures with eosinophilic lining cells (the "epithelial" component), immediately overlying and surrounded by prominent clear cells (the "myoepithelial" component). Classically, the stroma between the tumor nests is pink and hyalinized, and the individual tumor cells are bland with minimal mitotic activity. By immunohistochemistry, the ductal lining cells are positive for low-molecular-weight cytokeratins, and the outer cells are positive for calponin, smooth muscle actin, and p63 (all markers of myoepithelial differentiation). The differential diagnosis includes pleomorphic adenoma and the tubular variant (grade I) of ACC. Epithelial-myoepithelial carcinoma is a moderately aggressive tumor with a recurrence rate of 40%, metastases to lymph nodes, lung, and liver of 15%, and a survival of 80% at 5 years. Treatment is wide local excision with or without radiotherapy.

Basal cell adenocarcinoma is the rare, malignant counterpart to basal cell adenoma. The vast majority arises in the parotid gland[119] and has a typical morphology consisting of basaloid cells in tubular, trabecular, solid, or membranous patterns. The latter is called such because of the thick, hyalinized collagen that surrounds the nests of tumor cells. It is usually a low-grade carcinoma with histology showing a modest degree of cellular atypia and can only really be diagnosed as malignant on the basis of infiltrative growth into the surrounding tissue with or without perineural invasion.[119] Local recurrence occurs in a minority of patients, and metastases to regional lymph nodes in less than 10%. The prognosis is thus excellent.

Myoepithelial carcinoma is the uncommon malignant counterpart to myoepithelioma. About 60% occur in the parotid gland.[19] Like myoepitheliomas, these can have diverse cell types including epithelioid, spindled, plasmacytoid or hyaline, or clear cell. They have infiltrative peripheral borders, and one third of patients will die of metastatic disease, one third will have multiple local recurrences, and one third will be disease free after resection.

Adenocarcinoma NOS is a "salivary gland carcinoma that exhibits ductal differentiation but otherwise lacks the histologic features that define other types of salivary carcinoma." This should not be considered a "wastebasket" diagnosis; it is simply a gland-forming carcinoma outside of the usual "herd." There is an almost equal distribution between major and minor salivary glands.[120,121] They can range from bland but infiltrative tumors to pleomorphic and high-grade tumors with necrosis and wide infiltration. Thus given this heterogeneity, tumors should be graded into three categories: low grade, intermediate grade, and high grade.[121] In general, the prognosis for adenocarcinoma NOS is worse than for most other salivary gland carcinoma with reported 10-year survival rates of 55%[120] and 15-year survival rates of 41%, 34%, and 28% for low, intermediate, and high grade tumors, respectively.[121]

Metastases

Metastasis to the salivary glands or, more commonly, to intraglandular or periglandular lymph nodes, is a frequent occurrence. The parotid gland contains an average of 20 intraparenchymal lymph nodes, whereas the submandibular and sublingual glands do not contain any.[122] For this reason, the vast majority of metastases to the parotid gland are to intraparenchymal lymph nodes and thus from head and neck primaries,[123,124] while approximately 85% of those to the submandibular gland are from non–head and neck primaries. The parotid lymph nodes drain from the scalp, face, and ear skin and from the external auditory canal and tympanic membrane, so skin tumors such as squamous cell carcinoma and melanoma account for approximately 80% to 90% of metastases.[123,124] Merkel's cell carcinomas also spread to this area but are uncommon. The remaining are from non–head and neck primary tumors, most commonly kidney, lung, and breast carcinomas.[125] The opposite distribution is seen for the submandibular gland, with 85% of metastases coming from infraclavicular primary tumors, most commonly breast, kidney, and lung carcinomas (small cell carcinoma of the lung in particular).[125-128]

The histologic features of the tumors are identical to what is seen in the primary site lesions. In the parotid gland, when the tumors are smaller, they are seen as being "tropic" to the lymph nodes, a feature particularly important in identifying them as metastatic disease to the gland rather than emanating from it. They are focused within the lymph nodes, but they almost always have extracapsular extension with growth of the tumor into the adjacent normal salivary gland tissue. Many of them will obliterate the nodal tissue altogether (termed "soft tissue metastasis") and so may just be seen as a nodule within the salivary tissue composed entirely of tumor. In these cases the pathologist cannot always be sure that the tumor is not a primary lesion. This is particularly important for two tumors: squamous cell carcinoma and high-grade neuroendocrine carcinoma. Both are rare primary lesions. For squamous cell carcinoma, the distinction between primary versus metastasis must be clinically ascertained. For high-grade neuroendocrine carcinomas, the differential diagnosis includes primary parotid gland small cell carcinoma, metastatic pulmonary small cell carcinoma, and Merkel's cell carcinoma from the skin. As discussed earlier, immunohistochemistry can be helpful in this distinction.

Lymphoma

Primary lymphoma of the major salivary glands comprises approximately 5% of extranodal lymphomas and approximately 2% of all salivary gland tumors.[129,130] It is defined as arising in the salivary gland when there is absence of lymphoma in a noncontiguous site based on clinical evaluation.

Primary non-Hodgkin's lymphoma (NHL) occurs either as a de novo process unrelated to other diseases or as a secondary process related to lymphoepithelial sialadenitis. De novo NHL can be large B-cell lymphoma (35%), follicular lymphoma (35%), or another low-grade lymphoma (30%), with half of the latter being secondary forms of the extranodal marginal zone B cell lymphomas of the mucosa-associated lymphoid tissue (MALT) type or just MALT lymphomas.[129,131] Most patients are older with the average age between 50 and 70[130] and present with a solitary, painless mass in de novo cases. In contrast, there is often a history of waxing and waning enlargement of several glands in the secondary forms.[132] Most cases of salivary gland Hodgkin's lymphoma occur in the parotid gland and probably just represent disease involvement of intraparotid lymph nodes.

Grossly, salivary glands involved with lymphoma usually have a tan-white to yellow-tan color and are diffusely and homogeneously involved (so-called "fish-flesh" appearance). The microscopic appearance depends a great deal on the type of lymphoma. Primary diffuse large B cell lymphoma consists of sheets of large lymphocytes diffusely effacing the normal gland and infiltrating (with little tissue reaction) into and around anything that is left (Fig. 88-11A). The cells have modest amounts of cytoplasm, round to oval nuclei with pale chromatin, one to three prominent nucleoli, and brisk mitotic activity (see Fig. 88-11B). Other primary lymphomas will have a similar growth pattern but with different cells depending on the type. MALT lymphomas occur in the setting of lymphoepithelial sialadenitis, with this being prominent in the background. There is a somewhat heterogeneous infiltrate of B cells with sheets of medium-sized lymphocytes with abundant pale cytoplasm, uniform nuclei, and distinct cell membranes. These form "halos" around the epithelial cell nests and extend away from them in broad strands (see Fig. 88-11C).[129] There is also a mixture of small cleaved lymphocytes, plasma cells, and lymphoplasmacytic cells that have cytologic features of both of the former two cell types

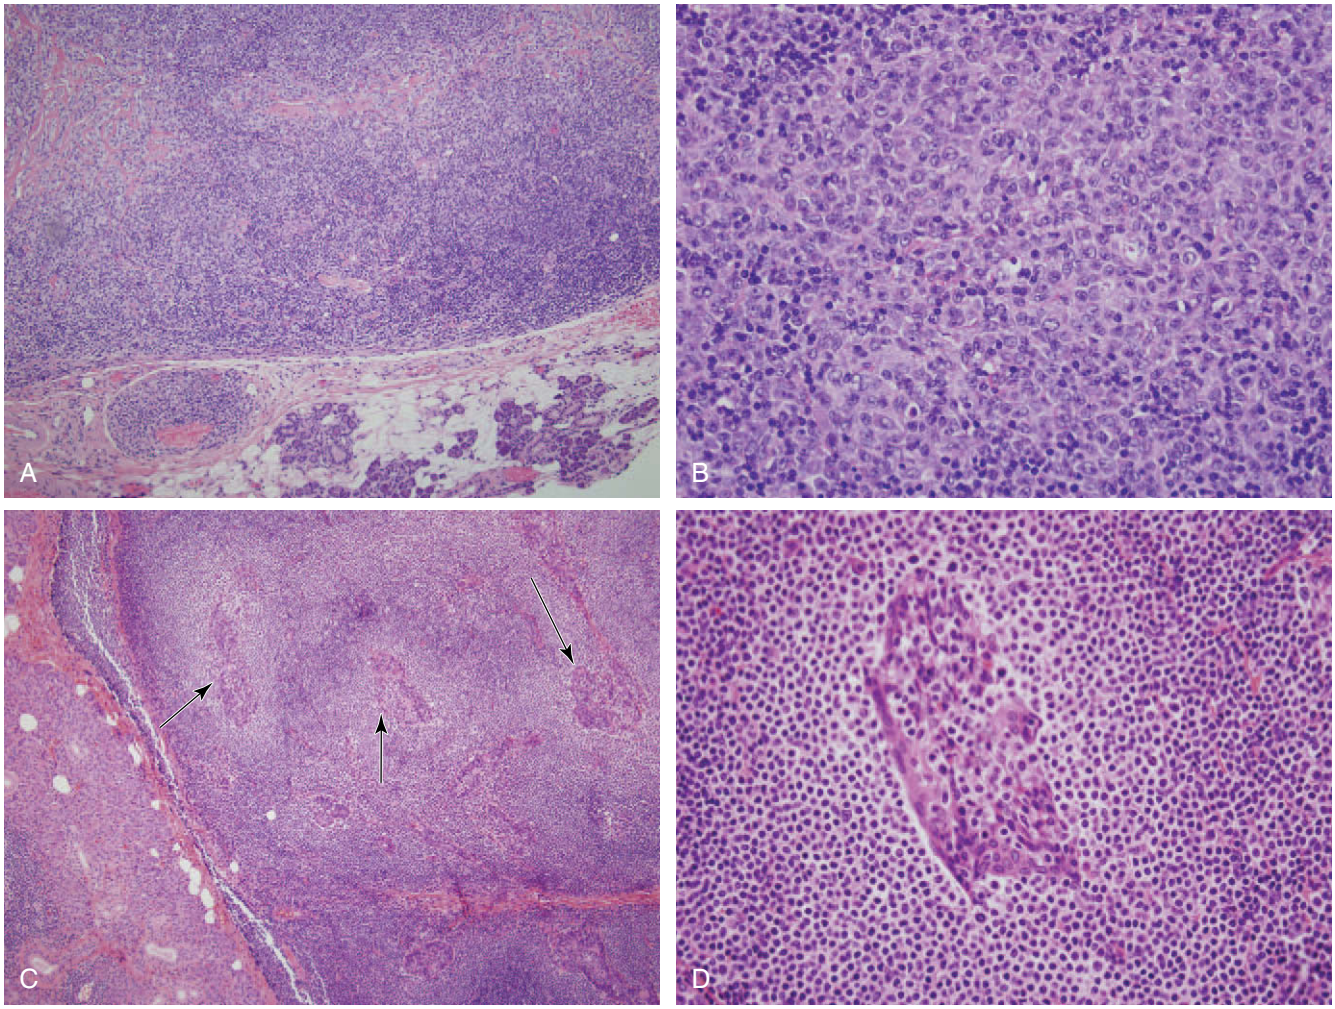

Figure 88-11. Salivary gland lymphoma. **A,** Large B-cell lymphoma growing as a sheet with infiltration of salivary gland tissue without any stromal reaction or fibrosis (100×). **B,** Cells of large B-cell lymphoma have modest amounts of pink cytoplasm and large nuclei with clumped chromatin and one to three prominent nucleoli (400×). **C,** Mucosa-associated lymphoid tissue lymphoma showing diffuse involvement of the parotid gland by sheets of lymphocytes, which manifests as clearing around the epimyoepithelial islands *(arrows)* from the plasmacytoid B cells with clear cytoplasm that are accumulating there (40×). **D,** Central epimyoepithelial island (residual inflamed duct epithelium) surrounded by sheets of plasmacytoid lymphocytes with round nuclei, clumped chromatin, and pale to clear cytoplasm (400×).

(see Fig. 88-11D). The lymphoma cells markedly expand the spaces between the epithelial islands and also infiltrate into these islands along with the non-neoplastic lymphocytes from the background non-neoplastic sialadenitis. FNA is quite useful for diagnosing salivary gland lymphoma with high sensitivity and specificity for the diagnosis, as well as for providing material for flow cytometry.[133]

Immunohistochemistry and molecular studies are critical to the diagnoses, particularly for MALT lymphoma, where the differential diagnosis includes inflammatory, non-neoplastic sialadenitis. In these cases, clonal immunoglobulin rearrangements by PCR combined with the light microscopic features makes the diagnosis of malignancy—both features are necessary.

Pediatric Salivary Gland Tumors

Pediatric salivary gland tumors are uncommon. The most common is the hemangioma followed by a long list of tumors, most of which are identical to adult forms such as mucoepidermoid carcinoma, acinic cell carcinoma, and ACC. Two are unique to the congenital period and bear mentioning here. Sialoblastoma is an extremely rare, potentially aggressive neoplasm that recapitulates the embryonic stage of salivary gland development and has been suggested to represent retained blastomatous cells. Local recurrence is relatively common, occurring in up to 30% of cases. Metastasis, however, is uncommon, and only one fatality has been reported. Salivary gland anlage tumor is a peculiar and unique hamartoma occurring in the perinatal period as a pedunculated mass attached to the wall of the nasopharynx.[134] These may obstruct the airway and, in this way, be clinically significant. Interestingly, they may be incidentally suctioned out of the newborn's airway or spontaneously expelled.

Prognostic Variables

The overall 10-year, disease-free survival rate of patients with salivary gland malignancies ranges from 47% to 74%.[4,32,135-139] Multiple studies have examined clinical, histologic, and molecular variables that may predict clinical outcome and survival. There is considerable variability in the results, and this is probably due to the fact that most of these studies have been of small numbers of patients. In addition, these data have been obtained entirely from retrospective studies; no prospective studies examining potentially prognostic variables have been reported. Nevertheless, some common themes can be gleaned from the available data (Table 88-6).

Clinical Variables

In general, several clinical characteristics of the primary tumor have been proposed to be predictive of outcome. Not surprisingly, advanced tumor (T) stage, which takes into account both tumor size and the

Table 88-6

Factors Associated with Occult Metastases and/or Poor Prognosis

Feature	Comment
Primary tumor site	Tumors of the submandibular and sublingual glands tend to metastasize more frequently than those of the parotid glands
Primary tumor size and extraglandular extension	T3 and T4 tumors tend to have a higher incidence of occult metastases and worse outcome
Age	Patients older than 50 years of age have a worse outcome
Presenting symptoms	Facial nerve paralysis and pain are associated with lymph node metastases
Histologic type/grade	Neoplasms with higher incidence of nodal metastases and poorer prognosis include high-grade mucoepidermoid carcinoma, undifferentiated carcinoma, squamous cell carcinoma, adenocarcinoma NOS, and salivary duct carcinoma
Local tissue invasion	Perineural invasion and local bone invasion portend a shorter disease-free and overall survival
Positive resection margins	Associated with worse locoregional control and lower survival rate
High Ki-67 and low p27 expression	Associated with shorter disease-free survival in adenoid cystic and mucoepidermoid carcinoma
HER-2/*neu* overexpression	Associated with shorter disease-free survival in salivary duct carcinoma and mucoepidermoid carcinoma

presence of extraglandular involvement, has been widely reported as being associated with the presence of metastases and poor survival.[138-146] The site of the primary tumor has also been proposed to have an association with poor survival. In particular, patients with malignant tumors of the submandibular and sublingual glands tend to have more frequent metastases and a worse outcome than patients with malignant tumors of the parotid gland.[1,145,147,148] The relationship between the presence of metastatic disease and the tumor's site and stage is reviewed later in "Surgery."

The age and gender of the patient have also been suggested to be associated with prognosis. In a multivariate analysis by Terhaard and colleagues,[138] more advanced age was an independent predictor of poor overall survival and male gender was associated with a 17% increased risk for distant metastasis. Hocwald and colleagues[142] also observed that patients older than the age of 50 years presented with more aggressive tumors and that men presented with higher T-stage tumors than women (53% vs. 26%). Similarly, O'Brien and colleagues[149] reported that patients 60 years or older had a significantly shorter survival but they did not find gender to be a significant factor for prognosis.

Presenting symptoms have also been examined for prognostic value. Specifically, facial nerve dysfunction and pain have been suggested in multiple studies to portend a poor prognosis. In the study by Terhaard and colleagues,[138] complete facial paralysis was an independent predictor of failed regional control, with a relative risk of 6.1. Likewise, in a multivariate analysis by North and colleagues,[150] facial nerve paresis was predictive of poor outcome with a 3-year, relapse-free survival of only 13%. In addition to its association with poor survival, facial nerve involvement has also been shown to be highly predictive of lymph node metastases.[146,151] Pain is another symptom that has been found to be associated with a poor clinical outcome in some studies[152]; however, due in part to its subjective measurement, pain has not always been highly predictive.[138]

Histologic Variables

It is generally accepted that certain histologic types of salivary gland malignancies can be placed into groups with either a favorable or poor clinical outcome. For example, patients with acinic cell carcinoma, low-grade mucoepidermoid carcinoma, PLGA, and basal cell adenocarcinoma tend to have better locoregional control rates and better disease-free survival following therapy compared with patients with other histologic types. Patients with high-grade mucoepidermoid carcinoma, undifferentiated carcinoma, squamous cell carcinoma, adenocarcinoma NOS, and salivary duct carcinoma tend to have a high incidence of nodal metastases and a poorer prognosis.

Tumor grade has been associated with prognosis for certain histologic types. Because the grading of salivary gland malignancies is subjective with variation between institutions and because there are many different histologic types, each with its own grading criteria, this variable has had mixed utility in predicting biologic behavior. Certain histologic types are inherently "high grade" or "low grade." For instance, salivary duct carcinoma is a "high-grade" cancer, whereas polymorphous low-grade adenocarcinoma, as the name implies, is "low grade" (for more discussion, see the specific tumor types in "Histopathology" earlier). It is important to note that "high grade" is used in the literature to refer to both high-grade histologic types (generally referred to as "*histologic grade*") and high-grade subtypes of certain specific malignancies, namely mucoepidermoid carcinoma and adenocarcinoma NOS.

When referring to *histologic grade,* high-grade malignant tumors are considered to include squamous cell carcinoma, undifferentiated carcinoma, high-grade mucoepidermoid carcinoma, and carcinoma ex-pleomorphic adenoma.[137,153] Low-grade malignancies include acinic cell carcinoma, low-grade mucoepidermoid carcinoma, low-grade adenocarcinoma (including basal cell and mucinous adenocarcinoma), and papillary cystadenocarcinoma. Intermediate-grade malignancies include adenoid cystic carcinoma and epithelial-myoepithelial carcinoma. In a multivariate analysis of 470 malignant tumors of the major salivary glands, Spiro and colleagues[137] found that histologic grade was an independent prognosticator of survival. This has been corroborated in another retrospective review by Chen and colleagues[139] of 207 patients with carcinomas of the major salivary glands that were treated with surgery alone. In this study, high histologic grade was also found to be an independent predictor of locoregional recurrence. Results such as these have led to the suggested role for postoperative radiation therapy in the treatment of high-grade salivary gland malignancies (discussed in "Radiation Therapy" later).

When considering a single histologic type of salivary gland malignancy, subtype grading of some malignancies is also highly correlated with clinical outcome. In general, grading seems to be most useful in predicting the clinical behavior of mucoepidermoid carcinoma and adenocarcinoma NOS.[1,154-157] In a review of 108 patients with mucoepidermoid carcinoma of the major and minor salivary glands by Guzzo and colleagues,[158] high-grade tumors were associated with a significantly reduced, 5-year, disease-free survival rate (22.5%) compared with low-grade tumors (97%, P <0.0001). Similarly, a recent review of 60 patients with mucoepidermoid carcinoma by Aro and colleagues[159] found patients with low-grade tumors to have a significantly better disease-free survival than those with either intermediate-grade or high-grade tumors. There was, however, no difference in disease-free survival between the intermediate and high-grade groups. Although adenoid cystic carcinoma has one of the more varied histologic phenotypes (tubular vs. cribriform vs. solid) allowing for easier grading classifica-

tion, there is controversy over the utility of tumor grade in predicting the prognosis of patients with this malignancy. Some have strongly advocated its utility,[160,161] but studies by Spiro and colleagues[1,47,51] did not find grade to be predictive of clinical outcome in patients with this tumor type.

Local tissue invasion, regardless of histologic type, appears to portend a worse clinical outcome. In particular, perineural invasion and spread has been found to be a predictor of a more aggressive tumor behavior. In the multivariate analysis by Terhaard and colleagues,[138] perineural invasion was an independent prognostic factor associated with the risk of distant metastasis (relative risk = 2.2). Similarly, Hocwald and colleagues[142] found perineural invasion to be an independent predictor of shorter disease-free survival in their multivariate analysis. Local bone invasion has also been shown to be independently associated with an increased risk of local recurrence and shorter overall survival.[138,162]

Not surprisingly, the presence of positive surgical margins has also been shown to be associated with a worse clinical outcome. Therkildsen and colleagues[135] found this variable to be independently associated with both worse locoregional control and lower survival rates. Terhaard and colleagues[138] also found the status of the resection margin to be independently associated with poor local control with a relative risk of 3.5. These observations are consistent with other studies in which poor local control was associated with positive resection margins.[56,163,164]

Molecular Markers

Markers of cell proliferation have been suggested to be prognostic for patients with salivary gland malignancy. Early studies looking at the proliferative fraction in salivary gland tumors using flow cytometry noted an association between proliferative activity and survival.[165] Two of the more commonly studied markers of proliferation are proliferating cell nuclear antigen (PCNA) and Ki-67. The expression of both PCNA and Ki-67 by tumor cells has been shown to correlate with higher-tumor grade and shorter, disease-free survival of patients with ACC and mucoepidermoid carcinoma.[166-171] In general Ki-67 is considered to be a more accurate marker of proliferating cells because it has a shorter half-life and hence more specific staining. In mucoepidermoid carcinoma, investigators have found that tumors with high expression of Ki-67 and low expression of p27 (a cyclin dependent kinase inhibitor, the action of which slows cell cycle progression) have a worse prognosis.[172,173]

Another potential indicator of prognosis is a specific translocation, t(11;19), which brings together the MECT1 and MAML1 genes. This translocation has been identified in up to 70% of mucoepidermoid carcinomas.[174] Tumors with this translocation were found to be better differentiated and were shown to have a better prognosis. Although provocative, this has not garnered enough attention nor proven useful enough to be instituted in practice in the management of patients with these tumors. Whether or not it adds information beyond grade and clinical stage is unclear.

Another marker that has been investigated as a potential prognosticator is a receptor tyrosine kinase of the ErbB family. HER-2/*neu* (also known as *ErbB2*) is frequently expressed in a subset of salivary gland malignancies, salivary duct carcinoma in particular, and expression correlates significantly with prognosis.[104,175] This oncogene is also overexpressed in approximately one third of mucoepidermoid carcinomas, and its overexpression appears to correlate with poorer prognosis.[176,177] Prognostic data such as these have become the basis for targeted therapy against HER-2/*neu*, as discussed later in "Chemotherapy."

Treatment

For the most part, salivary gland malignancies are primarily treated surgically when resectable. The following section is a general discussion of the surgical and nonsurgical management of salivary gland malignancies. Some aspects of the treatment for specific malignancies were also included earlier in "Histopathology".

Surgery

Parotidectomy

The parotid gland can be divided into a superficial (or lateral) and a deep "lobe" by a sagittal plane defined by branches of the facial nerve. The main trunk of the facial nerve, after it exits the stylomastoid foramen, gives off branches to the posterior belly of the digastric muscle and then runs through the parenchyma of the parotid tissue. It divides into an upper temporofacial division and a lower cervicofacial division at the pes anserinus, which is located approximately 1 to 2 cm from the stylomastoid foramen. The upper division divides further into the temporal, zygomatic, and buccal branches (Fig. 88-12). The lower division divides into the marginal mandibular and cervical branches. It is important to note that the parotid gland is actually unilobular and that the plane created by the fanning branches of the facial nerve is not a true anatomic separation of the gland into two discrete lobes. That being said, it is useful from a surgical standpoint to use the facial nerve as a plane of dissection.

When treating a salivary gland malignancy located in the lateral lobe, a superficial parotidectomy is generally adequate treatment for a small low-grade tumor that is well encapsulated, such as an acinic cell carcinoma. If the tumor is larger, a partial deep lobe resection can be performed to include an adequate margin of normal parotid tissue. A

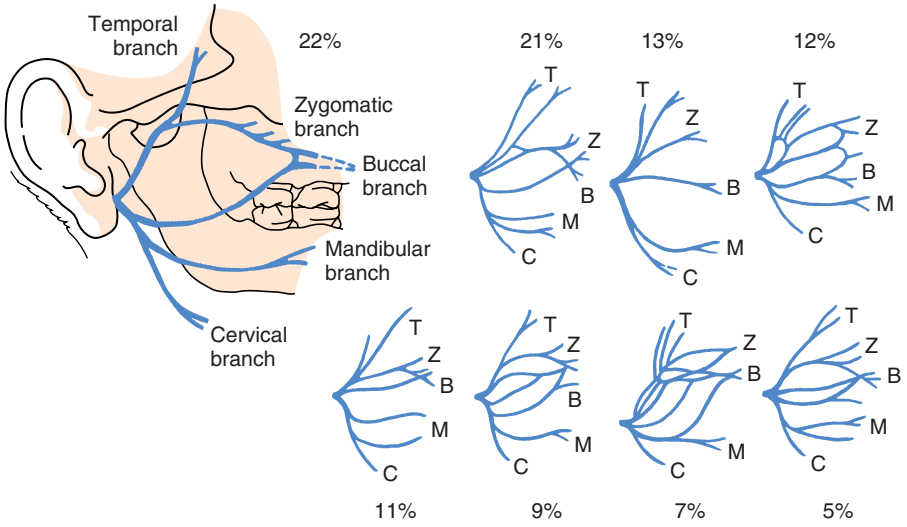

Figure 88-12. Branches of the facial nerve. Variations of the facial nerve branching in the parotid gland are depicted. *(Adapted from Davis RA, Anson BJ, Budinger JM, et al. Surgical anatomy of the facial nerve and parotid gland based upon a study of 350 cervicofacial halves.* Surg Gynecol Obstet. *1956;102:385-412).*

Figure 88-13. Modified Blair incision for parotidectomy operations.

total parotidectomy, removing all of the lateral and deep tissue, is indicated for (1) high-grade malignant tumors with a high risk for metastasis, (2) any parotid malignancy with an indication of having metastasized to intraglandular or cervical lymph nodes, and (3) any primary malignancy originating within the deep lobe itself.

When performing a parotidectomy, one begins by making a modified version of the Blair incision typically used in rhytidectomies (Fig. 88-13). It begins at the root of the helix and extends inferiorly in the preauricular crease, curving posteriorly just below the lobule and then extending inferiorly and anteriorly to lie in a skin crease approximately two fingerbreadths below the inferior border of the mandible at the level of the hyoid bone. The inferior part of the incision can be extended to provide exposure for a lymph node dissection should one be indicated. An anteriorly based skin flap is then elevated in the subcutaneous plan immediately over the superficial musculoaponeurotic system (SMAS) layer. The greater auricular nerve is identified and traced inferiorly. It is divided superiorly and reflected inferiorly, preserving as much length as possible in the event that the facial nerve is resected and a cable graft is required. The tail of the parotid is elevated off of the sternocleidomastoid muscle, and the posterior belly of the digastric muscle is identified. The parotid gland tissue is then elevated off of the anterior aspect of the tragal cartilage, and the dissection is carried into the deeper aspects of the gland. The main trunk of the facial nerve is identified approximately 1 cm medial to the tragal pointer (Fig. 88-14). The nerve exits the stylomastoid foramen immediately posterior to the styloid process and enters the parotid gland immediately anterior to the insertion of the digastric muscle into the mastoid tip. In this region the posterior auricular artery coming from the external carotid artery is typically encountered and should be ligated once the facial nerve is identified. The main trunk of the nerve is traced anteriorly to the pes anserinus, and the branches of the upper and lower divisions are then followed, separating the lateral lobe of the gland from the nerve. Deep to the lower branches of the facial nerve, the retromandibular (posterior facial) vein may be encountered and should be ligated if a deep lobe parotidectomy is to be performed. If the location of the tumor prevents the identification of the main trunk of the facial nerve, one can identify a distal branch and trace the branch in a retrograde fashion back to the main trunk. The marginal mandibular branch is often used for this and can be found by following the posterior facial vein superiorly (Fig. 88-15).

While performing a deep lobe parotidectomy, multiple intraglandular and periglandular vessels will be encountered. Specifically, branches of the external carotid artery must be identified and controlled, taking great care to identify and preserve the internal carotid artery. The external carotid artery is found just superior to the digastric muscle, and it should be controlled and/or ligated just before it enters the parotid gland. As mentioned earlier, the retromandibular (posterior facial) vein will often also need to be ligated to obtain access to the

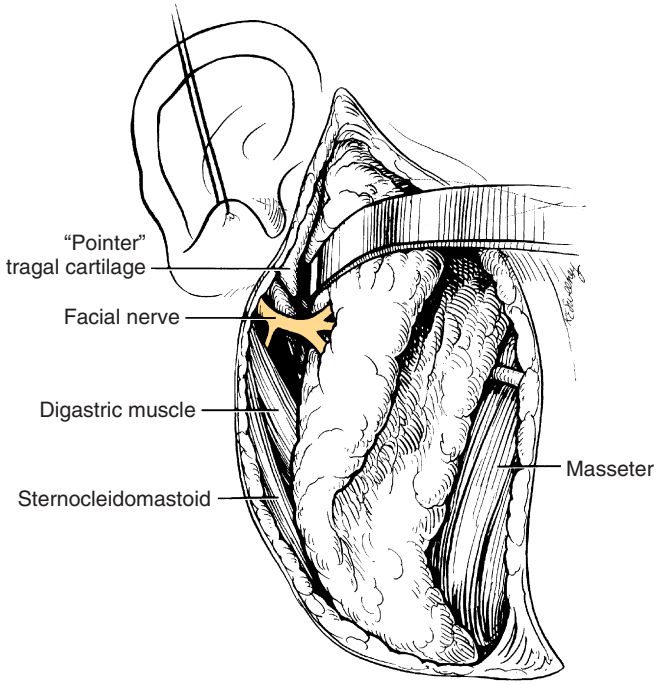

Figure 88-14. Identification of the main trunk of the facial nerve during a parotidectomy operation. The facial nerve exits the stylomastoid foramen and can be found approximately 1 cm medial and anteroinferior to the tragal pointer.

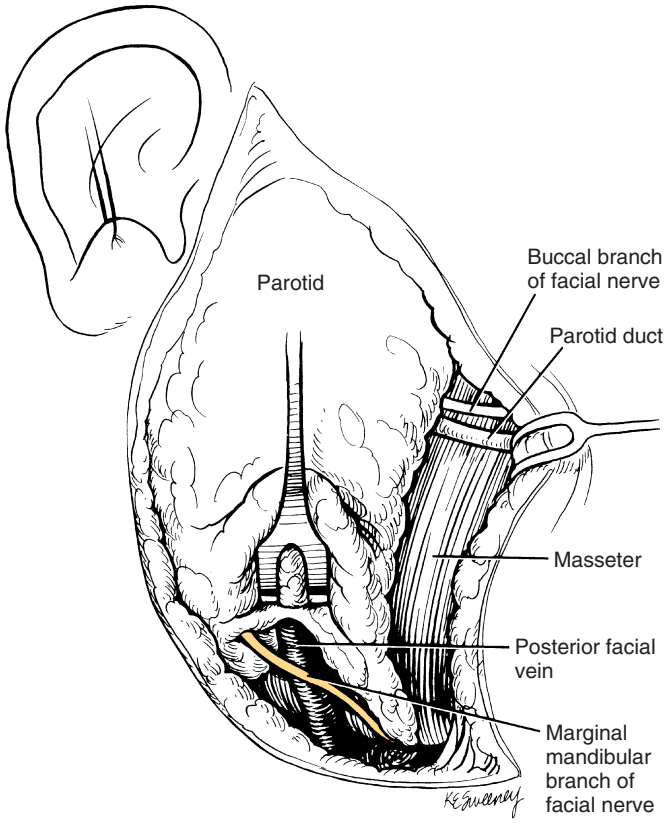

Figure 88-15. Identification of the marginal mandibular branch of the facial nerve. This branch can be found by carefully dissecting superiorly along the posterior facial vein. This can be useful when the location of the parotid tumor makes it difficult to identify the facial nerve at its main trunk. The marginal mandibular branch can be traced retrograde to the main trunk in these situations.

Figure 88-16. Dissection and removal of a deep lobe parotid tumor from the parapharyngeal space. The facial nerve has been dissected and mobilized over the tumor.

deep lobe. Once these vessels are controlled, the main trunk and branches of the facial nerve should be carefully elevated off of the deep lobe tumor (Fig. 88-16). Once this is accomplished, the gland can be dissected off of the deep musculature, mandible, and temporal bone. Intraglandular branches of the external carotid that will be encountered include the transverse facial artery and the internal maxillary artery. These should be ligated at the anterior aspect of the gland, at the posterior border of the mandibular ramus. If the tumor extends into the parapharyngeal space, it is dissected free using blunt dissection. Occasionally, the stylomandibular ligament will need to be divided so that the mandible can be retracted anteriorly to provide better access.

If the facial nerve is involved with tumor, it should be resected to negative margins. In general, if the preoperative facial nerve function is fully intact, the nerve is most likely not invaded, and all attempts should be made to preserve it. However, if the preoperative evaluation reveals a paretic or paralyzed facial nerve, it is likely invaded by the tumor and should be resected. The extent of the resection is dictated by intraoperative frozen section biopsies and should proceed until proximal and distal margins are deemed to be negative. This may require tracing the nerve into the mastoid region of the temporal bone by performing a mastoidectomy. The nerve is then reconstructed by primary neurorrhaphy or by placing an interposition graft, using either a segment of the greater auricular nerve or the sural nerve. Nerve mobilization after a mastoidectomy is often required in order to minimize tension on any reconstruction anastomosis. Facial nerve repair and facial paralysis rehabilitation is discussed in greater detail in another chapter within this textbook.

Advance parotid tumors may extend to adjacent structures including muscle (masseter, sternocleidomastoid, and pterygoid muscles), bone (mandible and mastoid tip), pharyngeal mucosa, and the overlying skin. In these situations the surgeon should be prepared to perform the type of operation that is necessary for complete extirpation of the tumor. This may require a partial mandibulectomy, a lateral or partial temporal bone resection, an extended resection of pharyngeal mucosa, or a resection of facial skin. Careful preoperative assessment of the extent of the tumor is essential to plan the extent of extirpation and reconstruction of the resulting defect.

Submandibular Gland Excision

For malignancies of the submandibular gland, excision of the gland along with the level Ib lymph node–bearing tissue is recommended. With the neck extended, a transverse incision is made approximately two fingerbreadths below the inferior border of the mandible within a neck skin crease, at the cranio-caudad level of the hyoid bone. This level is chosen to avoid injury to the marginal mandibular branch of the facial nerve. A superior skin flap is raised in the subplatysmal plane, looking for the nerve during this dissection. The nerve runs from the angle of the mandible, curving anteriorly and caudally to parallel the mandible. It passes over the posterior facial vein and curves cranially toward the commissure of the mouth. Once identified and isolated, the nerve is reflected superiorly to preserve it. The facial vein can be ligated, and the proximal stump can be retracted superiorly to help keep the nerve out of the field of active dissection.

The fatty lymph node–bearing tissue in level Ib is then separated from the inferior and medial aspect of the mandible. This is kept in continuity with the submandibular gland itself. The facial artery and vein are identified and ligated. Deep to the gland, the digastric muscle is identified and the dissection is carried anteriorly to the mylohyoid muscle. The mylohyoid muscle is retracted anteriorly, exposing the lingual nerve, the submandibular ganglion, and Wharton's duct. Deep to the duct and the anterior belly of the digastric muscle is the hypoglossal nerve, which should be identified and preserved unless grossly involved by the tumor. The submandibular ganglion and Wharton's duct are divided and ligated. Next, the specimen is separated from the digastric muscle. If a supraomohyoid neck dissection is planned, the digastric muscle fascia is separated from the muscle and the specimen is kept in continuity with levels II and III.

Sublingual Gland Excision

The pair of sublingual glands is located in the anterior floor of the mouth just deep to the mucosa. Treatment of sublingual gland malignancies involves a wide local excision and a level I neck dissection. In order to excise a tumor with an adequate margin, the excision often involves partial resection of adjacent structures, such as tongue musculature, mylohyoid muscle, mandible periosteum, mandibular bone, and lingual nerve. The excision is usually accomplished by a combined transoral and transcervical approach. For more advanced tumors, a lip-split incision and a posteriorly based cheek flap approach may be necessary to perform a composite resection that may include a marginal mandibulectomy, floor of mouth resection, and partial glossectomy. For tumors that have invaded the marrow space of the mandible, a segmental mandibulectomy may be required. Reconstruction of these defects may require a split-thickness skin graft, myocutaneous free or regional flap, and/or a free osteomyocutaneous free flap. The reconstruction of oral cavity defects following tumor extirpation is discussed in more detail in other portions of this textbook.

Minor Salivary Glands

The surgical management of minor salivary gland malignancies is dictated by the site of the tumor. The most frequent location is the palate, and in these situations, transoral and transfacial approaches are used in conjunction with partial or total maxillectomy for extensive lesions. Because minor salivary gland malignancies may arise in a wide variety of locations in addition to the palate (e.g., oropharynx, nasal cavities, paranasal sinuses, pharynx, larynx), the surgical approaches are not discussed here. Site-specific surgical approaches are discussed in detail in other chapters of this text.

Management of the N0 Neck

The decision of whether or not to treat a clinically N0 neck is controversial. Although some have advocated elective treatment of the neck in all patients with salivary gland malignancies, the majority have recommended that treatment of the neck be performed only in selected patients with tumors having poor prognostic features for metastasis (see Table 88-6).

The site of the primary tumor appears to be associated with the frequency of occult nodal involvement. Armstrong and colleagues[145] reviewed 474 cases of patients with major salivary gland malignancies

in order to define the indications for elective neck dissections. Of the cases, 407 (86%) had clinically N0 necks, and of these, an elective neck dissection was performed in 90 of the 407 (22%) patients. Occult metastases were discovered on histopathologic analysis in 34 of the 90 (38%) of the patients undergoing neck dissections. Albeit, these cases tended to be higher grade and more advanced. Tumors of the submandibular gland had a significantly higher incidence of occult metastasis to the cervical lymph nodes (21%) than those of the parotid gland (9%). These findings are corroborated by other studies. Spiro and colleagues[1] reviewed 2807 patients with salivary malignancies and also found that submandibular cancers had a higher incidence of lymph node metastases (28%) compared with parotid (18%) and minor salivary gland malignancies (15%). Yu and Ma[147] also found that submandibular and sublingual cancers tended to metastasize more frequently than cancers of other sites. Thus the site of the primary malignancy appears to be an important feature when considering treatment of the N0 neck.

The size of the primary tumor and the presence of extraglandular extension have also been correlated with risk of metastases. Armstrong and colleagues[145] demonstrated that tumors greater than or equal to 4 cm in size had a 20% risk of occult metastases compared with a 4% risk associated with smaller tumors ($P < 0.00001$). In a multivariate analysis of risk factors associated with occult metastases from parotid malignancies, Frankenthaler and colleagues[146] found that extraparotid tumor extension was among the most predictive variables. The T stage, which takes into account both the size of the primary and the presence of extraglandular extension, has been shown in multiple other studies to be associated with the risk of metastatic disease.[143,144] Thus results such as these have led to the suggestion that patients with high T stage (T3 and T4) tumors should undergo routine neck dissections even if they do not have clinical evidence of cervical lymph node metastases.

Other features that have been associated with a higher risk of occult metastases are the histologic type and grade of the primary tumor.[145-147,151,178-180] In general, histologic types considered to be at higher risk for occult nodal involvement include undifferentiated carcinoma, squamous cell carcinoma, high-grade mucoepidermoid carcinoma, adenocarcinoma NOS, carcinoma ex pleomorphic adenoma, and salivary duct carcinoma. Histologic types that have been deemed of lower risk include acinic cell carcinoma, adenoid cystic carcinoma, and low-grade mucoepidermoid carcinoma. The grade of the primary tumor has been reported to correlate with the incidence of occult nodal disease. Armstrong and colleagues[145] found that high-grade tumors had a 49% risk of occult metastases compared with a 7% risk for intermediate- and low-grade tumors. Similarly, Bhattacharyya and Fried[151] reported that high grading conferred a 1.99 odds ratio (95% CI 1.64 to 2.40) of having occult nodal involvement. These authors concluded that elective treatment of the neck is indicated in patients with high-grade histologic types such as adenocarcinoma and squamous cell carcinoma and high-grade subtypes such as high-grade mucoepidermoid carcinoma.

In sharp contrast to the authors of the studies cited earlier, Stennert and colleagues[143] found a much higher incidence of occult cervical lymph node metastases in all salivary gland malignancies, regardless of histologic type or tumor stage. As such, they have strongly advocated the elective treatment of the neck in all patients, raising controversy in the management of N0 necks. Their study of 160 consecutive patients was unique in that they treated all patients with an ipsilateral neck dissection in a nondiscriminatory manner. They found that of the 139 patients who were initially staged as having an N0 neck, 45% had occult metastases. The rates of occult metastases were particularly high for undifferentiated carcinoma (75%), squamous cell carcinoma (64%), and adenocarcinoma NOS (58%). These authors also found occult metastases to be surprisingly frequent in what has traditionally been considered "lower-risk" histologic types: acinic cell carcinoma (44%) and adenoid cystic carcinoma (36%). In addition, whereas occult metastases have most often been reported with larger tumors, Stennert and colleagues[143] found that even T1 and T2 lesions had frequent metastases (29% and 54%, respectively). From these data, the authors concluded that an ipsilateral neck dissection should be performed on all patients with salivary gland malignancies, regardless of histologic type or stage.

Another area of controversy has to do with how the neck should be treated once it has been actually decided to do so. Some have advocated the use of radiation therapy to treat an N0 neck because many of the features associated with occult disease are the same features that indicate the need for postoperative radiation of the primary site.[181] Others have advocated surgery in order to spare patients with pathologically N0 necks the morbidity of radiation and to obtain accurate staging of the disease. The arguments in favor of surgery also state that, in most cases, the exposure for the neck dissection is already established and/or partially completed during the resection of the primary tumor.

When a neck dissection is performed in a patient with a clinically N0 neck, a selective neck dissection is considered the treatment of choice. The levels of the neck to be dissected are determined by the site of the primary tumor. For parotid tumors, Armstrong and colleagues[145] demonstrated that 3 out of 30 patients (10%) had metastases in level I, 8 of 30 (27%) in level II, 7 of 30 (23%) in level III, 6 of 30 (20%) in level IV, and 1 of 30 (3%) in level V. They show that dissection of levels I through IV would have detected all occult metastases. The one patient with a positive level V node also had node-positive disease in levels II through IV. As such, the dissection of at least levels I through IV for parotid malignancies has been recommended. For submandibular and sublingual malignancies, occult metastases can be detected in N0 necks addressing levels I through III alone.[145,182] If occult disease is detected in the first echelon dissection for either parotid or submandibular primary malignancies, however, a comprehensive neck dissection is recommended to treat possible additional disease in the other levels.

Management of the N+ Neck

A consensus regarding treatment of the clinically N+ neck is more established. It is well accepted that an ipsilateral neck dissection should be performed in patients with palpable or radiographically enlarged cervical lymph nodes.[182] In addition, the use of radiation therapy following a cervical lymphadenectomy has been shown to improve locoregional control and survival (discussed in detail later).[183,184] Because salivary gland malignancies that have metastasized to regional lymph nodes can involve any of the five levels in the neck and can skip levels,[145] it has been recommended to perform a comprehensive modified radical neck dissection in N+ necks. However, because the incidence of nodal involvement in the contralateral neck is low, only the ipsilateral side should be treated.[144]

Radiation Therapy

Adjuvant Radiation Therapy

In general, the use of postoperative radiation therapy appears to improve locoregional control rates following resection of salivary gland malignancies. In a recent multivariate analysis of 140 patients with ACC, Chen and colleagues[185] observed that the omission of postoperative radiation therapy was an independent predictor of local recurrence with a hazard ratio of 5.82 (95% CI 1.96-17.26, $P = 0.002$). Although the rationale for the use of postoperative radiation is based entirely on retrospective studies such as this one, a number of these studies have revealed certain features where postoperative radiation is particularly useful in controlling locoregional recurrence (Table 88-7). These features include advanced-stage tumors, the presence of positive margins following resection, high-grade tumors, neural involvement, and bone involvement.

Local control following surgical resection of *advanced* stage tumors has been shown to be better when postoperative radiation is given. This improved local control, however, is less clear for earlier-stage tumors. In one of the largest retrospective multivariate analyses, Terhaard and colleagues[138] examined the outcomes and prognostic variables of 565 patients treated for a heterogeneous mixture of salivary gland malignancies in centers of the Dutch Head and Neck Oncology Cooperative Group. They found that patients who were treated by surgery alone had a relative risk of local recurrence of 9.7 and a relative risk of regional recurrence of 2.3 when compared with patients treated with surgery followed by radiation therapy. The local control of T3 and T4 tumors

Table 88-7

Indications for Adjuvant Radiation Therapy to the Primary Site

Feature	Reference
Advanced stage	Terhaard et al.[138,183]; Armstrong et al.[184]
Positive margins following resection	Garden et al.[56,188]; Hosokawa et al.[189]; Silverman et al.[190]
High-grade histologic types: squamous cell carcinoma, undifferentiated carcinoma, high-grade mucoepidermoid carcinoma, carcinoma expleomorphic adenoma, salivary duct carcinoma	Matsuba et al.[187]; Renehan et al.[153]
Local tissue invasion: perineural or bone invasion	Terhaard et al.[183]

treated with surgery followed by radiation was 84% at 10 years, and this was significantly improved compared with cases treated with surgery alone (18% at 10 years, $P < 0.001$).[183] This improvement in local control was not observed for T1 tumors (95% for surgery plus radiation vs. 83% for surgery alone) or T2 tumors (91% for surgery plus radiation vs. 88% for surgery alone). Furthermore, there did not appear to be any influence of radiation therapy on the development of distant metastases or overall survival. In a study by Armstrong and colleagues,[184] a retrospective matched-pair analysis also found that postoperative radiation improved local control in patients with stage III and stage IV disease. The 5-year local control rate in patients treated with surgery and postoperative radiation was 51%, and that of patients treated with surgery alone was 17%. The corresponding 5-year determinate survival rates were 51.2% and 9.5%, respectively. In comparison, there was not much difference in the outcomes between the two treatment groups among patients with stage I and II disease. These recent studies are consistent with previous observations demonstrating advantages of combining surgery and radiation.[136,150,186,187] Thus for advanced salivary gland cancers, there appears to be improved locoregional control and possibly an improvement in survival in patients treated with a surgical resection followed by radiation therapy.

In cases with positive margins, there tend to be increased rates of local recurrences overall (as discussed earlier in "Prognostic Variables"), and therefore it is not surprising that the addition of radiation therapy, when surgical margins are positive, appears to result in better local control. Garden and colleagues[56] retrospectively reviewed 198 patients with adenoid cystic carcinoma of the head and neck, with a median follow-up period of 93 months, and found that 18% of patients with positive margins developed local recurrences. In contrast, only 9% with close or uncertain margins and 5% with negative margins developed local recurrences ($P = 0.02$). In a separate study, Garden and colleagues[188] reviewed 166 patients with malignancies of the parotid gland and found that there was a trend for patients with positive margins to have improved local control when treated with radiation doses greater than 60 Gy. Similarly, Hosokawa and colleagues[189] reviewed 61 cases of mucoepidermoid carcinoma treated with either surgery alone or surgery followed by radiation and found that the use of higher doses of radiation (>55 Gy) resulted in better local control despite positive margins. More recently, a review of 75 patients with adenoid cystic carcinoma by Silverman and colleagues[190] demonstrated a statistically significant improvement in locoregional control of cases with positive margins when radiation therapy is administered following surgery. Thus postoperative radiation therapy is indicated when there are positive margins following tumor resection.

High-grade salivary gland malignancies have a propensity for locoregional recurrence, and postoperative radiation appears to be beneficial as adjuvant therapy. A study of high-histologic-grade malignancies of the parotid gland by Matsuba and colleagues[187] demonstrated a significantly improved 5-year local control rate when postoperative radiation was given (70%) compared with that of surgery alone (20%). Likewise, a retrospective multivariate analysis of 103 parotid gland carcinoma patients by Renehan and colleagues[153] found that the addition of postoperative radiation significantly reduced locoregional recurrence (15%) compared with surgery alone (43%) at 10 years and that this improved survival was seen mainly in patients with high-grade tumors. In contrast, postoperative radiation of low-grade malignancies did not affect locoregional control. Thus postoperative radiation therapy is recommended in cases of high-histologic-grade malignancies of the salivary glands.

Postoperative radiation is also recommended in cases where there is invasion into local tissues. Both perineural invasion and bone invasion are unfavorable histologic features and are associated with a poor clinical outcome. In the Terhaard study of 565 patients treated in centers of the Dutch Head and Neck Oncology Cooperative Group, postoperative radiation significantly improved the 10-year local control rates of cases with perineural or bone invasion compared with outcomes of surgery alone.[183]

Radiation of the Neck

The addition of postoperative radiation therapy of the neck in cases where there are lymph nodes positive for metastases from salivary gland cancers has been shown to improve locoregional control and survival. In a study by Armstrong and colleagues[184] comparing 16 patients with lymph node metastases treated with surgery alone with 23 patients treated with surgery and radiation, there was an improvement in 5-year locoregional control from 40% to 69% ($P = 0.05$). The corresponding 5-year survival improved from 19% to 49% ($P = 0.015$). The utility of postoperative radiation of the neck has been corroborated by the Terhaard and colleagues study.[183] They observed an 83% regional neck node control rate at 10 years in patients ($n = 22$) with pathologic N1 disease treated with postoperative locoregional radiation. In contrast, the 10-year regional neck node control rate was 57% in patients ($n = 10$) treated with no or only local postoperative radiation to the primary site ($P = 0.04$). Thus radiation therapy following surgical ablation of node-positive disease appears to improve outcome.

The use of radiation in the management of N0 necks, however, is less clear. In the Terhaard study, no significant benefit to regional control of the pathologic N0 neck was seen with the addition of postoperative radiation.[183] In contrast, a more recent study by Chen and colleagues[205] examined 251 patients with clinically N0 carcinomas of the salivary glands that were treated with surgery and postoperative radiation therapy. Elective neck irradiation was employed in 131 patients (90 ipsilateral and 41 bilateral). There was a significant reduction in the 10-year nodal failure rate from 26% to 0% ($P = 0.0001$). Of note, in the patients who did not receive elective neck irradiation, the nodal relapse occurred in cases of the more high-grade histologic types: squamous cell carcinoma, undifferentiated carcinoma, adenocarcinoma NOS, and mucoepidermoid carcinoma. No nodal recurrence was seen in cases of adenoid cystic or acinic cell carcinoma.

Neutron Beam Radiotherapy

Fast neutrons deliver more energy and thus result in greater radiation damage than what is created by conventional photon/electron radiotherapy. Because salivary gland malignancies have traditionally been considered to be fairly radioresistant, fast neutron therapy was proposed, and subsequently shown, to be effective in these cancers. In the only prospective randomized trial of radiation therapy of salivary gland neoplasms, fast neutron radiotherapy was compared with conventional photon radiotherapy in the treatment of unresectable and/or recurrent tumors. This study conducted jointly by the Radiation Therapy Oncology Group (RTOG) of the United States and the Medical Research Council (MRC) of Great Britain demonstrated a significant improvement in locoregional control with fast neutron radiotherapy.[191,192] Overall survival, however, was not significantly

different between the two groups. In this and subsequent studies, it appeared that patients tended to succumb to distant metastases despite the improvement in locoregional control and that this pattern of failure was the reason for the lack of improved survival, especially in cases of ACC.[193-196]

Chemotherapy

The use of systemic chemotherapy in the treatment of salivary gland malignancies is currently limited to palliative treatment of locally advanced unresectable, recurrent, and metastatic disease. A variety of agents have been explored; however, the studies that have been reported are nonrandomized and of small numbers of patients, making it difficult to assess the efficacy of these drugs. In addition, many of the reports are case series and retrospective reviews of heterogeneous types of malignancies and treatments. In order to circumvent the limitations of the available data, Rizk and colleagues[197] recently reported a meta-analysis of data from 205 patients obtained from 17 phase II or phase III trial studies. The chemotherapeutic agents used in these studies included cisplatin, carboplatin, epirubicin, cyclophosphamide, doxorubicin hydrochloride (Adriamycin), mitoxantrone, paclitaxel, 5-fluorouracil, vinorelbine, methotrexate, and bleomycin. All patients were treated for cancer of the major or minor salivary glands with either single-agent or multi-agent first-line palliative chemotherapy. Using meta-analysis linear regression, the authors found that patients treated with either platinum- or anthracycline (e.g., mitoxantrone)-based chemotherapy had an increase in their median survival. When looking at the data using a multivariate analysis, only platinum-based chemotherapy was found to be significantly associated with increased survival, but there appeared to be a positive interaction between platinum agents and anthracycline. Thus although the field is in need of prospective randomized trials, the available data suggest that these two agents may have a useful role, not only in palliative treatment, but also in definitive multimodality treatment of salivary gland malignancies prone to distant metastases.

Recently, attention has been directed to the possible role for directed therapy against biologic targets expressed in these cancers. These targets include receptor tyrosine kinases such as c-KIT and members of the ErbB family (the epidermal growth factor receptor (EGFR), Her2/*neu*). Adenoid cystic carcinoma has been shown to overexpress c-KIT in more than 90% of cases, and expression of c-KIT has been correlated with tumor grade.[198,199] EGFR (also known as *ErbB1*) is expressed in 79% of all parotid malignancies,[199] leading to the investigation of directed therapy against this target. Her2/*neu* (also known as *ErbB2*) is frequently expressed in a subset of salivary gland malignancies, namely salivary duct carcinoma, and expression correlates significantly with prognosis.[104,175] Observations such as these have established the rationale for investigating strategies to target these kinases in multiple phase II trials.[200-202] Unfortunately, no objective response was found when using either small molecule inhibitors or antibodies as monotherapy in patients with unresectable, recurrent, or metastatic disease. However, the therapeutics did appear to stabilize the disease in a substantial number of the patients in these trials, suggesting that inhibition of these targets was having some effect on the biology of these tumors. Indeed, there are promising data indicating that targeted therapy in combination with conventional chemotherapy may have a synergistic effect.[203]

CHAPTER EIGHTY-NINE

Physiology of the Oral Cavity

Joseph B. Travers

Susan P. Travers

James M. Christian

Key Points

- Somatosensory innervation of the oral cavity is provided by cranial nerves V (trigeminal), second and third divisions, and IX (glossopharyngeal): (1) V2—maxillary, hard, soft palates; oral mucosa of the maxillary vestibule; maxillary teeth, gingivae, and periodontal ligaments; (2) V3—mandibular, oral mucosa of the cheek and mandibular vestibule; anterior two thirds of tongue; mandibular teeth, gingivae, and periodontal ligaments; and (3) IX, posterior one third of tongue; oropharynx.
- Periodontal ligament (PDL—the ligament separating tooth from bone in healthy, functioning teeth) receptors initiate oral reflexes of jaw opening and salivation and, together with receptors in the temporomandibular joint, contribute to interdental force discrimination and oral stereognosis. Therefore, bite force is lessened with a corresponding decrease in these PDL receptors (i.e., with periodontal disease, tooth extraction, and consequent denture construction).
- Dental pain is mediated by C-fibers (dull, burning) and A-delta fibers (sharp, bright) located in the pulp chamber ("nerve" of a tooth) and extending a short distance into the dentinal tubules (A-delta only). When enamel is breached (by decay, fracture, wear), the fluid in the tubules responds to stimuli and activates these nerve endings ("hydrodynamic theory of dental pain").
- Chewing, swallowing, and breathing are produced by brainstem central pattern generators that control the fundamental rate and pattern of muscle contractions that define each function. Coordination of muscle activity occurs among functions, among motor groups, and within the muscles themselves and is affected by peripheral feedback mechanisms.
- The main function of the masticatory muscles is to break down solid food into amounts small enough to be swallowed. These are strong muscles—jaw openers and jaw closers—that generate significant forces across short distances and apply them via teeth (dentures). These forces must be controlled precisely and effectively—by cortical preprogrammed movement patterns, reflex stimulation, and peripheral input/feedback loops—to allow for smooth movements and successful deglutition.
- Recent molecular and functional data show that there is no specific tongue "map" for taste buds; responsiveness to the five tastes—sweet, sour, bitter, salty, and umami—is present in all areas of the tongue supplied with taste buds.
- Sweet taste sensations are associated with simple carbohydrates; sour taste is generated by weak organic acids; salty taste is stimulated mostly by NaCl (sodium ions); bitter taste arises from stimulation by plant alkaloids (potential toxins); and umami taste is associated with amino acids and peptides.
- The biology of taste perception, mediated by taste receptor cells in the taste buds and innervated by cranial nerves VII, IX and X, is complex, but there is no argument that the clinical recognition of taste affects our survival.

The oral cavity is a complex organ comprising muscle, glands, teeth, and specialized sensory receptors. For most animals, the orosensory and oromotor apparatus is critical for successful defense, reproduction, exploration, nutrition, and vocalization.[1] In humans, vocalization has evolved into complex speech production, but other human behaviors depend less on the mouth and tongue than on the eye and hand. In all animals, however, the mouth is essential for the ingestion of nutrients. The incorporation of nutrients by mastication and drinking involves a high degree of coordination within and between different oral motor systems. Chewing requires the reciprocal activation of antagonist trigeminal muscles to open and close the jaws and the tongue to position food between the teeth. A diverse array of highly specialized sensory systems guides these complex oromotor responses and initiates secretion of digestive enzymes. Mechanoreceptors in the tongue, palate, and periodontal ligament (PDL) all contribute to a three-dimensional (stereognostic) perception of the oral cavity.[2] The sense of taste serves in both food selection and protection from ingesting potentially toxic substances.

Recent reviews provide comprehensive coverage of specific aspects of oral function including mastication,* swallowing,[3,4] oral mechanoreception,[5,6] and the sense of taste.[7-10] In addition, several recent papers have reviewed oral pain[11,12] and taste dysfunction.[13]

This chapter provides a concise overview of orosensory and oromotor function. A brief synopsis of orosensory function describes the innervation and sensitivity of the oral cavity and a summary of central pathways. A section on sensorimotor function includes a discussion of masticatory, lingual, and autonomic reflexes followed by a discussion

of mastication and the oral phase of deglutition. The sense of taste is treated separately.

Sensory Function

Oral Somesthesia

Somatosensory innervation of the oral cavity is provided by the maxillary and mandibular branches of the trigeminal nerve and by the glossopharyngeal nerve. The mandibular nerve branches to innervate the oral mucosa of the cheek, anterior two thirds of the tongue, mandibular dentition, PDL, gingiva, and anterior mandibular vestibule. Branches of the maxillary nerve innervate the hard and soft palates, the oral mucosa of the maxillary vestibule, and the maxillary dentition, gingiva, and PDL. Somatosensory innervation of the back of the tongue and oropharynx is provided by the glossopharyngeal nerve. Although the entire oral cavity is densely innervated with sensory fibers, considerable evidence indicates that the innervation is not uniform. Specialized oral tissues including the lips, teeth, PDL, tongue, and palate each display specific patterns of sensitivity. Although specific parts of the oral cavity rival the hand in terms of absolute psychophysical thresholds for tactile and thermal sensitivity, the structure/function of somesthetic correlations so painstakingly deduced for the hand have little predictive veracity in the mouth.

Overall, the anterior oral cavity displays greater tactile sensitivity than does the posterior oral structure.[1,14] The tip of the tongue is particularly sensitive, with a discriminative capability equivalent to that of the digits (Fig. 89-1). The midline of the palate and tongue are more sensitive than lateral regions. A similar pattern of sensitivity applies to the teeth.[15] Adults with complete dentition could detect a 1-g von Frey hair applied to the anterior (midline) teeth but require nearly 10 g to detect stimulation of the first molar. The sensitivity to warm and cold stimuli also varies widely across oral tissues. Sensitivity to warm stimuli is relatively high on the tip of tongue but not particularly so on either the palate or buccolabial surfaces.[16,17] In contrast, the sensitivity to a cool stimulus is less differentiated within the oral cavity, and the sensitivity of the tongue tip, palate, and buccolabial surfaces is essentially equal. In general, the sensitivity to cool stimuli is greater compared with warm stimuli.

Recording from single human lingual fibers innervating the anterior tongue[18] confirms the small receptive fields and high sensitivity to low-threshold forces observed psychophysically (Fig. 89-2). On the basis of their small receptive fields and low thresholds, lingual fibers could be divided into those innervating the superficial (mucosal) surface of the tongue and those innervating deeper muscle tissue. The majority of the superficial fibers were rapidly adapting—a characteristic in common with other highly sensitive structures used in exploratory activity (e.g., the hand). In contrast, the deeper receptors were all slowly adapting and may provide information about the position of the tongue.

Trigeminal endings mediating somesthetic and thermal sensitivity of the tongue and palate range from free nerve endings to an intermediate group of "semi-organized" endings[19] to more highly organized endings variously referred to as Krause end bulbs,[20] mucocutaneous end organs,[19] or coiled terminations.[21] All investigators agree that there are no Pacinian corpuscles in the oral mucosa. Based on ultrastructural criteria, Munger[22] refers to many highly organized oral mucosa endings as Meissner corpuscles, similar to those found in glabrous skin of the hand. However, despite all this variation in nomenclature, many of the illustrations of the specialized endings are quite similar and show "finely wound nonmyelinated fibers" without a clearly defined capsule.[19] Ultrastructural studies further reveal that some of these organized endings in the palate (but not the lingual epithelium) send axonal processes into the overlying epithelial pegs and are associated with Merkel cells.[22,23] In the hand, Merkel cells are correlated physiologically with slowly adapting mechanoreceptors; however, a similar correlation has not been made in the palate, and their apparent absence in the lingual epithelium does not preclude slowly adapting mechanoreceptors in this structure (see Fig. 89-2). Thus unlike the hand, a correlation between the morphology of oral receptor endings and their response properties as rapidly or slowly adapting has not been demonstrated.

Mechanoreceptors in the PDL have been studied in some detail (see reviews by Jacobs and Steenberghe[24] and Maeda and colleagues[25]). In addition to detecting forces directed against the teeth, PDL receptors initiate oral reflexes of jaw opening and salivation and, together with receptors in the temporomandibular joint, contribute to interdental discrimination and oral stereognosis.[2,24] As many as six varieties of receptor morphology are found in the PDL, ranging from complex Ruffini-like branched endings to free nerve endings.[26,27] The cell bodies for PDL receptors are located peripherally in the trigeminal ganglion

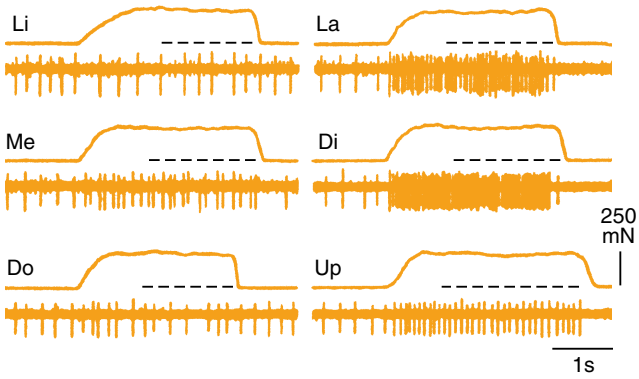

Figure 89-3. Responses of a single human periodontal afferent fiber to a force (≈250 mN) from various directions. The cell responded best to a force from the distal (Di) direction. Directions: lingual (Li), labial (La), mesial (Me), downward (Do), upward (Up). *(From Trulsson M, Johansson RS. Orofacial mechanoreceptors in humans: encoding characteristics and responses during natural orofacial behaviors.* Behav Brain Res. *2002;135:27-33.)*

and centrally in the mesencephalic trigeminal nucleus.[28] Mesencephalic trigeminal innervation of the PDL is primarily in the apical region near the root and consists mostly of small, myelinated, Ruffini-like endings.[29] Trigeminal ganglion innervation extends from the apical region to the more superficial region and includes small unmyelinated nerve endings.

Both rapidly and slowly adapting mechanoreceptors are found in the PDL, and it is likely that it is the location of the receptor in the ligament that determines its response characteristic. Because the tooth rotates about its fulcrum, forces directed laterally to the crown will translate to greater stretch at the root of the tooth compared with the fulcrum. Thus it is perhaps not surprising that lower-threshold fibers are found near the root and that they tend to be slowly adapting compared with receptors located near the fulcrum.[30] In addition, individual Ruffini endings are not uniformly distributed around the tooth and thus display directional sensitivity to the force required to activate them. Recordings from human nerves (microneurography) demonstrate the directional sensitivity of PDL receptors[31] (Fig. 89-3) and further indicate mechanical coupling between the teeth. Single fibers respond to stimulation of multiple (adjacent) teeth; however, there is no anatomic evidence that individual fibers innervate multiple teeth.[32]

The differential innervation of the PDL by the trigeminal ganglion and mesencephalic trigeminal nucleus has functional significance. Mesencephalic receptors are primarily medium and rapidly adapting receptor types, many with directional sensitivity. The central termination of these mesencephalic force detectors includes inhibitory connections to trigeminal jaw closer motoneurons via the supratrigeminal area.[33] Thus these receptors serve a protective role in preventing potentially damaging tooth contact during mastication. In contrast, trigeminal ganglion receptors include slowly adapting mechanoreceptors (position detectors) and high-threshold C fibers (nociceptors) in addition to rapidly adapting mechanoreceptors. Because these periodontal receptors from the trigeminal ganglion terminate centrally in the sensory trigeminal complex, the source for the ascending sensory pathway to the thalamus and cortex, they provide information about tooth displacement and dental pain to the forebrain.

Although mechanoreceptors in the PDL are not encapsulated, their response characteristics are influenced by the elastic properties of the ligament. When the attachment of the ligament is compromised (e.g., during periodontitis that loosens the connective attachments of the ligament), a corresponding loss in interdental force discrimination is observed.[34] Periodontal receptors also contribute to the regulation of bite force. Individuals with dentures could not bite as hard as normal dentulous subjects and could not perceive variations in their own bite force.[2,35] Similar results were obtained by anesthetizing the inferior alveolar nerve.[36] In contrast, anesthetizing the temporomandibular joint does not affect bite force discrimination but does impair jaw-positioning performance. Thus different populations of oral receptors may regulate sensing jaw position and controlling bite force during mastication.

Common Chemical Sense

Stimulation of the oral cavity with high concentrations of salts, acids, alkaloids, and other compounds elicits intense taste sensations but also evokes nontaste sensations ranging from stinging and burning to warm, cool, and painful. This sensitivity of the oral cavity, mediated by nonspecialized free nerve endings and shared by all mucosal membranes, is referred to as the common chemical sense or chemesthesis and should not be confused with taste. Although free nerve endings respond to many traditional gustatory stimuli, they typically display a much lower sensitivity. Electrophysiologic recordings from the lingual nerve, for example, indicate that single fibers require concentrations of sodium chloride (NaCl) 1000 times higher than those necessary to elicit a response from a gustatory fiber in the chorda tympani nerve (reviewed by Bryant and Silver[37]). Much lower concentrations of other types of chemical stimuli (e.g., menthol [10^{-4}]), however, are adequate to elicit a response in trigeminal nerve fibers. The types of chemical stimuli that elicit low-threshold responses in trigeminal fibers suggest that one function of the common chemical sense is to protect the oral cavity. Responses to common chemical stimuli include reflex salivation and coughing that function to diffuse and remove offending stimuli from the mouth. The common chemical sense is not purely protective, however. Spices such as horseradish, ginger, and red pepper are effective stimuli for trigeminal afferent fibers and contribute to the flavor of food. One of the receptors for chemesthetic stimulation was recently cloned.[38] A member of the TRP family of G-protein-coupled receptors, the vanilloid receptor termed "VR1" responds to both noxious heat and low concentrations of protons in addition to vanilloid compounds such as capsaicin, found in chili pepper. Stimulation of this receptor results in the opening of a cation channel, thus depolarizing the afferent fiber.

Dental Pain

Persons usually describe dental pain as either dull/burning or sharp.[39] Sensations of dull burning pain are associated with stimulation of C fibers terminating in the pulp chamber, whereas sharp "bright" dental pain is associated with A-delta fiber innervation that extends a short distance into the dentinal tubules matrix interposed between the pulp chamber and the enamel covering of the tooth (reviewed in Burgess and colleagues[40]). Unmyelinated C fibers constitute the majority of pulpal innervation (50% to 75%); however, endings within the pulp chamber may be unmyelinated terminals of A-delta (myelinated) afferent fibers. Polymodal C fibers innervating the pulp chamber respond to thermal stimuli and, in particular, to inflammatory mediators including histamine and bradykinin, endogenous factors associated with pulp pathology. C fibers innervating the pulp chamber contain neuropeptides such as substance P and calcitonin gene-related peptide.[41] The peripheral release of these neuropeptides on C fiber activation produces local vasodilation, thus increasing the pressure within the rigid pulp chamber and further augmenting C fiber activation (i.e., peripheral sensitization). The release of substance P in infected teeth has been directly measured in human patients using microdialysis, and patients with irreversible pulpitis had significantly higher levels of substance P in the pulp chamber compared with noninfected teeth.[42] Although the release of neuropeptides augments pain, there is evidence that it may also reduce inflammation and promote recovery. In experiments with animals, eliminating the afferent terminal release of neuropeptides by denervating the teeth reduced wound healing after lesions were experimentally induced.[43]

Sharp pain is mediated by A-delta fibers extending 0.2 to 0.3 mm into the dentinal tubules encasing the pulp chamber.[44] These nerve fibers respond to heat, mechanical, and osmotic stimuli applied to the distal end of the dentinal tubules that become exposed to environmental stimuli when the enamel layer is breached.[45] Because the dentinal tubules are filled with a fluid, the fluid transmits mechanical, thermal, and osmotic stimuli to the proximal end of the dentinal tubules where the nerve endings are located. This "hydrodynamic" theory of dental pain has gained anatomic, physiologic, and psychophysical support and further offers an explanation of dentinal hypersensitivity. When the

dentinal tubules are exposed by a cavity or other lesion, patients report sharp pain in response to innocuous stimuli such as mild temperature or osmotic stimuli (e.g., sweet compounds). However, the theory predicts that if the tubules are covered, thus limiting exposure to environmental stimuli, stimulated pain should be reduced. This had been experimentally assessed in human volunteers in whom a small cavity in a tooth was prepared (in a tooth scheduled for removal) and a conical chamber positioned over the cavity through which regulated air pressure could be delivered.[46] Creating a smear layer of amorphous tooth particles in the cavity, or dissolving it away with solvents, controlled the interface between the exposed dentinal tubules and the air pressure stimulus. When the smear layer was intact, covering the dentinal tubules, it took more air pressure to induce the perception of sharp pain than when the smear layer was dissolved.

Central Projections of Trigeminal System

Afferent fibers of the trigeminal nerve enter the brainstem in the pons, bifurcate, and terminate in either the principal sensory nucleus or descend to terminate in the spinal trigeminal complex in the medulla. The bifurcation of the trigeminal nerve at the level of the pons reflects a tendency toward a segregation of function.[47] In general, low-threshold mechanoreceptors predominate in the principal trigeminal sensory nucleus, indicative of a tactile discriminative function. In contrast, considerable evidence implicates the subnucleus caudalis in orofacial pain mechanisms, and many neurons in the subnucleus caudalis respond to noxious stimuli applied to the head and neck.[11] These neurons include those specifically activated by noxious stimuli (nociceptive-specific neurons) and wide-dynamic-range neurons, responsive to both low- and high-intensity stimulation.

Because the receptive fields for many nociceptive neurons in the subnucleus caudalis are large and include responses to nociceptive stimuli applied to the masticatory muscles, tooth pulp, and temporomandibular joint, a role for these neurons in referred pain has been suggested.[48] Anatomic studies confirm that afferent fibers innervating the oral cavity, tooth pulp, oropharynx, temporomandibular joint, masticatory muscles, and superficial skin all converge in the subnucleus caudalis.[49,50] In many patients, lesions in mandibular teeth have a high likelihood of producing referred pain to the maxillary region, the cheek, and the ear, in addition to the mandible itself.[51] Likewise, lesions in the maxillary teeth are often referred to the mandible, as well as the maxilla, temple, and orbital region.

In addition to subnucleus caudalis, other parts of the sensory trigeminal complex are also involved in trigeminal pain. Nociceptive responses have been obtained from extensive areas of the sensory trigeminal complex, and destruction of the subnucleus caudalis does not prevent all trigeminal pain function (reviewed in Sessle[52]). Case studies of patients who have undergone trigeminal tractotomy for intractable pain associated with cancer are completely analgesic on the face, but pulpal pain is intact.[52] Likewise, when the principal trigeminal nucleus and subnucleus oralis were damaged after a stroke, oral and perioral pain sensitivity was diminished, as well as normal tactile sensitivity from these structures.[53]

Neurons in both the rostral sensory trigeminal complex (subnucleus oralis) and the subnucleus caudalis may also form a substrate for "central sensitization" in which central neurons in the pain pathway have their response characteristics magnified as a result of peripheral stimulation.[54] These changes can last a variable amount of time and potentially contribute to both short-term hyperalgesia and long-term chronic pain. Fundamental to the concept of central sensitization is that neurons initially only responsive to high-threshold (nociceptor) input become responsive to low-threshold, non-nociceptive input. The increased responsiveness is thought to be mediated by A-β (non-nociceptive) input that only becomes functionally active after intense peripheral nociceptor input. One neural mechanism for the nascent response to non-nociceptive input has been studied in great detail. An intense afferent barrage of nociceptor input, following peripheral tissue damage or inflammation, "sensitizes" a central neuron via structural modification of an *N*-methyl-D-aspartate (NMDA) glutamate receptor. NMDA receptors are voltage sensitive and will not pass current, even in the presence of a ligand, unless the cell is sufficiently depolarized. The central release of a neuropeptide (e.g., substance P) by nociceptor afferents, however, may provide sufficient depolarization to modify NMDA glutamate receptors via intracellular signaling pathways, thereby allowing glutamate released by non-nociceptive (A-β) input to activate central neurons. A-β activation of a central nociceptor thus provides a neural mechanism for allodynia. Similar mechanisms have been demonstrated in the brainstem sensory trigeminal complex and may provide a substrate for chronic oral and facial pain.[11] Experimental studies demonstrate that neuropharmacologically blocking NMDA receptors prevents temporomandibular joint or tooth pulp afferents from inducing hyperactivity in central trigeminal neurons (i.e., central sensitization).[55,56]

Somatosensory information reaches the ventrobasal complex of the thalamus from all major subdivisions of the trigeminal sensory complex.[11] Many cells in the ventrobasal complex respond to low-intensity stimulation, indicative of a tactile discriminatory function; however, other neurons require high-intensity stimulation. The small receptive fields of both types of neurons suggest a role in localization. Other nuclei, including the posterior thalamic nuclei and the nucleus submedius, respond preferentially to high-intensity stimulation and may be involved in affective components of pain.[57] Both nociceptive and non-nociceptive trigeminally activated neurons from the thalamus project to the somatosensory cortex. Electrophysiologic mapping studies in primates indicate a complex, sometimes discontinuous somatotopic map of the facial and oral region.[58] In general, the face is represented medially on the cortical surface adjacent to the representation of the hand, with successively lateral representations of the teeth and tongue. Magnetic resonance imaging (MRI) in humans confirms this somatotopic representation.[59]

Motor Function

Oral motor functions include mastication, swallowing, respiration, and vocalization. This review will focus on mastication and the oral components of swallowing and respiration. One of the dominant concepts in oral motor physiology is central pattern generation. Chewing, swallowing, and breathing are each produced by brainstem central pattern generators that control the fundamental rate and pattern of muscle contractions that define each function. Although sensory pathways from the mouth play an intimate role in oral motor function, fundamental to the concept of central pattern generation is that afferent activity is not necessary to evoke rhythmic activity and does not provide the critical timing information for coordinated motor output.[60] Although organized in the brainstem, central pattern generators for chewing, swallowing, and respiration are influenced by descending inputs from virtually all major regions of the neuraxis. Detailed reviews of oromotor central pattern generation can be found in works by Nakamura and Katakura,[61] Rekling and Feldman,[62] and Jean.[3]

Fundamental to oral motor function is the complex interplay between behaviors competing for the same muscles. Chewing, swallowing, and respiration all require the coordinated activity of masticatory, lingual, facial, and infrahyoid muscles. Swallowing and respiration further depend on pharyngeal and abdominal muscles. Motor coordination takes place on multiple levels. At a behavioral or molar level, swallowing and respiration must be coordinated to prevent aspiration of food into the airway. How this coordination is achieved is only beginning to be understood but likely involves both interactions between central pattern generators and peripheral feedback. However, individual oral motor functions also require a high level of coordination. Bolus formation during mastication requires the coordinated activity of masticatory, lingual, and facial muscles, muscles innervated by motoneuron groups highly segregated in the brainstem. Although the jaws and tongue can function independently,[63] oftentimes the tongue and jaw appear inextricably "linked."[64,65] The nature of this linkage, and whether it relies on interactions between central pattern generators, reflex control, or peripheral mechanical linkage, represents a significant problem in oral motor control.

In addition to the complexity of coordination between functions and coordination between motor groups, another level of complexity in oral motor control can be found within the muscles themselves. Individual masticatory and lingual muscles are not homogeneously

functioning units; muscles are oftentimes composed of multiple compartments, with muscle fibers oriented in multiple directions. Thus different parts of a muscle can be more or less active during a given behavior.[66] Further adding to the complexity of oral musculature are the multiple isoforms of myosin heavy chain (MHC) proteins that form the contractile elements of the muscle fibers. The differential distribution of MHCs within different muscles and muscle compartments imparts additional degrees of freedom to motor output.

A myriad of "simpler" oral reflexes serve protective functions and contribute to complex rhythmic output. Muscle spindles in jaw-closer muscles, for example, may contribute to load regulation during chewing, and oral reflexes may assist coordination between the jaw and tongue. Autonomic oral reflexes modulate salivation and initiate digestive processes. Several recent reviews of oral reflex function are available.[63,67,68]

Muscles of Mastication and Reflex Control

The muscles of mastication can be divided into jaw openers and jaw closers. However, human jaw movement is more complex, even during stereotyped rhythmic mastication. During opening, the jaw translates forward; during closing it translates backward.[69,70] A given muscle is not isomorphic with a single movement. The masseter, temporalis, medial pterygoid, and superior head of the lateral pterygoid muscle have major jaw-closing (mandible elevation) functions, but contraction of the masseter and lateral pterygoid protrude the mandible, whereas contraction of the temporalis muscle retracts the mandible. Contraction of the anterior belly of the digastric opens retrudes the jaw; contraction of the inferior head of the lateral pterygoid lowers and laterally directs the mandible. Contraction of the mylohyoid muscle also depresses the mandible, as does contraction of the geniohyoid muscle, a muscle innervated by the hypoglossal nucleus.

Individual muscle fibers are physiologically classified as slow (S), fast fatigue resistant (FR), or fast fatigable (FF) and correlate to a high degree with specific isoforms of MHC contractile proteins.[71] Thus S fibers express the MHC-I isoform, FR units express the MHC-IIA isoform, and FF units express the MHC-IIB isoform. Individual fibers frequently contain more than one MHC isoform (i.e., hybrid isoforms),[72] and overall, masticatory muscles contain a larger proportion of hybrid isoforms compared with limb and trunk muscles.[73] Moreover, masticatory muscles express MHC isoforms not found in the limb and trunk, specifically MHC-fetal and MHC-cardiac-α. Thus muscle fibers in jaw-closing muscles (masseter, temporalis, and pterygoid) include numerous hybrids that expressed MHC-I combined with MHC-fetal and MHC-cardiac-α. Muscle fibers in jaw-opening muscles differ from their jaw-closing counterparts.[73] Overall, jaw-opening muscles have fewer hybrid fibers and a different distribution and relative weighting of the constitutive isoforms. In the anterior (and posterior) belly of the digastric, mylohyoid, and geniohyoid muscles, there were less MHC-I, MHC-fetal, and MHC-cardiac-α compared with jaw-closing muscles, but more MHC-IIA. The presence of both MHC-fetal and MHC-cardiac-α isoforms may reflect developmental factors, but functionally, hybrid isoforms confer intermediate contraction speeds and thus greater flexibility in motor output.[71]

Differences in MHC isoform reflect different motor demands on jaw-opening and jaw-closing muscles. The preponderance of slow and hybrid fiber isoforms in jaw-closing muscles reflects a muscle that contracts slowly and requires flexibility against a load during mastication. In contrast, jaw opening is more ballistic and does not normally work against a load. Even the relative distribution of MHC isoforms in different muscle compartments reflects functional specialization. Jaw-closing muscles that are particularly active during mastication (e.g., the anterior temporalis and the deep masseter muscles) have more MHC-I fibers than the posterior temporalis and the superficial masseter, which are less active. The cross-sectional size of individual masticatory motor units also imparts additional degrees of freedom in muscle control. Individual efferent axons from the motor trigeminal nucleus innervate a relatively small area of the target muscle, on the order of 5%, compared with innervation patterns of the limb and trunk, which are much greater.[71] Small cross-sectional innervation patterns allow specific areas of a muscle to be differentially controlled.

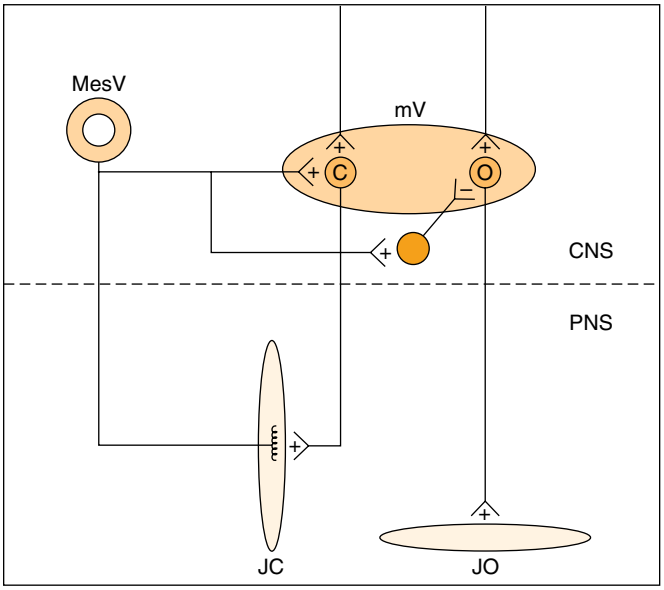

Figure 89-4. Circuit diagram for jaw-closing and unloading reflexes. Mesencephalic neurons innervate muscle spindles in jaw-closer neurons and monosynaptically excite jaw-closer motoneurons and interneurons with inhibitory connections to jaw-opener motoneurons. C, closer motoneuron; JC, jaw-closer muscle; JO, jaw-opener muscle; MesV, mesencephalic trigeminal nucleus; mV, motor trigeminal nucleus. *(From Orchardson R, Cadden SW. Mastication. In: Linden RWA, ed.* The Scientific Basis of Eating. *Basal, Switzerland: Karger; 1998.)*

Jaw-opener and jaw-closer muscles differ in their investment with muscle spindles, and hence reflex function. Muscle spindles, found only in jaw-closer muscles, are involved in multiple reflexes.[68,74,75] A "jaw-jerk" reflex that elevates the mandible (jaw-closing) can be elicited by a rapid depression of the mandible (i.e., tapping on the chin). This reflex, analogous to the patellar knee reflex, is mediated by muscle spindle afferents that respond to the rapid stretching of jaw-closing muscles and monosynaptically excite jaw-closing motoneurons. During mastication, these muscle spindle afferents potentially play an important role. During jaw closing against a food bolus, resistance to the load results in intrafusal fibers in the spindle that are (momentarily) shorter than the extrafusal motor fibers in which they are embedded. The consequent stretch of the spindle afferent adds excitatory drive to closer motoneurons, thus compensating for the load. This reflex action is termed the jaw-closing reflex.[75]

Muscle spindle afferents can also mediate a protective unloading reflex. When the jaws unexpectedly break through hard or brittle food, the rapid downward movement differentially shortens the extrafusal fibers compared with the intrafusal fibers, and muscle spindle afferent activity is decreased, thus producing a "silent period" in the jaw-closer muscle that limits excessive, potentially damaging forces directed against the teeth. These muscle spindle afferents can also indirectly potentiate jaw-opening during the unloading reflex through indirect, polysynaptic pathways. In addition to a monosynaptic excitatory synapse on jaw-closing motoneurons, these afferents can inhibit jaw-opening motoneurons through an inhibitory interneuron (Fig. 89-4). Thus during the jaw-closing phase of mastication, if there is concurrent excitation to jaw-opener motoneurons from a central pattern generator, jaw opening could be disinhibited by a lack of muscle spindle afferent input during unloading, thereby allowing the background excitation to dominate jaw-opener motoneuron activity. Damaging occlusal forces would thus be mitigated by a simultaneous lack of excitation to jaw closers and released excitation to jaw openers (see Fig. 89-4). The cell bodies for muscle spindle afferent fibers are located centrally in the mesencephalic trigeminal nucleus. Monosynaptic projections to jaw-closer motoneurons are well characterized; however, the location of inhibitory interneurons to jaw-opener motoneurons is more speculative.[76]

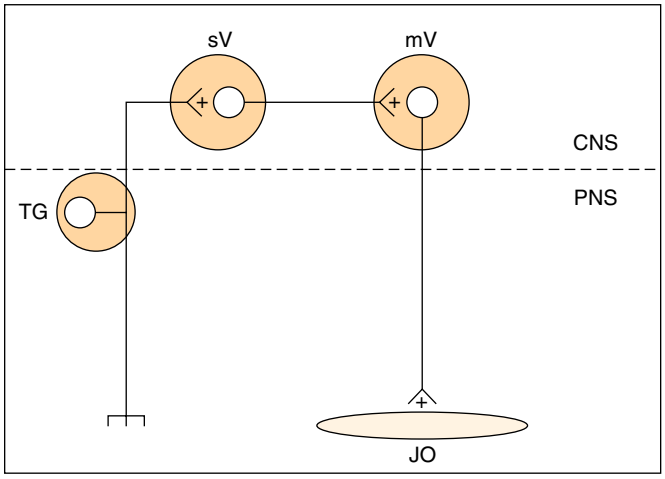

Figure 89-5. Circuit diagram for jaw-opening reflex. Nociceptor (and non-nociceptor) afferents in oral mucosa, muscle, and ligament terminate on interneurons in the sensory trigeminal complex to form a disynaptic pathway to jaw-opener motor trigeminal neurons. JO, jaw-opener muscle; mV, motor trigeminal nucleus; sV, sensory trigeminal nuclei; TG, trigeminal ganglion. *(From Orchardson R, Cadden SW. Mastication. In: Linden RWA, ed.* The Scientific Basis of Eating. *Basal, Switzerland: Karger; 1998.)*

Jaw-opening muscles do not have muscle spindles; thus during the jaw-closing phase of mastication, the corresponding lengthening of the jaw-opener muscles does not itself provide an afferent signal for a reciprocal reflex. However, stimulation of mechanoreceptors located in the PDL, tongue, and other soft tissues of the mouth can initiate reflexive jaw opening, at least in many nonprimate mammals.[68,74,75] The jaw-opening reflex is, at a minimum, disynaptic through neurons in the trigeminal sensory complex and may well involve additional interneurons (Fig. 89-5). Although the reflex can be elicited by non-noxious stimulation, it is generally thought to serve a protective function by protecting soft tissues (e.g., the tongue) against potentially damaging occlusal forces. The existence of a jaw-opening reflex in humans is still in doubt. Although it cannot be as readily demonstrated with sensory stimuli sufficient to produce it in experimental animals, robust electrical stimulation delivered to the upper lip produces electromyographic (EMG) activity in the anterior digastric muscle of humans.[76] It is of long latency, consistent with a polysynaptic substrate as suggested by animal studies.

Lingual Muscles and Reflexes

The tongue is composed of both intrinsic and extrinsic muscles innervated by the hypoglossal nerve (reviewed in Travers[77]). Extrinsic lingual muscles include the major tongue protruder muscle, genioglossus, major tongue retractor muscles, styloglossus and hyoglossus, as well as palatoglossus muscle. Intrinsic muscles of the tongue consist of the vertical, transverse, superior, and inferior longitudinal muscles. The geniohyoid often functions with the lingual muscles during tongue protrusion.[78,79] Most lingual movements involve both extrinsic and intrinsic muscles. The hydrostatic model of lingual function, in which the tongue is modeled as a closed bag, postulates that during tongue protrusion by contraction of the extrinsic genioglossus and geniohyoid muscles, the tongue is further lengthened by the simultaneous contraction of the intrinsic vertical and horizontal intrinsic muscles.[80] Likewise, shortening of the tongue during retraction is augmented by contraction of the longitudinal muscles together with the extrinsic hyoglossus and styloglossus muscles. Coactivation of different combinations of intrinsic muscles can curl or deviate the tongue.

Expression of different MHC isoforms varies across different human lingual muscles.[73,81,82] Intrinsic muscles of the anterior tongue have a large proportion of type MHC-IIA fast fibers in contrast to the posterior tongue, in which MHC-I (slow) and hybrid MHCs predominate. The geniohyoid, as with other suprahyoid muscles, has a large proportion of MHC-I fibers. The distribution of type II (fast) fibers in the anterior tongue is consistent with a role in fast, flexible movements compared with posterior tongue activity.

Although lingual muscles contain muscle spindles,[63,83,84] it is unclear whether there are any monosynaptic inputs from sensory afferents onto hypoglossal motoneurons (reviewed in Travers[77]). Rather, muscle spindle afferents travel in the ansa cervicalis and hypoglossal nerve and terminate in either the sensory trigeminal complex or the nucleus of the solitary tract. Electrical stimulation of the hypoglossal nerve elicits synaptic responses in hypoglossal motoneurons, as well as facial[85] and trigeminal motoneurons.[86] Lingual reflexes can also be elicited by stimulation of virtually any of the afferent nerves innervating the oral cavity. Depending on the site of stimulation, either a protrusive or retractive movement of the tongue is produced. An overview by Lowe[87] on the clinical significance of lingual reflexes emphasizes a protective role, either for the tongue itself during mastication or for the airway during swallowing.

Compounding the complexity of interpreting lingual reflexes are observations that reflex excitation of the tongue rarely influences a single lingual muscle, and contraction of a single lingual muscle can move the tongue in more than one plane.[88] For example, although a primarily retrusive movement of the tongue is produced by electrical stimulation of the lingual nerve, both protruder and retractor hypoglossal motoneurons are excited. Electrical stimulation of the glossopharyngeal nerve that innervates mechanoreceptors on the posterior aspect of the tongue and oropharynx also elicits tongue movement. Similar to the lingual nerve, stimulation of the glossopharyngeal nerve excites both protruder and retractor motoneurons, and the movement of the tongue is primarily retrusive. The simultaneous activation of the glossopharyngeal nerve afferent fibers by electrical stimulation, however, may mask a more complex reflex organization. Lowe has suggested that stimulation of lingual receptors innervated by the glossopharyngeal nerve elicits a primarily retrusive movement of the tongue, in contrast to the lingual protrusion produced by stimulating pharyngeal regions innervated by the glossopharyngeal nerve.[63] Thus both lingual and glossopharyngeal reflexes may protect the tongue during the occlusal phase of mastication with a retrusive movement.

In contrast, electrical stimulation of the superior laryngeal nerve that innervates laryngeal mechanoreceptors depolarizes protruder motoneurons and produces a protrusive action of the tongue. Thus mechanoreceptors in the oropharynx and larynx innervated by the superior laryngeal and the glossopharyngeal nerve may preserve airway patency during a swallow with a protrusive tongue movement. Lingual reflexes also play a protective role in respiration. When normal respiration is impeded by hypoxia, a normal breathing pattern, eupnoea, is replaced by gasps.[88,89] Gasps are associated with the coactivation of lingual protruder and retractor muscles that enlarge the upper airway.[90-92]

Jaw-Tongue Reflexes

Oromotor reflexes can involve multiple motor systems. Electrical stimulation of either the masseteric or anterior digastric nerves, for example, suppresses genioglossus activity, suggesting that proprioceptive or nociceptive signals from the trigeminal musculature inhibit lingual protrusion.[93] In contrast, passively depressing the mandible (in cats) excites the genioglossus muscle, suggesting that lingual protrusion may be reflexively assisted during jaw opening when the tongue is not subject to occlusal force.[94] Further evidence that masticatory muscle proprioceptive afferents influence hypoglossal motoneuron activity comes from experimental lesions of Probst's tract. Ishiwata and colleagues[95] showed that such lesions, which destroy descending mesencephalic projections, suppressed hypoglossal activity induced by passive jaw opening but left intact hypoglossal activity induced by stimulating a cutaneous oral sensory nerve. A jaw-tongue reflex in humans may also be mediated by masticatory muscle proprioceptive afferents.[96] Stimulation of the hypoglossal nerve, which contains some afferent fibers, inhibited the masseteric (jaw-closing) reflex.[86]

Autonomic Reflexes

In addition to somatomotor reflexes, stimulation of the oral cavity elicits numerous autonomic responses. Gustatory and mechanical

stimuli are highly effective in eliciting the flow of saliva during mastication.[97] The stimulation of receptors in the PDL may be one source for reflex salivation. In both rabbits and humans, there is a high correlation between parotid flow and mandibular movement, especially on the working, ipsilateral side. In humans, selective anesthetization of the nerves innervating the PDL significantly reduced the amount of saliva elicited from crushing a food stimulus held between the teeth.[98]

Both location and stimulus modality influence the release of saliva.[97,99] Stimulating the anterior part of the tongue is most effective for evoking salivation from the sublingual and submandibular glands, but posterior tongue stimulation is more effective for producing parotid gland flow. Aversive gustatory stimuli such as (sour) acids or (bitter) quinine hydrochloride are more effective for eliciting saliva than stimulation with weak salt or sucrose solutions. In animal experiments, sweet stimuli were the most effective stimuli for the release of the enzyme amylase from the parotid gland.[100]

Mechanical and chemical stimulation of the oral cavity also initiate the release of digestive enzymes. These cephalic phase responses include the release of gastric acid, insulin, glucagon, and pancreatic polypeptide.[101,102] An increase in gastric motility and emptying of the gallbladder also occurs. Although cephalic phase insulin release (CPIR) is a highly variable response not occurring in all individuals, insulin levels rise, on average, 25% above baseline within 2 minutes of oral stimulation. This release is neurally mediated because it does not occur in the absence of an intact vagus nerve.[103] In animal studies, sweet stimuli—particularly glucose—are most effective in triggering CPIR,[104,105] but are somewhat less effective in humans (discussed by Teff[102]). Rather, "palatable" stimuli appear more effective in general. Although cephalic phase insulin release accounts for perhaps only 1% of the total insulin release associated with a meal, this amount underestimates its potential importance in glucose metabolism. Experimental studies in which CPIR is bypassed by intragastric infusions can result in both hyperinsulinemia and hyperglycemia.[106,107] One possible mechanism for this is that vagally mediated insulin release acts as a signal on hepatic receptors to further regulate glucose metabolism; that is, it is acting as a signal to initiate metabolic events rather than simply to convert glucose.[102] Other cephalic phase responses represent larger fractions of total meal responses. In humans, cephalic phase gastric acid secretion can reach 50% of total meal release, antral motor activity can reach 70% of that achieved during a meal, and gallbladder emptying can reach 50%.[101]

Although cognitive factors and other sensory stimuli such as sight and sound can elicit cephalic phase responses, oral stimuli are usually the most effective. Oral stimuli signals carried by the gustatory and trigeminal nerves influence preganglionic parasympathetic vagal neurons located in the dorsal motor nucleus of the vagus.[108] Oropharyngeal receptors innervated by the superior laryngeal nerve may also influence digestive functions.[108] There is increased diuresis in response to drinking a saline solution as compared with the intragastric infusion of the same volume of fluid.[109]

Mastication

The orosensory apparatus of the mouth and perioral region is an integral part of the regulation of food and fluid intake. In general, the sensory receptors in the mouth are specialized for the consummatory phase of ingestion and play an important role in the sensory evaluation of food and in the sensory control of mastication and deglutition.

Food consumption through the oral cavity can be characterized as a series of stages or phases (Fig. 89-6). Different stages of ingestion have been defined by placing small metal markers in the jaws, hyoid, and tongue. These markers can be detected with high-speed cinefluorographic techniques, allowing the movements of the internal oral apparatus to be monitored during the entire ingestive sequence of the awake preparation. The division of feeding into five dynamic stages by Hiiemae and Crompton[64] is indicated on the second tier of Figure 89-6. The first stage of putting food into the mouth (ingestion) is followed by intraoral transport and the positioning of food between the molars (second stage) for mastication (third stage). Intraoral transport to the back of the tongue (fourth stage) initiates deglutition (fifth stage). The duration of each stage of feeding is highly species specific and variable, depending on what is being ingested. Fluid consumption does not require mechanical breakdown by mastication and thus has only three stages. In humans, drinking uses the same muscles as mastication, but the coupling among the facial, trigeminal, and lingual muscles is different. The orbicularis oris muscle contracts to form a tight seal during human drinking (sucking) but relaxes during mastication.

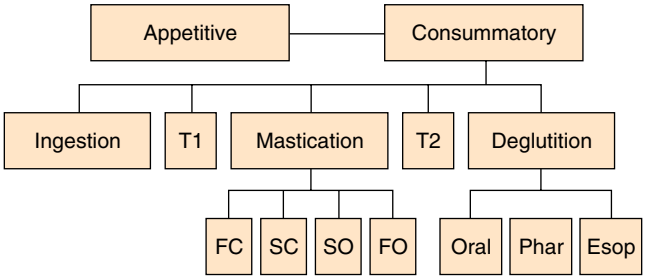

Figure 89-6. Schematic representation of different stages and substages of ingestive sequence. T1 and T2, first and second intraoral transfer; FC, fast closure; SC, slow closure; SO, slow open; FO, fast open.

The movements of mastication can be further subdivided. Kinematic measurements during mastication indicate that rhythmic masticatory movements of solid food typically involve several distinct components.[110,111] Beginning the masticatory cycle with an open mandible, the jaw closes rapidly and then more slowly. The transition from fast closure to slow closure occurs when the teeth make contact with solid food and is thought to involve sensory feedback from the PDL. More detailed analysis of the opening phase of mastication indicates additional complexity. After the slow-closure phase, when the teeth make maximal intercuspation, the masticatory cycle continues with a slow-opening phase followed by a fast-opening phase.

Feeding sequences analyzed using combined sirognathography and electromyography or video-fluorography present a modified picture of the human ingestive sequence.[112,113] Human jaw movements associated with eating natural foods do not show obvious changes in the rate of opening and closing during rhythmic mastication. Thus the stages of fast closing, slow closing, and slow opening were not evident as in animal studies. Nevertheless, the ingestive sequence could be divided into three stages, beginning with biting and transport of the bolus to the molars, chewing, and "clearance" (swallowing). A distinct stage from chewing to bolus formation for swallowing was not obvious, and swallowing occurred during mastication and as a terminal event.

Although mastication involves coordinated activity of the jaws, hyoid apparatus, and tongue,[64] the majority of electromyographic studies of mastication have focused on the jaw musculature. Jaw opening during mastication is associated with activity in the anterior digastric muscles and the inferior head of the lateral pterygoid muscle.[111,114] The closing phase of mastication begins with contraction of the masseter muscle, followed by the temporalis, medial pterygoid, and superior head of the pterygoid, which are recruited during the power stroke (slow closure). Food is typically chewed unilaterally. Although the trigeminal musculature is bilaterally activated during mastication, the ipsilateral (working) side is active earlier.

Food consistency is one factor affecting the masticatory rhythm. In a study of the effects of hardness on chewing, Plesh and colleagues[115] observed that most subjects chewed hard gum at a slightly slower rate than soft gum. The decreased frequency of chewing was associated with significantly longer opening and occlusal phases of chewing rather than with the closing phase, despite the significantly greater EMG activity in the masseter muscle. Age is another factor that affects the masticatory rhythm.[116] Older subjects chewed at the same frequency as younger subjects (approximately 1.4 Hz), but the structure of the rhythm was different. The older subjects opened and closed their mouths at a slower velocity but achieved the same overall chewing rate by not opening their mouths as far. Movement irregularities during chewing were also observed during the jaw-opening and jaw-closing phases of mastication in patients diagnosed with temporomandibular pain.[117] Unlike the smooth, uninterrupted alteration between opening and closing seen in

healthy persons, patients with temporomandibular pain frequently started reopening their mouths during the closing phase of mastication or reclosed during the opening phase.

Experimental studies indicate that the masticatory rhythm is centrally programmed; that is, a peripheral stimulus is not necessary to initiate the masticatory rhythm, nor is feedback from the active muscles necessary to sustain the response.[114] Fictive mastication evoked by central stimulation in a paralyzed experimental preparation indicates that neither the afferent limb of the jaw-opening reflex nor that of the jaw-closing reflex is necessary to generate the masticatory rhythm. Thus the alternating activation of a jaw-opening reflex followed by a jaw-closing reflex does not explain the origins of the masticatory rhythm.

Nevertheless, both the jaw-opening and jaw-closing reflexes are functionally entwined in rhythmic oral behavior, and the excitability of these reflexes varies as a function of jaw position during rhythmic opening and closing.[118] In general, the jaw-opening reflex is attenuated during rhythmic masticatory movements as compared with a stationary mandible. In particular, low-threshold mechanical stimuli are less effective than high-threshold stimuli in producing a jaw-opening reflex when applied during rhythmic masticatory movements. Thus during the occlusal phase of mastication, a protective jaw-opening reflex can be initiated in the presence of unexpected mechanical forces directed against the teeth or soft tissues, but innocuous mechanical stimulation associated with chewing will not interrupt the masticatory rhythm.

Transection studies relying on electrical stimulation to induce fictive jaw movements localized the central pattern generator for mastication to the medial core of the reticular formation. More recent studies using reversible pharmacologic lesion techniques in awake, freely moving (feeding) animal preparations indicate that a necessary substrate for rhythmic lingual/masticatory movements is in the lateral reticular formation in a region overlapping with substantial populations of preoromotor interneurons.[119,120] This region of the brainstem reticular formation is also the target of descending projections from metabolic integrative substrates in the hypothalamus and from the motor cortex.[61,121]

Although the basic neural circuitry necessary for the rhythmic alternating contraction of jaw-opening and jaw-closing muscles does not require sensory input, intraoral sensory receptors are critical for regulating bite force during mastication. Efficient eating requires that food be reduced in size for swallowing. This requires determining both the hardness and size of the food and correctly positioning food between the occlusal surfaces of teeth. Psychophysical studies in humans indicate that receptors in both the PDL and the temporomandibular joint contribute to the interdental discrimination required during eating.[2] The loss of PDL receptors associated with complete dentures results in impaired interdental discrimination, as does anesthetization of the dentition in individuals with natural teeth. Receptors in the temporomandibular joint also contribute to size discrimination in the mouth. When the temporomandibular joint is anesthetized, interdental discrimination decreases.

Oral Phase of Deglutition

After mastication and the intraoral transport of food to the back of the tongue, deglutition is initiated. The oral phase of deglutition consists of an upward movement of the tongue against the soft palate to force the bolus in the direction of the pharynx.[3,4] The precise nature of the stimulus that triggers the pharyngeal stage of deglutition is unknown. Both the volume and the rate of bolus accumulation interact to trigger swallows in experimental animals.[122] When the rate of licking (intraoral transport) increased in response to increased stimulus delivery, the volume per swallow also increased. Moreover, the physical nature of the bolus can influence the sequence and recruitment of individual muscles involved in the buccal phase of swallowing. In monkeys, the masseter muscle was recruited with the suprahyoid muscles (the anterior digastric, geniohyoid, and mylohyoid) during swallows of solid food, in contrast to fluid swallows.[123] Similarly, there is individual variation in the activation sequence of the suprahyoid muscles and the genioglossus muscle during voluntary swallows in humans.[124] In summary, the overall movement of a bolus from the dorsal surface of the posterior tongue to the pharynx characterizes the oral phase of swallowing. The precise motor sequence of individual muscles during the oral phase of deglutition can vary, depending on both the individual and sensory characteristics of the bolus. Contact of the bolus with sensory receptors in the oropharynx triggers peristaltic contractions of the pharyngeal musculature.

Like mastication, swallowing can be evoked from electrical stimulation of central structures in the absence of peripheral (muscular) feedback and is thus thought to be controlled by a central pattern generator.[3,4] The location of the central pattern generator for swallowing involves the caudal region of the nucleus of the solitary tract and the medullary reticular formation adjacent to the nucleus ambiguus. Cortical pathways that reach these medullary regions through descending pathways mediate voluntary swallowing.

Swallowing takes precedence over both respiration and mastication, causing a brief disruption of rhythm. Respiratory apnea associated with swallowing shows considerable variation across individuals, in one study ranging from 0.61 to 3.83 seconds.[125] For some individuals, the apneic period increases with the volume swallowed; for others it decreases. Spontaneous swallows tend to be associated with a shorter apneic period.[126] Swallows do not occur randomly throughout respiration. Rather, the majority of swallows occur during expiration or late inspiration and subsequently reset the respiratory rhythm (i.e., there is no modification of the postswallow rhythm to compensate for the swallow-induced apnea).[126] Sensory information from the oropharynx could reach the central pattern generator for respiration via the nucleus of the solitary tract to mediate adaptability of the respiratory rhythm to bolus size.[125] Alternatively, oropharyngeal afferents could influence the central deglutition substrate to modify respiration[126]; that is, there could be an interaction between central pattern generators for respiration and swallowing.[127]

Although swallowing affects the masticatory and licking rhythm in animals, it has only a minimal effect on human mastication.[128,129] Swallows most often occur during the early jaw opening phase of mastication and significantly prolong the masticatory cycle. In rodents, the prolonged lick cycle associated with a swallow equals the increased duration of tongue protrudor and retractor muscle contractions; that is, the increased cycle duration was used to accommodate the participation of the tongue in swallowing.[79] In addition to interactions between swallowing and mastication, there are also interactions between respiration and mastication. In general, mastication increases respiratory rate while at the same time decreases inspiratory and expiratory time.[129] In addition to possible metabolic demands of mastication on respiration (i.e., physical exertion), mastication can increase upper airway resistance by more closely apposing the tongue with the palate. In humans, there is a small but significant tendency for inspiration to occur during masticatory jaw opening.[128]

Specialized Sensory Systems: Taste

Gustatory Sensitivity

In contrast to the common chemical sense, taste sensations are evoked by relatively low concentrations of chemical stimuli when applied to the specialized gustatory receptor cells. Most investigators agree that there are a discrete number of taste sensations; the most common and easily recognizable are sweet, salty, sour, and bitter. Some contend that there is a fifth taste, umami (heavenly), associated with the taste of monosodium glutamate.[130] The sensations of flavor while eating are more diverse than those of pure taste and result from the interaction of taste with the smell and texture of food. The confusion between taste and flavor is well documented in taste and smell clinics. Self-reports of chemosensory dysfunction are highly unreliable; on testing, many individuals reporting loss of taste are frequently found to have impaired olfactory function with no loss in taste sensitivity.[131]

In addition to a sensory-quality dimension with four distinct tastes, taste stimuli can be categorized on a hedonic dimension with stimuli divided into those that are preferred and those that are disliked. The hedonic attribute of taste is concentration dependent and spans the different submodalities of sweet, sour, salty, and bitter. Low and medium concentrations of salt are preferred, but salt becomes aversive at high concentrations. Although there is a strong genetic component

to the hedonic values associated with gustatory stimuli, taste preferences are clearly modifiable by experience.[132] Human neonates find bitter solutions strongly aversive, but adults learn to enjoy coffee, alcohol, and other bitter-tasting substances. The hedonic attributes of taste are also subject to metabolic state.

Gustatory Structures

Approximately 7900 gustatory receptors in the human mouth are grouped into distinct subpopulations, defined by their intraoral location, gross morphology, and innervation.[133] Gustatory subpopulations differ in sensitivity to chemical stimuli; however, the overall morphology of the taste bud structure within each subpopulation is similar. Each taste bud contains 50 to 150 neuroepithelial cells arranged in spindle-like clusters. Some of the cells within the taste bud extend microvilli into a nonkeratinized "pore" region on the apical surface of the bud. Taste bud cells without microvilli occur both on the periphery of the bud (these are termed *marginal cells*) and at the base of the taste bud (designated basal cells).[134] Receptor cells die and are replaced over a 10- to 14-day period.[135] Marginal and basal cells may constitute replacement cells, but the lineage of replacement receptor cells within the taste bud remains controversial. Because taste cells undergo continuous differentiation, disruption of cell division by radiation or other agents can disrupt the sense of taste.

The chorda tympani branch of the facial nerve innervates two to five taste buds on each of approximately 400 fungiform papillae on the anterior aspect of the tongue.[136] Fungiform papillae density is greatest at the tip of the tongue and decreases along the dorsal and dorsolateral edges of the tongue. No fungiform papillae are found along the midline. Taste buds on the posterior aspect of the tongue are innervated by the glossopharyngeal nerve and located either in tightly packed clusters distributed along the walls of the trenches surrounding 7 to 10 circumvallate papillae or in the inner folds of the foliate papillae located along the lateral edges of the posterior part of the tongue. The 2400 taste buds in the circumvallate papillae and the 1300 taste buds in the foliate papillae constitute the largest percentage in the human oral cavity. A third large subpopulation of gustatory receptors located in the pharynx and larynx numbers approximately 2400 in humans. These taste buds are not associated with distinct papillae; however, the bud morphology is similar to that found on the tongue. Taste buds of the pharynx are innervated by the glossopharyngeal nerve, and the superior laryngeal nerve branch of the vagus innervates those in the larynx. A smaller subpopulation of taste buds (approximately 400 in humans) is found on the soft palate. These taste receptors, also not associated with distinct papillae, are innervated by the greater superficial petrosal nerve branch of the facial nerve. In rodent species, small populations of taste buds are also found on the buccal wall and the sublingual organ, but these have yet to be characterized in humans.[137]

The specific pattern of innervation of taste buds by a peripheral nerve has been characterized for the fungiform papillae on the front of the tongue. Single fibers of the chorda tympani nerve synapse on multiple receptor cells within a single taste bud and on receptor cells in adjacent taste buds.[138] Likewise, each receptor cell is innervated by more than one fiber of the chorda tympani nerve. Each fiber of the chorda tympani thus receives input from multiple receptor cells, and each bud is innervated by more than one fiber. This pattern of convergence of multiple receptor cells from adjacent taste buds onto a single afferent fiber provides an anatomic substrate for spatial interactions between adjacent taste buds. Successively lower perceptual thresholds in humans can be reached by stimulating multiple adjacent papillae with gustatory stimuli.[139]

Gustatory Physiology

A common observation in neurophysiologic studies of the gustatory system is that individual neural elements are usually sensitive to a variety of chemical stimuli. Receptor cells, afferent nerve fibers, and central neurons are often responsive to diverse chemical stimuli that elicit qualitatively different sensations in humans. The central issue in gustatory coding has been to determine how broadly responsive neurons code for such distinct sensations as sweet, salty, sour, and bitter. Recent work has focused on organizing gustatory neurons at different levels of the sensory pathway into neuron types.[99] Although many neurons are multiply sensitive to different-tasting stimuli, these sensitivities are not random. Neurons are not specifically tuned to a single stimulus, but typically respond best to one of the stimuli representing the four basic taste qualities. The representation (coding) of quality is thought to be mediated by comparison of activity across these classes of neurons.[140]

Gustatory Transduction

Discoveries made over the past 20 years and, in particular, in the brief time that has elapsed since the beginning of the 21st century, have shed remarkable light on the process by which chemical energy inherent in gustatory stimuli is transformed into cellular changes in the taste receptor cell. These studies on gustatory transduction have been the topic of several recent reviews.[8,141-144] Highlights and outstanding issues are emphasized here. Until the mid-1980s, hypotheses regarding gustatory transduction revolved around ill-defined interactions of taste stimuli with membrane-bound receptors. Molecular biologic studies of the past few years have revealed the chromosomal location and specific genetic sequence of receptors that transduce information about carbohydrates, artificial sweeteners, amino acids, and the diverse array of chemicals that humans describe as "bitter." All these receptors can be classified as G-protein-coupled receptors. Discoveries about these seven-transmembrane segment-spanning proteins have occurred rapidly, and though conforming in some ways to previous ideas, have revealed surprises and ignited controversies. However, well before molecular biologic investigations transformed the field, classic physiologic techniques revealed that one important ionic stimulus, Na^+, was transduced in part by transmembrane transport of the stimulus into the cell,[145] an event that would be expected to lead directly to depolarization.

The discovery of this mechanism was in conflict with prevailing ideas of stimulus-membrane interactions and the presumed impermeability of the receptor cell to its ligand.[146] Nevertheless, on the basis of the suppression of the peripheral nerve response to sodium salts after lingual application of amiloride across a variety of species, ranging from rodents (rat, gerbil, some mice) to primates (rhesus monkey, chimpanzee), a significant portion of the gustatory response to sodium salts appears to be due to entry of the sodium ions through amiloride-sensitive sodium channels located on the apical microvilli of taste receptor cells (reviewed by Halpern[147]). These sodium channels, which are epithelial Na^+ channels (EnaCs), resemble those found in a number of sodium-transporting epithelia such as kidney, lung, and colon (reviewed in Halpern[147] and Gilbertson and Margolskee.[8] In rodents, gustatory sodium transduction via ENaCs is reflected in the responses of particular subsets of primary afferent neurons, cells with relatively specific responses to sodium salts, as opposed to those cells with a broader sensitivity that extends to nonsodium salts and acids.[148]

In the rat, the amiloride-sensitive sodium channel has been demonstrated to be essential for behavioral discrimination of sodium from other salts,[149-151] but in the human, the significance of this transduction mechanism is not as clear. Although the overall intensity of NaCl is reduced by amiloride,[152] when subjects are asked to ascribe intensity ratings of NaCl to particular qualities, the main reductions in intensity are not in the "salty" taste per se but rather in the weaker "sour" taste that this stimulus elicits.[153,154] Thus although the ENaC channel is almost certainly present and operational in humans, it may have a more general function in detecting ionic stimuli than in rodents. Indeed, although sodium transduction via the amiloride-sensitive channel is widespread phylogenetically, in addition to the human there are other notable exceptions in which this mechanism appears less important (some mouse strains) or specific (dog).[96]

Further, although transduction via amiloride-sensitive channels plays an important role, not all sodium responsiveness, even in rodents, relies on this mechanism. A significant portion of the response to NaCl remains after blockade with amiloride, and therefore different transduction mechanisms must mediate the residual, amiloride-insensitive response. However, these mechanisms are not as well understood. Interaction with other apically located cation channels, as well as transport through the tight junctions of the taste bud to interact with basolateral ion channels, has been proposed. Importantly, the amiloride-insensitive mechanism(s) for sodium transduction is (are) not as specific for the

sodium cation as transduction via ENaC channels and thus is (are) generally believed to also explain responsiveness to nonsodium salts such as ammonium and potassium chloride (reviewed in Gilbertson and Margolskee[8]).

Transduction of the class of stimuli that taste sour to humans, namely organic and inorganic acids, is also not as well understood as the amiloride-sensitive mechanism for sodium. A variety of channels that exhibit responsiveness to or modulation by acids have been characterized and are suspected to have some function in taste tissue including members of the ENaC/degenerin superfamily, the acid-sensing channels, the mammalian degenerin-1 channel, and a group of hyperpolarization-activated channels that can be gated by cyclic nucleotides (HCN1 and HCN4) (reviewed in Gilbertson and Margolskee[8]). However, the contribution that these channels make to the transduction of acid stimuli in the taste system is not clear. An intriguing hypothesis regarding the "proximate" stimulus for acid transduction, however, has recently emerged. It has been proposed that taste cell responses to acids are a result of changes in intracellular pH caused directly by the entry of the acid stimulus into the receptor cell. Measurements of intracellular pH after stimulation with acids show systematic changes in intracellular pH that track concentration for a given acid. These changes are small, serving to keep the cell at a physiologic pH, but are highly reliable and explain a perplexing aspect of the perceptual characteristics of acids. Low pH is clearly the chemical feature that sour stimuli have in common and, for a given acid, sourness is a positive function of concentration and therefore pH. However, it has long been puzzling that, across acids, sourness is not correlated with pH. Rather, at a given pH, organic acids are much sourer. However, the intracellular measurements seem to solve this puzzle: sourness (and the magnitude of the chorda tympani response) is directly correlated with the intracellular drop in pH elicited by different acids. In the case of inorganic acids, hydrogen ions are proposed to enter the cell via ion channels, but organic acids enter the cells as electroneutral molecules by diffusing across the lipid bilayer and then are broken down by intracellular mechanisms.[155,156]

In contrast to simple ionic stimuli and acids, transduction of carbohydrates, amino acids, and bitter-tasting chemicals occurs via interactions of stimuli with distinct classes of G-protein-coupled receptors. In parallel with the diverse chemical substances that evoke the bitter quality, which include "… amino acids and peptides, flavonoids and terpenes, methylxanthines (caffeine), sulfimides (saccharin), ureas and thioureas (PTC, PROP), and organic and inorganic salts"[7] (referencing Rouseff[157]), transduction of bitter stimuli involves interaction with a large family of receptors, called T2Rs.[158,159] The identification of these receptors was aided by the sequencing of the human genome and genetic linkage studies in humans that localized variations in the threshold for a particular bitter substance, propylthiouracil, to a locus in chromosome 5.[160] The region identified by the linkage studies was screened, and this resulted in the identification of a family of candidate genes, arranged in groups in chromosome 5 and also in chromosomes 7 and 12, that encoded novel G-protein-coupled receptors. Homologous genes were identified in rodents. Additional investigation revealed that these genes showed a distant resemblance to chemosensory G-protein-coupled receptors found in the vomeronasal organ, as well as metabotropic receptors for the neurotransmitter, glutamate. Significantly, they are expressed specifically in taste buds.[158] Furthermore, the various T2R genes colocalized with each other and with a specific G-protein, "gustducin,"[158] which was already known to contribute to the ability of rodents to sense bitter stimuli.[161] The identification of naturally occurring variations in one T2R family member that correlated with the ability of different mouse strains to taste the bitter stimulus cycloheximide, along with heterologous expression experiments that conferred bitter responsiveness, provided compelling evidence that these genes code bitter receptors.[159] The large size of the gene family, the colocalization of the genes, and the specificity of responsiveness when heterologously expressed, prompted a hypothesis about the peripheral neural coding of the bitter quality—namely, the wide array of stimuli that humans perceive as bitter are likewise detected by a large number of distinct bitter receptors, each specifically tuned to particular substances but activating the same set of receptor cells.[159] However, fast on the heels of this proposal, a physiologic study using calcium imaging demonstrated that many individual taste receptor cells showed a high degree of specificity for particular bitter stimuli, suggesting that this simple hypothesis might not be adequate.[162]

Sweet stimuli and L-amino acids also are detected by a group of G-protein coupled receptors, termed T1Rs, although fewer distinct receptors appear to be involved. Both naturally sweet carbohydrates (i.e., mono- and disaccharides) and artificial sweeteners can be detected by a single receptor, a G-protein-coupled dimer of the subunits T1R2 and T1R3.[163] Interestingly, one mechanism for sensing amino acids involves one of these same subunits, T1R3, paired with a different one, T1R1.[164] A second amino acid taste receptor is a variant of the metabotropic glutamate receptor.[165,166] All of these receptors have been shown to be specifically localized to taste buds and to respond to appropriate ligands in heterologous expression systems, providing strong evidence for their gustatory function.

These discoveries about the molecular basis of taste transduction are all exciting, but the definition of receptors for amino acid stimuli may have a special significance for understanding taste function in mammals. Although it is widely agreed that the salty, sour, sweet, and bitter sensations represent distinct, fundamental gustatory qualities, the status of the amino acid taste has been more uncertain. Some have proposed that the taste evoked by certain amino acids, namely glutamate, especially in combination with nucleotide compounds like inosine monophosphate (IMP), evoke a unique umami sensation,[130] whereas others have considered the taste of amino acids to be a complex amalgam of the other qualities. The discovery of receptors for these stimuli has reawakened interest in this debate and led to more widespread acceptance of a "fifth basic quality."[83,164,167] However, it should be noted that even though specific receptors may detect such stimuli, this does not assure their independent status at higher levels of the gustatory system or as a perceptual quality. This issue is discussed later in "Central Gustatory Pathways and Function."

Although the T1, T2, and metabotropic glutamate receptors cover a broad spectrum of gustatory responsiveness, it is entirely possible that other receptors for bitter, sweet, and amino acid stimuli are yet to be discovered. There are currently no genetic knockouts for any of these receptors, which could assess the degree of their contribution to gustatory perception. In fact, other mechanisms have been proposed to contribute to bitter transduction. For example, quinine can directly block K^+ channels in taste receptor cells.[168] In addition, discrepancies between recent molecular findings and the much larger body of physiologic studies make it obvious that some of the seductively simple hypotheses about peripheral taste processing are probably not adequate. Questions about bitter processing were mentioned earlier. In addition, in situ hybridization studies demonstrate that T1 and T2 receptors are not colocalized within individual receptor cells (Fig. 89-7). These molecular findings suggest that entirely separate "labeled-lines" code for sweet, bitter, and amino acid stimuli at the most peripheral level of the taste system.[163] In contrast, physiologic studies of taste receptor cells using intracellular (reviewed by Herness[169]) and patch-clamp recording[170] or Ca^{2+} imaging[162] all suggest that, although individual taste bud cells are not equivalently responsive across taste qualities, they do exhibit at least some degree of broad tuning; in other words, they respond to more than a single quality (Fig. 89-8). The reason for the inconsistencies between the molecular biologic and the physiologic investigations is unclear, but the two types of studies give different pictures of taste quality coding by the most peripheral elements of the taste system.

Part of what complicates the interpretation of data on taste bud cells is how little is understood about processing within the bud itself. Aside from the obvious requirement that these cells must exhibit some degree of differential responsiveness across qualities, they also differ in several other characteristics. Importantly, only a fraction of the receptor cells have classic synapses onto the primary afferent nerve (reviewed by Witt and colleagues[134]). Because cells in the taste bud, like other epithelial cells, are in a constant state of turnover, it might be thought that the small number of cells with synapses merely reflect a small number of mature cells in the bud (i.e., cells without synapses are in the process of differentiating and thus can neither respond to taste

stimuli nor transmit information centrally). However, this simple explanation appears not to be true. None of the cells that express gustducin, a known element in bitter transduction, have classic synapses.[171] Thus the mechanism by which information from gustducin-containing, bitter-responsive cells reaches primary afferent neurons is mysterious. Perhaps these receptor cells communicate directly with primary afferent neurons using nonclassical synapses or first send information to other cells in the taste bud, which in turn, synapse with the primary afferent neuron. The possibility of intra-bud communication is bolstered by recent observations that taste bud cells contain and respond to a variety of neurotransmitters and peptides.[172,173] A recent molecular study[174] suggests that after receptor binding, downstream signaling events for bitter, sweet, and amino acid transduction all require the opening of a specific type of ion channel, the TRP channel. Animals in which the TRPm5 gene has been deleted show no evidence of responses to sweet, bitter, or amino acid stimuli, based either on recordings from the primary afferent nerves or behavioral responses to these stimuli.[174] These results are surprising because many other studies suggest that the downstream signaling events are much more heterogeneous (reviewed by Gilbertson and Margolskee[8]) and provide only limited evidence of TRP-mediated currents in response to taste stimuli in taste receptor cells.[175] A true appreciation of the logic of taste coding at the level of the receptor cell will clearly require a better understanding of the reasons for the discrepancies between the physiologic and molecular work and the nature of integrative processing in the taste bud–primary afferent nerve circuit.

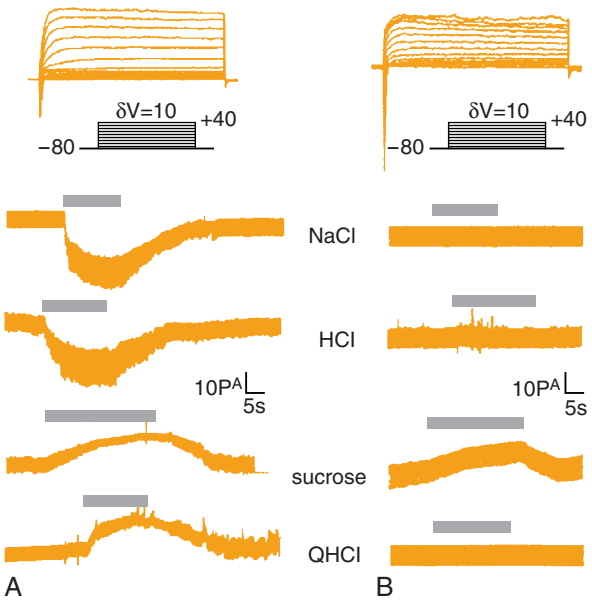

Figure 89-7. Patch-clamp recordings from two taste cells stimulated with four qualitatively different stimuli. The cell on the right **(B)** responds to just a single stimulus, but the cell on the left **(A)** responds to all four stimuli. The molecular data such as those presented in Figure 89-8, would not predict the coexistence of responses to sucrose (sweet) and QHCl (bitter) within a single cell. *(From Gilbertson TA, Boughter JD Jr, Zhang H, Smith DV. Distribution of gustatory sensitivities in rat taste cells: whole-cell responses to apical chemical stimulation.* J Neurosci. *2001;21:4931-4941.)*

Peripheral Sensitivity

REGIONAL DIFFERENCES. Regardless of the controversy surrounding the specificity of responsiveness of individual receptor cells in experimental animals, it is notable that single human fungiform papillae are broadly tuned across taste qualities. In humans, single fungiform papillae have an average of only about four taste buds,[139,176] and thus although there is certainly more than a single receptor cell in a given papillae, at the same time there is quite a limited number. Initial observations that single fungiform papillae were sensitive to a single taste quality resulted from stimulus concentrations that were too low.[177] In taste, as in other sensory systems, there is a trade-off between the area stimulated and the threshold concentration. The lingual threshold for a given gustatory stimulus requires progressively higher concentrations for progressively smaller areas. In one study, when single papillae were stimulated with sufficiently high concentrations, the majority of fungiform papillae mediated multiple taste sensations. Sixty-six percent of the fungiform papillae tested elicited recognition of at least three of the four standard taste qualities.[177] Similar results have been obtained by other investigators.[178,179]

Gustatory receptors sample food or fluid as it is ingested, masticated, and transported to the back of the mouth for swallowing. Receptor densities appear greatest at critical junctures of the ingestive sequence, which are outlined in Figure 89-6. Gustatory receptors at the tip of the tongue are contacted immediately as food enters the mouth and are optimally situated to determine whether to continue or abort the ingestive sequence. A second population on the back and sides of

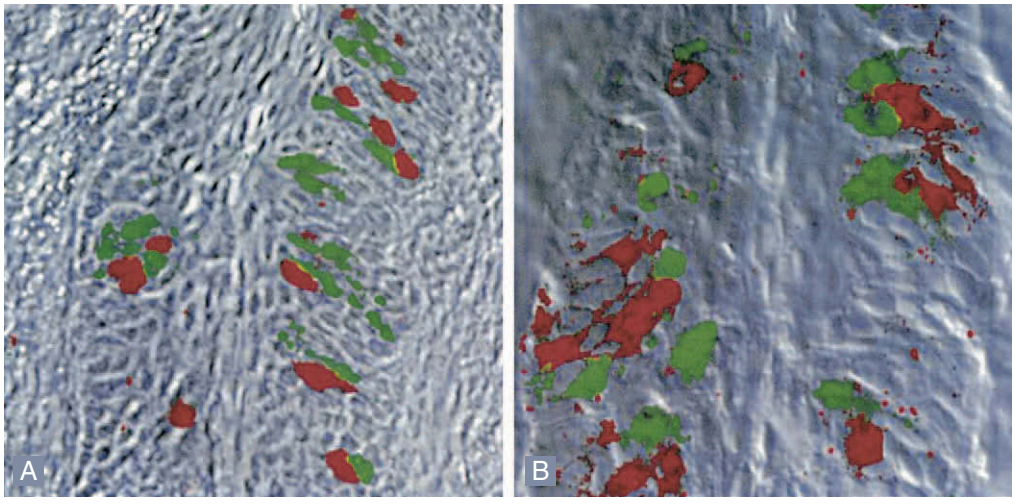

Figure 89-8. Photomicrographs of in situ labeling of taste receptor cells in the circumvallate **(A)** and foliate **(B)** papillae. The red labeling denotes staining with probes for the T2R class of receptors which transduce bitter stimuli; green with the T1R class that transduces sweet or amino acid stimuli. Note the lack of overlap of these classes of receptors within individual cells. These data are in some conflict with physiologic data, such as that shown in Figure 89-7. *(From Nelson G, Hoon MA, Chandrashekar J, et al. Mammalian sweet taste receptors.* Cell. *2001;106:381-390.)*

the tongue and on the opposing palate is probably stimulated during mastication when food is crushed between the molars. In addition to differences in location, the varied sensitivity of the various subpopulations of gustatory receptors to chemical stimuli suggests a differential contribution to gustatory function. However, it needs to be kept in mind that sensitivity differences are relative and not always related in a simple manner to variations in function.

The chorda tympani nerve in many animal species is highly sensitive to a variety of salts (e.g., NaCl). This sensitivity is consistent with human psychophysical studies that show a low threshold to NaCl on the anterior aspect of the tongue.[180] Studies in rats indicate that many individual chorda tympani fibers are sensitive to both NaCl and hydrochloric acid (which tastes sour to humans) but that a subset of peripheral nerve fibers are responsive exclusively to sodium salts.[148] When the sodium channel blocker amiloride was applied to the surface of the tongue, only the sodium-specific fibers lost their responsiveness to NaCl. Those chorda tympani fibers sensitive to both salts and hydrochloric acid maintained their sensitivity to NaCl stimuli in the presence of amiloride, implying that the sodium-specific neurons are particularly important for coding the salty quality of NaCl. Moreover, the recognition of NaCl decreases after chorda tympani nerve section in rats, further indicating a specialized role for this nerve in sodium recognition.[181]

Many mammals including humans have a high sensitivity to sugars and other sweet-tasting compounds on the anterior tongue. A common subject in gustatory research, the rat seems to be an exception because of its poor anterior tongue sensitivity to sweet stimuli. However, even in this species, a robust responsiveness to sweet stimuli is apparent in the anterior oral cavity, specifically in the nasoincisor ducts on the hard palate that lie in apposition to the anterior tongue.[182] The greater superficial petrosal branch of the facial nerve innervates the nasoincisor duct and soft palate receptors. In fact, the soft palate is also highly responsive to sweet stimuli.[183,184] Another rodent, the hamster, also exhibits a relatively greater responsiveness to sweet stimuli applied to the palate vs the tongue, but the hamster tongue also responds well to sweet stimuli.[185] Whether other mammals including humans are relatively more responsive to sweet stimuli applied to the palate is an open question. However, in humans, taste buds have only been described on the soft[186] but not the hard palate. Across a variety of species (e.g., rat,[187] sheep,[188] gerbil,[189] mouse,[190] monkey[191]), gustatory receptors on the posterior tongue are relatively more responsive to aversive, particularly bitter, stimuli than are receptors in the anterior oral cavity. Stimulation of taste receptors with bitter tastants initiates powerful rejection responses.[192-194] Consistent with this differential sensitivity, sectioning the glossopharyngeal nerves in rats attenuates the rejection response to quinine monohydrochloride to a greater degree than does sectioning the chorda tympani nerves.[195,196] However, surprisingly, section of the chorda tympani nerve actually has a greater effect on quinine discrimination.[197] These consequences of lesions and other considerations have led to the suggestion that the anterior oral cavity is more important in gustatory discrimination per se (regardless of quality), whereas the posterior oral cavity is more important in providing input for gustatory-guided reflexes.[187,197]

A specific function is particularly apparent for the superior laryngeal nerve. Chemoresponsive fibers in the superior laryngeal branch of the vagus nerve differ greatly from facial and glossopharyngeal nerve sensitivities. In general, superior laryngeal nerve fibers are insensitive to NaCl and sucrose but respond well to stimulation with potassium chloride, ammonium chloride, acids, and interestingly, water.[198,199] In fact, individual nerve fibers in the superior laryngeal nerve are not divisible into groups on the basis of their optimal sensitivity, as are fibers in the chorda tympani and glossopharyngeal nerves, but rather compose a single broadly responsive group.[200] The location of superior laryngeal nerve-innervated taste buds in the larynx and on the epiglottis indicates a protective-reflex role for these receptors, rather than contributing to gustatory quality perception. The superior laryngeal nerve is a particularly low-threshold nerve for eliciting swallows that could protect the airway.[201]

In addition to these neurophysiologic studies in animals, human psychophysical studies show clear regional variation in the recognition threshold to different gustatory stimuli.[180] The front of the tongue had the lowest threshold for both salty and sweet stimuli; sour stimuli had the lowest threshold when applied to the foliate papillae. Although the front of the tongue also had the lowest threshold for bitter stimuli such as quinine, stimulation of the circumvallate papillae produced a steeper intensity function than obtained by stimulating the front of the tongue. The psychophysical scaling results for quinine monohydrochloride are consistent with the frequent observation that bitter sensations are more intense in the back of the mouth. With the exception of the high sensitivity to sour stimuli on the sides of the tongue, the gradient for threshold to chemical stimuli on the tongue follows the gradient for thresholds to mechanical stimuli, with the anterior region the most sensitive.

Despite these regional variations in threshold and concentration response functions, sensations of sweet, sour, salty, and bitter can be elicited from each oral region where taste buds are present. Moreover, the loss of a single gustatory nerve may not be apparent to the individual and can often be ascertained only by specific psychophysical procedures.[202] In general, the high degree of specialization among the different gustatory nerves of experimental animals is not as obvious in humans. Destruction of the chorda tympani from middle ear surgery destroys taste sensitivity from the front of the tongue,[203,204] but there have been no reports of a disruption of salt intake. However, following third molar surgery, which has the potential to damage the chorda tympani nerve, patients incorrectly identified the taste of NaCl slightly more frequently after surgery.[205] It is also interesting to note that humans with laryngectomies reported thirst less often and were less able to localize thirst compared with a control group, suggestive of a role for the superior laryngeal nerve.[206] Although deficits after damage of single taste nerves are neither profound nor impressively specific, these data need to be interpreted cautiously due to their limited nature. Thus only a few studies of taste responsivity after chorda tympani damage have been carried out; no studies of the gustatory consequences of glossopharyngeal damage have been reported. In addition, perceptual testing has been limited and may not have detected subtle but significant effects on gustatory discrimination. Nevertheless, the regional intraoral variation of taste sensitivity of humans may represent only a vestigial form of reflex organization, superseded by a wider distribution of gustatory sensitivities within the oral cavity and by an increase in the voluntary neural control of ingestion.

INDIVIDUAL DIFFERENCES. Although there are regional differences in taste sensitivity within an individual, an equally salient feature of human gustatory perception is wide variation from person to person. Several studies have demonstrated as much as a 100-fold variation in detection threshold for both sucrose and NaCl across a wide age span.[207] The longest studied and perhaps clearest example of individual differences is the variation in both threshold and responsiveness to the chemically related compounds propothiouracil (PROP) and phenylthiocarbamide (PTC). Decades before anything was known of the molecular basis of bitter transduction, a fortuitous discovery by a chemist synthesizing PTC revealed that some persons found relatively low concentrations of this substance intensely bitter, whereas others found it nearly tasteless.[208] Genetic studies have found this variability to be a heritable trait, but there is still disagreement on the mode of inheritance.[209] Although thresholds for PTC and PROP show a bimodal distribution, there is a continuum of sensitivity in the middle range, suggesting that PTC/PROP sensitivity is not transmitted as a simple Mendelian dominant trait. Rather, partial dominance or multilocus models appear more appropriate.[209] In a recent study, Reed and colleagues[160,209] found a strong linkage to chromosome 5 and a suggestion of a linkage on chromosome 7 near sites where the molecular studies have identified G-protein-coupled receptors for bitter stimuli. Thus it might be tempting to speculate that PROP sensitivity is a consequence of phenotypic variation in the inheritance of partially dominant bitter receptors strongly responsive to PROP and related compounds. However, in some studies, persons who exhibit high or low responsiveness to PROP show similar differences to other stimuli including other bitter-[210,211] and sweet-tasting[211] compounds, as well as differences in responsiveness to a nongustatory stimulus, capsaicin, which produces a burning sensation.[211] Thus it seems possible that some of the variabil-

ity in PROP sensitivity reflects a more general variation in oral sensory sensitivity.

Indeed, differences in the number of fungiform papillae and pores have been identified in groups of people with high, moderate, and low sensitivity to PROP. "Supertasters" have the most fungiform papillae and highest sensitivity, "nontasters" have the fewest fungiform papillae and lowest sensitivity, and "medium-tasters" are in between on both measures.[212] Other studies have demonstrated a similar relationship between papillae number and sensitivity to gustatory stimuli including sucrose, NaCl, and PROP.[176] However, the relationship between fungiform papillae number and taste sensitivity, whether to PROP or other compounds, exhibits a high degree of variability, such that individuals assigned to various groups often overlap in their anatomic characteristics.[176,210,212] Thus the factors underlying individual differences in taste sensitivity are undoubtedly multifactorial and include not only multiple genetic factors (some yet to be discovered), but environmental factors such as nerve damage caused by otitis media,[213] as well as a decline in taste sensitivity with age.[214,215]

Whatever the underlying basis, it is interesting that a number of studies have made the suggestion that variation in taste sensitivity has the potential to affect health. Thus although there is not universal agreement, several studies have reported that people with a high PROP sensitivity claim less preference for certain vegetables (reviewed by Drewnowski[7]), and this appears to affect their intake.[216] Preliminary evidence suggests that these preferences could affect gastrointestinal health. A recent abstract[217] reported a positive relationship between colon polyps and PROP taster status. A relationship between oral health and PROP status has also been claimed, with individuals sensitive to PROP having fewer dental caries.[218-220] It has been speculated that this is due to a greater sensitivity to sweet, as well as bitter, substances, so highly sensitive individuals can consume lower amounts of sugar to achieve the same amount of satisfaction. However, given the lack of unanimous agreement on the positive relationship between PROP and general gustatory sensitivity, as well as the lack of any direct evidence regarding dietary habits in these individuals, more work is necessary to validate these claims and to understand their basis.

Central Gustatory Pathways and Function

Afferent gustatory fibers in the facial, glossopharyngeal, and vagus nerves synapse in the nucleus of the solitary tract (NST) of the medulla with a rostral to caudal organization.[221,222] In primates, taste information projects directly to the gustatory thalamus, which is situated medial to the oral somatosensory representation in the ventroposteromedial nucleus.[223] From the thalamus, taste information projects to the insular-opercular region of the cortex,[224] which comprises the primary gustatory cortex and then to a secondary gustatory cortical area located immediately anterior in the caudolateral orbitofrontal cortex.[225] The secondary gustatory cortex projects to several regions of the ventral forebrain including the hypothalamus and amygdala.[10] Positron emission tomography and functional MRI studies in humans have demonstrated that cortical regions analogous to those demonstrated on the basis of anatomic and physiologic studies in nonhuman primates most likely also comprise the primary and secondary gustatory cortical areas in people (Fig. 89-9).[226]

The gustatory pathway in rodents is organized somewhat differently. Taste information from the NST reaches an analogous thalamic relay in the ventro-posteromedial nucleus, but only after an additional synapse in the parabrachial nucleus of the pons.[227,228] The region identified as the primary gustatory cortex in rodents is also the insular cortex,[229,230] but a secondary taste cortex has not yet been identified. Instead, in rodents, taste information reaches limbic areas more directly, via a projection from the parabrachial nucleus.[231] However, regardless of species and the route the information takes, it has been hypothesized that the thalamocortical pathway can be specialized for perceptual/discriminative gustatory functions; the limbic projections may be more involved in the hedonic/motivational attributes of taste.[232] Local brainstem gustatory pathways, however, have the capacity to mediate basic gustatory discriminative functions. Decerebrate animals[233] and anencephalic human infants[193] discriminate palatable from unpalatable gustatory stimuli.

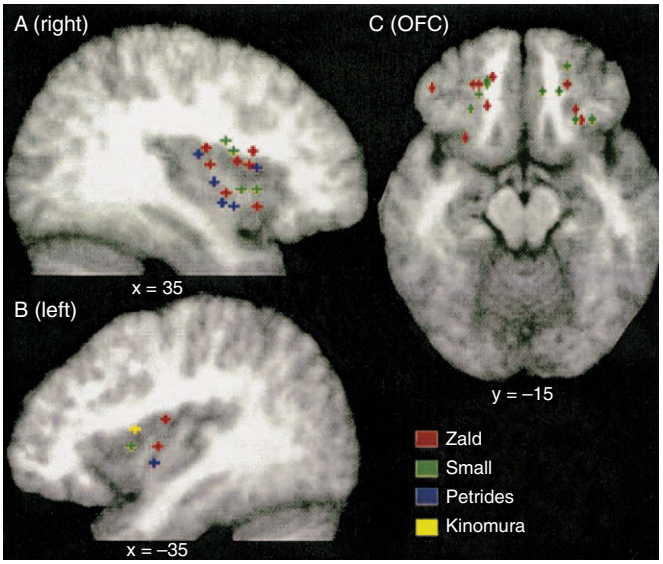

Figure 89-9. Human magnetic resonance images in the parasagittal (**A** and **B**) and horizontal **(C)** planes denoting the location of primary gustatory cortex in the insular-opercular region (**A** and **B**) and secondary gustatory, orbitofrontal **(C)** cortex. The different-colored symbols denote data from various laboratories. *(From Small DM, Zald DH, Jones-Gotman M, et al. Human cortical gustatory areas: a review of functional neuroimaging data.* Neuroreport. *1999;10:7-14.)*

Gustatory pathways are in close anatomic proximity with central pathways controlling the autonomic nervous system function. This proximity provides a substrate for interactions between gustatory and autonomic afferent information,[234] as do the numerous connections between limbic structures and the nuclei in the taste pathway.[140] In rodents, an early study demonstrated changes in the firing pattern of gustatory-responsive neurons in the nucleus of the solitary tract in response to gut distension that were indicative of interaction between the autonomic and gustatory systems.[235] More recent studies have extended these findings to the parabrachial nucleus. Indeed, not only does gut distention affect parabrachial taste neurons,[236] but another manipulation that mimics satiety, intraduodenal lipid infusion, also affects gustatory firing rates.[237] Specifically, lipid infusions depress taste responses, and furthermore this occurs mainly for responses to normally preferred gustatory stimuli. Thus lipid infusions most profoundly depress responses in neurons preferentially responsive to NaCl, and especially those responsive to sucrose. This is in contrast to a lack of effect on responses evoked by HCl and QHCl, stimuli that animals do not normally voluntarily ingest.[237] These effects of gastric and duodenal stimuli suggest a simple mechanism for the reduction in intake that occurs with the visceral sequelae of intake—namely, that neurons responsive to preferred taste stimuli, which normally drive ingestion, reduce their input into feeding circuits when the animal is satiated. Other changes in body state that affect ingestion have also been shown to have effects on early stages of taste processing in rodents. Both sodium deprivation and conditioned taste aversion have stimulus-specific effects in the NST.[238-240] In fact, different levels of dietary sodium even affect responses at the level of the peripheral nerve.[241,242] However, the nature of these neural changes induced by sodium appetite or conditioned taste aversion can be rather complex, and taken together they are not correlated in a straightforward way with the behavioral changes these state changes produce.[240] It is also of interest that these modulations observed at the early stages of gustatory processing in rodents appear only to occur at higher stages of processing in primates, although this has been evaluated only after inducing a state of satiety. In monkeys, recordings from the NST from awake, behaving animals showed that gustatory responses did not change as the animal was fed to a state of satiety.[243] In fact, taste responses were likewise stable in the primary insular-opercular cortex, regardless of whether the animal was

hungry or sated.[244] However, in secondary, orbitofrontal gustatory cortex,[245] as well as in the hypothalamus[246] and amygdala,[247] taste responses become progressively reduced during the course of feeding. A particularly interesting aspect of the primate phenomena is that the effect on taste responses exhibits what is known as "sensory-specific" satiety. That is, even within the realm of preferred stimuli, taste responses are most reduced for the stimulus that actually produces the satiety. For example, neurons responsive to both glucose and a complex stimulus, black currant juice, mainly exhibited reduced glucose responses if glucose was used to feed the monkey until he refused this stimulus. Neural and behavioral responsiveness to black currant juice, however, were relatively unaltered.[10]

Analogous to these effects demonstrated in experimental animals, changes in body state also affect perception of taste stimuli in humans. Such a phenomenon is readily demonstrated in short-term experiments, when subjects rate the pleasantness of a sweet taste before and after the induction of satiety. A classic study by Cabanac and colleagues[248] showed that ratings of the pleasantness of sucrose declined over time when subjects ingested the samples, drank an equivalent quantity of sucrose as a bolus, or received intragastric sucrose. Interestingly, ratings were unaffected by simple gastric distention, infusion of hypertonic saline, or intravenous glucose infusion. Later studies found similar effects.[9] Further, similar to the primate experiments just discussed, these changes in pleasantness exhibit sensory-specific satiety[249] and, accordingly, people will eat larger meals when the meals are composed of more varied foods.[250]

It has been more difficult to document preference of differences among populations of persons with different chronic conditions. For example, preferences for sweet stimuli in obese versus nonobese persons have been reported to be enhanced in some studies, but in other studies have been reported to be depressed or the same.[9] It seems likely that these equivocal results reflect the heterogeneity of the obese population in terms of etiology, chronicity, and dietary status, as well as the complexities involved in obtaining accurate preference ratings, particularly in a population of people who may feel self-conscious about their eating habits. Studies of diabetic patients are more consistent in reporting elevated psychophysical thresholds to glucose.[251,252] Loss of gustatory sensitivity in diabetics may result from a systemic lack of glucose receptors and from general neuropathy. However, even diabetes can be associated with multiple effects. An animal model of this disease, performed with the db/db mouse, shows elevated peripheral nerve responses to sugars.[253] Thus conditions that affect carbohydrate metabolism and body weight obviously have the potential to influence taste responsiveness, but the relationship is complicated and requires further study.

Recordings from the gustatory cortex of awake, behaving monkeys are relevant to current issues raised on the basis of cellular and molecular studies of taste transduction. One question is whether monosodium glutamate and related compounds evoke a unique gustatory quality, umami, with a status that is as distinct as the four classical taste qualities: sweet, salty, sour, and bitter. A related question is whether the gustatory world extends to fatty stimuli. Both questions have fundamental implications for understanding the functional organization of the taste system because they seek to expand the array of qualities that the system must represent and, furthermore, the qualities in question represent basic food groups important to human nutrition.

With regard to umami taste, evidence from cortex is in some disagreement. An initial study[254] suggested a unique status for this quality. Recordings from primary and secondary gustatory cortex demonstrated that the prototypic umami stimulus, monosodium glutamate (MSG), was just as effective as four standard gustatory stimuli—glucose (sweet), NaCl (salty), HCl (sour), and QHCl (bitter)—measured either by average firing rates or with regard to the number of neurons that responded optimally to a given stimulus. Furthermore, the neural representation of MSG relative to the other stimuli was just as distinct as the above four stimuli were from each other on the basis of correlations between responses to the stimuli evoked across the populations of neurons. Although the stimulus array used in that study was limited and did not allow a ready comparison between stimuli that are known to be the same and those known to be different, in a follow-up study with the four standard taste stimuli plus two umami stimuli,[255] it was indeed shown that the representation of MSG and the other umami stimulus, IMP, was more similar than any other stimulus pair. However, these data are not entirely compelling because the correlation between MSG and IMP (0.77) was actually only nominally greater than the correlation between MSG and the sour stimulus, HCl (0.71). Furthermore, in another study that used a large array of amino acids, MSG was not shown to be distinctly represented relative to the four standard qualities but was instead highly correlated with NaCl,[256] an observation that has been made frequently at lower levels of the rodent gustatory system.[257] Thus although amino acid stimuli activate a special set of gustatory receptors and are effective for stimulating taste neurons throughout the neuraxis, whether or not they represent a unique taste or a complex conglomerate of the classic four is still unresolved.

The neural representation of dietary fats has long been a mystery. Although the presumption had been that fat stimuli were represented not on the basis of their ability to stimulate the gustatory system but rather due to their olfactory and somatosensory properties, interest in a possible gustatory efficacy was reawakened by the discovery that certain free fatty acids were capable of stimulating taste receptor cells.[258] This neural representation of fat has recently been studied in the monkey orbitofrontal cortex.[259,260] This is a particularly appropriate brain region in which to study these stimuli because it receives not only gustatory but also olfactory and somatosensory inputs. Fatty stimuli (e.g., cream) were shown to activate a small subset of neurons in the orbitofrontal cortex. Occasionally, neurons were observed that responded to fat stimuli but not to standard taste stimuli, but more frequently fat-responsive cells were also taste responsive. There was not an obvious relationship between the gustatory sensitivity spectrum of a neuron and whether it responded to fat stimuli. Significantly, the chemical properties of the fats were not important in their effectiveness because nonfat stimuli including silicone and mineral oil were just as effective as dietary fats such as cream and vegetable oil. Thus at least in this sample of neurons, neither the olfactory nor the gustatory properties of the fats appeared to be responsible for driving the cells. Furthermore, the free-fatty acids specifically shown to stimulate taste receptor cells, linoleic and lauric, were poor stimuli for these cells, being no more effective than water. Indeed, this was true even though coconut oil, which contains high amounts of these fatty acids, was a highly effective stimulus. Thus it was concluded that the somatosensory properties of the fats were the determining factor. Interestingly, a parametric investigation of the responses of these cells to viscosity revealed that the responses of only a subset of these cells to fat could be predicted by their responses to viscosity. Thus a different, unidentified somatosensory property must be a critical variable in determining the effectiveness of fats as a stimulus.

Interaction between Saliva and Taste

The presence of saliva in the mouth continually stimulates gustatory receptors with low levels of salt ions. Correspondingly, recognition thresholds for NaCl are somewhat raised when the tongue is adapted with a solution containing salivary levels of sodium (4.3 mm compared with recognition thresholds using distilled water rinses, 0.14 mm).[261] By implication, the presence of other salivary constituents as a result of either disease or medication may affect gustatory sensitivity.[262] Salivary concentrations of pirmenol in patients being treated for ventricular arrhythmias, for example, can produce the bitter taste reported by these patients.[263] Increased salivary levels of glucose in diabetic patients provide one mechanism for the increased detection thresholds for glucose in this patient population.[252]

Saliva can also exert a trophic influence on gustatory receptors. Patients suffering long-term salivary loss as a result of Sjögren's syndrome had increased detection and recognition threshold to many gustatory stimuli.[264] Biopsy specimens of the circumvallate papillae from a subset of these patients indicated a profound loss of taste buds. The effects of desalivation on both taste bud morphology and gustatory sensitivity have also been explored in animals.[265,266] Surgically removing the salivary glands was associated with increased keratosis of the lingual epithelium and shrinking of the circumvallate papillae. Correlated with these morphologic changes was the increased consumption of nonpre-

ferred gustatory stimuli, indicative of a loss of gustatory sensitivity. Electron microscopic observation of the circumvallate papillae showed the infiltration of bacteria, suggesting that the loss of antibacterial agents in saliva permitted degenerative microbial action. Lack of salivation by acute pharmacologic manipulations in experimental human studies, however, had relatively little effect on gustatory sensitivity.[267]

The loss of taste acuity in humans after radiotherapy to the head and neck could result directly from the destruction of taste buds and indirectly from reduced salivary flow.[268] Direct irradiation of gustatory structures in experimental animals produced a loss of taste buds.[269] Radiotherapy can also influence the gustatory system through the formation of conditioned taste aversions.[270,271] Clinical observations of hedonic changes in taste may result, in part, from the pairing of a conditioned stimulus (food) with an unconditioned stimulus, the gastrointestinal distress resulting from either chemotherapy or abdominal radiation. Animal experiments indicate that such pairings can have a profound impact on gustatory preferences.[272] Animal studies also indicate that the formation of a conditioned taste aversion is a central phenomenon that requires an intact forebrain.

CHAPTER NINETY

Mechanisms of Normal and Abnormal Swallowing

Jeri A. Logemann

Key Points

- Knowledge of normal swallow physiology is the basis for identification of dysphagia.
- Evaluation of oropharyngeal dysphagia requires careful and detailed assessment of all physiologic aspects of the oropharynx, usually with videofluoroscopy or videoendoscopy.
- Treatment of oropharyngeal dysphagia is directed to each patient's specific abnormality.
- Treatment for oropharyngeal dysphagia is largely behavioral and may involve posture change, exercises, sensory stimulation, application of voluntary control of swallowing, and diet change.
- All types of treatment for oropharyngeal cancer can cause various abnormalities in oropharyngeal swallow.

Stages of Normal Deglutition

Swallowing is a complex neuromuscular function involving structures in the oral cavity, pharynx, larynx, and esophagus. Various researchers have divided normal swallowing into four stages: the oral preparatory stage, the oral stage, the pharyngeal stage, and the esophageal stage.[1-5] The first two stages, the oral preparatory and the oral, are under voluntary control, whereas the second two stages, the pharyngeal and esophageal, are involuntary, being under reflexive control.[6,7] The oral stage of swallow is under voluntary control, whereas the pharyngeal swallow is no longer considered a reflex but rather a programmed activity; the motor program varies with the characteristics of the food being swallowed (i.e., the bolus), voluntary control, and other as yet undefined parameters.

Voluntary Stages of the Swallow

Oral Preparatory Stage

The oral preparatory aspect of deglutition, which prepares food for the swallow, involves the coordination of (1) lip closure to hold food in the mouth anteriorly, (2) tension in the labial and buccal musculature to close the anterior and lateral sulci, (3) rotary motion of the jaw for chewing, (4) lateral rolling motion of the tongue to position food on the teeth during mastication, and (5) bulging forward of the soft palate to seal the oral cavity posteriorly and widen the nasal airway.[4] The forward position of the soft palate is not present during active chewing, and premature spillage while chewing is common and normal in people of all ages. Much of this coordination requires cerebellar input.[8] The oral phase of deglutition is mechanical in that it involves the reduction of solid food to a pulverized consistency that may be easily swallowed. The most important neuromuscular function involved in the oral preparatory phase is the lateral rolling motion of the tongue.[9] Without normal range-of-tongue motion, the manipulation and mastication of food during the oral preparatory phase would be impossible. At the termination of the oral preparatory phase, the tongue pulls the food together into a ball or bolus and holds it in a cohesive fashion on the floor of the mouth or against the hard palate (Fig. 90-1) in preparation for the beginning of the oral phase of the swallow.[4,7,10-13]

Oral Stage

The oral stage of the swallow is also a mechanical, voluntary stage and is designed to move food from the front of the oral cavity to the pharynx, wherein the pharyngeal stage of swallow is initiated. Again, tongue motion is the most critical element in this phase of the swallow because the tongue shapes, lifts, and squeezes the bolus upward and backward along the hard palate until the food reaches the pharynx.[14-17] During this posterior propulsion by the midline of the tongue, the lateral margins of the tongue are sealed against the alveolar ridge, providing resistance against which the midline of the tongue propels the bolus.[15] Tension in the buccal musculature is also thought to contribute to propelling the bolus backward, but to a much lesser degree than tongue movements.[18] When the head or leading edge of the mandible crosses the tongue base, the pharyngeal swallow should be triggered in healthy people of all ages (Fig. 90-2). The pharyngeal swallow is usually triggered by the glossopharyngeal nerve (C9). In healthy people, the oral stage lasts no more than 1 to 1.5 seconds and is slightly prolonged with increasing age and with increasing viscosity of the bolus swallowed.[5,19]

In animal studies and in healthy humans, the pharyngeal swallow has been found to be triggered not only from C9 but also from the superior laryngeal nerve at the inlet of the larynx.[20-25] Normal swallowing does not use this secondary mechanism for triggering the pharyngeal swallow because food would have almost entered the airway by the time the pharyngeal swallow was triggered. Thus when videofluoroscopic examination of a patient shows that the pharyngeal swallow triggers late, as food is about to enter the airway or after the bolus has come to rest in the valleculae or pyriform sinuses, the patient is said to have a disorder of swallowing called a *delayed triggering of the pharyngeal swallow.*

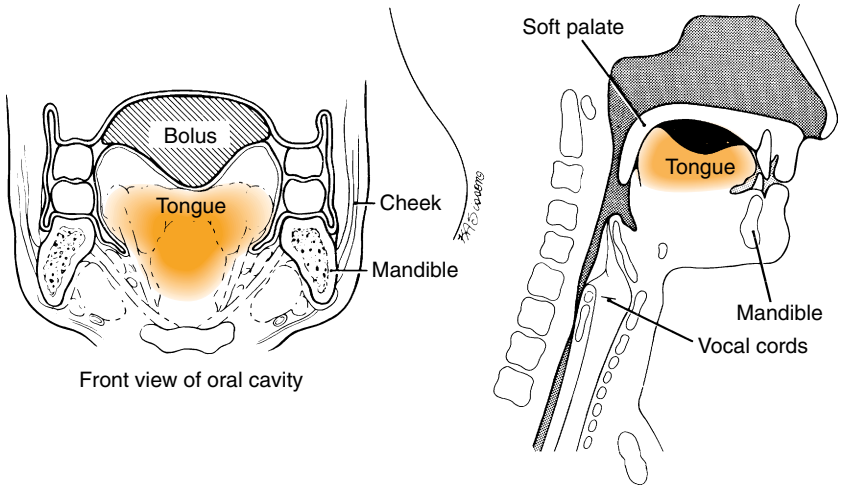

Figure 90-1. The anterior and lateral views of tongue position in holding bolus immediately before initiating oral stage of swallow.

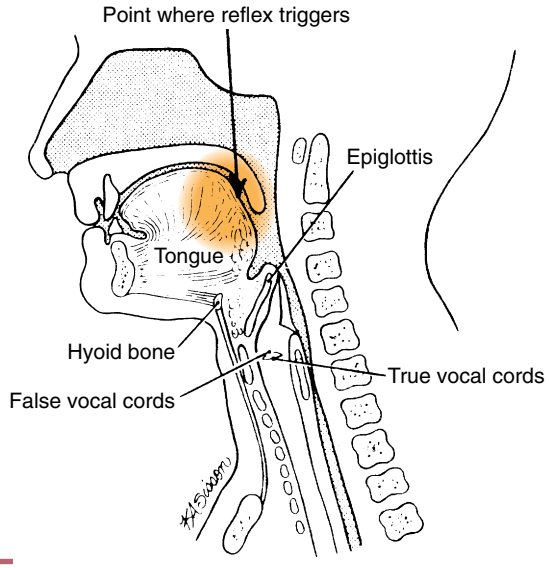

Figure 90-2. The lateral view of the head and neck illustrating the normal point at which swallowing reflex triggers.

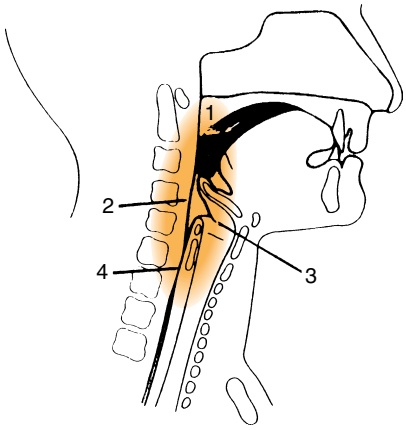

Figure 90-3. The lateral view of the head and neck, showing four neuromuscular components triggered by swallowing reflex: (1) closure of soft palate, (2) peristaltic action, (3) elevation and closure of larynx, and (4) relaxation of cricopharyngeal muscle.

Programmed Stages of the Swallow

Pharyngeal Stage

The pharyngeal stage of the swallow is the more physiologically important one because airway protection occurs during this stage in healthy people. The oral preparatory and oral stages of the swallow may be bypassed by reducing the consistency of food to liquid, by syringing food into the back of the mouth, or by positioning the head back so that gravity carries the food into the pharynx. The pharyngeal stage of the swallow cannot be bypassed.

The pharyngeal swallow is mediated in the lower brainstem (the medulla) in the reticular formation immediately adjacent to the respiratory center. Coordination exists between these two centers because respiration ceases for a fraction of a second when the airway closes during the pharyngeal swallow. There is also cortical input to the triggering of the pharyngeal swallow through the tongue movement patterns in the oral phase of the swallow.[20] The exact neurologic substrate for this cortical input is not clearly understood.[26]

Neuromuscular Activities Characteristic of the Pharyngeal Swallow

When the swallowing reflex is triggered, the brainstem swallowing center programs five neuromuscular activities to occur (Fig. 90-3). If triggering of the pharyngeal swallow is delayed, none of these neuromuscular activities occurs until pharyngeal swallow triggers (1) velopharyngeal closure to prevent backflow of material up the nose; (2) tongue base retraction to propel the bolus through the pharynx; (3) pharyngeal contraction to clear residue through the pharynx; (4) airway protection, which involves both elevation and closure of the larynx; and (5) cricopharyngeal or upper esophageal sphincter (UES) opening to allow the bolus to pass into the esophagus.[1,2,27-33]

Velopharyngeal closure and hyoid and laryngeal elevation occur as the first response to triggering the pharyngeal swallow. Then laryngeal closure occurs, followed closely by opening of the cricopharyngeal sphincter. These neuromuscular functions also overlap but do not all last for the entire pharyngeal stage of the swallow. Instead, each lasts only as long as the bolus is passing that part of the pharynx. When the bolus has reached the middle to lower pharynx, the soft palate lowers. At that time, the larynx is closed and elevated and the upper esophageal sphincter is open, preventing the passing bolus from entering the airway and allowing it to enter the esophagus. The duration of the pharyngeal stage of the swallow normally lasts a maximum of 1 second and does not vary dramatically with the consistency of food or age or gender of the patient.[5,19]

Airway Protection

Airway protection, as noted previously, involves two dimensions: elevation and closure. Elevation is created by contraction of strap muscula-

ture, which positions the larynx upward and forward under the tongue base as it is retracted at the end of the oral phase of the swallow. The larynx is pulled up and out of the way of the passage of the food bolus over the base of the tongue. Closure of the larynx involves three sphincters: the epiglottis and aryepiglottic folds, the false vocal folds and airway entrance, and the true vocal folds.[27,28,34-36] The relative importance of each of the three sphincters has been debated in the literature.[35,37,38] Most authors agree that the epiglottis and aryepiglottic folds play a relatively minor role in protecting the airway; their purpose is to divert food around the airway. The most important level of closure, airway entrance closure, is maintained only for the fraction of a second that the bolus is passing the airway.

Cricopharyngeal (Upper Esophageal Sphincter) Opening

The cricopharyngeus muscle acts in opposition to the function of the constrictor mechanism of the pharynx. At rest the constrictors are relaxed, and the cricopharyngeus muscle or upper esophageal sphincter is in tonic contraction to prevent air intake into the esophagus concurrent with inhalation into the lungs. Also, the contracted cricopharyngeus muscle prevents backflow from the esophagus into the pharynx.[1] During the swallow, as the constrictor mechanism is contracting, the cricopharyngeus muscle relaxes at the appropriate moment. The anterior superior movement of the larynx opens the UES, and the bolus passes into the esophagus. The duration of UES opening and airway closure increases as bolus volume increases.[39]

Pharyngeal Pressure Generation: Tongue Base Retraction and Pharyngeal Contraction

When the tail of the bolus reaches the tongue base, the tongue base moves rapidly backward like a piston, increasing pressure in the pharynx. As the tongue base moves backward, the lateral and posterior pharyngeal walls at the tongue base level move inward. The tongue base and pharyngeal walls should make complete contact. Electromyographic and radiographic studies have shown that pharyngeal contraction, or the squeezing action of the constrictor mechanism to move the bolus through the pharynx, occurs sequentially, beginning in the superior constrictor muscle and moving through the medial to the inferior constrictor muscle.[29,40]

Pharyngeal contraction is responsible for clearing material from the pharyngeal walls and pyriform sinuses. When residue or material remains in the valleculae after the swallow, it is interpreted as a symptom of reduced tongue base movement.[41] Tongue base movement occurs later as bolus volume increases.

Esophageal Stage

When the bolus has passed through the UES, the esophageal phase of swallow begins. The esophageal stage has greater variability in duration than the other stages of the swallow. Normal esophageal transit may vary from 8 to 20 seconds.[4] The upper third of the esophagus is composed of mixed voluntary and involuntary muscle, and the lower two thirds is composed entirely of involuntary muscle. The lower esophageal sphincter acts as a valve to the stomach, which must open in time to allow the bolus to pass from the esophagus into the stomach.

In summary, the pharyngeal stage of the swallow is responsible for transit of material into the esophagus and for airway protection, probably the most important aspect of deglutition.

Figure 90-4 illustrates the progression of the bolus through the pharynx. If an anatomic or neuromuscular disorder affects the pharyngeal stage of the swallow, aspiration may result.

Signs and Symptoms of Abnormal Swallow

Aspiration (Coughing, Choking)

Aspiration is the entry of material into the airway below the true vocal folds. The effect of chronic aspiration in adults is not well understood, but in the long term it may result in pneumonia or pulmonary changes. Patients who are observed to aspirate on a radiographic study of swallowing are at significantly greater risk of pneumonia developing than patients who do not show aspiration on such a study. Many patients with head and neck cancer who have chronic aspiration do not survive long enough to experience the long-term effects of their aspiration. Aspiration may occur before, during, or after the pharyngeal swallow.[4] Aspiration that occurs before the pharyngeal swallow may result from one of two disorders: reduced tongue control or a delayed or absent pharyngeal swallow. When tongue control is reduced during the oral preparatory or oral stages of the swallow, bits and pieces of food may fall into the pharynx and the open airway as the patient chews. Importantly, the airway is normally open during the oral preparatory and oral stages of the swallow. The airway is closed only for a fraction of a second during the pharyngeal swallow. Aspiration before the swallow can also occur because of a delayed or absent pharyngeal swallow. In these patients, the food is propelled out of the oral cavity by the tongue and falls into the pharynx, wherein it may come to rest in the valleculae, the pyriform sinus, or the airway before the pharyngeal swallow is triggered. The entry of food into the airway does not always trigger a cough, particularly in neurologically impaired patients and some patients with head and neck cancer in whom sensory input is damaged.[41,42]

Aspiration during the swallow takes place when airway closure is inadequate to prevent material from entering the airway during the pharyngeal swallow. Aspiration after the swallow occurs for a number of reasons including reduced laryngeal elevation, reduced tongue base retraction, reduced pharyngeal contraction, unilateral pharyngeal damage, or cricopharyngeal dysfunction. In all of these instances, residue remains in the pharynx after the swallow. When the patient opens the larynx to inhale as is normal after a swallow, some of this residue is sucked or falls into the airway. Determination of the cause of aspiration is critical for efficient treatment. Aspiration is only a symptom of a disorder. Evaluation of swallow is designed to identify the anatomic or physiologic cause of the aspiration. Treatment is designed to eliminate the reason for the aspiration. Each of the disorders noted previously as potential causes of aspiration is treated differently.

Inefficient Swallowing

Inefficient swallowing (i.e., inability to propel food or liquid into the stomach) at each meal can cause malnutrition, dehydration, and/or weight loss. Many different anatomic or physiologic swallowing disorders may cause these complications. As with aspiration, treatment is directed at the anatomic or physiologic disorder causing these complications.

Screening for Swallowing Disorders

Screening involves quickly reviewing patient characteristics to see whether they indicate the possible presence of a swallowing disorder and the need for a more in-depth examination. To screen a patient, the clinician may do a chart review, briefly talk with the patient, and/or observe him or her eating a meal.

Evaluation of Swallowing

Because inefficient swallowing or aspiration occurs in many patients without visible external symptoms such as coughing, a careful evaluation of swallowing is imperative for patients who have been temporarily removed from oral feeding because of surgery or a neurologic incident such as a cerebrovascular accident or closed head trauma. The currently available procedures to examine swallowing include fluoroscopy, manometry, ultrasonography, and endoscopy.

Bedside Evaluation

Bedside evaluation is the next step after screening a patient and includes assessment of facial, lip, tongue, pharyngeal, laryngeal, and respiratory control, as well as the patient's ability to follow directions. The bedside evaluation also includes an oropharyngeal structural examination. It ends with a recommendation as to whether the patient needs an instrumental assessment such as fluoroscopy or endoscopy. An instrumental assessment is necessary if the clinician suspects that the patient may have a pharyngeal stage abnormality that is invisible on bedside evaluation.

Videofluoroscopy

Videofluoroscopy is the only available procedure that allows direct observation of the upper aerodigestive tract during all four stages of

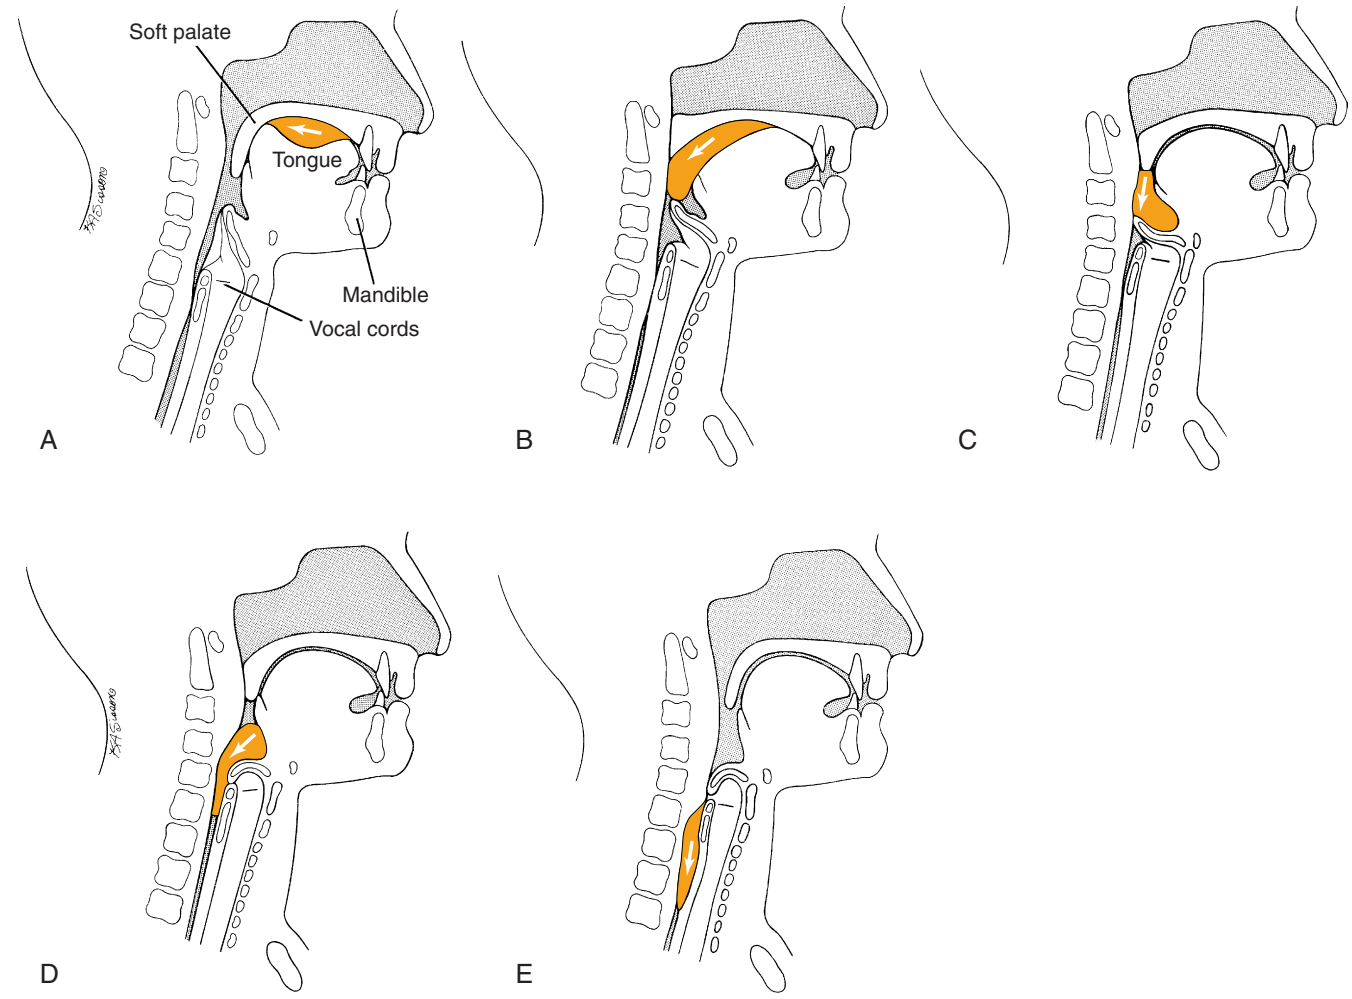

Figure 90-4. **A** through **E,** Lateral views of the head and neck illustrating progression of bolus through the pharynx.

deglutition, beginning with the oral preparatory phase and terminating with the esophageal phase. The standard barium swallow or "upper gastrointestinal (GI)" procedure is inappropriate for head and neck surgical patients or neurologic patients who have severe problems swallowing because of severe risk for aspiration.

In the usual barium swallow procedure, the patient is given a cup of barium and asked to swallow repeatedly. This procedure is designed to examine anatomy and motility in the esophagus, which is a collapsed tube that must be filled with barium to be viewed. For accurate evaluation of esophageal peristalsis without the effect of gravity, the patient lies in a supine position and usually viewed in the anteroposterior plane.

The modified barium swallow (MBS) technique is used to examine the oral cavity and pharynx radiographically, which presents different problems from those encountered when examining the esophagus. By definition, the oral cavity and pharynx are cavities. When they are filled with large amounts of material, visualization of their structure and function is obliterated rather than enhanced. In addition, the patient with an oral or pharyngeal swallowing disorder has greater difficulty handling a large bolus and is at much higher risk of aspiration. Thus modification of the barium swallow technique is necessary when assessing patients with oral and pharyngeal swallowing disorders. Only measured amounts of material are used because patients may exhibit difficulty in swallowing liquids as volume increases but not in swallowing heavier foods or vice versa.

During the MBS, the patient is seated upright in a normal eating position. In dysphagic patients, the physiology of the oral cavity and pharynx in the normal eating position must be established first. Then, if desired, the patient's position can be changed to note the postural effects on food flow during swallowing. In the modified barium swallow procedure, the patient is initially viewed in the lateral plane with the fluoroscopy tube focused on the lips anteriorly and the seventh cervical vertebra inferiorly as shown in Figure 90-5. This allows complete assessment of oral and pharyngeal motility and of aspiration during the pharyngeal aspect of the swallow. In the anteroposterior view, the trachea overlies the esophagus, making assessment of aspiration difficult.

The major purposes of the modified barium swallow are to (1) define the immediate oral and pharyngeal motility disorders during the swallow; (2) identify the presence of aspiration during swallow of any food consistency; (3) assess the speed of the swallow (compared with normal); and (4) assess the effects of therapy strategies such as postural changes, heightened sensory input, and therapy procedures including swallowing maneuvers.[16,36,41,43-50] If the patient aspirates or has a highly inefficient swallow, treatment procedures are introduced during the videofluoroscopic study to improve the swallow and allow the patient to continue to eat orally or return to oral intake as quickly as possible. The purpose of the test is to restore oral intake—not to stop the patient from eating.

Endoscopy

Endoscopy by way of transnasal placement of a flexible fiberoptic scope has been used to evaluate some selected aspects of the swallow.[50-53] The oral stages cannot be viewed, and during the swallow the image disappears as the pharynx contracts and closes against the scope. Any residual food in the pharynx after the swallow may be identified, as may any aspiration of the residue after the swallow.

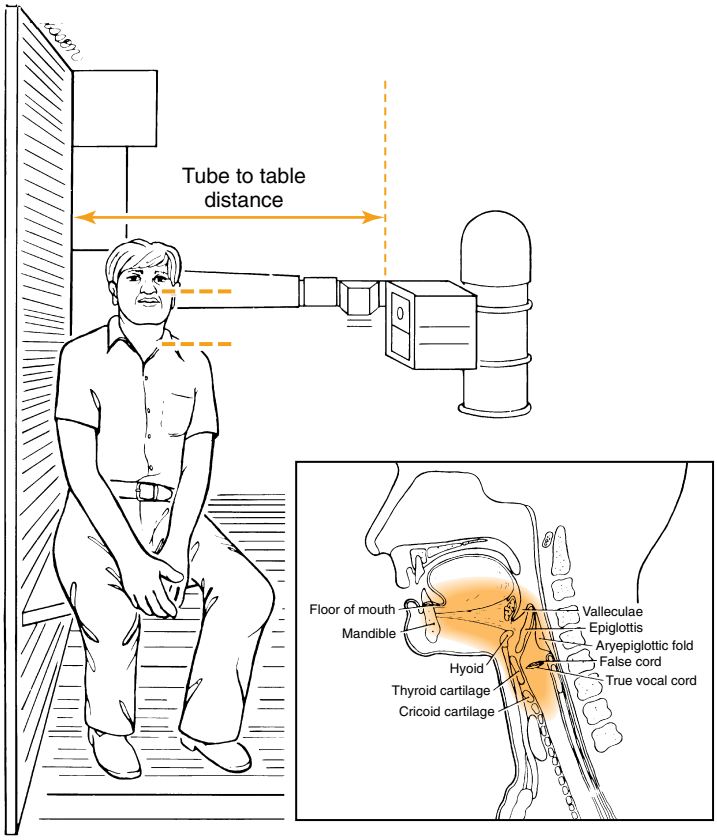

Figure 90-5. Positioning of patient during modified barium swallow. The structures to be examined in this lateral view are shown in lower right corner.

Manometry

Manometry is usually used to examine esophageal peristalsis and the adequacy of functioning of the upper and lower esophageal sphincters.[3,54,55] The patient swallows a soft tube containing pressure sensors. These sensors are positioned so that one registers the pressure in the UES, the second registers pressure changes in the body of the esophagus, and the third registers pressure in the lower esophageal sphincter. The gauges also may be positioned to register pressure in the pharynx, cricopharyngeal sphincter, and the body of the esophagus, thus permitting observation of the temporal relationship between pharyngeal contraction and opening of the cricopharyngeal sphincter.

Ultrasonography

Ultrasonography is used to assess the anatomy and physiology of the tongue during swallowing, but it currently cannot be used to examine the pharynx or larynx because of skeletal interference.[12] Thus it is limited to the study of the oral stage of deglutition.

Swallowing Disorders Resulting from Treatment for Head and Neck Cancer

Radiotherapy

Radiotherapy for the oral cavity and pharynx, in addition to reducing salivary flow and causing short-term oral or pharyngeal edema, may lead to difficulties with triggering of the pharyngeal swallow, laryngeal elevation, and pharyngeal contraction that may begin immediately or months after the therapy is completed.[4,56] Presumably, the problem with laryngeal elevation and pharyngeal contraction relates to increased fibrosis after radiation. The symptoms vary in duration and severity and may appear 6 months or more after completion of a full course of radiotherapy. The long-term effects of radiotherapy on swallowing deserve greater attention and more thorough study.

Chemoradiation

In recent years, treatment protocols that use high-dose concurrent chemoradiation have been increasingly used. Some of the patients undergoing these protocols develop severe swallowing problems, generally including a delayed triggering of the pharyngeal swallow, reduced laryngeal elevation, and reduced pharyngeal contraction, and must take nutrition nonorally. Over time (3 to 12 months), these disorders may reduce in severity so that some of these patients can return to oral intake. A great deal more research is necessary on measurement and treatment of these swallowing disorders after chemoradiation.

Surgical Treatment

The effects of surgical treatment for patients with head and neck cancer on swallowing depend on the site and extent of the resection and the nature of reconstruction.[4,57,58] Some data indicate that the reconstruction determines the swallowing pattern of the patient postoperatively, particularly when smaller amounts of tissue are resected.

Tongue

Within the oral cavity, the tongue is the most important organ for maintaining normal food intake. The tongue is responsible for oral manipulation and chewing to prepare food for the swallow and is responsible for the oral initiation of the swallow. Every effort should be made to permit as much range and coordination of tongue motion as possible. Use of the tongue in surgical closure may dramatically reduce the patient's ability to handle a normal diet.[16]

Posterior Oral Cavity

When a tumor invades the posterior oral cavity, a number of swallowing actions may be affected[59] including tongue mobility during oral preparation and the oral initiation of the swallow, triggering of the pharyngeal swallow, velopharyngeal closure, tongue base retraction, and pharyngeal contraction. Surgery at the tonsil and base of the tongue

directly invades the sensory area where the pharyngeal swallow is usually triggered and also damages the attachments of the pharyngeal constrictors into the base of the tongue, thus reducing tongue base retraction and pharyngeal contraction. Reconstruction of this area with a thick and bulky flap interferes with functioning of the pharynx, tongue, and remaining healthy tissues.[60]

Pharynx

Surgical involvement of the pharyngeal wall itself may dramatically impair pharyngeal contraction. If the surgical resection involves only one side of the pharynx, the patient may turn his or her head to the operated side to assist swallowing on the unoperated and less damaged side, thus directing food down the more normal side.[43] Alternately, the patient may tilt his or her head toward the more normal side to assist gravitational drainage of food down the stronger side. As in the oral cavity, the nature of the reconstruction may interfere with function on the unoperated side so that even with a change in head position the patient is permanently unable to handle food thicker than liquid and may even have difficulty with liquid. Greater pharyngeal peristalsis is required to move heavier and thicker food than is required for liquid.

Larynx

Resection of a part of the larynx, as occurs in hemilaryngectomy or supraglottic laryngectomy, may interfere with three aspects of the swallow: laryngeal elevation, laryngeal closure, and tongue base retraction.

After hemilaryngectomy, laryngeal closure is the greatest problem.[4] Depending again on the nature of the reconstruction and on the nature and amount of tissue positioned on the resected side, many patients regain normal swallowing in a relatively short time (1 month) after hemilaryngectomy with swallowing retraining, which usually involves laryngeal adduction exercises.[61]

Patients who have undergone supraglottic laryngectomy often have multiple problems with swallowing, which may include reduction in laryngeal elevation, laryngeal entrance closure, and tongue base retraction.[62] During the supraglottic laryngectomy procedure, portions or all of the hyoid bone are removed, and thus laryngeal suspension from the hyoid is disturbed.[63,64] Resultant residue at the top of the larynx may be aspirated after the swallow when the patients open the larynx and inhale. Airway protection in these patients is achieved by retraction of the tongue base to contact the anteriorly tilting arytenoid cartilages.[65] Any damage to the tongue base or the arytenoid cartilages or their function in adduction and anterior tilting results in inability to protect the airway and aspiration after the swallow.

Post-treatment Complications

In addition to the disorders that result from various treatment procedures, post-treatment complications that worsen swallowing may occur. For example, after radiotherapy, osteoradionecrosis of the mandible may affect chewing. After surgical procedures, scar tissue may form or a fistula that results in additional scar tissue may develop, further interfering with normal swallowing.

Summary

Dysphagia or swallowing difficulty and aspiration are generic terms for problems that have a number of specific anatomic or physiologic causes. Treatment of aspiration in head and neck surgical patients requires accurate identification of the reason for the aspiration. Each of the known causes of aspiration (e.g., reduced tongue control, delayed triggering of the pharyngeal swallow, reduced laryngeal closure, reduced laryngeal elevation, reduced tongue base retraction, reduced pharyngeal contraction) requires a different treatment procedure. The best available procedures should be used to assess the patient's swallowing physiology, and the findings should be compared with normal data. Currently, a videofluoroscopic procedure, the modified barium swallow, gives the most valid results for the evaluation of swallowing physiology and the assessment of aspiration and its cause. The other techniques for assessment of swallowing including bedside evaluation, manometry, ultrasonography, and endoscopy cannot accurately assess all aspects of oropharyngeal swallow physiology, the causes of aspiration, and the effectiveness of treatments.

Studies have shown that the bedside evaluation of aspiration may be as much as 40% in error in identifying patients who are aspirating[50] and cannot identify the underlying causes so that effective management may be planned. Optimum treatment of a patient with a swallowing disorder involves videofluoroscopic evaluation of swallowing at the time oral feeding is to be reinitiated so that appropriate swallowing therapy may be planned, the patient may be quickly advanced to as normal a diet as possible, and potential complications from chronic aspiration, malnutrition, or dehydration may be avoided.

A swallowing therapist should be involved in the patient's treatment from the time that head and neck cancer is diagnosed so that timely evaluation and management of swallowing disorders may be initiated and as much normal function as possible may be restored in the shortest postoperative time.

CHAPTER NINETY-ONE

Oral Mucosal Lesions

James J. Sciubba

Key Points

- Appreciate that leukoplakia carries a small but significant risk of malignant transformation, and that the proliferative verrucous form has a far greater incidence of recurrence, multifocality, and absence of the usual risk factors and transformation rates than typical leukoplakia.
- At the moment there is no effective chemoprevention strategy for the management of leukoplakia.
- The risk of malignant transformation in cases of oral lichen planus and oral mucosal lichenoid lesions must be considered in the long-term aspect of patient follow-up.
- The role of areca (betel) nut in the pathogenesis of oral submucous fibrosis in India and many other countries forms the basis for the high rate of oral squamous cell carcinoma reported in those locations.
- Appreciate the various forms of oral candidiasis and the management options.
- Identify the specific antigenic target in pemphigus vulgaris as a member of the cadherin family of intercellular adhesion molecules.
- Appreciate the differences between pemphigus vulgaris and mucous membrane (mucosal) pemphigoid in terms of antigenic targeting and their anatomic localization.
- Aphthous ulceration may present in three forms with a variable approach to management ranging from observation only to the use of systemic agents.
- Recurrent herpes virus activation may form the basis for the development of recurrent erythema multiforme. Thus consideration is to be given for the use of prophylactic viral suppression treatment.
- The differential diagnosis of oral mucosal pigmentation includes the range of entities from innocuous to life-threatening. Thus the index of suspicion of such lesions is an important clinical consideration.

Red/White Lesions

Leukoedema

Definition

Leukoedema presents as a diffuse and generalized mild surface opacification that chiefly involves the buccal mucosa. It essentially represents a normal variation of surface mucosal texture and characteristics and can be identified in large numbers within the population; however, it is most marked in those possessing higher levels of cutaneous and mucosal pigmentation, being present in the majority of black adults and in nearly half of black children.

Etiology and Pathogenesis

No clear cause of this condition has yet been established. Factors that may have a role in the manifestation of this condition include smoking, alcohol ingestion, bacterial infections, electrochemical interactions, and possibly inflammatory salivary disorders, although no specific, reproducible, or definitive cause has been proven to date. Many authorities indicate that this hardly represents a disease entity but rather may be considered a variation of what is normal. Similar edematous alterations of mucosa may also be seen in the vagina and larynx, further supporting the notion that this is indeed a normal variant of mucosal surface appearance. The incidence of leukoedema increases with age up to 40 to 49 years, followed by a decline.[1]

Clinical Features

Leukoedema is asymptomatic in nature and is usually discovered incidentally during routine examination or by the patient. The distribution tends to be symmetric and involves the buccal mucosa and, to a lesser extent, the labial mucosa. The appearance may be that of a diffuse filmy grayish surface with white streaks, wrinkles, or milky alteration (Fig. 91-1). At rest the tissue may appear opaque, whereas when stretched, the opaque alteration dissipates to the point where it is barely visible.

Simply stretching the mucosa will cause the altered area to essentially disappear; however, leukoplakia or hyperkeratotic conditions will not demonstrate similar attenuation, thus allowing separation of this condition from leukoplakia. Other conditions that should be clinically separated from leukoedema include white sponge nevus, reactive keratosis caused by chronic low-grade trauma, the homogeneous form of lichen planus, and hereditary benign intraepithelial dyskeratosis.

Histopathologic Features

The surface of the epithelium is usually parakeratinized, whereas the epithelial ridges are broad and elongated with occasional spike-type morphology. Dominating the histomorphology is marked intracellular edema within the prickle cell or spinous cell layer, where individual cells will appear enlarged and optically clear or vacuolated, with peripherally displaced pyknotic nuclei and an overall bland appearance in association with a volumetric increase in the thickness of the epithelial layer (Fig. 91-2).

Figure 91-1. Leukoedema is characterized by a milky, translucent, and diffuse alteration of the buccal mucosa.

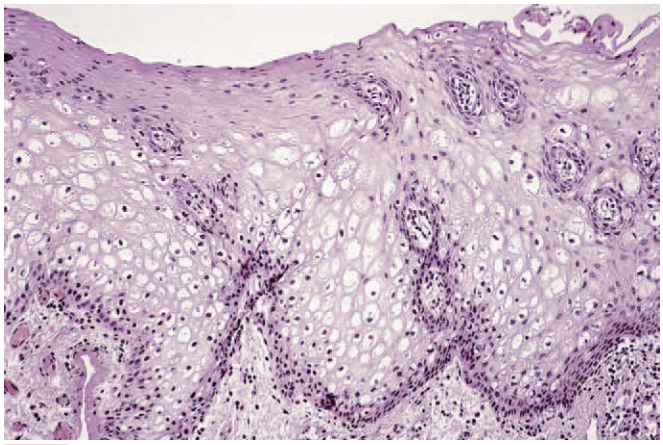

Figure 91-2. Leukoedema demonstrates large, pale epithelial cells with peripherally displaced pyknotic nuclei and broad epithelial ridges.

Management

This particular mucosal alteration does not require treatment because it is totally benign. There have been no reported cases of dysplastic alteration or transformation to carcinoma. The major concern relative to this condition is separating such from leukoplakia.

Oral Leukoplakia

Definition

Oral leukoplakia can be defined as a white patch or plaque that cannot be otherwise characterized clinically as representing any other disease entity. This de facto removes the concept of leukoplakia from the histopathology laboratory to the clinician in terms of definition and utility. From a historical perspective, albeit erroneous, many pathologists and clinicians use the term *leukoplakia* synonymously with *microscopic alteration,* in particular that of degrees of epithelial dysplasia or in situ carcinoma. The exclusionary diagnosis of leukoplakia will therefore eliminate more easily recognizable conditions including leukoedema, lichen planus, candidiasis, and white sponge nevus.

Experts commonly agree that leukoplakia represents the most common premalignant oral mucosal lesion; however, most cases are benign and remain so over time. The concept of malignant transformation is essentially related to the development of cancer or preinvasive cancer that is further characterized by variable degrees of epithelial dysplasia. The possibility of carcinoma and dysplasia must be carefully considered, with the percentages of leukoplakia showing microscopic evidence of dysplasia ranging from 3.7%[2] to 28.7%.[3] A more recent review[4] pointed out that the malignant transformation potential of leukoplakia was noted by Sir James Paget in 1851, when he provided the essential description of what we currently consider to be representative of leukoplakia. The entity of oral leukoplakia was initially and specifically described in the latter half of the 19th century by the Hungarian dermatologist Schwimmer. Since the late 18th century and into the 19th century, oral leukoplakia has been recognized and fully established as a definitive precancerous lesion, often serving as a harbinger for the development of oral cancer. The major clinical factor of importance in this lesion resides in its relationship to the general morbidity and relatively high overall mortality associated with invasive squamous cell carcinoma.

Conceptually, therefore, the definition of a premalignant lesion may be that of a morphologically altered tissue within which cancer is more likely to develop when compared with its apparently normal counterpart. In a more contemporary sense, the work of Waldron and Schafer (1975)[5] and Bouquot and Gorlin (1986)[6] established the clinical and microscopic correlation of leukoplakia in a large number of persons within the United States. In those studies the presence of dysplasia, carcinoma in situ, and invasive carcinoma in relation to oral leukoplakia from all sites ranged from 17% to 25%.

Figure 91-3. Lower lip vermilion surface affected with leukoplakia interspersed with patchy melanotic pigmentation.

Etiology

Although the cause of oral leukoplakia is unknown, several associated habits or behaviors are associated with the presence of this clinical lesion. Most closely associated with leukoplakia is the use of tobacco in its many forms including smoking and several forms of smokeless tobacco use. In other cultures the use of areca (betel) nut preparations with or without tobacco forms an additional source for this condition in patients.

By far, the most common cause of oral white lesions is trauma that includes frictionally related keratosis; however, this is not a true leukoplakia in that it represents a response to trauma in the form of hyperkeratosis, with reversal of such on elimination of the traumatic influence. A common site for frictionally induced hyperkeratosis is along the buccal mucosa at the occlusal line. At this location the formation of a linea alba is noted, whereas over the labial mucosa, a lip-biting habit can produce a slightly granular hyperkeratotic surface alteration, or so-called *morsicatio.* No evidence suggests that chronic frictional trauma transforms into dysplastic or frankly malignant disease.

Along the lower lip vermilion surface, patches of leukoplakia may develop in response to chronic sun exposure (actinic cheilitis), demonstrating close correlation with cumulative exposure and the level of cutaneous pigmentation (Fig. 91-3).

A recently described form of keratosis has been attributed to the use of mouthwash preparations and toothpaste containing an herbal

root extract, sanguinaria (Viadent). Characteristically, the lesion develops along the labial alveolar mucosa of the maxilla as an often translucent to slightly opaque white patch with well-defined margins and generally smooth surface features (Fig. 91-4). The relationship to development of dysplasia or malignant transformation in association with this entity remains controversial, with reversal of lesions often noted on withdrawal of sanguinaria-containing products.[7,8]

Figure 91-4. Viadent-related leukoplakia involves a portion of the maxillary alveolar mucosa as a well-defined thin keratotic surface alteration.

Clinical Features

A widely variable clinical pattern characterizes leukoplakia. In general the appearance can range from a thin grayish surface alteration demonstrating a white translucent quality with ill-defined margins (Fig. 91-5A) and generally smooth surface qualities to discrete, sharply marginated, thick and opaque plaques. In general terms such lesions may be homogeneous and smooth, focal or diffuse, or heterogeneous and multifocal with variable textures (see Fig. 91-5B and C). Surface textural alterations can range from a fine granularity to a slightly papillary outline. In addition, leukoplakia can appear ulcerative, erosive, speckled, nodular, or verrucous to the naked eye. Importantly, the various forms of leukoplakia often transition from one to another; however, this change of clinical appearance may not necessarily correspond to a shift in biologic behavior.[9,10] In cases where there is a clinical shift in

Figure 91-5. Leukoplakia. **A,** A homogeneous, slightly opaque alteration that is well marginated superiorly but merges with the gingival mucosa inferiorly. **B,** Hard palatal leukoplakia with a minimally elevated surface crossing the palatal midline. **C,** A thick, sharply marginated focal leukoplakia of the ventral/lateral tongue with a uniform erythematous periphery. **D,** Speckled or heterogeneous leukoplakia where the leukoplakia element is set on an erythroplakia. **E,** A diffuse thin leukoplakia of the ventral tongue surface with very homogeneous qualities and slightly diffuse peripheral margins.

appearance from homogeneous leukoplakia to a heterogeneous, speckled, or nodular form, a rebiopsy is mandatory (see Fig. 91-5D) because of the well-established correlation between increasing levels and frequencies of dysplasia and an increase in the level of regional heterogeneity or speckled quality.[11]

The term *thin leukoplakia* (see Fig. 91-5E) has been used to describe early leukoplakia formation. Such lesions generally progress over time from a macular to a slightly elevated translucent plaque with blending margins into normal-appearing mucosa, to later developing a more thickened appearance lending a more opaque white color to the lesion. Likewise, textural features may develop with increasing duration, which may be furrowed, leathery, or wrinkled in appearance. Similarly, lesions can become exophytic or verruciform in quality and might project above the surface. Although many lesions may remain for extended periods as homogeneous or more textured, thickened alterations, some lesions may disappear over time.

A recently described, uncommon variant of leukoplakia, *proliferative verrucous leukoplakia,* requires separate designation in that it is often noted in individuals without the usual risk factors for leukoplakia development, with lesion development noted in areas less commonly affected by oral squamous cell carcinoma. Behavior of this variant of leukoplakia is characteristically aggressive with changing histopathologic features, a more relentless behavior pattern, and greater tendency to develop into squamous cell carcinoma.[12] No linkage to human papillomavirus has been demonstrated in comparison with other forms of oral leukoplakia.[13] It is characteristically multifocal and persistent and tends to occur more often in women. An evolution from a thin, flat, white patch to a leathery, thickened, and ultimately papillary to verrucous stage characterizes this lesion over time (Fig. 91-6). When the lesion is microscopically evaluated at the papillary or verrucous stage, the diagnosis can vary from that of a benign or atypical verrucous hyperplasia to verrucous carcinoma or squamous cell carcinoma with papillary features. Likewise, characterizing this entity is persistence, a high recurrence rate, and development of squamous cell carcinoma in up to 74% of cases.[14,15] Gaining a better understanding of the behavioral qualities and variation across the spectrum of oral leukoplakia involves several factors including clinical appearance, location, and the presence and degree of dysplasia. Recent studies have demonstrated an association between progression of oral mucosal premalignancy and a loss of heterozygosity (LOH).[16] An essential step in the initiation of escape from normal epithelial proliferation and differentiation involves LOH at 3p and 9p where a modest 3.8-fold relative risk for oral cancer development has been noted. However, in cases where additional losses (4p, 8p, 11q, or 17p) existed, there was a 33-fold increase in relative risk for cancer development.[17] Lending a risk-targeting or prognostic strategy to this concept has been controversial, with earlier work concerning ploidy analysis being discredited and more recent studies refuting this claim.[18] No single or specific molecular pathway has been identified as the primary factor in the progression of epithelial dysplasia to squamous cell carcinoma. Continuing studies have revealed a range of molecular and genetic changes associated with oral squamous cell carcinoma tumorigenesis including mitochondrial alteration and several epigenetic changes, with continued ongoing investigation including those of altered methylation patterns and early carcinogenesis.[19] Finally, the relationship between the site of leukoplakia and the presence and risk of dysplasia or carcinoma must be considered. Earlier and more recent studies have underscored this relationship with the floor of the mouth, ventrolateral tongue, and retromolar trigone/soft palate complex carrying risk levels greater than other oral sites.[5,20]

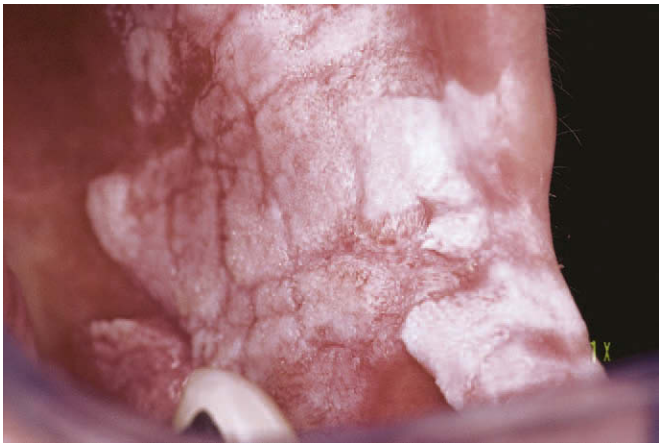

Figure 91-6. Developing proliferative verrucous leukoplakia with a thickened, elevated surface outline and coarsely granular to minimally warty surface qualities.

Histopathologic Features

A spectrum of histologic alterations characterizes idiopathic or true leukoplakia that ranges from hyperkeratosis and acanthosis to variable degrees of dysplasia or carcinoma in situ and ultimately invasive squamous cell carcinoma (Fig. 91-7). Cellular atypia, a component of dysplasia, refers to abnormal cellular features, whereas dysplasia refers to disordered cell growth and architectural distortion. With dysplasia, a grading system of mild, moderate, or severe is the convention; the level is determined subjectively in an attempt to convey tissue alteration to the level of intraepithelial localization or non-neoplastic or noninvasive quality.

Specific microscopic features of dysplasia include drop-shaped epithelial ridges, basal cell hyperplasia, irregular stratification and cellular maturation sequence, increased levels and abnormal quality of mitotic activity, individual cell or group level keratinization between the suprabasal and surface layers, cellular pleomorphism, altered nuclear-cytoplasmic ratio, reduced intercellular adhesion, and loss of basal layer polarity with "streaming" of spinous layer cells toward the surface.

An extension of these microscopic alterations to involve the entire epithelial compartment (i.e., "top-to-bottom effect") allows use of the carcinoma in situ designation. Alternatively, the term can also be used to designate particularly severe epithelial dysplasia that may not be fully developed from basal through the surface layers.

Treatment

Management of idiopathic leukoplakia will depend on the nature of the associated histologic findings obtained by incisional biopsy because the clinically defined term of leukoplakia requires microscopic characterization. With extensive lesions, multiple biopsies may be required to preclude errors of sampling, with the most clinically suspicious areas such as erythematous, granular, ulcerated, and indurated areas included.

Once defined as benign, premalignant, or malignant, a treatment plan can be formulated. In the case of benign or minimally dysplastic lesions, periodic simple observation or excision is an elective option, whereas premalignant lesions of moderate dysplasia or worse demand removal. The issue of how to manage mildly dysplastic lesions may concern itself with careful follow-up and observation or removal, if clinician and patient are committed to such. Complete removal of these lesions can be accomplished by a wide array of modalities including scalpel excision, laser ablation, electrocautery, or cryoablation.

The role of chemoprevention strategies in cases of mild dysplasia or treated dysplasia remains an active and important area of research, though there is no proven and effective prevention strategy regarding malignant transformation. Retinoids, antioxidants, and cyclooxygenase (COX)-2 inhibitors hold promise as management alternatives within the area of chemoprevention, though no effective strategy has yet been proven by randomized clinical trials. In general there is no effective treatment in preventing malignant transformation of leukoplakia.[21] On balance and regardless of location, the dynamic nature of oral leukoplakia and its cancer-related potential should be appreciated and understood. The key to limiting the likelihood of late-stage disease evolving from such lesions concerns itself with an appreciation of the potential of this group of mucosal alterations coupled with the establishment of early diagnosis, intervention, and follow-up.

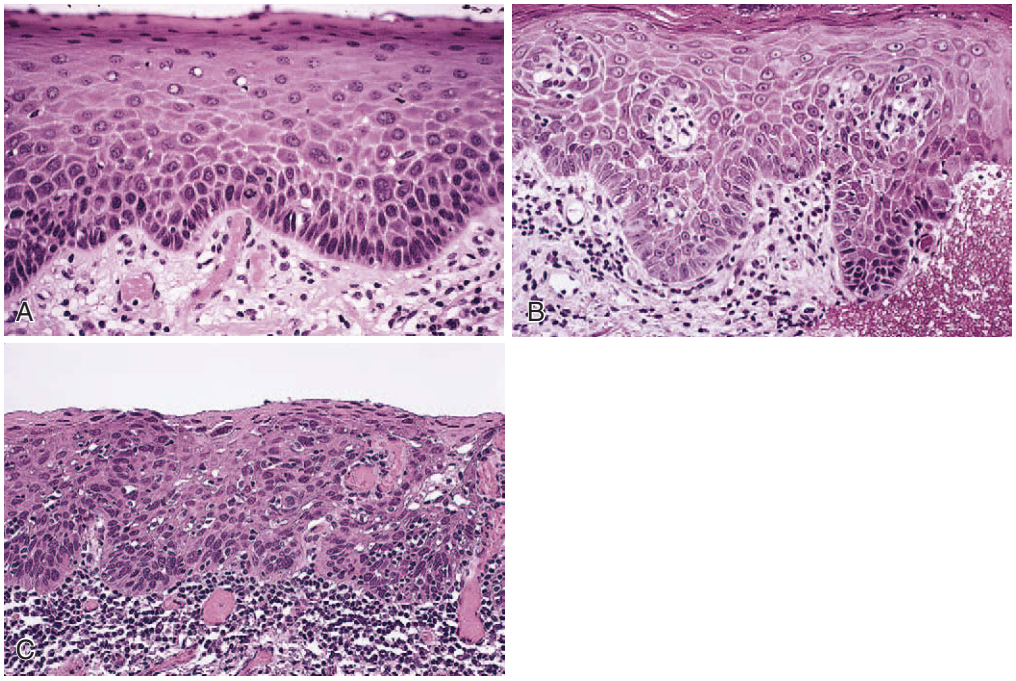

Figure 91-7. Epithelial dysplasia. **A,** Mild epithelial dysplasia with cytologic atypia confined to the lower epithelial strata. **B,** Moderate epithelial dysplasia contains several layers of atypical cells; however, the upper half of the epithelial thickness remains with a normal-appearing maturational sequence. **C,** Severe epithelial dysplasia with essentially full-thickness epithelial cell atypia, without evidence of invasion.

Figure 91-8. Oral hairy leukoplakia along the lateral tongue margin is characterized by vertically corrugated keratotic ridges.

Figure 91-9. A low-power view of oral hairy leukoplakia shows a thick parakeratotic surface layer and a characteristic pale subsurface layer above the spinous layer.

Oral Hairy Leukoplakia

Definition

A distinctive asymptomatic white lesion of the oral mucosa, oral hairy leukoplakia has been defined both clinically and microscopically with a distinct relationship in the vast majority of cases with systemic immunosuppression. The Epstein-Barr virus is considered the etiologic agent of this lesion that characteristically arises along the lateral tongue margins bilaterally, ranging from subtle white keratotic vertical streaks to thick corrugated and then to shaggy surface alterations (Fig. 91-8).[22] Early lesions may be more smoothly textured and macular in presentation. Less common sites include the dorsum of the tongue, buccal mucosa, and floor of the mouth.

Diagnosis by routine microscopy and in situ hybridization to demonstrate the presence of the Epstein-Barr virus is essential in that the confirmed diagnosis almost always correlates with systemic immunosuppression. The microscopic features suggesting this diagnosis include hyperkeratosis and irregular surface projections and irregularities (Fig. 91-9). Ballooning degeneration of the subsurface layers with nuclear alterations consisting of clearing and chromatin displacement by viral replication occurs along the inner aspect of the nuclear membrane in the form of "beading." Confirmation of the impression of a viral process can be achieved by in situ hybridization, Southern blot procedure, polymerase chain reaction, or ultrastructural demonstration of virus.

Management of hairy leukoplakia is not necessary in that establishment of the diagnosis remains the crucial task. In patients with proven association of HIV-AIDS, disappearance of the lesion usually accompanies antiretroviral therapy.

Oral Lichen Planus

Oral lichen planus is a relatively common mucocutaneous disease of immunologic origin that is mediated by a T-cell lymphocytic reaction

to antigenic components within the surface epithelial layer. The overall frequency of this condition is between 0.2% and 2% of the population. Characteristically over the oral mucosa, lichen planus typically presents as white striaform lesions that are bilaterally symmetric in their distribution, which, in this particular state, are relatively asymptomatic. However, other variants, in particular the erosive and ulcerative forms, will often be quite painful and may be what directs patients to seek care. In addition to its relative frequency, the importance of this particular entity concerns itself with the overall differential diagnosis, its similarity to other mucosal disorders, and its not infrequent symptomatic behavior.

Although the general etiology of lichen planus is unknown, it is generally thought to represent a T-cell-mediated or immunologically driven chronic inflammatory process in the absence of any consistent serologic changes. Immunologic studies have demonstrated that the lymphocyte subpopulations involve cells of mixed $CD4^+$ and $CD8^+$ types that express α-1 integrin molecules. The majority of the T cells present are activated $CD8^+$ cells.[23] Existing data suggest a complex nonspecific mechanism might be involved in pathogenesis including major histocompatibility complex (MHC) class 1- and MHC class 2-restricted antigen presentation by lesional keratinocytes, activation of antigen-specific $CD4^+$-positive helper T cells and $CD8^+$-positive cytotoxic T cells, clonal expansion of antigen-specific T cells, and keratinocyte apoptosis triggered by antigen-specific $CD8^+$-positive cytotoxic T cells. More recent studies, however, have discussed the monoclonal nature of lesional T cells in oral lichen planus.[24] Antigen-specific mechanisms therefore include antigen processing by resident dendritic cells and antigen-specific keratinocyte killing by $CD8^+$-positive cytotoxic T cells. A host of nonspecific mechanisms also seem to be involved in pathogenesis including activation of matrix metalloproteinases, mast cell degranulation, alterations in the epithelial basement membrane region, and elaboration of an array of proinflammatory cytokines including RANTES, which play a vital role in inflammatory cell recruitment into the area of the affected skin or mucosa.

An additional important factor in pathogenesis concerns basal and parabasal layer keratinocytes expressing MHC class 2 molecules, which they present to cells bearing $CD4^+$-associated T-cell receptors. The above-stated basement membrane alterations result in deposition of large amounts of fibrinogen in this region, which proves valuable within the context of the direct immunofluorescence testing and helps in establishing a diagnosis. In the process of basement membrane damage, up-regulation of additional molecules occurs including laminin, fibronectin, and types 4 and 7 collagen.

As a result of lymphocyte adhesion along the inner aspect of superficial vessels within the lamina propria of the mucosa, they soon exit the vasculature to traverse the basement membrane and migrate into the overlying epithelium secondary to the up-regulation of chemoattractants by keratinocytes.[25]

Clinical Features

Oral mucosal lesions of reticular lichen planus are most commonly seen in the middle-aged population with a characteristic distribution over the buccal mucosa in a symmetric bilateral manner. The surface of the mucosa is characterized by delicate white keratotic striae that intersect and arborize over a mucosal surface that may be diffusely erythematous to normal in quality (Fig. 91-10). Striae may be preceded by keratotic papules, which fuse and ultimately form the striae. The pattern is generally lacy to annular in configuration with extension over the buccal mucosa and often inferiorly into the mucobuccal folds. Striae may also appear over the dorsum and lateral portion of the tongue and less frequently over the attached gingiva and vermilion portion of the lip. Of note is the general freedom from symptoms related to this form or variant of oral lichen planus.

Other forms of oral lichen planus include the plaque form, atrophic or erythematous form, and erosive form. Characterizing the erosive form is a typically multifocal pattern of distribution, usually over the lateral and ventral tongue and buccal mucosa. Plaques can be smooth and macular to slightly elevated and minimally fissured. Although this form may be noted as the only presentation of oral lichen planus, it can also develop in late stages or previous areas of erosive lichen planus that had been successfully treated.

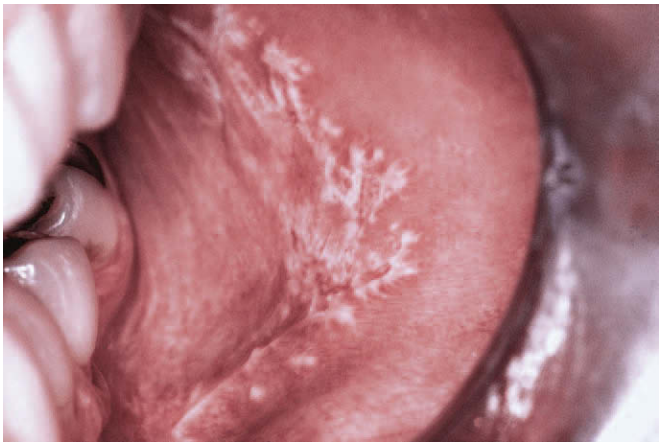

Figure 91-10. Reticular-type lichen planus with delicate striae over the posterior buccal mucosa.

Figure 91-11. Atrophic lichen planus with characteristic erythema and edema, loss of surface keratinization, and an overall glassy appearance.

Atrophic or erythematous lichen planus demonstrates only faint white striae, being dominated by thinned, reddened mucosa, often noted concomitantly with reticular or erosive forms of this disease. The attached gingiva is most likely to be involved by this type of lichen planus where there is a loss of the usual pink, stippled quality of the tissue surface (Fig. 91-11). In its place is a glossy, edematous, and erythematous alteration that is tender and bleeds easily, leading indirectly to the accumulation of large amounts of dental bacterial plaque. This usually results from the inability of patients to maintain their usual levels of dental hygiene given the friability and tenderness of the gingiva, which bleeds with the slightest provocation. Bacterial antigens and toxins in turn elicit the formation of inflammatory cytokines locally that further enhance the immunologically driven process within the lichen planus.[26]

Erosive lichen planus is characterized by central ulceration that can be deep and painful but is usually superficial in nature (Fig. 91-12). The ulcer is surfaced by a pseudomembrane or firmly adherent fibrinous plaque, which is usually sharply demarcated. Often it is possible to identify peripherally localized white striae, which gradually transition to an erythematous, nonstriaform region as the ulcerated area is approached. As the erosions heal, new areas will break down into ulcerations with variable patterns of change noted over time.

Rarely encountered is the bullous variant of oral lichen planus, with bullae ranging in size from a few millimeters to greater than 1 cm.

Figure 91-12. Erosive lichen planus of the buccal mucosa demonstrates irregularly marginated, intense erythema with patchy superficial erosions.

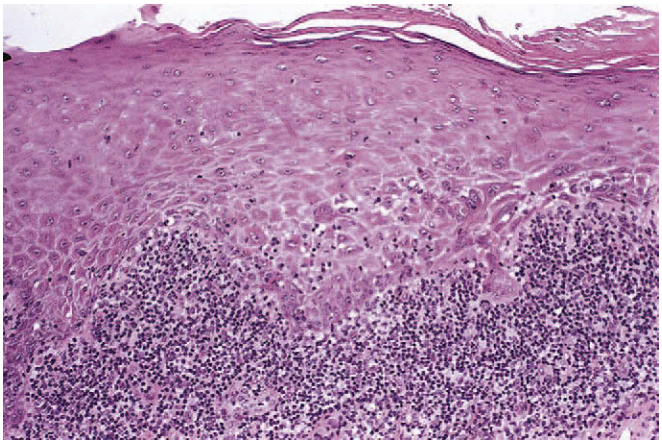

Figure 91-13. A characteristic intense lymphocytic infiltrate abuts the basal layer in mucosal lichen planus. Lymphocytes track into the epithelium, and intercellular edema is noted in the lower spinous layer with focal basal layer edema.

As with most oral bullae, they are transient and, on rupturing, painful ulceration results, with most lesions noted over the inferior and posterior aspects of the buccal mucosa. Identification of more typical forms of oral lichen planus likely to be present elsewhere in the mouth in association with this variant makes the clinical diagnosis less difficult.

Clinical Differential Diagnosis

The multifocal, bilateral nature of oral lichen planus will usually help exclude certain mucosal abnormalities such as traumatic keratosis and leukoplakia. Included, however, are lupus erythematosus, lichenoid drug reactions, graft-versus-host disease, candidiasis, and oral hairy leukoplakia. Plaque-type lesions can be confused with squamous cell carcinoma and leukoplakia; however, bilaterality and additional lichenoid alterations elsewhere will usually help separate these entities. With erosive/atrophic lichen planus involving the gingiva, consideration must be given to mucous membrane pemphigoid, pemphigus vulgaris, contact hypersensitivity, chronic atrophic candidiasis, lupus erythematosus, and erythema multiforme.

Association with Systemic Diseases

Oral lichen planus has been reported in conjunction with primary sclerosing cholangitis, lupus erythematosus, primary biliary cirrhosis, and Sjögren's syndrome.[27,28] Although controversial in certain geographic areas, within the United States there appears to be a lesser association between oral lichen planus and many systemic diseases, in particular hepatitis B and C, in comparison with patients with oral lichen planus in Italy and Japan, thus suggesting genetic susceptibility or predisposition.

Histopathologic Features

At the free surface of the epithelium, hyperkeratosis/parahyperkeratosis will be present. A slightly thinned to atrophic spinous layer overlies the basal and parabasal layers, which are often degenerate and vacuolated (Fig. 91-13). Over time, the epithelium becomes thin and may assume a sawtooth pattern on occasion. Scattered throughout the epithelium are increased numbers of dendritic cells that have been reported to function as antigen processing units, delivering prepared antigen to the subjacent lymphocyte population, which morphologically forms a dense bandlike pattern at the epithelial connective tissue junction.[29] At this junctional zone, occasional ovoid, anucleate eosinophilic droplets with hyaline features are noted. These represent apoptotic keratinocytes termed colloid or Civatte bodies.[30] Although nonspecific and nondiagnostic of lichen planus, they are highly suggestive of such when correlating other pathologic and clinical findings.

Reflective of the altered basement membrane region is the nonspecific deposition of fibrin that can be demonstrated by direct immunofluorescence studies as a uniform linear deposition along the basement membrane (Fig. 91-14). This pattern can be noted in up to 90% to 100% of cases.

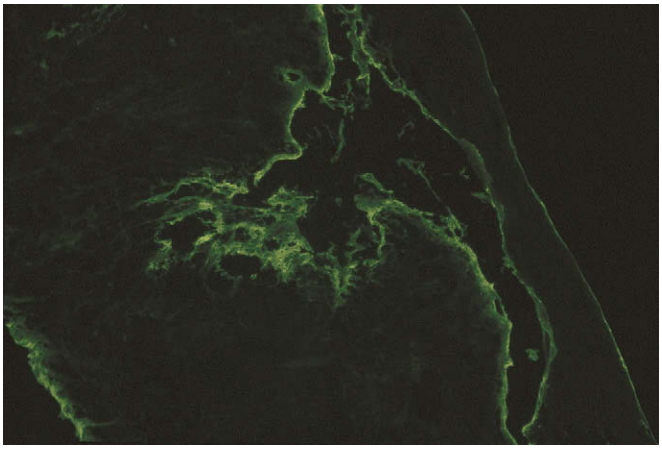

Figure 91-14. Fibrinogen reactivity at the basement membrane zone characterizes the direct immunofluorescence findings in lichen planus.

Treatment

Important in communicating the therapeutic end point to the patient is the notion that the goal of management is relief of symptoms because immediate cure is not to be achieved. Topically applied agents, usually corticosteroids, are the mainstay of management in most forms of oral lichen planus that are symptomatic in nature. The specific form or choice of corticosteroid will relate to the potency of such, with moderate to ultra-potent agents considered the modality of choice. More recently, the nonsteroidal topical agents tacrolimus and pimecrolimus have been shown to be effective in the management of symptomatic or lichen planus without the usual adverse effects related to topical steroid use, most commonly oral candidiasis.[31]

Management of recalcitrant focal areas of isolated lichen planus can be accomplished through the use of intralesional injections of corticosteroids such as triamcinolone suspension (10 or 40 mg/mL).

Systemic management of lichen planus can be used in cases of severe involvement using corticosteroids for a brief time until clinically obvious improvement is noted. Subsequently and for the longer term, topical management strategies can be used as noted earlier. Alternatives to systemic corticosteroids include hydroxychloroquine, azathioprine, and systemic retinoids.

Relationship to Oral Squamous Cell Carcinoma

A considerable degree of controversy exists as to whether a small percentage of lichen planus cases are capable of transforming into oral squamous cell carcinoma. Microscopic confusion, with epithelial dysplasia having an overall lichenoid quality, further adds to the controversy. There does, however, appear to be a small but bona fide risk of carcinoma evolving from proven oral lichen planus. Also important to understand is that when such transformation develops, it is far more likely to be seen in conjunction with the atrophic or erosive form of the disease rather than the far more common reticular or striaform type. This emphasizes the need for long-term follow-up, given the chronic nature of the disease process and the therapies employed for such.

The notion of lichenoid dysplasia versus dysplasia developing in lichen planus may not be readily settled. However, studies suggest a significant degree of allelic loss in dysplastic oral lichenoid lesions. Reports stating a degree of dysplasia in association with lichenoid features should alert the clinician to either remove the balance of the altered mucosa or follow the patient carefully.[32] Mattsson and colleagues[33] support the relationship between oral lichen planus and oral squamous cell carcinoma, yet they dispute, on an economic and practical basis, the need for continuous recall of these patients in specialists' offices and clinics.

Finally, the issue of an "oral lichenoid lesion" versus oral lichen planus has been discussed within the context of malignant transformation. Stated is the possibility of an increased risk of transformation within the context of lichenoid lesions, whereas true lichen planus may be less of a transformation risk.[34]

Submucous Fibrosis

Definition

Submucous fibrosis represents a multifactorial disorder with the considered chief etiologic factor being the consistent and habitual use of areca (betel) nut, either in the form of chewing or simply placing a quid of material (paan masala) in the buccal or labial sulcus several time per day, or in a packaged powdered form with other components (guthka), over many years. Submucous fibrosis is considered a premalignant condition, with transformation rates as high as 7.6% reported from India over a 17-year period.[35] Other researchers have reported 2.54% of cases demonstrating epithelial dysplasia.[36]

Etiology and Pathogenesis

Some experts believe the basic process is a failure of collagen remodeling and that altered epithelial-mesenchymal interactions result in formation of collagenous bands and aggregates within the submucosa and lamina propria. A diminished level of functional collagenase levels has been postulated as another mechanism to explain increased collagen accumulation.[37]

Clinical Features

Initial mucosal alterations characteristic of oral submucous fibrosis include erythema with or without vesiculation. The former reaction (erythema) is believed to be related to increased levels of inducible nitric oxide synthetase.[38] This is followed by slow diminishment of erythema and a progressive decrease in the degree of oral opening and tongue mobility reflective of the altered collagen metabolism. Pallor of the normally pink mucosa becomes evident as the underlying chronic inflammation recedes and fibrosis and hyalinization progress. Scar bands may become evident deep within the buccal soft tissues, further limiting jaw opening and function.

Development of squamous cell carcinoma is characterized by a gradual thickening of the epithelial surface with hyperplastic to verrucous surface qualities becoming evident.

Histologic/Diagnostic Features

Dominating the histopathology is a juxtaposition of atrophic epithelium surfacing a subjacent fibrosis. Early connective tissue alterations are characterized by delicate and loosely arranged collagen fibers with progressive degrees of hyalinization until, in the late stages, there is complete hyalinization of the supportive connective tissue. Variable degrees of chronic inflammation occur in the form of lymphocytes and plasma cells. Variable levels of dysplasia have been noted. In one study, mild dysplasia was present in 46% of cases, moderate dysplasia in 52%, and severe dysplasia in 2%.[39]

Treatment

Management of oral submucous fibrosis is problematic, particularly in advanced cases and when the use of areca-containing products remains in place. Surgical release procedures of scar bands have been only modestly successful. More recently collagenase and pentoxifylline administration in separate studies has been proposed.[37,40]

Verruciform Xanthoma

Definition

Verruciform xanthoma represents an uncommon benign oral mucosal lesion that also has a cutaneous counterpart where such lesions arise, particularly on the genitalia.

Etiology and Pathogenesis

The cause is unknown. The cellular lineage of the proliferative xanthoma cells is that of monocyte/macrophage type. They are noted chiefly in the fifth decade and have been classified into three types according to their microscopic surface qualities. These include the verrucous, papillary, and flat types.[41]

Clinical Features

As noted, three growth types have been identified. They are further characterized by being well circumscribed and with minimally to obviously granular surfaces. A wide size range has been reported, ranging from 0.2 cm to 2 cm. The surface may be depressed or flat, as well as elevated, and variably granular in texture.

Histopathologic/Diagnostic Features

Variable levels of surface hyperkeratosis cover a papillary or verrucous configuration with deeply invaginated crypts alternating with papillary extensions. Epithelial ridges composed of normal keratinocytes are elongated and extend uniformly into the lamina propria, which is engorged with numerous xanthoma cells containing characteristic foamy to flocculent cytoplasm. PAS-positive and diastase-resistant granules are present within the cytoplasm of these cells, as well as lipoid droplets, and are macrophages in nature.[42]

Treatment

Conservative surgical excision is the treatment of choice, with no recurrence potential noted.

Candidiasis

Definition

Candidiasis is a common opportunistic infection of the oral cavity, oropharynx, and corners of the mouth. Several clinical forms of this condition are noted—the easily recognized pseudomembranous form (thrush) in addition to erythematous, atrophic, and hyperplastic forms.

Etiology and Pathogenesis

Candida albicans represents the most common candidal species, whereas *Candida tropicalis, Candida krusei,* and *Candida glabrata* among others are less commonly involved. In immunosuppressed and neutropenic patients, however, these latter species are more often present. Of note is the essential shift from a commensal state to that of a "pathologic" state, in which former asymptomatic carriers of the organism now suffer from its overgrowth. Risk factors for development of candidiasis may include local and systemic factors (Tables 91-1 and 91-2). Commonly, systemic conditions such as poorly controlled diabetes mellitus and immunosuppression are associated with oropharyngeal candidiasis. Local effects or altered ecology of the region by topically delivered drugs (corticosteroids), xerostomia (with loss or diminution of saliva's protective function), heavy smoking, and denture appliances favor development of candidal overgrowth.[43-46]

Table 91-1

Oropharyngeal Candidiasis: Risk Factors

Local factors (mucosal barrier function)	Heavy smoking Foreign bodies (dentures, nasogastric tubes) Radiation-induced mucositis Inhalational and topical corticosteroid use Xerostomia Mucosal tumors
Systemic factors	Immunosuppression, age, viral-retroviral, chemotherapy, corticosteroid use Diabetes mellitus Intrinsic immunodeficiency Myelodysplasia/leukemia Antibiotic administration

Table 91-2

Clinical Forms of Oral/Oropharyngeal Candidiasis

Acute candidiasis	Pseudomembranous (thrush) Erythematous/atrophic
Chronic candidiasis	Hyperplastic (candidal leukoplakia) Denture-related (chronic erythematous/atrophic) Median rhomboid glossitis
Angular cheilitis	

From Akban A, Morgan R. Oral candidiasis. *Postgrad Med J.* 2002;78:455-459.

Figure 91-15. Acute erythematous candidiasis over the hard palate mucosa developed subsequent to a course of broad-spectrum antibiotics.

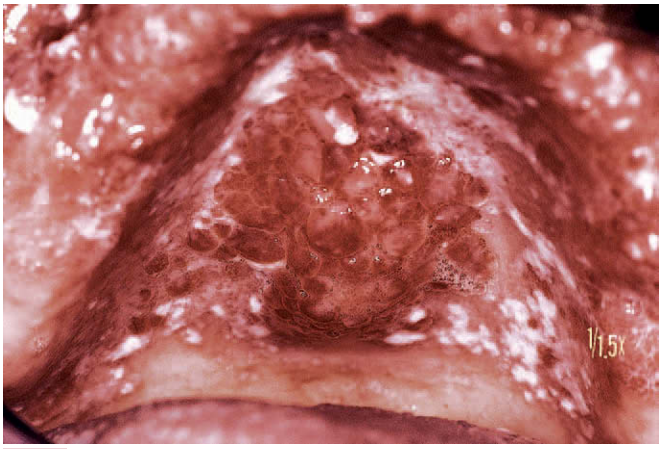

Figure 91-16. Pseudomembranous candidiasis (thrush) in a poorly controlled diabetic denture wearer.

Figure 91-17. Angular cheilitis caused by a lip-licking habit extending to perilabial skin.

Crucial to the establishment of infection, which implies a shift from commensalism, is fungal adhesion to mucosal surfaces and subsequent replication. Yeast adherence to several ligands is complex. It is aided by intrinsic candidal adhesion that in turn binds to salivary proteins that are absorbed onto cell surfaces.[47,48] Such binding, one measure of virulence, is a covalently mediated bonding in part related to fungal synthesis of this hyphae-associated proline-rich surface protein.

Clinical Features

Symptoms of oral/oropharyngeal candidiasis range from none or minimal ones to those that may include burning, dysgeusia, sensitivity, and generalized discomfort. Odynophagia may be noted in association with pharyngeal/hypopharyngeal involvement.

Of the clinical forms, the erythematous, atrophic, and pseudomembranous types are most likely to produce symptoms (Fig. 91-15). So-called denture sore mouth (chronic erythematous/atrophic candidiasis) is generally minimally to completely asymptomatic, whereas the acute forms are uniformly problematic. Deeply invasive candidal infection in immunosuppressed persons may present as an ulcerative lesion. Of note is the tendency of the various clinical forms to cycle from a bland, asymptomatic state to a symptomatic one in relation to general host factors or degree of medical compromise. Acute pseudomembranous candidiasis (thrush) with characteristic soft, white, and superficial colonies of organisms may be widespread and often asymptomatic (Fig. 91-16).

Angular cheilitis (Fig. 91-17) is generally considered to be a candida-related condition, although supervening or coinfection with staphylococcal species may be noted. In such instances the labial commissures can appear fissured, macerated, or erythematous, often with extension onto the adjacent skin.

Figure 91-18. So-called *candidal leukoplakia* may represent a hyperplastic response to long-term, asymptomatic oral candidiasis.

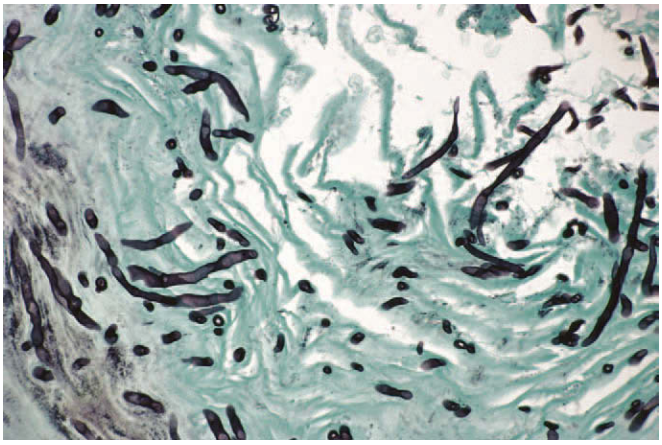

Figure 91-19. Fungal colonization of the oral mucosal surface with characteristic septate hyphae (methenamine silver stain).

Hyperplastic candidiasis, or leukoplakic-type hyperkeratosis, appears as asymptomatic keratotic plaques, often placed posterior to the labial commissures along the occlusal line. A triangular pattern of hyperkeratosis is noted with the apex directed posteriorly (Fig. 91-18). Less commonly, similar lesions may be present on the cheeks, palate, and lateral tongue surfaces. Because idiopathic leukoplakia may become secondarily colonized by candidal organisms, confusion may arise, often demanding a tissue biopsy to confirm the nature of the clinical lesion.

Differential Diagnosis

The manifold presentation of oral/oropharyngeal lesions permits a broad differential diagnosis. Of these entities, erythroplakia, speckled or nodular leukoplakia, and papular, erosive/atrophic lichen planus are to be considered. Squamous cell carcinoma, vitamin deficiency/malnutrition, hereditary dyskeratotic syndromes, and white sponge nevus can also be considered.

Histopathologic/Diagnostic Features

Clinical presentation of the diagnosis is often sufficient to allow for a diagnosis. The finding of atrophic red patches or white curdlike surface colonies with or without angular cheilitis in relation to discomfort in the more acute forms of the disease is usually compelling. The denture-related form of chronic erythematous candidiasis with restriction to the area covered by the appliance likewise forms the basis of a confident clinical diagnosis.

Confirmation of the diagnosis can be obtained by scraping the mucosal surface followed by smear preparation and placement of potassium hydroxide over the smear or use of a tissue stain such as periodic acid-Schiff (PAS) or methenamine silver preparations (Fig. 91-19). Finally, culture on Sabouraud medium may be considered and results of this test should be coupled with clinical findings. Of note is the fact that approximately 50% of adults (normal carriers) will have culture tests positive for intraoral candidal organisms; thus the clinicopathologic correlation becomes an important consideration.

Treatment

A wide spectrum of topical and systemic agents is available for several clinical classes. These include the topical polyene compound, nystatin, while the azole/triazole group of both topical and systemmic agents forms a larger treatment alternative. The nonabsorbable polyene compound in liquid or cream form may be useful for most mild to moderate infections, whereas the partially absorbed clotrimazole may be useful both topically and to a lesser extent systemically.[49] Systemically administered triazoles including fluconazole and itraconazole, as well as ketoconazole, are effective in eradicating more severe forms of this disease.[50,51]

Vesiculobullous/Ulcerative Lesions

Pemphigus Vulgaris

Definition

The term pemphigus relates to a group of autoimmune mucocutaneous diseases that may be life threatening and are characterized by intraepithelial cleavage or clefting with approximately 0.1 to 0.5 patients per 100,000 of the population per year affected by the most common form of this condition.[52,53] Despite the relative frequency in the population, otolaryngologists should be aware of this disease and its presentation; of note, at least 70% of patients with pemphigus vulgaris present with lesions in the upper aerodigestive tract as the initial manifestation, oftentimes heralding or preceding skin lesions by months to years.

In an effort to fully understand the pathophysiology or etiopathogenesis of this disease, one must understand that the mucosal lining of the nasal cavity, nasopharynx, oropharynx, oral cavity, and larynx is similar to that of the skin but differs in several important ways, not the least of which concerns the desmosomal components. Adhesion molecules desmogleins 1 and 3 (Dsg1 and Dsg3) are both expressed in the skin; however, mucosal epithelium expresses only Dsg3.[54] This particular desmoglein carries a 130-kilodalton molecular weight and resides in the extracellular space predominantly, although there is an intracellular domain that is bonded to an 85-kilodalton fraction, plakoglobin. Desmogleins as a group represent transmembrane glycoproteins and are members of the cadherin family of adhesion molecules. Dsg3 in particular is considered to represent the pemphigus antigen in the oral and oropharyngeal mucosa, is the specific target of the immune system in pemphigus vulgaris, and is targeted by immunoglobulins of the immunoglobulin (Ig) G class in the vast majority of cases; however, the IgA antibodies can also be the targeting antibody.

Several variants within the pemphigus group, the most common of which is pemphigus vulgaris, frequently involve the mouth, with its main importance being that this lesion or disease tends to run a chronic course. Before the introduction of corticosteroids, it was often fatal, secondary to complicating infections of the skin that ultimately led to sepsis, electrolyte imbalance, and fluid loss. In cases of pemphigus vulgaris in which only mucosal involvement is present, all antibodies are directed against the Dsg3 entity; however, when skin is involved, the antibodies to Dsg1 will also be present. In instances where antibodies to Dsg1 only are being synthesized, the condition pemphigus foliaceus develops with no evidence of disease in the upper aerodigestive tract because Dsg1 is not expressed in these locations.

A recently discovered form of pemphigus, paraneoplastic pemphigus, is usually associated with lymphoproliferative disease, although other types of malignancy may supervene. This entity was originally described by Anhalt and others[55] with numerous intraepithelial and

basement membrane antigens targeted simultaneously by a wide array of autoantibodies.

Etiology/Pathogenesis

As noted, autoantibodies directed against Dsg3 are the driving force in the development of mucosal dominant pemphigus vulgaris. The specific initiating factor or triggering event, as with any autoimmune disease, is unclear. However there is, in many instances, a genetic basis for the development of this disease. The latter is noted in particular within individuals demonstrating specific human leukocyte antigen (HLA) class 2 allele associations. These include rare haplotypes HLA-DR4 (DRBI *0402, DRw14, DRBI *1041).[52,56] The role of the HLA class 2 alleles appears to be important relative to recognition of Dsg3 peptides by the T lymphocytes, which are affecting the recognition response before the generation of specific antibodies by B lymphocytes.

In this disease there is a deposition of antibodies of the IgG class within the intercellular space that produces direct damage to the desmosomes, in particular the extracellular domain of the Dsg3 adhesion molecule.[57]

The specific mechanisms of epithelial cell dysfunction or acantholysis subsequent to immunoglobulin binding to the Dsg3 over the cell surfaces are being intensively studied. Several mechanisms being evaluated include down-regulation of desmoglein binding within the intercellular space, antibody-related altered transmembrane signaling, and possibly increased epithelial cell surface plasminogen activation that degrades nondesmoglein adhesion molecules.[57,58] Antigens other than desmogleins have been proposed as possibly contributing to the acantholysis process including a novel α-9 acetylcholine receptor that regulates keratinocyte adhesion, a keratinocyte annexin-like molecule, pemphaxin, and catenin.[59-61] The latter area of investigation remains controversial at the moment, with most authorities agreeing that the major antigen subset attacked in pemphigus vulgaris involving mucosal sites is Dsg3. The main effect of the process of antibody binding to target antigens within the epithelial intracellular space is epithelial cell dysadhesion or separation (acantholysis). This microscopic lesion results in the clinical evolution of vesicles and bullae.

Clinical Presentation

Oral and oropharyngeal lesions of pemphigus vulgaris are rarely seen in children and are usually noted in the fifth decade and beyond. The early oral manifestations tend to run a chronic course producing erosions, blisters, and ulcerations with the initial vesiculobullous lesions being short-lived; ease of rupture is followed by development of new vesicles as the older lesions collapse, and immediately after there is ulceration and pain.[62] The major clinical manifestations early on, therefore, are painful erosions and ulcerations seen predominantly in the oropharynx, soft palate, buccal mucosa, and labial mucosa (Fig. 91-20).

Figure 91-20. Pemphigus vulgaris of the buccal mucosa with patchy and irregular superficial ulcerations and surface slough representing collapsed bullae.

In contrast to mucous membrane pemphigoid, the mucosal ulcerations of pemphigus vulgaris heal relatively quickly and without scarring or complication. Healing is quickly followed, however, by formation of new lesions that run a similar clinical course. If the gingiva is involved, a desquamative process is evident as intensely erythematous, very friable surface qualities, with the slightest provocation producing tearing of the surface epithelial layer away from the deeper layers and resulting in transient bleeding (Fig. 91-21). Lesions will extend from the gingival margins to the alveolar mucosa, whereas the oropharyngeal lesions will favor the lateral aspects of the soft palate with extension to the lateral pharyngeal wall and inferiorly toward the vallecula.

Clinical Differential Diagnosis

To be considered along with pemphigus vulgaris in a clinical differential diagnosis are mucous membrane or cicatricial pemphigoid, lesions of lupus erythematosus, erythema multiforme and erosive lichen planus/bullous lichen planus, and paraneoplastic pemphigus.

Histopathologic Features

The dominant histopathologic feature of diagnostic importance represents separation or cleavage of the suprabasal layer from the basal layer of the overlying epithelium (Fig. 91-22). The basal cells will remain attached to the lamina propria, sometimes forming a so-called tombstone-like effect. Nonadherent spinous cells will separate and float freely

Figure 91-21. Subtle desquamative, tender lesions of pemphigus vulgaris involving the mandibular attached gingiva and alveolar mucosa.

Figure 91-22. A low-power view of clinically intact mucosa adjacent to ulcerated lesions of pemphigus vulgaris showing a discrete, uniform separation of the parabasal and superficial epithelium from the basal layer, which remains adherent to the basement membrane.

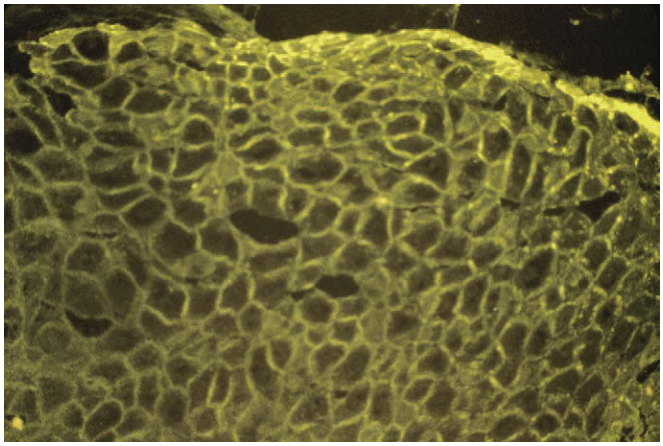

Figure 91-23. Fluorescence of the intercellular space regions with labeled anti-IgG antibody is diagnostic for pemphigus vulgaris.

Figure 91-24. Mucous membrane (cicatricial) pemphigoid with characteristic intact vesicles of the attached gingiva.

within the blister fluid (Tzanck cells), often becoming spherical in shape and demonstrating a somewhat eosinophilic quality.

Direct immunofluorescence examination is crucial in substantiating and formalizing the diagnosis, and results are positive in all cases of pemphigus vulgaris. Here one notes the presence of IgG localized to the intracellular spaces of the epithelium (Fig. 91-23), while C3 is localized to the intracellular spaces in approximately 80% of cases. Finally, indirect immunofluorescence will have positive results in nearly 80% of cases. Correlating the indirect immunofluorescence titers, as obtained by serial serum dilution, with the corresponding level of clinical severity will often be used to help determine treatment efficacy.

The diagnosis therefore becomes related to the nature of the clinical appearance, the mucosal manifestations, as well as the routine histologic investigation and the direct and indirect immunofluorescence study results.

Treatment

The mainstay of treatment concerns itself with systemic immunosuppression, using prednisone and nonsteroidal agents. Generally speaking, the initial attempt at management involves prednisone administration, 1 mg/kg, supplemented with either azathioprine or mycophenolate mofetil. Cyclophosphamide can be used, sometimes in conjunction with plasmapheresis, where severe disease is present, requiring rapid antibody reduction. For recalcitrant cases or for those unable to tolerate more routine immunosuppressive regimens, IV IgG may be appropriate. In cases of initially severe disease, plasmapheresis coupled with systemic immunosuppressive agents may be necessary.

The prognosis of pemphigus vulgaris remains guarded on the basis of the managing strategies necessary to suppress the disease and the risk of systemic infection, as well as treatment-related adverse effects. There is a 5% mortality rate due to long-term systemic corticosteroid use as a recognized treatment-related complication.

Mucous Membrane (Cicatricial) Pemphigoid

Definition

Mucous membrane, or cicatricial pemphigoid (MMP), is a heterogeneous cluster of autoimmune subepithelial vesiculobullous diseases immunologically characterized by a linear deposition of IgG and C_3 at the mucosal basement membrane zone. This group of conditions is disparate in terms of disease severity and the specific location of lesional activity at the microscopic or molecular level. Sites of mucosal involvement within the head and neck region include ocular, nasopharyngeal, oral, laryngeal, nasal, and esophageal areas.

Etiology and Pathogenesis

Mediation of this group of conditions involves the formation of autoantibodies directed against an increasing number of recently discovered

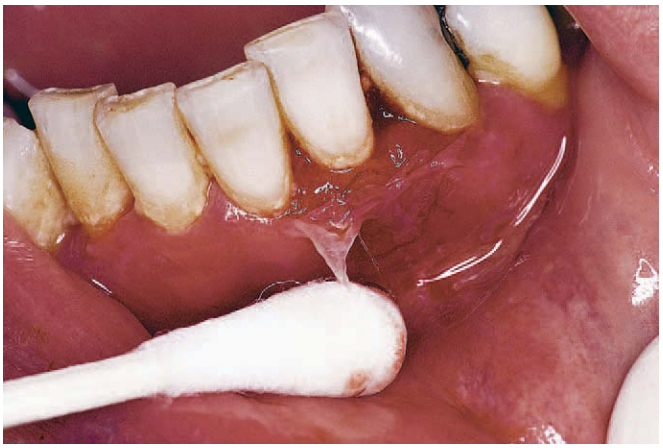

Figure 91-25. Stripping away the full thickness of gingival epithelium in mucous membrane pemphigoid with a dry cotton swab is helpful in identifying a cleavage disorder of the mucosa.

molecular components of the basement membrane zone. Most members of this group carry sequelae of scarring and loss of function, except for some cases in which exclusive oral mucosal involvement is present.[13] Pathogenic factors include antibodies to bullous pemphigoid antigen 2, laminin 5, β_4 integrin subunit, and bullous pemphigoid hemidesmosomal antigen 180.[63-65] To date, no specific correlation has been made between a target-specific autoantibody and a specific clinical form or subtype within this group.

In contrast to pemphigus vulgaris, a limited immunogenetic relationship has been noted, that being an increased occurrence of the HLA-DQB1 *0301 allele in patients with MMP.[66] Future studies investigating specific relationships between cell surface HLA-DQ molecules over antigen-presenting cells to T cells and specific autoantigens are necessary to better understand further details concerning the role of HLA-DQ alleles in this antigen-recognition process.

Clinical Features

The oral mucosa is the most commonly involved head and neck site in MMP, followed by ocular, nasal, and nasopharyngeal locations (Figs. 91-24 to 91-26). Oral and nasal sites will demonstrate erythematous features with patchy distribution of vesicles and bullae. At the site of a recently collapsed bulla, a pseudomembrane will surface an underlying ulcer. The most common location for this type of lesion is the keratinized tissue investing the palatal and attached gingival sites. Less commonly, the buccal mucosa and conjunctiva will be involved. Although

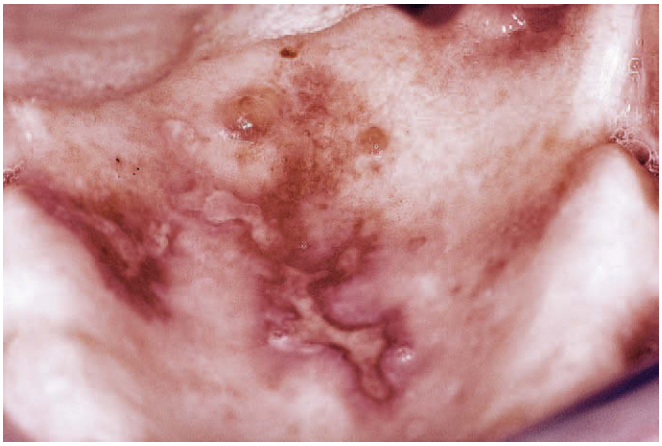

Figure 91-26. Intact vesicles and serpentine ulceration of the soft palate in mucosal pemphigoid are characteristic.

Figure 91-27. Ocular scarring (symblepharon) with bridging of the palpebral and bulbar conjunctiva in mucosal (cicatricial) pemphigoid.

intraoral scarring is not always present, ocular scarring is frequent with resultant complications that include symblepharon, ankyloblepharon, corneal opacification, entropion, and trichiasis. Scarring within the larynx and esophagus,[67] as well as within the trachea, may occur (Fig. 91-27).

Clinical Differential Diagnosis

As with pemphigus vulgaris, the differential diagnosis is a relatively broad one. Categories of inclusion would be those that are immunologically mediated, those related to aphthous ulcerations and Behçet's disease, and the group represented by reactions to drugs and other chemicals.[68] A summary of diagnostic considerations is seen in Table 91-3.

Histopathologic Features

On routine laboratory processing of formalin-fixed and hematoxylin-eosin stained tissue, a suggested diagnosis of mucous membrane pemphigoid could be made by virtue of demonstrating a separation of the mucosal epithelium from the underlying lamina propria in the absence of significant inflammation (Fig. 91-28). The site of tissue procurement should be an area adjacent to an inflamed, erosive, or bullous lesion, given the friable nature of clinically altered tissue. Thus a putative diagnosis of pemphigoid can be established, with a more definitive diagnosis related to performance of direct immunofluorescence testing. Perilesional mucosa will show linear immune deposits at the epithelial basement membrane zone composed of any one or combination of IgG, IgA, and C_3 in a continuous and homogeneous pattern (Fig. 91-29).

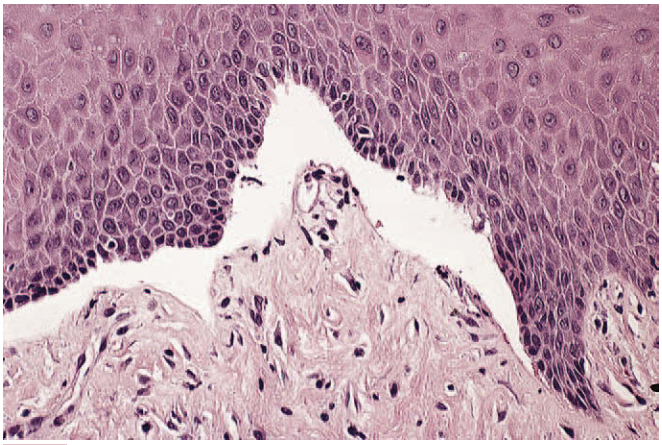

Figure 91-28. A sharply defined subepithelial cleft in the absence of significant inflammation is characteristic of mucous membrane pemphigoid but not completely diagnostic.

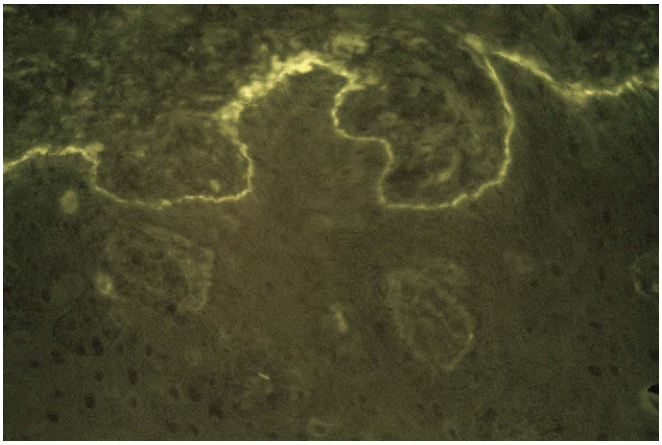

Figure 91-29. Mucous membrane pemphigoid (direct immunofluorescence) with linear IgG fluorescence along the basement membrane.

Table 91-3

Differential Diagnosis: Mucous Membrane Pemphigoid

Drug/substance/food reaction	
Viral (herpetic) infection	Primary herpes simplex Recurrent intraoral herpes simplex Intraoral varicelliform eruptions
Erosive lichen planus	
Epidermolysis bullosa acquisita	
Pemphigus vulgaris	
Paraneoplastic pemphigus	
Stevens-Johnson syndrome	
Erythema multiforme	
Linear IgA disease	

This pattern of fluorescence will allow separation of mucous membrane pemphigoid from other mucosal vesiculo-erosive diseases such as lichen planus, pemphigus vulgaris, erythema multiforme, and drug-induced lesions. Incorporation of clinical findings remains the final integrative step in finalizing this diagnosis.

Treatment

Factored into treatment must be the specific site of involvement, as well as the severity of involvement. With rapidly progressive disease that includes ocular mucosa, larynx, and esophagus, systemic prednisone and cyclophosphamide should be considered.[69,70] In cases of mild disease at several mucosal sites, initial treatment with Dapsone for 12 weeks can be used.[70] In cases in which only oral mucosa is involved, topical corticosteroids (moderate to high potency) could be the initial agents used. With gingival involvement, the use of soft acrylic removable carrier appliances can be helpful. Systemic tetracycline/nicotinamide has been used effectively as a nonsteroid-based approach in some studies.[71,72] Severe or unresponsive oral disease, however, may require oral prednisone with or without an additional immunosuppressive, steroid-sparing agent.[73]

Herpes Simplex Virus

Primary Herpes Simplex Infection

DEFINITION. Oral and oropharyngeal lesions caused by the human herpes simplex virus (HHV-1) are the most common virally induced oral/oropharyngeal ulcerative conditions, affecting from 60% to 90% of the population.[74,75] Each year in the United States, approximately 600,000 new cases of primary herpes simplex infection develop in the young, and less commonly in adults, without primary immunity. Spread of primary herpes simplex infection is usually through direct contact with an individual with active primary or recurrent disease. Additionally, asymptomatic shedding of HHV within the saliva of recovering or distantly infected persons serves as a source of infection.

ETIOLOGY AND PATHOGENESIS. HHV consists of a DNA core surrounded by a protein capsule assuming the three-dimensional form of an icosahedron enclosed within a protein envelope structure, measuring approximately 200 nm, and is subclassified into various subtypes on the basis of the level of virulence demonstrated within tissue culture. HHV-1 and -2 fall within the so-called α group of virulence classification, whereas more aggressive viral types fall within the β or γ groups.

The mode of oral infection involving HHV-1 (and rarely, HHV-2) relates to initial specific binding of virus to cell surface or plasma membrane receptors, specifically to envelope proteins on the virion surface. The viruses bind to keratinocytes, as well as neurons, and subsequently enter the cytoplasm of the cells by an endocytosis process. The viruses ultimately migrate through the nuclear pores and into the nucleoplasm, where propagation, virus core assembly, and release occur; in the process a nucleocapsid structure is acquired. Mature viral particles are then transported into the cytoplasm and ultimately are released through the cell membrane into the extracellular space whereupon they move ahead to infect adjacent cells. As a consequence of the replication and propagation of the virus within the nuclei of keratinocytes, there are terminal changes evident within the nuclei and plasma membrane to the point where plasma membrane leakage occurs and intracellular metabolic activity ceases. Ultimately, the cell becomes necrotic and releases large numbers of viral particles into the surrounding extracellular space. The lytic infectious process spreads from cell to cell, finally producing a clinically visible lesion in the form of a vesicle.

Also occurring during this time is the probable entry of virus into adjacent neurons, again by surface receptor engagement and endocytosis. This, in fact, represents the initial phase of latency development where virus reaches the trigeminal ganglion and, less commonly, other neuronal ganglia such as the nodose (vagal), dorsal root, and sympathetic ganglia.[75] Replication occurs within a minority of neurons between 2 and 10 days after provocation of recurrent infection, as noted in animal experiments.

CLINICAL FEATURES. The primary oral herpes simplex infection develops approximately 5 to 7 days subsequent to contact with an infected person. A prodrome lasting up to 48 hours can be characterized by focal mucosal tenderness and erythema, quickly followed by evidence of a group of small vesicles over the oral mucosa. Such vesicles are thin-walled, delicate, and short-lived. An inflammatory periphery surrounds each vesicle, followed by the development of shallow, painful, and discrete superficial ulcerations. In the primary phase of this disease, oral mucosal surfaces can be affected in both the keratinized and nonkeratinized regions. The presence of gingival lesions in the primary infection represents a key clinical diagnostic criterion in which the gingiva appears erythematous, boggy, and tender, with the free margin of gingiva discretely and distinctly involved by this process (Fig. 91-30). In this location, clusters of small superficial ulcerations are present in concert with lesions of similar quality elsewhere in the oral cavity. The infection can extend into the oropharynx and occasionally into the perioral skin region. The duration of the entire process ranges from 7 to 14 days with a generally self-limiting course. There is the potential that viral synthesis and presence within the oral cavity may continue for several weeks after clinical resolution (viral shedding), resulting in a continued ability to infect others lacking primary immunity.

Figure 91-30. Primary herpetic gingivostomatitis with tender, widespread vesicles and ulceration.

DIFFERENTIAL DIAGNOSIS. Clinical entities that may require separation from and that may resemble primary HHV-1 infection include herpangina (Coxsackie viruses A2, 4-6, 8-10), hand-foot-mouth disease (Coxsackie virus A16), chicken pox (varicella), measles (paramyxovirus), and erythema infectiosum ("fifth disease").

DIAGNOSIS. The establishment of a diagnosis of primary HHV-1 infection is made by virtue of the clinical presentation where the symptoms of prodrome are further characterized by the development of vesicular lesions that are quickly followed by ulceration and marginal gingivitis. It is generally not necessary to use laboratory methodologies to establish the diagnosis beyond the clinical recognition and affirmation; however, techniques including viral isolation and culture, cytologic analysis of vesicle content, and serum antibody titers as infection progresses are all valid techniques to verify and confirm the diagnosis.

TREATMENT. The management of primary intraoral HHV infection is generally considered to be symptomatic and supportive in nature as the patient develops antibodies to the infectious agent.

Recurrent Herpes Simplex Infection

DEFINITION. Recurrent HHV-1 infection ("secondary HHV-1") represents a recrudescent viral infection that occurs in a person previously infected with HHV-1. Underlying the recurrence is a formerly established latency state and abrogation of this former state of homeostasis between dormant virus and host immunity.

ETIOLOGY AND PATHOGENESIS. Escape or release from latency of virus from the dermatome-associated ganglionic neurons begins the process of recurrent disease progression. HHV-1 enters the neuron with sufficient DNA copies available to affect replication; however, the immune system suppresses such replication and α gene expression. A viral reservoir is necessary for maintenance of latency within infected

Figure 91-31. Recurrent herpes labialis with clustered intact vesicles at the skin-vermilion junction.

Figure 91-32. Recurrent intraoral herpes simplex in an adult with numerous, widely scattered vesicles and ulcers in association with pain, tenderness, and fever.

neuronal cells. Laboratory studies have shown that latency-infected neuronal cells range from 4% to 35% within the ganglion affected, on the basis of demonstrated virally directed RNA synthesis.[76]

Recurrences, as reflective of latency escape or viral activation, occur predominantly in the form of herpes labialis; however, intraoral recurrent disease also occurs, almost always within the keratinized epithelium of the hard palate and attached gingiva, and less commonly over the dorsal tongue surface. In such cases, multiple, shallow, closely cropped, tender erosions and ulcerations are noted. When on the hard palate, lesions often occur along the distribution of the greater palatine nerve, in particular in the first molar and premolar areas. The distribution is usually unilateral and involves the gingiva but does not cross the midline. When involving the mandibular-attached gingiva, the molar and premolar area is the site of predilection, as is the case in the maxilla.

Herpes simplex labialis represents the most common clinical form of HHV-1 recurrent disease, with a significant prevalence of HHV-1 primary immunity in the United States ranging from 40% to 60%.[77] The frequency of recurrent episodes ranges from 5% to 23% in some, whereas 58% to 61% suffer recurrences every 1 to 4 months.[78]

CLINICAL FEATURES. Characterizing recurrent herpes labialis is the initial prodrome period, which may be described as a focal area of altered sensation often described as painful, tingling, or burning with the subsequent development of vesicles at the prodrome site. The site most commonly involved occurs over the vermilion portion of the lip with overlap and extension to the skin surface immediately adjacent to this junction (Fig. 91-31). This site of involvement is generally repetitive or consistent from one recurrent episode to another. As vesicles form, they are initially pinhead in size and clustered, occur over an erythematous and edematous background, and often coalesce before rupturing with formation of tender ulcerations and ultimately crusting. Vesicles can remain intact for approximately 24 to 48 hours, and the crusting phase may persist for 5 to 7 days before healing without scarring, although in immunosuppressed individuals, in whom lesions tend to be larger and of longer duration, scarring can be observed.

Of note is the unusual presentation of widespread intraoral recurrent disease in adults with vesicle/ulcer distribution and corresponding pain and dysfunction (Figs. 91-32 and 91-33).

DIFFERENTIAL DIAGNOSIS. In the case of recurrent herpes labialis, a narrow clinical differential diagnosis exists. Contact sensitivity, angular cheilosis, traumatized perioral dermatitis, primary syphilis, and erythema multiforme can mimic this condition. However, the history, appearance, and distribution of the above-mentioned lesions will aid in their separation from herpes labialis.

HISTOPATHOLOGY. In cases in which recurrent herpetic lesions are biopsied, the usual circumstance is that of a recurrent intraoral vesicular lesion. In such instances, an intraepithelial vesicle forms in association with intense focal mixed inflammatory infiltrate (Fig. 91-34).

Figure 91-33. Typical recurrent intraoral herpes simplex infection along the course of the greater palatine nerve.

Infected keratinocytes will be enlarged with multilobulated viral inclusions (Tzanck cells), which will also be evident on a smear preparation obtained by unroofing an intact vesicle, removing the vesicular fluid for viral culture studies, and scraping the vesicle floor, followed by spreading the contents of the scraped cellular elements on a slide for a Tzanck prep and subsequent pathologic evaluation for the presence of viral cytopathic effect (Fig. 91-35).

TREATMENT. The management of recurrent herpetic infection in immunocompetent adults generally does not require the use of systemic antiviral agents. However, for the common labial recurrences, new topically delivered agents, docosanol cream and penciclovir cream, are available. Both agents target the viral replication process. At the intracellular level, in the case of penciclovir, the agent inhibits replication by way of inhibiting HHV-1 DNA polymerase formation. Docosanol, a saturated 22-carbon primary alcohol compound, prevents the initial fusion interaction between the viral envelope and keratinocyte plasma membrane, thus preventing access to the intracellular environment.[79]

Recurrent Aphthous Stomatitis

Definition

Recurrent aphthous stomatitis (recurrent aphthous ulcerations) represents the most common nontraumatic form of oral ulceration with an incidence range between 20% and 40% of the population. This remains an incompletely understood mucosal disease, chiefly affecting the oral and oropharyngeal mucosa, and less commonly, the genital mucosa. Of

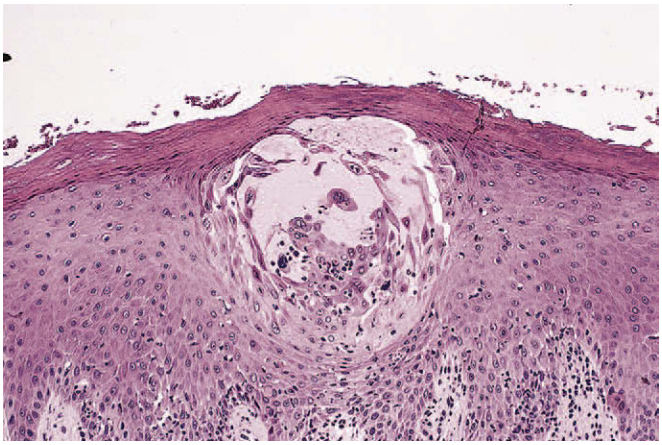

Figure 91-34. An intact vesicle of a herpes simplex lesion is intraepithelial in location and filled with serum and free-floating, virally infected keratinocytes and inflammatory cells.

Foods	Chocolate Tomatoes Walnuts, hazelnuts, Brazil nuts
Menstrual cycle	

note are data indicating a greater prevalence among those in professional groups,[80] those of higher socioeconomic status, and nonsmokers.

Etiology and Pathogenesis

The specific etiopathogenesis of this entity is not known, although it is generally understood that there is a range of apparently disparate states or conditions with oral aphthous ulceration as a common feature. Included in this are Crohn's disease, Behçet's syndrome, gluten-sensitive enteropathy or celiac disease/nontropical sprue, and food hypersensitivity (e.g., nuts, spices, chocolate) (Table 91-4).

The ingestion of certain drugs including nonsteroidal anti-inflammatory agents, β-blockers,[81] and potassium-channel blockers[82] has also been associated with aphthous-type oral ulcerations. Withdrawal or avoidance of these agents in those affected will eliminate future recurrences, thus helping separate such lesions from true idiopathic aphthous ulcers.

Finally, two other systemic conditions, Sweet's syndrome (acute febrile neutrophilic dermatosis) and PFAPA syndrome (periodic fever, aphthous ulcers, pharyngitis, and adenitis), will demonstrate true aphthous ulcers as a component of the disease complex.[83,84]

A correlation or association with the presence of the HLA-B51 genotype[85] has been made in an attempt to explain familial clustering of this condition. Elaboration or up-regulation of the powerful cytokine TNF-α and other cytokines and chemokines of keratinocyte and lymphocyte origin, in association with up-regulation of adhesion molecule synthesis, results in keratinocyte lysis. Both T-cell–mediated and antibody-mediated processes are present, although the specific antigen remains unidentified.

An appreciation of the immunopathogenesis in the early phase of lesion formation, where a lymphocytic infiltrate at the site of the future ulcer is noted, is responsible for the clinical preulcerative phase of this process. This is quickly followed by the formation of a tense and tender focal tissue alteration characterized by a circumferential area of erythema that indicates a localized vascular engorgement and dilation along with a mild vasculitis. Within 24 hours, the papular tender area breaks down, forming the typical ulceration. Importantly, there is no sign of vesicle formation or blistering, versus primary or recurrent HHV infection, with a distribution of the lesions over the nonkeratinizing mucosal surfaces (labial, buccal, ventral and lateral tongue, floor of the mouth, soft palate, tonsillar pillars).

The complexity of lesion initiation and progression is emphasized by the likely multifactorial etiology with triggering and predisposing factors at play.[86] The latter include local physical trauma, psychic stress, the aforementioned hormonal influences, and a negative association in tobacco smokers and users of smokeless tobacco.[87,88]

Clinical Features

The traditional view concerning the clinical forms and presentations of recurrent aphthous stomatitis states the minor, major, and herpetiform types, with ulcer size being the major differentiating feature. More recent studies[86] have divided aphthous ulcers into three classes on the basis of their clinical presentation. Considered are the duration of the ulceration, their frequency/chronicity, and the level of symptomatology. From a practical standpoint, this form of lesional or disease classification can be more readily integrated with the type and intensity of treatment.

Minor aphthous ulceration accounts for up to 85% of all aphthous ulcers. Ulcers range up to 10 mm in diameter and are located over nonkeratinized mucosa, usually in the anterior portion of the oral cavity. The duration of ulcerative episodes ranges from 7 to 10 days, followed by healing without scarring (Fig. 91-36).

Major aphthous ulcers account for approximately 10% of aphthous ulcers.[89] They are large (>1 cm), occur typically in the posterior aspect of the oral cavity and oropharynx, may be associated with odynophagia, and are deeply cratered, sharply marginated, and painful

Figure 91-36. **A** and **B,** Minor aphthous ulcers of the labial mucosa and ventral tongue show a yellow fibrinous base, sharply marginated periphery, and erythematous periphery.

Figure 91-37. A solitary major aphthous ulcer at the posterior margin of the soft palate.

(Fig. 91-37). The duration of each episode may be up to 6 weeks but may persist for longer periods in the immunocompromised host, in whom they tend to be more severe, deeper, and more painful than minor-type aphthous ulcers, and they may serve as a marker for HIV disease progression.[90,91]

Herpetiform-type aphthous ulcers represent the least common variant of aphthous ulcers, with most cases affecting the moveable or nonkeratinized surface tissue, although there may be lesions of keratinized areas affected on occasion. Presentation occurs as multiple pin-

Figure 91-38. Herpetiform aphthous ulcerations of the lower labial and alveolar mucosa are pinhead in size, numerous, and of shallow depth.

Table 91-5

Recurrent (Two-Degree) HHV versus RAS (minor)

	HHV	RAS
Etiology	Herpes simplex I/II	Varied/immune dysfunction
Location	Keratinized tissue; mucosa	Moveable/ nonkeratinized
Vesicle phase	Yes	No
Duration	7-14 days	Varies (usually 7-10 days)
Management	Topical (docosanol, penciclovir), oral antivirals	Severity-related, usually topically-based steroids
Prodrome	Often	Uncommonly
Triggers	Stress, trauma	Stress, ultraviolet light, foods
Biopsy findings	Viral cytopathic effect	Nonspecific

HHV, human herpes virus; RAS, recurrent aphthous stomatitis.

head-sized to 2-mm shallow craterform ulcers with a widespread distribution (Fig. 91-38). Clinical resemblance to the lesions of primary HHV infection is noteworthy—hence their designation as herpetiform. To contrast these lesions with those of herpes simplex, one will note the absence of a vesicular phase before ulcer formation, and adult onset and pain levels are disproportionately greater than the extent of lesion development.

Differential Diagnosis

Separation of aphthous ulceration from the ulcers of intraoral HHV infection and traumatic ulcers remains the major differential diagnosis. Paramount in the separation of these conditions is an understanding of the general differences in location and the presence (herpetic infection) or absence of a vesicular phase (aphthous ulcer) in addition to other factors noted in Table 91-5.

Histopathologic Features

An absence of any pathognomonic features characterizes all forms of aphthous ulcers. An early central zone of keratinocyte necrosis/ulceration is evident. Ulcers are surfaced by a thin fibrinous plaque, whereas deep to the surface a mixed inflammatory infiltrate in association with an increased number of engorged, dilated vascular elements is present. Perivascular aggregates of lymphocytes and histiocytes are present in the absence of vasculitis.

Treatment

Mild and infrequent episodes of minor aphthous ulcers generally require little more than symptomatic management. When treatment is necessary, the general mainstay is the use of topical steroids. When lesions are severe or occur as a continuous series of outbreaks, short-term administration of systemic corticosteroids is effective. Intralesional steroid delivery can be useful in cases of larger (major) aphthae or those less than fully responsive to other forms of treatment.

Erythema Multiforme

Definition

Erythema multiforme (EM) represents a self-limiting, usually acute, mucocutaneous hypersensitivity reaction characterized by cutaneous or oral ulcerations. A less severe chronic or persistent form of this condition also exists, in which lesions of the skin, lips, and mouth may be noted concurrently or asynchronously. The condition may range from a self-limited, mild, exanthematous process with skin and minimal oral involvement (EM minor) to a more fulminant, progressive process with epithelial necrosis of skin and mucosa—Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN).[92] It may be prudent to view EM, SJS, and TEN as an overlapping spectrum of the same process with varying degrees of severity.

Etiology and Pathogenesis

Controversy exists concerning the initiation event of this reactive disease process; however, it is clear that numerous triggers have been associated with this condition including photosensitivity, medications, and viral infections including Epstein-Barr virus, chronic hepatitis C, HHV-1, and parvovirus B19, with recurrent HHV-1 the most common trigger.[93-97] Although approximately 50% of cases can be associated with triggering agents or events (infections, drugs),[98] the latter group of cases (drug-induced EM) are most commonly identified as being associated with antiseizure medications such as carbamazepine and phenytoin, as well as sulfonamides, other antibiotics, and some analgesics. The strongest association, however, is between recurrent HHV-1 infection and EM; in two series, respectively, 79% to 100% of EM cases followed such an infection.[99,100] Controversies of etiology aside, it is clear that in a high percentage of EM cases, preceding recurrent HHV infection or another infectious process (e.g., viral, mycoplasma) or drug ingestion serves as the major etiologic factor. Also reported is the frequency of circulating immune complexes in the serum of patients with EM.[101]

At the tissue level, antigen-antibody complexes diffuse from local vasculature to initiate activation of the complement cascade followed by development of local vasculitis and a directed movement of neutrophils and macrophages into the epithelium and lamina propria. Keratinocyte necrosis follows with formation of oral and cutaneous ulceration.

Clinical Features

An acute and self-limiting reaction, EM involves mucosa and skin with bullae or ulceration in a symmetric distribution. Classic target or iris lesions develop over the skin and are characterized by concentric circles or annular configurations of slightly erythematous to pigmented quality (Fig. 91-39). At the center, bullae or vesicles may develop. The oral mucosa and vermilion portion of the lips may demonstrate aphthous-like ulcers and erosions, and on occasion vesicles or bullae may be present. Mucosal ulcers are symmetrically distributed, irregular in size and shape, tender, and covered with a fibrinous plaque (Fig. 91-40). Crusted, hemorrhagic plaques over the vermilion portion of the lips with edema, fissure formation, and extreme tenderness are characteristic (Fig. 91-41). Oral and oropharyngeal dysfunction includes sialorrhea, pain, odynophagia, and dysarthritic-type speech. Hydration and food intake may be impossible due to pain and the inability to chew and swallow. Severe EM (EM major/SJS) may best characterize this latter constellation of signs and symptoms along with involvement of other mucosal sites including eyes, genitalia, and uncommonly the esophagus and pulmonary tract. Of note is the occasional finding of antibodies to desmoplakin I and II in some patients with EM, suggesting a possible humoral mechanism at play, as well in the pathogenesis of the major form of this condition.[102]

Figure 91-39. Numerous "iris" or "target" lesions of erythema multiforme over the thenar eminence in a patient with oral and oropharyngeal involvement by this condition.

Figure 91-40. Intraoral ulcerations of erythema multiforme showing thick pseudomembranous lesions over the ventral tongue surface and floor of the mouth.

Differential Diagnosis

Other mucocutaneous diseases to be ruled out in the absence of iris or target lesions include severe aphthous ulceration, pemphigus vulgaris, mucosal (cicatricial) pemphigoid, and erosive lichen planus. The clinical diagnosis of EM is often one of exclusion, however, with a biopsy occasionally being necessary to exclude these conditions.

Histopathologic Features

Routine histopathology will, on perilesional or nonulcerated mucosa, show spongiosis, apoptotic basal and parabasal cells, intense lymphohistiocytic infiltration (often in a perivascular distribution), and edema, with extension of this process from the submucosa into the superficial lamina propria. Preulcerative areas will show keratinocyte necrosis,

Figure 91-41. Exudative, tender lesions of the lower labial vermilion surface and mucosa of erythema multiforme.

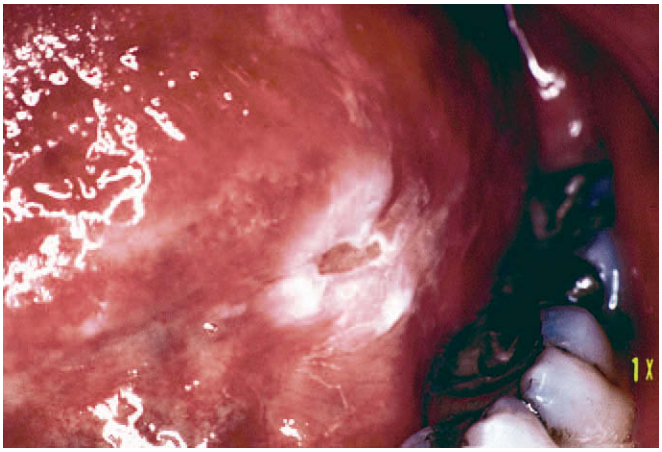

Figure 91-42. A so-called traumatic (eosinophilic) granuloma presents as a chronic, sharply marginated ulcer, often with a variable level of peripheral hyperkeratosis.

edema within the lamina propria, intercellular and intracellular edema, and vacuolar degeneration at the basement membrane zone.

Although the direct immunofluorescence findings are not pathognomonic, there will be an absence of antibody binding within the epithelium. However, blood vessel walls will contain fibrin, C_3, and IgM.

Treatment

Specifics and philosophy of managing EM are on one hand controversial and on the other related to the level of severity. Whereas prior HHV-1 (recurrent herpes labialis) infection was noted, dosing with antiviral drugs at less than full therapeutic doses has reduced further episodes of EM.[95] When only oral lesions are present (EM minor), management may be symptomatic only or with a short course of conservative corticosteroid administration. Details of symptomatic management will include use of oral hygiene aids, bland mouth rinses or compounded rinses containing combinations of topical steroids, and antifungal and local anesthetic agents. Analgesics may be useful in an effort to manage odynophagia, thus allowing adequate levels of hydration and caloric intake.

Traumatic (Eosinophilic) Granuloma

Definition

The traumatic or eosinophilic granuloma is a benign, usually large, and self-limiting chronic oral ulcer that is often of long duration. It is usually seen in association with a putative deep mucosal injury.

Etiology

In spite of its designation as "traumatic," it is unusual for affected individuals to isolate a prior traumatic event in relation. Most feel that the origin of the process is unknown.

Clinical Features

Presentation generally occurs in the fifth through seventh decades of life as a painful ulcer of rapid onset, with the majority of lesions developing along the lateral and ventral tongue surface. On occasion, dorsal tongue surface lesions may be seen. The average diameter ranges from 1 to 2 cm with a craterform center, sharply marginated periphery, and firm, indurated peripheral qualities (Fig. 91-42). Duration is usually several weeks but may persist for several months. Often, the peripheral or bordering epithelial surface is milky white to opaque/white in appearance over the indurated margin.

Differential Diagnosis

The location, texture, appearance, and chronic duration may suggest squamous cell carcinoma. Major aphthous ulceration, oral ulcers of Crohn's disease, syphilis, granulomatous diseases, and lymphoma may also be considerations at the clinical level.

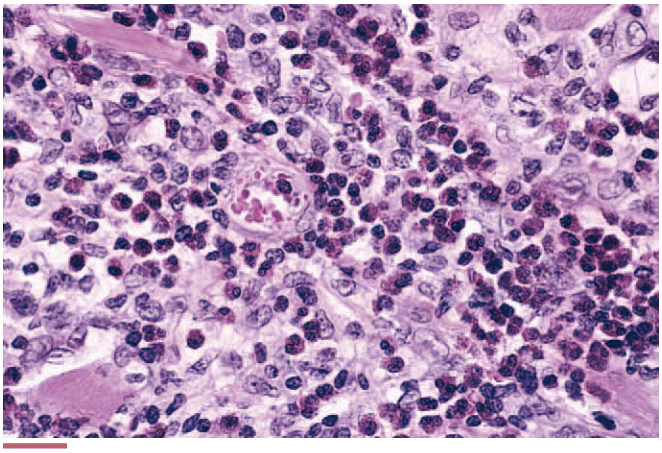

Figure 91-43. An intense chronic inflammatory infiltrate containing numerous scattered eosinophils between skeletal muscle bundles is characteristic of the traumatic granuloma.

Histopathologic Features

Deep ulceration extending into underlying skeletal muscle dominates the pattern, with an intense diffuse and polymorphous inflammatory infiltrate evident. The latter is characterized by the presence of large numbers of histiocytes, endothelial cells, and eosinophils (Fig. 91-43). Muscle bundles are often separated by the chronic inflammatory/granulomatous process. Myofibroblastic cells have also been identified within the stroma, although experts believe these cells are a reactive component.[103]

Immunohistochemical studies have demonstrated an unclear and complex array of staining results. Prominent are CD30 (Ki-1)-positive cells, which are found in Hodgkin's disease and benign reactive conditions. One study demonstrated highly active T cells, CD68-positive cells, and dendrites cells (CD1a+) suggesting a possible relationship to cutaneous CD30-positive lymphoproliferative disorders.[104] Histologic and behavioral similarities have been noted with the atypical histiocytic granuloma, implying the likelihood that this entity may form a subset or a histologic variant of the traumatic eosinophilic ulcer.[105]

Treatment

Because these lesions are self-limiting but often chronic, the clinician may choose a tactic of observation only. Use of topical or intralesional corticosteroids may hasten resolution. Excision is a consideration if the clinical presentation is in question.

Figure 91-44. Discrete, uniformly pigmented macules of the lower labial vermilion surface characterize the melanotic macule.

Figure 91-45. Focal melanosis ("smoker's melanosis") is characteristic over the buccal mucosa as scattered, macular, evenly pigmented patches.

Pigmented Lesions

Oral mucosal pigmentation of melanocytic type includes a wide variety of conditions including racial and physiologic types, nevi, and benign melanocytic proliferation to preinvasive and invasive melanoma. The variety of oral mucosal melanoma (<1% of all cases of all melanoma) has made a comprehensive analysis of this entity impossible; however, it is clear that melanoma can occur at any mucosal site with subtype variation similar to that seen at cutaneous sites.[106] Crucial for clinicians to appreciate as far as the overall poor prognosis for oral mucosal melanoma in general is a delay in recognition of early disease and a corresponding delay in diagnosis by physicians. Often noted is the lack of recognition or appreciation of oral melanotic or pigmented macules and plaques that can represent the radial growth phase of melanoma evolution.[107] In an effort to further define oral pigmented lesions of potential significance, the initial step is a determination of whether the pigmentation is intrinsic (e.g., melanocytic, inflammatory, non-melanin–containing) or extrinsic (e.g., amalgam tattoo, medication-related, traumatic implantation of exogenous material).[108]

Melanotic Macules

Definition

An often troubling pigmented lesion of the vermilion portion of the lower lip (30%), gingiva and alveolar mucosa (23%), and buccal (16%) labial mucosa (9%) is the melanotic mucosal macule.[109] Studies to date have identified a distinct female predilection with site (lower lip), sex (female, 2:1), and racial (white) predominance (Fig. 91-44).

Etiology and Pathogenesis

Mucosal melanotic macules can be idiopathic (ephelis), postinflammatory, syndrome-associated (Peutz-Jeghers, Laugier-Hunziker), or related to systemic disease (Addison's disease) (see Table 91-6 for a more complete listing). Melanocytic lesions derive from the neural crest–derived melanocyte. Melanocytic proliferation is common to mucosal melanocytic nevi that arise from intraepithelial melanocytes, while the submucosal/"dermal" melanocyte gives rise to the blue nevus. Other benign melanocyte-derived processes, the ephelides and melanotic macules, are representative of excess melanin production rather than melanocytic overgrowth/hyperplasia. Melanoma and its precursors (superficial spreading melanoma) relate to the malignant quality of melanocyte proliferation with markedly altered morphology, distribution, and behavior relative to typical melanocytes and nevus cells.

Clinical Features

MUCOSAL MELANOTIC MACULE. As the name mucosal melanotic macule indicates, a macular zone of hyperpigmentation, generally less than 10 mm in diameter with even, well-defined margins, and homogeneous pigment distribution characterize these benign hypermelanotic lesions (Fig. 91-45).

MUCOSAL MELANOCYTIC NEVI. Mucosal melanocytic nevi, on the other hand, as a result of nevus cell (altered melanocyte) proliferation, can appear in the young or at birth as focal macular to papular hyperpigmented lesions and may persist throughout childhood. Oral melanocytic nevi may be nonpigmented in up to 20% of cases, with the palate being the most common site affected, followed by the buccal/labial mucosa, gingiva, and alveolar ridge.

Table 91-6

Oral Mucosal Pigmented Diseases and Conditions

Etiology	Disease/Agent
Idiopathic-melanocytic	Ephelis (focal) Nevi (junctional, compound, intramucosal, blue, focal) Melanoma and melanoma precursors
Postinflammatory (diffuse)	
Syndromic (association)	Peutz-Jeghers (focal) Laugier-Hunziker (focal) McCune-Albright (diffuse) Neurofibromatosis (diffuse) Cushing's (diffuse) Addison's (focal and diffuse)
Medication-related (all diffuse)	Minocycline Clofazimine Chloroquine, antimalarials Azidothymidine Chlorpromazine Heavy metal–containing drugs Quinidine Cyclophosphamide
Extrinsic	Amalgam tattoo Traumatic implantation

Melanoma

Oral mucosal melanoma is a rare neoplasm with a racial predilection for Asians and blacks. Although a preexisting melanosis may be a precursor, this, when present, likely represents lateral spread or superficial spreading melanoma. Although oral melanomas do not fit neatly into the well-defined cutaneous melanoma categories, these are parallels to acral lentiginous and nodular melanomas.[110] Those melanomas evolving from an earlier or precursor lateral spreading or superficial spreading form are almost always found in adults. Early melanoma of this type is flat, irregularly marginated, and heterogeneously pigmented. With progress, the degree of pigmentation increases, as does the surface area, with a deeper brown to variegated gray-brown color noted. Most oral melanomas derive from the macular form; however, some arise ab initio as a rapidly growing nodule (nodular melanoma).

Most oral mucosal melanomas (40%) occur on the hard or soft palate, whereas gingival melanomas (Figs. 91-46 and 91-47) comprise approximately one third of melanomas.[109] Most intraoral lesions (85%) are invasive at initial discovery or show both invasive and in situ features. This site distribution is at odds with that of Pliskin,[111] who found 57% of cases originating in gingival soft tissue in his series.

Differential Diagnosis

A relatively narrow field of entities may be considered as clinical diagnostic alternatives within the spectrum of oral pigmented lesions. Melanotic mucosal macules must be separated from superficial spreading melanoma, Kaposi's sarcoma, and exogenous pigmentation such as amalgam tattoo. Nodular melanoma and intramucosal nevi can show clinical overlap, as can venous/vascular mucosal varicosities.

Histopathologic Features

The ephelides and melanotic macules are characterized by accumulation of melanin pigment within the basal layer of the mucosal epithelium, often with variable degrees of melanin incontinence into the superficial lamina propria (Fig. 91-48).

Mucosal melanocytic nevi, depending on specific type, are characterized by altered melanocyte ("nevus cell") accumulation within the epithelium exclusively, often in aggregates or as so-called "theques" in junctional nevi. In compound nevi, aggregates of nevus cells are present concurrently within the epithelium and lamina propria. When nevus cells are exclusively located in the lamina propria and superficial submucosa only, an intramucosal nevus is present. Finally, proliferation of the deeply located submucosal melanocyte forms epithelioid and spindle-shaped cells, often highly pigmented, in the blue nevus.

At early stages, melanoma histomorphology will show aggregation of atypical melanocytes at the epithelial-connective tissue junction, with extension toward the epithelial surface often noted. Later lesions will demonstrate melanocytic extension into the lamina propria and deeper structure as the vertical phase of growth establishes itself (Fig. 91-49).

Melanomas, as the great imitator, can assume a wide array of patterns and can demonstrate numerous cell morphologies including epithelioid, spindle (Fig. 91-50), stellate, and plasmacytoid forms.

Figure 91-46. Melanoma of the hard palate with uneven pigmentation, diffuse margins, and widespread distribution.

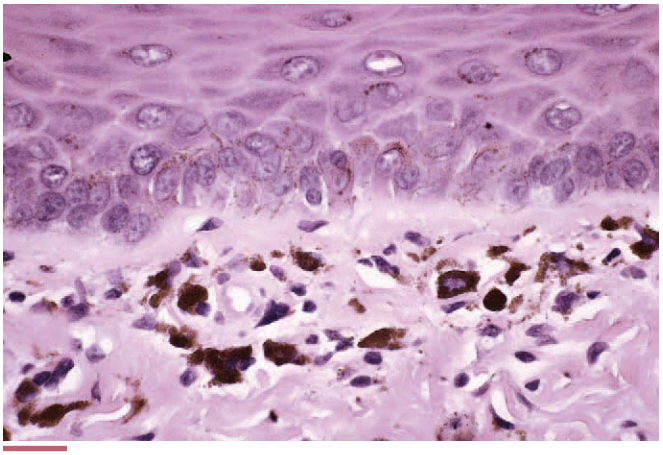

Figure 91-48. A focal melanotic macule with barely discernible dendritic processes of melanocytes within the epithelium in association with clusters of melanophages and free melanin in the lamina propria.

Figure 91-47. Gingival melanoma. This lesion arose as a slightly nodular pigmented surface alteration with more macular or superficial spreading qualities at the free gingival margin.

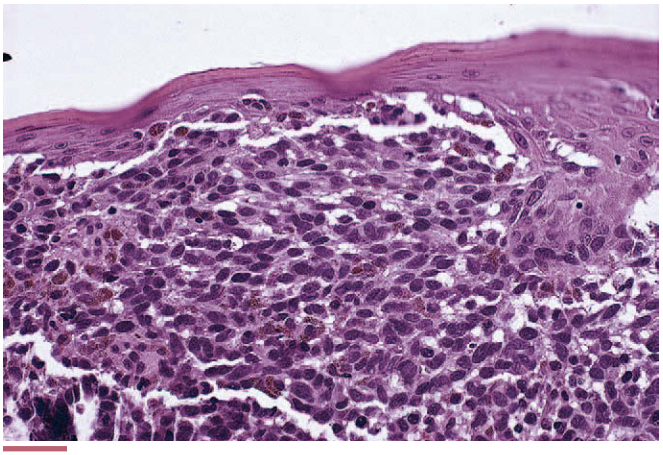

Figure 91-49. Melanoma of the palate with epithelioid and spindle-shaped melanocytes invading the epithelium and extending deeper into the lamina propria.

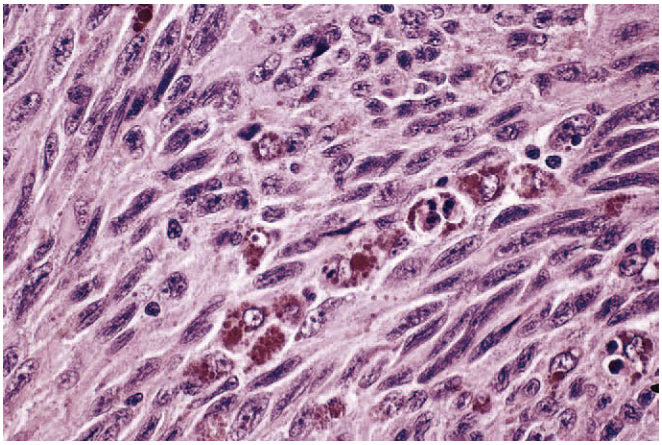

Figure 91-50. Melanin-laden melanoma cells of polyhedral shape within a prominent spindle cell population of melanoma cells.

Figure 91-51. An amalgam tattoo of the labial mucosa with a characteristic gray-black color, macular surface, and slightly diffuse margins.

Patterns formed may be likewise variable, including organoid clusters, sheets, spindle-neurotropic, alveolar, and desmoplastic variants. In cases of amelanotic melanoma or other variants, it may be necessary to use immunohistochemical techniques such as S-100, HMB-45, and melan-A expression to identify melanocyte lineage.

Treatment

Benign melanocytic lesions (e.g., macules, ephelides, melanocytic nevi) can be conservatively excised as the excisional biopsy during the diagnostic phase of investigation.

Superficial spreading and invasive and nodular melanoma remains, with surgery, the prime treatment modality. Depth, surface coverage of lesion, and location will determine the extent of excision.

Prognosis remains quite poor, independent of the site within the oral cavity. As with cutaneous melanoma, thickness of tumor and clinical stage are correlated with overall survival. Excellent sources discussing prognostic factors in head and neck melanomas are those of Batsakis and colleagues[112] and the consensus statement from the WESTOP Banff workshop[110] on oral mucosal melanomas. The overall 5-year survival for all oral mucosal melanomas is 15%, and there is a median survival time of 46 months in the absence of lymph node involvement versus an 18-month survival in the face of positive lymph node findings.[109]

Amalgam Tattoo

Definition

The amalgam tattoo is an extrinsically derived mucosal pigmentation that results from traumatic implantation or chronic low-grade frictional transfer of dental silver amalgam into adjacent oral mucosa.

Etiology

Subsequent to silver particles entering the lamina propria/submucosa, a minimal chronic inflammatory infiltrate becomes established. Macrophages, and less commonly, multinucleated giant cells ingest the material, thus allowing dispersal into the immediate vicinity. The migration of these phagocytic cells into regional lymph nodes may, as in the case of decorative tattoos, deposit particulate silver amalgam in regional draining lymph nodes, thus mimicking metastatic melanoma.[113]

Clinical Features

Usually well-defined, macular grayish-black focal macular mucosal discoloration characterizes the amalgam tattoo. These tattoos are noted characteristically on the mandibular-attached gingiva, mucobuccal fold, and alveolar gingiva or buccal mucosa (Fig. 91-51). On occasion, they may be evident on routine dental radiographs when traumatic implantation of sufficient material occurs. They range in size from 1 mm to 1.5 cm, with most being 0.4 cm or smaller.[114]

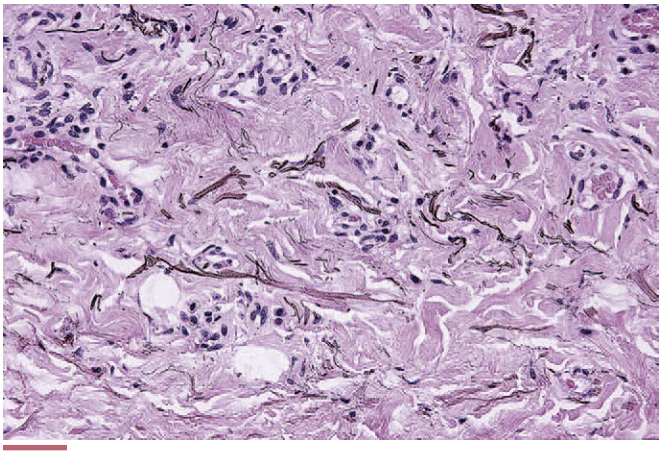

Figure 91-52. Fine particles of amalgam within this amalgam tattoo are distributed along collagen bundles within the submucosa.

Differential Diagnosis

A wide range of conditions may be considered at the clinical level within the context of the amalgam tattoo. These include melanoma; vascular malformations; melanotic lesions such as blue nevus, intramucosal, and other melanocytic nevi; and other traumatic implantations such as graphite.[115]

Histopathologic Features

Black (reduced) foreign metallic material will be located within the lamina propria and submucosa. Older lesions will contain collections of finely granular silver-containing deposits along the basement membranes of vasculature, nerves, and epithelium, as well as along collagen bundles (Fig. 91-52). Multinucleated giant cells, though not invariably present, will contain ingested material, as will macrophages. Energy-dispersive x-ray analysis has been used to demonstrate the presence of silver and copper in these tissues.[116]

Treatment

Management may relate to establishing a clinicopathologic correlation and observation only. Often a biopsy procedure will simply confirm the clinical diagnosis; however, once identified, removal is elective. Specific treatment strategies include simple surgical excision or, as has been reported, with use of a Q-switched ruby laser.[117]

CHAPTER NINETY-TWO

Oral Manifestations of Systemic Diseases

Jonathan A. Ship

Michael D. Turner

Key Points

- Recent epidemiologic studies have demonstrated an association, but not a causal relationship, between heart disease and dental/periodontal diseases because of periodontal pathogens and certain serologic proteins found in the gingival sulcus that cause systemic inflammation.
- Antibiotic prophylaxis before certain dental procedures is recommended for persons with cardiac valvular abnormalities at risk for developing subacute bacterial endocarditis. Recent modification of the antibiotic recommendations simplified and clarified the regimen to reduce overuse of antibiotics, potential adverse effects, and drug resistance. Dental procedures for which endocarditis prophylaxis is reasonable are events that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa.
- Patients on cardiovascular medications can have hyposalivation, which is deleterious to oral and pharyngeal health and function. Specific etiologies include classes of medications such as diuretics, calcium channel blockers, and angiotensin-converting enzyme inhibitors.
- Early detection of oral cancer is critical because patients with early-stage tumors have considerably better survival rates than those with late-stage cancers that have already spread to regional tissues and the lymphatic system.
- Head and neck cancer patients must undergo preoperative dental evaluation and treatment before definitive therapy so as to remove oral pathology (e.g., dental caries, periodontal disease, nonrestorable teeth) before developing the common oral sequelae of surgery, chemotherapy, and radiotherapy.
- The motor, sensory, and cognitive alterations that accompany cerebrovascular diseases have deleterious effects on oral health and function. A cerebrovascular accident (CVA, or stroke) can cause permanent oral sensory and motor deficits, resulting in poor tongue function and lip seal, difficulty eating and drinking, impaired use of dentures, and visuospatial problems with adverse social and psychologic consequences.
- Most patients on anticoagulation requiring simple oral surgical procedures, if local hemostatic and conservative surgical techniques are used, do not need to discontinue their anticoagulation regimen.
- Patients who control their diabetes have fewer oral health problems than those with poorly controlled diabetes. There is an association between severe periodontitis and an increased risk of poor glycemic control.
- Sjögren's syndrome (SS), a systemic autoimmune disorder associated with inflammation of epithelial tissues, is the most common medical disorder associated with xerostomia and salivary dysfunction.
- Herpes simplex virus (HSV-1) and varicella-zoster virus (VZV) are the most common viral infections in the oral-facial region. They can present as herpes labialis or primary herpetic gingivostomatitis (HSV-1) or acute, painful, oral-facial lesions (VZV).
- The most frequent oral fungal infection is caused by *Candida albicans.* The overgrowth of *C. albicans* in the oral-pharyngeal region has many etiologies: endocrine disorders (e.g., diabetes), immunosuppression, nutritional deficiencies, medications (particularly antibiotics and long-term immunosuppressants), salivary gland hypofunction, removable dental prostheses, and poor oral and denture hygiene.
- Lichen planus is a chronic, mucocutaneous, autoimmune disorder that can be precipitated by a number of conditions such as genetic predisposition, emotional stress, or drug, food, or dental material hypersensitivity.

The oral cavity plays a major role in physiology. Three critical functions are performed by the oral cavity: the intake of foods and beverages, communication, and the protection of the host from noxious substances. Multiple head, neck, and oral tissues have evolved to carry out these vital functions including the following: muscles of facial expression, mastication, and deglutition (including the tongue); oral mucosal, dental, and periodontal tissues; salivary glands; and taste and smell receptors. These tissues continually work together to keep a person hydrated and nutritionally healthy, to protect the upper aerodigestive tract, and to provide chemosensory information about foods, beverages, and potentially dangerous substances. Many of these processes and tissues can remain remarkably intact throughout the course of a person's life, yet numerous systemic diseases and their treatment (e.g., medications, surgery, head and neck radiation, chemotherapy) can cause significant impairments to oral health. These problems can subsequently lead to malnutrition, infection, impaired communication, pain, and an impaired quality of life.

The oral cavity has been frequently referred to as a window into a person's body. Several systemic diseases manifest initially through oral manifestations, which can be readily examined via noninvasive techniques. Saliva and crevicular fluid (exudate from the periodontal ligament) may replace certain serologic tests in the future, and buccal epithelial cells may provide diagnoses for systemic diseases. Recognition of normal and unusual oral conditions will help improve the prevention, diagnosis, dissemination, and management of many systemic diseases. Systemic conditions may require modifications of oral treatments (Table 92-1), and drugs can affect oral health (Table 92-2). This clearly requires a multidisciplinary approach to health care involving numerous specialties from medicine and dentistry.

The purpose of this chapter is to provide an overview of the oral manifestations of the most prevalent medical conditions and their treatments. Recognition and treatment of many systemic conditions can help prevent the development of certain oral diseases. Conversely, diagnosis and management of numerous head, neck, and oral diseases can help minimize the progression and severity of several systemic diseases.

Diseases of the Heart

Diseases of the heart such as ischemic heart disease, myocardial infarction, and hypertension have remained the number one cause of death for the past 5 decades. Given that these diseases are common chronic ailments affecting the elderly, any oral manifestations of the conditions, as well as their treatments, will become more common in the future with the expansion of the older population.

Some cardiovascular conditions and their subsequent treatment have oral-facial signs and symptoms and therefore have oral treatment considerations. Anginal pain can appear as referred pain to the neck, clavicle, and mandible, and it can be localized to the mandible and teeth. A comprehensive differential diagnosis must include consideration of dental-alveolar origin (e.g., caries, periodontal disease), temporomandibular joint (TMJ) disease, referred musculoskeletal pain, central or peripheral nervous system pain, and myocardial infarction.

Table 92-1

Oral Treatment Considerations Due To Systemic Conditions

Systemic Condition	Cause	Oral Considerations	Treatment Considerations
Coagulation disorders	Anticoagulation therapy Chemotherapy Liver cirrhosis Renal disease	Increased bleeding risk	Alter anticoagulation therapy Limit dental-alveolar surgery Use topical anticoagulation methods
Immunosuppression	Alcoholic cirrhosis Chemotherapy Diabetes Medications Organ transplant therapy Renal disease	Microbial infections	Appropriate antimicrobial medications
Joint replacements	Accidents Osteoarthritis Rheumatoid arthritis	Increased risk for late prosthetic joint infections	Antibiotic prophylaxis
Radiation sequelae	Head and neck radiation	Salivary hypofunction Mucositis Osteoradionecrosis Increased caries risk Dysphagia Dysgeusia Difficulty with mastication Microbial infections Impaired denture retention	Regular fluoride use Salivary substitutes and stimulants Aggressive oral hygiene and recall Pain management
Steroid therapy	Autoimmune diseases Organ transplant therapy	Microbial infections Increased risk for adrenal insufficiency	Appropriate antimicrobial medications Steroid supplementation for dental procedures
Valvular damage/heart murmur	Acquired heart defects Congenital heart defects Valvular transplants	Increased risk for developing subacute bacterial endocarditis	Antibiotic prophylaxis

Table 92-2

Overview of Oral Sequelae of Medication Intake for Systemic Diseases

Drug Category	Drug	Oral Problem
Analgesics	Aspirin	Hemorrhage, erythema multiforme
	NSAIDs	Hemorrhage
	Barbiturates, codeine	Erythema multiforme
Anesthetics (local)	Benzocaine, procaine HCl, lidocaine	Taste disorders
Antiarrhythmics	Procainamide	Lupus-like reaction
	Quinidine	Lichenoid mucosal reaction
Antiarthritic, antipyretic, anti-inflammatory	Allopurinol, auranofin, colchicine, dexamethasone, hydrocortisone, levamisole, D-penicillamine, phenylbutazone, salicylates, 5-thiopyridoxine	Taste disorders
	Gold salts	Taste disorders, lichenoid reaction, oral pigmentation, vesiculo-ulcerative stomatitis
Antibiotics	All	Oral candidiasis
	Erythromycin	Hypersensitivity reaction, vesiculo-ulcerative stomatitis
	Penicillin	Hypersensitivity reaction, erythema multiforme, vesiculo-ulcerative stomatitis
	Chloramphenicol, ciprofloxacin, clindamycin, dapsone, isoniazid, sulfa antibiotics, tetracyclines	Erythema multiforme
	Minocycline	Melanosis
	Chlorhexidine	Brown pigmentation of teeth & tongue
	Ampicillin, cefamandole, ethambutol, hydrogen chloride, griseofulvin, lincomycin, metronidazole, niridazole, sulfasalazine, tetracyclines	Taste disorders
Anticoagulants	All	Hemorrhage
Anticonvulsants	Carbamazepine	Erythema multiforme, taste disorders
	Phenytoin	Erythema multiforme, gingival enlargement, taste disorders
Antidiarrheal agents	Bismuth	Dark pigmentation of tongue
Antihistamines	All	Salivary dysfunction
	Chlorpheniramine maleate	Taste disorders
Antihypertensives	All	Salivary dysfunction
	Calcium-channel blockers	Gingival enlargement
	Angiotensin-converting enzyme inhibitors	Vesiculo-ulcerative stomatitis, pemphigus vulgaris
	Chloramphenicol	Vesiculo-ulcerative stomatitis
	Hydralazine	Lupus-like reaction, erythema multiforme
	Methyldopa	Lupus-like reaction and lichenoid mucosal reaction
	Thiazide diuretics	Lichenoid mucosal reaction
	Minoxidil, verapamil	Erythema multiforme
	Acetazolamide, amiloride, captopril, diazoxide, diltiazem, enalapril, ethacrynic acid, nifedipine	Taste disorders
Antilipidemics	Cholestyramine, clofibrate	Taste disorders
Antimycotics	Griseofulvin	Erythema multiforme, black pigmentation of the tongue
	Amphotericin B	Taste disorders
Antineoplastics	All	Oral candidiasis, oral hemorrhage, recurrent oral viral infections, aphthous stomatitis, vesiculo-ulcerative stomatitis
Anti-parkinsonian	All	Salivary dysfunction
	Levodopa	Taste disorders

Continued

Table 92-2

Overview of Oral Sequelae of Medication Intake for Systemic Diseases—cont'd

Drug Category	Drug	Oral Problem
Antireflux agents	All Cimetidine	Salivary dysfunction Erythema multiforme
Antithyroids	Carbimazole, methimazole, methylthiouracil, propylthiouracil, thiouracil	Taste disorders
Antioxidants	Octyl gallate	Allergic ulcerations
Anxiolytics	Benzodiazepines	Salivary dysfunction
Chelating agents	Penicillamine	Ulcers and pemphigus vulgaris
Corticosteroids, immunosuppressants, antiproliferatives	All Azathioprine, bleomycin, carmustine, doxorubicin, 5-fluorouracil, methotrexate, vincristine sulfate Cyclosporin	Oral candidiasis, recurrent oral viral, infections, vesiculo-ulcerative stomatitis Taste disorders Gingival enlargement
Hypoglycemics	Sulfonylurea agents Glipizide, phenformin and derivatives	Erythema multiforme Taste disorders
Muscle relaxants	All Baclofen, chlorzoxazone	Salivary dysfunction Taste disorders
Others	Etidronate, germine monoacetate, idoxuridine, iron sorbitex, vitamin D	Taste disorders
Psychotherapeutics	All Glutethimide, meprobamate Phenothiazines Lithium carbonate Trifluoperazine HCl	Salivary dysfunction Erythema multiforme Oral pigmentation, tardive dyskinesia Erythema multiforme, taste disorders Taste disorders
Sympathomimetics	Amphetamines, amrinone	Taste disorders
Vasodilators	Bamifylline hydrogen chloride, dipyridamole, nitroglycerin patch, oxyfedrine	Taste disorders

HCl, hydrogen chloride; NSAIDs, nonsteroidal anti-inflammatory drugs.

Several recent epidemiologic studies have demonstrated an association, but not a causal relationship, between heart disease and dental/periodontal diseases.[1-5] Periodontal pathogens and certain serologic proteins found in the gingival sulcus (particularly C-reactive proteins) have been found in carotid atheromas and shown to induce platelet aggregation. However, the role of periodontal infection as a risk factor for cardiovascular disease requires further scientific validation. Recent data have further demonstrated a possible link between periodontal conditions and systemic measures of inflammation. Intensive periodontal treatment resulted in acute, short-term systemic inflammation (increased levels of C-reactive protein, interleukin-6, and the endothelial-activation markers soluble E-selectin and von Willebrand factor), as well as mild endothelial dysfunction. However, importantly, 6 months after therapy, without any adverse events, marked benefits in periodontal health were statistically associated with improvement in endothelial function.[6]

The treatment of cardiovascular diseases with drugs also has deleterious oral consequences. For example, antihypertensive medications have been shown to cause salivary dysfunction (as in the cases of diuretics, calcium channel blockers, β-blockers), gingival enlargement (calcium channel blockers), lichenoid mucosal reactions (thiazide diuretics), and disturbances in taste (ACE inhibitors, calcium channel blockers). Higher salt detection thresholds have also been observed in persons with hypertension.[7] Consideration of possible alteration of drug regimens is appropriate.

Persons who have undergone cardiac transplantation and are receiving postoperative immunosuppressive pharmacologic regimens must be evaluated for potential oral complications. Immunosuppressive therapy increases the prevalence of oral opportunistic infections such as reactivation of herpes simplex virus and overgrowth of *C. albicans.* Cyclosporine, a frequently used antirejection drug, has been reported to cause gingival enlargement in up to 13% to 85% of patients.[8]

Consideration must be given to cardiac conditions before dental treatment is undertaken. Patients receiving anticoagulation therapy may present with hemorrhagic lesions of oral mucosal tissues (see "Cerebrovascular Diseases" later). Antibiotic prophylaxis is recommended for persons with cardiac valvular abnormalities at risk for developing subacute bacterial endocarditis (Table 92-3). Recent modification of the antibiotic recommendations simplified and clarified the regimen to reduce overuse of antibiotics, potential adverse effects, and drug resistance.[9] Dental procedures for which endocarditis prophylaxis is reasonable (see Table 92-3) are events that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa. The regimen for antibiotic prophylaxis is provided in Table 92-4.

Table 92-3

Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis for Which Prophylaxis with Dental Procedures Is Reasonable

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous IE
- Congenital heart disease (CHD)*
  - Unrepaired cyanotic CHD including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure†
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

*Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
†Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.
From Lockhart PB, Loven B, Brennan MT, Fox PC. The evidence base for the efficacy of antibiotic prophylaxis in dental practice. *J Am Dent Assoc.* 2007;138(4):458-474; and Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *J Am Dent Assoc.* 2007;138(6):739-745, 747-760.

Although the dental office environment and dental treatment can increase heart rates and blood pressures, treatment can be safely rendered to patients with ischemic heart disease with adequate anxiety and pain control.[10] The use of local anesthetics with epinephrine can be a concern in the treatment of cardiac patients because of the effect of increased heart rate, stroke volume, and cardiac output. However, at low doses, epinephrine has been found to have few of these systemic effects and in stable cardiovascular patients it can be safely used. For patients with a questionable cardiac history, 0.04 mg of epinephrine should be the maximum dose given (≈two 1.8-mL carpules of local anesthetic with 1:100,000 epinephrine), whereas unstable cardiac patients should receive epinephrine only for emergency dental treatment.

Malignant Neoplasms

Oropharyngeal cancer involves the soft palate, tonsil, base of the tongue, and vallecula and is diagnosed in nearly 9000 men and women in the United States annually.[11] Cancers of the oral cavity and pharynx, which represent 2.1% of all neoplasms in the United States, have a direct and frequently permanent deleterious effect on oral health and function. Although men experienced a much greater likelihood of developing oral-pharyngeal cancer in the past, the male-female ratio is now 2:1. The prevalence and mortality of oral cancers increase with age, and the major preventable risk factors are tobacco use and excessive alcohol consumption.

Common signs include nonhealing crusting and ulcerated leukoplakic and erythemic lesions. Pain is not necessarily a symptom of oral cancers, and patients should be advised to see their dentists or physicians for definitive diagnosis if a lesion or swelling has not resolved within a 2- to 3-week period.

Most of the remaining 10% of head and neck tumors are salivary gland tumors or lymphomas; further, approximately 1% of all tumors originate below the clavicles and metastasize to the head and neck.[12] Accordingly, visual inspection and palpation of the head and neck region must include lymph nodes, muscles of mastication and facial expression, and salivary glands. Furthermore, a histopathologic examination is required of all nonhealing head, neck, and oral lesions.

Early detection of oral cancer is critical because patients with early-stage tumors have considerably better survival rates than those with late-stage cancers that have already spread to regional tissues and

Table 92-4

Antibiotic Regimens for a Dental Procedure as Recommended in Table 92-3

Situation	Agent	Regimen—Single Dose 30-60 Minutes before Procedure	
Oral	Amoxicillin	Adults 2 g	Children 50 mg/kg
Unable to take oral medication	Ampicillin or Cefazolin or ceftriaxone	2 g IM or IV 1 g IM or IV	50 mg/kg IM or IV 50 mg/kg IM or IV
Allergic to penicillins or ampicillin Oral	Cephalexin* or Clindamycin Azithromycin or clarithromycin	2 g 600 mg 500 mg	50 m/kg 20 mg/kg 15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone† Clindamycin phosphate	1 g IM or IV 600 mg IM or IV	50 mg/kg IM or IV 20 mg/kg IM or IV

*Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.
†Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.
IM, intramuscular; IV, intravenous.
From Lockhart PB, Loven B, Brennan MT, Fox PC. The evidence base for the efficacy of antibiotic prophylaxis in dental practice. *J Am Dent Assoc.* 2007;138(4):458-474; and Wilson W, Taubert KA, Gewitz M, et al. Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *J Am Dent Assoc.* 2007;138(6):739-745, 747-760.

the lymphatic system. For example, 5-year survival rates for small and localized tongue cancers (stage I and II) and those tongue cancers with lymph node involvement and possible metastasis (stage III and IV) are 67% and 30%, respectively. Accordingly, since 1980, the American Cancer Society has recommended a cancer-related checkup every 3 years for persons aged 20 to 39 years and annually for individuals 40 years and older.[13] This is particularly relevant for the elderly population, which sees their dental practitioner less frequently than their younger counterparts, and in particular, older edentulous adults.

The treatment of most cancers will indirectly or directly affect oral health and function. Chemotherapy causes reversible mucositis, stomatitis, salivary hypofunction, smell and taste dysfunction, diminished appetite, and increased susceptibility to oral microbial infections. Clinically significant nutritional deficiencies and dehydration can occur in the presence of severe oral and pharyngeal mucositis and recurrent microbial infections. Because of the significant morbidity and mortality of antineoplastic therapies, these patients require frequent and long-term follow-up by dental professionals.

Treatment for oral-pharyngeal neoplasms includes surgery, radiation therapy, and chemotherapy, depending on the tumor stage and extent of regional spread.[14] Extensive removal of the cancerous growth and affected lymph nodes can result in significant facial disfiguration, dysphagia, altered speech and mastication, trismus, facial and oral paresthesia, salivary gland dysfunction, and diminished neck and shoulder mobility. Head and neck radiation is frequently used after surgery for the treatment of residual and microscopic disease; however, it also has significant adverse effects. These sequelae include mucositis, stomatitis, dysphagia, permanent salivary gland dysfunction, smell and taste dysfunction, oral microbial infections (e.g., reactivation of herpes simplex and varicella zoster viruses, *C. albicans* infections), and increased risk of developing osteoradionecrosis.[14]

Importantly, these patients must undergo preoperative dental evaluation and treatment before definitive therapy so as to remove oral pathology (e.g., dental caries, periodontal disease, nonrestorable teeth) before developing the common oral sequelae of surgery, chemotherapy, and radiotherapy. Both dentate and edentate postoperative patients must continue to perform scrupulous oral hygiene and maintain a regular recall schedule with their oral health professionals to reduce the risk of developing osteoradionecrosis, oral microbial infections, and other oral pathologies.

Recent findings of osteonecrosis of the maxilla and mandible have been associated with the bisphosphonate class of antiosteoclastic medications. A majority of the reported cases were found in patients being treated for osteometastatic breast carcinoma or multiple myeloma. The pathophysiology of the disease has not yet been determined.[15]

Cerebrovascular Diseases

The motor, sensory, and cognitive alterations that accompany cerebrovascular diseases have deleterious effects on oral health and function. A cerebrovascular accident (CVA) can cause permanent oral sensory and motor deficits, resulting in poor tongue function and lip seal, difficulty eating and drinking, impaired use of dentures, and visuospatial problems with adverse social and psychologic consequences.[16] Nutritional deficiencies and diminished quality of life can result from impaired food and fluid intake.

The location of the CVA determines the oral-facial deficits. Left cerebral cortex lesions cause right-sided paralysis and difficulty with auditory memory, speech, language, and the oral phase of swallowing. Right cortex lesions cause left-sided paralysis with subsequent neglect of affected sites, pharyngeal dysfunction with potential for aspiration, and difficulty with memory and performing certain tasks (such as tooth brushing). Oral-facial motor and sensory impairments can lead to improper dental and denture hygiene and food accumulation or pocketing around teeth, in the buccal vestibules, and underneath the tongue. Ultimately, this can lead to dental and periodontal diseases and oral microbial infections that can become exacerbated by the lack of sensory detection by the patient. Some patients experience problems with communication, judgment, and memory, which inhibit accurate solicitation of the patient's pertinent medical history, chief complaint, and compliance with home care instructions.

Anticoagulation therapy, the standard preventive treatment after a stroke, will produce hemorrhage, petechiae, ecchymoses, and purpura of all oral mucosal tissues. Dental treatment can be safely performed if the prothrombin time is within twice the normal range or if the international normalized ratio (INR) is less than 3.[17] However, if excessive dental-alveolar surgery is planned, conversion to low-molecular-weight heparin or heparinization in a hospital setting is recommended. Aspirin use is popular in adults at risk for cardiovascular thrombotic events, and low-dose aspirin is an excellent preventive agent; however, its antiplatelet properties have contributed to a perceived increased risk for bleeding after dental extractions. For most patients requiring simple oral surgical procedures, if local hemostatic and conservative surgical techniques are used, discontinuation of aspirin may not be necessary.[17]

Head and neck radiographic findings and oral/periodontal status may aid in identification of persons at risk of CVAs. Carotid calcifications of atherosclerotic plaques have been found on 4% of panoramic radiographs of asymptomatic persons older than 55 years.[18] In addition, periodontal disease and tooth loss are associated with increased risk of stroke.[19,20] It is hypothesized that the infectious burden of oral disease can initiate proliferation of inflammatory cells and clotting factors resulting in atherogenesis and thromboembolic events.[20] In addition, periodontal bacteria have been isolated from the atheromatous plaques after a CVA. The evidence to support a CVA-periodontal disease relationship is stronger than that found in investigations of cardiovascular and oral diseases.

Pulmonary Diseases

A common link between pulmonary diseases (COPD; bronchitis, asthma, and emphysema) and oral health is smoking. Smoking, one of the two preventable causes of oral cancer (see "Malignant Neoplasms" earlier), is also associated with benign oral mucosal pathology (nicotinic stomatitis, oral fungal infections). Little is known regarding the direct effects of COPD on oral health, yet it is well established that a common treatment modality of COPD (corticosteroids) has many oral consequences.[21] Chronic use of corticosteroids suppresses the hypothalamic-pituitary-adrenal axis that can result in acute adrenal insufficiency during stress. Therefore steroid replacement therapy is sometimes required for extensive dental and surgical procedures.[21] Many patients use steroid inhalers that should be brought to all dental appointments for use if necessary to ensure protection of a patent airway. Chronic use of systemic and inhaled corticosteroids also predisposes patients to oral fungal infections. Finally, nitrous oxide use is contraindicated in persons with severe COPD, secondary to oxygen-driven respiratory function.

Aspiration pneumonia, a common condition, particularly in hospitalized and older adults with compromised host defense mechanisms, is caused by the aspiration of gastric or oropharyngeal secretions. Oropharyngeal swallowing dysfunction, a consequence of neuromuscular and cerebrovascular diseases, debilitation, salivary hypofunction, and medications, is a frequent risk factor for aspiration pneumonia.[22] Colonization of the oropharynx with gram-negative bacilli predisposes to bacillary pneumonia.[23] A major source of anaerobe infection is the gingival crevice. Furthermore, the prevalence of bacterial colonization increases with poor oral hygiene and periodontal disease. Therefore patients at risk should receive routine dental examinations and treatment, and they may benefit from daily antimicrobial rinses.[24] Broad-spectrum antibiotics are the standard treatment regimen for pneumonia. Extended antibiotic use increases the risk of developing oral fungal infections and antibiotic resistance.

Tuberculosis, a major global health problem caused by the spread of *Mycobacterium tuberculosis,* manifests infrequently in the oral cavity. The classic oral mucosal lesion is a painful, deep, irregular ulcer on the dorsum of the tongue, with additional sites including the palate, lips, buccal mucosa, and gingival.[25] *M. tuberculosis* can also infect the cervical and submandibular lymph nodes (referred to as *scrofula*) and rarely affects the salivary glands.[26]

Oral tuberculosis lesions require diagnosis and appropriate antimicrobial management, as well as education on possible transmission via infected oral sites. A recent investigation reported positive oral cultures of *M. tuberculosis* from samples of saliva, dental plaque, caries

lesions, and denture plaque collected from tuberculosis patients, demonstrating the possibility of oral infectivity of these patients.[27] Interestingly, detection rates from these oral sites using polymerase chain reaction techniques were considerably higher (between 89% and 100% detection rates) than traditional culture methods (0% to 17%).[28] With the growing rate of human immunodeficiency virus/acquired immunodeficiency syndrome in the world, a disease that frequently manifests with tuberculosis, clinicians must be familiar with infection control procedures to protect workers against exposure to pathologic and possibly aerosolized microorganisms.

Endocrine and Exocrine Disorders

Diabetes Mellitus

The presence or absence of diabetes and the degree of glucose metabolic control in patients significantly influence the level and severity of diabetes-related oral diseases. Patients who control their diabetes have fewer oral health problems than those with poorly controlled diabetes,[29] and some data suggest that persons with controlled diabetes have the same incidence of oral disease as the general population.[30] Alternatively, poorly controlled diabetes is associated with a plethora of oral health problems. The most common oral disease seen in persons with diabetes and in greater prevalence than persons without diabetes is periodontal disease.[29,31] Many studies have shown that poor glycemic control precedes the incidence and progression of periodontitis. Furthermore, there is an association between severe periodontitis and an increased risk of poor glycemic control.[16,29,32]

Several mechanisms have been proposed to explain the increased susceptibility of persons with diabetes to periodontal diseases including alterations in host response, subgingival microflora, collagen metabolism, vascularity, gingival crevicular fluid, and heredity patterns.[32] Multiple pathophysiologic mechanisms (e.g., compromised neutrophil function; decreased phagocytosis and leukotaxis) have also been implicated in the increased alveolar bone loss found in persons with diabetes,[29,30] increased tendency for more active carious lesions and missing teeth,[33] and increased susceptibility to oral infections and mucosal lesions.[34] Autoimmune phenomena have been suggested as the cause of the increased prevalence of oral lichen planus in persons with diabetes.[35]

Diabetes predisposes an individual to sensory and peripheral neuropathies, which inhibit pain perception and may produce chemosensory deficits such as impaired taste function and decreased smell sensitivity.[30] This sensory dysfunction can inhibit the ability to maintain a proper diet, which leads to poor glycemic regulation. Persons with diabetes also have reported increased complaints of glossodynia and stomatopyrosis (burning mouth syndrome), as well as increased complaints of dry mouth (xerostomia). There is no consensus demonstrating a relationship between glycemic control and salivary gland dysfunction. However, the xerostomic complaints may be due to a variety of reasons including salivary gland basement membrane changes and diabetes-associated thirst.

Adrenal Diseases

Oral manifestations of Addison's disease, caused by primary adrenal insufficiency or hypoadrenalism, include diffuse, cutaneous pigmentation of the skin and mucous membranes. However, this presentation is not found in persons with secondary adrenal insufficiency, the result of chronic corticosteroid administration.

Persons diagnosed with hyperadrenalism or Cushing's disease (caused by an adrenal disorder or long-term, high-dose administration of corticosteroids) often present with characteristic moon-shaped faces. Oral symptoms include an increased susceptibility to oral infections (such as candidiasis) and muscle weakness manifested as difficulty with speaking, eating, and swallowing.

Pituitary Diseases

The chronic hypersecretion of growth hormone in acromegaly results in significant orofacial changes from the bony and soft tissue overgrowth. Tooth separation and malocclusion can be a consequence of alveolar enlargement of the maxilla and mandible. Extraoral facial features include frontal bossing, nasal bone hypertrophy, mandibular prognathism, and enlargement of the paranasal sinuses. Soft tissue overgrowth can present in the oral mucosal and salivary gland tissues, tongue, and lips. As a result of these structural changes, speech abnormalities and myofascial pain have been reported.

Thyroid Diseases

Macroglossia is the primary oral manifestation of hypothyroidism, which is often caused by chronic autoimmune thyroiditis (Hashimoto's thyroiditis) or is secondarily acquired (e.g., induced by surgery, radiation, or medication). Infants with undiagnosed congenital hypothyroidism may develop macroglossia, pronounced lips, and delayed tooth eruption with subsequent malocclusion.

Hyperthyroidism, or thyrotoxicosis, is commonly caused by an autoimmune disorder termed Graves' disease. Facial and skin manifestations include upper eyelid retraction with exophthalmos and hyperpigmentation and erythema of the skin. Young children can present with early loss of primary teeth with subsequent rapid eruption of permanent teeth. The hyperplasia of lymph tissue commonly found in Graves' disease can manifest in the tonsillar and oral pharynx region.

Parathyroid Diseases

Bone demineralization with subsequent fibrous-tissue replacement can produce well-defined cystic radiographic radiolucencies characteristic of hyperparathyroidism. Tooth mobility, loss of lamina dura, and a radiographic osteoporotic appearance may also be found.

Idiopathic hypoparathyroidism is an acquired autoimmune disease associated with polyendocrine glandular deficiency and with mucocutaneous candidiasis and pernicious anemia. Pseudohypoparathyroidism is an inherited disorder characterized by end-organ unresponsiveness to parathyroid hormone effects, a moon face, and brachymetacarpalism. These signs may appear together with trophic changes of the skin and nails, dryness of the mucous membranes, angular cheilitis, and enamel hypoplasia caused by chronic hypocalcemia.

Collagen-Vascular and Granulomatous Disorders

Sjögren's Syndrome

Sjögren's syndrome (SS), a systemic autoimmune disorder associated with inflammation of epithelial tissues, is the most common medical disorder associated with xerostomia and salivary dysfunction. SS was reclassified in 2002[36] and occurs in primary and secondary forms. Primary SS involves salivary and lacrimal gland disorders with associated decreased production of saliva and tears. In secondary SS, the disorder occurs with other autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus (SLE), scleroderma, polymyositis, and polyarteritis nodosa.[37]

Focal, periductal, mononuclear cell infiltrates in exocrine tissues and autoantibodies (particularly anti-Ro/SSA, anti-La/SSB, and rheumatoid factor) are the hallmarks of SS. The salivary and lacrimal infiltrates consist predominantly of T cells ($CD4^+$ T helper cells), with fewer B cells, macrophages, and mast cells.[38] Clinical manifestations of the ensuing salivary hypofunction include cracked and ulcerated lips, desiccated oral mucosal tissues, fungal infections, new and recurrent dental caries, gingivitis, dysphagia, impaired use of removable prostheses (dentures), and difficulty speaking without the use of fluids. There is a reported 44-fold increase in the frequency of B-cell lymphomas among patients with SS[39]; accordingly, oral, head, and neck examinations must be performed on these patients on a regular basis.

Treatment for SS must address all organ systems affected by the disease.[27] Dry mouth and its associated oral sequelae require constant dental evaluations to reduce the risk of developing dental caries, oral microbial infections, dysphagia, dysgeusia, impaired eating, and wearing removable dentures.

Systemic Lupus Erythematosus

Approximately one quarter of SLE patients have oral lesions, which are usually superficial ulcers with surrounding erythema.[28] These lesions can occur on the lips and all oral mucosal surfaces and can be indistin-

guishable from those of lichen planus or leukoplakia, therefore requiring histopathologic diagnosis. Direct and indirect immunofluorescence of these lesions shows staining of the basement membrane of the dermal-epidermal junction with immunoglobulins and complement, similar to what is seen in the skin lesions. Other manifestations of SLE include periodontal diseases,[33] xerostomia, and hyposalivation that can occur independent of SS or can be associated with secondary SS. Patients with SLE (particularly those with long-standing disease) should undergo cardiac evaluation to determine whether they are candidates for antibiotic prophylaxis for dental treatment likely to result in bacteremia and bleeding.[24]

Scleroderma

The oral manifestations of this disease result from deposits of collagen in the tissues or as a result of collagen deposition around nerves and vessels. Difficulty opening the mouth occurs due to fibrosis of masticatory muscles, and immobility of the tongue and disorders in deglutition are also possible. The oral manifestations most commonly recognized are wide periodontal ligament spaces and occasional gingivitis.[40] Scleroderma can also be associated with SS and CREST (*c*alcinosis cutis, *R*aynaud's phenomena, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia) syndrome,[40] and these patients can complain of accompanying xerostomia.

Dermatomyositis-Polymyositis

Dermatomyositis-polymyositis is an immunologic disease of muscle that can also involve the tongue and the upper portion of the esophagus. Patients can have difficulty with phonation, chewing, and deglutition, and they can also develop stomatitis.[41] Due to problems with swallowing, aspiration pneumonia is also a possible sequela. As part of secondary SS, patients can exhibit xerostomia and salivary hypofunction.

Sarcoidosis

Sarcoidosis, a systemic granulomatous disease, can appear with masses on the tongue, lips, mandible, and maxilla.[41] Biopsy results demonstrate characteristic noncaseating granulomas consistent with extraoral manifestations. The differential diagnosis includes other granulomatous diseases (e.g., infectious granuloma, Wegener's granulomatosis, lethal midline granuloma), infectious granulomatous diseases (e.g., histoplasmosis, blastomycosis), or even lymphoma.

Wegener's Granulomatosis

Wegener's granulomatosis is a rare disorder that is histologically characterized by granulomatous inflammation and vasculitis. The destructive granulomatous inflammation also occurs in the oral cavity as red to purple hyperplastic gingival lesions with petechiae.[31] In addition, patients can have tooth mobility leading to removal of teeth and failure of oral wounds to heal. The disease may remain localized and restricted to the oral cavity for a long period before multiorgan involvement occurs. Oral biopsy is critically important to establish an early diagnosis and to prevent destruction caused by this progressive disease.

Infectious Diseases

Viral Diseases

Herpes simplex virus (HSV-1) and varicella-zoster virus (VZV) are the most common viral infections in the oral-facial region. They can present as herpes labialis or primary herpetic gingivostomatitis (HSV-1) or acute, painful, oral-facial lesions (VZV).[42] Initial infection usually occurs in childhood. However, the dormant virus located in the sensory ganglia can be reactivated secondary to immunosuppression, trauma, stress, sunlight, gastrointestinal disturbances, and concurrent infection. After a prodrome, the HSV-1 fluid-filled vesicles will rupture, crust, and resolve in 1 to 2 weeks. Reactivation of childhood VZV infection appears as vesicles on skin and mucous membranes usually following a unilateral distribution of the ophthalmic, maxillary, or mandibular divisions of the trigeminal sensory nerves. Blindness, facial paralysis, auditory deficits, and vertigo are also potential sequelae of postherpetic neuralgia.[43]

Immediate treatment is required for HSV-1 lesions, ideally as soon as prodromal symptoms develop. Antiviral drugs, either topical and/or systemic, are required depending on the patient's immunologic status. Treatment of VZV infection in the oral-facial region may require several concomitant drugs: antivirals to suppress viral replication, analgesics and anxiolytics for pain relief, and immunosuppressive drugs to control virally caused inflammation.

Oral complications and manifestations of HIV disease and AIDS are numerous due to the immunocompromised state experienced by these patients.[44] Some of the most commonly presenting oral conditions in persons with AIDS (e.g., candidiasis, Kaposi's sarcoma, hairy leukoplakia) can be indicative of the level of immune suppression. Other common lesions affecting persons with HIV disease and AIDS include aphthous stomatitis, HIV periodontal disease (linear gingival erythema and necrotizing ulcerative periodontitis), salivary gland disease, non-Hodgkin's lymphoma, and lymphadenopathy.[45] Coinfection with cytomegalovirus, occurring in 90% of persons with HIV, can cause oral ulcerations, esophagitis, and retinitis. Hairy leukoplakia, a corrugated white lesion occurring on the lateral or ventral surfaces of the tongue, is caused by reactivation of Epstein-Barr virus in HIV-infected persons.

Hepatitis has oral-facial manifestations, especially during the icteric phase of the disease. Clinical findings include a yellow-brown hue to the oral mucosa, eyes, and skin.[46] Persons with chronic hepatitis C infection can develop lichen planus and lymphocytic sialadenitis caused by autoantibody production.[37]

Fungal Diseases

The most frequent oral fungal infection is caused by *C. albicans.* The overgrowth of *C. albicans* in the oral-pharyngeal region has many etiologies: endocrine disorders (e.g., diabetes), immunosuppression, nutritional deficiencies, medications (particularly antibiotics and long-term immunosuppressants), salivary gland hypofunction, removable dental prostheses, and poor oral and denture hygiene. Many varieties of oral manifestations of candidiasis exist including pseudomembranous (white, easily removable patches), acute erythemic or atrophic (erythemic or erosive lesions), chronic hyperplastic/denture stomatitis (hyperplastic lesions usually found underneath dentures), and angular cheilitis (erythematous, cracked, or fissured lesions located at commissures of lips).[47] Angular cheilitis is often caused by a loss of vertical dimension secondary to edentulism and drooling resulting from a stroke or other neuromuscular disorder.[35]

Bacterial Diseases

The oral cavity is host to numerous species of bacteria responsible for causing oral and pharyngeal infections. *Porphyromonas gingivalis* and *Treponema denticola* are often implicated in the development of periodontal disease, whereas *Staphylococcus aureus* and *Streptococcus viridans* are known to cause salivary gland infections. *Streptococcus mutans* and *Lactobacillus* sp are the common causes of new and recurrent dental caries. Dental infection that spreads through the teeth into underlying bone can result in a dentoalveolar abscess. The oral and facial swelling and asymmetry that develop as the infection progresses through the alveolar bone can become life threatening (e.g., Ludwig's angina). *M. tuberculosis* infections are uncommon in healthy persons and are primarily seen in immunocompromised patients (see "Pulmonary Diseases" earlier).

Sexually transmitted diseases caused by *Neisseria gonorrhoeae* and *Treponema pallidum* can also cause oral disorders.[41] *N. gonorrhoeae* infections are associated with submandibular lymphadenopathy, gonococcal stomatitis (ulcerations and erythema of mucosal tissues), and pharyngeal gonococcal infection (mild sore throat). In syphilis, the stage of the disease determines the oral manifestations. Primary syphilis causes a lip chancre, whereas secondary syphilis is associated with papular lesions, erythematous or grayish-white erosions, pharyngitis, lymphadenopathy, and parotid enlargement. Mucosal and skin lesions during this phase are highly infectious. Congenital syphilis causes dental abnormalities such as Hutchinson's incisors and mulberry molars.

Arthritides and Bone Disorders

Rheumatoid Arthritis

Rheumatoid arthritis (RA) causes progressive destruction of articular and periarticular structures including the temporomandibular joint (TMJ).[48] Multiple signs and symptoms of TMJ pathology occur in these patients including clicking, locking, crepitus, tenderness to palpation in the preauricular area, pain during mandibular movement, swelling (infrequent), and shifts in the relationship between the maxilla and mandible caused by erosion of the condylar heads. In addition, these progressive problems can cause considerable pain during mastication that could affect nutrition. RA is also frequently associated with other autoimmune connective tissue diseases such as Sjögren's syndrome.

The pharmacologic management of RA and other arthritic conditions can have serious adverse sequelae affecting oral health and the delivery of dental treatment.[49] Gold compounds, penicillamine, methotrexate, and other high-dose/chronic immunosuppressive drugs have been associated with acute stomatitis and recurrent microbial infections (e.g., oral candidiasis, recurrent HSV infections).[1,44] Newer anti-inflammatory biologic agents will also increase the tendency for patients to develop oral microbial infections. Surgical replacement of hips, knees, and other degenerated joints with prostheses requires antibiotic prophylaxis before dental procedures for 2 years after joint replacement and for a lifetime in patients at potential increased risk for hematogenous total joint infection (Table 92-5).[50] The antimicrobial guidelines are provided in Table 92-6 for dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa.

Other drugs used for RA such as high doses of nonsteroidal anti-inflammatory drugs (NSAIDs), salicylates, and immunosuppressive medications can increase the risk of excessive bleeding during or after dental-alveolar surgery.[24,49] The use of long-term immunosuppressive therapy causes adrenal insufficiency, and glucocorticoid supplementation is necessary before extensive dental procedures.[21]

Management of the arthritic-associated TMJ symptoms is frequently palliative (e.g., soft diets, pain/anti-inflammatory medications) but can also involve construction of hard acrylic intraoral orthotic devices, physical therapy, and TMJ surgery.[51] Arthritic deformities will ultimately impede mobility and dexterity that are required for daily oral hygiene and regular visits to the dental office. Daily assistance with oral hygiene may be necessary to maintain oral health.[52]

Osteoarthritis

Most forms of osteoarthritis (OA) have fewer serious systemic complications than RA, yet many of the concerns discussed for the RA patient are relevant for this population as well.[48] Patients may have greater problems performing oral hygiene, difficulty tolerating long dental treatments or placement in the supine position, and signs and symptoms of TMJ and related disorders. Adults with OA may have prosthetic joints and consequently require antibiotic prophylaxis before dental treatment.[50] Medical management with drugs (see "Rheumatoid Arthritis" earlier) may necessitate appropriate precautions before dental treatment or stomatologic follow-up for adverse effects.

Reiter's Syndrome

Reiter's syndrome is a recurrent arthritic condition characterized by conjunctivitis, asymmetric lower extremity arthritis, nongonococcal urethritis, circinate balanitis, and keratoderma blennorrhagia. Oral lesions appear as papules and ulcerations on the buccal mucosa, gingiva, and lips. Lesions on the tongue resemble geographic tongue.

Paget's Disease

Paget's disease is an acquired disorder of excessive bone resorption with variable attempts at repair. The skull and maxilla are frequently involved. Extensive enlargement and deformation of the maxilla occurs, with spacing and mobility of the teeth. These clinical findings are confirmed radiographically, with the presence of multiple radiolucent-radiopaque lesions of the affected bones.

Ewing's Sarcoma

Ewing's sarcoma is a rare tumor of bone, occasionally involving the mandible. Clinical presentation may include chin and lip paresthesias, which must be diagnosed after radiographic and nuclear images and biopsy specimens are obtained. Differential diagnosis includes granulomatous diseases, Paget's disease, Langerhans cell histiocytosis, and hyperparathyroidism.

Dermatologic Conditions

Lichen Planus

Lichen planus is a chronic, mucocutaneous, autoimmune disorder that can be precipitated by a number of conditions such as genetic predisposition, emotional stress, or drug, food, or dental material hypersensitivity.[53] It has a variety of clinical appearances: plaquelike, bullous, atrophic, reticular (lacy white lines known as Wickham's striae), and erosive (ulcerative lesions accompanied by peripheral striae). The lesions most often occur on buccal mucosa, gingiva, and tongue but

Table 92-5

Patients at Potential Increased Risk of Hematogenous Total Joint Infection

Immunocompromised/Immunosuppressed Patients
Inflammatory arthropathies: rheumatoid arthritis, systemic lupus erythematosus
Disease, drug, or radiation-induced immunosuppression
Other Patients
Insulin-dependent (type 1) diabetes
First 2 years following joint placement
Previous prosthetic joint infections
Malnourishment
Hemophilia

Table 92-6

Suggested Antibiotic Prophylaxis Regimens for Orthopedic Joint Patients

Patients not allergic to penicillin	Cephalexin, cephradine, or amoxicillin, 2 g orally 1 hour before dental procedure
Patients not allergic to penicillin and unable to take oral medications	Cefazolin 1 g or ampicillin 2 g IM or IV 1 hour before the procedure
Patients allergic to penicillin	Clindamycin 600 mg orally 1 hour before the dental procedure
Patients allergic to penicillin and unable to take oral medications	Clindamycin 600 mg IV 1 hour before the procedure

From American Dental Association. Advisory statement. Antibiotic prophylaxis for dental patients with total joint replacements. American Dental Association; American Academy of Orthopaedic Surgeons. *J Am Dent Assoc.* 1997;128(7):1004-1008.

can also be found on the lips and palate.[53] Histopathologic samples are required for diagnosis to differentiate lichen planus from other common mucocutaneous oral lesions (e.g., aphthous stomatitis, pemphigus, pemphigoid, lupus). The goal in the treatment of many of these autoimmune mucocutaneous oral mucosal conditions is to reduce oral discomfort and inflammation. Depending on the extent of oral lesions, topical immunosuppressants (most commonly, glucocorticosteroids in the forms of ointments and gels) may be sufficient for patient comfort and prevention of exacerbation of lesions. If topical therapy is insufficient in controlling lesions, then systemic immunosuppressant therapy should be considered. Some evidence suggests that lichen planus lesions are predisposed to malignant transformation[53]; therefore lesions, particularly those with ulcerations, must be re-evaluated on a regular basis.

Pemphigus Vulgaris

Pemphigus vulgaris is an autoimmune disease caused by antibodies created against desmoglein 3, causing a disassociation of the epithelium at the suprabasal layer with acantholysis. Clinical presentation includes bullous lesions developing into vesicles that rupture, resulting in painful, bleeding ulcerations. The lesions can occur on oral and ocular mucosa and skin and resolve after 2 weeks with treatment. The oral mucosa of the palate, gingiva buccal mucosa, and tongue are the most common locations.[54] The diagnosis can be made with the production of a positive Nikolsky's sign, whereby a new lesion develops after slight pressure is applied to the asymptomatic oral mucosa. Histopathology and direct immunofluorescence tests are required as well.[55] Treatment strategies for pemphigus vulgaris are similar to those employed for lichen planus. However, due to the possible widespread extent of lesions, systemic steroids and immunosuppressants may be more likely to be used to prevent secondary complications such as recurrent infections, electrolyte imbalance, and dysphagia caused by lesion spread into the pharynx, larynx, and esophagus. A variant of pemphigus vulgaris, paraneoplastic pemphigus, is an autoimmune blistering disease that occurs in association with underlying neoplasms and requires carefully monitored multidisciplinary care.[38,56]

Mucous Membrane Pemphigoid

Antigens located at the base of the epithelium cause subepidermal detachment and subepithelial bullae formation in the mucous membrane pemphigoid.[55,57] Similar to pemphigus, the initially presenting erythemic and vesicular oral lesions rupture, resulting in pseudomembranous ulcerations. Intraorally, these lesions often occur on the gingival tissue, causing desquamative gingivitis and subsequent scarring.[58] Blindness is a complication of ocular lesions causing corneal damage and conjunctival mucosal scarring. Therefore definitive diagnosis is critically important, with subsequent management involving a multidisciplinary health care team.

Erythema Multiforme

Erythema multiforme is an acute, recurrent, self-limiting autoimmune disease commonly causing blistering oral and skin lesions.[59] It is believed to be precipitated by a type III hypersensitivity reaction, drug allergy, or herpetic infection. Presentation includes acute development of vesicles with subsequent rupture causing painful ulcers of the buccal mucosa, lips, palate, and tongue. Cutaneous lesions often present as a characteristic target or bull's-eye, and lips can become swollen, bleeding, and crusted. With corticosteroid and antiviral therapy or drug withdrawal, complete resolution occurs after 14 days. A more severe form of the disease, known as *Stevens-Johnson syndrome,* is usually triggered by a drug rather than an infection and involves oral and other cutaneous and mucosal surfaces.[11]

Gastrointestinal Disorders

Crohn's Disease and Ulcerative Colitis

Patients with inflammatory bowel disease, Crohn's disease, and ulcerative colitis can develop oral recurrent aphthous ulcers.[60] With ulcerative colitis, the aphthous ulcers are frequently associated with other mucous membrane involvement, iritis, arthritis, and erythema nodosum. Ulcerative colitis may also manifest with pyostomatitis, a progressive necrotic and inflammatory involvement of all oral mucosal tissues. In addition to oral aphthous ulcers, Crohn's disease is associated with nodular swellings, a cobblestone appearance of the mucosa, and deep granulomatous-appearing ulcers.

Behçet's Syndrome

Behçet's syndrome is an idiopathic condition that consists of recurrent oral and genital ulcers, arthritis, and inflammatory disease of the eyes and gastrointestinal tract. Oral ulcers appear as recurrent aphthous ulcers, which occur in the vast majority of patients and typically precede other sites of involvement.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease manifests in the oral cavity as mucosal and gingival erosions and inflammation thought to be caused by acid. When reflux continues for a long time, erosion of tooth enamel can occur.

Malabsorption Diseases

A plethora of gastrointestinal conditions lead to malabsorption of vitamins and nutrients, causing oral pathologies to occur. Gluten-sensitive enteropathy or celiac disease can manifest with recurrent aphthous ulcers. Vitamin A deficiency produces dyskeratotic changes of the skin and mucous membranes, angular cheilitis (fungal infection of the labial commisures), and defects in the dentin and enamel of developing teeth. Vitamin B_2 (or riboflavin) deficiency is associated with angular cheilitis and burning pain in the lips, mouth, and tongue. Deficiencies in vitamin B_{12}, as well as folate, can also produce recurrent aphthous ulcers. Niacin deficiency (pellagra) can involve the tongue and other oral mucosal tissues by causing the tongue to become swollen and press against the dentition.

Scurvy, or vitamin C deficiency, is associated with perifollicular hemorrhages and petechiae in the mouth caused by vascular integrity compromise, gingival hyperplasia, and stomatitis. The teeth may become loose, and involved gingival tissues can be the source of halitosis. Vitamin D deficiency will complicate calcium metabolism because vitamin D is required for calcium absorption. Calcium deficiency can contribute to mandibular osteopenia or osteoporosis (particularly in edentulous mandibles), as well as enamel hypoplasia caused by chronic hypocalcemia. Vitamin K deficiency leads to a hemorrhagic diathesis that often presents with oral hemorrhagic bullae. Folate and iron deficiencies produce atrophic glossitis caused by the atrophy of the filiform papillae, angular cheilitis, and occasionally hyperkeratotic lesions in the oral mucosa. Zinc deficiency has been associated with taste changes, which could result in a significant change in dietary intake of fluids and beverages.

Neurologic Diseases

Dementias Including Alzheimer's Disease

The progression of dementia is accompanied by a gradual inability to perform self-care including adequate oral hygiene because of self-neglect and a loss of cognitive and motor skills,[61] and these problems have been found to increase with the severity of dementia.[62] Persons with Alzheimer's disease, the most common form of dementia, have impaired oral health as a result of poor oral hygiene.[35] They have a greater prevalence of dental plaque, gingival bleeding, and calculus compared with age- and sex-matched adults,[44] and evidence of salivary gland hypofunction, even when not taking medications.[63]

Older adults with cognitive impairment have significantly older dentures and dentures that are less clean compared with individuals without dementia.[64] Another sequelae of poor oral hygiene is a trend toward increased coronal and root caries, which is observed with increasing dementia severity.[35] Many of these oral disorders are the result of the pharmaceutical treatment of dementing illnesses. Medications with anticholinergic side effects, such as antidepressants, are frequently used for dementia and are the cause of salivary dysfunction, which is ultimately the source of multiple oral and pharyngeal disorders.[65] Many of these patients do not have intact oral sensory or cogni-

tive function, and are unable to report symptoms of oral pain, infection, or pathology. Therefore, it is imperative that they undergo more frequent oral health exams as the disease progresses. Furthermore, as the level of dementia worsens, caregivers become critically important in providing daily oral hygiene, identifying stomatologic diseases, and facilitating dental treatments.[66]

Parkinson's Disease

Increased amounts of acetylcholine present in the brain in persons with Parkinson's disease can produce esophageal dysmotility and dysphagia. The ability to form a lip seal is impaired, resulting in drooling, and ultimately leading to a fungal infection of the lip commissures (referred to as angular cheilitis). Anticholinergic medications commonly used to help parkinsonian symptoms (e.g., levodopa, selegiline) cause salivary hypofunction and xerostomia. An adverse effect of long-term levodopa therapy is tardive dyskinesia, which is characterized by involuntary orofacial movements including lip smacking, grimacing, and tongue flittering.[67] Loss of facial expression, difficulty with mastication, slow speech, and tremors of the head, lips, and tongue are commonly found symptoms that increase with the severity of the disease.[68]

Myasthenia Gravis

Myasthenia gravis, an autoimmune disorder caused by loss or dysfunction of acetylcholine receptors, results in episodic muscle weakness. Orofacial symptoms include dysphagia with subsequent choking, nasal regurgitation, and alteration in voice.

Bell's Palsy

Unilateral facial paralysis, known as Bell's palsy, occurs due to a defect of cranial nerve VII. Facial appearance is distorted due to the lack of control of the muscles of facial expression. Functional ability of the lips and cheek is lost on the affected side; this can produce decreased natural cleansing and unilateral dental decay if appropriate oral hygiene is not maintained.

Multiple Sclerosis

The loss of muscle coordination resulting from the demyelination of long nerves in multiple sclerosis can severely impair oral care. Weakness of the tongue and loss of upper extremity use impairs dental and denture hygiene, as does wearing dental prostheses. Trigeminal neuralgia is common in these patients; it is characterized by excruciating unilateral pain of the lips, gingiva, or chin that can be triggered by contact with certain areas of the face, lips, or tongue.

Myotonic Muscular Dystrophy

The muscular weakness and subsequent wasting of myotonic muscular dystrophy severely compromise oral function and health. The inability to relax muscles after contraction results in difficulty chewing, pursing the lips, and turning the head. Facial muscle involvement inhibits the ability to wear dentures. Medications used to treat myotonic muscular dystrophy (quinine) are known to cause xerostomia and oral mucosal edema. Flared anterior teeth and mouth breathing are commonly seen due to weakness of the facial muscles and the enlargement of the tongue caused by fatty deposits.

Renal Diseases

Renal insufficiency or renal failure ultimately require peritoneal or hemodialysis. These patients are susceptible to numerous oral diseases, including salivary hypofunction, impaired wound healing, recurrent oral mucosal infections, dental caries, gingivitis, and periodontitis.[69,70] These problems, particularly those associated with microbial infections, are enhanced in patients taking long-term corticosteroids and other immunosuppressants. Uremic stomatitis is a condition unique to patients receiving dialysis that typically presents as an erythemic thickening of the buccal mucosa with a pseudomembranous covering, ulcerative lesions, gingival and mucosal hemorrhage, and ecchymoses.[71] Appearance of these lesions often corresponds to an acute increase in blood urea nitrogen levels, and they heal spontaneously after resolution of the uremic state.[71]

Bleeding from oral mucosal surfaces is also due to altered platelet aggregation and decreased platelet factor III, and hemodialysis patients experience increased bleeding due to platelet destruction. The oral manifestations of bleeding problems are petechiae and ecchymoses.

Bony changes commonly observed in renal failure include loss of lamina dura, demineralized bone, localized radiolucent jaw lesions (central giant cell granulomas with subsequent tooth displacement), and widened trabeculations.[71] These lytic bone lesions are the result of hyperparathyroidism. Smell and taste changes have been observed in patients with renal failure, and there is some evidence that chemosensory function improves after dialysis and renal transplantation.[72] Since heparin is administered during dialysis to prevent blood coagulation, dental procedures should be performed on alternate days of dialysis, and precautions should be taken to avoid excessive hemorrhage. Evaluation and management of potential anemic or hypertensive conditions are required when dental treatment is provided.

Renal transplantation is a treatment option for patients with severe renal failure. After transplantation, patients are administered long-term immunosuppressants that have multiple oral sequelae (e.g., cyclosporine-induced gingival hyperplasia, steroid-induced oral fungal infections). Renal transplant recipients have been reported to have a greater prevalence of oral lesions such as candidiasis, leukoplakia, dysplasia, and cancer of the lip.[73,74] These patients require pretransplantation oral evaluations and treatment, and close follow-up after transplantation to help maintain oral health and function and to diminish the likelihood of developing oral infections that may disseminate to the systemic circulation in an immunosuppressed person.

Peritoneal dialysis presents no additional problems in dental management, yet patients receiving hemodialysis are potentially at risk for developing infective endocarditis.[24] Approximately 10% to 17% of infective endocarditis cases in patients receiving hemodialysis are caused by organisms that can arise from the oral cavity (e.g., *S. viridans, Lactobacillus* sp).[75] Therefore it has been suggested that prophylactic antibiotics are prudent for hemodialysis patients with arteriovenous shunts/grafts when invasive dental procedures are performed.[24]

Chronic Liver Diseases and Cirrhosis

Poor oral hygiene and neglect resulting in dental caries, and periodontal diseases are frequent oral disorders in patients with chronic alcoholism.[24] However, even moderate consumption of alcohol has been reported to increase the risk of developing periodontal disease, perhaps due to alcohol's deleterious effect on neutrophil, macrophage, and T-cell function.[76] Nutritional disorders due to alcoholism and oral diseases can produce glossitis and loss of tongue papillae, as well as recurrent oral fungal infections of the oral mucosal surfaces and the labial commissures (angular cheilitis). Excessive alcohol intake and tobacco use are major risk factors for oral cancer (see "Malignant Neoplasms" earlier). Accordingly, oral examinations in these alcoholic patients must include scrutiny of high-risk sites such as the anterior floor of the mouth, the lateral border of the tongue, and the posterior oral-pharynx.[77]

Oral microbial infections and impaired wound healing are the most common oral complications of patients with cirrhosis, resulting from alcohol-induced immunosuppression.[41] Susceptibility to oral infections increases when patients require liver transplants and the requisite postoperative immunosuppressive regimens. These patients must receive close monitoring from their dentists to reduce their risk of developing stomatologic diseases. Diminished smell and taste function that can inhibit nutritional intake and parotid gland hypertrophy leading to reversible salivary gland dysfunction have been reported in patients with liver cirrhosis.

Coagulation disorders are a concern for patients with liver dysfunction, and accordingly persons are at risk for developing hemorrhage after undergoing oral surgical procedures. Mucosal petechiae and ecchymoses and spontaneous gingival bleeding can also result from coagulation abnormalities.[17] Presurgical coagulation tests are required before gingival, periodontal, and alveolar bone surgery, and special steps may be required to ensure adequate thrombus formation.[17]

Hematologic Disorders

Bleeding Disorders

Anticoagulation therapy for stroke and atrial thrombosis prevention predisposes patients to bleeding disorders. Anticoagulants (e.g., heparin, warfarin, vitamin K antagonists, direct thrombin inhibitors), antiplatelets (aspirin, adenosine diphosphate, or adenosine diphosphate receptor blockers), and thrombolytic or fibrinolytic drugs (e.g., first generation—streptokinase, second generation—alteplase; third generation—reteplase) can cause hemorrhagic oral mucosal lesions such as petechiae, ecchymoses, and purpura.[17]

Bleeding problems can also result from congenital platelet disorders and coagulopathies. Von Willebrand's disease, the most common hereditary bleeding disorder, is caused by the deficiency of secondary factor VIII (vWF), resulting in poor platelet adhesion. In mild cases, normal bleeding occurs after surgery or trauma; however, in more severe disease, spontaneous oral mucosal bleeding can occur, resembling hemophilia A disorder. Hemophilia A, a congenital coagulation disease, is caused by a deficiency or defect in factor VIII. The frequency and severity of bleeding problems in hemophilia A is directly associated with the blood levels of factor VIII. In severe cases, spontaneous and excessive bleeding in the oral cavity, lips, and joints can be initiated readily. The immunodeficiency produced in the X-linked recessive inherited disease, Wiskott-Aldrich syndrome, can result in recurrent infections, eczema, and chronic thrombocytopenia (with manifestations of hemorrhage and purpura of the skin and oral mucosa).

A decreased number of platelets due to deficiency, destruction, or consumption results in thrombocytopenic purpura. Primary idiopathic thrombocytopenia is thought to be an autoimmune process, whereas secondary thrombocytopenia can be caused by medications or systemic diseases such as leukemia. Oral manifestations include petechiae and hemorrhagic bullae of the oral mucosa.

White Blood Cell Disorders

Leukemias and their treatments have a profound effect on the oral cavity. Oral mucosal changes such as bleeding and ulceration, petechiae, and gingival hyperplasia may be the initial sign of leukemia.[78] Due to their immunocompromised state, patients are at risk for development of bacterial, fungal, and viral infections. Chemotherapy can cause mucositis and mucosal ulcerations.[79] Poor oral hygiene results in gingival inflammation and bleeding, mucosal ulcerations, and periodontal disease; however, these oral sequelae can be reduced by adequate oral hygiene, frequent dental visits for cleanings, and antimicrobial therapy. Graft-versus-host disease, the reaction of host antigen against donor cells, is a common occurrence after bone marrow transplant. Oral sequelae include mucosal ulcerations, mucositis, xerostomia, and dysphagia.[80]

The acute reduction in leukocytes produced in agranulocytosis can be precipitated by chemotherapeutic agents or immunologic diseases. Oral manifestations include necrotic and ulcerative lesions of the mucosa, pharynx, and skin. Recurrent bacterial infections, oral ulcerations, and periodontal disease are common oral manifestations of Chédiak-Higashi syndrome. Persons with this hereditary disease of the lysosomal membrane of granulocytes also often develop non-Hodgkin's lymphoma.

Oral manifestations of persons with anemia are associated with the cause of the reduction in the oxygen-carrying capacity of the blood. Pale oral mucosa, loss of tongue papillae (with associated soreness), and angular cheilitis are characteristic of vitamin B_{12}- and iron-deficiency anemia.[24] Severe iron-deficiency anemia can progress to Plummer-Vinson syndrome, resulting in oral soreness, dysphagia, and an increased risk for oral and pharyngeal carcinoma. The tissues of persons with sickle cell anemia may appear jaundiced, whereas radiographic bone findings include osteoporosis and trabecular changes. Delayed eruption and dental hypoplasia can also be found.

Hemoglobin Problems

Thalassemia is an inherited disorder of hemoglobin production causing chronic anemia and bone marrow overexpansion. Oral manifestations of this bony overgrowth can include a prominent maxilla with associated malocclusion, rarefaction of the alveolar bone, cranial nerve palsies, and tooth discoloration due to high iron deposition.[41] Porphyrias are disorders caused by defective metabolic assembly of the heme portion of the hemoglobin molecule. Reddish discoloration of the teeth (erythrodontia) can be found in congenital porphyria due to the deposition of porphyrin in the dentition.

Women's Oral Health and Disease

Many of the oral manifestations that are unique or typically found in women are thought to be precipitated or exacerbated by hormonal changes. These hormonal modulations throughout a woman's life span result in varying oral lesions that are often particular to a specific life stage (e.g., puberty, menses, pregnancy, menopause).

Puberty

Intraoral microfloral changes and increased inflammatory and hyperplastic gingival reactions to food debris and plaque have been reported to develop during puberty.[81] Eating disorders may initially be identified during this developmental stage from oral findings. Self-induced vomiting and chronic regurgitation of gastric contents observed in bulimia nervosa and anorexia nervosa can cause erosion of the lingual enamel of the teeth, most commonly in the maxillary anterior region. Other oral manifestations of these disorders include traumatized oral and pharyngeal mucosal tissue, angular cheilitis, dehydration, and parotid gland enlargement.[81]

Menses

Some oral changes are only associated with particular times within the menstrual cycle. These symptoms include swollen and erythematous gingival tissues, development of aphthous ulcers, activation of herpes labialis, prolonged hemorrhage following oral surgery, and swollen salivary glands.[81] Intake of oral contraceptives can cause oral changes such as gingival inflammation, intraoral microbial alterations, and increased risk for osteitis after third molar extraction.

Pregnancy

Pregnancy gingivitis, which is characterized by erythematous gingival and interproximal tissues, is the most common periodontal condition developing in approximately two thirds of all pregnancies. These symptoms usually appear during the first trimester and continue throughout the pregnancy. Inflammatory gingival hyperplasia, which is initiated by an increased reaction to local irritants, can develop into a mucosal condition known as a *pyogenic granuloma* (also called *pregnancy tumor, epulis gravidarum,* or *pregnancy granuloma*). It occurs in less than 10% of pregnancies, but can be found as a single tumor-like growth on interproximal tissues in the maxillary anterior region. Surgical excision is usually required for complete resolution.

Maternal periodontal disease has been identified as a possible risk factor for preeclampsia, preterm birth, and growth restriction.[82,83] A recent study demonstrated that treatment of periodontitis in pregnant women improves periodontal disease and is safe but does not significantly alter rates of preterm birth, low birth weight, or fetal growth restriction.[84] Therefore there are few contraindications for pregnant women to undergo active treatment for periodontal diseases.

Menopause and Postmenopause

Menopause has been associated with oral complaints (e.g., stomatodynia, stomatopyrosis or burning mouth syndrome, xerostomia), but the etiopathogenesis has not been clearly elucidated.[81] Burning mouth syndrome requires an extensive evaluation to rule out oral microbial, salivary, dental-alveolar diseases, nutritional deficiencies, and metabolic disorders before treatment with low-dose antidepressants is recommended.[45,85] Perimenopausal and postmenopausal oral mucosal changes include menopausal gingivostomatitis, which is characterized as pale, dry, shiny, and easily bleeding gingival tissues. Some studies have demonstrated a relationship between residual ridge resorption and osteoporosis. However, it is unknown whether systemic bone loss affects the severity of periodontal disease or contributes to alveolar bone

resorption and subsequent tooth loss. Some evidence indicates that hormone replacement and bisphosphonate therapy can contribute to decreased alveolar bone and tooth loss, but further clinical trials are required.[34] Oral bisphosphonates rarely contribute to unusual alveolar problem, termed *bisphonate-induced osteon ecrosis of the jaws* (BIONS), although IV bisphosphonates for oncologic purposes are most commonly the cause of this disorder of osteoclasts in the mandible and maxilla.[15]

Inherited and Congenital Disorders

Numerous congenital malformations have head, neck, and oral manifestations. Only the most common are discussed in this review; the reader is referred to specialized textbooks for details on all disorders.[11,41,86,87]

Several disorders affect the dentition,[88] one of the most common being stained or mottled teeth caused by ingestion of tetracycline or excessive fluoride during permanent tooth development. Congenital syphilis is associated with abnormalities on the incisors (notched edges; Hutchinson's teeth) and molars (dome-shaped or mulberry molars). In osteogenesis imperfecta (brittle bone disease), alveolar bone and dentin are affected. Teeth are opalescent and mobile, and pathologic bony fractures can occur in the facial bones as well. Dentinogenesis imperfecta manifests itself in a defective junction between enamel and dentin, resulting in teeth highly susceptible to fracture and dental caries. Malformed and supernumerary teeth are found in other skeletal system diseases such as cleidocranial dysostosis.

Abnormalities in the palate are evident in Turner's syndrome (a high palatal vault), Marfan's syndrome (high-arched soft palate as well as dental crowding), and the relatively more common cleft lip and palate disorders (see Chapter 186, Cleft Lip and Palate). Oral-facial-digital syndrome, or orodigitofacial dysostosis, is characterized by a short upper lip, hypertrophy of the frenula of the lips and tongue, and clefts of the hard and soft palates. Macroglossia and a cleft or high-arched palate may be observed in Down syndrome (trisomy 21) with a hypoplastic maxilla, as well as hypodontia or anodontia. These patients are more susceptible to early necrotizing gingivostomatitis and periodontitis.

Unusual oral mucosal pigmentations are the result of many disorders. Mucous membranes may show multiple angiomas and port-wine staining of the facial skin and oral mucosa in a unilateral trigeminal distribution in Sturge-Weber syndrome (encephalofacial angiomatosis). Telangiectasias of lip and oral mucosa surfaces appear during childhood and increase with age in several diseases: Rendu-Osler-Weber syndrome, hereditary hemorrhagic telangiectasia, and Fabry's disease (angiokeratoma corporis diffusum universale) have telangiectasias of the tongue, oral cavity, and nasal mucosa, which become apparent at puberty and increase as the patient ages. Melanosis of the gingiva can occur as a normal variant in the black population but also occurs in hemochromatosis, an autosomal dominant disorder of increased iron absorption from the gastrointestinal tract. Albright's disease (polyostotic fibrous dysplasia) demonstrates melanosis of the gingival tissues, café-au-lait spots on facial skin ("coast of Maine spots"), and migration and mobility of teeth caused by jaw involvement with the fibrous dysplasia. Melanosis of the perioral skin and gingival tissues is also present in Peutz-Jeghers syndrome. Tangier's disease, a disorder of lipoprotein metabolism, is associated with pathognomonic xanthomas that appear as yellow tonsils or yellowish-white to gray spots in the soft palate.

Fibromas of the maxilla, mandible, or tongue have been connected with at least five systemic syndromes[9]: Congenital von Recklinghausen's disease is an autosomal dominant disease with multiple neurofibromas of the skin and bone, café-au-lait spots on the skin, and oral melanosis.[53] Multiple endocrine adenomatosis type 3 is associated with neurofibromas of the tongue and lips.[38] Cowden's disease is dominantly inherited and is characterized by warty papules on the face, arms, and mucous membrane of the mouth.[56] Tuberous sclerosis, a neurocutaneous syndrome, also has café-au-lait spots and intraoral fibromas.[69] Melkersson-Rosenthal syndrome is a developmental abnormality with unilateral facial paralysis, edema of the periorbital skin, and a fissured tongue with papillary projections that reveal fibromas at biopsy.

Several congenital disorders develop bony lesions of the maxilla and mandible. Langerhans cell histiocytosis, Letterer-Siwe disease, Langerhans' cell eosinophilic granuloma, and Hand-Schüller-Christian disease all are associated with infiltrative-destructive lesions of the bone caused by overgrowth with histiocytes and may appear as a gingival epulis, loose teeth, or mucosal erosions. Gaucher's disease is characterized by a reduction in normal cerebroside breakdown with resultant accumulation of lipid-laden histiocytes; this results in radiolucent lesions in the jaw. Osteopetrosis has mandibular and maxillary hyperostosis, similar to that seen in Paget's disease, fibrous dysplasia, histiocytosis X, and acromegaly.

CHAPTER NINETY-THREE

Odontogenesis, Odontogenic Cysts, and Odontogenic Tumors

John W. Hellstein

Key Points

- Odontogenesis is a complicated intermingling of processes with many levels of induction. There are many interactions between mesenchymal and epithelial tissues. Of particular interest is the embryology of Rathke's pouch as well as the normal distribution of dental laminae in the alveolar arches. In addition, portions of the enamel organ are the origin of most of the commonly known odontogenic cysts and tumors.
- The nomenclature of odontogenic and nonodontogenic cysts of the oral region is varied. Though many of these cysts are not directly covered in the Key Points, it may be beneficial for the reader to review Box 93-1 as an aid in formulating differential diagnosis lists.
- The keratinizing odontogenic cyst is specifically separated from the odontogenic keratocyst due to its much more innocuous presentation. The odontogenic keratocyst has also recently been renamed as keratocystic odontogenic tumor.
- The term primordial cyst continues to be used by some authors. However, its use often differs depending on the background of the author. Of most concern is that the term primordial cyst in many European publications is used synonymously with what it now termed the keratocystic odontogenic tumor (odontogenic keratocyst). In this chapter we will use the term *odontogenic cyst of undetermined origin* to describe those lesions that appear histologically identical to a dentigerous cyst or radicular cyst but are not anatomically related to any particular tooth.
- The odontogenic keratocyst has also been known as the parakeratinizing odontogenic keratocyst, and the WHO has recently renamed it the keratocystic odontogenic tumor. In addition, this cystic neoplasm is associated with basal cell nevus syndrome.
- The botryoid odontogenic cyst radiographically presents as a multilocular lesion and may recur. Histologically the lining is identical to the lateral periodontal cyst.
- The problem with the glandular odontogenic cyst diagnosis is that it is becoming overused due to lack of calibration and variability in its histologic definiton.
- For odontogenic tumors, in general readers are encouraged to always look over the general treatment considerations for each patient's situation. Specifically there is some concern about the evidence-based nature of treatment recommendations related to many of the odontogenic tumors. In the case of the calcifying epithelial odontogenic tumor, older texts and even modern texts often recommend rather aggressive therapy, although there is little evidence-based literature to support initial aggressive therapy in some tumors. With the exception of the ameloblastoma, there are only sparse reports of any of the benign odontogenic tumors "getting away" from the surgeon even if a recurrence does happen.

Odontogenic tumors are often intricate admixes of neoplastic and non-neoplastic lesions. Even the "simple" odontogenic lesions have their origin traced back to odontogenesis. But odontogenesis is far from simple. By understanding odontogenesis, the reader's appreciation for these lesions should be enhanced. In fact, it is the unique interaction of ectomesenchymal tissues with epithelial tissues during odontogenesis that make these cysts and tumors unique. These interactions of the mesenchyme and epithelium occur across short distances and within the confined volume of the jaws. Complications in histologic interpretation include artifacts caused by demineralization, sampling errors, separation of hard and soft tissues at the grossing bench, and general difficulties in sectioning disparate tissue types. Separation of disparate tissue at the grossing bench can make it impossible to analyze the relationship of tissues later under the microscope. Even when these background problems are not encountered, the result is often still a histopathologic hodgepodge. In the end, odontogenic lesions that contain both epithelial and mesenchymal components are often difficult to assess histologically.

A basic understanding of odontogenesis by the surgeon/clinician may help to predict behavior, enlighten the clinician on what information to give the pathologist, and guide proper treatment. Thus odontogenesis and the jaws' unique status within the body create a wide set of possibilities for clinical, radiographic, and histopathologic differential diagnosis lists. It is the goal of this chapter to review odontogenesis, as well as odontogenic cysts and tumors. It is hoped by the end of this chapter that a better understanding of odontogenic cysts and tumors will lead to a more thorough appreciation of this intricate and complicated set of diseases.

Background

Odontogenesis begins within generally well-defined areas of the stomodeum, then by maturational extension the oral cavity and alveolar

processes of the jaws. Unfortunately, simply knowing the location does not necessarily allow the clinician to always positively ascertain a lesion as being odontogenic in origin. Confounding elements include the embryologic nature of Rathke's pouch, extension of large odontogenic lesions outside the confines of the alveolar processes, and the propensity of products of odontogenesis to "wander." Thus reports of sinonasal ameloblastomas and craniopharyngiomas of the sella should not be surprising and still be considered odontogenic in origin. Simply put, the only prerequisite is that all odontogenic cysts and tumors must be derived from elements of stomodeal origin.

Histologically the rather unique epithelial portions of odontogenesis often remain distinct enough in cysts and tumors to allow for proper determination of origin. Unfortunately, the mesenchymal components of the dental papilla (as seen in myxomas) and cemental components (as seen in odontogenic fibromas) are impossible to definitively identify histologically as being of odontogenic origin. The only hope in identifying these as odontogenic is if they occur in association with other odontogenic epithelial elements. But generally, these mesenchymal lesions are identified as odontogenic on the basis of their location in the jaws.

Though this section focuses only on odontogenesis, remember that the oral and maxillofacial region is also associated with developmental remnants of salivary glands, seromucous glands, sinonasal epithelium, nasopalatine duct epithelium, and dermal epithelia. Due to these nearby, possibly confounding embryologic tissues, the true origin of any given lesion may be cloudy at best. However, by knowing the specific location, history, and histopathologic features and being additionally armed with knowledge of odontogenesis, the proper designation for any given lesion can almost always be filtered to arrive at a relatively short differential diagnosis list.

The enamel organ is generally divided into the bud stage, cap stage, and bell stage. The bud stage begins as a proliferation of the basilar cells of the stomodeum. This proliferation occurs along the area of the future alveolar mucosa apical to and separated from the vestibular mucosa. In this early stage the ectoderm of the stomodeum is lined by two to three cells. It is during the sixth week that the ectoderm in the region of the future alveolar processes begins to proliferate and form two somewhat horseshoe-shaped epithelial bands. Before being differentiated into the epithelial surfaces of the alveolar processes, each band is called a *dental lamina.* These dental laminae will eventually form the 20 separate proliferations necessary for the deciduous teeth. These 20 areas of proliferation are each called *tooth buds.* Each tooth bud then proliferates apically into the underlying ectomesenchymal tissue. Eventually at the bell stage the connection between the overlying stomodeum and the enamel organ will become separated. But the actual process of bud proliferation varies by arch, as well as by tooth type (i.e., deciduous central incisor, deciduous lateral incisor, deciduous canine, deciduous first molar and deciduous second molar). By the end of the eighth week all 20 buds have been produced.

During all phases of morphodifferentiation, histodifferentiation, and apposition the features of the enamel organ and the physiologic support of the enamel organ are changing. But with apposition of the dentin and vascularization near the outer enamel epithelium the enamel organ is further defined with a fourth cell layer termed the *stratum intermedium.* The cells of the stratum intermedium occupy an ill-defined area of flattened cells between the inner enamel epithelium and the stellate reticulum. Though the area of phenotypic change that defines the stratum intermedium must be present before enamel can be laid down, actually identifying these cells individually is extremely subjective.

Root Development

In the tooth root, the dentin forms the huge majority of the root volume, which is then sheathed in a layer of cementum instead of enamel. But the odontoblasts still cannot lay down dentin without induction by epithelium derived from the enamel organ. To accomplish this feat as the reduced enamel epithelium reaches the cemento-enamel junction, it becomes reduced to back-to-back inner and outer epithelial cells. This produces a collar of cells that separate from the reduced enamel epithelium. This separated collar is known as *Hertwig's epithelial root sheath.* Hertwig's root sheath as it moves apically to guide root formation will "leave behind" epithelial rests known as *rests of Malassez.* These rests will reside in the region of the periodontal ligament and provide a basis for several potential odontogenic cysts and tumors.

The periodontal ligament is actually a joint known as a *gomphosis joint.* Though the cementum cannot be distinguished except by location, the body, for instance, during orthodontic movement will resorb the bone on the lamina dura side of the periodontal ligament and not the cementum on the tooth side of the ligament. The tooth with the periodontal ligament will retain a certain amount of mobility within the joint. The reader is again referred to various texts for a more in-depth coverage of odontogenesis.[1-5,5a]

Summary

There are a number of odontogenic epithelial stages and each may provide a basis for odontogenic cysts or tumors. The four main stages considered are (1) dental lamina, (2) enamel organ, (3) reduced enamel epithelium, and (4) Hertwig's epithelial root sheath. The rests of Serres and Malassez are considered along with their respective progenitors of the dental lamina and Hertwig's root sheath. In addition, the stomodeal epithelium gives rise to Rathke's pouch, which retains odontogenic potential. Shafer and colleagues[6] suggest the original basal epithelium of the stomodeum also retains potential. In the adult this basal epithelium is represented by the gingival and alveolar mucosal surfaces.[6] This concept seems to be supported when peripheral ameloblastomas appear to develop directly from overlying gingival epithelium. With that said, most clinicians would consider the adult basal epithelium to be a rare source of odontogenic neoplasia. The rests of Malassez are common sources of inflammatory odontogenic cysts but retain little neoplastic potential. The rests of Serres, the enamel organ, and reduced enamel epithelium are generally considered the stages most likely to become neoplastic. All stages have the potential to form cysts but to variable degrees. Dentigerous cysts with their origin from the reduced enamel epithelium and radicular cysts from rests of Malassez make up the overwhelming majority of odontogenic cysts.

Odontogenic Cysts

Classification

When reading various sources it becomes quickly clear that what a cyst "is" varies by author and that the classification schemata are in disarray as well. The modified classification scheme seen in Box 93-1 is my attempt at organization. The odontogenic cyst of undetermined origin is a new, admittedly descriptive "diagnosis" used by some oral pathologists. Unfortunately the descriptive nature of that term will not be available to look up in other texts or journals. However, it replaces the diagnosis of primordial cyst. The need to use a descriptive term instead of primordial cyst is due to the ambiguous use of primordial cyst both as an odontogenic keratocyst (OKC) and a simple nonkeratinizing cyst that cannot be classified in relation to the tooth. The descriptive role is to provide a pigeonhole in which to place lesions that are histologically ambiguous, not directly associated with a tooth but located in the alveolus and thus presumably odontogenic in origin.

Several classification schemata for odontogenic cysts and oral and maxillofacial cysts exist.[7-9] The classification scheme seen here is modified from that of the World Health Organization (WHO). In 1992 WHO published the second edition of *Histological Typing of Odontogenic Tumors.*[10] Unfortunately the most recent WHO treatise on odontogenic tumors is contained within the *Pathology and Genetics of Head and Neck Tumors.*[11] In this change odontogenic cysts are no longer covered within the text. Box 93-1 also contains selected non-odontogenic cysts for completeness and comparison.

By definition a cyst is considered a "pathologic cavity at least partially lined by epithelium." To be an odontogenic cyst the epithelial lining must be derived from odontogenic epithelium. The best advice to the reader is that all classification schemata are artificial to some extent. The key is to organize them the way that is most useful to you. This modification in Box 93-1 is an attempt at self-

Box 93-1

Classification of Odontogenic with Other Selected Maxillofacial Cysts

Odontogenic cysts
- Developmental cysts
  - Dental lamina cyst (gingival cyst of newborn)
  - Odontogenic keratocyst (called keratocystic odontogenic tumor by WHO)*
  - Dentigerous cyst (follicular cyst)
  - Eruption cyst
  - Lateral periodontal cyst
    - Botryoid odontogenic cyst
  - Gingival cyst of adults
  - Keratinizing odontogenic cyst
  - Glandular odontogenic cyst
- Calcifying odontogenic cyst (Gorlin cyst)
- Odontogenic cyst of undetermined origin (replaces the term *primordial cyst*, which has been irretrievably confused in the literature. This new descriptor also serves as a useful designation for some lesions that do not classify well.)
- Inflammatory cysts
  - Periradicular cysts
    - Periapical cyst (apical periodontal cyst)
    - Lateralized periradicular cyst
  - Residual cyst
    - Dentigerous origin
    - Periapical origin
  - Paradental cyst
    - Mandibular infected buccal bifurcation cyst
  - Inflammatory collateral cyst

Nonodontogenic cysts
- Nasopalatine duct cyst (incisive canal cyst)
- Cyst of the incisive papilla
- Nasolabial cyst (nasoalveolar cyst)
- Palatal cysts of infants
  - Epstein's pearls (midline of hard palate)
  - Bohn's nodules (scattered on palates especially at junction of hard and soft)
- Lymphoepithelial cysts
- Oral lymphoepithelial cyst
- Cervical lymphoepithelial cyst (branchial cleft cyst)
- Gastric heterotopic cyst
- Thyroglossal duct cyst
- Salivary duct cyst
- Maxillary antrum associated
  - Surgical ciliated cyst
- Soft tissue cysts
  - Epidermoid cyst
  - Thymic cyst
  - Bronchogenic cyst
  - Trichilemmal cyst (pilar cyst)
- Pseudocysts
  - Idiopathic bone cavity (e.g., traumatic bone cavity, traumatic bone cyst, simple bone cyst, hemorrhagic bone cyst)
  - Aneurysmal bone cyst
  - Mucus-retention phenomenon (mucous-retention cyst)
  - Mucocele of the sinus
  - Cystic hygroma
- Miscellaneous
  - Dermoid cyst
  - Polycystic disease of the parotid
  - HIV-associated lymphoepithelial lesion

Nonexistent/spurious cysts

The following cysts are generally considered embryologically impossible or have been reclassified in previous descriptions of cysts.
- Globulomaxillary cyst (dismissed on the basis of embryology)
- Median mandibular cyst (dismissed on the basis of embryology)
- Median maxillary alveolar cyst (subcategory of nasopalatine duct cyst)

*Primordial cyst specifically *not* used synonymously.
HIV, human immunodeficiency virus; WHO, World Health Organization.

clarification and will hopefully be useful for others in either its pure or modified form.

Pathogenesis

Many odontogenic cysts are surfaced by nonkeratinized epithelium. Histologically the following nonkeratinizing cysts can look identical and cannot be separated except by clinical, historical, and/or radiographic means. These include dentigerous cyst (follicular cyst), eruption cyst, odontogenic cyst of undetermined origin, periapical cyst (apical periodontal cyst), lateralized periradicular cyst, residual cyst, and paradental cyst.

These cysts make up the majority of odontogenic cysts. As a group they are known as the *common odontogenic cysts.* For proper diagnosis of these common odontogenic cysts the clinician must provide sufficient information for the diagnosis to be made. The reader is urged to closely note the necessary or significant features when each of these cysts is specifically discussed later in this section.

The other odontogenic cysts will display histologic features to allow for the proper diagnosis, though history and communication are of course always appropriate and often essential. It is important to note that the presence of a specific type of keratin is not pathognomonic for an OKC and may be seen with other odontogenic cysts.

Cyst expansion occurs because of numerous factors including accumulation of inflammatory cells, fibrin, serum, and desquamated epithelial cells. As these products enter the cystic cavity, it is the accumulation of the intraluminal products that spurs the cystic expansion of the wall.[12-14] Alternatively, cyst expansion may be spurred on by the inherent mitotic activity of the cyst wall itself. If this mitotic activity is the major component of the cyst expansion, it may be better to consider the lesion a cystic neoplasm rather than a simple cyst.[14-20] This debate lies at the center of how to classify the OKC, as well as the calcifying odontogenic cyst.[21] In the case of the OKC, WHO has renamed it the *keratocystic odontogenic tumor.* Discussion of this entity is in the odontogenic cyst section. In the case of the calcifying odontogenic cyst (the tumor version), the reader is referred to more detailed articles on the epithelial odontogenic ghost cell tumor.

Multilocularity may in itself be a signal that the lesional growth is mitotically or multifocally driven rather than hydraulically driven.[22-25] For this reason the potentially multilocular odontogenic cysts, such as the botryoid odontogenic and glandular odontogenic cyst, may arguably have a neoplastic potential as well.[22,26-30] However, in the case of the botryoid cyst the possibility of multifocality cannot be ignored. Cell regulation protein studies to determine cell inhibition and division activities may be helpful in future classifications.[31,32] In addition, the ability of epithelia to break down elements of the connective tissue wall could be important.[33-37]

However, even simple cysts like the periradicular cyst derived from rests of Malassez must possess some mitotic activation, or growth would be impossible. Activation is thought to occur as a result of inflammatory production within the periodontal membrane.[13,38] In the skin and gingiva it has been shown that inflammation leads to release of inhibitors, which then allow the renewal of mitotic activity.[15] Once a solid epithelial sphere has been formed, it is thought that it eventually outgrows its vascular nourishment and the central area degenerates to form a lumen.[15,16] Following the formation of the central lumen, transepithelial flow of fluid is sustained by osmotic forces. Thus hydrostatic pressure plays a role in the development of the classic unilocular appearance of most cysts. How the pressure results to produce osteoclastic resorption is less clear.[17,39-41]

Cysts that are derived from the more neoplastic dental lamina, or are in themselves "cystic neoplasms," probably occur as a result of self-sustained or unregulated mitotic activity.[42] Even in neoplastic cysts, luminal expansion may occur through degenerative effects, debris accumulation, and hydraulic and mitotic activity.[43-45]

Periapical Cyst (Radicular Cyst, Periradicular Cyst)

The periapical cyst must be associated with a nonvital tooth. The tooth may be rendered nonvital by trauma, caries, or periodontal space extension. As such, these cysts may be seen at any age, although permanent teeth are more likely to be involved than deciduous teeth.[46] They are thought to be derived from rests of Malassez.

Figure 93-1. Occlusal radiograph of large periapical cyst associated with two endodontically treated maxillary incisors.

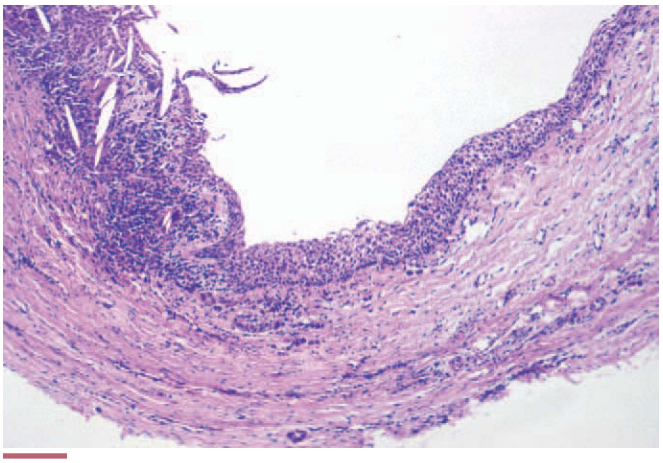

Figure 93-2. Photomicrograph of periapical cyst showing nonkeratinizing stratified squamous epithelium with inflammation. Cholesterol slits are seen toward the left side of the luminal surface and appear as empty white clefts.

Radiographic Features

Periapical cysts present as a unilocular radiolucency at the apical portion of the tooth. Though well defined, the border varies from corticated to sclerotic to merely well defined. Variations depend on the amount of inflammation present. Long-standing, neglected lesions can get quite large, though most are less than 1 cm in diameter (Fig. 93-1).

Microscopic Features

This is the classic inflamed "common odontogenic cyst" and as such the luminal lining will consist of nonkeratinized stratified squamous epithelium. This is an inflammatory cyst and inflammation is invariably present if sufficient sampling is performed (Fig. 93-2). Rests of Malassez are possible in the connective tissue. However, odontogenic rests are rarely seen in the cyst wall even though these rests are thought to be the source of the epithelial proliferation. Cholesterol slits, foreign body giant cells, and hemosiderin deposits are common findings. As in all "common odontogenic cysts," squamous odontogenic tumor-like" proliferations may be seen in long-standing lesions. These epithelial islands will be cytopathologically benign without evidence of dysplasia. If squamous odontogenic cystlike proliferations are noted, they should essentially be ignored and are of no prognostic significance. In endodontically treated teeth, foreign bodies secondary to endodontic therapy are common.[47] Bacterial colonies may also be seen in these cysts. Though actinomycetes colonies may portend a tendency for being slow

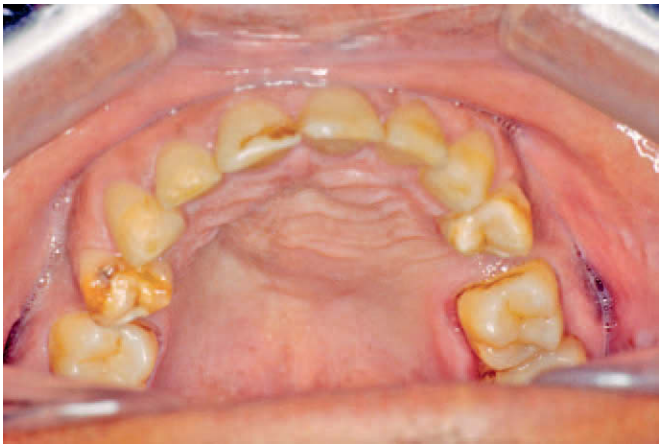

Figure 93-3. Clinical photograph of cyst seen in Figure 93-1 before enucleation.

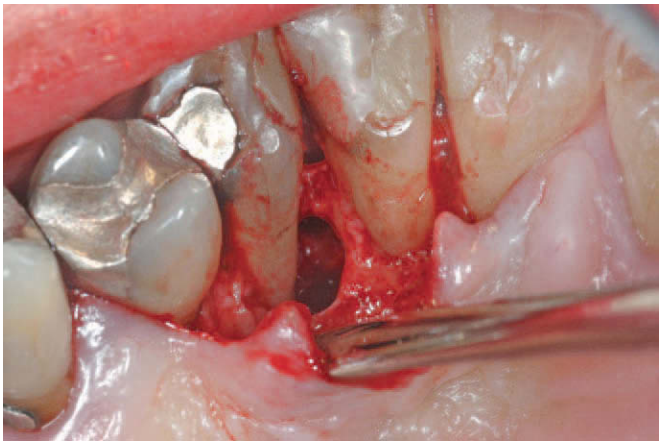

Figure 93-4. Intraoperative photograph of an inflammatory collateral cyst. Tooth is vital with periodontal pocket leading to intrabony cystic area.

to resolve, their presence should not result in a diagnosis of osteomyelitis. Such colonies are more commonly an incidental rather than a significant finding. Thus, for multiple reasons, the proper diagnosis of periapical cyst requires radiographic or clinical corroboration.

Treatment

This cyst is treated with simple enucleation (Fig. 93-3). Enucleation is often accomplished at the time of tooth extraction. Uncounted numbers of these cysts are probably adequately resolved with endodontic therapy. If a radiolucency persists longer than 6 months following endodontic therapy, enucleation and histopathologic review are necessary.[48-50]

Lateralized Radicular Cyst (Lateral Radicular Cyst, Lateral Periapical Cyst)

This cyst is simply a variant of the periapical cyst. It is associated with a nonvital tooth, but instead of being at the apex of the tooth the cyst is located lateral to the tooth root(s). This happens because the root canal system of teeth sometimes has exits on the lateral aspect of the root, not just at the apex. Therefore if the path of least resistance is out one of these lateral canals the lesion will be present laterally. Otherwise, the clinical, microscopic, radiographic, and histologic features are identical to the periapical cyst.

Residual Cyst

The majority of these cysts will be the result of leaving a periapical cyst "behind" following tooth extraction. All of these cysts are inflammatory cysts. Occasionally an inflamed dentigerous cyst is incompletely removed and could also be the source of a residual cyst. The clinical, microscopic, radiographic, and histologic features are identical to the periapical cyst.[48,49,51,52]

Inflammatory Collateral Cyst

This may or may not be considered by some to be a true cyst. However, because it is an occasionally used diagnosis, a quick summary is included here. This lesion is associated with periodontal disease of a vital tooth. Uncommonly, a deep intrabony periodontal pocket may be sufficiently isolated to allow for hydraulic expansion of the bone (Fig. 93-4). As such, radiographically there will be a radiolucent periradicular lesion (Fig. 93-5). There will also be a periodontal pocket associated with that radiolucency. This diagnosis should be limited to those cases where the clinician indicates the diagnosis as the most likely choice. Otherwise, the clinical, microscopic, radiographic, and histologic features are identical to the periapical cyst.[53]

Dentigerous Cyst (Follicular Cyst)

The dentigerous cyst by definition must be associated with the crown of an unerupted tooth, developing tooth, or odontoma. The eruption

Figure 93-5. Radiograph of inflammatory collateral cyst.

cyst is essentially a subtype of dentigerous cyst that is confined just by the overlying alveolar mucosa. Dentigerous cysts form when fluid accumulates between reduced enamel epithelium and tooth crown.[14] As alluded to earlier, the accumulation of fluid may be partially or largely surrounded by connective tissue and epithelium.[54,55] Because the third molars and maxillary canines are the teeth most frequently impacted, they are also the most likely to be associated with dentigerous cysts. However, any impacted tooth has an increased risk. There also may be inherent differences in impacted tooth development and how the reduced enamel epithelium is transformed/resorbed.[56] They are generally found in the teenage years and early adulthood.[57] However, the longer a tooth is impacted, the greater the chance a dentigerous cyst will develop.[58]

Figure 93-6. Radiograph of large dentigerous cyst associated with molar crown.

Figure 93-7. Clinical photograph of device used for cyst decompression. Note two holes to allow for proper irrigation (*arrows*). The device is constructed from acrylic resin with a central "waist" and blunderbuss ends. To keep it in place, nonresorbable sutures may be necessary for 2 to 3 weeks.

Radiographic Features

A dentigerous cyst presents as a unilocular radiolucency, which is associated with an unerupted tooth (Fig. 93-6). Dentigerous cysts may also involve odontomas that, by nature, also have "tooth crowns." The radiolucency is generally well demarcated and well corticated. The border may become sclerotic or display rarifying osteitis if secondary infection is present. Even large cysts that have pushed the associated tooth considerable distances will display evidence of origin from the cementoenamel junction if the film angle is adequate. In large lesions the origin from the cementoenamel junction is best visualized as an area of cortication at the cementoenamel junction. There is considerable overlap between the appearance of small dentigerous cysts and hyperplastic follicles.[56]

Microscopic Features

The specimen will present primarily as variably dense fibrocollagenous connective tissue with some areas being loose and myxomatous. Odontogenic epithelial rests are usually scattered within the connective tissue and are most common near the epithelial lining. The luminal lining consists of nonkeratinized stratified squamous epithelium. The presence of mucous prosoplasia within the lumen is not uncommon. Care should be taken to not overinterpret the mucus prosoplasia. Cholesterol slits and their associated multinucleated giant cells may be present in inflamed cysts and are generally associated with the connective tissue wall.[47] As mentioned earlier, the lumen may be partially or mostly lined by connective tissue.[14] If present in the specimen, crevicular epithelium may make microscopic separation of an inflamed dentigerous cyst from pericoronitis impossible. Thus proper diagnosis requires radiographic or clinical corroboration.

Neoplastic Potential

Dentigerous cysts appear to retain the ability to transform into true neoplasms. One study reported that 17% of ameloblastomas were associated with an existing dentigerous cyst.[59] This figure varies by study, however.[60-62] Both squamous cell carcinomas and mucoepidermoid carcinomas have been reported.[63-67]

Treatment

Dentigerous cysts are usually easily enucleated at the time of tooth extraction. In large lesions decompression with subsequent enucleation may be appropriate (Fig. 93-7).

Eruption Cyst

The eruption cyst is a form of dentigerous cyst that is found in the soft tissue overlying an erupting tooth. Because by definition it must be associated with an erupting tooth, eruption cysts occur only during the ages of tooth development.[7] They may be seen with erupting deciduous or permanent teeth, but the majority of lesions are seen in the first decade.[68] The lesion will present as a soft tissue swelling of the alveolar ridge overlying an area of age-appropriate tooth development. Some eruption cysts will have a slightly blue hue color, though the normal coral pink color of the surrounding mucosa is common (Fig. 93-8). Unlike dentigerous cysts, it is not uncommon for an eruption cyst to be associated with deciduous teeth. Eruption cysts may be seen in newborns with an incidence of 2 per 1000 births reported.[69] Clinical follow-up may also serve to confirm the diagnosis because the tooth will erupt within several weeks to months through the cystic expansion.[70-74]

Figure 93-8. Clinical photograph of maxillary eruption cyst found incidentally in an infant.

Treatment

The eruption cyst almost always resolves without intervention. In uncommon cases eruption of the underlying tooth may be impeded or delayed. In such cases a "deroofing" will allow eruption.

Paradental Cyst

The paradental cyst is considered by some to be a variant of the dentigerous cyst. This is because the various forms of paradental cyst all originate from the cementoenamel junction just like the dentigerous cyst. However, the paradental cysts are almost uniformly inflamed, so they are generally classified as inflammatory cysts rather than as developmental cysts. Paradental cysts occur on the buccal or distal aspect of

an erupted mandibular molar. Though the mesial aspect of a mandibular tooth may rarely be involved, there have been no reported occurrences to the lingual. Craig[75] reported the occasional presence of developmental enamel projections near the furcation of some teeth. This is particularly true of the subcomponent of paradental cysts known as *infected buccal bifurcation cysts.* How big a role these projections play in pathogenesis remains debatable.[76-81] In one series the paradental cyst accounted for 3% of all odontogenic cysts.[82]

Radiographic Features

The lesion will present as a well-defined radiolucency associated with but not surrounding the coronal area of a partially erupted tooth.[81]

Odontogenic Cyst of Undetermined Origin

It is with great regret that another diagnosis is added to the list of odontogenic cysts, but there appears to be no good alternative. On occasion the clinician and pathologist may come upon a lesion that is not classifiable by histologic, radiographic, or clinical features. As mentioned earlier, several odontogenic cysts have identical microscopic features. Odontogenic cysts with identical or potentially identical histologic features are referred to as the *common odontogenic cysts.* These "common" cysts are separated on the basis of clinical features alone.

The problem in diagnosis comes when a cyst is not associated with the crown of a tooth, residually or with the root of a nonvital tooth. Additionally, the cyst is not consistent with a fissural cyst but is at least partially located in the alveolar process. Historically, any cyst that occurred in an area where a tooth should have developed, or where supernumerary teeth could occur, were originally called primordial cysts.[83] This term was used to allude to development from the tooth primordium. Unfortunately, this was proposed in 1945 before delineation of the features defining the OKC and a large percentage of these "primordial" cysts had features of what would now be diagnosed as an OKC. When the OKC was defined in the 1950s, some pathologists had already recognized those histologic features in what they termed primordial cysts and thus they began to use the term interchangeably with OKCs. International journals, especially, came to use the term *primordial cyst* as a synonym of the OKC.[45,84] Americans often avoided the term *primordial* or left the moniker of primordial cyst for those lesions without features of a keratocyst.

The term primordial cyst is avoided to eliminate any confusion between the histopathologist and the clinician. This is intended to ensure that aggressive treatment of an OKC is *not* performed for this innocuous lesion.

Definition of the Odontogenic Cyst of Undetermined Origin

An odontogenic cyst of undetermined origin is a unilocular radiolucent cyst of the jaws with histologic features of common odontogenic cysts but lacking the clinical, histologic, and radiographic features of any defined common odontogenic cyst (Fig. 93-9).

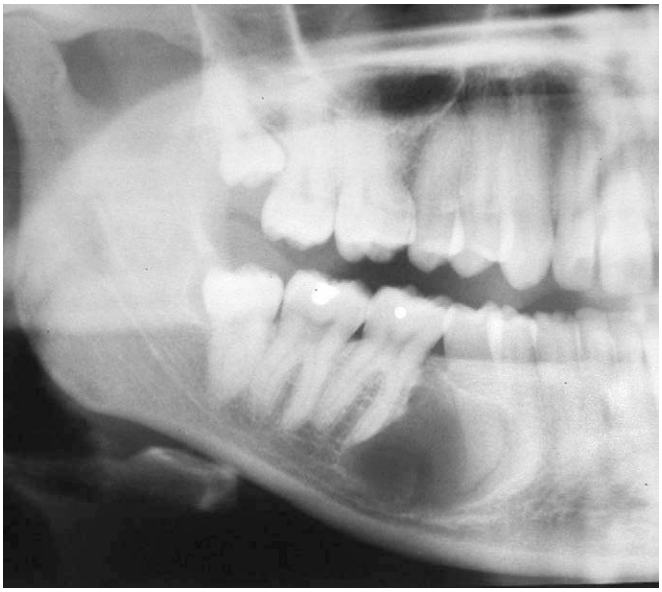

Figure 93-9. Radiograph of an odontogenic cyst of undetermined origin.

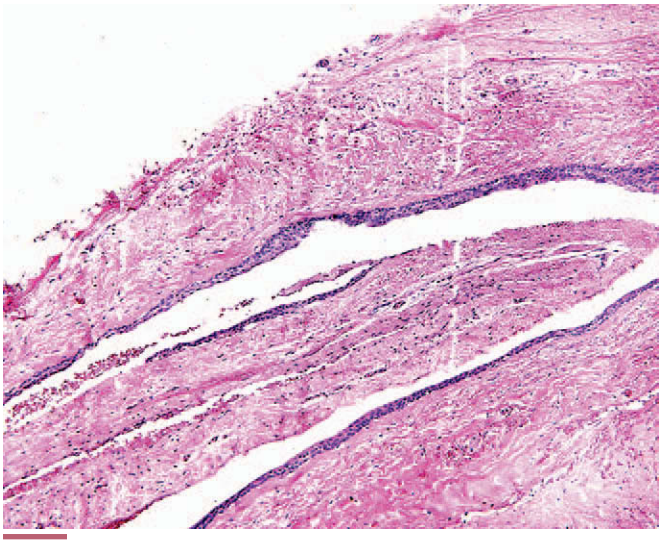

Figure 93-10. Photomicrograph of generally thin cyst lining typical of the lateral periodontal cyst.

Lateral Periodontal Cyst

These cysts are thought to be derived from the dental lamina and are thus thought to retain some limited neoplastic growth potential. This limited neoplastic potential is best displayed by the associated lesion known as a *botryoid odontogenic cyst.* Lateral periodontal cysts are located on the lateral surface of a vital tooth.[85,86] This assumes that the tooth has not been rendered nonvital by dental caries or trauma unrelated to cyst formation. The most common location is the mandibular premolar/canine area. If present in the maxilla, the lateral incisor area is the most common location. However, the lateral periodontal cyst may be seen in any area of the alveolar processes. This cyst is seen in the interproximal area between tooth roots and is usually an incidental radiographic finding.[87,88] Demographically the cyst is most common in males by a 2:1 ratio with a peak incidence in the fifth and sixth decades.[89] The gingival cyst of the adult and the botryoid odontogenic cysts are essentially subtypes of lateral periodontal cysts. Other cysts, especially the OKC, odontogenic cyst of undetermined origin, and the lateralized periapical cyst, also present interproximally. Histopathologic features and tooth vitality are important diagnostic considerations to separate these lesions. All of these lesions can be separated histologically and the lateralized periradicular cyst will be associated with a nonvital tooth.

Radiographic Features

The lesion presents as a unilocular radiolucency of the alveolus that is usually well corticated. Larger lesions may result in diverged roots.[90] Multilocular lesions are a special subset and are classified as botryoid odontogenic cysts (see "Botryoid Odontogenic Cyst" later).[27]

Microscopic Features

The cyst lining is composed of nonkeratinized simple to stratified squamous epithelium. The lining is most notable for being only a few cells in thickness (Fig. 93-10). Intermixed within this otherwise thin epithelial lining are nodular epithelial thickenings or plaques. The plaques may display somewhat whorled epithelial cell aggregates. The central cells in the aggregate may display cytoplasmic clearing. The clear

cells contain glycogen, which can be digested with diastase. Scattered mucous cells may be seen in some lesions but should not be a dominant feature.[90,91] The diagnosis of lateral periodontal cyst must be reserved for lesions displaying the thin epithelium described earlier. The plaque-like thickenings are helpful microscopic features but are not always found. The connective tissue wall may contain dental lamina rests, but they are not required for diagnosis.

Treatment

These cysts are treated with simple enucleation, though the surgeon is reminded to look for intraoperative multilocularity, which may not have been evident radiographically. If multilocularity is present, the lesion is probably a botryoid odontogenic cyst. In such cases light curettage of the surrounding bone wall is advised. Recurrence of the simple lateral periodontal cyst is not a problem and even the recurrences of botryoid cysts are usually easy to manage.

Botryoid Odontogenic Cyst

The botryoid odontogenic cyst will usually present as a multilocular lesion and is a special variant of the lateral periodontal cyst. Botryoid refers to the fact that these lesions may appear like grapelike clusters, both histologically and usually radiographically as well.[23,25,27]

Radiographic Features

Radiographically the botryoid odontogenic cyst presents in the same preferred alveolar process locations as the lateral periodontal cyst. Small locules may not be seen on radiographs.[23]

Treatment

Like the lateral periodontal cyst, treatment consists of enucleation with bony curettage. The multilocular nature may make this difficult, especially if teeth are to be spared. With full enucleation, light bone curettage recurrence should be uncommon. The slow growth of these lesions suggests that a 10-year radiographics is reasonable, though the small sample size makes this a suggestion at best.

Gingival Cyst of the Adult

Clinical Features

This lesion is essentially the soft tissue equivalent of the lateral periodontal cyst. As with the lateral periodontal cyst, it derives from dental lamina or rests of Serres.[92-94] These lesions generally present as an asymptomatic bluish nodule on the facial aspect of the gingiva. The sessile elevation will be centered in the attached gingiva, though extension below the mucogingival line is possible. Unlike the lateral periodontal cyst, there may be a slightly increased incidence in women.[95] The mandibular gingiva is most commonly involved and the peak incidence occurs in the fifth and sixth decades.[9,96] Other odontogenic cysts may also occur in the gingiva. Histologically distinctive odontogenic cysts that are appropriately diagnosed histopathologically should not be descriptively called *gingival cysts.* The possibility of some cysts of the gingivae arising from traumatically implanted surface epithelium does exist. Whether it is best to call these histologically different cysts *epithelial inclusion cysts* is debatable.[95] The term *gingival cyst of the adult* must be reserved for those lesions with histologically distinct microscopic criteria.

Radiographic Features

The lesion may sometimes display superficial cupping of the cortical bone. This cupping is usually only detected intraoperatively.

Gingival Cyst of the Newborn (Dental Lamina Cyst, Alveolar Cyst of the Newborn)

These cysts occur on the alveolar ridge of newborns. They are generally only a few millimeters in diameter and seen only in the first few months of life. Though studies are appropriately devoid of histologic sampling data, some clinical reports estimate these cysts occur in up to 50% of all newborns. The cysts are sessile and vary from normal in color to yellow or white. Similar-appearing inclusion cysts of the palatal midline (Epstein's pearls) or at the junction of the hard and soft palates (Bohn's nodules) are differentiated by location. The gingival cyst of the newborn is a soft tissue cyst and does not have an intrabony component (Fig. 93-11).[97]

Figure 93-11. Clinical photograph of possible gingival cyst of the newborn. Light color favors dental lamina cyst rather than eruption cyst. Cyst spontaneously resolved.

Microscopic Features

These cysts should generally never appear for pathologic review.

Treatment

These cysts almost always spontaneously rupture and require *no* therapy whatsoever. Occasionally a cyst will be large enough to interfere with nursing or persist to 6 or more months of age. In these rare cases, simple enucleation or even deroofing is sufficient.

Keratinizing Odontogenic Cyst (Orthokeratinizing Odontogenic Cyst, Orthokeratinizing Odontogenic Keratocyst)

Recognition of the keratinizing odontogenic cyst is a rather recent phenomenon. When the OKC was first defined, the definition did not separate these lesions. Over time several reviewers noted and separated keratinizing cysts that did not seem to otherwise conform with the microscopic criteria of the OKC.[98-100] The most notable difference in these cysts was the presence of orthokeratin rather than parakeratin, though other features such as lack of tombstoning, corrugation, and hyperchromatism are more important criteria. Wright[101] was the first to formally separate this group of cysts and proposed the name of OKC, orthokeratinizing variant. He noted the different histopathologic features and ably reported the lack of recurrences associated with these orthokeratinized cysts. However, the nomenclature of including the term *keratocyst* has created quite a bit of confusion, at least anecdotally. Historically, older texts and articles described keratinization of various odontogenic cysts and recognized the difference of these cysts from OKCs.[47,100]

The designation as *orthokeratinized OKC* (OKC, orthokeratinized variant) has evolved since first being described. Current nomenclature has evolved to avoid confusion with the "standard" OKC. It is also worth noting that some OKCs can contain orthokeratin, and the original series of "orthokeratinizing OKCs" described by Wright included 7 of 60 cysts with parakeratin.[101] Thus classification based solely on the type of keratin alone is unwise.

The separation of the keratinizing odontogenic cyst is clinically important because the reported recurrence rate of the keratinizing odontogenic cyst is only 2%. The peak incidence of keratinizing odontogenic cysts is in the third, fourth, and fifth decades, with about three fourths of them being in a dentigerous cyst relationship. Other locations are possible, in various relationships to the teeth. Most cysts are asymptomatic, though pain and swelling was reported respectively in 22% and 13% of cases.[98,99] The keratinizing odontogenic cyst is *not* associated with basal cell nevus syndrome (Gorlin-Goltz syndrome).

Figure 93-12. Radiograph associated with crown of impacted mandibular canine. Note that the tooth is the left canine, which has translocated across the arch.

Radiographic Features

The cyst presents as a well-defined unilocular radiolucency with the border generally being well corticated. If it is in a dentigerous cyst position, a cyst may be large (Fig. 93-12).

Microscopic Features

The epithelial lining will most often be thin with keratinization. However, the thickness will be somewhat variable. Keratin production varies and may only occur on a portion of the cyst wall. Orthokeratin is characteristic but *not* pathognomonic.[102] Most notable are the features that are not present. The features defining an OKC are absent.

Glandular Odontogenic Cyst (Sialo-odontogenic Cyst)

Clinical Features

Controversy encompasses this lesion and undoubtedly further delineation of features will evolve. The glandular odontogenic cyst is usually asymptomatic and involves the mandible more often than the maxilla.[29,103] Large cysts may be destructive and expansile.[104,105] The glandular odontogenic cyst involves adults and its pathogenesis is not yet understood.[106] This cyst may be either multilocular or unilocular. The cyst is generally well defined and often well corticated.

Radiographic Features

The lesion is radiolucent and may be unilocular, but it is more commonly multilocular. The radiographic margins are well defined and usually display a sclerotic rim.[107]

Microscopic Features

This cyst is lined by cuboidal epithelium of varying thickness, which may display cilia. Unfortunately, separating this particular microscopic feature from "normal" (and insignificant) mucus prosoplasia is sometimes difficult. The following features are more important in establishing the diagnosis. The cyst lining will be mucicarmine positive. The mucin detected by mucicarmine collects in small pools. Characteristically there are cuboidal cells near the surface, which give a slightly papillary appearance to the lumen.[103] The epithelium will also contain spheroid aggregates of cells.[108,109] The presence of mucous cells in other odontogenic cysts is *not* diagnostic for this lesion. This lesion, in this author's opinion, is "overcalled" and second opinion is often necessary. Standard "common odontogenic cysts" with mucus prosoplasia are often "upgraded" to glandular odontogenic cysts (Fig. 93-13). Glandular odontogenic cysts may be "upgraded" to central mucoepidermoid carcinoma. Great care to properly designate these lesions is necessary to ensure proper patient care.

Treatment

Recurrence after enucleation has been reported.[103] As in any multilocular lesion, nucleation and curettage of bone is recommended. Few cases are available to draw further treatment conclusions, but the overall prognosis is good.[30] Suggestions to treat this cyst aggressively appear to be misguided.

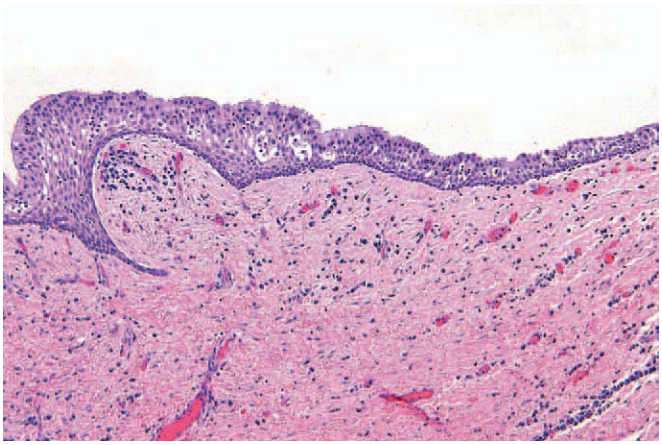

Figure 93-13. Photomicrograph showing mucus cells and spherical aggregate of glandular cells. **Note:** A single focus of such changes is not sufficient to make the diagnosis of glandular odontogenic cyst.

Odontogenic Keratocyst (Parakeratinizing Odontogenic Keratocyst, Keratocystic Odontogenic Tumor)

The OKC remains an enigma for the clinician and researcher, although knowledge gains in recent years have allowed for an improved understanding of this interesting lesion. The lesion was first described by Philipsen in 1956, but even 5 decades later the debate continues over the pathogenesis, behavior, treatment, and classification of this cystic neoplasm.[18-20] One major dilemma is whether to classify it as a cyst or a neoplasm. The current World Health Organization (WHO) nomenclature stresses the neoplastic nature and uses the term *keratocystic odontogenic tumor.*

Soft tissue extension, extension into adjacent bones, and expansion with associated bony destruction have been reported. These reports have prompted clinicians to question what the most appropriate method of treatment really is. Scharfferter and colleagues[110] documented increased mitotic activity within the epithelial lining of the OKC, which seems to support its neoplastic nature.

OKCs occur over a large age range. Lesions are often found during and slightly after odontogenesis of the permanent teeth. Peak incidence is in the second and third decades but may occur at any age. The mandible is more often involved than the maxilla, but treatment of maxillary lesions is often more problematic. OKCs are most common in the mandibular third molar area, but any area of the jaw may be involved. Patients are often symptomatic with swelling, pain, trismus, sensory deficits, and infection being the most common complaints. However, the lesion may also present as an incidental radiographic finding.

Of particular interest to the clinician is the biologic behavior of the OKC. Recurrence rates of up to 62.5% have been reported with enucleation alone. However, modern reports have a much lower recurrence rate when enucleation and careful curettage are performed. Most modern recurrence rates are less than 10%.[111,112] Reasons to explain the recurrence rate include daughter or satellite cyst formation[113]; incomplete removal of the epithelial lining, leaving satellite cysts left behind; collagenase activity of the cyst[114]; dental lamina rests left in the cyst wall or overlying mucosa; prostaglandin-induced bone resorption[115]; and increased mitotic activity. A handful of articles have demonstrated that the OKC can proliferate within muscle, and death from intracranial extension of mandibular OKCs has been reported by Jackson and colleagues.[84,116,117] Though these case reports should be remembered, the need to aggressively treat *all* OKCs should be resisted.

Radiographic Features

OKCs may be unilocular or multilocular, multiple, or single. OKCs with calcifications within a cyst wall have been reported, but calcification is rare and OKCs are considered radiolucent lesions. OKCs are highly variable in size (Fig. 93-14). They can appear pericoronally,

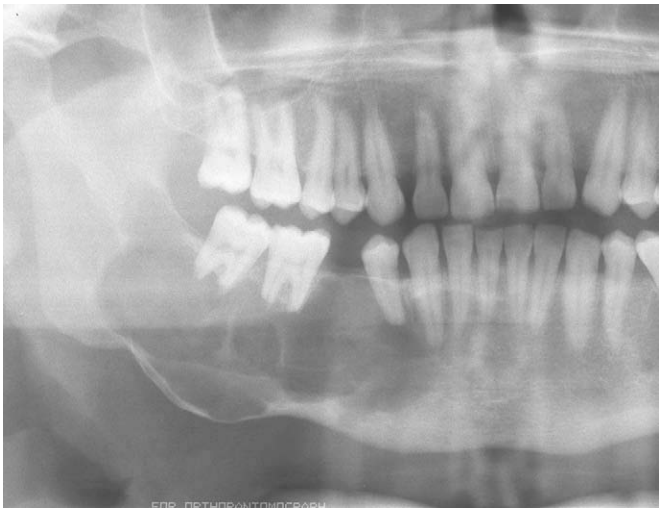

Figure 93-14. Radiograph of odontogenic keratocyst with bowing of inferior border and scalloping.

periradicularly, interradicularly, apically, and even peripherally. In summary, OKCs may occur in all areas of odontogenesis and they may extend significant distances.[97] The borders are well defined and often corticated.[98,118] Patients involved with Gorlin syndrome are more likely to present with metachronous or synchronous cysts. CT scans may be helpful in assessing large lesions and CTs are often essential in assessing maxillary lesions.[119-121]

Microscopic Features

The OKC has a specific microscopic appearance and the mere presence of a keratin lining or keratin within the cyst lumen is not sufficient to assure a diagnosis of OKC. The other features unique to the OKC must also be seen. The stratified squamous epithelium is generally 4 to 10 cells thick. The basal cell nuclei are particularly hyperchromatic, but even the parabasalar cells are more hyperchromatic than the spinous cells seen in other odontogenic cysts. The basal layer consists of cuboidal to columnar cells with a palisaded or "tombstone" appearance. Corrugated surface changes are often seen at the surface. Of perhaps least diagnostic help is the finding that OKCs are surfaced by parakeratinizing stratified squamous epithelium. Again, parakeratin is not pathognomonic for an OKC.

Treatment

A handful of reports with significant complications have led some clinicians to perform aggressive surgical procedures on *all* lesions. Debate persists about how to best manage OKC lesions in general. Treatment should center on decreasing the recurrence rate to a rate expected of the modern era and one that reduces patient morbidity. The reader is referred to other articles. After reading many treatises, the following is my opinion.[111,112,122-130]

Close radiographic follow-up is perhaps the most important modality to prevent complications secondary to recurrence. Recurrences, which often occur in the first 5 years, can take many years to present. Recently at this institution, my colleagues and I saw a recurrence 40 years after initial treatment, though the possibility of a new occurrence could not be eliminated. Establishing a diagnosis is important. Adequate material must be sent to be histologically diagnosed. Common problems are that the inner "layer" of keratin within the lumen is sampled and the diagnostic lining and wall are not submitted. Additionally, the diagnostic histologic features can be lost when inflammation is present.

If the patient has more than one cyst, the possibility of basal cell nevus syndrome is elevated. All cysts should still be examined histopathologically to confirm diagnosis. Clinical work-up to assess for syndrome is always prudent when multiple concurrent or sequential OKCs are diagnosed. Even when OKCs are in teenagers or younger patients are diagnosed with a single lesion, at least a cursory family history and gross clinical assessment for the syndrome should be performed. Some investigators have claimed good success with decompression and subsequent enucleation, while others advocate enucleation, excision of overlying mucosa, peripheral osteotomy, and chemical curettage.[125,129]

The use of Carnoy's solution is controversial. Carnoy first reported use of his fixative for the study of nematodes in 1887.[131] His goal was to fix the tissue and preserve nuclear detail for microscopic examination. However, fixation of the tissue intraoperatively for future microscopic exam is not really the effect that surgeons desire. Surgeons desire the chemical cauterization effect that the solution produces.

Regardless of the technique, the cyst lining must be entirely removed including satellite cysts and dental lamina rests. Thus careful enucleation is followed by some bone removal. Generally this is removal of daughter cysts and rests accomplished through curettage, peripheral ostectomy with rotary bur, or excision of one anatomic boundary such as periosteum (when bone penetration has occurred).

Recurrent OKCs may need to be treated more aggressively than primary lesions, but in syndrome patients "recurrences" should be considered new occurrences rather than recurrences. Large lesions may leave no other option than resection. However, one should consider decompression to shrink the lesion, followed by enucleation and curettage. In this manner a discontinuity defect or damage to vital structures is reduced or eliminated. If cortical perforation is encountered, frozen sections to assess margins may be necessary. Regardless, patients must be followed on a regular basis for many years following treatment of an OKC. As with most odontogenic lesions, surgery should be dictated by the destruction already caused by the lesion at hand, rather than simply on the histologic diagnosis.

Basal Cell Nevus Syndrome (Gorlin Syndrome, Gorlin-Goltz Syndrome, Nevoid Basal Cell Carcinoma Syndrome)

This complex syndrome is called by many names, and the nomenclature often depends on what portions of the syndrome (e.g., bifid ribs, OKC) are present. In the Gorlin and colleagues[132-134] description, no fewer than 37 anomalies have been associated with this syndrome. The reader is referred to the original sources.

OKCs are often the first diagnosis of the syndrome to present in childhood and often aid in establishing a diagnosis. This is especially true in cases in which there are new mutations with no prior familial history.[135] Up to 40% of cases may be new mutations, though genetic testing is advancing and there may be large variations in expression in this autosomal dominant disease.[134] One patient's first cyst occurred in the seventh decade. For this reason the syndrome should not be ruled out even in a middle-aged patient, and family history and phenotype may help in all age groups.

Treatment

The key to management of these patients is to at least phenotypically evaluate any patient that has an OKC for the syndrome. The assessment may be as simple as screening the patient for clinical evidence of any anomalies. In syndromic patients, "recurrences" should be presumed new occurrences rather than recurrences. Decompression is highly desirable in large lesions, and teeth should generally be saved rather than extracted if possible. Undoubtedly some teeth will need to be removed for access, but canines, incisors, and first molars should be heavily favored for retention. Each case is highly variable. As a medical advisor for this syndrome's support group I invite all providers to contact www.bccns.org for information.

Calcifying Odontogenic Cyst (Gorlin Cyst)

The calcifying odontogenic cyst (COC) is an unusual odontogenic lesion. As with the OKC, experts debate whether to classify the COC as a cyst or neoplasm. In this chapter the primarily cystic lesion with ghost cells is considered first, and the more solid epithelial odontogenic ghost cell tumor is considered later. The cyst was described by Gorlin and colleagues[136,137] in 1962. It is worthy of delineation because of its unusual clinical and histopathologic features. The COC occurs both

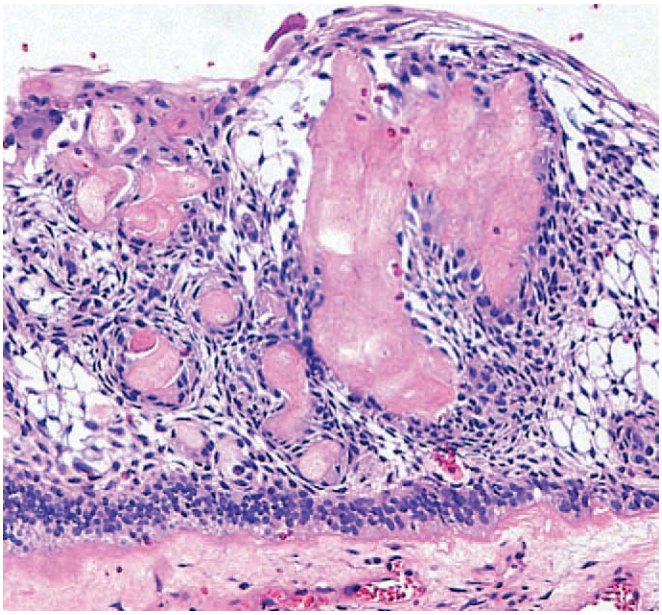

Figure 93-15. Photomicrograph showing ghost cells, odontogenic epithelium, and stellate reticulum-like areas.

within the bone and peripherally in the gingiva. COCs are often associated with odontomas or active products of odontogenesis.[138]

The separation of the cystic lesions from the solid lesions is appropriate. The solid/neoplastic version is considered briefly in the odontogenic tumor section under epithelial odontogenic ghost cell tumor.[139] The occurrence of the COC compared with the epithelial odontogenic ghost cell tumor may approach 40:1. Subclassification of the cysts is more of a histologic exercise than of prognostic or therapeutic importance. The reader is directed to articles by Praetorius and colleagues and Hong and colleagues for subclassification schemata.[140,141]

The origin of the COC is probably the early dental lamina. This may be best supported by the fact that craniopharyngiomas of the pituitary region often mimic the COC. COCs occur over a large age range. Though the mean age at occurrence is in the fourth decade, the peak incidence is in the second and third decades. Lesions in young adults are often associated with odontomas. The anterior portion of the jaws is more commonly involved than posterior regions, though any area can be involved. There is essentially equal distribution between females and males when all types are considered. There may be a slight maxillary predominance over the mandible.[139] Peripheral COCs will be centered in the attached gingiva.

Radiographic Features

The radiographic appearance is highly variable. As with the OKC, it may be either unilocular or multilocular, though unilocular lesions are more common. This is one of the odontogenic lesions that is classically considered to be mixed radiolucent radiopaque, though most lesions are purely radiolucent in the absence of an associated odontoma. If mineralization occurs in COCs without an odontoma, the radiopacities are often peripherally located. This appearance has been compared to "snowdrifting."[142]

Microscopic Features

Ghost cells are the classic cells seen in the COC. Ghost cells are *not* pathognomonic of COCs. In fact, ghost cells may be seen with other lesions such as odontomas, ameloblastic fibro-odontomas, and ameloblastomas. Of more significance is the presence of odontogenic epithelium with hyperchromic nuclei and somewhat of a palisaded basilar layer (Fig. 93-15). The thickness of the cyst wall is fairly thin and generally less than 10 cells thick. However, the thickness varies along the luminal wall and plexiform connections are often present, which creates a multicystic appearance in more complicated cysts.

Treatment

Treatment of the COC is simple enucleation of unilocular lesions. As in any multilocular lesion, enucleation with bony curettage is adequate therapy for the central lesions. The peripheral lesions require simple excision.[143] Recurrence is not expected, though radiographic follow-up is prudent.

Conclusion, Odontogenic Cysts

This chapter does not address every cyst that can affect the jaws. However, the intent by the author was to provide an overview of odontogenic cysts from the standpoint of behavior. Most cysts involving the jaws can be treated adequately with enucleation with or without curettage. In general multilocular cyst or cysts with scalloped borders need enucleation with bony curettage. Unilocular cysts can be simply enucleated. However, some cysts such as the OKC or certain variants of the calcifying odontogenic cyst, due to their neoplastic nature, may require additional surgical treatment, with enucleation and bony curettage advisable in all lesions. As stressed repeatedly, the treatment is often dictated more by the behavior (destruction the lesion has already caused) than by the histologic diagnosis.

Malignant Odontogenic Tumors and Malignancies Arising in Odontogenic Cysts or Tumors

Malignant transformation of odontogenic cysts is fortunately a rare occurrence but nonetheless occurs.[144-146] Many malignant transformations are considered to arise from residual cysts and occur in an edentulous area.[147,148] Transformation from an associated dentigerous cyst is seen in 25% of the reported cases.[146] Some OKCs have shown dysplastic features with few actually undergoing malignant transformation.[149,150] In summary, any cyst can undergo malignant transformation but such lesions are rare. Malignant lesions are likely to present with pain and swelling, but dysthesia is a foreboding symptom. Gardner reviewed the literature from 1889 to 1967 and found 25 acceptable examples of carcinoma arising from an odontogenic cyst.[151] A MEDLINE search for this chapter yields more than 100 additional examples.

Central mucoepidermoid carcinomas are thought to arise directly from prosoplastic cells of odontogenic cyst linings.[67,152-154] However, almost all types of salivary gland malignancy have been reported centrally in the jaw and the possibility of entrapped salivary tissue cannot be totally excluded. Bruner and Batsakis[153,155-157] reviewed a total of 66 reported cases of central mucoepidermoid carcinomas of the jaws, which indicates they may be more commonly reported than central squamous cell carcinoma malignancies.

Elzay[156] offered a classification for primary intraosseous carcinomas of the jaw in 1982. A scheme of classification is offered in Box 93-2 with modifications from that of Elzay to allow for salivary malignancies (especially mucoepidermoid carcinomas), origin from odontogenic tumors (other than ameloblastoma), and inclusion of sarcomas.

Verifying carcinomas arising de novo is difficult, but de novo cancers may be assumed if confined to intra-alveolar bone without a soft tissue component. Cysts appear to be a more common site of origin than odontogenic tumors. But nearly all odontogenic tumors have been reported to have malignant counterparts. The age at occurrence is in the sixth or seventh decade with some reports of a 2:1 male predominance, but full-ranging reviews are lacking.[157] And even if such reviews were available for all lesions seen in Box 93-2, their wildly variable characters would most likely be as appropriate as comparing apples with oranges.

Microscopic Features

All malignant lesions are based on histopathologic criteria.

Treatment

Significant treatment and prognostic differences exist between central squamous cell lesions and central mucoepidermoid lesions.[158] Treatment is based on size, histologic type, and histologic grade.

Box 93-2

Classification of Malignant Odontogenic Tumors with Other Selected Malignancies

Type I Arising ex odontogenic cyst
- a. Squamous cell carcinoma
- b. Mucoepidermoid carcinoma

Type II Odontogenic carcinomas
- a. Ameloblastoma derived
  - 1) Malignant ameloblastoma ("normal" ameloblastoma found as a metastatic lesion)
  - 2) Ameloblastic carcinoma (cytologically malignant)
- b. Clear cell odontogenic carcinoma
- c. Malignant epithelial odontogenic ghost cell tumor
- d. Malignant calcifying epithelial odontogenic tumor

Type III Arising de novo (presumed from odontogenic epithelium)
- a. Squamous cell carcinoma
  - 1) Nonkeratinizing
  - 2) Keratinizing
- b. Mucoepidermoid carcinoma
  - 1) Low-grade
  - 2) High-grade
- c. Most salivary gland malignancies have been reported centrally in the jaws

Type IV Sarcomas of possible odontogenic origin or with mesenchymal component
- a. Ameloblastic fibrosarcoma
- b. Fibrosarcoma
- c. Myoepithelial carcinoma

Box 93-3

Classification of Odontogenic Tumors

Epithelial odontogenic neoplasms
- Ameloblastoma
- Adenomatoid odontogenic tumor—Case 2
- Calcifying epithelial odontogenic tumor
- Squamous odontogenic tumor
- Keratocystic odontogenic tumor
- Epithelial odontogenic ghost cell tumor

Mixed epithelial and mesenchymal odontogenic neoplasms
- Ameloblastic fibroma
- Ameloblastic fibrosarcoma
- Ameloblastic fibro-odontoma
- Odontoma
  - Complex odontoma
  - Compound odontoma
- Odontoameloblastoma

Mesenchymal odontogenic neoplasms
- Odontogenic myxoma
- Cementoblastoma
- Ossifying fibroma

Odontogenic Tumors

The odontogenic tumors are a heterogeneous group of tumors that are generally separated in classification schemes by what components of odontogenesis are present within the tumor. Box 93-3 shows the classifications used in this chapter. When reviewing the treatment of these tumors, multiple considerations must be accounted for. When many articles are reviewed it becomes clear that there is a great desire for a "cookie cutter" type of recipe approach for every lesion based on diagnosis alone. Unfortunately, this just is not a realistic approach and in this author's opinion has resulted in gross overtreatment in a number of patients. As with the odontogenic cysts, the presence of scalloping and particularly multilocularity makes curettage following enucleation necessary. Although scalloping and multilocularity may be seen on planar films, intraoperatively the surgeon is in an ideal position to assess for these features in three dimensions. If scalloping or multiple locules are noted intraoperatively, curettage is appropriate at the time of biopsy to avoid having to reoperate.

The maxillofacial community has, in general, been a poor steward in defining criteria, measuring outcomes, reporting postoperative morbidities, and analyzing methods in relation to benign odontogenic tumors. This poor stewardship is true in both arches but is especially problematic when attempts are made in assigning therapeutic modalities indiscriminately to both the mandible and maxilla. In actuality the anatomic problems in each jaw differ dramatically and surgical differences abound.

In the mandible more emphasis needs to be paid to inferior and posterior cortical bone relationships to the tumor to potentially avoid discontinuity resections of these benign lesions. With the exception of ameloblastoma, there are only a handful of reports of mandibular benign odontogenic tumors "getting away" from the surgeon into soft tissues or nearby bones. Yet a cookie cutter approach is often applied. Ameloblastoma-like therapeutic models are applied to many benign odontogenic tumors. I am not aware of any studies on the morbidities associated with nonameloblastoma recurrences in the modern world of imaging. Likewise, despite studies associated with the jaw resections and obturators (generally in cancer therapy),[159-168] there are no studies on quality-of-life issues associated with benign odontogenic tumor therapy. Evidence to support recommended treatment margins is usually based on comparing recurrence rate with ameloblastomas, not the biologic behavior of the tumor. In addition, the 1-, 1.5-, and 2-cm margins recommended are often unclear. Regarding benign odontogenic lesions other than ameloblastomas, studies that have actually controlled for confirmed resection margins, pathologically and radiographically before and after surgery, are terribly lacking. For ameloblastomas Carlson and Marx[169] do a credible job in advocating resection. They also account for frozen sections, biologic barriers, and utilization of intraoperative radiographs (Fig. 93-16). However, they fail to recognize the simple fact that the actual goals are to ensure *and* confirm tumor removal, not to have a one-size-fits-all guideline. They also discuss confusion about solid and nonunicystic cystic ameloblastomas. More discussion of this problem is provided later. Gardner does an excellent job on the problems of doing retrospective analysis of the literature on ameloblastomas.[170]

In the maxilla, 1-cm bony margins are sometimes recommended in the proximal-distal direction. However, the anatomy of the sinuses, nasal cavity, orbit ethmoids, and pterygoid plates in many instances makes the use of anatomic boundaries more appropriate. In general, one or two anatomic boundaries are sufficient to ensure excision. In all lesions, even the ameloblastoma, the periosteum is thought to be an effective tumor barrier.[171] The interested lifetime/evidence-based learner is invited to perform a MEDLINE search of actual invasive benign odontogenic tumors. A 4-decade review by Leibovitch and colleagues[172] found only 11 reported cases of ameloblastomas with orbital involvement. A MEDLINE search for this chapter revealed about the same amount of reports (using search terms of ameloblastoma combined sequentially with "invasi," "extension," and "involve") revealed, in a cursory review of abstracts, approximately 25 to 40 cases/reports with the majority being from an original maxillary lesion. Without a doubt, soft tissue extension of recurrent ameloblastomas is a real problem, with Sampson and Pogrel documenting a high percentage of ameloblastomas involving soft tissues in a series of 26 cases.[173] But the ameloblastoma is a special case and is covered more thoroughly later. The following section discusses general principles concerning the other odontogenic tumors. With the exception of malignant variants, the reports of other odontogenic tumors extending, involving, or invading other adjacent structures are extremely rare.

Figure 93-16. Intraoperative radiograph. Note that the posterior margin is closer than the desired 1-cm margin. Such intraoperative radiographs help obviate the inability to perform frozen sections on bony tissue.

In assessing the benign odontogenic tumors, it is essential to critically read reports on how margin measurements were defined and how those margin measurements were confirmed both intraoperatively and postoperatively. I know of no adequately described prospective report. For example, I believe such measurements are in relation to the medullary bone and do not necessarily imply cortical bone. Surgically and restoratively, the loss of thin cortical bone on the buccal, lingual, and alveolar aspects is different from losing the inferior border of the mandibular body, the posterior border of the ascending ramus, or for that matter the condylar head or condylar neck. In all cases, it is this author's plea to always ask first, "Is there any realistic chance of this mandibular benign tumor getting away from me, if it recurs?" Second, ask, "Has the tumor already destroyed any of the critical structural elements of the mandible?" Third, ask, "Is there a reasonable chance of radiographic and patient follow-up?" I believe the first question will result in the surgeon realizing that loss of critical bony structures is unnecessary in most cases and the cookie cutter approach can be modified for the patient at hand. In the second question, if the lesion has not already destroyed critical structures, there are probable criteria *not* to iatrogenically destroy them. A huge caveat to this is that the lesion must be far enough away from these important structural elements to allow for a radiographically clear margin on the resected specimen. The clear margin will also then need to be confirmed histopathologically. If critical structures have already been destroyed by the lesion, the surgical decisions are straightforward. In the third question there are probably as many reasons or more to follow a person with history of tumor, a segmental resection, and a graft as compared with patients at risk of a recurrence alone. There are no reports of recurrence rates dropping to 0% after segmental resection. The surgeon is urged to review the literature with an eye to evidence-based data.

The maxillary lesions are more problematic due to the short distance needed to involve areas difficult to operate in and oblate the tumor. Such areas include but are not limited to the pterygoid plates, orbital floor, and pterygopalatine fissure. The head and neck surgeon realizes that in some areas any benign tumor is difficult to access and completely remove. Thus persistence of tumors in these areas is more a problem of location than of the inherent invasive potential of the tumor. Carlson and Marx[169] do a good job of discussing biologic barriers in their article.

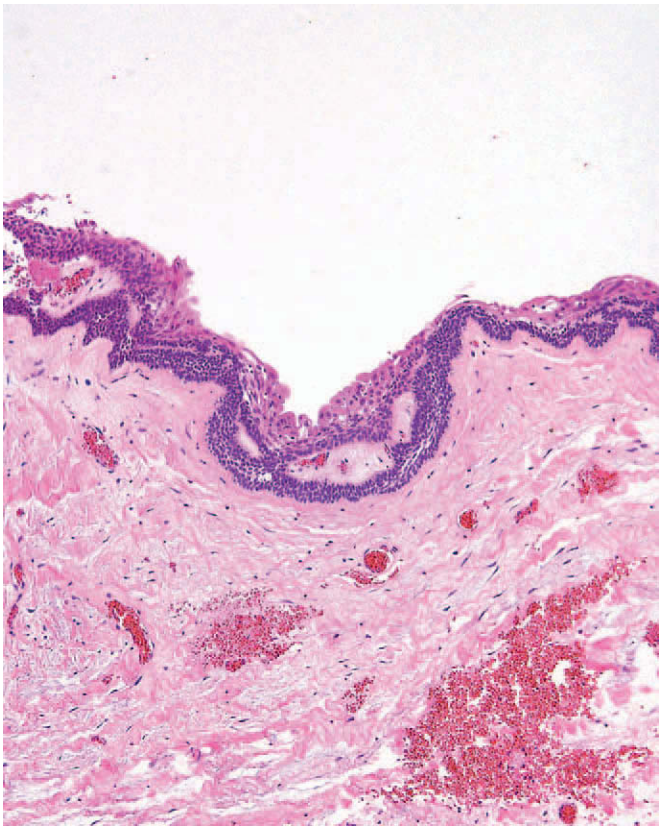

Figure 93-17. Photomicrograph of unicystic ameloblastoma with typical ameloblastomatous changes.

Unicystic Ameloblastoma

Unicystic ameloblastomas account for approximately 15% of all ameloblastomas. Unicystic ameloblastomas may be found in any odontogenic tissue–bearing area. Most unicystic ameloblastomas are found in the posterior mandible. Unicystic ameloblastomas most often occur in the second and third decades, a somewhat younger population than reported for the solid ameloblastoma. As with other odontogenic cysts and tumors, unicystic ameloblastomas are usually asymptomatic unless secondarily inflamed.[97]

Radiographic Features

Unicystic ameloblastomas present as radiolucent, unilocular lesions, with well-demarcated, corticated borders, indistinguishable from most odontogenic cysts or tumors. Many unicystic ameloblastomas appear to be dentigerous cysts both on radiographic and gross examination. However, they may be found in any location.

Microscopic Features

The microscopic features known as *Vickers and Gorlin criteria* define the unicystic ameloblastoma. These features are (1) columnar basilar cells, (2) palisading of basilar cells, (3) polarization of basilar layer nuclei away from the basement membrane, (4) hyperchromatism of basal cell nuclei in the epithelial lining, and (5) subnuclear vacuolization of the cytoplasm of the basal cells. Above the basal layer, loosely aggregated stellate cells resembling the stratum spinosum of a developing tooth are noted (Fig. 93-17).[174] It is important to realize that some portions of unicystic ameloblastomas may not show all these features. A variation of unicystic ameloblastoma described by Gardner allows for a plexiform variant. Inflammation may disrupt the diagnostic features of unicystic ameloblastoma.[175-177]

As in all odontogenic cysts and tumors of the jaws, the entire specimen needs to be embedded because the treatment depends on the presence or absence of ameloblastomatous epithelium in the fibrous wall.

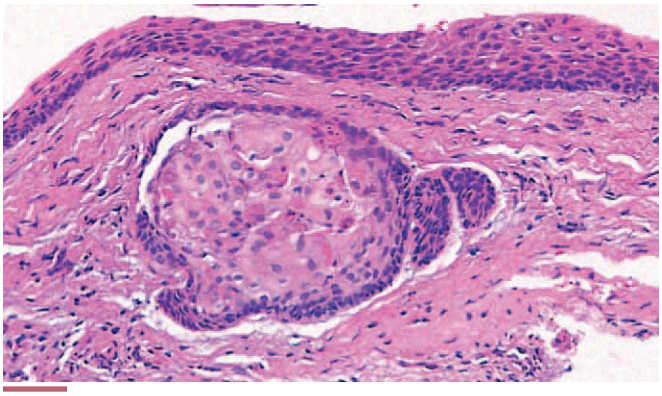

Figure 93-18. Area in a generally cystic ameloblastoma where the tumor has invaded the connective tissue wall. This portends an increased risk of incomplete removal and thus recurrence.

Definitions, Clarifications, and Treatment Recommendations

A unicystic ameloblastoma must be unilocular, as well as unicystic, and display the pathologic features of an ameloblastoma lining the lumen but not invade the connective tissue (Fig. 93-18). From the beginning, criteria have varied and caused confusion, but this definition applies in the following discussion.

The unicystic ameloblastoma was separated from the "standard" ameloblastoma by Robinson and Martinez in 1977.[178] The subtitle of that seminal paper was "a prognostically distinct entity." Since that time the application of their original definition has been problematic, with others often further muddying the picture. A number of authors have attempted to provide evidence of predicted behavior for different types of unicystic ameloblastomas.[178-183]

The first premise in this chapter's coverage of the unicystic ameloblastoma is that the only reason to separate the unicystic ameloblastoma is for therapeutic planning and expected clinical behavior. Ever since the original paper, it has been regrettable that multilocularity and connective tissue invasion were sometimes allowed within the diagnostic criteria. Ackermann and colleagues[183] have analyzed unicystic ameloblastomas with connective tissue invasion as "type 3." They found that they often recur if only enucleation is performed as therapy. For this reason, though, they should be more thoroughly studied and managed like a standard ameloblastoma. And thus separation as a "unicystic" ameloblastoma is spurious at best. Likewise, Philipsen and Reichart[182] found that multicystic or multilocular cystic ameloblastomas recurred with simple enucleation. Again, this should make it clear that they should not be grouped under the designation of unicystic ameloblastoma. These features are seen in "regular" ameloblastomas, and determining where to draw the line of what is too much multilocularity or too much connective tissue proliferations is totally subjective and unwise unless future studies define a method to separate lesions. Until such studies, unicystic ameloblastomas should be considered as such only if they are unicystic and unilocular and display no connective tissue invasion.

Some additional background information may also be helpful. Eversole and colleagues[184] found recurrences more common (actually all four recurrences) in lesions larger than 2 cm. Unfortunately they did not stratify their data to state whether these larger lesions were multilocular or how the connective tissue wall was invaded.[184] But this report implies that large or expansile lesions may recur even if the ameloblastoma is cystic. Likewise, a review of the original paper by Vickers and Gorlin,[174] which defined the features of ameloblastomas, reveals that all their cases were recurrences of what today would have been diagnosed as unicystic ameloblastomas.

Unicystic does not mean unilocular. Some authors allow for a multilocular radiographic appearance.[185] These authors often use terms such as *cystic* or *cystogenic* instead of unicystic. Regardless, the intent is to attempt to group these lesions with the unicystic ameloblastoma. Some purport that histologically the multilocular lesion was unicystic (how they confirm three dimensionally how a single cyst can make multiple locules and remain unicystic has never been adequately explained in my opinion). However, in my review of the literature, multilocularity increases the chance of recurrence and multilocular lesions should be at least enucleated and curetted rather than just enucleated. In my institution, multilocular and multicystic lesions would be signed out simply as ameloblastoma and presumed to be treated as such. Unilocular lesions may be histologically multicystic. Multicystic lesions are *not* unicystic lesions, so they should be considered standard ameloblastomas and treated as such.

In their review of 193 "unicystic" ameloblastomas, Philipsen and Reichert[182] found wide variations in definitions, nomenclature, and what lesions were included under the heading "unicystic" ameloblastoma. Simply put, the literature is horrible. Even separation of terms such as luminal, intraluminal, and mural varies among authors.

As proposed originally by Robinson and Martinez,[178] the reason for the diagnosis of "unicystic ameloblastoma" was to separate "a prognostically distinct entity." Even in their report, Robinson and Martinez had a recurrence rate of about 20%. But they allowed for connective tissue nests, multilocularity, and large cysts. Two of their three lesions described as "large dentigerous cysts" recurred. Eversole and colleagues[184] later used 2 cm as a cutoff for size because they found that larger "cystogenic" ameloblastomas had a propensity to recur with simple enucleation. Robinson and Martinez[178] did not separate lesions by connective tissue involvement. But authors including Philipsen, Reichart, and Ackerman and colleagues (in various publications) have shown that connective tissue involvement is an important predictor of recurrence with simple enucleation. They designate these as what they call type 3 unicystic ameloblastomas and state that they tend to recur (i.e., behave like "standard" ameloblastomas if only enucleation is performed). Current wisdom is that the 20% recurrence rate of Robinson and Martinez may have been due to large size or connective tissue proliferations.

Needless to say, inconsistencies have led to confusion. A goal of this chapter is to emphasize that the reason for the unicystic designation is to use the minimal amount of surgical intervention while minimizing the chance of recurrence. The literature is fairly clear that a subset of unicystic ameloblastomas can be managed with enucleation alone (or perhaps combined with minimal bony curettage). In this analysis the subset is the definition of unicystic ameloblastoma used.

Simple Unicystic Ameloblastoma

A unicystic ameloblastoma (referred to here as a "simple unicystic ameloblastoma") requiring enucleation *only* must have the following characteristics:

1. Histologic features conform to criteria established by Vickers and Gorlin for the diagnosis of an ameloblastoma.

2. Radiographic evidence of a singular unilocular radiolucency exists. Definitive septation requires exclusion, so evidence of peripheral scalloping (except between tooth roots) may eliminate the possibility of a lesion being considered unilocular.

3. Intraoperative confirmation of unilocularity, *any* multilocular/multicystic characteristic, and cortical perforation or soft tissue involvement preclude interpretation of the lesion as unicystic.

4. Histologic features display only luminal or intraluminal involvement. Proliferation of the ameloblastoma into the fibrous connective tissue wall, whether plexiform or follicular, precludes diagnosis of the lesion as unicystic.

5. Size of the lesion must be less than 2 cm.

I can only hope that further studies continue to define and separate the unicystic ameloblastomas, as well as delineate the line of when to designate a lesion as simply an ameloblastoma. Experience is available to justify the separation, and hopefully the science will follow.

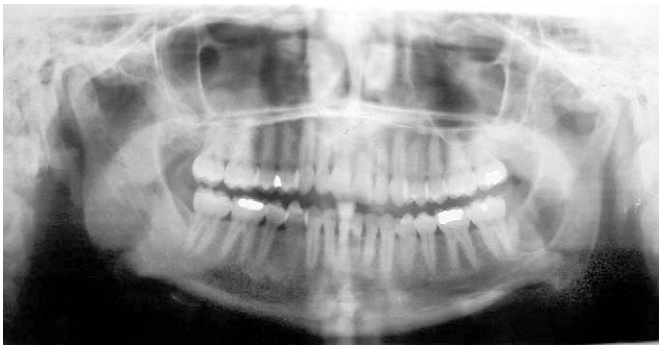

Figure 93-19. Pantomograph with ameloblastoma in area where a third molar was extracted several years previously.

Ameloblastoma, Intraosseous Type*

Definition

The ameloblastoma is a neoplasm of the enamel organ that recapitulates the cells necessary for tooth crown development. Intraosseous ameloblastomas arise from the lining of an odontogenic cyst, reduced enamel epithelium, or odontogenic rests. In the soft tissues of the oral cavity, specifically the gingiva or alveolar mucosa, they may arise from the basal cell layer. Those that arise from the overlying soft tissue are called *peripheral ameloblastomas* and are covered separately. In this chapter the three clinical types of ameloblastoma are unicystic ameloblastoma, peripheral ameloblastoma, and ameloblastoma. Here the modifiers of multicystic or solid are not used. They are not separated here because they are treated the same. Of these three, unicystic and peripheral have a much better clinical outcome after a conservative removal and assured margins. For clarification, I use the term *intraosseous ameloblastoma* to clarify that the lesion discussed is *not* peripheral.

Intraosseous ameloblastomas occur in the mandible and maxilla with the mandible accounting for about 80% of all cases. In the maxillae, ameloblastomas may evolve in the maxillary sinonasal region, as well as during the alveolar process. The location of the tumor is an important factor in the long-term prognosis. Tumors that are in the anterior maxilla or body of the mandible or are confined to the mandible are less likely to cause significant problems. Conversely, those penetrating the mandible in the posterior ramus region and those of the posterior maxilla can extend into areas difficult to manage.[186]

Radiographic Findings

Small ameloblastomas appear as a unilocular radiolucency with well-demarcated and at least partially corticated borders. These radiolucent lesions are indistinguishable from other cysts or benign tumors of the jaws (Fig. 93-19). Larger lesions may be easier to recognize radiographically. The classic description of larger lesions is a "soap bubble" or honeycomb appearance. Roots of adjacent teeth may show resorption in long-standing lesions. An ameloblastoma commonly displaces unerupted or erupted teeth. These radiographic features describe all histologic variants except for some desmoplastic ameloblastomas. In desmoplastic ameloblastomas of sufficient duration, a mixed radiolucent radiopaque lesion rather than a pure radiolucency may be seen. Additionally, the desmoplastic ameloblastoma is more common in the maxilla and anterior portion of the jaws.[97]

Microscopic Features

Multiple microscopic subtypes of ameloblastoma exist. Although they are of importance to the pathologist, these histologic subtypes are not of therapeutic or prognostic importance. But in summary, histologic subtypes include follicular, plexiform, granular cell, acanthomatous, desmoplastic, basal cell, and keratinizing. The classic features of ameloblastoma were described by Vickers and Gorlin.[174] These features are columnar basilar cells, palisading of basilar cells, polarization of basilar layer nuclei away from the basement membrane, hyperchromatism of basal cell nuclei in the epithelial lining, and subnuclear vacuolization of the cytoplasm of the basal cells. Above the basal layer, loosely aggregated stellate cells resemble the stratum spinosum of a developing tooth (Fig. 93-20).

*Includes solid types and all ameloblastomas that, although being cystic, do not conform to criteria within the unicystic ameloblastoma section.

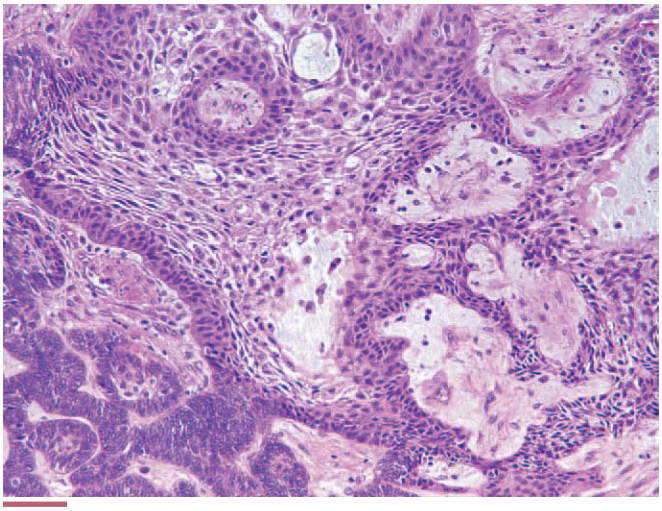

Figure 93-20. Photomicrograph of plexiform ameloblastoma with typical Vickers and Gorlin features. Stellate reticulum is also somewhat acanthomatous.

Natural History and Treatment

Gardner pointed out two main factors that explain the behavior of ameloblastomas: (1) their ability to infiltrate medullary bone and a relative inability to infiltrate compact bone; (2) the location of the tumor. As noted earlier, tumors near vital structures such as the orbit or cranial base are much more difficult to control and pose greater clinical problems. Free margins of excision are difficult to obtain in ameloblastomas arising in the posterior maxilla. Dense compact bone such as that of the inferior border of the mandible or ramus acts as the first-line barrier.[187] The outer periosteum appears to serve as a backup barrier to prevent tumor spread, but once it is broken, access to vital structures may occur.[171] In the maxilla, only a thin cortical plate exists between contiguous bones and is generally thought of as a poor barrier to prevent the spread of ameloblastomas.[169] Tumors of the posterior maxilla involving the orbit are the most difficult to treat and manage. Undoubtedly such lesions will present with unique and specific problems related to the individual case.[188]

Simple enucleation of ameloblastomas is not considered standard care in the United States. Even when it is combined with curettage, ameloblastomas are known to recur. Yet successful results with enucleation and curettage have been reported.[189,190] The recurrence rate is thought to be due to the fact that ameloblastoma infiltrates the trabeculae of cancellous bone. The reported success with curettage (or peripheral ostectomy with rotary bur) is probably due to relatively efficient/aggressive medullary bone removal. It is generally considered a fact that tumor infiltration frequently extends beyond the apparent radiographic margin. Ensuring even amounts of bone removal with enucleation and curettage can be difficult. Small bits of tumor may remain within the bone without the ability to assess margins grossly or histologically. It is thought that resection with adequate margin is the most predictable method to assure that the tumor will not recur. A resected specimen allows for intraoperative radiographic assessment of adequate margins and postoperative histologic confirmation of margins.

Histologically simply clear margins are acceptable. How pathologists deal with resected bone specimens in the pathology laboratory is inconsistent. The surgeon should explicitly request that the *entire* bony specimen be demineralized and margins fully assessed. The surgeon should mark surfaces that are not margins such as the vestibule, gingiva, alveolar mucosa, and sinus mucosa. As a pathologist, I know how much

work such requests entail. Although I dread these specimens coming into the laboratory, I believe this is the only way to assess therapy and plan for future reconstruction.

What an adequate radiographic margin should be is more controversial and probably varies by case. Even after en bloc resections, reportedly well past radiographic evidence of tumor, recurrence rates of 10% to 15% have been reported. Although some surgeons advocate larger margins, the general consensus is that resection should be 1 cm past the radiographic limits of the tumor. Unfortunately, there are no well-controlled studies of radiographs of the resected specimen compared with postsurgical defects to actually confirm what margins were achieved. Likewise, although there are anecdotal reports, there are no controlled studies of resected specimens correlated with radiographs to assess how far the tumor actually extended histologically past that radiographic evidence. Carlson and Marx have made initial attempts to accumulate such data, but a well-documented study has not yet been performed.[169] Due to the lack of reliable data, the following discussion is yet another anecdotal opinion on how to manage ameloblastomas.

Management of Mandibular Ameloblastomas

One-centimeter medullary bone margins, referring to the proximal and distal directions, are preferred. Lingual and buccal cortical bone is sacrificed, but 1-cm margins do *not* imply inclusion of soft tissue outside the periosteum. In the mandibular body and in the anterior ramus overlying mucoperiosteum, teeth, gingiva, and mucosa are submitted with the resected specimen. In essence, portions of the bone resection specimen without muscle attachments will have overlying mucosal soft tissue included in the specimen. In the depth of the lingual and buccal vestibules, as well as the ascending ramus where muscle attachments begin, the periosteum will remain with the resection specimen. These periosteal surfaces will represent the surgical margins of the specimen. If the coronoid process is more than minimally undermined, it is also sacrificed (following detachment from the temporalis muscle) and included or separate from the main resection specimen. If extension is suspected past any periosteal surface, frozen tissue margin protocols should be applied and specimens should be handled separately.

Management of Maxillary Ameloblastomas

Assessing bone margins in maxillary bone resection specimens is even more important. Some authors recommend 1- to 2-cm margins in the maxillae. The larger end of the range is probably unnecessary in the anterior region and difficult to obtain when lesions approach the orbit or pterygoids, or both. Again, such margin recommendations pertain to attempted bony margins and not to soft tissues. Soft tissue margins must be assessed by frozen section or on properly oriented permanent sections. Treatment of maxillary lesions varies greatly and depends on both CT and MRI interpretation. Follow-up of maxillary lesions is extremely important and it is assumed that attempts to spare vision and vital structures of the region may alter initial treatment plans. Excision to extend two biologic barriers past the tumor serves as a rule of thumb. The en bloc specimen should be examined intraoperatively from multiple radiographic views. Final margin assessment occurs after demineralization. Though not often recommended, radiotherapy may occasionally play a role in unresectable tumors.[191] Similar to the mandibular tumors, the periosteum above the level of muscle attachment is the surgical margin. Overlying mucoperiosteum, teeth, gingiva, and mucosa are submitted with the resected specimen.

Summary

In summary, the ameloblastoma is the most aggressive of the benign odontogenic tumors. Numerous reports on treatment are available, but well-controlled prospective studies are necessary to answer many questions.[126,173,187,189,192-208]

Peripheral Ameloblastoma (Extraosseous Ameloblastoma)

Peripheral ameloblastomas present as mucosal masses and arise from the gingiva or alveolar mucosa. The actual proliferation may come from dental lamina rests or basal cells of the overlying mucosa. Histopathologically the lesions appear as any of the previously mentioned variants, though the basal cell variant is the classic subtype. By definition these tumors do not infiltrate the underlying bone. If there is an intraosseous component, the lesion is *not* a peripheral ameloblastoma. If there is bone involvement, the lesion is treated as an intraosseous ameloblastoma. Peripheral ameloblastoma may become quite large. Lesions may be imaged with MRI or CT. Treatment is to assure excision with histopathologically confirmed margins.[209-218]

Malignant Ameloblastoma

Malignant ameloblastomas are lesions that have any of the classic benign histopathologic features of ameloblastoma but metastasize to a distant location. In many cases the metastases are long delayed and may occur years after the initial tumor was treated. The lung is the most common site for metastases. Cervical lymph node involvement has also been reported. Treatment varies by degree and site of involvement. Though excision is preferred, radiotherapy may be the only practical option.[219-224]

Ameloblastic Carcinoma

Ameloblastic carcinoma, in contrast to malignant ameloblastoma, shows cytopathologic features associated with malignancy (e.g., increased mitotic activity, increased nuclear and cytoplasmic ratio, nuclear pleomorphism, hyperchromatism). The cytopathologic/histopathologic features allow for this being diagnosed in the primary location. The tumor may or may not metastasize, but like the primary tumor the cytopathologic features display the anaplastic features of malignancy. These are rare lesions.[225-234]

Ameloblastic Fibroma

The ameloblastic fibroma is a benign odontogenic neoplasm characterized by proliferation of immature mesenchymal and ameloblastic cells, both of which are characteristic of a developing tooth. Unlike the ameloblastic fibro-odontoma or the odontoma (complex and compound), the ameloblastic fibroma does not have the capacity of producing enamel, dentin, or cementum. The tumor can be found in any tooth-bearing site. However, the tumor is most often seen in the premolar-molar region of the posterior mandible. There is no gender predilection, but the lesion is usually identified in a bimodal age distribution. The majority of lesions are diagnosed before age 20, though another smaller group of lesions is seen in middle age. As with other odontogenic neoplasms, the lesion is slow growing and asymptomatic unless secondarily inflamed. A firm expansion of the buccal cortical plate of the mandible or maxilla is the most common clinical finding. The lesions are most often small and unilocular. It is thought that an early version of odontoma necessarily goes through a stage that is histopathologically indistinguishable from an ameloblastic fibroma. Separating these early odontomas from a "real" ameloblastic fibroma is impossible. However, there are reports of large and destructive ameloblastic fibromas that clearly require the ameloblastic fibroma to be classified as a neoplasm rather than a hamartoma. The tumors that become large and destructive are perhaps more likely to be seen in older patients.[235-239]

Radiographic Features

The ameloblastic fibroma usually presents as a well-defined radiolucency. The border is often corticated though sclerotic changes may also be seen. Small lesions are usually unilocular, whereas larger, more aggressive tumors are usually multilocular. The majority of lesions are seen in association with the crown of an unerupted tooth.

Microscopic Findings

The histopathologic features of an ameloblastic fibroma are characterized by the proliferation of both epithelial and mesenchymal elements. The mesenchymal component presents as a relatively cellular-young, basophilic, fibromyxoid tissue suggestive of a developing tooth pulp or dental papillae. The fibroblastic cells vary from stellate to spindled. Admixed within the mesenchymal background are islands, cords, or nests of odontogenic epithelium. The outer epithelial cells near the basement membrane become cuboidal and occasionally columnar, at

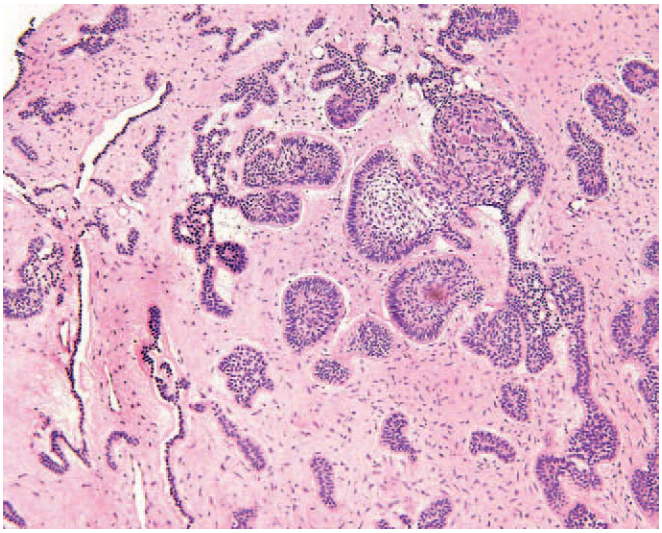

Figure 93-21. Photomicrograph of follicles that are essentially identical to an ameloblastoma, but the background stroma is consistent with dental papilla. Eosinophilic induction effect is seen around a few epithelial islands.

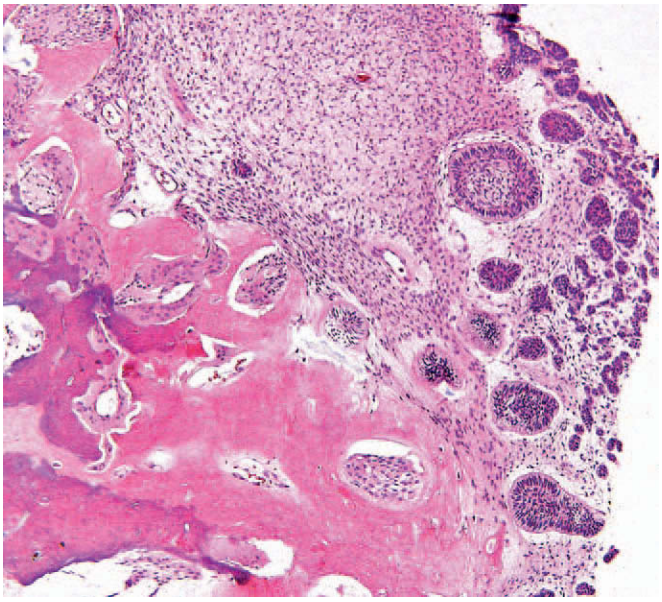

Figure 93-22. Photomicrograph in which an area identical to an ameloblastic fibroma dominates the right side of the image, but mineralized products dominate the left side and confirm the diagnosis as an ameloblastic fibro-odontoma.

least focally. These islands are essentially identical to islands seen in follicular ameloblastomas. By definition, ameloblastic fibromas will have no areas of mineralization. If mineralization is seen, the lesion is actually an ameloblastic fibro-odontoma (Fig. 93-21).[97]

Treatment

Conservative surgical enucleation of the tumor is the treatment of choice for all small, unilocular lesions. The tumor does not have the infiltrative margins characteristic of an ameloblastoma and therefore recurrence rates are low. With early detection and removal, the long-term prognosis is favorable. However, larger multilocular lesions may be destructive and reports of recurrence up to 40% were reported in a 1972 article from a series of cases at the Armed Forces Institute of Pathology.[239] Segmental resection is not indicated in any tumor except those that have essentially already destroyed the integrity of the jaw involved.

Ameloblastic Fibro-odontoma

The ameloblastic fibro-odontoma is a rare odontogenic tumor. The lesion has had some controversy in the literature in regard to its appropriate classification. Similar to the ameloblastic fibroma, it is thought that a maturing odontoma necessarily goes through a stage that is histopathologically indistinguishable from an ameloblastic fibro-odontoma. However, reports of large and destructive ameloblastic fibro-odontomas clearly confirm its ability to act as a neoplasm rather than a hamartoma. The majority of patients with ameloblastic fibro-odontoma are young, with a mean age of 10 years. Whether these data are skewed from improper inclusion of maturing odontomas is difficult to assess. Undiscovered tumors can cause significant cortical plate expansion. Most are discovered during other radiographic studies or when a tooth has failed to erupt. Occasionally the tumor can persist or recur. It is probably most prudent to assess the individual tumor and patient in its context. If the tumor is large and destructive, it is more likely to be acting neoplastically. Multilocular tumors should be assumed to be neoplastic.[97,240,241]

Radiographic Findings

The tumor is a well-circumscribed, unilocular or multilocular lesion.[242] Though evidence of mineralization must be present histopathologically to make the diagnosis, the mineralizations will not always be evident radiographically. Therefore early lesions may be radiolucent. The amount of mineralization varies widely.

Microscopic Findings

The histopathologic features of an ameloblastic fibro-odontoma are characterized by the proliferation of both epithelial and mesenchymal elements. The mesenchymal component presents as a relatively cellular-young, basophilic, fibromyxoid tissue suggestive of a developing tooth pulp or dental papillae. Admixed in the fibromyxoid tissue are mineralized and premineralized elements including enamel, enamel matrix, dentinoid, dentin, cementoid, and cementum. Admixed within the mesenchymal background are islands, cords, or nests of odontogenic epithelium. These scattered epithelial components are identical to those seen in the ameloblastic fibroma (Fig. 93-22).[243-246]

Treatment

Small ameloblastic fibro-odontomas are generally treated with simple enucleation. Multilocular lesions should be additionally treated with curettage/peripheral ostectomy with a rotary instrument. Unerupted teeth associated with the tumor may be retained. Depending on the amount of displacement and root development, they may or may not need orthodontic intervention to ensure eruption. Very large, inherently destructive lesions require complete but conservative surgical removal. Recurrences have been reported but are extremely rare. Segmental resection is not indicated in any tumors except those that have essentially already destroyed the integrity of the jaw involved.[247,248]

Epithelial Odontogenic Ghost Cell Tumor (Dentinogenic Ghost Cell Tumor, Odontogenic Ghost Cell Tumor)

In conjunction with this brief section, please refer to the earlier discussion on the calcifying odontogenic cyst. The epithelial odontogenic ghost cell tumor is an unusual jaw lesion that consists of a complex (at least focally), solid, tumor-like mass, though a cystic area is usually present as well. As with other odontogenic neoplasms and cysts, the lesion can occur in any tooth-bearing site. Most reports indicate that the lesion occurs most often in the posterior mandible. Most lesions arise centrally within bone; however, lesions may be identified as arising peripherally within the gingiva. Extensive data on these tumors is scarce but is assumed to have a similar age distribution as the calcifying odontogenic cyst. Terms such as *malignant* and *aggressive* have been appended to this diagnosis. Personally the malignant appendage should only be

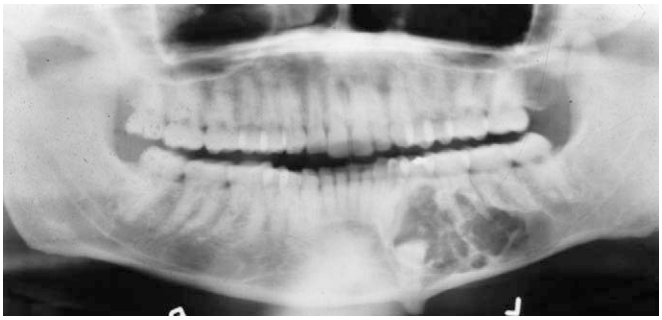

Figure 93-23. Radiograph of a large calcifying epithelial odontogenic tumor displacing a premolar and having a mixed radiographic appearance.

Figure 93-24. Gross specimen showing the gelatinous nature of an odontogenic myxoma.

used in cases where cytomorphologic characteristics of malignancy are noted. "Aggressive" lesions are identified by inherent destructive behavior or recurrence. Central bony lesions usually present as a firm, expansile mass of the buccal cortical plate. The lesions are asymptomatic unless secondarily inflamed. Gingival lesions appear as a firm, smooth, sessile, soft tissue enlargement involving the attached gingiva or edentulous alveolar ridge. These peripheral masses may present on either the buccal or lingual aspect.[139,140,249-261]

Review of the International Collaborative Study on Ghost Cell Tumours is a must-read when one of these lesions is encountered.[139] A pathologist well versed with all forms of this tumor should be consulted for proper classification.

Calcifying Epithelial Odontogenic Tumor (Pindborg Tumor)

The calcifying epithelial odontogenic tumor is an unusual odontogenic neoplasm characterized by sheets of hyperchromatic, pleomorphic cells with foci of amyloid and mineralization. Calcifying epithelial odontogenic tumors occur more often in the mandible than the maxilla with a ratio of about 2:1. Within the arch, they are often located in the molar-premolar region. As with other odontogenic tumors, they may or may not be associated with unerupted tooth crowns. Those seen in the second decade are often associated with an unerupted tooth. The tumors are rare but have been reported more often in males. The tumor most often occurs in the third through fifth decades.[97] This tumor is rarely seen peripherally as a gingival mass or alveolar ridge mass.[262,263]

Radiographic Findings

The tumor is usually well circumscribed with a multilocular appearance being more common than a unilocular lesion. Though evidence of mineralization is often present histopathologically, radiographically the mineralizations will sometimes not be evident. However, this is one of the classic mixed radiolucent-radiopaque lesions of the jaws. The amount of mineralization varies widely with some lesions having minimal evidence of radiopacity (Fig. 93-23). The peripheral lesions may produce a cupping effect of the underlying bone. In these instances the cupping is thought to be secondary to pressure resorption.

Microscopic Findings

The tumor is characterized by islands and sheets of epithelial cells dispersed throughout a nonspecific fibrous stroma. In many instances the polygonal, epithelial cells show remarkable pleomorphism and nuclear hyperchromasia. Borders of the epithelial cells are well defined and prominent intracellular bridges are characteristic. The cytoplasm is often strikingly eosinophilic, but tumors may display a prominent clear cell component.[264,265] Foci of homogeneous eosinophilic amyloid may be present.

Treatment

Conservative surgical excision is the treatment of choice for the extraosseous variant. Small unilocular and multilocular lesions are generally treated with simple enucleation and curettage. Very large or inherently destructive lesions require complete but conservative surgical removal. Recurrences have been reported. Segmental resection is not indicated in any tumors except those that have essentially already destroyed the integrity of the jaw involved.

Tumors with clear cell changes may be more clinically aggressive than standard tumors. Tumors with cytopathologically malignant features should be considered separately.[266]

Odontogenic Myxoma

The odontogenic myxoma is a relatively uncommon, benign neoplasm apparently arising from the mesenchymal portion of the tooth-forming unit known as the *dental papillae/dental sac.* Odontogenic myxomas have been identified most often in the posterior tooth-bearing areas of the dental arches and present in both upper and lower jaws. The mandible is more commonly involved than the maxilla. Most tumors are identified during the second or third decades of life. No gender predilection has been identified. As with other odontogenic neoplasms, clinical findings usually consist of a smooth, bony, hard expansion of the alveolus. The primary process of the odontogenic myxoma is to infiltrate through medullary spaces. Intraoperatively the myxoma is seen as gelatinous material (Fig. 93-24). Judging where the gelatinous material ends intraoperatively and especially radiographically may be difficult. In some instances odontogenic myxomas do penetrate the cortex. They have also been reported as forming outside the body of the mandible, in which case they would present as a smooth-surfaced gingival enlargement.[97,267-271]

Radiographic Findings

As with many other odontogenic neoplasms, an odontogenic myxoma may present as either a unilocular or multilocular radiolucency. Most lesions show radiolucency with variable cortication. When the cortical bone is penetrated, a periosteal reaction may result in apparent osseous production. Residual or reactive bone may also be seen intraosseously[272] and give a somewhat mixed radiopaque/radiolucent appearance. Cone beam CT may be helpful.[273] When residual bone is somewhat organized, the appearance has been described as similar to either a honeycomb or tennis strings.[274]

Microscopic Findings

Odontogenic myxomas are characterized by a relatively acellular myxoid tissue. Occasional strands and cords of odontogenic epithelium may be noted, but these rests are not seen in all neoplasms. Tumors may be somewhat collagenous/fibromatous, but the myxomatous features should dominate the histopathologic picture.

Treatment and Prognosis

Due to the loose, gelatinous nature of the tumor, surgical enucleation can be difficult to judge. However, the odontogenic myxoma is another lesion where the tumor has not been reported to "get away" from the surgeon on recurrence. The goal of treatment should center on removal of medullary bone well past the radiographic borders. Recommenda-

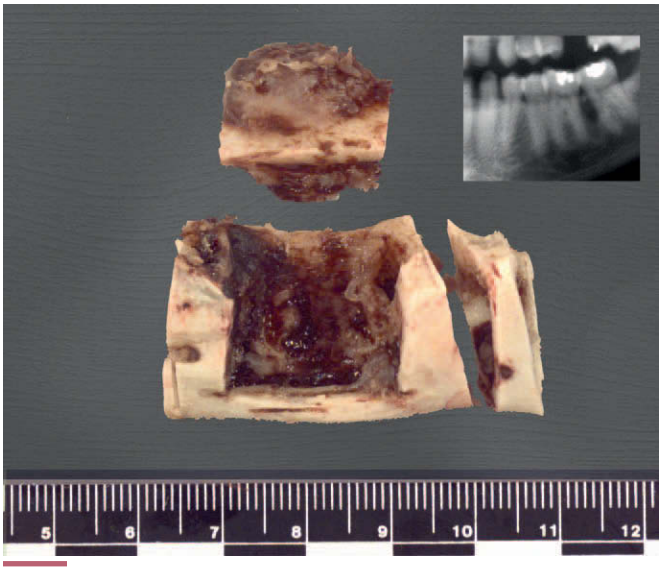

Figure 93-25. Although originally apparently small, intraoperatively gelatinous material was at resected margins, which necessitated successive removal of additional bone. Gelatinous material is not well seen on these fixed specimens.

tions of how much medullary bone to remove vary,[271,275] but 0.5 to 1 cm of medullary bone removal appears to be prudent. Removal of cortical bone in areas of penetration is also recommended. Recurrence rates can vary significantly from case to case and often show a direct correlation with the size of the lesion at initial diagnosis. Large and clinically aggressive tumors may necessitate segmental resection. In such cases the surgery is derived not from the diagnosis but by the nature of the lesion at hand. Intraoperative radiographs as described in treatment of ameloblastomas are also appropriate. Confirmation of margins histopathologically is also essential before reconstruction. Grossly the gelatinous material may also be easily seen at resected margins intraoperatively (Fig. 93-25).

Adenomatoid Odontogenic Tumor

The adenomatoid odontogenic tumor is a relatively infrequent odontogenic tumor that has vague histologic similarities to ameloblastoma. Unfortunately the histologic similarity led to past nomenclature as adenoameloblastoma or ameloblastic adenomatoid tumor. The vague microscopic similarity is this tumor's only similarity with that more aggressive tumor. Clinically the adenomatoid odontogenic tumor is by far the most innocuous odontogenic tumor, at least if the odontoma is considered a hamartoma. It appears that the tumor derives from the enamel organ epithelium but may arise from dental lamina rests. Though the actual ratio varies slightly by report, the adenomatoid odontogenic tumor is often known as the *two-thirds tumor* because it occurs two thirds of the time in females and two thirds of the time in the maxilla. Two thirds of the time this tumor is associated with impacted teeth (especially the canine), and two thirds of these tumors are found in teenagers. It is unusual in patients older than 30 years of age. Occasionally an adenomatoid odontogenic tumor arises peripherally within the gingiva. It is most often discovered radiographically when exploring the reason that a canine has not erupted long after its contralateral partner.[97,276-279]

Radiographic Features

The adenomatoid odontogenic tumor usually presents as a unilocular radiolucency with a sharp, circumscribed border. The border is well corticated to sclerotic. It is often associated with an uninterrupted tooth. The radiographic feature of the tumor blending with a follicle can sometimes be confused radiographically with a dentigerous cyst. Although purely radiolucent lesions are most common, this is another one of the classic radiolucent/radiopaque lesions of the jaws.

Microscopic Features

The tumor consists predominantly of spindle-shaped epithelial cells that form whorled masses or rosettes in a scant fibrous stroma. Ductlike structures lined by cuboidal or columnar epithelial cells are the classic histopathologic feature. Foci of amyloid, if present, are usually seen in the rosette/adenomatoid arrears. Other mineralized material may also be seen. These mineralizations are usually not well organized but may resemble dentin, cementum, or aborted attempts at enamel production.[280-282] Cystic spaces are also common. Some may be true luminal surfaces, though the largest surface lumen is probably adjacent to the tooth crown.

Treatment

These lesions are very well encapsulated and therefore easily enucleated. Aggressive behavior is never anticipated and recurrence is not a problem, though large lesions have been reported.[276] The lesion can be enucleated and the tooth can be left in place for eventual eruption or orthodontic therapy.

Odontomas

Odontomas are the most commonly diagnosed odontogenic tumors. They are considered by many to be a hamartoma rather than a true neoplasm. Odontomas are subdivided into two subtypes: complex and compound odontomas. Complex odontomas, when fully developed, consist almost entirely of intermingled aggregates of enamel, enamel matrix, dentin, and cementum arranged in a haphazard manner. Compound odontomas consist of enamel matrix, dentin, and cementum. Unlike the complex odontoma, the mineralized elements are organized with the overall appearance suggestive of multiple small, malformed, but easily identifiable teeth. These toothlike elements can easily be seen at the grossing table. Some epithelial elements may be seen peripherally. These epithelial cells represent the reduced enamel epithelium from which the hard tissues were formed. Odontogenic rests are also seen peripherally. Just as with an unerupted tooth, these epithelial linings and rests may lead to formation of dentigerous cysts. Likewise, any odontogenic cyst or tumor may also develop in association with an odontoma. Complex and compound odontomas occur with equal frequency and some lesions show features of both subtypes. Depending on size and location, they may deform adjacent teeth or delay eruption.[97,283,284]

Radiographic Findings

Both complex and compound odontomas show a well-demarcated radiolucency with a uniform corticated border delineating the lesion from surrounding bone. This has been described as a well-defined central radiopacity(s) surrounded by a thin radiolucent line surrounded by a thin radiopaque line. This is exactly the description of an erupting tooth. Centrally, there are differing brightness values associated with the radiopacities. The variation is due to the fact that enamel is more radiopaque than the dentin and cementum. Dentin and cementum cannot be differentiated radiographically. Compound odontomas will be a "sack of teeth," and complex odontomas will be a disorganized aggregate.

Microscopic Findings

Complex odontomas, when mature, consist almost entirely of a conglomeration of dentin, cementum, and enamel matrix. Following demineralization, the areas of mature enamel are lost and appear as empty spaces. In complex odontomas only scant amounts of reduced enamel epithelium remain. Peripherally, follicular tissue and odontogenic rests are common. During the demineralization process necessary for routine microscopic sectioning, the enamel portion of the specimen will be reduced to a retracted and fragmented, homogeneous, basophilic material. Less than 1% of the enamel is organic, and only this 1% is observed following demineralization procedures.

Treatment

Complex and compound odontomas are treated with simple enucleation and avoidance of damage to adjacent structures and teeth. If the term *never* can be used in health science, then odontomas never recur.

Squamous Odontogenic Tumor

This tumor is mentioned briefly because it is extremely rare with fewer than 100 ever reported. The lesions are generally small and usually present as "inverted" periodontal bone loss. Gingival tumors have also been described.[285,286] That is, in periodontal disease the triangular base is toward the cementoenamel juntion. In the squamous odontogenic tumor the base is toward the tooth apex. Familial and multifocal cases have been reported. Any portion of the tooth-bearing area may be involved, and the paucity of cases does not allow for much demographic analysis. The importance of the tumor is that the squamous epithelial islands seen microscopically may be misinterpreted. The squamous islands are cytopathologically totally benign. Yet their presence deep in connective tissue may be misinterpreted as invasion. The invasive appearance may lead to misdiagnosis as either an acanthomatous ameloblastoma or, worse, a squamous cell carcinoma. Tumors are easily treated with enucleation and simple conservative curettage.[286-289] Squamous, odontogenic, tumor-like proliferations are well known as being occasionally associated with inflammatory odontogenic cysts. These proliferations are inconsequential and do not warrant additional treatment or diagnostic proclamation.[290-292]

Odontoameloblastoma

Controversy surrounds the definition of odontoameloblastoma, and several lesions have likely been described under this designation. One subset of lesions given the moniker of odontoameloblastoma most likely represents an ameloblastoma arising from the epithelial elements of an odontoma. Other reports describe aggressive, large tumors that would be difficult to separate histologically from an "aggressive" ameloblastic fibro-odontoma.[293-295] One report of dentinoid production with an ameloblastoma could be an additional subset.[296] LaBriola and colleagues[297] also reviewed the difficulties associated with this diagnosis and reported one case, as did other researchers.[298,299] Generally these tumors define themselves by their destructive and/or recurrent behavior. Because of difficulties in histologic criteria, the diagnosis should always be made in consultation with a pathologist well versed in head and neck/oral pathology.

CHAPTER NINETY-FOUR

Temporomandibular Joint Disorders

Bruce E. Rotter

Key Points

- Temporomandibular disorders is a collective term describing both intracapsular disorders and muscular disorders, or myofascial pain dysfunction.
- The general presenting complaints of temporomandibular disorders include facial pain, earache, and headache.
- The temporomandibular joint (TMJ) is a diarthrotic joint, with each joint incapable of independent movement.
- The TMJ is a ginglymoarthrodial joint, capable of both translational and rotational movement.
- TMJ dislocation occurs when a hypermobile joint translates anterior to the articular eminence and becomes locked in that position.
- The primary intracapsular disorders of the TMJ are (1) anteriorly displaced disk with reduction, (2) anteriorly displaced disk without reduction, and (3) degenerative disease.
- Anteriorly displaced disks (ADDs) are typically caused by frequent episodes of microtrauma such as clenching or grinding the teeth.
- ADDs with reduction are typically characterized by clicking or popping sounds on mouth opening. ADDs without reduction are typically characterized by a closed lock.
- Degenerative joint disease (DJD) is the most frequent abnormal condition affecting the TMJ.
- Absolute indications for TMJ surgery include treatment of neoplasms, growth abnormalities, and ankylosis of the joint.
- Relative indication for TMJ surgery is treatment of pain and dysfunction, which is refractory to nonsurgical therapy where there is confirmatory imaging evidence of pathology.
- Myofascial pain dysfunction (MPD) syndrome is a muscular disease that is believed to be induced by stress and muscular hyperactivity from parafunctional habits.

Temporomandibular disorders, or TMDs, is a collective term that has been used traditionally to describe multiple disorders. These include both intracapsular disorders, or true abnormalities of the temporomandibular joint (TMJ), and muscular disorders, or myofascial pain dysfunction syndrome (MPD). Additionally, some disorders have not been considered under the umbrella of TMD but either directly or indirectly affect the structures of the TMJ. Examples of these disorders are congenital and developmental deformities, trauma, and neoplastic disease.

The general presenting complaints of the temporomandibular disorders include facial pain, earache, and headache. Therefore it is important for otolaryngologists to be familiar with the diagnosis and treatment of these various conditions. Much of the difficulty encountered in the treatment of TMDs relates to the failure to distinguish between these disorders and other causes of head and facial pain because of the similarity of the signs and symptoms with which they present. The emphasis in this chapter is on the diagnosis of TMDs, with a subsequent discussion of what is known about the etiology of the various conditions, forming the basis for a rational approach to therapy.

Anatomy

The anatomy and function of the TMJ are unique in several ways. The TMJ is a diarthrotic joint. Because the mandible is hinged at both ends, each joint is incapable of independent movement. This is clinically important because dysfunction in one joint can adversely affect the function of the contralateral joint, producing bilateral symptoms.

Each individual joint consists of the condylar process of the mandible, which is housed within the glenoid fossa of the squamous portion of the temporal bone. The anterior wall of the glenoid fossa is formed by the articular eminence, which is the articulating counterpart to the condylar process. The articulating surfaces are lined with fibrous connective tissue and are enclosed by a fibrous capsule.

Interposed between the articulating surfaces of the TMJ is the articular disk. The disk is a unique structure that is concavo-convex on its superior surface and concave on its inferior surface, where it contacts the convex condylar head. The presence of the articular disk divides the joint into two distinct compartments and contributes to the dual action of this ginglymoarthrodial joint. The inferior compartment, or inferior joint space, allows for purely anterior and posterior rotational movement between the condyle and disk. The superior joint

space allows for translational movement between the disk and the glenoid fossa and articular eminence. In addition to assisting movement within the joint, the disk acts to compensate for any incongruencies between the articular surfaces and acts as a shock absorber within the joint.[1]

The degree of condylar movement is governed by the limiting actions of the joint capsule, the articular disk, and the joint ligaments. The primary ligaments of the TMJ are the lateral, sphenomandibular, and stylomandibular ligaments. The relationship of the articulating components of the joints is also influenced by the presence of the teeth. When the mouth is in an open position, the degree and direction of movement of the joints are influenced by the components discussed earlier. However, when the teeth come into contact, this occlusal relationship determines the final position of the condyle with respect to the rest of the joint. This factor becomes increasingly important in individuals who exhibit occlusal disharmony or parafunctional habits.

Diseases and Disorders

The TMJ is susceptible to the same conditions that affect other joints in the body such as congenital and developmental anomalies, traumatic injuries, dislocations, internal derangements of the articular disk, ankylosis, various arthritic conditions, and, rarely, neoplastic diseases (Table 94-1). Although many of these conditions are treated in the same manner as in other joints, the previously described anatomic and functional differences of the TMJ often require some variations of therapy.

Congenital and Developmental Anomalies

Because the condyle has an important role in mandibular growth, congenital and developmental anomalies such as condylar agenesis, condylar hypoplasia, or condylar hyperplasia can produce severe facial deformity. It is important to diagnose and treat these conditions early in order to limit the degree of mandibular, as well as compensating, facial deformity. However, examination of the current concepts regarding the diagnosis, preparatory treatment, and surgical therapy of the dentofacial deformities is beyond the scope of the current discussion. The reader is encouraged to explore the many good publications that thoroughly discuss orthognathic surgery.[2-10]

Trauma

The condyloid process and, more specifically, the condylar neck is one of the most frequent sites of fracture after trauma to the mandible. Condylar or subcondylar fractures will usually produce preauricular pain and tenderness, difficulty in opening the mouth, and malocclusion. Unilateral fracture will produce jaw deviation to the affected side on attempted mouth opening. Bilateral fractures frequently produce an anterior open bite due to loss of structural support in the ascending ramus.

Treatment of condylar and subcondylar fractures varies on the basis of multiple factors. Nondisplaced fractures with minimal dysfunction may be treated with soft diet and guiding elastics. Moderate changes in occlusion or function may require short-term maxillomandibular fixation. In situations where the malposed segment is significantly displaced or interferes with jaw function, there are no occluding teeth on the involved side, or the condyloid processes are fractured bilaterally and grossly displaced, open reduction should be performed.[11] Additional considerations for open reduction are the inability to perform maxillomandibular fixation and the presence of concomitant fractures in the mandible, maxilla, or midface.

Dislocation

Dislocation occurs when the hypermobile mandible becomes fixed in an open position with no or only the most posterior teeth contacting. Acute dislocation occurs when the condyle translates anterior to the articular eminence and becomes locked in that position. It is treated with manual reduction by applying downward pressure on the posterior mandible while placing upward and backward pressure on the chin. This manipulation is supplemented by the use of local anesthesia, intravenous sedation, or general anesthesia. Postreduction, the patient should restrict mandibular opening for 2 to 4 weeks. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be prescribed for control of pain and inflammation.

Dislocation that is chronic can be treated by injection of a sclerosing agent into the TMJ capsule and lateral ligament to produce scarring of the stretched tissues,[12] capsulorrhaphy, lateral pterygoid myotomy, temporal myotomy, or condylectomy.[13] Decision as to the appropriate surgical procedure is based on the etiology, severity, and persistence of the dislocation.

Neoplasms

Primary neoplasms originating in the TMJ are extremely rare. Chondroma, osteochondroma, and osteoma are examples of benign tumors affecting the TMJ. Malignant tumors, which are even more uncommon, include fibrosarcoma, chondrosarcoma, and multiple myeloma. Direct extension of neoplasms from adjoining tissues and metastasis from distant neoplasms have been reported.

Tumors of the TMJ cause joint pain, restriction of opening, and malocclusion. Radiographic examination may demonstrate radiolucent, radiopaque or mixed lesions. Biopsy is necessary to establish a definitive diagnosis. Surgery is the treatment of choice for both benign and malignant neoplasms. Most malignant neoplasms that affect the TMJ are not radiosensitive, so radiotherapy is generally not considered.

Intracapsular Disorders

Intracapsular disorders of the TMJ include the following: (1) anterior disk displacement with reduction on opening the mouth, (2) anterior disk displacement without reduction, and (3) degenerative joint disease.

Anterior disk displacement is typically caused by trauma. This may be a single, macrotraumatic event or, more likely, frequent episodes of microtrauma that occur over a prolonged period. The majority of microtraumatic events are the parafunctional habits such as tooth clenching or grinding, which is also known as bruxism.[14]

Anterior Disk Displacement with Reduction

Anterior disk displacement *with* reduction is typically characterized by clicking or popping sounds on mouth opening (Fig. 94-1). Reciprocal or closing clicks are not consistently present. Patients who present with anterior disk displacement with reduction generally exhibit a normal range of mandibular motion. There may or may not be pain associated with mandibular movement. Multiple studies have shown that asymptomatic anterior displacement with reduction is common and often persists for years without signs of progression.[14-16] It is believed that these asymptomatic, nonprogressive cases represent physiologic accommodation of the joint.[17] They require no treatment. When pain is present, it is the general determinant of any functional limitation that exists. Treatment of these painful joints consists of soft diet, self-limitation of opening, NSAIDS, splint therapy, and physical therapy. Patients refractive to these conservative modes of therapy may be candidates for more invasive procedures such as arthrocentesis, arthroscopy, or open joint surgery.

Anterior Disk Displacement without Reduction

Anterior disk displacement *without* reduction is characterized by a closed lock (Fig. 94-2). In the nonreducing joint, forward translation of the condyle on mouth opening forces the disk anteriorly, causing it to become a physical impediment to further opening. The maximum interincisal opening (MIO) is generally only 25 to 30 mm, and the mandible deviates toward the affected joint. Lateral excursive movements of the mandible are generally restricted to the contralateral side but not to the ipsilateral side. Pain is a common symptom, particularly on forced opening (beyond the MIO).

Acutely displaced disks without reduction can often be successfully treated by manual manipulation of the mandible with coincident reduction of the disk. In chronic conditions, manual reduction is much less likely to lead to satisfactory reduction of the disk. This is generally due to loss of disk morphology. Patients who exhibit a chronically nonreducing disk should be initially treated with a stabilization splint in order to reduce the pressure on the retrodiskal tissues produced by

Table 94-1

Differential Diagnosis of Temporomandibular Joint Disorders

Disorder	Pain	Limitation	Diagnostic Features
Agenesis	No	Yes	Congenital; usually unilateral; mandible deviates to the affected side; unaffected side long and flat; severe malocclusion; often ear abnormalities; radiograph shows condylar deficiency
Condylar hypoplasia	No	No	Congenital or acquired; affected side has a short mandibular body and ramus, fullness of face, deviation of the chin; body of the mandible elongated and face flat on the unaffected side; malocclusion; radiograph shows condylar deformity, antegonial notching
Condylar hyperplasia	No	No	Facial asymmetry with deviation of chin to the unaffected side; cross-bite malocclusion; prognathic appearance; lower border of the mandible often convex on the affected side; radiograph shows symmetric enlargement of condyle
Neoplasia	Possible	Yes	Mandible may deviate to the affected side; radiographs show enlarged, regularly shaped condyle or bone destruction depending on the type of tumor; unilateral condition
Infectious arthritis	Yes	No	Signs of infection; may be part of systemic disease; radiographs may be negative early, but later can show bone destruction; fluctuance may be present; pus may be obtained on aspiration; usually unilateral
Rheumatoid arthritis	Yes	Yes	Signs of inflammation; findings in other joints (e.g., hands, wrists, feet, elbows, ankles); positive laboratory tests; retarded mandibular growth in children; anterior open bite in adults; radiograph shows bone destruction; usually bilateral
Traumatic arthritis	Yes	Yes	History of trauma; radiograph negative except for a possible widening of joint space; local tenderness; usually unilateral
Degenerative arthritis	Yes	Yes	Unilateral joint tenderness; often crepitus; temporomandibular joint may be the only joint involved; radiograph may be negative or show condylar flattening, lipping, spurring, or erosion
Ankylosis	No	Yes	Usually unilateral but can be bilateral; history of trauma may exist; young patient may show retarded mandibular growth; radiographs show a loss of normal joint architecture
Internal disk derangement	Yes	Yes	Pain exacerbated by function; clicking on opening, or opening limited derangement to under 35 mm with no click; positive arthrographic or magnetic resonance imaging findings; history of trauma may exist; usually unilateral

masticatory and parafunctional forces. When pain is a significant component of this disorder, more aggressive or invasive procedures may be indicated.

Degenerative Joint Disease

Degenerative joint disease or degenerative arthritis is the most frequent abnormal condition affecting the TMJ. Primary degenerative arthritis is seen in older persons and is associated with normal aging. Symptoms are generally mild and rarely require treatment other than patient education and conservative homecare measures. Secondary degenerative arthritis is usually initiated by either macrotrauma or microtrauma. In the case of macrotrauma, the initial findings may be consistent with that of hemarthrosis and are initially characterized by TMJ pain, tenderness, and limitation of jaw movement. The radiograph may be negative or may show widening of the joint space caused by intra-articular edema or hemorrhage. Concomitantly, the teeth may exhibit a posterior open bite on the affected side. Degenerative arthritis caused by microtrauma is more common and is often the product of unresolved, nonreduced, anteriorly displaced disks. It produces more severe symptoms of pain and tenderness, clicking or crepitation, and limitation of jaw movement. The radiograph frequently will show flattening, lipping, osteophyte formation, or erosion of the articular surface of the condyle.

Treatment of degenerative joint disease includes administration of NSAIDs, soft diet, limited jaw movement, and use of a stabilizing bite splint to help reduce the effects of chronic clenching or bruxism. When nonsurgical management fails to relieve the symptoms, and when there is radiographic evidence of bony change on the articular surface of the condyle, surgical intervention may be indicated. This should involve removal of only the minimal amount of bone necessary to produce a smooth articular surface. Unnecessary removal of the entire cortical plate, as occurs with the so-called condylar shave or condylotomy, can lead to continued resorptive changes in some instances and should be avoided if possible.

Infectious arthritis is rare in the TMJ. It can be associated with a systemic disease or as an extension of a local infection. Clinically, there are typically signs of systemic disease and local signs of inflammation and limited jaw movement. Radiographic findings are initially negative

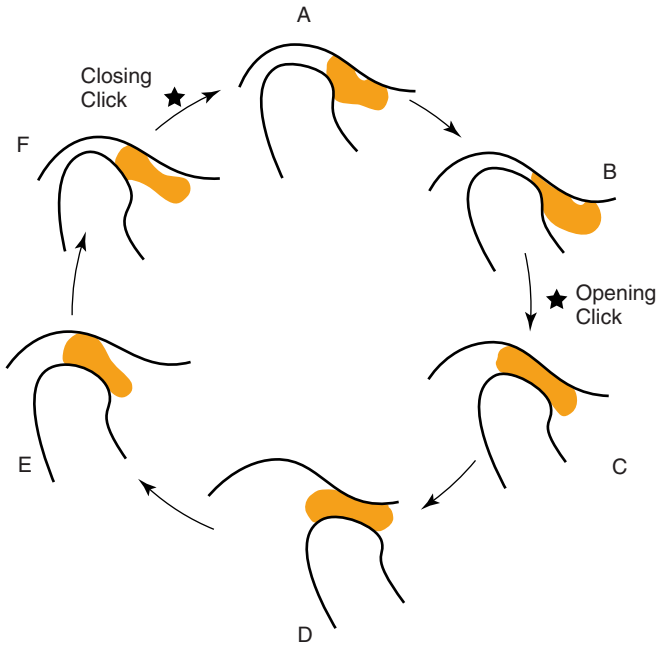

Figure 94-1. Anterior displacement of the intra-articular disk with reduction. Jaw closed; condyle seated in fossa with disk anteriorly displaced (*A*). Condyle beginning translation (*B*). Opening of the mouth (*C*). A clicking or popping sound occurs as the disk returns to its normal position in relation to the condyle. Condyle fully translated; disk in normal position (*D*). During closure, the disk again becomes anteriorly displaced, sometimes accompanied by a second sound (reciprocal click) (*E, F*). *(Modified with permission from McCarty W. Diagnosis and treatment of internal derangements of the articular disc and mandibular condyle. Figure 94-2. Anterior displacement of the intra-articular disk without reduction. Jaw closed; condyle seated in fossa with disk anteriorly displaced (*A*). Condyle beginning translation (*B*). Attempted mouth opening (*C*). The displaced disk acts as a barrier and prevents full translation of the condyle. Jaw closure; condyle returns to seated position in fossa (*D, E*). *(Modified with permission from McCarty W. Diagnosis and treatment of internal derangements of the articular disc and mandibular condyle. In: Solberg WK, Clark GT, eds.* Temporomandibular Joint Problems: Biologic Diagnosis and Treatment. *Chicago: Quintessence; 1980.)*

but may show extensive bone destruction later in the disease process. Treatment includes antibiotics, proper hydration, control of pain, and restriction of jaw movement. Suppurative infections may require drainage or sequestrectomy.

Rheumatoid arthritis occasionally can occur in the TMJ. It generally produces bilateral pain, tenderness and swelling, and limitation of jaw motion. In the early stages, the disease may not be radiographically evident, but with progression of the disease the articular surface of the condyle is destroyed and the joint space is obliterated. As a result, an anterior open bite can occur. There is a possibility for ankylosis of the joints to occur.

Treatment of rheumatoid arthritis in the TMJ is similar to that in other joints.[18] Anti-inflammatory drugs are used during the acute phases, and mild jaw exercises are used to prevent excessive loss of motion when the acute symptoms subside. In patients with severe cases, drugs such as steroids, disease-modifying antirheumatic drugs (DMARDs), immunosuppressants, interleukin-1 receptor antagonists, T cell inactivating drugs, and B cell inhibitors are also used to control the pain and inflammation. Surgery may be necessary if ankylosis develops.

Ankylosis

The most common causes of TMJ ankylosis are rheumatoid arthritis and traumatic injuries, although it also may result from congenital abnormalities, infection, or neoplasia. It is important to distinguish between true intracapsular ankylosis, which produces an abnormal condyle and fossa relationship, and false ankylosis, which involves extra-articular conditions such as enlargement of the coronoid process, depressed fracture of the zygomatic arch, or scarring from surgery or irradiation. In intracapsular ankylosis, radiographs usually show condylar deformity and either a narrowing or irregularity of the joint space.

In the surgical treatment of ankylosis, a cut is made through the condylar neck at the highest possible point on the ramus to maintain maximum ramal height and to minimize postoperative shift of the mandible. An interpositional material is placed in the newly created gap to prevent fusion of the bone ends. Patients must undergo long-term, aggressive physical therapy postsurgically in order to maintain the functionality of the newly formed joint.[19]

Temporomandibular Joint Surgery

As with many disorders, there are both absolute and relative indications for TMJ surgery. Absolute indications include treatment of neoplasms, growth abnormalities, and ankylosis of the joint. Relative indications for TMJ surgery tend to be nonspecific and lacking objective criteria. Experts generally agree that TMJ surgery is indicated to treat pain and dysfunction that is refractory to nonsurgical therapy where there is confirmatory imaging evidence of pathology.

Dolwick established criteria to guide the surgeon in determining the need and appropriateness of TMJ surgery[20]:

1. The more localized the dysfunction and pain are to the joint, the better the surgical prognosis. Localized, continuous TMJ pain that worsens with function or progresses through the day is an indication for surgical intervention. Patients who have pain that arises from a muscular source (myofascial pain dysfunction or MPD) or other nonintracapsular sources are not surgical candidates.

2. Surgery is indicated when TMJ pain or dysfunction is refractory to nonsurgical therapy. This nonsurgical therapy includes patient education, anti-inflammatory medication, physical therapy, occlusal therapy, and counseling. deBont and colleagues[21] suggest that surgical correction of intracapsular disorders should be considered only after reasonable nonsurgical efforts have failed and only when quality of life is significantly compromised. It should be noted that surgical correction of TMJ disorders is rarely performed in isolation; rather, it is supported by both presurgical and postsurgical therapy.

3. Imaging evidence should support the clinical findings. Imaging should not be used alone in diagnosis or as the primary determinant for surgical intervention.

Arthrocentesis

Arthrocentesis is the simplest and least invasive of the TMJ surgical procedures.[20] It is generally performed as an office-based procedure under intravenous sedation and local anesthesia. Arthrocentesis allows the surgeon to perform (1) TMJ lysis and lavage; (2) placement of anti-inflammatory medications into the superior joint space, although the benefit of injecting medication into the joint is still unproven; and (3) examination of the joint for range of motion under anesthesia.

The procedure is accomplished by inserting two 18-gauge needles into the superior joint space. The first needle serves as the injection port and the second as the outflow port. Injection of lactated Ringer's solution through this system provides lavage of the superior joint space, while blockage of the outflow port allows lysis of adhesions through distention of the superior joint space when coupled with concomitant mandibular manipulation.

Postoperative care consists of a nonchew diet for several days, range-of-motion exercises, and analgesics as needed. Multiple retrospective studies have indicated that arthrocentesis produces a 70% to 90% success rate in reducing TMJ pain and improving mandibular range of motion.[22-27] Arthrocentesis is not associated with any significant postoperative complications. Most patients note a temporary swelling and soreness in the TMJ region and exhibit mild posterior open bite, which is typically resolved within 24 hours.

Arthroscopy

Arthroscopy, like arthrocentesis, is a minimally invasive surgical procedure. Unlike arthrocentesis, it is generally accomplished in a surgical suite under general anesthesia. The procedure requires placement of a small surgical telescope into the superior joint space. A second access port is inserted anterior to the telescope. It acts primarily as an outflow port but can be used for instrument access to the superior joint space. The primary advantage that arthroscopy exhibits over arthrocentesis is the ability to visualize the anatomy and pathology of the superior joint space. Although more sophisticated operative procedures can be performed using the surgical telescope, most surgeons limit the use of arthroscopy to visualization of the superior joint space, lysis, and lavage.

Postoperative care is similar to that described for arthrocentesis. Multiple retrospective studies have indicated that the success rate for arthroscopic lysis and lavage approaches 80% to 90%.[28-33] In fact, Murakami and colleagues,[34,35] in both a 5-year and a 10-year follow-up, showed that lysis and lavage procedures were equally successful to open joint surgeries for all stages of internal derangement. Because the results of arthrocentesis parallel those achieved with arthroscopy and because it is a less invasive procedure, it has been suggested that arthrocentesis be attempted initially.[20]

Arthrotomy

Arthrotomy, or open joint surgery, encompasses a range of surgical procedures including débridement, disk repositioning or plication, diskectomy, arthroplasty, and joint replacement. Joints indicated for open joint surgery are those that exhibit an internal derangement or osteoarthritis that produces extensive mechanical interference with function or that have failed to respond to less invasive procedures.

The postoperative sequelae to arthrotomy are generally swelling at the surgical site, moderate discomfort, limitation of opening, and occlusal changes. These sequelae are transient and generally subside within 2 weeks of surgery. Patients often note preauricular numbness that may last 6 to 8 weeks. The most significant postoperative complication to arthrotomy is damage to the facial nerve. This occurs in only about 5% of surgical cases and most commonly affects the temporal branch of the nerve. In most instances this injury is self-limiting, but it has been shown to produce permanent deficit in less than 1% of cases.[20]

Variable success rates following open joint surgery have been reported in the literature, with many reports indicating a 80% to 95% success rate in reducing pain and restoring function to the joint.[36-42] It should be noted, however, that repeat surgeries show rapidly declining success rates.

Myofascial Pain Dysfunction Syndrome

MPD syndrome is a muscular disease that is believed to be multifactorial in origin.[43] It is generally accepted that centrally induced muscle tension from stress and anxiety combined with parafunctional habits such as clenching or grinding of the teeth results in abnormal muscle function and hyperactivity. This leads to fatigue and spasm of the muscles that ultimately produces pain and dysfunction. The pain stimulates muscle fibers to react, leading to further muscular dysfunction and spasm. Thus one can appreciate the cyclic nature of this disorder. Similar symptoms can also occasionally result from muscular overextension, muscle overcontraction, or trauma (Fig. 94-3).

MPD syndrome most frequently affects females in the 20- to 40-year age group. Men are much less affected, with a ratio of approximately 1:4. Children are rarely affected.

MPD syndrome is characterized by diffuse, poorly localized pain that ranges from complaint of preauricular pain to generalized pain throughout the muscles of mastication. The pain is often described as dull, aching, radiating pain that may be more severe in the morning. Patients also complain of pain and limitation of opening during function. The condition generally involves only one side of the face, and on examination, tenderness can usually be elicited in one or more of the muscles of mastication or their tendinous attachments.[44] Headache is frequently mentioned as a symptom. Ciancaglini and Radaelli[45] report a significant increase in headache in patients with TMD symptoms (27.4% vs. 15.2%). The only type of headache that is functionally related to MPD syndrome, however, is the tension-type headache, with other types being coincidental findings. The same is true for multiple complaints noted by MPD patients such as decreased hearing, tinnitus, burning tongue, and neuralgic pains. MPD syndrome that is left untreated can ultimately lead to organic changes in the TMJ and the masticatory muscles and may even cause alterations in the dentition.

The cardinal signs and symptoms of MPD syndrome are similar to those produced by intracapsular disorders, as well as by a variety nonarticular conditions (Tables 94-2 and 94-3). A careful history and thorough clinical evaluation should be performed to rule out these other clinical entities. Screening radiographs, particularly intraoral periapical films and a panoramic film delineating the structures of the jaws and the TMJ, can be helpful. If the screening views of the TMJ show some abnormality, tomographic views or CT scans are useful in further evaluating bony abnormalities. Magnetic resonance

Table 94-2

Differential Diagnosis of Nonarticular Conditions Mimicking Pain of Myofascial Pain Dysfunction Syndrome

Disorder	Limitation	Muscle Tenderness	Diagnostic Features
Pulpitis	No	No	Mild to severe ache or throbbing; intermittent or constant; aggravated by thermal changes; eliminated by dental anesthesia; positive radiograph findings
Pericoronitis	Yes	Possible	Persistent mild to severe ache; difficulty swallowing; possible fever; local inflammation; relieved with dental anesthesia
Otitis media	No	No	Moderate to severe earache; pain constant; fever; history of upper respiratory infection usually present; no relief with dental anesthesia
Parotitis	Yes	No	Constant aching pain, worse when eating; pressure feeling; absent salivary flow; ear lobe elevated; ductal suppuration
Sinusitis	No	No	Constant aching or throbbing; worse when head position changes; nasal discharge; often molar pain not relieved by dental anesthesia
Trigeminal neuralgia	No	No	Sharp stabbing pain of short duration; trigger zone; pain follows nerve pathway; older age group; often relieved by dental anesthesia
Atypical (vascular) neuralgia	No	No	Diffuse throbbing or burning pain of long duration; often associated autonomic symptoms; no relief with dental anesthesia
Temporal arteritis	No	No	Constant throbbing preauricular pain; artery prominent and tender; low-grade fever; possible visual problems; elevated sedimentation rate
Trotter's syndrome (nasopharyngeal carcinoma)	Yes	No	Aching pain in ear, side of face, lower jaw; deafness; nasal obstruction; cervical lymphadenopathy
Eagle's syndrome (elongated styloid process)	No	No	Mild to sharp stabbing pain in the ear, throat, or retromandible; provoked by swallowing, turning head, carotid compression; usually post-tonsillectomy; styloid process longer than 2.5 cm

From Laskin DM, Block S. Diagnosis and treatment of myofascial pain-dysfunction (MPD) syndrome. *J Prosthet Dent.* 1986;56:75.

imaging is valuable in evaluating soft tissue structures particularly when an internal derangement of the TMJ is suspected. In addition, certain laboratory tests may be helpful in some patients. These tests include a complete blood cell count if an infection is suspected; serum calcium, phosphorus, and alkaline phosphatase measurements for possible bone disease; serum uric acid determination for gout; serum creatinine and creatine phosphokinase levels as indicators of muscle disease; and erythrocyte sedimentation rate, rheumatoid factor, latex fixation, and antinuclear antibody tests for suspected rheumatoid arthritis. In patients suspected primarily of MPD syndrome, muscular function may be evaluated through electromyography. Many clinicians recommend psychologic evaluation, primarily to help determine patient compliance and to predict anticipated treatment outcomes.

Treatment

Laskin and Block[46] have delineated a treatment regimen for MPD syndrome and have divided it into four appropriate stages of therapy (Fig. 94-4). Their regimen remains an appropriate and timely course of therapy for MPD syndrome patients today and is as follows:

1. Once a definitive diagnosis is made, stage 1 therapy is started. This initially involves providing the patient with some understanding of the problem. Because patients often have difficulty accepting a psychophysiologic explanation for their condition, the discussion should deal with the issue of muscle fatigue and spasm as the cause of the pain and dysfunction, delaying consideration of the role of stress and psychologic factors until the symptoms have improved and the patient's confidence has been gained. Relating the symptoms to the specific masticatory muscles from which they originate helps the patient understand the reason for the type and location of the pain; for example, headache from the temporalis muscle, jaw ache from the masseter muscle, discomfort when swallowing and stuffiness in the ear from the medial pterygoid muscle, and earache and pain behind the eye from the lateral pterygoid muscle.

   In addition to the initial explanation, the patient is counseled regarding home therapy. Counseling includes recommendations about avoidance of clenching and grinding of the teeth; eating a soft, nonchew diet; use of moist heat on, and massage of, the masticatory muscles; and limitation of jaw motion. Because the patient has muscle spasm and pain, a muscle relaxant and an NSAID are prescribed. Diazepam and ibuprofen are commonly used.

2. About 50% of the patients will have a resolution of their symptoms within 2 to 4 weeks with stage 1 therapy. For those whose symptoms persist, stage 2 therapy is initiated. Home therapy and medications

Table 94-3

Differential Diagnosis of Nonarticular Conditions Producing Limitation of Mandibular Movement

Disorder	Pain	Muscle Tenderness	Diagnostic Features
Odontogenic infection	Yes	Yes	Fever; swelling; positive radiographic findings; tooth tender to percussion; pain relieved and movement improved with dental anesthesia
Nonodontogenic infection	Yes	Yes	Fever; swelling; negative dental findings on radiograph; dental anesthesia may not relieve pain or improve jaw movement
Myositis	Yes	Yes	Sudden onset; movement associated with pain; areas of muscle tenderness; usually no fever
Myositis ossificans	No	No	Palpable nodules seen as radiopaque areas on radiograph; involvement of nonmasticatory muscles
Neoplasia	Possible	Possible	Palpable mass; regional nodes may be enlarged; possible paresthesia; radiograph may show bone involvement
Scleroderma	No	No	Skin hard and atrophic; masklike facies; paresthesias; arthritic joint pain; widening of periodontal ligament
Hysteria	No	No	Sudden onset after psychologic trauma; no physical findings; jaw opens easily during general anesthesia
Tetanus	Yes	No	Recent wound; stiffness of neck; difficulty swallowing; spasm of the facial muscles; headache
Extrapyramidal reaction	No	No	Patient taking antipsychotic drug or phenothiazine tranquilizer; hypertonic movement; lip smacking; spontaneous chewing motions
Depressed zygomatic arch	Possible	No	History of trauma; facial depression; positive radiographic findings
Osteochondroma coronoid process	No	No	Gradual limitation; jaw may deviate to the unaffected side; possible clicking sound on jaw movement; positive radiographic findings

From Laskin DM, Block S. Diagnosis and treatment of myofascial pain-dysfunction (MPD) syndrome. *J Prosthet Dent.* 1986;56:75.

are continued, but at this point, a bite appliance is made for the patient. Although numerous types have been used, the Hawley-type maxillary appliance is probably most effective because it prevents contact of the posterior teeth and thereby also prevents most forms of parafunctional activity. Generally, the appliance is worn at night, but it can be worn for 5 to 6 hours during the day if necessary. It should not be worn continuously because the posterior teeth may supraerupt in some patients.

With stage 2 therapy, another 20% to 25% of patients will become free of symptoms in 2 to 4 weeks. The medications are stopped first, and wearing the bite appliance is discontinued next. If the patient has a return of symptoms when the appliance is not worn at night, its use can be continued indefinitely.

3. Patients who do not respond to the use of a bite appliance are entered into stage 3 of treatment for 4 to 6 weeks. In this phase, either physical therapy (e.g., ultrasound, electrogalvanic stimulation) or relaxation therapy (e.g., electromyographic biofeedback, conditioned relaxation) are added to the regimen. There is no evidence to show that one form of treatment is better than the other, and either can be used first. If one is not successful, the other can be tried. Stage 3 therapy usually helps another 10% to 15% of patients.

4. If all of the previous approaches fail and if there is no question about the correctness of the diagnosis, psychologic counseling is recommended. This involves helping patients identify possible stresses in their lives and cope with such situations. If there is doubt about the diagnosis, the patient should first be referred for appropriate dental and neurologic consultation and evaluation. Another alternative is to refer patients with recalcitrant MPD syndrome to a TMJ center or pain clinic because such patients generally require a multidisciplinary approach for successful treatment.

Summary

The successful treatment of patients with TMDs depends on establishing an accurate diagnosis. The clinician must distinguish among muscular disorders (MPD), true intracapsular TMJ disorders, and those disorders that are often not included under the TMD "umbrella," but which either directly or indirectly affect the structures of the temporomandibular joint. Only then can proper therapy, based on an understanding of the cause of the condition, be instituted. Of particular importance is understanding that not all TMD patients are surgical candidates. MPD syndrome patients do not benefit from surgical intervention and should not be considered for surgery. Even in those patients in whom surgical intervention is an acceptable alternative, many of the commonly encountered conditions such as arthritis and internal disk derangement respond well to nonsurgical or minimally invasive therapy. This type of treatment should be attempted before more aggressive surgical therapy is considered.

CHAPTER NINETY-FIVE

Benign Tumors and Tumor-Like Lesions of the Oral Cavity

Timothy S. Lian

Key Points

- Benign neoplasms of the oral cavity are typically best treated with complete surgical excision. Generally, recurrence is rare, as is malignant transformation.
- Treatment for tumor-like lesions involves either conservative medical management or surgical excision depending on the particular clinical entity.
- Development of aphthous ulcerations occur in up to 60% of the population of the United States. Ulcerations that persist beyond 2 weeks should be biopsied.
- Necrotizing sialometaplasia is a benign inflammatory condition of the minor salivary glands that has an appearance similar to that of malignancy. Biopsy is necessary to establish the correct diagnosis.

A plethora of conditions manifest themselves as tumor or tumor-like conditions that involve the oral cavity and oral pharynx. Conditions that more commonly appear and should be familiar to the otolaryngologist head and neck surgeon are presented in this chapter. For convenience, these nonmalignant entities are grouped into congenital, inflammatory/traumatic, and neoplastic conditions when formulating differential diagnoses.

Congenital Conditions

Torus

Torus palatinus and torus mandibularis represent developmental anomalies that usually present in the second decade of life and continue to grow slowly throughout life.[1] Tori present as mucosally covered bony outgrowths of the palate and mandible. Tori of the oral cavity occur in 3% to 56% of adults and are more common in women.[2,3] The tori of the palate are found only in the midline of the hard palate, whereas mandibular tori are found to involve only the lingual surface of the anterior mandible, primarily in the premolar region.[1,4] Tori are typically pedunculated or multilobulated, broadly based, smooth, bony masses (Fig. 95-1). They consist of dense lamellar bone with relatively small marrow spaces that do not involve the deeper cancellous bones of the mandible or palate. Patients with tori are usually asymptomatic, unless the torus interferes with denture placement or is repeatedly traumatized when the patient eats. In symptomatic patients, the tori can be treated by removing them from the underlying cortex with osteotomes or cutting burs. Recurrence is occasionally seen; however, malignant transformation has not been reported.

Lingual Thyroid

Approximately 90% of all ectopic thyroid tissue is associated with the dorsum of the tongue.[5] Presence of the lingual thyroid reflects the lack of descent of thyroid tissue during development. The lingual thyroid is found in the midline in the area of foramen cecum. The true incidence of lingual thyroid may never be known because this entity does not always result in clinical manifestations; however, studies involving neonatal screening for hypothyroidism revealed that approximately 1/18,000 to 1/100,000 live births were associated with ectopic thyroid tissue involving the tongue.[6,7] Although usually asymptomatic, the presence of lingual thyroid can be associated with hypothyroidism. Studies have shown that up to 70% of patients with a lingual thyroid also have hypothyroidism.[8] Other symptoms might also be related to the mass effect of the lingual thyroid and might cause airway obstruction and/or difficulties with swallowing. Patients may complain of dysphagia or the sensation of a lump in their throat. Less common complaints include dysphonia or bleeding. Symptoms may occur at times of increased metabolic demands such as growth spurts during adolescence or during pregnancy.[9] Malignant transformation is rare.[10] Treatment for hypothyroid patients involves thyroid replacement therapy, which may also reduce the size of the lingual thyroid and, in turn, reduce any obstructive symptoms. Treatment for symptomatic euthyroid patients typically involves surgical excision. A number of different approaches for surgical excision of lingual thyroid have been described and include transcervical routes by means of lateral pharyngotomy or transhyoid pharyngotomy, as well as transoral excision with use of the CO_2 laser.[11] One must be prepared to administer postoperative exogenous thyroid hormone replacement therapy because approximately 70% of patients will have the lingual thyroid as the only functioning thyroid tissue.[8]

Developmental Cysts

Congenital cystic conditions of the oral cavity and oropharynx are relatively rare. These usually include dermoid cyst, duplication cysts, and nasoalveolar cysts. Dermoid cysts are cystic masses found along embryonic fusion lines and form from epithelial rests.[12] Histologically, dermoid cysts are lined by squamous epithelium of the keratinizing variety. They contain elements of epidermal appendages including hair follicles, sweat glands, and connective tissue. Approximately 7% of

Figure 95-1. Torus palatinus.

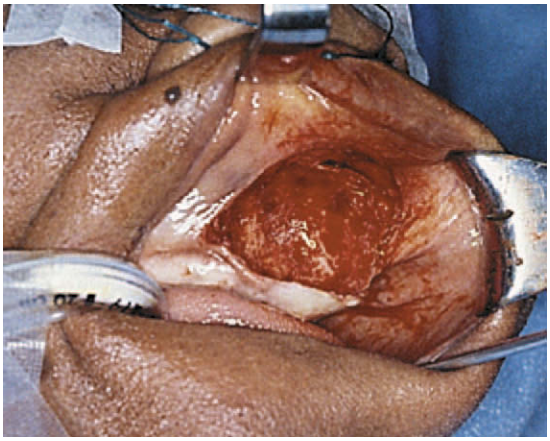

Figure 95-3. Remodeling of the maxilla associated with a nasoalveolar cyst.

Figure 95-2. Duplication cyst involving the tongue.

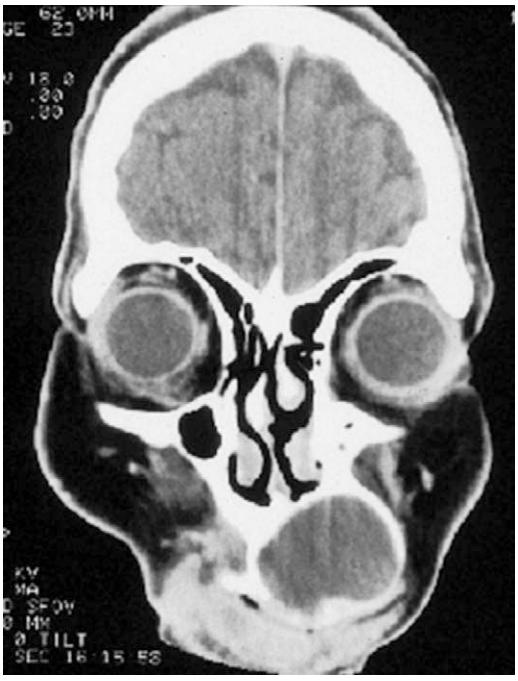

Figure 95-4. Sublabial approach to a nasoalveolar cyst.

dermoid cysts are found in the head and neck. Of these, 6.5% to 23% are found in the floor of the mouth.[13] Enteric duplication cysts are considered choristomas that contain elements of gastrointestinal mucosa.[14] The cysts are lined with stratified squamous and columnar epithelium. They are found anywhere along the digestive tract including the tongue and floor of the mouth. In the oral cavity, duplication cysts present at birth as an asymptomatic swelling involving the tongue and/or the floor of mouth (Fig. 95-2). As dermoid cysts and duplication cysts of the oral cavity enlarge, functional problems such as difficulties with deglutition, speech, and respiration can be expected to occur. Treatment for both dermoid cysts and duplication cysts requires complete excision of the cyst to include all epithelial components.

Nasoalveolar cysts are thought to originate from trapped nasal epithelium between the developing lateral and medial maxillary nasal processes. The manifestations of nasoalveolar cysts usually occur in adulthood as the cyst increases in size.[15] Patients typically present with swelling in the nasolabial area, which causes unilateral elevation of the nasal ala. Intraorally, a smooth, mucosal, covered mass in the gingival labial sulcus is seen. Remodeling of the anterior maxilla is also seen (Fig. 95-3). Treatment of nasoalveolar cysts involves complete excision, usually by a sublabial approach (Fig. 95-4). Care should be taken to repair any disrupted nasal mucosa such that the risk of postoperative oronasal fistula is diminished.

Inflammatory/Traumatic Conditions

Fibroma

Irritation fibroma is a common tumor-like condition of the oral cavity and oropharynx. It represents an inflammatory and fibrous hyperplastic response to chronic irritation or trauma. This entity should not be confused with true fibromatous neoplastic conditions such as fibrous histiocytoma, which is uncommon in the oral cavity and oropharynx. It is found in 1.2% of adults and has a 66% female predilection.[16] Although this condition can occur at any age, it usually becomes apparent during or after the fourth decade of life. The fibromas are usually solitary and seldom are larger than 1.5 cm. They characteristically present as an asymptomatic, sessile or pedunculated, firm mass involving typically the buccal mucosa and less commonly the labial, or tongue mucosa (Fig. 95-5). Histologically, fibromas are composed of dense and minimally cellular fascicles of collagen fibers and have a relatively avas-

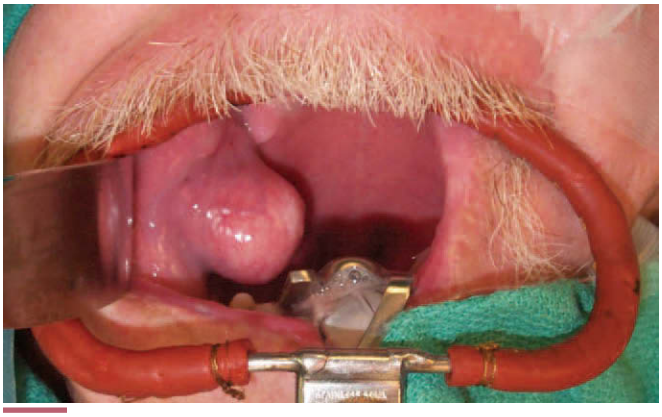

Figure 95-5. Fibroma involving the buccal mucosa.

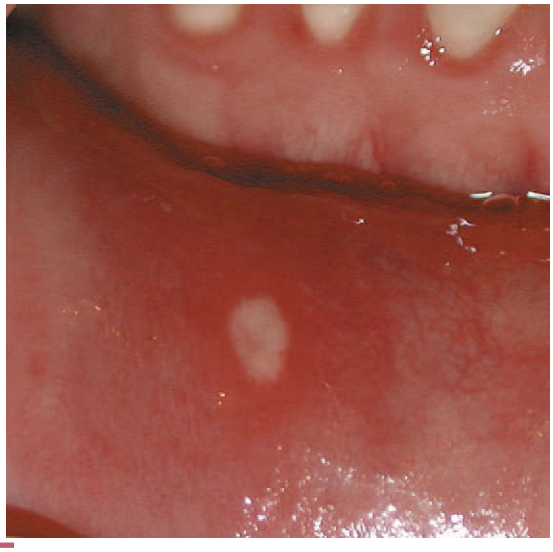

Figure 95-6. Aphthous ulcer with the characteristic erythematous halo surrounding a saucerized ulcer bed of fibrinoid necrotic debris.

cular appearance. Treatment is with conservative excision, and recurrence is unlikely, unless the precipitating trauma is continued or repeated.

Mucosal Ulcerations

Benign mucosal ulcerations can have the appearance similar to malignant lesions. Numerous local and systemic conditions can manifest themselves, in part, with benign mucosal ulcerations such as recurrent aphthous stomatitis, Crohn's disease, Behçet's syndrome, hematinic deficiency, or immunoincompetence. Likely the most common cause for benign ulcerations of the oral cavity and the oropharynx is recurrent aphthous stomatitis. Aphthae represent inflammatory mucosal ulcerations that occur in 20% to 60% of the U.S. population.[16] Development of aphthous stomatitis is thought to be related to cell-mediated mechanisms; however, the precise immunopathogenesis is unknown. Stress, local trauma, and/or allergy may play a contributory role in the development of aphthous ulcers. Characteristic features are a painful ulceration surrounded by an erythematous halo with a thin line of coagulation necrosis separating the halo from the saucerized ulcer bed of fibrinoid necrotic debris (Fig. 95-6). Immunoincompetent conditions do not produce the surrounding erythematous ring. Most aphthous ulcerations resolve without therapy within 10 days. Further workup for ulcerations that persist beyond 10 to 14 days should include tissue analysis. Further information pertaining to aphthous stomatitis can be found elsewhere in this text.

Figure 95-7. Pyogenic granuloma of the lateral tongue.

Pyogenic Granuloma

Pyogenic granulomas of the oral cavity and oropharynx can occur on any mucosal surface subject to acute or chronic trauma or infection.[17] Variants also arise in association with special events such as pregnancy or recent tooth extraction, resulting in epulis gravidarum and epulis granulomatosa, respectively. Most pyogenic granulomas involve the gingiva; however, other common sites include the labial mucosa, the buccal mucosa, and the tongue (Fig. 95-7). They typically present as raised or pedunculated lesions that remain less than 2.5 cm in size. They may bleed with minor trauma. Histologically, pyogenic granulomas consist of a rich profusion of anastomosing vascular channels in an edematous inflammatory and fibrosis stromal background. Lesions usually persist indefinitely, except for those associated with pregnancy. Treatment is by excision and removal of potential traumatic or infective factors.

Necrotizing Sialometaplasia

Necrotizing sialometaplasia is a self-healing, ulcerative, inflammatory reaction of unknown etiology. It has been postulated that it may be precipitated by local trauma that results in vascular compromise.[18] This entity typically arises from minor salivary glands and in 77% of cases involves the palate.[18] Most cases present with a painful ulceration and surrounding area of swelling that clinically stimulates a malignancy such as squamous cell carcinoma or mucoepidermoid carcinoma. Lesions are typically less than 2 cm. Histologic analysis is required to make the appropriate diagnosis. Light microscopy reveals lobar necrosis and sialadenitis mixed with squamous metaplasia of excretory ducts and acini. Pseudoepitheliomatous hyperplasia is usually seen in the associated surface epithelium, which may, due to sampling error, result in a pathologist reporting squamous cell carcinoma. Once definitively diagnosed, treatment is with supportive care because these lesions are self-limiting. Healing takes place within 3 to 6 weeks. Close follow-up during the healing process is necessary because necrotizing sialometaplasia can be found in conjunction with a malignancy.

Amyloidosis

Amyloidosis is a disorder that involves abnormal deposition of extracellular fibril proteins into tissues. Twenty-three different proteins have been identified in amyloidosis with each protein related to a particular clinical setting such as dialysis-associated amyloidosis (β_2-microglobulin), plasma cell disorders, (immunoglobulin light chains), or familial amyloidosis (transthyretin). The most common head and neck manifestation of amyloidosis is macroglossia (Fig. 95-8). Amyloid deposition can be such that the function of the tongue becomes limited, resulting in difficulties with speech and swallowing. The diagnosis is made by biopsy, which classically reveals intense green fluorescence also known as *apple green birefringence* with use of polarized light after Congo red staining. Treatment includes addressing the underlying cause of amyloid deposition if possible, as well as local excision in the case of

Figure 95-8. Amyloidosis of the tongue. Note the marked crusting and dryness of the exposed dorsum of the tongue.

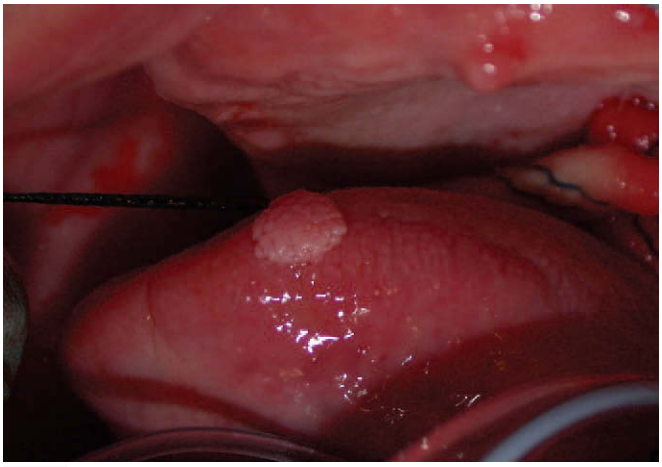

Figure 95-9. Squamous papilloma of the tongue.

macroglossia to include tongue reduction. Recurrences can be treated with further conservative resection.

Benign Neoplasms

Papilloma

Various unique squamous-derived entities of the oral cavity and oropharynx exist; however, one of the most frequently occurring conditions is squamous papilloma.[19] Approximately 4 out of 1000 adults in the United States have this condition of the oral cavity or oropharynx.[16] Squamous papillomas are most commonly associated with HPV-6 and HPV-11 virus subtypes.[19] Lesions typically present in adults and generally have a lower recurrence rate, are singular, and are less proliferative than squamous papillomas of other sites of the head and neck such as the larynx.[20] Development of precancerous proliferative verrucous leukoplakia within squamous papillomas is rare. Sites of occurrence typically involve the lingual, buccal, and labial mucosa, as well as the tongue (Fig. 95-9). Squamous papillomas typically present as a single, asymptomatic, soft, pedunculated mass with numerous finger-like projections at the surface. Histologically, the projections have fibrovascular cores and demonstrate a relatively narrow base. Treatment involves surgical excision or ablation with use of a CO_2 laser. Recurrence in the oral cavity or oropharynx is unlikely.

Figure 95-10. Granular cell tumor of the lingual dorsum.

Figure 95-11. Congenital epulis involving the maxillary gingiva.

Granular Cell Tumor

Granular cell tumors are commonly thought to be neural in origin. Granular cell tumors are usually diagnosed during or after the third decade of life. Although this entity can be found throughout the body, more than half of all cases occur in the oral cavity. Greater than a third of granular cell tumors involve the dorsum of the tongue. Other sites of occurrence include the soft palate, uvula, and labial mucosa.[16] Up to 15% of patients will have synchronous lesions. Granular cell tumors typically present as firm, painless, relatively immobile, sessile, nodular-appearing lesions less than 1.5 cm in greatest dimension (Fig. 95-10). Histologically, granular cell tumors show large polygonal, oval, or bipolar cells with abundant granular eosinophilic cytoplasm. Cells often appear in a ribbon pattern and extend to the surface epithelium and demonstrate pseudoepitheliomatous hyperplasia. The malignant variety of granular cell tumors represents approximately 1% of all cases. Surgical excision is the treatment of choice. Recurrence is less than 10%, even with a microscopically positive margin. Congenital epulis is the neonatal form of granular cell tumors. The congenital epulis is evident at birth and characteristically involves the maxillary gingiva (Fig. 95-11). Typically these unifocal growths measure no more than 2 cm, but they may interfere with feeding. Similar to the adult variant, treatment involves surgical excision, which can usually be performed at the bedside. Recurrence is rare.

Neurofibroma

Neurofibroma is the most common of the peripheral nerve neoplasms. The lesion is derived from a mixture of Schwann cells and perineural fibroblasts. Neurofibroma of the oral cavity and oropharynx is typically diagnosed in adolescents and young adults. The finding of multiple neurofibromas may be associated with von Recklinghausen's neurofi-

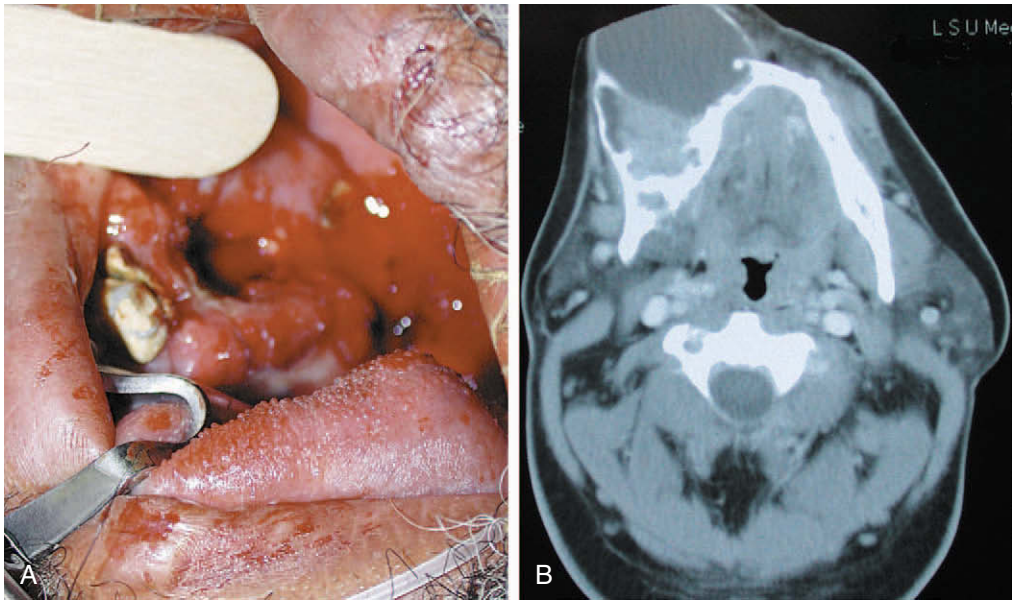

Figure 95-12. **A,** Ameloblastoma of the molar and ramus of the mandible. **B,** Bony infiltration and remodeling of the mandible as the result of ameloblastoma.

bromatosis (NF1). Approximately 70% of all cases of von Recklinghausen's neurofibromatosis involve the oral cavity, primarily the tongue. Solitary neurofibromas of the oral cavity usually involve the tongue, buccal, or labial mucosa[16] and present as soft, painless, slow-growing masses, but tender to pressure or palpation. Treatment ideally involves complete surgical excision. Solitary neurofibroma can be excised with relatively little risk of recurrence. Solitary neurofibromas rarely undergo malignant transformation into sarcoma; however, up to 15% of those with von Recklinghausen's neurofibromatosis develop a malignancy.

Lipoma

Lipoma is a relatively uncommon neoplasm of the oral cavity and oropharynx. Lipomas of the oral cavity and oropharynx usually occur after the third decade of life and present as a soft, slowly enlarging, mucosal-covered, smooth, painless mass. Lipoma is typically found in the buccal, lingual, or floor of mouth areas. Histologically, lipomas consist of mature adipocytes that are encapsulated and are typically clearly demarcated from surrounding tissues, although those that involve muscle can have an infiltrative appearance. Treatment of lipoma is surgical excision.

Hemangioma

Hemangioma of the head and neck is relatively common. Hemangioma of the oral cavity represents 14% of all hemangiomas.[16] Although usually present at birth with a rapid proliferative phase, they may become clinically evident later in life. They may be associated with a number of conditions including Sturge-Weber-Dimitri syndrome and von Hippel-Lindau syndrome. The lip is the most frequent site of hemangioma involving the oral cavity.[16] A mucosal hemangioma will present as a soft, painless mass that is red or blue. Hemangiomas are typically less than 2 cm in greatest dimension; however, they can become quite extensive to involve significant portions of the oral cavity and oropharynx to include the tongue. Hemangiomas tend to spontaneously regress over the years; however, there may be incomplete involution or associated fibrosis.[21] Hemangiomas that limit the form and function of the oral cavity and oropharynx are usually treated with conservative surgical excision. Recurrence or persistence is not unusual. Intralesional sclerosing agents, interferons, laser treatment, local and systemic steroids, and radiation have been reported as primary or adjunctive treatment with varying success.[21,22]

Ameloblastoma

Conditions of odontogenic origin can present as tumors or tumor-like conditions of the oral cavity. Ameloblastoma is the most common neoplasm of odontogenic origin. Ameloblastomas are thought to arise from rests of primitive dental lamina related to the enamel organ in alveolar bone. Patients are typically seen in the third decade of life with a painless mass involving the maxilla or mandible (Fig. 95-12A). In approximately 85% of cases, the mandible is involved, usually at the molar/ramus area.[23] Plain radiographic imaging usually reveals a unilocular or multilocular radiolucency. Cortical bone expansion can be seen (see Fig. 95-12B). Histologically, ameloblastomas are solid infiltrating tumors with a follicular or plexiform pattern, which exhibit an element of cystic change. Treatment for ameloblastoma is en bloc resection with at least 1-cm margins of normal-appearing tissue. The overall recurrence rate is 22%, with nearly half of all recurrences occurring within 5 years.[24] Lifelong follow-up is recommended. Malignant transformation can occur but is rare. Further information regarding ameloblastoma and odontogenic conditions can be found elsewhere in this text.

Pleomorphic Adenoma

Minor salivary glands are unencapsulated seromucinous glands located immediately beneath the mucosa throughout the oral cavity and oropharynx. Less than 10% of salivary gland tumors arise from minor salivary glands. Approximately 40% of tumors arising from minor salivary glands are benign.[25] Pleomorphic adenoma is the most frequently encountered benign tumor of minor salivary glands.[26] Other benign minor salivary gland tumors include canalicular adenoma, papillary cystadenoma, oncocytoma, and myoepithelioma. The most commonly occurring site of pleomorphic adenoma in the oral cavity is the hard palate (Fig. 95-13). Other presenting sites include the lip, buccal mucosa, alveolar ridge, floor of mouth, and tongue in decreasing order of frequency. Pleomorphic adenomas of the oral cavity tend to appear smooth and are relatively slow growing.

Treatment of pleomorphic adenomas of the oral cavity involves complete surgical excision. Unlike pleomorphic adenomas involving the parapharyngeal space, oral cavity pleomorphic adenomas are excised transorally. Because pleomorphic adenomas are encapsulated, complete excision makes recurrences rare. Excision typically involves both blunt and sharp dissection, although using the CO_2 laser as a cutting tool is also efficacious. Given their location in the oral cavity, intra-oral pleo-

Figure 95-13. Minor salivary gland pleomorphic adenoma of the retromolar trigone.

morphic adenomas can be identified before obtaining a relatively large size. Thus the resulting defect after excision can typically be addressed with local tissue rearrangement.

CHAPTER NINETY-SIX

Malignant Neoplasms of the Oral Cavity

Richard O. Wein

James P. Malone

Randal S. Weber

Key Points

- Early detection of oral cancer directly results in improved survival after treatment.
- Tobacco use and habitual alcohol consumption synergistically increase the risk of developing oral carcinoma.
- For most presentations of cancer of the oral cavity, the risk of occult spread to the regional lymphatics exceeds 20% and warrants elective treatment of the regional lymphatics.
- Functional recovery after a significant oral cavity resection depends on adequate mobility and bulk of the soft tissue components and frequently requires free tissue reconstructive techniques.
- For patients with advanced-stage oral cavity carcinomas (overall stage III or IV), combined modality treatment with surgical resection of the primary, neck dissection to address the regional lymphatics, and postoperative radiation (or chemoradiation) therapy is the treatment of choice.

The topic of malignant neoplasms of the oral cavity is synonymous with a discussion of oral squamous cell carcinoma. The oral cavity is unique in that, unlike other anatomic regions of the upper aerodigestive tract, the routine detection of early-stage lesions is possible. However, given the relatively common presentation of other benign pathology within the oral cavity such as aphthous ulceration, delay in diagnosis can occur.

Perhaps more so than in other sites within the head and neck, primary surgical management represents the treatment of choice for oral cavity malignancies. In assessing the treatment strategy, the surgeon attempts to maximize locoregional control of the tumor while respecting the potential functional impact of a procedure on speech and swallowing. The appropriate selection of reconstructive techniques that assist appropriate wound healing while maximizing the patient's capacity for oral rehabilitation requires a broad knowledge and experience with the options available.

Etiology

Tobacco and alcohol consumption are considered the most common preventable risk factors associated with the development of oral cavity squamous cell carcinoma. In addition, this relationship is synergistic, with alcohol serving as a promoter for the carcinogenic effects of tobacco. When compared with nonsmokers, smoking confers a 1.9-fold risk to males and 3-fold risk to females for development of head and neck squamous cell carcinoma. The risk is directly proportional to the years spent smoking and the number of cigarettes smoked per day. Alcohol alone confers a 1.7-fold risk to males drinking 1 to 2 drinks per day compared with nondrinkers. This risk rises to more than 3-fold for heavy drinkers. Individuals who both smoke (two packs per day) and drink (four units of alcohol per day) are 35 times more likely to develop cancer when compared with controls.[1] The reported incident rates of developing head and neck cancer based on smoking status are higher in males than females, respectively (nonsmokers 24.4:4.8, former smokers 36.9:17.2, and current smokers 147.3:75.7); however, hazard ratios suggest smoking leads to a higher proportion of females (12.96 for females, 5.45 for males) eventually developing head and neck cancer with the same risk exposure.[2] Users of smokeless tobacco have a 4-fold increased risk of oral cavity carcinoma compared with nonusers.[3]

Tobacco is the leading preventable cause of death in the United States and is responsible for one out of every five deaths.[4] As of 1999, approximately one quarter of U.S. adults used tobacco products (25.7% of males and 21.5% of females).[5] The evidence supporting the benefit for head and neck cancer patients to cease smoking is compelling. In a study by Moore, 40% of patients who continued to smoke after definitive treatment for an oral cavity malignancy went on to recur or develop a second head and neck malignancy. For patients who stopped smoking after treatment, only 6% went on to develop a recurrence.[6] Induction of specific p53 mutations within upper aerodigestive tract tumors has been noted in patients with a history of tobacco and alcohol use.[7]

When smoking status in patients with head and neck squamous cell carcinoma is assessed, differences exist between the two populations (smoker vs. nonsmoker). Koch and colleagues noted that nonsmokers were represented by a disproportionate number of women and were more frequently at the extremes of age (younger than 30 or older than 85 years of age). Tumors from nonsmokers presented more frequently in the oral cavity, specifically within the oral tongue, buccal mucosa,

Figure 96-1. Extensive floor of mouth squamous cell carcinoma extending to the mandible anteriorly.

Figure 96-2. Lower lip ulcerative squamous cell carcinoma extending toward the gingivobuccal sulcus.

and alveolar ridge. Smokers presented more frequently with tumors of the larynx, hypopharynx, and floor of the mouth (Fig. 96-1). Common genetic alterations such as loss of heterozygosity at 3p, 4q, and 11q13 and the overall number of chromosomal microsatellite (repeated base sequences) losses were significantly more likely in the tumors of smokers. In addition, the rate of p53 mutations was markedly increased in this group of patients.[8] Smoking and habitual use of alcohol have also been associated with p15 gene methylation.[9] Former smokers, defined as those individuals who had quit more than 10 years earlier, demonstrate a genetic profile more consistent with nonsmokers.[8] Additionally, multiple mesenchyme-associated, stroma-specific, genetic alterations may have a significant role in the development and progression of smoking-related head and neck cancers.[10]

In India and Southeast Asia, the product of the Areca catechu tree, known as a *betel nut,* is chewed in a habitual manner and acts as a mild stimulant similar to that of coffee. The nut is chewed in combination with lime and cured tobacco as a mixture known as a *quid.* The long-term use of the betel nut quid can be destructive to oral mucosa and dentition and has been demonstrated to be highly carcinogenic.[11] Another habit associated with oral malignancy is that of reverse smoking, where the lighted portion of the tobacco product is within the mouth during inhalation. The risk of hard palate carcinoma is 47 times greater in reverse smokers compared with nonsmokers.[12]

The human papillomavirus (HPV) is an epitheliotropic virus detected to varying degrees within samples of oral cavity squamous cell carcinoma. Infection alone is not considered sufficient for malignant conversion; however, results of multiple studies suggest a role of HPV in a subset of head and neck squamous cell carcinoma.[13]

Environmental ultraviolet light exposure has been associated with the development of lip cancer. The projection of the lower lip, as it relates to this solar exposure, has been implicated in the pathogenesis of squamous cell carcinomas arising on the vermilion border of the lower lip (Fig. 96-2).[14] Pipe smoking has also been associated with the development of lip carcinoma. Mechanical irritation, thermal injury, and chemical exposure are suspected etiologic factors contributing to lower lip cancer development in pipe-smoking patients.[15]

Other entities associated with oral malignancy include Plummer-Vinson syndrome (achlorhydria, iron deficiency anemia, and mucosal atrophy of the mouth, pharynx, and esophagus); chronic infection with syphilis; ill-fitting dentures; and long-term immunosuppression (30-fold increase with renal transplant). Although evidence linking HIV infection to squamous cell carcinoma of the head and neck is lacking, Kaposi's sarcoma may arise in the oral cavity.[16]

Molecular Biology

Tumor development represents the loss of multiple signaling mechanisms regulating the control of cell growth. After malignant transformation, the processes of replication (mitosis), programmed cell death (apoptosis), and the interaction of a cell with its surrounding environment are altered. Advances in molecular biology have allowed for the identification of many of the mutations associated with this transformation. Contemporary molecular analysis of tumors is providing insight into the processes of malignant transformation and tumor progression.

H-ras, a member of the ras gene family, encodes a plasma protein (p21), which has a role in the transduction of mitogenic signals to the intracellular environment. A synergism between H-ras and HPV is believed to play a role in the induction of squamous cell carcinoma. In human studies, 22% of oral squamous cell carcinomas expressed H-ras, whereas 11% expressed H-ras and HPV. All specimens of oral verrucous carcinoma that expressed H-ras (25%) demonstrated evidence of HPV DNA.[17]

HPV is a mucosotropic virus that has been closely associated with cervical carcinoma in women, such that HPV 16 and 18 are considered carcinogenic. In oral cavity specimens, variable detection has been reported with rates ranging from 19% to 78%.[18,19] Findings of HPV 16 within normal tissue at the margins of tumor specimens have suggested that infection is not a sole event preceding malignant transformation. Rather, it has been postulated that HPV may play a role in the early events of carcinogenesis. HPV oncoproteins E6 and E7 have the ability to bind and degrade tumor suppressor gene products of p53 and pRB, respectively. This binding can impair the capacity of the cell cycle to arrest for the repair of DNA damage and results in an accumulation of genetic changes assisting transformation.[13]

Smith and colleagues detected a significant increase in the presence of HPV DNA within oral cavity carcinoma samples (15%) compared with controls (5%). In addition, they noted that HPV (odds ratio [OR]-3.7) was a risk factor for carcinoma, independent of tobacco (OR-2.63) and alcohol use (OR-2.57).[20] Maden and coworkers noted an increased risk for oral cavity carcinoma with the presence of HPV 6 and HPV 16. Similar to Smith and colleagues, they also demonstrated HPV infection to be a risk factor, independent of age and tobacco and alcohol use.[21]

Costa and colleagues examined resectable oral cavity carcinomas for biomarkers predictive of chemosensitivity before primary surgical treatment. They found that tumors negative for glutathione S-transferase (GST-π) were more responsive to cisplatin and 5-fluorouracil than tumors that were GST-π-positive. They also noted that lack of bcl-2 expression was consistent with an improved 3-year disease-free survival. No relationship between p53 activity and chemotherapeutic response was observed.[22]

Overexpression of mutant p53 has been associated with carcinogenesis at multiple sites. Point mutations in p53 have been reported in up to 45% of head and neck carcinomas. Brennan and colleagues have evaluated the concept of primary site margin assessment of specimens on the basis of p53 staining to guide the need for further treatment.[23,24] Koch and others have noted that p53 mutation is a key event in the malignant transformation of greater than 50% of head and neck squamous cell carcinomas in smokers.[8]

Her2-Neu overexpression has been demonstrated in a subset of squamous cell carcinomas.[25] Expression of Her2-Neu and heat shock protein (HSP)-27 have been associated with regional treatment recurrence in patients with oral cavity and oropharyngeal carcinomas treated with primary radiotherapy.[26]

Koch's tumor progression model has demonstrated that 3p is a site of early loss of heterozygosity, 4q is a late event, and 11q13 is the site of the cyclin D1 gene. Reviews of the head and neck literature have suggested the role for p53, EGFR, TGF-α, and cyclin D1 in predicting clinical outcome for patients with squamous cell carcinoma.[27]

The Akt receptor has been correlated with the histologic progression of oral premalignant lesions to oral carcinoma. Massarelli and colleagues[28] demonstrated that phosphylated-Akt, when highly expressed, is associated with recurrence and shorter disease-free survival independent of a patient's overall staging.

Epidemiology

Oral cavity malignancies (excluding lip lesions) account for 14% of all head and neck cancers.[29] In a review (1985-1996) of the National Cancer Data Base (NCDB), patients diagnosed with an oral cavity cancer had a mean age at presentation of 64 years with a male predominance (60%). Squamous cell carcinoma (SCC) represented the majority of lesions (86.3%), and adenocarcinoma (5.9%), verrucous carcinoma (2.0%), lymphoma (1.5%), and Kaposi's sarcoma (1.5%) accounted for the remainder. At the time of diagnosis, 55% of patients had early-stage lesions (stage I-II). Patients 35 years old or younger were more likely to present with oral tongue SCC than older patients (76.1% vs. 33%) and less likely to present with a floor-of-mouth SCC (10.5% vs. 35.9%). Of note, the NCDB data did not reveal a poorer overall prognosis for those patients diagnosed at a younger age. In fact, younger patients demonstrated a better 5-year survival (63.7%) than older stage-matched patients (51% for 36 to 65 years of age and 47.6% for older than 65 years of age). Blacks and lower income patients more frequently presented with advanced-stage lesions. Five-year survival was found to be worse for males, blacks, and older patients (older than 65 years). Adenocarcinoma presented more commonly in women than men and was most frequently diagnosed on the hard palate.[30]

A study by Schantz and Yu[31] noted that the incidence for oral tongue carcinoma in patients younger than 40 years of age increased 60% from 1973 to 1984 and has since stabilized. During this same timeframe the incidence of carcinoma at all other oral cavity subsites remained constant or decreased.[32] The rise was related to patients born during the years 1938 to 1948. Despite this increase, the 5-year determinant survival of these patients was better than that for older individuals. Although the exact cause for the increase was considered unclear, etiologies of increased smokeless tobacco and marijuana use and human papillomavirus (HPV) infection were considered possible factors.[19]

Anatomy

Because of the pivotal role the oral anatomy has on articulation and deglutition, treatment of an oral malignancy can have a significant impact on a patient's quality of life. An understanding of the complex anatomic relationships among the salivary glands, maxilla, mandible, tongue function, and dentition are paramount to achieving satisfactory oncologic and functional results. The oral cavity extends from the vermilion border of the lip, posterosuperiorly to the hard palate–soft palate junction, inferiorly to circumvallate papillae (linea terminalis), and laterally to the anterior tonsillar pillars. It is divided into seven specific subsites. These subsites are the lips, dentoalveolar ridges, oral tongue, retromolar trigone, floor of mouth, buccal mucosa, and hard palate (Fig. 96-3).

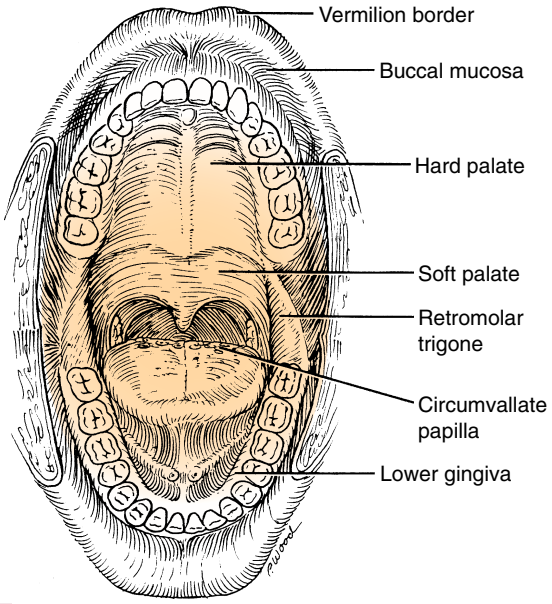

Figure 96-3. Overview of the oral cavity demonstrating the posterior boundary at the hard palate–soft palate junction and the location of the retromolar trigone relative to the inferior alveolar ridge.

The local, regional, and distant spread of oral cavity malignancies is dependent on the course of the neurovascular anatomy, lymphatic pathways, and the fascial planes of the head and neck. The latter serves as a barrier to the direct spread of tumor and can influence the pattern of local and regional lymphatic spread. In addition, perineural and angioinvasion can act as a conduit for the spread of head and neck malignancies. When present, these histologic findings can have a profound impact on the patient's prognosis and long-term survival.[33,34] Patients previously treated with either surgery or radiation for an oral malignancy may demonstrate atypical patterns of local invasion and regional spread of tumor.[35] A brief discussion of the vascular and lymphatic anatomy pertinent to the oral cavity while reviewing the unique attributes of the oral cavity subsites is necessary before considering diagnostic and treatment options.

Arteriovenous Anatomy

The arterial supply to the oral cavity includes multiple contributions from the external carotid artery. The lingual artery provides the majority of the vascular supply to the oral tongue and tongue base. Identification of the artery within the neck requires the exposure of the floor of the submandibular region. The artery is found deep to the hyoglossus muscle and requires the division of the muscle for maximal exposure. Superficial to the hyoglossus and deep to the mylohyoid muscle is the hypoglossal nerve and lingual veins (Fig. 96-4). An understanding of this relationship can aid in the localization of the artery when necessary for microvascular reconstruction or selective ligation. The vein, which closely approximates the nerve in this region, is prone to injury during dissection and necessitates care when attempting to obtain hemostasis if hypoglossal nerve injury is to be avoided.

The hard palate blood supply is derived from the greater palatine and the superior alveolar arteries. After branching off the descending palatine artery at the greater palatine foramen, in the region medial to the second maxillary molar, the artery runs anteromedially within the

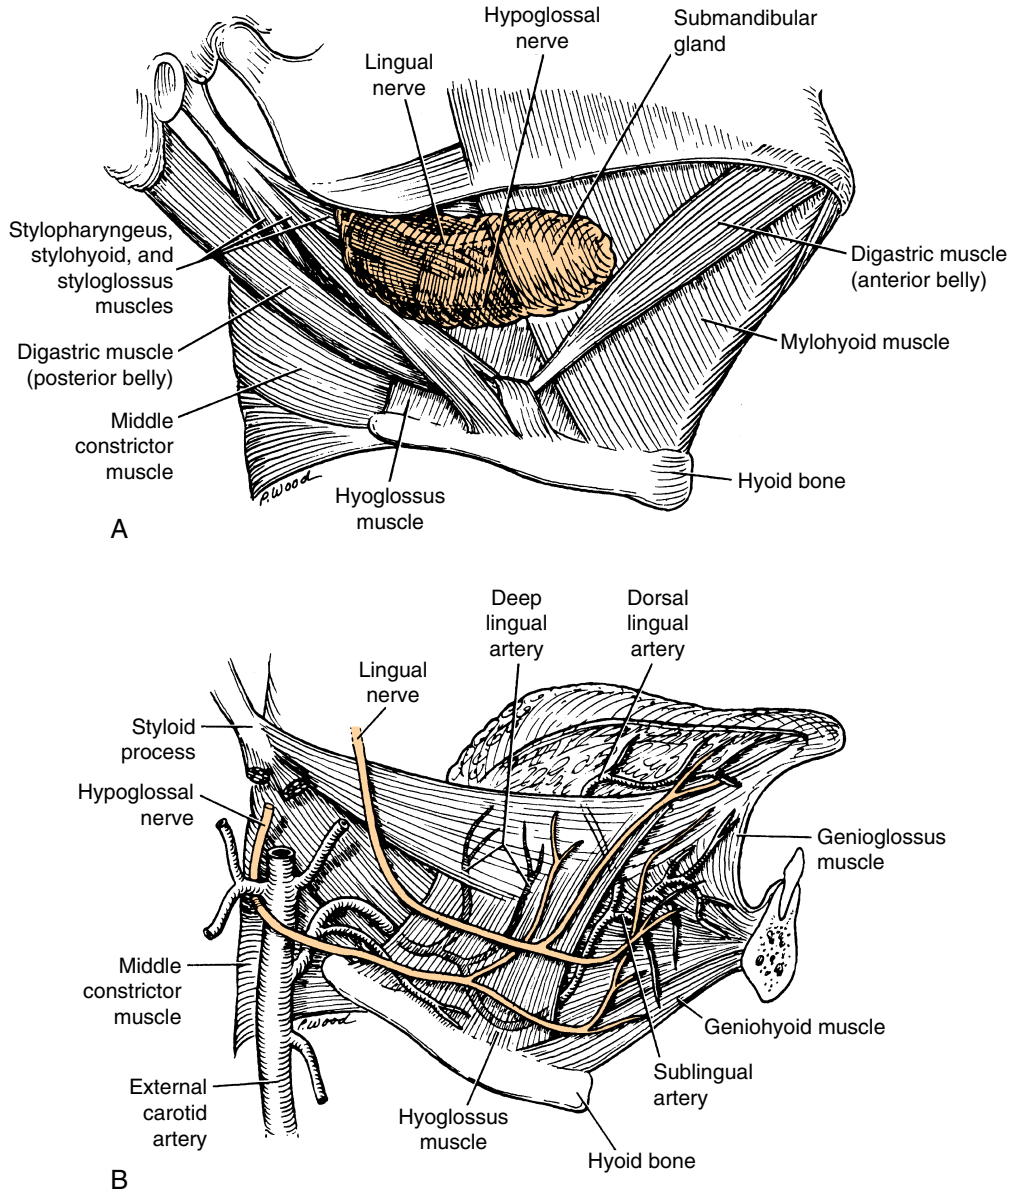

Figure 96-4. **A,** Musculature of the submandibular region and relationship of the lingual and hypoglossal nerves to the submandibular gland. **B,** Deeper anatomy of the submandibular fossa. The hypoglossal nerve runs deep to the mylohyoid muscle and superficial to the hyoglossus muscle. The lingual artery runs deep to the hyoglossus muscle and ascends to divide into deep and dorsal lingual arteries and the sublingual artery.

soft tissue of the hard palate (Fig. 96-5). The venous drainage is to the pterygoid plexus and subsequently to the internal jugular venous system. The superior alveolar arteries (anterior, middle, posterior) arise as terminal branches after the transition of the internal maxillary artery to sphenopalatine artery at the pterygopalatine fossa. These arteries provide blood supply to the maxillary gingiva, alveolar ridge, and dentition.

The facial artery crosses over the lateral aspect of the mandible approximately 1 cm anterior to the ascending ramus and courses toward the oral commissure where it gives rise to the labial arteries. These paired vessels are readily apparent during lip-splitting procedures and anastomose in the midline to create a vascular ring.

The primary vascular supply to the mandible and the lower dentition is from the inferior alveolar artery. Blood supply from the mandibular periosteum becomes more important with advancing age. The inferior alveolar artery, vein, and nerve enter the mandibular foramen along the medial aspect of the ramus of the mandible. Before their entry into the foramen, both the nerve and artery send off branches that extend anteriorly to supply the mylohyoid muscle.

The posterior floor of the mouth and retromolar trigone have an arterial supply and venous drainage similar to that of the anterior tonsillar region. The ascending pharyngeal and lesser palatine vessels contribute to the vascularity that may be encountered with surgical procedures at this site.

Subsites of the Oral Cavity

Lips

The lips represent a transition from external skin to internal mucous membrane that occurs at the vermilion border. The underlying musculature of the orbicularis oris, innervated by the facial nerve, creates a circumferential ring that allows the mouth to have a sphincter-like function. The sensation for the upper lip is supplied by the infraorbital nerve (CN V_2), whereas the lower lip is provided by the mental nerve

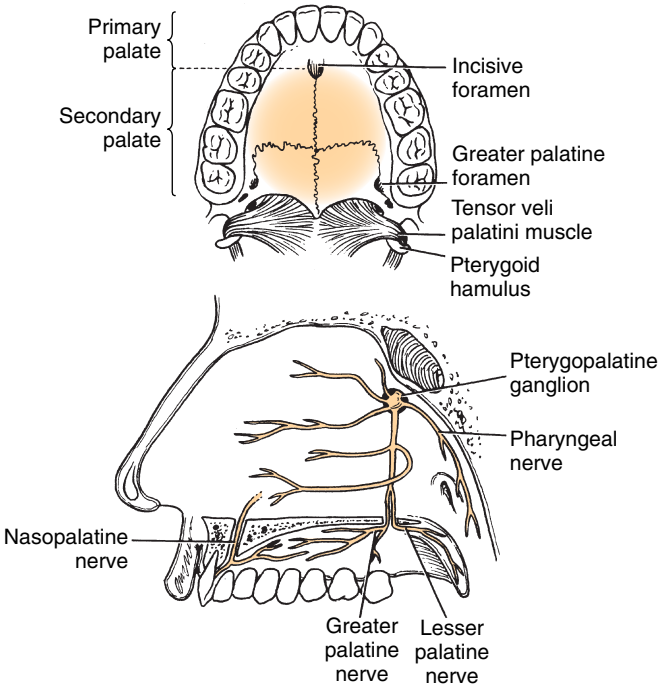

Figure 96-5. Primary and secondary portions of the hard palate. The relationship of the hard palate to the course of palatine nerves is important to consider when perineural invasion is suspected with squamous cell carcinomas or minor salivary gland malignancies in this region.

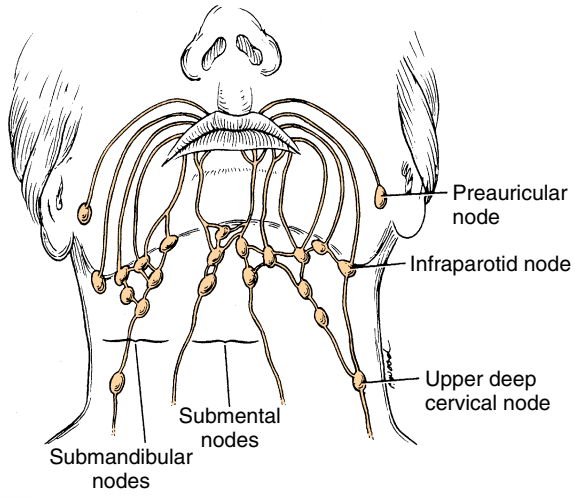

Figure 96-6. Lymphatic drainage pattern for the upper and lower lips.

(CN V_3). Lymphatics from both the upper and lower lips drain primarily to the submandibular lymph nodes, yet midline lower lip lesions may present with submental lymphatic spread. In addition, the upper lip may drain to preauricular, infraparotid, and perifacial lymph nodes (Fig. 96-6).

Alveolar Ridge

The lateral aspect of each alveolar ridge is represented by the mucosal sulcus created by the transition of tissue to buccal mucosa. On the lower alveolus, the medial margin is marked by the transition to the floor of the mouth and, on the upper alveolus, the transition is the horizontal orientation to the hard palate. The posterior margin of the lower alveolus is the ascending portion of the ramus of the mandible; whereas it is the superior aspect of the pterygopalatine arch for the upper alveolus. The close approximation of mucosa to underlying bone assists early bone invasion for malignant tumors in this region.

Oral Tongue

The oral cavity portion of the tongue is defined as that portion anterior to the linea terminalis. The tongue is composed of four intrinsic and four extrinsic muscles separated at the midline by the median fibrous lingual septum. The extrinsic muscles originate outside the substance of the tongue and include the genioglossus, hyoglossus, styloglossus, and palatoglossus. Of these, the genioglossus, which functions to depress and protrude, provides the majority of the bulk to the tongue. The paired intrinsic muscles of the tongue (superior-inferior longitudinal, transverse, and vertical) lie superficial to the genioglossus and function to alter the overall shape of the tongue. These muscles run with the tongue in three different orientations. This lack of distinct planes between muscles can allow for a diffusely infiltrating pattern of tumor growth. All of the musculature of the tongue derives its innervation via the hypoglossal nerve with the exception of the palatoglossus, which is supplied by a pharyngeal branch of the vagus nerve. The general sensory innervation of the anterior two thirds of the tongue is provided by the lingual nerve. It arises deep to the lateral pterygoid muscle, spirals from lateral to medial around the submandibular duct, and divides into several branches that lie in the submucosa of the oral tongue. The special sensory innervation of the oral tongue for taste is provided by the chorda tympani nerve (CN VII) that travels to the anterior tongue along with the lingual nerve. In contrast, both functions are performed by the glossopharyngeal nerve for the base of tongue.

The lymphatic drainage of the oral tongue varies by the region within the tongue. The tip drains preferentially to submental nodes, whereas the lateral tongue drains primarily to the levels I and II (Fig. 96-7). However, it is important to note that a defined lymphatic pathway from the lateral tongue does exist and drains directly to the level III/IV nodal group. The base of the tongue drains to the upper cervical lymphatics. The lack of anastomoses between the anterior tongue lymphatics results in lateralized oral tongue lesions tending to drain ipsilaterally. This is not the case with base-of-tongue lesions where crossover and bilateral cervical lymphatic spread may readily occur.

Retromolar Trigone

This region is represented by the mucosa overlying the ascending ramus of the mandible toward the coronoid process. It is continuous with the buccal mucosa laterally and the anterior tonsillar pillar medially. The superior extent is the maxillary tuberosity and the anterior margin is the posterior aspect of the second mandibular molar. The same considerations that were true for alveolar lesions exist for this anatomic site, given the close approximation of mucosa to the underlying mandible. Lower lip paresthesia may be an indication of perineural invasion at the level of the mandibular foramen with these lesions. The sensation to this region is provided by the lesser palatine nerve and branches of the glossopharyngeal nerve. It is the presence of CN IX that causes patients with lesions within this area to present with referred otalgia. The primary lymphatic drainage for this region is to the upper cervical-jugulodigastric nodal group (Fig. 96-8).

Floor of Mouth

The floor of mouth is a mucosal surface bordered by the oral tongue and alveolar ridge laterally and anteriorly. The posterior margin is the anterior tonsillar pillar. The lingual frenulum divides the region into two oval spaces. The mylohyoid and hyoglossus muscles provide the structural support for contents of the space. The significance of the floor of mouth comes from the anatomy that the region overlies. Hypoglossal or lingual nerve dysfunction may be the presenting complaint for patients with lesions in this portion of the oral cavity. The sublingual gland is vulnerable to direct invasion from lesions in this region. A branch of the lingual nerve provides sensation for the floor of mouth. The lymphatic drainage of the anterior aspect of this space may cross to contralateral submental-submandibular nodes, whereas

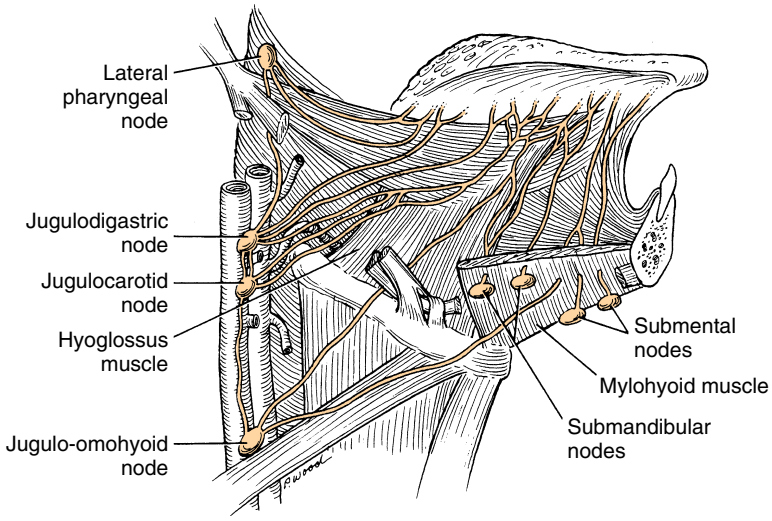

Figure 96-7. Lymphatic drainage pattern of the oral tongue, base of tongue, and floor of mouth.

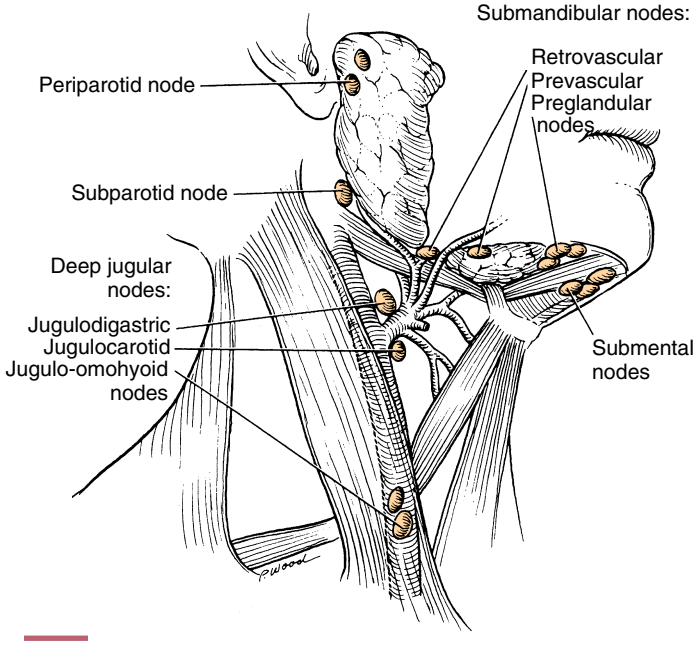

Figure 96-8. Lymphatic regions of the upper neck.

the posterior portion of the space tends to drain to ipsilateral upper cervical lymph nodes.

Buccal Mucosa

This surface extends from the posterior aspect of the lip to the alveolar ridges medially and the pterygomandibular raphe posteriorly. The parotid duct orifice is located next to the second maxillary molar after it exits the parotid and pierces the buccinator muscle. The sensation is provided by branches of the trigeminal nerve (CN V_2 and CN V_3). The lymphatics of this region drain preferentially to submental and submandibular lymph nodes.

Hard Palate

The hard palate has the maxillary alveolar ridges as anterior and lateral margins and the soft palate as a posterior border. Invasion through the hard palate results in extension of tumor into the nasal cavity or maxillary sinus. Infrastructure maxillectomy is frequently required for invasive lesions. A prosthetic obturator or flap reconstruction is necessary to re-establish oral competence and avoid hypernasal speech. The nasopalatine nerve (CN V_2) provides sensation to the region. Most of the lymphatic drainage from this site is to the upper cervical lymphatics or lateral retropharyngeal nodes.

Pathology

Certain histopathologic findings have significant implications on treatment. Tumor thickness, in particular with oral tongue carcinoma, has been the subject of many reports. Tumor thickness has been shown to have a direct relationship to the incidence of regional metastatic spread and survivorship.[36] The degree of differentiation and the presence of vascular or perineural invasion have important prognostic implications and may warrant the use of postoperative radiation therapy.

Premalignant Lesions

A discussion of the premalignant lesions of the oral cavity requires a review of the definitions commonly used in describing the gross and histologic appearance of these growths.

Leukoplakia is white, mucosal-based keratotic plaque that cannot be wiped free from the underlying tissue. This is a clinical term without a definitive histologic definition. Leukoplakic lesions may demonstrate parakeratosis, hyperkeratosis, and acanthosis on histologic examination. Paradoxically, an increased risk of malignant transformation of leukoplakic lesions is seen more commonly in nonsmokers compared with smokers. If a leukoplakic lesion is associated with an area of dysplasia (in 1% to 3% of all lesions), the risk of progression to malignancy increases seven-fold. Banoczy followed 670 patients with leukoplakic lesions for 3 years and noted that 31% of lesions disappeared, 30% improved, 25% experienced no change, and 7.5% demonstrated local spread. Only 6% of lesions demonstrated eventual progression to squamous cell carcinoma.[37] Syphilitic leukoplakias seen in tertiary syphilis have a higher reported rate of malignant transformation.[38]

Erythroplakia is a red mucosal plaque that does not arise from any obvious mechanical or inflammatory cause and persists after removal of possible etiologic factors. The associated risk for progression to carcinoma is significantly greater than that for leukoplakic lesions. Shafer and Waldron[39] resected erythroplakic lesions in 58 patients and found that 91% had evidence of invasive, carcinoma in situ, or severe dysplasia within specimens.

Submucosal fibrosis, most frequently encountered in individuals who chew betel nut, is associated with poor oral hygiene, advanced periodontitis, and oral carcinoma. The buccal mucosa becomes thickened and the entire cheek becomes fibrotic, resulting in trismus. Resection of tumors arising in the buccal mucosa in patients with submucosal fibrosis can be challenging and reconstruction can be complicated by wound breakdown and poor healing.

Lichen planus, in particular the erosive subtype, has also been associated with the development of oral carcinoma. The etiology of

lichen planus is unknown. T-cell lymphocyte infiltration is noted in this lesion, yet the development of lichen planus is not typically associated with immunologic disorders. The typical patient is a female in the fourth decade of life. Lesions demonstrate a lacy pattern of white striae. Atrophic lesions are red and smooth, whereas erosive lesions have depressed margins and are covered by a layer of fibrinous exudate. An estimated 1% risk of malignant change over 10 years has been reported.[38]

Dysplasia is the abnormal maturation and differentiation of mucosal epithelium with features of an increased nuclear-to-cytoplasmic ratio, loss of polarity, increased mitoses, and loss of intercellular adherence. Dysplasia is graded as mild, moderate, and severe.

Verrucous hyperplasia is a histologic finding that appears similar to verrucous carcinoma yet differs from the malignant form in that it does not invade the lamina propria.

Necrotizing sialometaplasia, although appearing clinically ominous, is benign. The typical feature is a butterfly-shaped area of ulceration at the junction of the hard and soft palate in the region of the palatine foramen. The etiology of this clinical lesion is necrosis of minor salivary acini usually secondary to localized pressure injury. This may be seen in the scenario of a poorly fitting or overused denture.

Squamous Cell Carcinoma and Variants

Several variants of squamous cell carcinoma exist and may be encountered in the oral cavity.

Sarcomatoid squamous cell carcinoma demonstrates a heterogeneous appearance with spindle-shaped cells interwoven with squamous cells. The cytologic behavior of this variant is considered aggressive with a reported metastatic rate of 37%.[40] Basaloid carcinoma is also considered a high-grade variant with reported 64% incidence of regional metastases and 44% incidence of distant metastases, and it is associated with 38% mortality at 17 months.[41] However, one report notes that when clinical T and N staging are matched, the 5-year disease-free survival associated with oral basaloid carcinoma is similar to that of poorly differentiated and moderately differentiated oral carcinomas.[42]

A thick zone of nonproliferating and nonkeratinizing cells distinguishes verrucous carcinoma histologically. The typical presentation is on the buccal mucosa (50%). It is considered a low-grade variant of squamous cell carcinoma and is exophytic in appearance. It has the capacity to invade locally yet carries a low risk of regional spread. Traditionally, this lesion has been considered to be "radioresistant" and surgical excision has been the treatment of choice.

Other Pathologies

Additional pathologies to consider in the differential diagnosis of oral cavity lesions include pyogenic granuloma, pseudoepitheliomatous hyperplasia, lymphoma, minor salivary gland tumors, and sarcomas.

The most common minor salivary gland malignancies are adenoid cystic carcinoma, mucoepidermoid carcinoma (low and high grade), polymorphous low-grade adenocarcinoma, and adenocarcinoma. They may present as a painless, slow-growing, submucosal mass at the junction of the hard and soft palate. Adenoid cystic carcinoma can present with perineural invasion that can extend within the greater palatine nerve to the pterygopalatine ganglion and ascend to the skull base.

Sarcomas of the oral cavity usually arise in the mandible or hard palate and include osteosarcoma (Fig. 96-9), chondrosarcoma, malignant fibrous histiosarcoma, rhabdomyosarcoma, and liposarcoma. Patel and colleagues demonstrated a 5-year local control rate for head and neck osteosarcoma of 78% and overall survival of 70%. Patients presented with osteosarcoma within the maxilla and mandible with approximately equal frequency, 45% to 41%, respectively. Surgery was performed in all patients, and neoadjuvant chemotherapy was used in 68% of patients. Positive surgical margins were found to be the only significant negative predictor with respect to disease-specific survival.[43]

Kaposi's sarcoma (KS) is the most common HIV-associated malignancy. The head and neck is the site for 63% of all presentations. KS may present as a mucosal or cutaneous lesion with a nodular or macular appearance and most commonly occurs on the hard palate. Despite being considered an incurable disorder, a variety of treatment options that may offer remission for limited disease are available. Local therapies include radiation, intralesional injection of chemotherapy, cryotherapy, alitretinoin gel, laser therapy, and surgical excision. Systemic chemotherapy is reserved for advanced disease.[16]

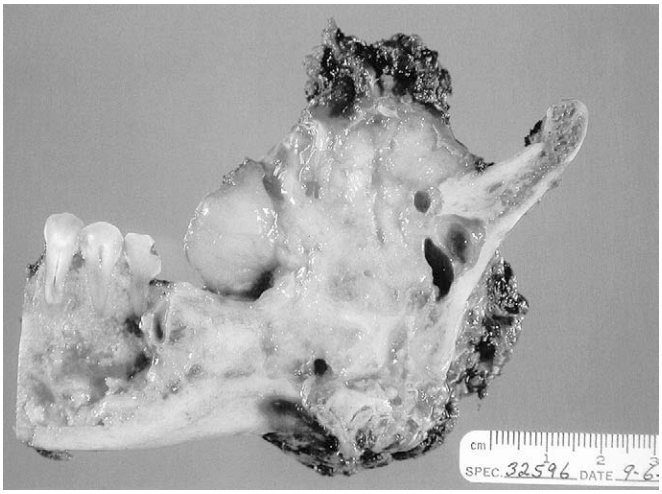

Figure 96-9. Osteosarcoma specimen of the right hemimandible.

Desmoplastic neurotrophic melanoma is a nonpigmented lesion of the lower lip that presents as an ulceration and has a high incidence for perineural invasion. Mucosal melanoma typically presents as a pigmented lesion of the oral cavity that may be associated with preexisting melanosis. Pigmented lesions of the oral cavity should be considered for biopsy to exclude this diagnosis.[44]

Diagnostic Evaluation

History and Physical Examination

A detailed history and physical examination are critical to the comprehensive evaluation of all head and neck cancer patients. When evaluating a patient for an oral lesion, inquiries into changes in the fit of a preexisting denture, otalgia, trismus, oral-dental pain, bleeding, halitosis, weight loss, dysphagia, odynophagia, dysarthria, and facial numbness should be made.

Patients should be questioned about specific medications, allergies, medical diagnoses, and previous surgical interventions. This information can be critical when formulating a treatment plan tailored to a patient's comorbidities. In addition, a detailed history of the patient's tobacco and alcohol use should be obtained.

The head and neck physical examination should allow for accurate staging of the tumor, assess the patient's functional capacity before treatment, and include a careful search for synchronous upper aerodigestive tract cancers. The physician should evaluate the dimensions of the index lesion and the potential anatomy involved by direct spread of tumor (Fig. 96-10). The lesion should be palpated to assess for fixation to the underlying periosteum suggesting potential mandibular or maxillary involvement. Determination of midline extension, regional lymphatic spread, and the need for reconstruction should be considered. The appropriateness of specific donor sites for free and/or pedicled flap reconstruction should also be assessed.

At the initial evaluation, if tissue pathology has not been previously obtained, a punch biopsy of the perimeter of the primary tumor and/or FNA (potentially ultrasound-guided) of suspected regional metastases should be performed. If the patient underwent biopsy at an outlying site before consultation, the specimen should be obtained and reviewed with the pathologist at the surgeon's facility to confirm the tissue diagnosis.

For patients with imaging already performed, films are reviewed for the extent of the primary disease and regional lymphadenopathy. Film quality, date of imaging, and need for supplemental imaging should be assessed. Before initiating treatment, the patient should be presented at a multidisciplinary tumor conference with representation

Figure 96-10. Tongue deviation to the right with atrophy suggestive of cranial nerve XII involvement by a floor-of-mouth cancer with right submandibular lymphadenopathy noted at pretreatment evaluation.

by surgeons, radiation oncologists, medical oncologists, and reconstructive surgeons for a discussion of available treatment options.

Future screening for oral cancer may be possible with outpatient biomarker laboratory assays. St. John and colleagues[45] have described the use of an assay for salivary interleukin (IL)-8 and serum IL-6 with promising results in patients with oral cavity and oropharyngeal carcinoma.

Preoperative Assessment

Obtaining information that either confirms or alters the strategy of the operative intervention and assesses the patient's overall readiness for surgery is necessary. Preoperative evaluation depends on the patient's age and comorbidities. In most instances an electrocardiogram, chest x-ray, and basic laboratory profile should be obtained. Patients with a history of alcohol abuse should have a liver profile performed. For patients with significant comorbidities, the patient's primary care physician or cardiologist should be included in the preoperative risk assessment.

Imaging to assess the primary extent of tumor and cervical lymph nodes includes either computed tomography (CT) or magnetic resonance imaging (MRI). CT is best for demonstrating cortical bone erosion and lymph node metastases. MRI is favored for demonstrating soft tissue invasion by tumor and extension into medullary bone. A Panorex may be obtained preoperatively in patients with suspected mandibular invasion and can assist dental evaluation. Dentascan imaging, using a dental CT-based software program, can be helpful in assessing the likelihood of mandibular invasion, with a reported sensitivity of 95%.[46] Goerres and colleagues noted the assessment of cortical invasion of the mandible was best assessed by conventional contrast-enhanced CT (as well as the CT component of PET-CT) with a sensitivity of 100% and accuracy of 97%.[47] The extent of imaging is frequently driven by physician preference and the complexity of the presenting lesion. Patients with T_1 lesions, without clinical lymphadenopathy, may not require extensive imaging to aid operative decision making.

Newer imaging modalities such as positron emission tomography (PET), PET-CT, single photon emission computed tomography (SPECT) scanning have been used to stage patients with head and neck cancer, but their role in preoperative assessment is not uniform and continues to evolve. Assessment for distant metastases may be performed using one of these modalities or via CT of the chest with contrast. Suspicion of distant metastases may require CT-guided biopsy for confirmation. Patients with distant metastases are not typically considered optimal candidates for curative treatment and may be better served by exploring palliative care options while preserving maximal quality of life.

Preoperative Interventions

Anticipating the nutritional needs of patients may prevent an extended need for hospitalization or treatment breaks during postoperative radiation. Malnutrition in the perioperative period can predispose patients to wound complications. Preoperative consultation for gastrostomy tube placement should be considered for those patients in which the ability to take oral nutrition is compromised before surgery or anticipated to extend for a prolonged period of time postoperatively. For those requiring postoperative radiation therapy, mucositis can result in a delay in the normal resumption of oral intake for several weeks to months.

In addition, dental evaluation is essential for patients with poor dentition and those who may require radiation as part of their treatment. Prosthodontic evaluation is indicated for those who will undergo maxillectomy and require a surgical obturator.

For patients with the potential for significant speech and swallowing impairment postoperatively, consultation and counseling with a speech-language pathologist can aid in long-term rehabilitation.

Endoscopy

Panendoscopy including bronchoscopy, esophagoscopy, and direct laryngoscopy has been advocated for the preoperative assessment of head and neck cancer patients. Given that the reported risk of harboring synchronous second lesion is between 5% and 10% in newly diagnosed patients, some consider panendoscopy necessary. Others advocate direct laryngoscopy but reserve performing esophagoscopy and bronchoscopy in symptomatic patients (with pretreatment dysphagia, odynophagia, cough, and/or hemoptysis) or if the preoperative thoracic imaging (chest x-ray or CT) is abnormal. If a percutaneous endoscopic gastrostomy tube placement is planned before definitive surgery, evaluation of the esophagus can be deferred to that procedure. Alternatively, a preoperative barium swallow can serve as a screening tool to exclude a second primary tumor; however, false-negative findings associated with the technique can occur. The extent of investigations for excluding second primary tumors is individualized according to physician preferences and the needs of an individualized patient.

Staging

Staging for oral cavity malignancies is defined by the American Joint Committee on Cancer (AJCC)[48] and follows TNM (primary Tumor, regional Nodal metastases, distant Metastasis) staging format (Table 96-1).

Histopathologic findings have been shown to have prognostic significance. Tumor characteristics such as keratin production, level of differentiation, nuclear appearance, mitoses, and host factors such as inflammation, desmoplastic reaction, patterns of invasion, and vascular invasion have been examined as an adjunct to clinical staging for predicting outcome. Nevertheless, staging remains based on clinical examination and diagnostic imaging.

Prognosis

Several studies examining the prognostic implications of primary tumor pathology that have been published are briefly reviewed.

Patients with tumors that display "pushing" margins (when the peripheral invasive margin is assessed as it relates to the surrounding soft tissue) as opposed to "infiltrative" growth patterns have better outcomes.[49] In addition, the depth of invasion of oral squamous cell carcinoma and its relationship to the risk of regional metastasis and 5-year survival has been examined. For lesions with a depth of invasion less than 2 mm, 13% of patients demonstrated regional metastases and a 95% 5-year survival was noted. For lesions with a 2- to 9-mm depth of invasion, 46% of patients had regional metastases and the 5-year survival rate decreased to 85%. When depth of invasion increased to

Table 96-1

American Joint Committee on Cancer Staging

Primary tumor

T_X	Unable to assess primary tumor
T_0	No evidence of primary tumor
T_{is}	Carcinoma in situ
T_1	Tumor <2 cm in greatest dimension
T_2	Tumor >2 cm and <4 cm in greatest dimension
T_3	Tumor >4 cm in greatest dimension
T_4 (lip)	Primary tumor invading cortical bone, inferior alveolar nerve, floor of mouth, or skin of face (e.g., nose, chin)
T_{4a} (oral)	Tumor invades adjacent structures (e.g., cortical bone, into deep tongue musculature, maxillary sinus) or skin of face
T_{4b} (oral)	Tumor invades masticator space, pterygoid plates, or skull base or encases the internal carotid artery

Regional lymphadenopathy

N_X	Unable to assess regional lymph nodes
N_0	No evidence of regional metastasis
N_1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
N_{2a}	Metastasis in single ipsilateral lymph node, >3 cm and <6 cm
N_{2b}	Metastasis in multiple ipsilateral lymph nodes, all nodes <6 cm
N_{2c}	Metastasis in bilateral or contralateral lymph nodes, all nodes <6 cm
N_3	Metastasis in a lymph node >6 cm in greatest dimension

Distant metastases

M_X	Unable to assess for distant metastases
M_0	No distant metastases
M_1	Distant metastases

TNM staging

Stage 0	T_{is}	N_0	M_0
Stage I	T_1	N_0	M_0
Stage II	T_2	N_0	M_0
Stage III	T_3	N_0	M_0
	T_{1-3}	N_1	M_0
Stage IVa	T_{4a}	N_0	M_0
	T_{4a}	N_1	M_0
	T_{1-4a}	N_2	M_0
Stage IVb	Any T	N_3	M_0
	T_{4b}	Any N	M_0
Stage IVc	Any T	Any N	M_1

greater than 9 mm, the risk of lymph node metastasis increased to 65% and the 5-year survival decreased to 65%.[50]

Loss of cadherin expression (E-cad and P-cad) as it relates to oral cavity squamous carcinoma correlates with the invasive potential of a cancer and locoregional disease recurrence. In particular, P-cad expression is considered an independent prognostic marker.[51] Marcus and colleagues[52] demonstrated that monocyte chemoattractant protein 1 was up-regulated in oral cavity carcinoma and the resultant increase in macrophage content was statistically associated with regional metastasis, extracapsular spread, and advanced-stage disease. Tissue inhibitor of metalloproteinase 1 and collagen type 11 alpha-1 have also been demonstrated to be increased in expression in oral cavity and oropharyngeal cancers that are metastatic.[53]

Laimer and colleagues[54] noted that a high STAT1 activation (>35%) in oral cavity carcinoma specimens was associated with a negative lymph node status and a better prognosis in patients receiving adjuvant chemotherapy when compared with nonexpressing counterparts. Xie and colleagues[55] noted that patients with higher numeric aberrations of chromosome X and 11 had shorter disease-specific survival. Podoplanin, a glycoprotein important in lymphangiogenesis, is expressed preferentially in oral tongue carcinoma. High levels of podoplanin have been shown to be predictive of lymph node metastasis and shortened disease-specific survival.[56] Additionally, intratumoral lymphangiogenesis in patients with early-stage oral carcinoma has been correlated with locoregional recurrence.[57]

The 5-year distant metastatic rate in patients with oral carcinoma after treatment is approximately 10%. This rate increases from 6.6% in patients with locoregional control to 21.4% in patients who develop a locoregional recurrence. Additional risk factors noted at the time of initial treatment associated with the development of distant metastasis in the two groups were greater than or equal to five positive lymph nodes, extracapsular spread, poor differentiation, and advanced pathologic stage (III or IV).[58]

In a study examining whether oral tongue carcinoma was associated with a worse prognosis when compared with other oral cavity subsites, Bell and colleagues demonstrated no significant difference in disease-free survival between the groups. Risk factors that were found to statistically affect overall and disease-specific survival were tumor grade and overall staging.[59]

Table 96-2 demonstrates the 5-year observed survival rates for patients with oral cavity squamous cell carcinoma stratified by stage as reported by the AJCC for 1985 to 1991.

Second Primary Tumors

Patients with smoking-related head and neck cancer are at risk for the development of a second primary tumor. A second primary tumor detected simultaneously or within 6 months of the initial primary tumor is defined as a *synchronous lesion.* Emergence of a second primary lesion more than 6 months after discovery of the index tumor is referred

to as *metachronous.* The incidence and site of subsequent primaries vary depending on the site of the initial primary lesion.

The overall incidence for synchronous and metachronous lesions for patients diagnosed with a primary head and neck malignancy is approximately 14%. Of these malignancies, 80% are metachronous cancers with 50% of cases presenting within the first 2 years of initial treatment of the primary tumor. For patients with oral cavity and oropharyngeal malignancies, the site of a second malignancy is most frequently in the cervical esophagus. New symptoms of dysphagia or odynophagia in this patient population should prompt a diagnostic evaluation with barium swallow or esophagoscopy.[60] There appears to be a bimodal pattern for second primary tumors in the esophagus, with an early group developing tumors within 2 years of treatment of the index primary tumor and a later group that develops esophageal cancer greater than 5 years after primary treatment.[61]

Treatment Considerations

The precise assessment of the tumor stage for oral cancers is necessary in order to develop an appropriate treatment approach. The general physical and psychologic condition of a patient should also be taken into consideration. Key questions that must be answered are: Is the patient medically fit for an extensive procedure? Can the patient's health status be optimized? Does the patient comprehend the treatment options and possible sequelae?

Perioperative antibiotics, in cases with aerodigestive tract exposure to the operative field, can decrease infectious complications associated with surgical intervention. Prophylactic antibiotics are most effective when administered immediately before surgery and for up to 24 hours postoperatively. Extended use of antibiotics in postsurgical patients has not been shown to decrease the risk of infectious complications or fistula formation. The inappropriate use of antibiotics increases the risk for pseudomembranous colitis and the emergence of resistant organisms. Selection of a prophylactic antibiotic for clean-contaminated head and neck surgery should provide adequate gram-positive in addition to anaerobic coverage.[62]

Multiple general statements can be made concerning the surgical management of oral cancer as a whole. A detailed discussion of the treatment of each oral cavity subsite follows within this chapter. For early-stage lesions of the oral cavity (T_1/T_2), transoral resection tends to be possible with complete tumor removal and adequate margin control. Primary closure, healing by secondary intention, or placement of a split-thickness skin graft may be used for reconstruction of small defects. Larger and more posteriorly located lesions may require a pull-through or mandibulotomy-based technique to aid exposure for resection and reconstruction. When the tumor closely approximates the mandible, marginal versus segmental mandibulectomy needs to be considered. Reconstructive options for advanced T-stage lesions include microvascular free tissue or pedicled flap reconstruction. Traditionally, T4b lesions have been considered inoperable. Liao and colleagues demonstrated equivalent results with T4a and selected T4b lesions (without carotid encasement and skull base extension) when aggressive surgical management of the primary site and regional lymphatics with postoperative radiation or chemoradiation therapy was performed. Free tissue reconstruction was necessary in 95% of patients. Local control, disease-free, and overall survival numbers were similar.[63]

When considering options for repairing larger soft tissue defects, one must consider the impact on speech, swallowing, and airway. Patients may require temporary tracheostomy and feeding tube placement in the perioperative period until adequate healing has occurred. The cosmetic implications of composite resection in advanced lesions also need to be weighed with the individual patient's expectation; however, the goal of treatment should remain an oncologic approach to achieve the best opportunity for long-term survival while maintaining quality of life.

Surgery—Treatment of the Primary Lesion

Operative Approaches

The surgical approach to the oral cavity primary site is dictated by the size, location, and associated involved anatomy relative to the tumor's presentation. Resection of limited (T1, small T2s) primary lesions can typically be performed transorally. Using transtumoral cuts, larger lesions can also be excised to a negative margin using the transoral approach. Advanced-stage oral tongue lesions, in particular those with posterior extension, may require a mandibulotomy-based approach to allow adequate access for the resection of the posterior margin of the tumor and allow for reconstruction. Advanced-staged tumors of the anterior oral tongue and floor of mouth, in particular those that involve the genioglossus and mylohyoid musculature (without mandibular involvement), can be efficiently managed with a visor or degloving approach. This approach can allow for excellent visualization enabling wide resection of the deeply invasive primary lesion while sparing the patient from a mandibulotomy and a possible postoperative nonunion. Specific considerations relative to the resection of various types of presentations at the different oral cavity sites are discussed as follows.

Lip

The majority of neoplastic lesions that affect this subsite present on the lower (88% to 95%) as opposed to the upper lip (2% to 7%) or the commissure (1%) (Fig. 96-11). For the lower lip, squamous cell carcinoma predominates, whereas basal cell carcinoma disproportionately arises on the upper lip. In addition to basal and squamous cell carcinoma, the differential diagnosis of a lip lesion includes keratoacanthoma, minor salivary gland tumors, malignant melanoma, and tumors of mesenchymal origin (malignant fibrous histiocytoma, leiomyosarcoma, fibrosarcoma, angiosarcoma, and rhabdomyosarcoma).

The typical patient with a squamous cell carcinoma of the lip is a male 50 to 70 years of age. Risk factors include prolonged exposure to sunlight, fair complexion, immunosuppression, and tobacco use.

Clinical findings in lip cancer usually include an ulcerated lesion on the vermilion or cutaneous surface or, less commonly, on the mucosal surface. The majority of patients present with early-stage lesions and without evidence of neck metastases.[64] A nodular or sclerotic lesion may infiltrate into the deeper tissues, and careful palpation is important for determining the actual size of the lesion. Minor salivary gland tumors present as a submucosal nodule on the inner surface of the lower lip. The presence of paresthesias or dysesthesias in the area adjacent to the lesion indicates possible mental nerve involvement.[65]

Figure 96-11. Squamous cell carcinoma of the lip at the oral commissure.

Neck metastases are an infrequent finding with lower lip squamous cell carcinomas and occur in only 10% of cases. Lower lip lesions may metastasize bilaterally because of the communicating pattern of the lymphatics. An increased risk of regional metastasis is associated with commissure and upper lip lesions. Adverse prognostic features of lip primaries include perineural invasion, bony involvement, cancer arising on the upper lip or commissure, regional lymphatic metastasis, and age younger than 40 years at onset.[66] Lip cancer results in fewer than 200 patient deaths annually and is stage dependent. Diagnosed early and with adequate treatment, cure rates are high. Obtaining an adequate cosmetic result and functional outcome without microstomia can be challenging with advanced-staged lesions.

The surgeon should consider several factors when planning a resection and reconstruction for a patient with a lip carcinoma (Fig. 96-12). The typical lip length is 6 to 8 cm. Reconstructive algorithms are based on the proportion of lip resected. Realignment of the vermilion border during the reconstruction and preservation of the oral commissure (when possible) are important principles in attempting to attain an acceptable cosmetic and functional result.

Small primary lesions may be treated with surgery or radiation with equal success and acceptable cosmetic results. However, surgical excision with histologic confirmation of tumor-free margins is the preferred modality. The reconstruction of lip defects after tumor excision requires innovative techniques to provide oral competence, maintenance of dynamic function, and acceptable cosmesis. With small lesions, defects up to one third of the lip's length, simple excision with primary closure is possible. When lesions require resection of up to one third to two thirds of a lip's length, reconstructive options include a lip-switch (Abbe-Estlander) (Fig. 96-13) or a Johansson stepladder flap.[67] For tumors requiring resection of more than two thirds of the lip, the reconstructive options are the Gilles fan flap, bilateral advancement flaps, Karapandzic, or a free radial forearm with palmaris longus tendon. The Karapandzic flap (Fig. 96-14) is a sensate, neuromuscular flap that includes the remaining orbicularis oris muscle. The blood supply for this flap is the corresponding branches of the labial artery. Microstomia is a potential complication with these methods of lip

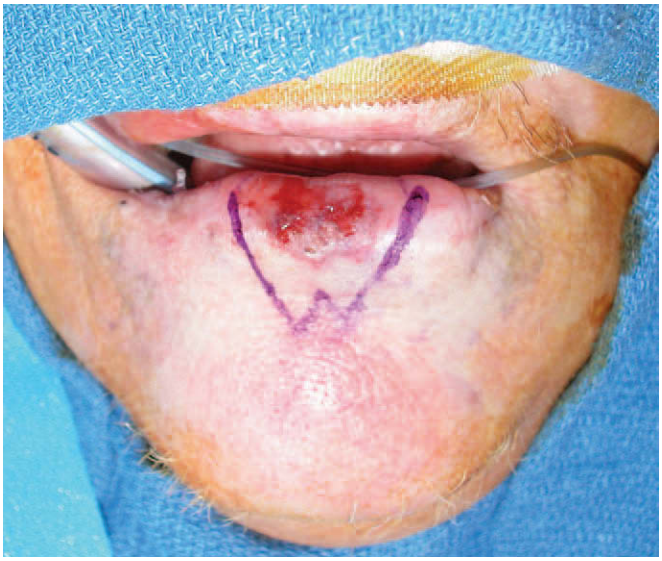

Figure 96-12. Midline lower lip squamous cell carcinoma noted with ulceration extending to the vermilion border. Wedge resection with primary closure is planned.

reconstruction.[68] For large defects, Webster or Bernard procedures using lateral nasolabial flaps with buccal advancement have been described.[69] In addition, for aggressive and advanced-staged lesions, an evaluation for perineural spread should be performed at the time of resection. Potential biopsy of the mental nerve with a retrograde dissection in an attempt to obtain a negative margin should be considered. With extensive perineural invasion, a drill-out of the mental nerve or hemimandibulectomy may be required.

The primary echelon of nodes at risk for metastatic spread is the submandibular and submental region. Diagnostic evaluation for potential nodal spread includes fine-needle aspiration with or without ultrasound or CT guidance. In the presence of clinically evident neck metastasis, therapeutic neck dissection is indicated. Unnecessary sacrifice of both facial arteries (when bilateral neck dissections are required) could have implications on the vascularity of facial structures used for a complex lip reconstruction. Elective neck dissection is not typically advocated for lip carcinoma because the incidence of occult metastases is low.

The 5-year survival for stage I and II lesions is 90%. For patients with cervical metastases, the survival decreases by 50%.[67] Patients with oral commissure and upper lip carcinomas have a worse overall prognosis when compared with similar tumors of the lower lip. Postoperative radiation therapy is considered for patients with close or positive margins, lymph node metastases, or perineural invasion.

Alveolar Ridge

Squamous cell carcinoma of the mandibular and maxillary alveolar ridges represents approximately 10% of all oral cavity cancers. Lower alveolar ridge carcinomas present more frequently than upper lesions.

In a review of 155 patients with lower alveolar ridge carcinoma, the mean age at presentation was 66.7 years. In this group, 63% of tumors were located over the mandibular body and 25% arose over the symphysis. More than half of all lesions were diagnosed in edentulous patients. The majority of patients (67%) were noted to have early-stage lesions (T_1/T_2).[70]

Given that the mucosa closely approximates the underlying bone of the alveolus, osseous erosion and/or invasion at presentation is common. Tumors extending within adjacent dental sockets are associated with a higher likelihood of bone invasion. In this situation, preoperative radiographic evaluation can significantly aid in treatment planning. Close and colleagues[71] noted that the CT scan was more sensitive and specific than the bone scan and Panorex in predicting mandibular invasion. The need to address periosteal and bone invasion may be seen in up to 50% of patients. With mandibular invasion, the inferior alveolar nerve may become secondarily involved by perineural invasion. Treatment options of marginal versus segmental mandibulectomy are dependent on whether the tumor invades the periosteum, cortical, or medullary bone (Fig. 96-15). When tumors approach but do not invade the periosteum, a subperiosteal resection with mandibular preservation is possible with primary closure or split-thickness skin graft reconstruction. When the periosteum is invaded, marginal mandibulectomy is indicated. Marginal resection may be performed in two planes. The classic "rim" or coronal marginal mandibulectomy removes the superior aspect of the involved mandible, whereas a lingual sagittal marginal mandibulectomy removes the lingual cortex of the mandible contacting the tumor (Fig. 96-16). With lesions surrounding intact dentition, extraction and alveolar resection are required to obtain an adequate margin. When the tumor extends down the tooth socket into the medullary bone, segmental mandibulectomy is frequently necessary. With segmental mandibular defects of the symphysis, reconstruction with vascularized free tissue transfer with an osseous flap remains the standard of care. For lateral mandibular defects, the options are more varied and may include primary closure, pedicled and/or vascularized free flap soft tissue reconstruction, or vascularized osseous free tissue transfer.

When extensive maxillary alveolar ridge cancers are encountered, potential extension into the nasal cavity and paranasal sinuses should be anticipated.

General guidelines for neck dissection with oral cavity malignancies in the N_0 patient include treatment of the neck when the risk of occult metastatic spread to the regional lymphatics exceeds 20%. Upper alveolar ridge tumors tend to regionally metastasize to jugulodigastric lymph nodes, whereas lower alveolar ridge tumors drain to submandibular lymphatics. Among patients with clinical evidence of lymphadenopathy (N^+), regional treatment typically requires a modified radical neck dissection (levels I-V). Eicher and colleagues noted that levels IV and V harbored metastases in 20.9% of patients with inferior alveolar ridge cancer undergoing therapeutic neck dissection for clinically evident adenopathy. Patients undergoing elective dissection demonstrated occult metastases in levels I (53.3%), II (40%), and III (6.7%). Presence of an advanced T-stage (T_3, T_4) lesion and bony mandibular invasion have been correlated with the development of regional metastases. As such, elective neck dissection removing levels I to III is advocated for all advanced-staged primaries (T_3, T_4) and T_1-T_2 lesions at the mandibular symphysis or for tumors with moderate to poorly differentiated tissue pathology.[70] The overall risk of metastases with alveolar ridge carcinoma is 25%.[70,72] In patients with a clinically N_0 neck, occult metastases have been noted in 15% of operative specimens. The 2- and 5-year survival for patients with occult metastases who underwent END is better than for patients who underwent therapeutic neck dissection after the eventual development of metastatic adenopathy.[70]

The 5-year survival ranges from 85% (T_1, T_2) to 65% (T_3, T_4) for patients without metastatic spread. Among patients with regional or distant metastases, the 5-year survival has been reported to range from

35% to 59%.[73,74] Decreased local control rates are seen with lesions greater than 3 cm and positive surgical margins. Significant prognostic factors include advanced T stage (T_3, T_4), margin status, mandibular invasion, and the presence of regional metastases. Neither local control nor survival are affected by the extent of mandibular resection, dental intervention near the site of the primary, perineural invasion, or histologic grade of the tumor.[72] Postoperative radiation therapy is advocated for patients with T_4 tumors, positive margins, perineural invasion, and regional metastasis.[70,72]

Oral Tongue

The oral tongue is a muscular structure with overlying nonkeratinizing squamous epithelium. The posterior limit of the oral tongue is the circumvallate papillae, whereas the ventral portion is contiguous with the anterior floor of mouth. Subsites include the lateral tongue, the anterior tip, the ventral tongue, and the dorsal oral tongue. Carcinomas of the tongue arise in the epithelium and invade into the deeper musculature. The most common presentation is that of a painful ulcerated or exophytic mass (Fig. 96-17).

Oral tongue carcinoma typically presents in males with a history of tobacco and alcohol use in their sixth or seventh decade of life. The majority is squamous cell carcinoma and approximately 75% occur on the posterolateral aspect of the oral tongue. The second most common site (20% of lesions) is the anterolateral and ventral surface of the tongue. The direct contact of carcinogens from tobacco or other agents is considered causative in the development of cancer at this site. Tumors may present on the dorsal surface of the tongue; however, this represents a minority of lesions (3% to 5%). The differential diagnosis for dorsal lesions of the tongue is broad and should include amyloidosis, median rhomboid glossitis, granular cell myoblastoma, and erosive lichen planus. Because of the rarity of carcinomas of the dorsal tongue, a delay in diagnosis is not infrequent.[75] The differential diagnosis of submucosal oral tongue tumors is those derived from mesenchymal tissues including leiomyomas, leiomyosarcoma, rhabdomyosarcoma, and neurofibromas.

Local invasion by tongue carcinoma may progress by various routes depending on the site of origin. A tumor of the anterolateral tongue may spread medially across the central raphe to the contralateral side, posteriorly to the tongue base, and inferiorly into the suprahyoid muscles and the muscular "root" of the tongue. Lateral spread to involve a significant portion of the floor of mouth is not uncommon. The lingual and hypoglossal nerves may be invaded directly by tumors. Their involvement produces the clinical findings of loss of sensation of the dorsal tongue surface and deviation on tongue protrusion, fasciculations, and atrophy. In addition, the patient may complain of referred otalgia. The extreme of lateral tumor extension, beyond floor of mouth, includes direct invasion of the mandible, requiring composite resection (Figs. 96-18, 96-19, and 96-20).

At the time of diagnosis, the majority of oral tongue carcinomas (75%) are T_2 or smaller. The surgical treatment for limited, small (T_1 to T_2) primary tumors is transoral wide local excision. Frozen section confirmation of the margin status is necessary before pursuing reconstruction. Advanced-stage lesions that approach the mandible or invade into the deep musculature are best accessed via a pull-through or mandibulotomy technique. When a segmental resection is warranted, access to the oral cavity through the mandibulotomy cuts provides wide access to the primary tumor.

A partial glossectomy, which may remove a significant portion of the lateral oral tongue, can still permit reasonably effective postoperative function. However, treatment of larger tumors that invade deeply within the tongue can result in a significant functional impairment. With resection of approximately one quarter to one third of the oral tongue, healing by secondary intention is an acceptable option. If a

limited portion of the floor of mouth is resected, reconstruction with a split-thickness skin graft should be used to prevent tongue tethering. Resection of approximately one half of the tongue results in loss of tongue bulk and scar contracture if limited reconstructive options are pursued. Lingual contact with the palate, lip, and teeth is decreased and can result in impaired articulation. Posterior propulsion of the food bolus and liquids may also be affected. The use of soft pliable fasciocutaneous free flaps such as a radial forearm or anterolateral thigh free flap can provide intraoral bulk and preservation of existing tongue mobility. A palatal augmentation prosthesis allows for contact between the remaining tongue tissue and the palate and may improve speech and swallowing function. For patients undergoing a partial glossectomy with a significant resection of the floor of mouth, free flap reconstruction to maintain tongue mobility is indicated.

Kurokawa and colleagues[76] noted that in patients with moderately differentiated squamous cell carcinoma of the oral tongue, tumor depth of invasion equal to or greater than 4 mm was associated with occult cervical lymph node metastases. Spiro and colleagues[77] demonstrated that increasing tumor thickness, and not T stage, correlated with treatment failure and survival. Disease-related death was uncommon for patients with depth of invasion less than 2 mm. The depth of invasion can be used to guide the necessity for elective neck dissection in N_0 patients with early-stage lesions.

At initial presentation, 40% of patients with oral tongue carcinoma demonstrate evidence of cervical metastases. For patients with T_1 and T_2 tumors with clinically N_0 neck examination, 20% to 30% of elective neck dissection specimens are pathologically positive. Byers and colleagues noted that 15.8% of lateral tongue carcinoma patients demonstrated "skip" metastases to lymph nodes, bypassing levels I and II, and presenting with level III or IV metastatic disease. They concluded that elective supraomohyoid neck dissection was inadequate for the control of regional lymphatics of oral tongue carcinoma patients and advocated for levels I to IV neck dissection in this situation.[78] When lesions approach the midline, the likelihood for bilateral regional metastasis is high and requires bilateral lymphadenectomy.

Patients with advanced-stage lesions (III or IV) require surgery and postoperative radiation therapy to achieve the best locoregional control rates. Franceschi and colleagues noted an increase in locoregional control for stage III and IV patients from 57% to 71% with the addition of postoperative radiotherapy. In this study the only factor predictive of locoregional recurrence was a positive surgical margin. The majority of patients (78%) recurred within 2 years.[79] Among patients developing a local recurrence, attempts at surgical salvage to control disease are frequently unsuccessful.

The 5-year survival for stage I or II tumors is 75% and less than 40% for stage III or IV tumors.[79,80]

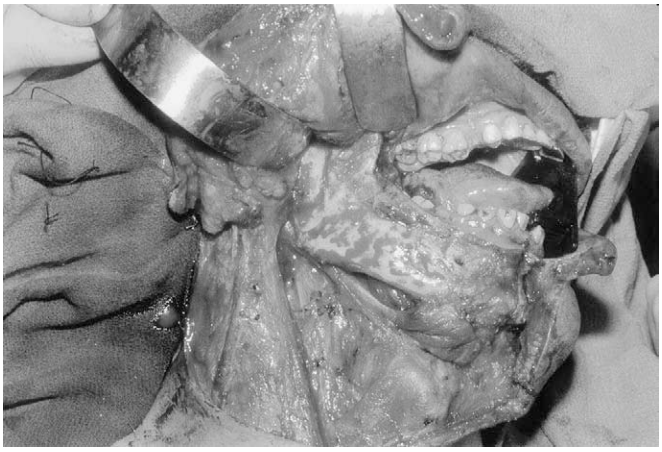

Figure 96-19. Approach for a composite resection for a T_4 tongue squamous cell carcinoma invading the lateral mandible.

Retromolar Trigone

The majority of patients with retromolar trigone carcinomas tend to present with advanced disease. At the time of presentation, up to 50% of patients present with regional metastatic disease. Mandible involvement is common given the thin layer of soft tissue separating these tumors from the ascending ramus. Trismus suggests involvement of the medial pterygoid muscle. As tumors progress in this location, extension to the faucial arch, tonsillar fossa, and the base of the tongue is common. In addition to squamous cell carcinoma, the differential diagnosis of lesions in this region includes minor salivary gland neoplasms, osteosarcoma, and soft tissue sarcomas.

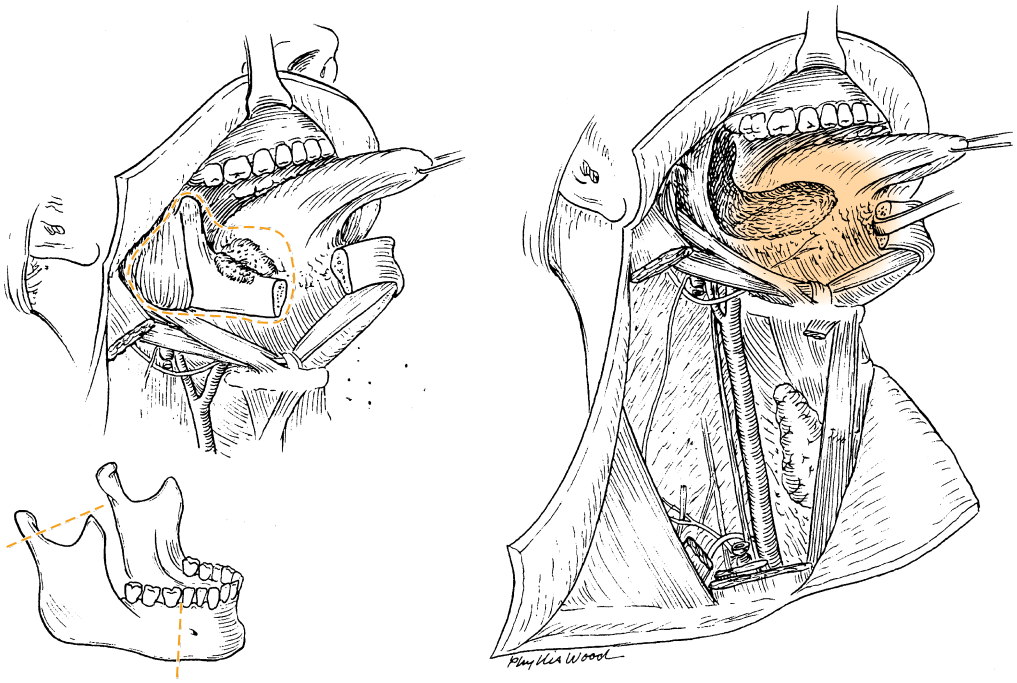

Figure 96-20. Hemimandibulectomy for posterior floor of mouth–lateral tongue tumor with associated modified radical neck dissection (type 1). Reconstruction options include soft tissue reconstruction of the deficit or osseous free tissue transfer.

Figure 96-21. Postresection appearance after L-shaped marginal mandibulectomy for a posterior alveolar ridge–retromolar trigone squamous carcinoma.

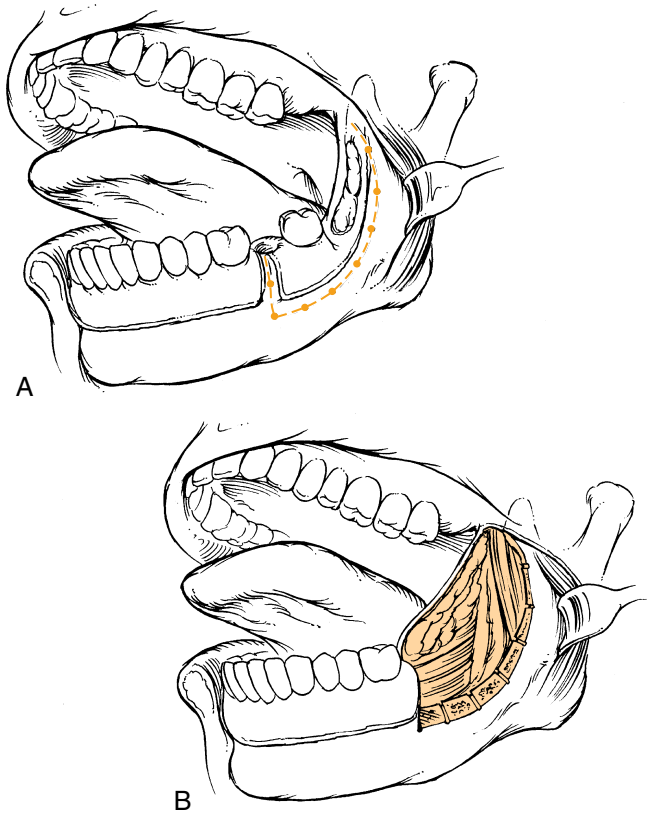

Figure 96-22. L-shaped marginal mandibulectomy for a retromolar trigone tumor. A generous portion of cortical bone remains at the posterior body-angle-ramus of the mandible such that the defect requires only soft tissue reconstruction. **A,** Planned approach for marginal mandibulotomy with wide local incision for retromolar carcinoma without gross bony invasion. **B,** Appearance after surgical resection of tumor prior to reconstruction revealing medial pterygoid and deep tongue musculature. *(From Silver CE, Rubin JS.* Atlas of Head and Neck Surgery. *2nd ed. New York: Churchill Livingstone; 1999.)*

Given the proximity of the mucosa to the underlying ramus of the mandible, surgical resection of early-stage retromolar trigone lesions may require a resection of a portion of the mandible. Treatment options include an L-shaped coronal marginal mandibulectomy, segmental mandibulectomy, and hemimandibulectomy. With the L-shaped marginal mandibulectomy, the superior aspect of the body—extending toward the angle and ascending the ramus—is resected (Figs. 96-21 and 96-22). Segmental mandibulectomy is performed for more extensive lesions with gross bone destruction.

Huang and colleagues demonstrated a 5-year, disease-free survival for T_1 lesions of 76%, which declined to 54% for T_4 disease. Patients with N_0 disease had a 5-year survival of 69%. Survival fell to 56% for those who were N_1 and to 26% for patients with N_2 disease. The recurrence rate for patients treated with radiation therapy alone was 44% compared with 23% for patients undergoing surgical resection with postoperative radiation therapy. Complications reported in patients undergoing treatment with radiation included osteoradionecrosis, soft tissue necrosis, or severe trismus.[81]

Floor of Mouth

Carcinomas of the floor of mouth typically present in males in their sixth decade of life. Approximately 35% of these patients present with an advanced T-stage (T_3, T_4) lesion on initial diagnosis.[50] The floor of mouth musculature plays an important role in the modes of tumor spread. The floor of mouth is composed of the slinglike genioglossus, mylohyoid, and the hyoglossus muscles, which serve as a barrier to the spread of disease. Invasion into these muscles can lead to tongue hypomobility and dysarthria. In addition, tumors of the anterior floor of mouth may extend posteriorly into the ventral aspect or "root" of the tongue, causing fixation.

Deep invasion into the intrinsic musculature of the tongue causes fixation and mandates a partial glossectomy in conjunction with resection of the floor of mouth. Lesions in the anterior floor of mouth may directly invade the sublingual salivary gland or submandibular duct and require in-continuity resection with the primary lesion. Direct extension of tumors through the sublingual space into the submaxillary space indicates the need for an in-continuity resection of the primary tumor and neck.

Anterior or lateral extension to the lingual aspect of the mandible is of primary importance in preoperative treatment planning for these lesions. Imaging studies of the mandible including CT, MRI, and Panorex are useful in conjunction with careful clinical evaluation by bimanual palpation to ascertain adherence to the mandible. The absence of fixation of the lesion to the inner mandibular cortex indicates mandible-preserving techniques are feasible.

The treatment of choice for early-stage lesions, not involving the mandible, is transoral resection. For more extensive anterior and lateral floor of mouth cancers without mandibular involvement, a pull-through technique can spare the need to perform a mandibulotomy. Paramedian or lateral mandibulotomy is seldom necessary except for some posterior floor of mouth tumors. The resection of larger tumors of the floor of mouth usually requires immediate reconstruction. The goals of reconstruction are to obtain a watertight closure to avoid salivary fistula and preserve tongue mobility. For extensive mucosal and soft-tissue deficits, the radial forearm free flap offers the best reconstructive option to accomplish these goals. Additional reconstructive options include the nasolabial, platysma, and pectoralis major flaps. The platysmal flap can be used for small lateral defects, whereas the pectoralis major myocutaneous flap can be used for larger soft tissue defects, preferably when the posterolateral mandible is resected.

For lesions without evidence of bony invasion but demonstrating involvement with the lingual periosteum, a coronal partial mandibulectomy may be required (Fig. 96-23). For massive lesions associated with

mandibular destruction, composite resection with segmental mandibulectomy is necessary (Fig. 96-24).

Cervical metastases are noted in approximately 50% of patients with floor of mouth carcinoma. The submandibular lymph nodes (level IB) are most frequently involved.[50] Bilateral metastases are common with lesions of the anterior floor of mouth.

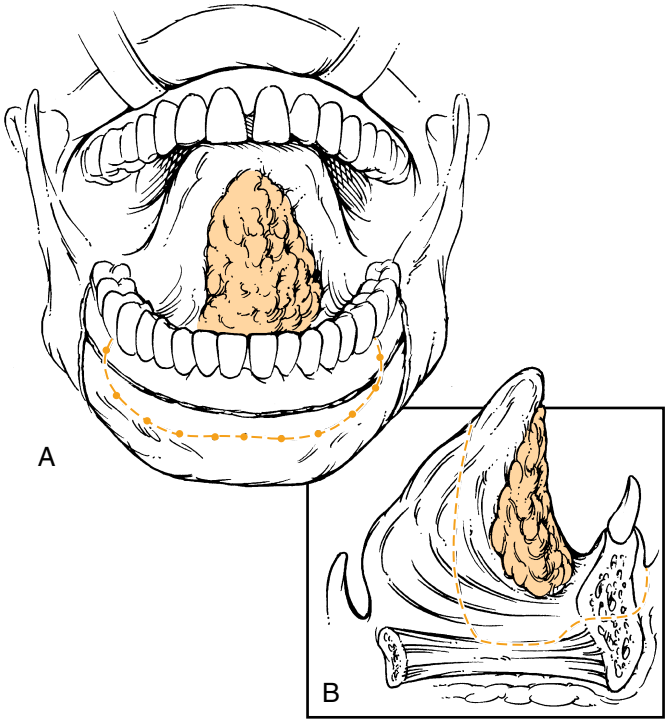

Figure 96-23. Anterior floor of mouth carcinoma treated with a marginal mandibulectomy with a visor flap approach. New York: Churchill Livingstone; 1999.)*

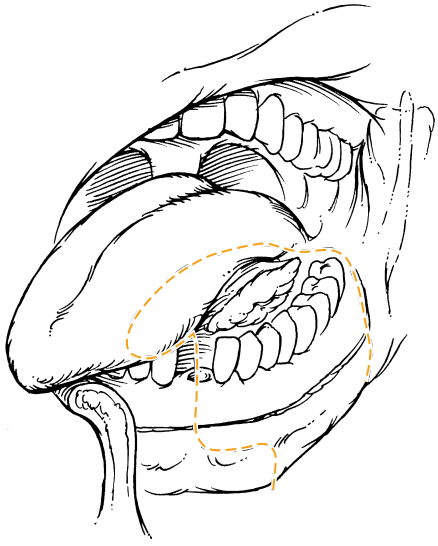

Figure 96-24. Composite resection of floor of mouth carcinoma with segmental mandibulectomy. To obtain wide surgical margins, a significant portion of lateral oral tongue is resected with the specimen. *(From Silver CE, Rubin JS.* Atlas of Head and Neck Surgery. *2nd ed. New York: Churchill Livingstone; 1999.)*

The 5-year survival for carcinomas of the floor of mouth are 90% for stage I, 80% for stage II, 65% for stage III, and 30% for stage IV disease.[50,82]

Buccal Mucosa

Carcinomas of the buccal mucosa represent 5% to 10% of all oral cavity malignancies (Fig. 96-25). There is a 4:1 male predominance and the typical patient is in the sixth decade of life. An association between smokeless tobacco use and buccal carcinomas has been noted. An increased incidence of these tumors is seen in the Southeastern U.S. population. In India, betel nut use is associated with a high incidence of buccal carcinoma.

Verrucous carcinoma usually arises on the buccal mucosa and is considered a low-grade malignancy. Poor oral hygiene, tobacco use, and viral infection have all been suggested as potential etiologies. Although considered low grade, foci of invasive carcinoma and areas of dedifferentiation may be found within an individual specimen. Surgical resection is the treatment of choice.[83] Elective treatment of the regional lymphatics is not necessary given the low likelihood of regional metastasis. The differential diagnosis for epithelial-based lesions presenting in the buccal mucosa should also include squamous papilloma and pseudoepitheliomatous hyperplasia. Minor salivary gland tumors may also present as a submucosal mass within this region.

The site of the buccal mucosa where squamous carcinomas are most frequently noted is adjacent to the third mandibular molar. Patients with advanced-staged disease may present with trismus as a result of direct invasion of the tumor into the muscles of mastication. Parotid duct involvement may produce obstructive sialoadenitis. Anterior lesions metastasize regionally to submandibular nodes, whereas posterior buccal lesions metastasize to upper jugulodigastric lymph nodes.

Small lesions can be excised transorally. Intermediate-staged primary tumors may be resected transorally or through a lip-splitting incision. With the exception of superficial lesions, the buccinator muscle should be resected in continuity, thus providing an adequate deep margin. Although primary closure or healing by secondary intention is acceptable for small primary tumors, larger defects should be repaired with a fasciocutaneous flap to avoid scar contracture and trismus, which are frequent sequelae of skin grafting. Local intraoral spread may necessitate resection of the alveolar ridge of the mandible or maxilla. For invasive squamous cell carcinomas and minor salivary gland tumors, the buccinator muscle should be included with the

specimen at the time of resection. Deep invasion into the cheek may require through-and-through resection (Figs. 96-26, 96-27, and 96-28). Ideal reconstruction to provide both internal and external lining is best accomplished with a folded fasciocutaneous free flap. Surgery as a primary modality is advocated for buccal carcinoma, whereas combination therapy is advised for advanced lesions. As with most lesions of the oral cavity, tumor thickness has a direct correlation to prognosis. In T_1/T_2 N_0 tumors, depth of invasion greater than 5.17 mm at the primary site has been correlated with a risk of ipsilateral regional lymphatic spread.[84]

Diaz and colleagues reviewed a series of 119 (previously untreated) patients with buccal carcinoma undergoing treatment at the MD Anderson Cancer Center. Primary tumors were staged as follows: T_1—21%, T_2—38%, T_3—23%, and T_4—15%. The majority of patients (72%) were N_0 at presentation. The majority of patients were treated exclusively with surgery (71%). No patients were treated with radiation therapy alone, and postoperative radiation therapy (dosage 50 to 60 Gy) was used for patients with extracapsular nodal spread or positive margins. Transoral excision was performed in the majority of patients

Figure 96-28. Closure of "through-and-through" buccal carcinoma accomplished with a cervicofacial advancement flap and pectoralis major flap. A portion of the pectoralis major flap lines the oral cavity, a portion is desquamated to transition externally, and a portion is external at the oral commissure extending to the advancement flap.

with only 27% of patients requiring a lip-splitting incision and cheek flap for resection. Modified radical neck dissection was performed for patients with N_+ necks, and supraomohyoid neck dissection was used for those with N_0 necks. The 5-year survival for all patients within the series was 63%. Five-year survival declined from 70% for N_0 patients to 49% for patients with metastatic lymphadenopathy. Within the series of patients, 45% experienced recurrence (23% local, 11% regional, 9% local and regional) and salvage therapy was successful in only 22%. Stensen's duct involvement and buccinator muscle invasion had no effect on locoregional recurrence.[85]

Reported 5-year survival is 75% to 78% for stage I, 65% to 66% for stage II, 30% to 62% for stage III, and 20% to 50% for stage IV disease.[82,85,86]

For patients who are not considered appropriate candidates for extensive surgical resection and reconstruction, primary radiation or chemoradiation is a viable treatment option. The reported results on the use of primary radiation therapy in patients with locally advanced disease demonstrate high recurrence rates (45%) and compromised overall survival (38%) after treatment.[87]

Hard Palate

Squamous cell carcinoma is the most common malignancy of the palate (Fig. 96-29). A close second in frequency are minor salivary gland tumors that include adenoid cystic carcinoma, mucoepidermoid carcinoma, adenocarcinoma, and polymorphous low-grade adenocarcinoma.[88] Mucosal melanoma most commonly arises on the hard palate and the maxillary gingiva and presents as a nonulcerated, pigmented plaque. The typical patient is 40 to 50 years of age, and the prognosis is poor because of the locoregional aggressiveness of the tumor and propensity for distant metastases. Kaposi's sarcoma of the palate is the most common intraoral site for this tumor.[89] Chronic irritation from ill-fitting dentures may also play a causal role in the development of dysplasia. Inflammatory lesions arising on the palate may mimic malignancy and can be differentiated by biopsy. Necrotizing sialometaplasia appears on the palate as a butterfly-shaped ulcer and resembles a

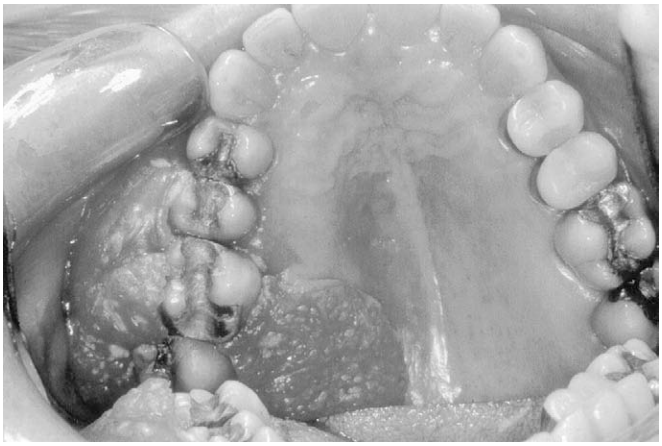

Figure 96-29. Hard palate squamous cell carcinoma extending over the upper alveolar ridge to the gingivobuccal sulcus. Margin control for this tumor would extend to the soft palate posterior and require an infrastructure maxillectomy. Retrograde spread along the greater palatine nerve could result in skull base extension.

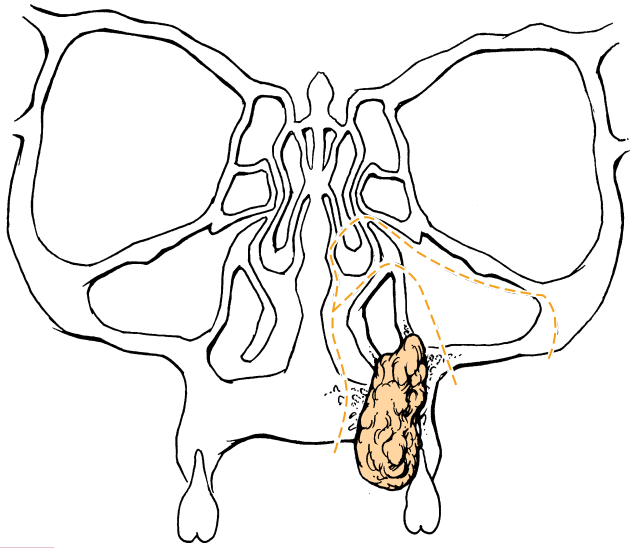

Figure 96-30. Bone cuts on an infrastructure maxillectomy for a hard palate malignancy. *(From Silver CE, Rubin JS.* Atlas of Head and Neck Surgery. *2nd ed. New York: Churchill Livingstone; 1999.)*

malignancy. Treatment is symptomatic and biopsy confirms its benign nature. Torus palatini are exostoses or bony outgrowths of the midline palate and maxillary bone that do not require surgical treatment unless patients are symptomatic.

The typical patient with a carcinoma of the hard palate is an elderly male with a history of tobacco use. A high incidence of hard palate carcinoma is seen in countries where reverse smoking is practiced.

Minor salivary gland tumors typically present as a submucosal nodule. Ulceration is rare unless a biopsy has been previously performed. Minor salivary gland tumors tend to arise at the junction of the hard and soft palate. Direct infiltration of bone may lead to extension into the floor of the nose or the maxillary antrum. Neurotropic spread along the greater palatine nerve may result in extension to the foramen rotundum or CN V ganglion.

Squamous carcinoma of the hard palate is treated surgically. Small lesions may be treated with transoral wide local excision. The resection may be performed to the level of the bony portion of the hard palate with anticipated re-epithelialization. Because the periosteum of the palatal bone acts as a barrier to spread, excision with bony preservation is adequate for small lesions. Involvement of the periosteum requires removal of a portion of the bony palate. Partial or subtotal maxillectomy is required for larger lesions or those involving the maxillary antrum (Fig. 96-30). For malignancies extending along the greater palatine nerve, biopsy of this nerve is important for identifying neurotropic spread. Small- to medium-sized defects may be reconstructed with the aid of local advancement flaps or a buccal fat pad flap. Oronasal postresection fistulas of the palate require a dental prosthesis for rehabilitation of speech and swallowing. For lesions resulting in a palatal defect after resection, prosthetic rehabilitation can offer the patient an excellent functional result. In this circumstance a maxillofacial prosthodontist may construct a splint preoperatively for use at the time of resection. A split-thickness skin graft is used to cover edges of bone from osteotomy and replace sites within the sinuses where mucosa was removed as part of the resection. The cavity is then packed with petroleum gauze, and a lag screw can be used to secure the prosthesis to the maxilla, providing support to the underlying repair (Figs. 96-31, 96-32, and 96-33). The temporary prosthesis is removed approximately 1 week later and the packing is evacuated. An interim prosthesis is worn until a more permanent option can be tailored to the resultant defect.[90] Adjuvant radiation is indicated for advanced staged tumors, perineural invasion, and positive margins.

Primary radiotherapy has been investigated as a therapy for hard palate carcinomas with an 80% 5-year local control rate reported for T_1 and T_2 tumors; however, this control rate falls to 24% for T_3 and

Figure 96-31. Hard palate squamous cell carcinoma before resection.

T_4 lesions. Nevertheless, surgery is the favored primary modality for carcinoma of the hard palate. In this study, 5-year survival was 48% for squamous cell carcinomas and 63% for minor salivary gland carcinomas.[91]

For patients with hard palate malignancies, 10% to 25% present with cervical metastases, most frequently to the submandibular and upper jugular cervical nodes.[92] Given the low incidence of occult metastases, elective neck dissection is not indicated in most cases.

The reported 5-year survival for patients ranges from 40% to 60%.[92,93]

Surgery—Treatment of the Mandible

The management of the mandible as it applies to oral cavity malignancies has evolved over time. Initially, squamous cell carcinoma of the oral cavity was believed to invade the mandible through the adjacent lymphatics. Direct invasion is now recognized as the most common pathway. In a paper by Marchetta and colleagues in 1971,[94] it was demonstrated that tumors involve the mandible by first invading the periosteum. When the periosteum was free of direct tumor invasion, a mandible-sparing operation was considered feasible.

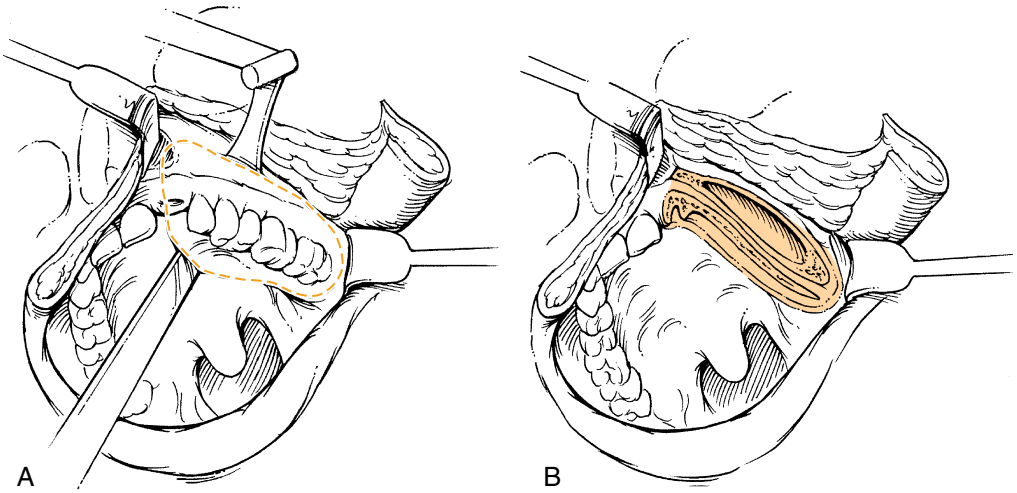

Figure 96-32. Approach to resection of a hard palate tumor. Weber-Ferguson incision with lip-split is shown for superoanterior exposure. Resection exposes the inferior aspect of the nasal cavity and maxillary sinus to the oral cavity. **A,** Planned cuts for resection of lateral maxillary alveolus and palate. **B,** Post-resection defect prior to reconstruction demonstrating communication with the lower aspect of the maxillary sinus. *(From Silver CE, Rubin JS.* Atlas of Head and Neck Surgery. *2nd ed. New York: Churchill Livingstone; 1999.)*

Figure 96-33. Obturator in place after infrastructure maxillectomy. Split-thickness skin graft covers the osteotomy margins and relines the maxillary sinus cavity and is held in place by petroleum gauze supported by the obturator.

Mandible-sparing procedures including vertical and horizontal marginal mandibulectomy (Fig. 96-34) and pull-through techniques have gained popularity as organ conservation philosophies have emerged within the field (Figs. 96-35 and 96-36). In addition, pull-through techniques offer the advantage of avoiding a lip-splitting incision and allow adequate exposure for free tissue reconstruction. A pull-through is contraindicated in patients with gross mandibular destruction but may be performed in continuity with resection of the lingual plate of the mandible.

Mandibulotomy for access in oncologic resection and reconstruction of oral cavity malignancies is typically reserved for advanced-stage primaries with extensive oropharyngeal spread. Placement of the osteotomy in the midline or paramedian locations (with mental nerve preservation) is the preferred site. The paramedian mandibulotomy offers the advantage of ipsilateral geniohyoid and genioglossus muscle preservation, whereas midline osteotomy requires transection of these muscles. At times, sacrifice of a mandibular incisor or canine tooth may be required to perform an osteotomy. Creation of a mild to moderate malocclusion, independent of technique, has been shown to be a common finding.[95] With the bone cut for the mandibulotomy, loss of a fine column of cortical bone occurs. This can be lessened by partially sawing through the lingual cortex and greenstick fracturing the posterior table with an osteotome. Placement of a titanium plate before actual osteotomy is a strategy that will allow for retention of the patient's normal occlusion when the mandible is reapproximated at the end of the procedure. The placement of drill holes for the plate at the inferior aspect of the mandible in patients with intact dentition avoids iatrogenic tooth root injury. If a lag screw technique is used, care needs to be exercised to avoid overcorrection with fixation of the mandibulotomy ends and creation of a malocclusion. Lateral mandibulotomy, at the level of the body or ramus, should be avoided because of poor healing at the osteotomy site and the interruption of the inferior alveolar artery and nerve at the time of osteotomy.

Complications from mandibulotomy have been extensively reported in the literature and range from 23.2% to 47.6%.[96,97] These include plate exposure, lip contracture, ankyloglossia, cellulitis-abscess, temporomandibular joint dysfunction, nonunion, and osteoradionecrosis. When mandibulotomy is performed in the setting of a marginal mandibulectomy, the risk of nonunion and infection associated with devascularization of the involved mandible has led some surgeons to abandon combining the two techniques.[96] Eisen and colleagues examined the morbidity of midline mandibulotomy in patients requiring postoperative radiation therapy. They found a complication rate of 11% in patients whose mandibulotomy site was included in the radiation field.[98]

Assessing the need for segmental mandibulectomy can be a difficult treatment decision to make (Table 96-3). Although gross mandibular invasion clearly mandates a segmental mandibulectomy, situations in which periosteal adherence and subtle cortical invasion are suggested (by clinical examination or radiographic imaging) require the experience and judgment of the surgeon as to whether to proceed with a marginal mandibulectomy versus segmental mandibular resection. Marginal resection in the setting of alveolar ridge carcinoma has been advocated by some authors when radiographically detected bony erosion fails to extend below the level of the mandibular canal.[99]

Segmental resections of the anterior mandible (including the symphyseal and parasymphyseal regions) mandate reconstruction with vascularized bone and soft tissue. Posterior segmental mandibular defects, in particular in edentulous patients or individuals with comorbidities limiting the ability for free tissue bony reconstruction, may be adequately repaired with soft tissue reconstruction only. Although the resection without bony reconstruction of the lateral mandible leaves patients with a J-shaped mandibular "swing," speech and swallowing function are generally good and patients are capable of decannulating if tracheostomy is performed at the time of procedure. Cosmetic

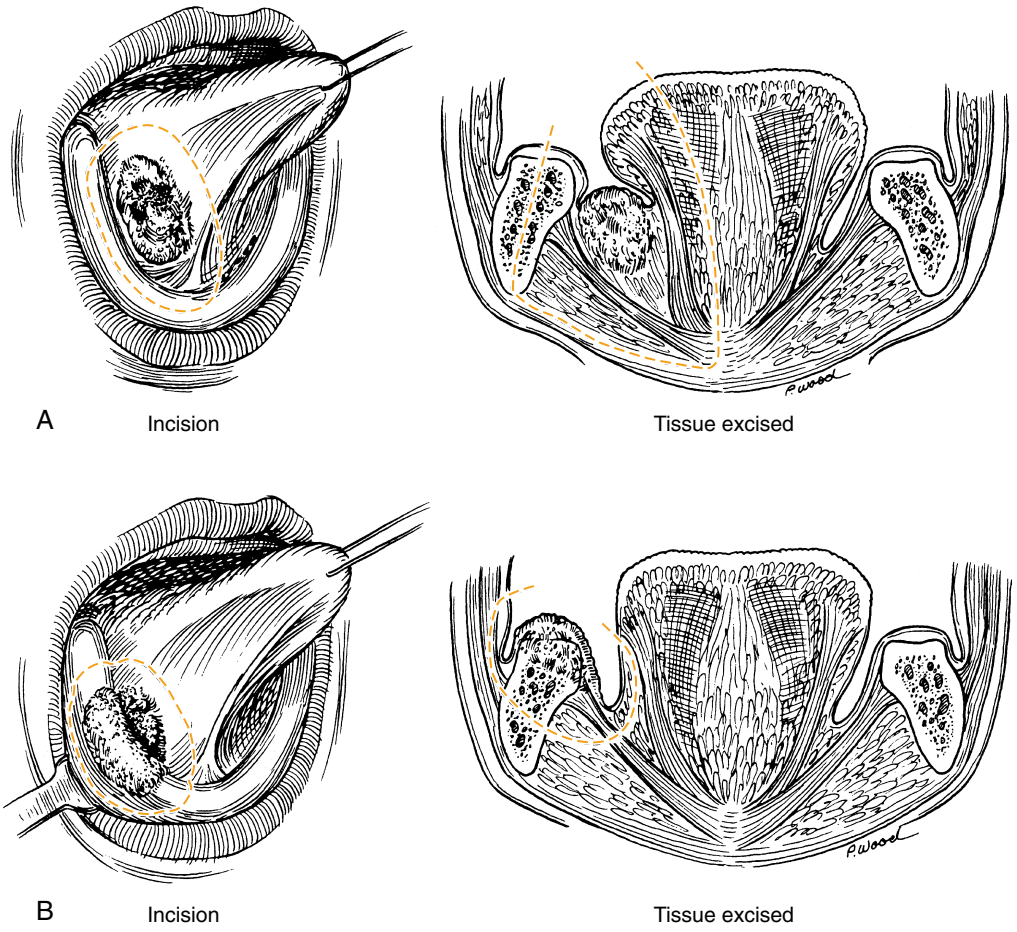

Figure 96-34. **A,** Floor of mouth tumor removed with a lingual sagittal marginal mandibulectomy. **B,** Floor of mouth–alveolar ridge tumor removed with a coronal "rim" marginal mandibulectomy.

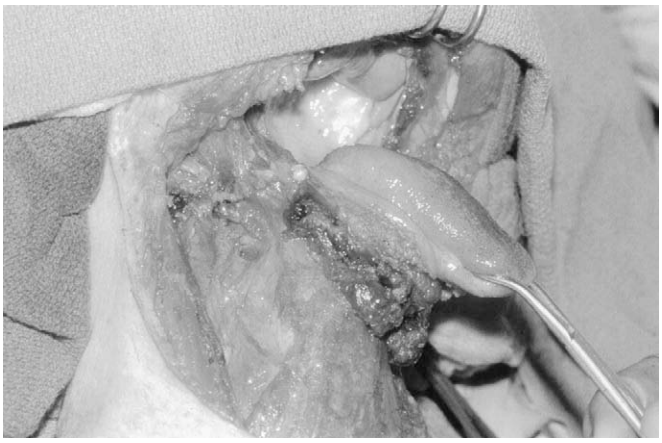

Figure 96-35. Pull-through technique for extensive floor of mouth carcinoma extending into the oral tongue.

Table 96-3

Indications for Surgical Treatment of the Mandible

Type of Presentation	Intervention Required
Mucosal lesion with mandibular approximation, freely mobile	Wide local excision with removal of adjacent periosteum
Mucosal lesion with isolated adherence to the mandible, lingual aspect	Lingual-sagittal marginal mandibulectomy
Mucosal lesion with isolated adherence to mandible, gingival aspect	"Rim"-coronal marginal mandibulectomy
Gross cortical invasion, inferior alveolar nerve involvement	Segmental mandibulectomy

asymmetry consistent with a concavity in the region of the mandibular ramus is notable. Chin drift may occur without the opposing aspect of mandible but can be reduced if a bulky soft tissue flap (e.g., pectoralis major) is used for reconstruction of the posterior mandibular site. Alternatively, the lateral mandibulectomy defect can be spanned with a titanium mandibular reconstruction plate to maintain the continuity of the mandible, maintain occlusion, and avoid the chin drift observed from allowing the mandible to "swing." This type of reconstruction should be done in combination with intraoral soft tissue reconstruction using a pedicled musculocutaneous flap (e.g., pectoralis major flap).

Surgery—Treatment of the Neck

Patterns of spread from primary tumor sites in the head and neck to cervical lymphatics are well described. The location and incidence of

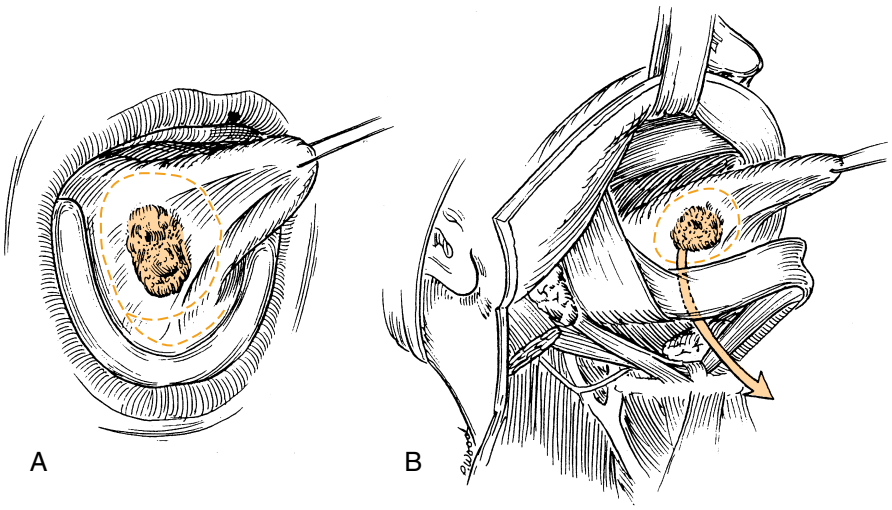

Figure 96-36. **A,** Floor of mouth tumor. **B,** Proposed pull-through approach. After raising the apron flap superiorly, the mylohyoid and anterior belly of the digastric are detached, allowing the delivery of the tumor for resection to a cervical location and sparing the need for mandibulotomy for selected lesions.

metastasis vary according to the primary site. Primary tumors within the oral cavity and lip typically metastasize to the nodes in levels I, II, and III (Fig. 96-37).

The need to perform a neck dissection in the N_0 patient has undergone considerable investigation. Lymphoscintigraphy with sentinel node biopsy in the setting of the N_0 oral carcinoma patient has been reported to have a negative predictive value of 100%.[100] Even in previously treated oral carcinoma patients, sentinel node biopsy has a high reported negative predictive value (91%).[101] Although initial results appear promising, most reported series reflect the experience of only a limited number of patients. Sentinel node biopsy is not currently considered standard of care for oral cavity carcinoma. Myo and colleagues reported on the use of cyclin D1 gene numeric aberrations assessed on FNA samples in stage I and II oral cancer patients. Cluster-type amplification of the cyclin D1 gene correlated with future regional recurrence in patients when the neck was not treated electively.[102]

For a patient with an oral cavity malignancy who is clinically and radiographically N_0, with a risk of occult metastases exceeding 20%, many consider elective treatment to the regional lymphatics necessary. Options for treatment of the regional lymphatics include elective neck irradiation versus neck dissection.[103,104] With time, modifications of neck dissection have evolved from radical neck dissection through modified radical neck dissection to selective neck dissection. Surgeons have traditionally treated the N_0 neck with surgery.[105] Selective neck dissection can serve as a staging procedure to determine the need for postoperative adjuvant radiotherapy. For the clinically N^+ neck, the surgical treatment of choice has traditionally been modified radical neck dissection (MRND) or radical neck dissection (RND), although some authors advocate selective neck dissection (SND) for the treatment of limited N_1 disease.[106] Kuntz and Weymuller examined quality-of-life data for patients undergoing RND, MRND, and SND. Shoulder disability at 6 months was the least for SND patients and similar for SND and MRND patients at 12 months. Additionally, MRND and SND patients were noted to have fewer problems with pain than RND patients.[107]

The most common selective neck dissection performed for the management of the regional lymphatics in patients with oral cavity cancers is the supraomohyoid neck dissection (SOHND), which includes removal of lymph node levels I, II, and III. The reported incidence of regional recurrence after elective SOHND is as low as 3%.[108] Inclusion of level IIb nodes within the neck dissection is advocated for oral cavity primaries because of a reported 10% incidence of spread to this region[109]; however, some authors disagree that the inclusion of level IIb is necessary in the setting of elective neck dissection.[110] The occurrence of skip metastases with oral tongue lesions makes possible the involvement of nodes in levels III or IV without involvement of higher echelons of levels I or II. Byers and colleagues[78] noted that patients with lateralized oral tongue squamous cell carcinoma with an ipsilateral N_0 neck had a 15.8% rate of "skip metastases." As a result, Byers and colleagues advocated a level I to IV neck dissection rather than a standard supraomohyoid neck dissection for patients with oral tongue carcinoma and an N_0 neck. Level V nodes are involved in some cases and are seen with concomitant involvement of higher echelon nodes.[111] Midline lesions have a high incidence of bilateral spread to cervical lymphatics and treatment of both necks is indicated in these scenarios. When considering the routes of spread, extensive hard palate lesions must be viewed with concern. Given the predilection for retropharyngeal spread of soft palate tumors, hard palate lesions with posterior extension should be considered for postoperative radiation therapy to address this region that might otherwise go untreated with standard neck dissection. For all sites, the actual presence of cervical

metastasis has a negative impact on survival and, as such, aggressive preoperative investigation and close follow-up for head and neck cancer patients is necessary.[112]

Sentinel node biopsy, as it is currently applied for skin malignancies, has been explored for early-stage (T_{1}-$_{2}N_{0}$) lesions of the oral cavity through the American College of Surgeons Oncology Group (ACOSOG). With the exception of floor of mouth tumors, promising initial results (with negative predictive values >95%) have been reported. Additional investigation of the technique will be required before it is considered standard of care for this clinical scenario.

The decision for surgery versus radiation therapy for treatment of the neck is determined by the modality of treatment chosen for the primary tumor. If the primary tumor is treated with surgery, the neck is generally managed surgically. If the primary tumor is treated with radiation, then the neck is treated similarly.[105] For advanced cervical lymphatic disease (N_2, N_3) or metastasis with extracapsular spread, surgical management of the neck alone is inadequate and postoperative adjuvant radiation therapy is necessary.

Surgically debulking of metastatic disease does not improve survival and is not advocated. Surgical salvage for recurrent neck disease after comprehensive neck dissection or radiation is associated with poor survival.[112]

Figure 96-38. Brachytherapy catheters in place for oral tongue carcinoma resected with narrow surgical margin on final pathology after radial forearm free flap reconstruction.

Radiation

Role of External Beam Radiation

Indications for radiation therapy with oral cavity malignancies include those common in other regions of the head and neck and are stratified by pathologic findings at the primary site and the neck. When indications at either site exist for postoperative radiation, the primary site and both sides of the neck are treated comprehensively. Indications include multiple pathologically positive nodes in the neck, perineural invasion, angiolymphatic invasion, extracapsular spread, close margins (<5 mm) at the primary site, tumor thickness of 10 mm or larger, and advanced T stage.

Of note, two of the indications for postoperative radiation therapy, perineural invasion and vascular invasion, may be identified less frequently than is actually present with standard hematoxylin and eosin staining. Kurtz and colleagues[113] demonstrated an increase in the identification of these pathologic findings when immunohistochemical staining with S-100 (for perineural invasion) and CD31 (for vascular invasion) was used.

Conventional dosing is 1.8 to 2 gray (Gy) per fraction, once a day, 5 days a week, to a dose of 62 to 70 Gy. For locally advanced head and neck cancer, radiation delivered in hyperfractionation and accelerated fractionation with concomitant boost protocols has been demonstrated to provide better locoregional control than conventional radiation dosing.[114]

The most common complication of radiation therapy to the oral cavity is xerostomia. A less common but more serious complication is osteoradionecrosis (ORN). Factors predisposing to ORN include poor dentition, inadequate soft tissue coverage of bony structures, mandibular tori, and mucosal trauma. Aggressive dental care in these patients by a dentist skilled in managing patients requiring radiation therapy is essential. To prepare the patient for radiation, pretreatment dental extraction, removal of tori, and meticulous closure of mucosa are necessary. For patients with preserved dentition, long-term fluoride treatments may prevent progressive caries and subsequent ORN.

Package Time

Rosenthal and colleagues[115] examined treatment package time, defined as the length of time from surgery to completion of radiation therapy, as it related to outcome for patients with locally advanced squamous cell carcinoma of the head and neck. Their findings supported the concept that a total treatment package time of less than 100 days was associated with improved locoregional control and survival. These findings emphasize the importance of developing a surgical treatment plan that minimizes the risks of complications that would delay the onset of radiation therapy and using a radiation protocol that minimizes the need for treatment breaks.

Brachytherapy

Brachytherapy catheter placement for localized radiation boost has a limited role in the treatment of oral malignancies. Brachytherapy has been used for oral tongue and floor of mouth cancers surgically resected with close surgical margins on final histopathologic interpretation. Intraoperative placement is necessary and tracheostomy may not be required (Fig. 96-38). Loading of the catheters occurs within a hospital setting in a protected room after placement. The use of brachytherapy does require a prolonged hospital stay compared with standard surgical treatment requirements. Brachytherapy as a primary treatment has not been advocated because of the creation of post-treatment fibrosis limiting monitoring for recurrence of disease, as well as the risk of post-treatment ORN.

Adjunctive Chemotherapy

Induction chemotherapy has been advocated to decrease the magnitude of resection; however, clinical trials supporting this approach are lacking. Induction (neoadjuvant) chemotherapy is not currently considered standard of care and potentially delays the timing of the definitive therapeutic procedure. Robbins and colleagues have reported on the use of a neoadjuvant RADPLAT protocol (intra-arterial infusion of cisplatin and intravenous infusion of sodium thiosulfate with concurrent radiation therapy to 50 Gy) in the setting of T_2 and T_3 oral carcinomas with varying levels of N staging. Surgery was described as a tumor nidusectomy performed after 8 weeks of therapy. Completed response was noted in 80% of the primary sites and 79% of the regional lymphatic fields. Five-year disease-specific survival rate was 64%, with a locoregional control rate of 74%.[116]

Increased survival with postoperative methotrexate and 5-fluorouracil (5-FU) has been demonstrated in patients with extracapsular nodal spread.[117,118] Evidence suggests a response to chemotherapy is predictive of the likelihood of response to radiation therapy.[119,120]

Cooper and colleagues examined patients at high risk for locoregional recurrence that would benefit from the concurrent addition of cisplatin to postoperative radiation. High-risk patients were identified as having two or more metastatic lymph nodes, presence of extracapsular nodal spread, or positive surgical margins. In reviewing trial data from the Radiation Therapy Oncology Group (RTOG) #85-03 and RTOG #88-24, a benefit in locoregional control was suggested in the concomitant chemoradiation patients defined as "high risk" as opposed to those who received postoperative radiation alone. A difference in survival benefit was not seen between the two groups; however, factors

such as lack of adequate randomization, limited group size, and length of follow-up were sited as reasons necessitating additional study.[120]

The role of induction polychemotherapy followed by radiotherapy or chemoradiotherapy for advanced-stage squamous cell cancer of the oral cavity, oropharynx, hypopharynx, or larynx has recently been reported in two randomized, phase three clinical trials. The European study (EORTC 24971/TAX 323) compared docetaxel, cisplatin, and fluorouracil (TPF) to cisplatin and fluorouracil (PF) as induction chemotherapy followed by radiation therapy for patients with previously untreated, unresectable squamous cell carcinoma.[121] Patients in the TPF group demonstrated a significant improvement in progression-free and overall survival as compared with patients in the PF group. A similar study by Posner and colleagues[122] (TAX 324) compared induction chemotherapy with TPF or PF followed by concomitant chemoradiotherapy with weekly carboplatin. The study population included previously untreated patients with either unresectable disease or advanced-stage disease where organ preservation therapy was being considered. The results were similar to the TAX 323 study, with patients receiving TPF demonstrating a significant improvement in progression-free and overall survival. Unfortunately, neither study included a control group of chemoradiotherapy alone for comparison to the induction chemotherapy group.

Additional Therapies

Photodynamic Therapy

Photodynamic therapy (PDT) may have a potential role in the treatment of widespread premalignant and superficial oral carcinoma. Use for residual tumor at positive resection margins has also been considered.[123] This modality has been used for palliative treatment of gastrointestinal tract, bladder, and lung cancers. Photofrin, a light-activated dye, which theoretically localizes to tumor tissue, is activated by exposure to a 620-nm light and produces oxidizing free radicals. Through disruption of the vasculature, tumor necrosis occurs.[124] Ideally, PDT should preferentially affect tumor tissue; however, histologic examination of post-PDT specimens have demonstrated the resultant tissue damage is not absolutely tumor-specific because tissues separate from the tumor also show evidence of necrosis.[125] Advantages of PDT include the potential for multiple treatments with favorable functional and cosmetic results. A disadvantage of PDT includes the prolonged skin photosensitivity that may last up to 6 weeks. Newer generations of photosensitizers may be more specific for neoplastic tissue and result in less long-term photosensitization.

In a review of the use of PDT for the treatment of carcinoma in situ (CIS) and early-stage lesions of the head and neck, Biel examined the response of CIS and T1 recurrent squamous carcinomas of the oral cavity.[123] A complete response to therapy was noted after one treatment in the 29 patients; however, 5 patients developed recurrences within a follow-up period of 70 months.[126] Intraoperative adjuvant treatment with PDT for advanced-stage and recurrent tumors at the tumor's primary site or regional lymphatic bed has also been advocated.[123]

Organ Preservation Protocols

An organ preservation approach to oral cavity carcinoma similar to laryngeal preservation treatment has been explored. Chemoradiation protocols have demonstrated effective organ preservation for advanced cancers and would be an attractive alternative for patients facing the need for total glossectomy if bony involvement is absent. Attempts at intra-arterial chemotherapy for advanced disease have demonstrated promising results; however, the toxicity and technical ability to perform this therapy remain obstacles to widespread utilization.[127]

Chemoprevention

The concept of chemoprevention has been investigated in clinical studies. The goals of treatment are to reverse oral premalignancy and prevent emergence of second primary tumors. Several agents have been used including peroxisome proliferator-activated receptor (PPAR), isotretinoin, and COX-2 inhibitors.[128] Because of the side effects associated with some agents (in particular with retinoids) and lack of proven efficacy, general application in the clinical setting has not occurred. Investigation into the use of a "biofilm" created with a mucosal adhesive film to allow for topical administration of tretinoin has been demonstrated to be safe in the animal model and has the potential to decrease the toxicities associated with conventional use of the medication.[129]

In animal models, lyophilized black raspberries and vitamins C and E can reduce the number of dimethylbenz(a)anthracene (DMBA)-induced tumors within a hamster cheek pouch and may prove to have a role in chemoprevention.[130,131] However, in a randomized controlled trial, research examining the potential protective effects of vitamin E and beta-carotene supplementation failed to demonstrate a protective effect on the development of oral cancers in male smokers.[132] Studies have also suggested the Bowman-Birk protease inhibitor may be an agent of interest for treating premalignancy. A response was noted in approximately one third of patients treated for leukoplakia with low associated toxicity.[133]

Regular use of aspirin has been shown in a case-control study to decrease the risk of developing head and neck cancer. The effect was noted to be more significant in women and low to moderate users of alcohol and tobacco products. Heavy smokers and users of alcohol failed to demonstrate a chemoprotective benefit from regular aspirin use.[134]

Reconstruction

For a successful reconstruction after oncologic resection, several important principles must be taken into consideration. These include maximizing mobility of the remaining tongue, reconstructing adequate bulk, obtaining adequate access to inset tissue for reconstruction, performing a watertight closure, and reconstructing the appropriate sulci such that prosthetic rehabilitation is not hindered.

The method chosen for reconstruction depends on the nature of the defect and the patient's comorbidities. Options, after the resection of small lesions, include allowing the wound to heal by secondary intention, primary closure, and split-thickness skin or dermal grafting. Depending on the size and location of the defect, various advancement and rotation flaps serve as reconstructive options. Use of buccal fat, temporoparietal fascia, or pectoralis major flaps each offer unique options for soft tissue reconstruction. Reconstruction of the mandible is a more significant challenge. Anterior mandibular defects mandate osseous reconstruction (Fig. 96-39). The expanded reconstructive armamentarium provided by free-tissue transfer affords a one-stage method for restoring form and function in patients with complex defects. Reliability of free-tissue transfer is greater than 95% at experienced centers.[135] The possibility of distraction osteogenesis to address

Figure 96-39. Postresection of a T_4 floor of mouth squamous cell carcinoma requiring composite resection extending from mandibular angle-to-angle. Note the extent of the soft tissue defect around the inferior aspect of the tongue. Osseous free tissue reconstruction was required.

smaller mandibular defects is currently under investigation and may provide an alternative to free-tissue transfer in selected patients.[136]

Indications for Free Flap Reconstruction

Pectoralis major pedicled flaps and microvascular soft tissue reconstruction allow for the correction of the mucosal and soft tissue defects associated with tumor resection. For full-thickness buccal defects and extensive glossectomy defects, the pectoralis major flap can be partially de-epithelialized or rotated back on itself to provide resurfacing of the oral cavity components and the external lower one third of the face. However, the optimal treatment for many of these complex defects often requires microvascular free tissue reconstruction. The radial forearm free flap allows for a reconstruction that is tailored in shape to the oral defect without the burden of excessive bulk; offers the option for neural anastomosis, thus providing sensate reconstruction; and is associated with a limited donor site morbidity. When additional soft tissue is required, the anterolateral thigh,[137] rectus, and parascapular-scapular flaps may be harvested with larger skin paddles and associated muscle for additional bulk.

As discussed earlier in this chapter, reconstruction of the mandible depends on the location of the defect. In a review of their experience, Urken and colleagues reported on 210 cases requiring mandibular reconstruction. The need for segmental mandibulectomy was necessary for the treatment of benign and malignant tumors of the oral cavity and in the management of stage III osteoradionecrosis. They compared four groups of patients that included those reconstructed with iliac crest, patients who were not reconstructed (lateral defects), normal denture wearers, and normal dentate patients. The study demonstrated that speech and swallowing function were determined by the soft tissue reconstruction. Bite force was best if osteointegrated implants were achieved in patients with bony reconstructions. In addition, oral competence was improved with reconstructed patients.[135]

Indications for a fibula osteocutaneous free flap reconstruction include total-subtotal mandibular reconstruction, reconstruction of "bone-only" defects (osteoradionecrosis), reconstruction of the atrophic mandible, pediatric mandibular reconstruction, and secondary reconstruction of the subcondylar-condylar complex (Fig. 96-40).[135]

Patients with advanced-staged complex primary lesions often present reconstructive dilemmas. For defects requiring additional soft tissue reconstruction, double free-tissue transfer with a soft tissue flap and an osseous flap have been advocated.[135] A scapular composite flap offers the advantage of multiple skin paddles with bone.[138] In addition, the presence of a musculoskeletal abnormality of the lower extremities may preclude a fibular free tissue transfer. Use of two microvascular free flaps, the fibula free flap combined with radial forearm free flap, has also been described to accomplish a reconstruction consistent with the needs of the specific defect. When external skin resurfacing is necessary, a cervicofacial advancement flap is a desirable option to consider in combination with a separate intraoral reconstructive technique.

Reconstructive options for composite resections of the oral cavity are dependent on location and the functional status of patients. An anterior mandibular defect in a healthy young patient is viewed differently than a lateral mandibular defect in a deconditioned elderly patient with poor dentition. Despite technical feasibility, not every patient requires free flap reconstruction to attain the postoperative goals of adequate speech and effective swallowing. An understanding of a patient's expectations and an understanding of the attainable reconstructive results, while using the support of prosthodontists and speech and swallowing therapists, can create an atmosphere for successful rehabilitation.

Vessel anastomosis is noted in the neck. *(Adapted from Silver CE, Rubin JS.* Atlas of Head and Neck Surgery. *2nd ed. New York: Churchill Livingstone; 1999.)*

Long-Term Management and Rehabilitation

Speech and Swallowing

To achieve the optimal functional outcome, it is important that the speech and swallowing therapist evaluates the patient before treatment. Preoperative consultation will provide an assessment of the patient's pretreatment functional status and allow counseling concerning the potential functional outcome after treatment. The educated patient has more realistic expectations with respect to dysphagia, nutritional supplementation, xerostomia, and mucositis that may occur with treatment. A successful speech and swallowing outcome requires a high degree of patient motivation and cooperation.

As a rule, the more limited the surgical resection, the less likely a patient is to experience significant functional impact on speech and swallowing. Patients requiring wide surgical resections of the retromolar trigone or procedures that extend deep within the tongue base experience the most significant impact on swallowing. Floor of mouth resections are associated with a detrimental effect on chewing.[139] Radiation, alone or in combination with surgery, has a side effect profile including problems such as xerostomia, lymphedema, and fibrosis with scar contracture. Postoperatively, the speech and swallowing therapist will assess the patient's ability to progress to normal oral intake. Prevention of aspiration pneumonia in these patients is vital. An early postoperative evaluation of swallowing function with a flexible laryngoscope (with a fiberoptic endoscopic evaluation of swallowing protocol) or modified barium swallow can guide the direction of swallowing rehabilitation.

Pain Management

Patients undergoing treatment of oral cavity malignancies, in particular those having extensive surgical procedures with reconstruction, require a comprehensive pain management plan. Initial postoperative pain management is accomplished by the use of patient-controlled analgesia (PCA). A transition from intravenous analgesia to oral administration is important as the patient progresses to discharge. A visual analog pain scale will aid the physician and patient in adjusting the amount of analgesia required. A balance must be struck between providing adequate pain control and excessive sedation, which delays ambulation and rehabilitation. The importance of physical therapy for patients recovering from extensive surgical and reconstructive procedures is significant. Finally, for patients whose pain management is difficult, consultation by the pain management service is helpful for tailoring the analgesia regimen.

Palliative Care

Palliative care options should be considered for patients with unresectable disease or when recurrence precludes curative therapy. Palliative chemotherapy and radiation can provide symptom relief when pain and tumor growth adversely affect quality of life. Decisions to place a tracheostomy and gastrostomy tube are individualized and may provide significant comfort without unnecessarily prolonging life. Hospice consultation is important for aiding the patient and family with making end-of-life decisions.

Follow-up

Follow-up occurs in two phases for patients undergoing surgery and radiation for oral malignancies. In the initial phase, when the patient is recovering from surgery or radiation therapy, weekly follow-up may be necessary to assess nutritional status and monitor rehabilitation goals. The second phase is cancer surveillance. See Table 96-4 for the American Head and Neck Society guidelines for cancer surveillance.[140]

In addition to monitoring for locoregional recurrence, an annual chest radiograph, liver function tests, and comprehensive head and neck examination are important for detecting metachronous lesions. A biannual thyroid-stimulating hormone (TSH) determination is necessary for patients after neck irradiation, as are frequent dental evaluations for dentate patients.

Long-term survival in the face of disease recurrence is limited. Argiris reported on the experience of 399 patients in Eastern Cooperative Oncology Group trials (ECOG 1393 and 1395) receiving palliative chemotherapy in the setting of locoregionally recurrent or metastatic disease. At 1 year, the overall survival was 32%. At 2 years, 49 patients (12%) were alive. Only 6 patients lived to 5 years after the diagnosis of recurrence.[141]

Complications

Postoperative complications are common after extensive head and neck surgical procedures. In the immediate postoperative period the patient is at greatest risk for pulmonary embolism, gastric ulceration, hemorrhage, delirium tremens, and aspiration pneumonia. Vigilance for symptoms indicative of these adverse events may permit early detection and life-saving interventions.

A late complication after radiation therapy is osteoradionecrosis. Early treatment may prevent substantial bone loss and includes hyperbaric oxygen therapy, antibiotics, and sequestrectomy. When mandibular loss occurs, microvascular reconstruction has been successful in salvaging the remaining healthy tissue while reconstructing the necrotic tissue lost.

Delayed pathologic fracture may occur after marginal mandibulectomy when inadequate mandible remains. After bony reconstruction, a nonunion may occur and lead to infection, mobility, or fistula formation.

Summary

The oral cavity is a unique site within the head and neck in that the accessibility of the region readily allows for the identification of premalignant and early-staged lesions. The preferred primary treatment modality for oral cavity malignancies is surgical. Given that speech and swallowing function are profoundly affected by the treatment of oral tumors, oncologic resection and reconstruction require careful preoperative planning. For advanced-staged lesions, the use of combination therapy—surgery followed by postoperative radiation therapy—remains the optimal treatment option. Management by a multidisciplinary team is critical to provide the patient with the best chance for control of cancer while achieving the best functional outcomes.

CHAPTER NINETY-SEVEN

Reconstruction of the Mandible

Brian Nussenbaum

Key Points

- Advances in surgical techniques and improved hardware options enabled the development of successful methods used today for mandibular reconstruction.
- Most mandible defects are caused by resection of neoplasms, most of which are malignant. The effectiveness of associated soft tissue reconstruction, especially if it involves the oral tongue, is frequently the major determinant in functional recovery.
- Marginal mandibulectomy involves excising a rim of mandible but with maintenance of the mandibular arch. These defects should be made in a curvilinear manner, and at least 1 cm of mandibular height should be retained.
- Segmental mandibulectomy involves resection of a full-thickness segment of bone, which creates a discontinuity defect. Lack of reconstruction causes significant functional and cosmetic morbidity.
- Segmental anterior defects should be corrected by reconstruction with osseous free tissue transfer in combination with a locking reconstruction plate. Lateral defects are generally corrected by reconstruction with either osseous or soft tissue flaps in combination with a locking reconstruction plate. The best long-term stable, successful reconstructions are with osseous free flaps.
- A soft tissue flap is less often used than a bone flap for lateral mandibulectomy defects because of extrusion (within 1 year of surgery) or fracture (within 2 years) of the plate in this setting.
- Patients who require segmental mandibulectomy because of malignancy have a poor prognosis, which sometimes influences the choice of the method of reconstruction.
- Fibular free-flap reconstructions for oromandibular defects are durable, lasting at least 10 years, and this vascularized bone graft does not undergo significant resorption, even in the setting of postoperative radiation.

Major advances in patient care generally occur through paradigm shifts (Fig. 97-1). For reconstruction of the mandible and maxilla, the first major paradigm shift occurred with the development of reliable free tissue transfer options along with advances in hardware devices. Before these advances, techniques involving nonvascularized bone grafts, vascularized pedicled bone grafts, and alloplastic materials were not reliably successful for primary reconstruction, especially in the typical defects that were caused by tumor-ablative surgery.[1,2] Both advances in surgical techniques and improved hardware options were crucial for this first paradigm shift, which occurred circa 1990 for mandibular reconstruction and circa 2000 for maxillary reconstruction. Although current options have proved to be reliably successful for single-stage primary reconstruction in the mandible and maxilla, these procedures remain highly complex and challenging, and donor sites are still required. In addition, it is difficult to restore the intricate three-dimensional structure precisely in many defects with bone from distant sites because of differences between the size and shape of the bone graft and the defect configuration. Advances in biotechnology, specifically in the field of tissue engineering, will probably have an effect on mandibular and maxillary reconstruction and will cause another paradigm shift within the foreseeable future.[3]

Anatomy, Physiology, and Pathophysiology

The mandible is the strongest facial bone.[4] It is a U-shaped bone with a horizontal portion (body), which carries an alveolar process with teeth, and two vertical portions (rami), which, through the temporomandibular joints, articulate with the skull bilaterally (Fig. 97-2). The mandible is attached to other facial bones by ligaments and muscles, and it articulates with the maxilla through occlusion of the teeth.

The body of the mandible has a dense cortical structure on the lateral and medial surfaces with a small core of spongiosa that contains nerves, blood vessels, and lymphatic vessels. The lower portion of the body contains heavy, thick bone that changes very little throughout life. The upper portion of the body, called the *alveolar process,* contains the dental sockets that support the teeth. Changes in the alveolar process occur throughout adult life, especially after dental extractions, which cause subsequent atrophy of this bony segment (Fig. 97-3). The mental foramen is midway between the inferior border and upper edge of the alveolar process, at the level of the second premolar tooth. The mental nerve branch of the inferior alveolar nerve and the associated vessels pass through this foramen. In an edentulous mandible, the mental foramen drifts to the upper border of the bone as a result of atrophy of the alveolar process (see Fig. 97-3).

The rami, the two vertical portions of the mandible, are composed of broad, thin plates of dense bone. Each ramus joins with the body to form the angle of the mandible. Each ramus ends anteriorly in the coronoid process and posteriorly in the condylar process. The coronoid and condylar processes are joined by a concave ridge called the *mandibular notch.* The condylar process is composed of the condyle and condylar neck. The superior surface of the condyle articulates with the temporomandibular joint.

The mandible is traversed by the alveolar canal, which begins on the inner surface of each ramus at the mandibular foramen and extends toward the symphysis to open on the lateral surface at the mental

foramen. The inferior alveolar nerve passes through this canal to provide sensation to the teeth roots and to the soft tissue of the lower lip and chin through the mental branch, which exits the mandible through the mental foramen.

The movement of the mandible is dependent primarily on two groups of muscles. The depressor-retractor group, which is anterior, is the weaker of the two groups and is composed of the geniohyoid and digastric muscles. These muscles insert into the inferior inner aspect of the symphyseal region and exert downward posterior force. The elevator group, which is posterior, is composed of the masseter, medial pterygoid, and temporalis muscles. The masseter muscle inserts along the outer aspect of the inferior edge of the angle. The medial pterygoid muscle inserts on the inner surface at the mandible angle, thus producing the masseteric-pterygoid sling. The masseter and medial pterygoid muscles always act simultaneously and hold each other in balance, but the angulation of the attachments at the angle is more favorable for the medial pterygoid. Thus, although the medial pterygoid muscle is weaker than the masseter in the intact mandible, it usually overpowers the masseter in segmental defects as a result of this more favorable angulation; this accounts for the typical displacement patterns that occur. Other muscles with more minor influence on the movements of the mandible include the lateral pterygoid and mylohyoid muscles. The lateral pterygoid muscle inserts mostly on the anterior inner aspect of the condylar neck and pulls primarily the neck medially and anteriorly. The mylohyoid muscle has minimal influence on movements of the intact mandible, inasmuch as most of its bundles insert into the muscle's midline raphe rather than onto the mandible.[4]

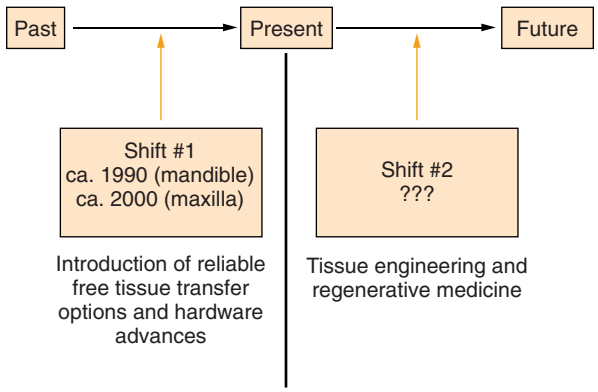

Figure 97-1. Advances in mandibular reconstruction.

The damage to the oral cavity after tumor extirpation was described by Conley in 1962.[5] Options for bone or soft tissue reconstruction were limited at that time, but the serious effects of extirpative surgery on function and cosmesis were clearly recognized. Functions of the oral cavity structures include mastication, swallowing, maintenance of oral competence, articulation, taste, oral hygiene, and airway protection.[6] Effective reconstruction of the oral cavity soft tissue components is crucial for functional restoration, especially in preserving mobility, position, and shape of the tongue, which is probably most critical for functional rehabilitation.[6]

There are two types of mandibulectomies: marginal and segmental (Fig. 97-4). In a marginal mandibulectomy, a rim of bone is resected, but continuity of the mandibular arch is maintained. When this type of mandibulectomy is performed, a curvilinear excision configuration must be used, and a minimal 1 cm height of inferior bone must be preserved, in order to avoid iatrogenic fracture.[7,8] The bone defect in a marginal mandibulectomy does not necessitate any specific reconstruction except for soft tissue coverage, usually with a soft tissue flap or skin graft.[9] The reconstructive plan in this setting is directed by the characteristics of the soft tissue defect and influenced mostly by the extent of soft tissue loss and whether the tissue has been previously irradiated.

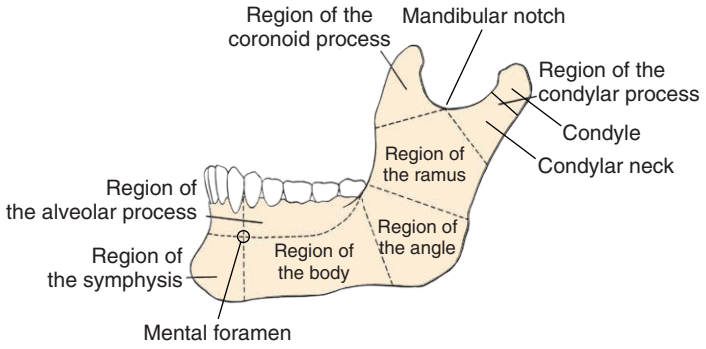

Figure 97-2. Anatomic regions of the mandible. *(From Dingman RO, Natvig P.* Surgery of Facial Fractures. *Philadelphia: WB Saunders; 1964.)*

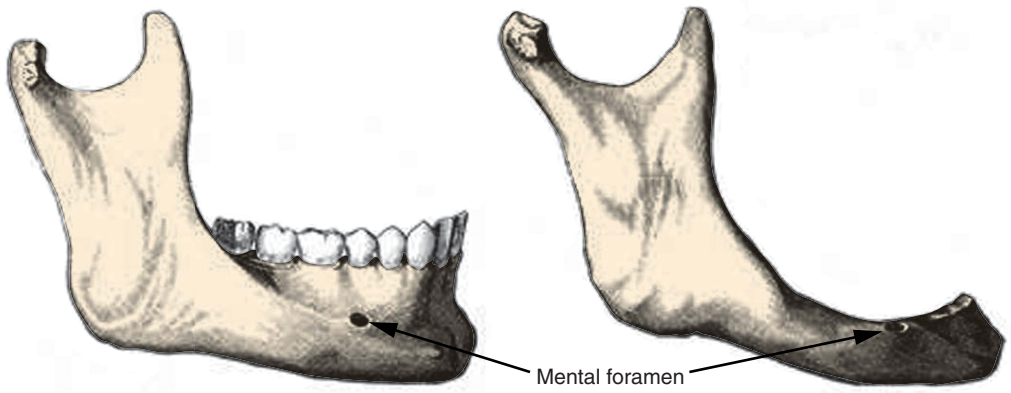

Figure 97-3. Comparison of the anatomy of a dentulous mandible (*left*) with an edentulous mandible (*right*). *(From Dingman RO, Natvig P.* Surgery of Facial Fractures. *Philadelphia: WB Saunders; 1964.)*

Segmental mandibulectomy involves resection of a full thickness of bone, which creates a discontinuity defect (see Fig. 97-4). Significant cosmetic and functional morbidity are associated with segmental defects. For defects involving the anterior mandible (between both mental foramina), the lateral segments act independently, and the displacement pattern is influenced by the remaining attached muscles (Fig. 97-5).[10,11] The medial pterygoid muscle overpowers the masseter and pulls the segments upward, posteriorly, and medially. This movement brings the teeth out of alignment and disrupts mastication. There is complete loss of projection of the lower midline third of the face, which causes an overhanging upper jaw, the so-called Andy Gump appearance. The tongue loses anterior support, thus becoming malpositioned with posterior displacement. The oral sulci become obliterated. The upward movement of the larynx is lost with swallowing as a result of detachment of the suprahyoid musculature. The lower lip is numb as a result of resection of the mental nerves. All these changes lead to a cosmetically and functionally disabling situation for the patient. For defects involving the lateral mandible (posterior to the mental foramina), the remaining bone deviates toward the defect through the action of the remaining muscles of mastication, primarily the medial and lateral pterygoid muscles (Fig. 97-6).[10,11] This causes malalignment of the teeth, which affects mastication. The deformity is accentuated by opening the mouth or chewing.

Most mandibular segmental bone defects are caused by ablative surgery for benign or malignant neoplastic tumors; the majority of affected patients have oral cancer. An associated loss of oral soft tissues also occurs in most of these patients, which causes an oromandibular defect. An important consideration for these patients is whether they have a history of treatment with radiation or whether postoperative irradiation will be required. Fewer patients have a segmental defect caused by trauma, osteoradionecrosis, bisphosphonate-induced osteonecrosis, or osteomyelitis.

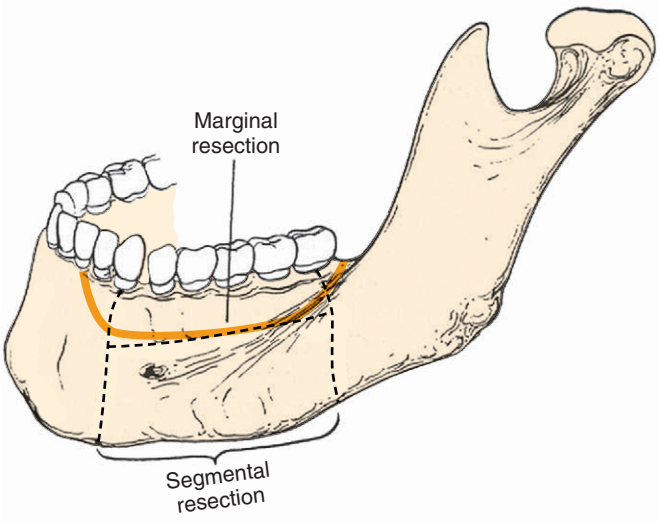

Figure 97-4. Techniques of mandibulectomy: marginal and segmental. *(From Silver CE, Rubin JS.* Atlas of Head and Neck Surgery. *2nd ed. London: Churchill Livingstone; 2002.)*

Classification of Defects

A combination of the extent of bone and soft tissue loss determines the reconstructive method. Classification systems that account for this fact are useful. Various classification schemes that have been described for segmental mandibulectomy defects can be used for documenting the defect components, which helps with planning the reconstruction (Fig. 97-7). In Boyd and colleagues'[12] classification, *H* defects are lateral defects of any length up to the midline that include the condyle; *L* defects are lateral defects that exclude the condyle; and *C* defects involve the central segment containing the four incisors and two canines. The three lowercase letters in this classification system describe the associated soft tissue components: *o* (no skin or mucosal component), *s* (skin), *m* (mucosa), and *sm* (skin plus mucosa). Boyd and colleagues recognized the reconstructive and functional problems posed by the absence of the condyle and mentum; thus, their system is similar to Pavlov's classification system, described before the era of free tissue transfer.[12] With loss of the condyle, reconstruction of an articular surface is difficult. Loss of the central segment poses problems with restoration of stomal competence, restoration of an anterior gingivo-

labial sulcus to fit prosthetics for dental rehabilitation, and restoring the lip height for cosmesis.

Another classification scheme, described by Urken and associates,[13] is similarly based on functional considerations caused by the detachment of different muscle groups and difficulties with cosmetic restoration. This reconstruction scheme has similar anatomic designations, including separate components of the condyle (*C*), ramus (*R*), body (*B*), total symphysis (*S*), hemisymphysis (S^{H}), and palate (*P*). Urken and associates' classification system also includes a detailed description of soft tissue and neurologic deficits.

Neither of these two classification systems describes the absolute length of the defect. Before the use of free tissue transfer, the chance of healing and bony union depended more significantly on size when nonvascularized bone grafts were used. When osseous free flaps are used, outcomes are less dependent on the length of the graft required to bridge the defect.[12]

Goals of Mandibular Reconstruction

The primary objective of tumor resections that necessitate mandibulectomy is cure, but the functional and cosmetic rehabilitation are crucial for the physiologic and psychologic well-being of patients. The ideal reconstruction for a segmental mandibulectomy (1) restores oral competency, (2) maintains occlusal relationships with remaining teeth, (3) allows for prosthetic dental restoration, (4) restores bone continuity, and (5) restores facial symmetry and contour to the lower third of the face.[14] In addition, wound closure should be immediate and complete in order to maximize early functional recovery, avoid orocutaneous fistula, avoid infection, create a safe wound that can undergo postoperative radiation 6 weeks later, and facilitate early hospital discharge. To achieve these goals, basic principles of reconstructive surgery dictate that the simplest method to achieve the desired results should be chosen for each individual patient.

Background and History

Before the development of advances in surgical techniques and improvements in hardware, reconstructive options were limited and yielded disappointing results. The available options for bone replacement at that time included nonvascularized autogenous bone grafts, allogeneic bone grafts, and vascularized pedicled bone grafts.[11] The failure rate of vascularized pedicled bone grafts was as high as 50%.[1] Nonvascularized

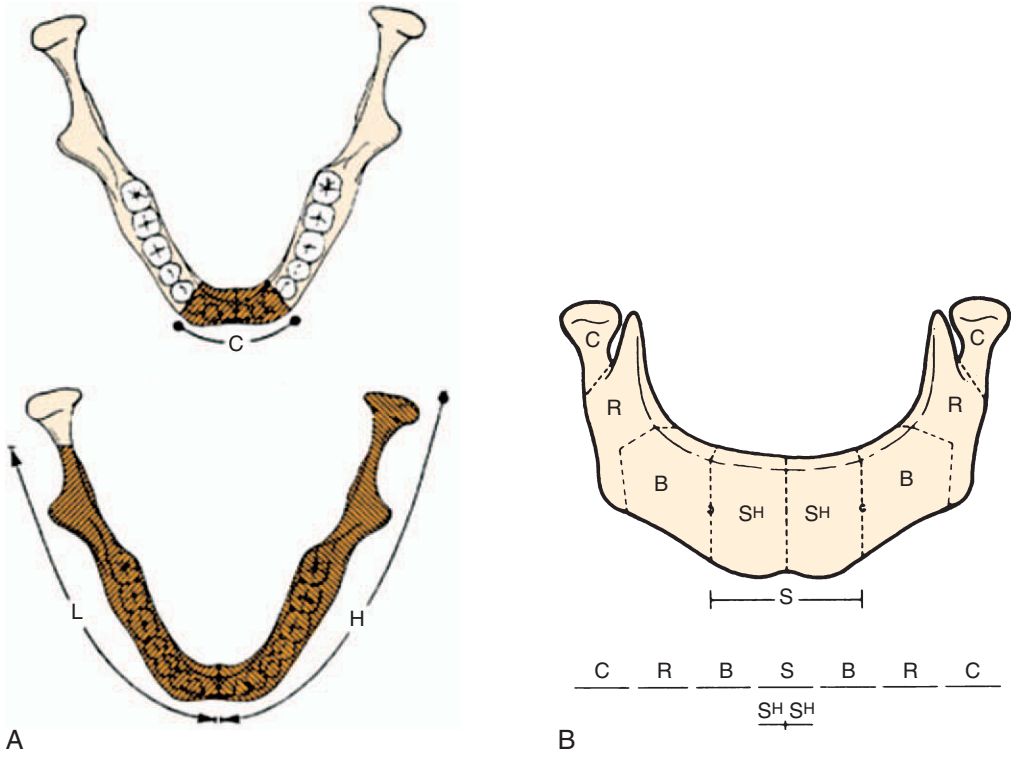

Figure 97-7. Systems of classification of mandible defects described by Boyd and colleagues[12] **(A)** and Urken and associates[13] **(B).** *(**A,** From Boyd JB, Gullane PJ, Rotstein LE, et al. Classification of mandibular defects.* Plast Reconstr Surg. *1993;92:1266-1275.* ***B,*** *From Urken ML, Weinberg H, Vickery C, et al. Oromandibular reconstruction using microvascular composite free flaps. bone grafts, which rely on neovascularization, were found to be prone to infection, extrusion, or resorption when placed into defects in which the oral mucosa was violated or in the setting of perioperative irradiation. Hardware options included alloplastic materials such as trays, prostheses, and Kirschner wires. These devices were designed to prevent displacement of the remaining mandibular segments, support the surrounding soft tissue, and minimize wound contracture.[15] Unfortunately, these devices yielded disappointing results because of loosening, migration, exposure, and fracture.

Many studies, including those published by Adamo and Szal,[2] Lawson and Biller,[1] and Komisar,[16] consistently revealed poor results of mandibular reconstruction with the available approaches and technologies. Mandible reconstruction usually proceeded in multiple stages fraught with complications. The management of these complications increased the number of hospitalizations by an average of three per patient.[16] These complications sometimes delayed the postoperative treatment with radiation, which affected the ability to cure the cancer. Primary reconstruction yielded the best results but had the highest rate of complications. Secondary reconstruction produced fewer complications but suboptimal results.[1,2,16,17] In the secondary setting, soft tissue contracture and fibrosis caused by prior irradiation would fixate the remaining bone segments in a malpositioned orientation, and the fibrosis of the remaining muscles of mastication accentuated this problem.

Even with the successful reconstructions, although most patients demonstrated cosmetic improvement, few experienced significant functional benefits.[15-17] The functional limitations resulted from misalignment of the mandible, trismus caused by fibrosis, soft tissue losses, and failure of a bony segment capable of supporting a dental prosthesis. Gullane[15] reported that the functional outcomes for patients with primarily lateral defects were more dependent on the soft tissue loss than on the bone reconstruction. At this point, the decision to perform reconstruction needed to be weighed against the overall poor results, increased complications, increased morbidity, and possibility of introducing delays in receiving postoperative radiation treatment. Although the outcomes were suboptimal, many important factors for success that were learned during this era are still basic tenets for mandible reconstruction: (1) stable immobilization of the mandible segments to minimize distortion and maintain occlusal relationships, (2) performance of as much primary reconstruction as possible, (3) importance of soft tissue reconstruction for functional restoration and minimizing hardware complications, and (4) importance of good wound bed vascularity. These early efforts were also important strides toward the development of reliable, one-stage primary reconstructive techniques that are frequently used today.

The paradigm shift toward current reconstructive options occurred with advances in surgical techniques involving free tissue transfer and with the introduction of improved hardware options with mandibular reconstruction plates that replaced Kirschner wires and metal trays. Successful transplantation of autologous vascularized composite tissue was the most important innovation that allowed for this paradigm shift. Although improvements in bone fixation methods were also important, their importance was secondary to the reliability and adequacy of bone and soft tissue healing, which were provided with free flaps.

In 1976, Panje and coworkers[18] introduced successful reconstruction for large oral soft tissue defects after tumor-ablative surgery. A free groin flap was used for reconstruction in four patients, and these tissue transfers were successful despite preoperative or postoperative irradiation and oral bacterial contamination. Inclusion of bone with a skin flap was a natural extension of the free flap concept for repairing composite oromandibular defects. Pioneering experimental and anatomic studies proved the feasibility of using composite flaps consisting of bone and soft tissue that were based on a single vascular pedicle.[19-22] Subsequently, successful reconstruction for large oromandibular defects with bone from the ilium was described.[23-25] The transfer of vascularized fibular bone, which was initially described for complicated extremity reconstruction, was subsequently described for oromandibular reconstruction.[26,27] In the majority of medical centers, the fibular osteocuta-

neous flap is now the most common free tissue transfer used for oromandibular reconstruction.

Hardware for use in the mandible was initially composed of Vitallium (an alloy containing cobalt, chromium, and molybdenum), but because of poor malleability, the metal was subsequently changed to stainless steel and then to titanium for better tissue compatibility.[15] In a study of 60 patients treated from 1974 to 1986, Klotch[28] described the effectiveness of reconstruction plates for bridging the defect and providing stabilization of the remaining mandibular segments. These plates could be placed rapidly, were well tolerated by tissue, were structurally rigid, and could be readily shaped to the contour of the defect. Hardware problems, however, still occurred frequently with these plates until the development of more reliable methods of soft tissue reconstruction with pedicled and distant flaps.[15,28-30] The initial combination of well-vascularized soft tissue reconstruction with reconstruction plates significantly improved the short-term results of primary reconstruction; however, because of continued problems with plate extrusion, plate fracture, and screw loosening, this combination did not provide long-term stability.[31] Without bone reconstruction for the defect, the hardware still tended to fail as a result of metal fatigue, leveraged forces with mastication (especially for patients who still had teeth), and volume losses.[32] Using this technique anterior mandibulectomy defects continued to have a particularly high rate of extrusion, and affected patients were not considered good candidates for this approach.[29,33] The subsequent development and application of osseous free flaps in combination with plates further improved the reliability (short- and long-term) and outcomes of one-stage primary reconstruction for both anterior and lateral mandible defects.[34]

Current Methods

Three options for reconstructive treatment of segmental mandibulectomy defects are available: (1) reconstruction plate alone, (2) reconstruction plate combined with an osseous free tissue transfer, and (3) reconstruction plate combined with a soft tissue flap. Decision making can be quite complex, being influenced by the patient's age, performance status, comorbid conditions, tumor characteristics, prognosis, dental status, patient's anatomy, patient's preferences, surgeon's comfort level, and characteristics of the defect components. Use of a reconstruction plate alone should be considered as only a temporizing short-term method because of the high risk of hardware complications. This technique should be considered only for patients with small lateral defects, minimal associated soft tissue defects, severe medical comorbid conditions, and poor cancer prognosis.

Reconstruction plate combined with an osseous free tissue transfer is the preferred reconstructive method for anterior defects because other methods have a high rate of hardware extrusion and because of the significant morbidity associated with not performing reconstruction for the defect.[29,33] For lateral defects, this approach has several advantages: (1) restoration of the bone continuity of the mandible, (2) facilitation of dental restoration, (3) the most consistent long-term outcomes and stability of the reconstruction with minimal hardware complications. The disadvantages of this approach include (1) donor site morbidity, (2) technical difficulty of complicated tissue inset in accurately reconstituting the three-dimensional shape of the resected bone, and (3) the possibility that the associated soft tissue defect is not suitable for reconstruction with the soft tissue available with the bone flap, which would then necessitate two flaps. Figure 97-8 depicts typical harvested fibular and scapular osseous free flaps, and Figure 97-9 depicts the scapular flap inset into an anterior mandibulectomy defect. Table 97-1 summarizes and compares the major characteristics of each of the bone donor sites commonly used for oromandibular reconstruction.[35-46] The decision of which flap to use is complex and dependent on the defect characteristics, the patient's characteristics and preferences, and plans for dental restoration.

Osseous free flap reconstruction for an oromandibular defect can be divided into three steps: planning, harvest, and inset. The considerations for planning include the anticipated bone defect (height, length, and location) and the anticipated soft tissue defect (surface area, volume, and subunits involved). If a single flap cannot provide both the soft tissue and bone needed for the reconstructive needs

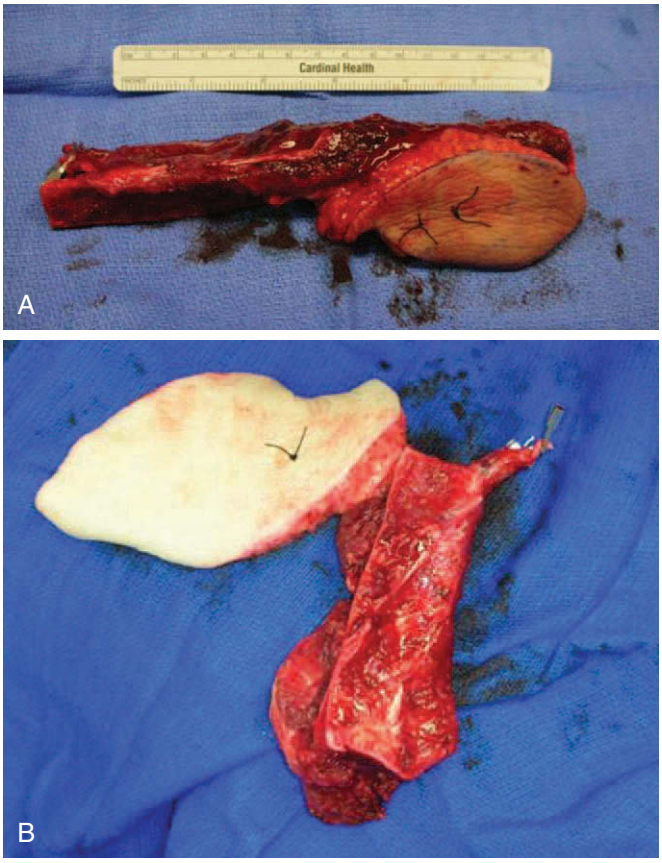

Figure 97-8. Vascularized flaps commonly used for oromandibular reconstruction. **A,** Fibular. **B,** Scapular.

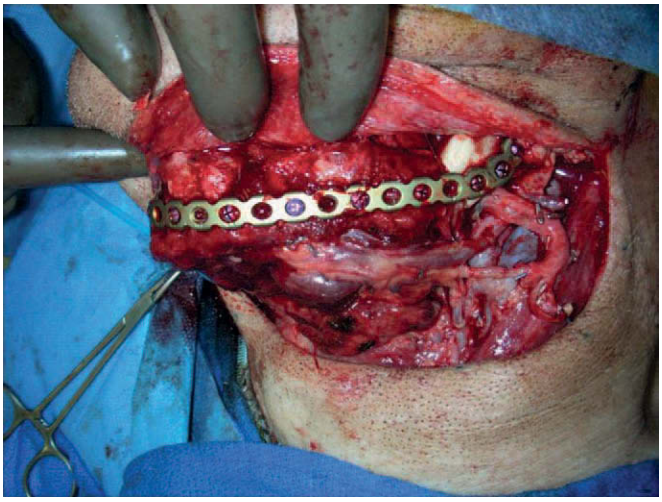

Figure 97-9. Scapular osteocutaneous free flap inset into anterior mandibulectomy defect.

of the defect, then two flaps must be considered, versus using a flap-plate option. In this alternative approach a reconstruction bar is used alone to maintain mandibular continuity, and a soft tissue flap is used to reconstruct the soft tissue components in the defect. Surgical planning also involves positioning of the patient for flap harvest. The scapular osteocutaneous flap needs to be harvested with the patient in at least a 30-degree lateral decubitus position, whereas the other options can be harvested with the patient in a supine position, which facilitates two-team surgery. Planning the side of the flap harvest

Table 97-1

Different Osseous Free Tissue Transfer Options for Mandible Defects

Feature	Fibula	Iliac Crest	Scapula	Radius
Ease of harvest	++	+/–	–	+
Bone characteristics	20-25 cm in length Bicortical Thick Short (1½ cm)	10-15 cm in length Tall and thick	10-12 cm in length Short and thin	Maximum 10 cm in length Very thin Blood supply is tenuous
Soft tissue characteristics	Thin, pliable skin paddle with large surface area Some difficulty with orientation changes in relation to bone Usually good reliability	Thin broad muscle Thick skin relatively fixated to bone	Thicker skin paddle that is independent from bone Possibility of independent skin paddles Possibility for "mega flap" when combined with latissimus flap	Thin, pliable skin paddle with large surface area Fixed to orientation of bone
Donor site morbidity	Favorable	Unfavorable (hernias, chronic pain)	Variable (shoulder function)	Favorable (plate can be used to prevent radial bone fractures)
Dental restoration	+	++	+/–	–

Symbols: ++, Excellent; +, adequate; +/–, mixed; –, inadequate.

is also an important consideration. For fibular flaps, preoperative vascular imaging is recommended because anatomic variations in the vascular blood supply to the foot and atherosclerotic disease might preclude the use of the flap. With conventional angiography, the test results help determine which side to use in up to 25% of patients.[47] Other methods described for preoperative evaluation before fibular flap harvest include magnetic resonance angiography, computed tomography–angiography, and color-flow Doppler imaging.[48-50] Preoperative evaluation before a radial forearm osteocutaneous flap consists of Allen's test.[46] For flaps from the scapula and iliac crest, preoperative imaging or tests are not necessary to determine which side to use to harvest the flap.

The hardware used during inset is usually a locking reconstruction plate, although the alternative use of miniplates has been described.[51] The plate should be bent to the preexisting mandible contour before resection. At the same time, holes should be drilled for fixation screws to ensure that the plate can be reapplied after mandibulectomy, with the bone fragments maintaining anatomic alignment. In general, the reconstruction bar is placed on the lower border of the mandible to avoid tooth roots, maintain optimal aesthetic facial contour, and to lessen chances for intraoral exposure.[32] In fibular flaps, however, this can make restoration with osseointegrated implants problematic because of the short bone height in comparison with a dentulous mandible.[52] In these cases, several options should be considered: placing the reconstruction plate 1 cm above the inferior mandible border, using a double-barrel fibular flap construct, or choosing an alternative donor site with more bone height, such as an iliac crest flap.

During inset, the bone must be contoured to the reconstruction plate, and the surgical team must be aware of how bone inset affects the geometry of the soft tissue component and the vascular pedicle. This portion of the inset is complex and crucial for the success of the tissue transfer. For fibular flaps, closing wedge ostectomies are performed to provide the proper bone shaping, whereas opening osteotomies are performed for the other bone flap options.

Reconstruction plate combined with a soft tissue flap is generally an option only for lateral defects; when this approach is used for anterior defects, the rate of hardware complications is high. There are several advantages to using this approach as an alternative to osseous free flaps in reconstruction for lateral defects: (1) Application is easy and quick, (2) rigid fixation of the remaining mandible segments is provided, (3) morbidity of bone donor site is avoided, (4) cosmetic restoration is adequate, and (5) the range of flap choices is wider for optimal reconstruction in the soft tissue defect, which can have a more significant effect on functional recovery. Screw loosening is not a problem with locking plates, because the stability of the fixation is not dependent on the screw-bone interface. One consideration with this approach, however, is the overall poor rate of survival that has been consistently reported from multiple institutions; thus, a reconstructive technique that maximizes functional restoration and minimizes operative risk is favored.[16,53-56] Because of this and other disadvantages, including subacute and long-term hardware complications (extrusion and fracture) and the difficulty with dental restoration, this approach is not widely favored.

An example of plate extrusion is shown in Figure 97-10A. Reconstruction plate extrusion usually occurs extraorally, and the mean time from surgery to exposure is approximately 10 months.[54,57] The pathophysiologic development of plate exposure is postulated to be related to plate characteristics and the size of the defect. The extrusion rates for stainless steel and titanium plates are not significantly different, but the use of low-profile plates has decreased the extrusion rate from 29% to 7%.[56-58] The volume of the bone and soft tissue deficit has also been shown to be predictive of exposure.[31,32] Without replacing bone within the defect, wound contracture medial to the plate can occur during wound healing as a result of inadequate volume replacement; the contracture causes a slow but steady pressure of the plate on the overlying skin, thus resulting in extrusion. A volume-based approach with "over-reconstructing" the soft tissue defect medial to the plate can be used to avoid a dead space in this area; this approach has been shown to decrease the exposure rate from 38% to 8% (Fig. 97-11).[54]

An example of plate fracture is depicted in Figure 97-10B. The average time from surgery to plate fracture is 21 months.[54] Plate fractures occur primarily because of metal fatigue. This is accentuated by the forces involved in mastication, especially in dentulous patients. Although reconstruction plates can fracture in any patient, those with teeth are at particularly high (up to 26%) risk.[30,54] Therefore, dentulous patients who require reconstruction for lateral mandible defects should be considered better candidates for osseous free flaps than for soft tissue flaps, especially when the associated soft tissue defect

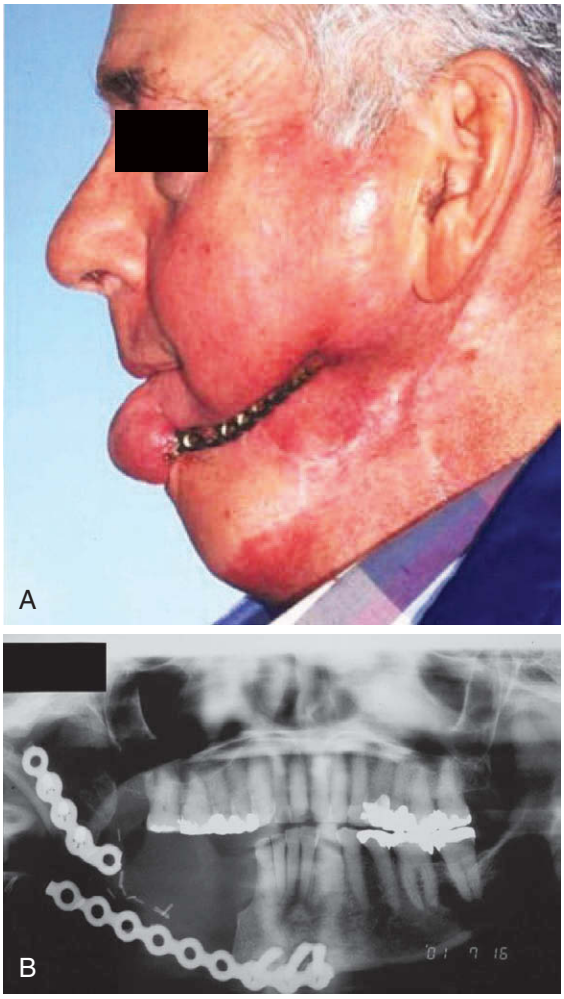

Figure 97-10. Plate complications. **A,** Extrusion. **B,** Fracture.

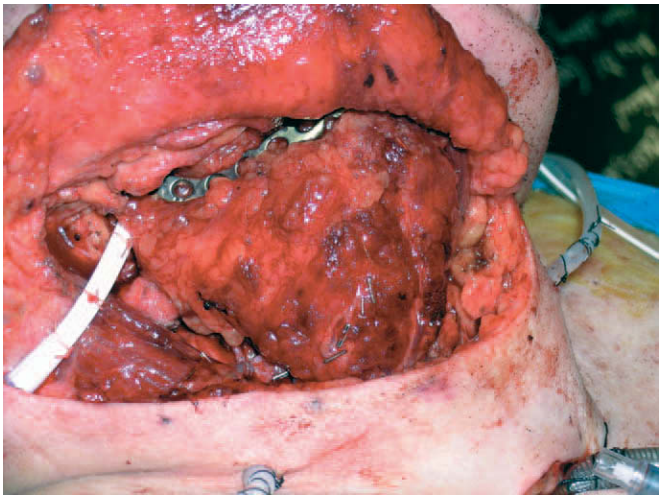

Figure 97-11. Lateral mandible defect that was corrected by volume-based reconstruction with an anterolateral thigh free flap and a locking reconstruction plate.

is not complex. In addition, dentulous cancer survivors who undergo reconstruction with a plate combined with a soft tissue flap are at particularly high risk for subsequent plate fracture; to avoid this complication, planned secondary bone reconstruction should be considered for these patients.[59]

Outcomes

Cordeiro and colleagues[60] reported on short-term results of oromandibular reconstruction in which osseous free flaps were used in 150 consecutive patients during a 10-year period. Of these flaps, 90% were fibular, and testing was performed at least 6 months after surgery. Swallowing, speech, and aesthetic results were all favorable. Of the patients, 45% tolerated an unrestricted diet and 45% were on a soft food diet. Only 9% had unintelligible speech, and only 14% were considered to have poor aesthetic results. Hidalgo and Pusic[39] subsequently reported long-term outcomes of oromandibular reconstruction after a follow-up period of at least 10 years. Of the 82 patients who had undergone osseous free flap reconstruction for oromandibular defects from 1987 to 1990, only 32 were still alive in 2002, and 20 agreed to participate in the study. The mean bone defect length was 13 cm, and 75% of defects were associated with radiation exposure either before (n = 2) or after surgery (n = 13). The aesthetic result was judged to be excellent for 55% of patients and good for 20%. Seventy percent of patients tolerated a regular diet, and the rest were on soft-food diets. Speech was easily intelligible in 85%. There were no cases of fracture or osteoradionecrosis of the transferred bone. This study demonstrated that the favorable functional and aesthetic results remain stable over time.

The value of mandible reconstruction has also been measured through objective testing and patient questionnaires. Urken and associates[61] studied multiple different functional and aesthetic outcome measures in a group of patients who underwent placement of an iliac crest free flap with dental implant, in comparison with patients with similar defects who underwent no bone reconstruction. Patients were also compared to normal denture wearers and normal dentulous patients. Overall, patients with bone free flap reconstruction had better oral competence, mastication, and cosmesis. In Wilson and coworkers' study,[62] patients who had undergone hemimandibulectomy were surveyed with regard to whether mandible reconstruction was performed. Mandible reconstruction was associated with a better appearance, better eating ability, and a better overall quality of life.

Long-term follow-up has revealed that the bone transferred with fibular flaps maintains bone mass and height, even in the presence of postoperative radiation.[39,63] On average, bone height decreased between 4% and 7%. The retention of bone height is not affected by site of reconstruction, patient's age, length of follow-up, adjuvant irradiation, or osseointegrated implants.

Developments

For osseous free flap reconstructions, establishing proper contour of the reconstruction plate is crucial for obtaining correct alignment of the temporomandibular joints, reestablishing normal occlusion, and providing an aesthetically appropriate shape to the mandible.[52] Ideally, the plate is contoured to the native mandible shape before the bone cuts for the mandibulectomy are made. This technique is not possible when the tumor extends through the buccal-labial cortex of the mandible or if the tumor margin might be violated in attempts to expose the outer cortex of the mandible. In addition, secondary mandibular reconstruction in the presence of preexisting occlusal problems is a challenge to contouring a reconstruction plate accurately. Previous techniques to overcome these challenges have included placing the patient in temporary maxillomandibular fixation to align the mandibular fragments before or after tumor resection and then contouring the plate "free hand" with a best estimation to ensure tandem movement of the temporomandibular joints and correct positioning of the occlusion.

For these challenging cases, techniques are now commercially available for using stereolithographic modeling of patients' anatomy for surgical planning and accurately contouring the reconstruction plate. These models can be made from acrylic, cellulose, or plaster. They are constructed in a computer-assisted process based on computed tomography imaging. The models are accurate to within 1 mm. The computer-assisted design process can be used to manipulate the three-dimensional image and mirror normal anatomy in order to create a "perfected" mandible for which a model can be made, and then the reconstruction plate is contoured to the model during surgery. An example of the effective use of this technique is shown in Figure 97-12. Advantages of this approach for selective cases include providing an

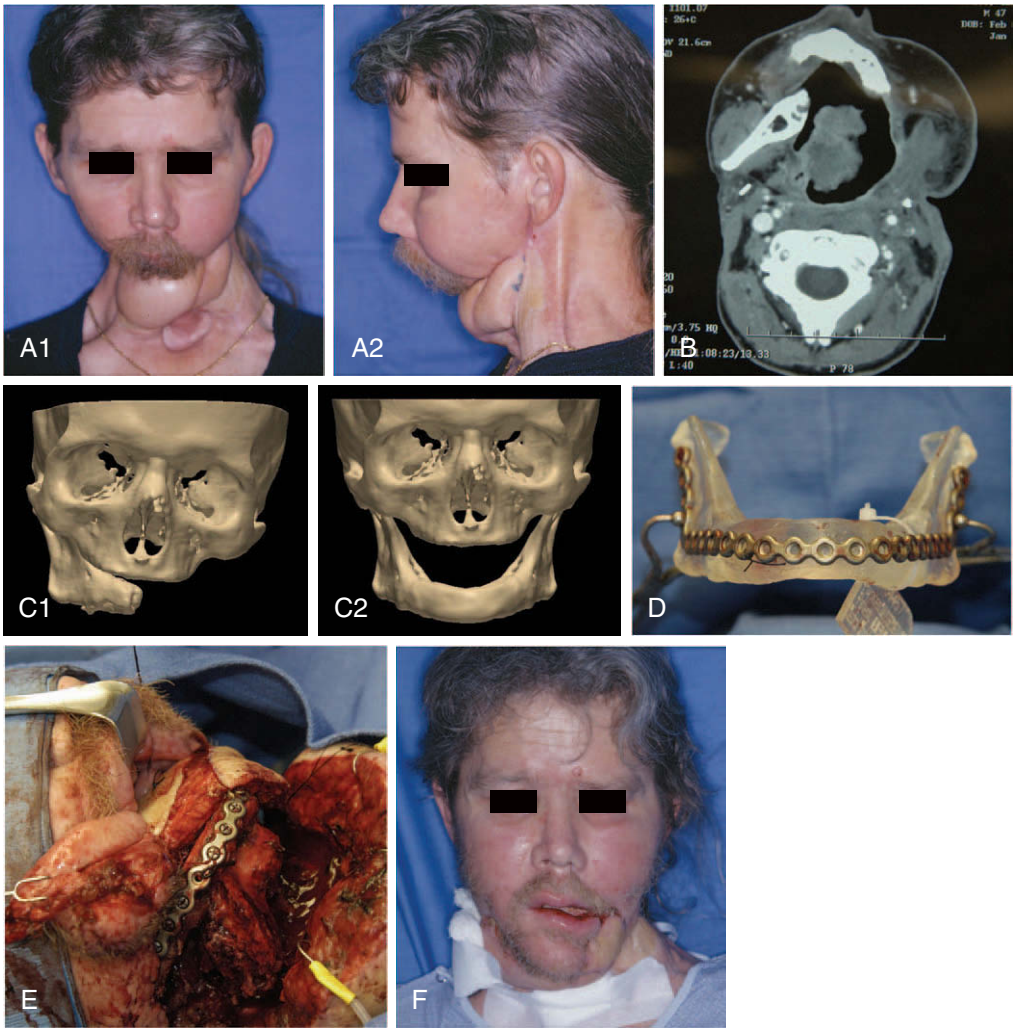

Figure 97-12. Example of using medical models as an adjunct to accurate reconstruction. The patient had an Andy Gump deformity 5 years after undergoing curative treatment for an oral carcinoma (**A**). **B,** A 1-mm cut, helical computed tomography scan of the neck is obtained. **C,** Computer-assisted design is then used to make a three-dimensional representation of the patient's existing anatomy and then to make a "perfected" mandible that is based on a mirror image from the existing anatomy. **D,** Computer-assisted manufacturing is then used to make a stereolithographic model, which in turn is used to contour the reconstruction plate for implantation at the time of the fibular flap reconstruction (**E, F**).

accurate template for contouring the reconstruction plate, saving time during the operation by bending the reconstruction plate preoperatively, allowing for surgical simulation, improving treatment planning, and assisting with preoperative counseling. The disadvantages are the necessity for additional time to make the model (usually can be done in less than 1 week) and the high cost (up to $3000). D'Urso and colleagues[64] prospectively studied the use of medical models in 45 patients with various sites of disease in the craniofacial region. Use of models decreased operating room time by 18%, improved planning, and improved measurement accuracy. In addition, patients found the education provided for informed consent helpful.

Future Approaches

Although current methods of reconstruction for mandibular defects are effective, limitations are still significant. These limitations include measurable donor site morbidity, increased surgical time for harvesting the flap, possible complications from flap harvest, difficulty of tissue inset, and unavailability of autologous bone grafts that truly reflect the three-dimensional shape of the resected bone. Therefore, advancements in tissue engineering are starting to be applied for mandible reconstruction. *Tissue engineering* can be defined as the regeneration or repair of new tissues through the use of biologic mediators and matrices. This regeneration occurs through the recapitulation of key events that occur during tissue formation and growth, which includes cellular migration, proliferation and apoptosis, differentiation, inductive and inhibitory interactions, and tissue patterning and morphogenesis. Signaling molecules, cells, and a scaffold are required for most tissue engineering approaches in order to reproduce this developmental sequence of events.[3]

Most tissue engineering strategies for mandible reconstruction have been based on bone morphogenetic proteins (BMPs). BMPs were discovered by Urist[65] in 1965 as the osteoinductive component of demineralized bone matrix, and these proteins were subsequently isolated, cloned, and purified in the 1980s.[66] BMPs are a large subgroup within the transforming growth factor β (TGF-β) family of growth and differentiation proteins.[67] The human genome encodes 20 known BMPs; BMP-2, BMP-4, BMP-6, BMP-7, and BMP-9 have demonstrated osteoinductive activity. Human recombinant BMP-2 and BMP-7 are now commercially available, and human recombinant BMP-2 was approved by the U.S. Food and Drug Administration in March 2007 for specific orodental applications (sinus floor augmentation, localized alveolar ridge augmentation for extraction socket defects).

Preclinical data regarding the use of osteoinductive BMP therapies for healing mandibular and calvarial defects in animal models (mice, rats, rabbits, dogs, pigs, and nonhuman primates) are extensive. More

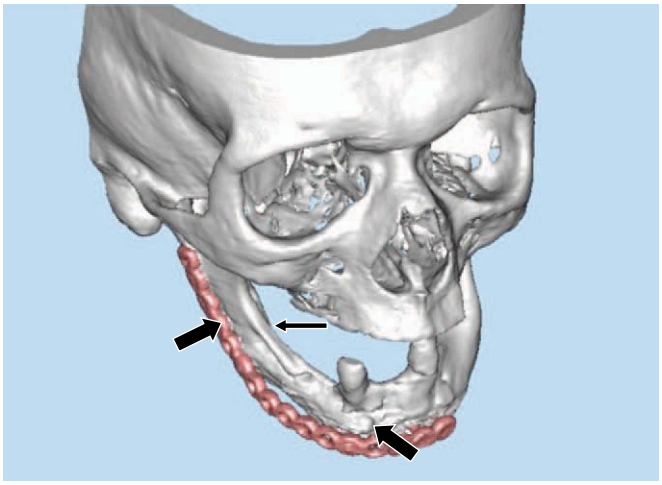

Figure 97-13. Three-dimensional computed tomography scan of a mandible reconstruction in which bone morphogenetic protein 2 (BMP-2) was used. The 6-cm lateral defect involving the body (between *the large arrows*) was caused by débridement of a sequestrum from a nonunion fracture. The *small arrow* points to an area of bone remodeling to the form of a neo-alveolus. A technetium-99m bone scan performed 9 months postoperatively demonstrated appropriate metabolic uptake in the regenerated bone. *(From Nussenbaum B, Krebsbach PH. The role of gene therapy for craniofacial and dental tissue engineering.* Adv Drug Deliv Rev. *2006;58:577-591.)*

recently, case reports and small case series have documented the use of BMPs for reconstruction for segmental mandibulectomy defects in humans.[68-70] An example is shown in Figure 97-13. In the cases so far described, BMPs have been used in defects caused by resection of benign neoplasms or caused by trauma. Use of BMPs is currently contraindicated in wounds caused by tumor-ablative surgery because the effects of these growth factors on the cancer cells are unknown. Also, their use in previously irradiated wounds or wounds that will receive postoperative radiation is not currently advisable.[71,72] At the time this chapter was written, use of BMPs for mandible reconstruction was recommended only in clinical trials in carefully selected patients because the ultimate success of this technique was unknown, although very promising.

CHAPTER NINETY-EIGHT

Prosthetic Management of Head and Neck Defects

Jeffery C. Markt

Thomas J. Salinas

William Donald Gay

Key Points

- Dentoalveolar evaluations should be accomplished prior to radiation therapy in the interest of establishing lifelong prognoses for those teeth to be included in potential radiation therapy fields. Those teeth not enjoying good prognoses should be extracted before radiation therapy, preferably at the time of a surgical ablation if a surgical ablation is endeavored.
- The risk of osteoradionecrosis secondary to invasive dentoalveolar procedures is substantial in areas that have received more than 5000 cGy of radiation.
- The Marx hyperbaric oxygen regimen is used to diminish the risk of osteoradionecrosis when invasive dentoalveolar procedures must be done in areas that received more than 5000 cGy of radiation.
- Xerostomia-induced carious lesions are common among patients whose major salivary glands are included in radiation therapy fields. Topical fluoride gel and meticulous oral hygiene are paramount for the prevention of carious lesions for patients who have been rendered xerostomic secondary to radiation therapy.
- Maxillofacial prosthodontists can offer radiation oncologists a host of devices to lend assistance to the delivery of radiation therapy. These include shielding and positioning devices, tissue equivalency devices, and brachytherapy devices.
- Maxillofacial prosthodontists can offer assistance in evaluating the relative safety associated with invasive dentoalveolar procedures following radiation therapy by way of evaluating dose distributions, simulation radiography, and computed tomography.
- Maxillofacial prosthodontists are uniquely positioned to mitigate palatopharyngeal insufficiency or palatopharyngeal incompetence through the fabrication of palatal lift prostheses, speech aid prostheses, and obturator prostheses.
- Maxillofacial prosthodontists routinely offer mandibular resection prostheses for patients with discontinuity defects or defects that have been reconstructed with microvascular free flap procedures.
- Endosseous titanium implants are often necessary for the rehabilitation of patients with congenital or acquired intraoral and extraoral dentoalveolar and maxillofacial defects. Endosseous titanium implants are often placed in grafted microvascular osseous tissues, as well as native maxillary or mandibular bone.
- Maxillofacial prosthodontists work closely with speech language pathologists to prosthetically mitigate dysfunctional articulation and dysphagia.
- Orbital, ocular, nasal, and auricular prostheses constitute the most common extraoral prostheses provided by maxillofacial prosthodontists.
- The construction of facial prostheses requires impression making, wax or clay sculpting, fabrication of molds, casting of pigmented elastomers such as silicone, and painting surface skin tones.

Maxillofacial prosthetics comprises a subspecialty of prosthodontics directed toward the prosthetic habilitation of patients with congenital maxillofacial defects, the prosthetic rehabilitation of patients with acquired maxillofacial defects, and the medical management of patients undertaking treatment for essentially any maxillofacial pathosis. Maxillofacial prosthodontists are often involved in hospital-based multidisciplinary craniofacial and cleft lip and palate teams and head and neck oncology teams either as institutional staff members or participating private practitioners. The maxillofacial prosthodontist's role in patient care often begins with an otolaryngology or oral and maxillofacial surgery referral at the onset of a diagnosis because the prosthodontist's contribution early in the course of a patient's care can foster the prosthetic management necessitated by either the patient's condition or the treatment of the condition. This is true for patients affected by congenital anomalies or trauma-related anatomic deficits, as well as oncologic patients treated primarily by ablative surgery, radiation therapy alone, or combinations of surgery, radiation therapy, and chemotherapy.

Because the treatment of head and neck cancer has evolved into a complex multidisciplinary approach, the maxillofacial prosthodon-

tist's participation in the tumor boards of centers actively treating oncology patients can be quite meaningful. Prosthetic care may address common issues relating to routine dental health and occlusal rehabilitation, as well as matters as diverse as dysphonia, dysphagia, and facial cosmesis, so the prosthodontist's diagnostic input before a surgical ablation can assist the reconstructive phase of virtually all head and neck oncology patients regardless of the primary tumor site. Additionally, the maxillofacial prosthodontist's diagnostic contribution for patients who have or will be treated with radiation therapy can aid in the prevention of osteoradionecrosis and obtund or prevent mucosal or dental disease in patients suffering from early or late effects of radiation therapy. The maxillofacial prosthodontist's role in evaluating dose distributions to assist safe oral surgical care when it is necessary after radiation therapy is also paramount.

This chapter reviews some of the duties of maxillofacial prosthodontists associated with multidisciplinary head and neck oncology teams from the perspective of three staff maxillofacial prosthodontists in different tertiary care settings. Although the chapter principally relates to an oncology population, the sections pertaining to intraoral and extraoral prosthetic rehabilitation correspond quite readily to patients whose defects are traumatically acquired or congenital.

Maxillofacial Prosthetics and the Radiation Oncology Patient

Given that the treatment of head and neck neoplasms often involves radiation therapy alone or in combination with surgical ablation or chemotherapy, it is useful for the maxillofacial prosthodontist to become involved in patient care during the diagnostic phase of any proposed intervention. Because the risk for osteoradionecrosis is increased when a poor dentition is allowed to remain within irradiated maxillary or mandibular alveolar bone, a thorough evaluation of the dentition and periodontium is extremely useful in establishing dental prognoses before the initiation of radiation therapy. Additionally, because the xerostomia induced by a majority of head and neck radiation fields requires an increased diligence respecting home care and follow-up during and after radiation therapy, the maxillofacial prosthodontist's early consultation can help prevent dental disease that could later contribute to added debility, possibly including osteoradionecrosis.

Because many head and neck cancers are treated by surgical ablation followed by radiation therapy, the maxillofacial prosthodontist's diagnostic efforts should be performed preoperatively so that any necessary oral surgical interventions can be accomplished in conjunction with the otolaryngologist's surgical encounter. This allows a sufficient amount of time for mucosal and alveolar bone healing before the initiation of radiation therapy, which usually occurs 6 weeks later. Patients whose dentoalveolar evaluations are accomplished after ablative surgeries are sometimes fast approaching a juncture in their care when radiation therapy should expeditiously commence in the interest of controlling local and regional oncologic disease, and delays associated with healing oral surgical wounds may be unacceptable. Likewise, the maxillofacial prosthodontist must consider similar delays in the initiation of radiation therapy when treatment plans call for primary radiation therapy or radiation therapy to be delivered concurrently with chemotherapy in the absence of an ablative surgical encounter.

Dental Diagnoses and Oral Surgical Management Preceding Radiation Therapy

Any dentoalveolar evaluation in preparation for radiation therapy should include a thorough assessment of the periodontium, as well as the dentition, and should be done with the intent of establishing lifelong prognoses for those teeth likely to be included in radiation therapy fields anticipated to receive doses in excess of 5000 cGy.

Extractions are indicated for teeth with poor prognoses meeting the criteria listed in Box 98-1.[1-13] Although the assessment is accomplished in the interest of preventing osteoradionecrosis, it is also done considering the potential for any prosthetic rehabilitation that may become necessary. Because this assessment requires consideration of primary tumor size and location, as well as regional lymph node status, diagnostic information gleaned through participation in multidisciplinary head and neck tumor board conferences supplements decisions made in the dental clinical setting where medical imaging is limited and endoscopy is not typically available.

Box 98-1

Clinical Presentations Leading to the Assignment of Questionable or Poor Lifelong Prognoses

- 5-mm periodontal pockets
- Class I, II, or III furcation involvement
- Active endodontic or periapical pathosis
- Mobile primary teeth
- Nonrestorable teeth
- Nonfunctional or unopposed teeth
- Impactions

In addition to an evaluation of the dentoalveolar structures, the maxillofacial prosthetic assessment includes intraoral and extraoral palpation and visualization of hard and soft head and neck tissues, panoramic radiography, and intraoral radiography of those teeth thought to be sound enough to retain vis-à-vis imminent radiation therapy. Although the intraoral radiography generally includes routine bitewing and periapical exposures, occlusal radiographs are sometimes helpful for primary tumor staging by affirming bony erosion associated with oral cavity lesions affecting gingivae, buccal or palatal mucosa, or the floor of mouth.

With respect to the periodontium, teeth with periodontal sulci equal to or greater than 5 mm in depth may be assigned poor prognoses and should be considered candidates for extraction before radiation therapy. Likewise, teeth with mucogingival defects or furcation involvement should be given similar prognoses and should be considered for extraction. Although prior successful endodontic treatment should not necessarily condemn a tooth for extraction, the unpredictability of endodontically treating active periapical or pulpal pathoses in the usually limited time available before radiation therapy should give rise to enough caution that the extraction of endodontically involved teeth should be strongly considered. Although gingival recession is not in itself a definite indication for exodontia in the absence of deep periodontal sulci, consideration must be given to the maintenance of radicular surfaces exposed to the xerostomic oral environment as a result of recession, because cementum is more prone to the development of inoperable carious lesions than is the more mineralized coronal enamel.

With regard to the dentition, mobile primary teeth should be extracted from alveolar bone to be irradiated, as should any unrestorable teeth. If no plan is or can be made to restore the occlusion of unopposed posterior teeth that will be irradiated, consideration should be given to their extraction, because subsequent supraeruption can contribute to expansive gingival embrasures that are difficult to maintain free of plaque and food debris, possibly resulting in localized periodontitis or radicular carious lesions that are difficult or even impossible to repair. Although extracting impacted teeth from alveolar bone soon to be irradiated is meritorious, consideration should be given to the length of healing time often required of associated surgical sites. This is particularly true of impacted third molars that carry an increased risk for developing acute alveolar osteitis. When deciding whether an impacted tooth should be extracted before radiation therapy, the impacted tooth's likelihood of erupting enough to gain exposure to the oral environment should be considered. If a bony impacted tooth is unlikely to erupt permucosally, the relative risk of it contributing to a future osteoradionecrosis should be judged low and the tooth should be allowed to remain in situ, unless of course there is a pathosis associated with the tooth that overrides a conservative approach. Conversely, an impacted tooth within a proposed radiation field whose anatomic position suggests a potential for intraoral eruption should be deemed a candidate for extraction before radiation therapy.

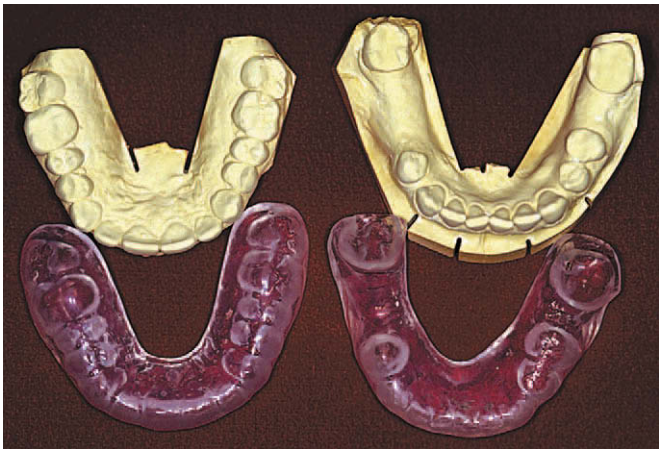

Figure 98-1. Thermoplastic vinyl fluoride gel carriers and the models on which the gel carriers are made.

The presenting or oftentimes soon to be rendered edentulous or partially edentulous condition of many newly diagnosed head and neck cancer patients also demands evaluation of maxillary or mandibular exostoses, tori, and tuberosities primarily in preparation for removable, but sometimes fixed, prosthodontic rehabilitation after the completion of oncologic care. Preprosthetic surgery to include the removal of tori and exostoses and the reduction of tuberosities that could prove obtrusive relative to future prosthetic considerations should coincide with any necessary exodontia as far in advance of radiation therapy as possible. The reduction of these anatomic structures can improve prosthetic-bearing areas and reduce the risk of prosthetic-induced mucosal violations that could contribute to the development of osteoradionecrosis. Although the completion of such preprosthetic surgery before radiation therapy is paramount for those structures lying within proposed radiation fields, the extended mucogingival flaps required for removing bony prominences require consideration for the removal of such prominences even if their juxtaposition to the primary field does not lend to an anticipated dose exceeding 5000 cGy.

Patients using removable prostheses should be advised to minimize prosthetic use during and immediately after radiation therapy to diminish the risk of exacerbating mucositis underlying intaglio prosthetic surfaces, particularly when prostheses are ill fitting and radiation therapy fields directly encompass the oral cavity. Even small prosthesis-related mucosal ulcerations could result in the exposure of alveolar bone and the initiation of osteoradionecrosis. When oral cavity mucositis is anticipated, restorative dental care of high priority should be expeditiously undertaken considering the fact that compromised patient comfort will make restorative dental care difficult or impossible after as little as 1000 to 2000 cGy of radiation. Routine dental prophylaxes should also be sought before head and neck radiation therapy because the relative attenuation of plaque and calculus could diminish the severity of gingival mucositis induced by direct oral cavity irradiation and could decrease the potential for cariogenic dental colonization associated with xerostomia. Additionally, a hiatus in orthodontic care could be considered for those whose radiation therapy coincides with orthodontia because the removal of bands, brackets, and wires could lend to a diminution of trauma to inflamed mucosal surfaces.

For patients retaining a full or partial natural dentition whose head and neck radiation therapy will induce xerostomia, it is important to institute a daily and lifelong regimen of topical fluoride gel use to concur with the initiation of radiation therapy.[1-7,9,12,14-18] This is true for patients whose retained dentition is or is not encompassed by radiation therapy fields. Dental casts generated from clinical impressions recorded before radiation therapy but subsequent to any oral surgical procedures in preparation for radiation therapy should be used to fashion thermoplastic vinyl fluoride gel carriers (Fig. 98-1) into which topical fluoride gel can be applied. After routine brushing and flossing, patients should be instructed to place pharmacy-prescribed 1.1% neutral sodium fluoride or 0.4% stannous fluoride gel into the dental aspects of the fluoride gel carriers for 5 to 10 minutes every day indefinitely before applying them to their dentition. The topical fluoride gel application should be followed by expectoration of excess gel and a period of 30 minutes during which the patient is encouraged not to rinse, eat, or drink.

Prosthodontic Support of the Radiation Oncologist

The maxillofacial prosthodontist may be called on to lend support to the radiation oncology team in their efforts to manage dosimetry by way of patient posturing,[19-22] anatomic displacement or shielding,[3,6,19,23,24] fabrication of brachytherapy appliances,[3,25] or construction of devices capable of mimicking normal tissues.[3,19,24] Although the devices should be constructed following any oral surgical procedures that are done in preparation for radiation therapy, they must be manufactured before radiation therapy simulation appointments in that they must be positioned at the time of simulation.

The undulating topography of head and neck cutaneous structures makes the uniform delivery of radiation difficult at best without the use of boluses constructed of materials considered more or less to be tissue equivalent in terms of their relative resistance to photon or electron penetrance. Consequently, the radiation oncologist may call on the maxillofacial prosthodontic team to assist with facial moulage recording and bolus fabrication when evaluating the physics associated with treating malignant head and neck skin lesions. A facial moulage cast with a gypseous dental stone can aid the radiation oncology team's delineation of a proposed treatment field and prescription of an appropriate bolus thickness before a bolus is constructed of dental baseplate wax or polymethylmethacrylate. Boluses can be particularly useful for providing more even dose distributions for nasal (Fig. 98-2) or orbital malignancies.

Although Aquaplast masks are routinely used to immobilize patients throughout the course of head and neck radiation therapy,[19] customized intraoral devices can be used to provide a stable maxillomandibular relationship when attempts are made to precisely localize an external photon or electron beam relative to oral cavity anatomy. The use of intraoral positioning devices is particularly useful when there is a desire to shield all or part of the maxilla or the mandible from radiation when the opposing jaw is to be included in an external beam field. By positioning the mandible in a prescribed open position with the use of a polymethylmethacrylate appliance that prevents deviation from an arranged spatial relationship to the maxilla, the radiation oncology team can make shielding possible by way of replicable daily positioning of patients from the time of simulation to the completion of radiation therapy. This strategy is helpful when mandibular structures are to be spared from sinonasal or maxillary radiation or when maxillary structures are to be excluded from fields involving the floor of mouth, oral tongue, or other sites encompassing the mandible. In addition to stabilizing the maxillomandibular relationship, the incorporation of radiopaque materials such as orthodontic wire, ball bearings, or gutta percha into such devices can lend support to the radiation oncology team's efforts to identify structures for inclusion in proposed radiation fields at the time of simulation (Fig. 98-3).

Furthermore, intraoral polymethylmethacrylate appliances can be constructed that harbor Lipowitz's alloy.[19,21,26] Being the same metal used by radiation oncology teams to create the portals and shields suspended from frames situated between patients and linear accelerator collimators that fashion conventional three-dimensional (3D) conformal radiation therapy fields, Lipowitz's alloy, a low-fusing combination of lead, bismuth, tin, and cadmium, can suitably shield intraoral anatomy when electron beam therapy is indicated. These devices typically serve the dual purposes of shielding and maxillomandibular positioning because their interocclusal construction also stabilizes the maxillomandibular relationship. These alloy-containing intraoral appliances are often fabricated for lip (Fig. 98-4) and ipsilateral parotid gland (Fig. 98-5) fields. The protective intent of these appliances is supplemented when they are constructed in such a fashion as to physically displace soft tissues away from the source of an electron beam. When

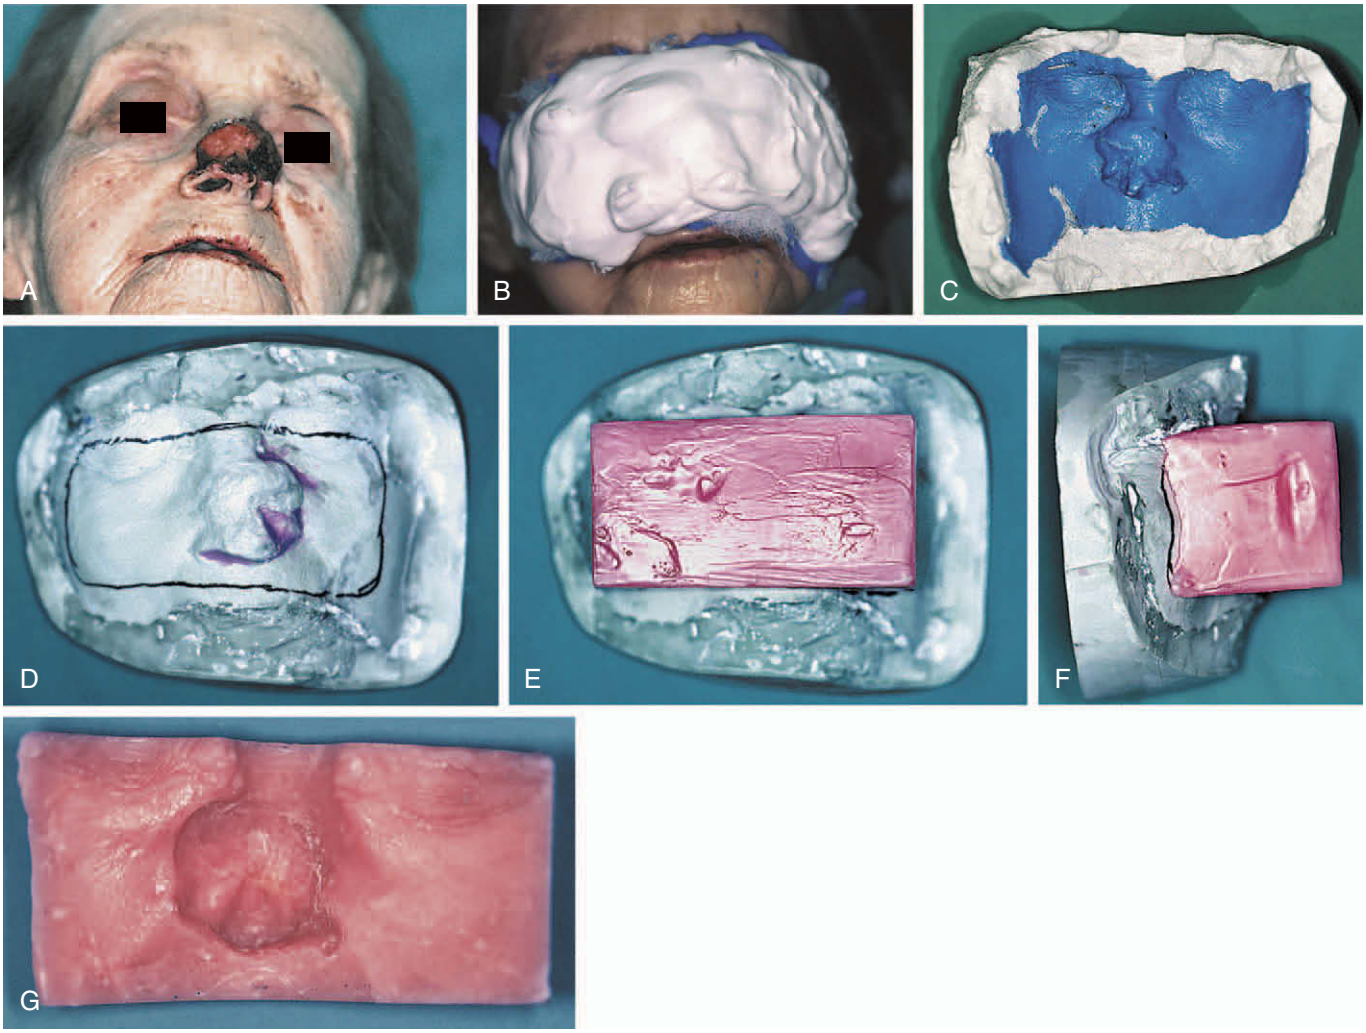

Figure 98-2. **A,** Basal cell carcinoma of the nasal bulb to be treated with external electron beam radiation therapy. **B,** Facial moulage being recorded. **C,** Facial moulage prepared for casting. **D,** Model on which the wax bolus was fabricated. **E,** Frontal view of the bolus. **F,** Lateral view of the bolus. **G,** Intaglio surface view of the bolus.

parotid gland shielding devices are used, patients are instructed to position the tongue anteriorly during treatment. Doing this while occluding on the interocclusal appliance forces the bulk of the tongue into a contralateral position where less radiation is encountered. When parotid gland malignancies are treated with a combination of photons and electrons, radiation oncologists sometimes find it helpful to use two appliances, one with Lipowitz's alloy and one lacking metal. The use of the appliance devoid of alloy during the delivery of photons offers the advantages of consistent day-to-day maxillomandibular positioning and soft tissue displacement without the electron backscatter potentially associated with an appliance that harbors a large volume of metal.

The radiation oncologist's desire for tissue equivalence is not limited to the application of surface boluses because postoperative tissue voids can give rise to an uneven distribution of radiation resulting in suboptimal dosing or overdosing of tissue peripheral to cavernous surgical defects such as those resulting from a maxillectomy. Unfortunately, however, the rigidity of wax and polymethylmethacrylate does not solely allow the dependable use of these materials as intracavitary tissue mimicking materials by virtue of soft tissue and bony undercuts usually associated with these defects. Consequently, filling an intracavitary void with tissue-equivalent material in the interest of improving radiation therapy dose distribution often requires the use of pliable materials that assist daily insertion and removal without unduly traumatizing surrounding tissue. The combination of an inflexible customized intraoral device that stabilizes the maxillomandibular relationship with a pliable material that fills an intracavitary void can, however, overcome the limitations posed by the complex nature of a maxillectomy defect. This combination can be achieved by constructing an intraoral positioning device that incorporates a shelf of polymethylmethacrylate immediately inferior to the maxillectomy defect. The device is capable of supporting a balloon that can be inflated with a tissue-equivalent mixture of radiopaque liquid and water before radiation therapy simulation and each fraction (Fig. 98-6).

Although the maxillofacial prosthodontist is not likely to lend assistance in the clinical application of interstitial brachytherapy, the management of intracavitary brachytherapy often requires the combined efforts of the radiation oncology and maxillofacial prosthetic teams. The orbit and nasopharynx comprise the most common intracavitary head and neck brachytherapy sites, and the stents used for these sites are typically constructed of polymethylmethacrylate that surrounds catheters into which radioisotopic seeds are inserted. The radiation oncologist or physicist, in accord with an intended dose distribution specific for the radioisotope proposed for use, prescribes the catheter positions in consultation with the maxillofacial prosthodontic team after the generation of a master cast from an impression of the site to be treated. When the stents are positioned, they are retained for the duration of treatment by anatomic soft tissue undercuts (Fig. 98-7) or dentoalveolar structures.

Bilateral pillars engage the maxillary model to maintain a consistent maxillomandibular relationship during each radiation therapy fraction. **D,** Clinical view of the anterior aspect of the polymethylmethacrylate positioning device. A segment of orthodontic wire placed within the midsagittal plane of the positioning device identifies the dorsum of the microvascular free flap structures during radiation oncology simulation and ensures its inclusion in proposed radiation therapy fields. **E,** Simulation radiograph exposed with the positioning device positioned intraorally.

Dental Management during Radiation Therapy

Recalling patients every 2 to 3 weeks during radiation therapy is beneficial from the standpoint of identifying dental, periodontal, and mucosal pathoses that may coincidentally appear or arise secondary to radiation therapy. Such a follow-up interval is also meritorious for reinforcing the import of increased hygiene vigilance and the use of topical fluoride gel. It is not uncommon for patients with newly diagnosed life-threatening neoplasms to forget virtually everything that was discussed during an initial maxillofacial prosthodontic evaluation that may have coincided with appointments in otolaryngology, radiation oncology, diagnostic radiology, nuclear medicine, medical oncology, anesthesia, internal medicine, and oral surgery. The overwhelming nature of patients' initial oncologic experience lends to a necessary redundancy with respect to patient communication and education.

Although restorative dental care can be accomplished during radiation therapy, procedures that potentially exacerbate mucositis should be avoided. However, particularly in cases involving oral cavity radiation, patients may reach a point—usually after 2 to 3 weeks of fractionation—where mucositis is severe enough that they do not want to be subject to dental restorative procedures. Regardless of the need for restorative dental care, a readily concocted mouthrinse to obtund mucositis consists of mixing 1 teaspoon of baking soda and 1 teaspoon of salt in a quart of water that is warmed before use. Alternatively, a compounded solution of tetracycline, diphenhydramine, nystatin, and hydrocortisone termed "magic mouthwash" can be obtained from a pharmacy. Two teaspoons of magic mouthwash swished and gargled thrice daily before swallowing serves to mollify radiation-induced stomatitis and pharyngitis.

Dental Management after Radiation Therapy

Follow-up examinations should be arranged every 4 to 8 weeks after the completion of radiation therapy with patients returning to a standard interval thereafter as long as they comply with hygiene and daily topical fluoride gel regimens. Patients can be considered routine patients in terms of their candidacy for restorative dental care after head and neck radiation therapy; however, they must understand that they should not undertake bone-exposing oral surgery within anatomic areas that received more than 5000 cGy of radiation. Such exposures could prompt the development of osteoradionecrosis that could precipitate a pathologic fracture or necessitate a bony resection.[2,6,7,9,12,27-34] Therefore when patients complete their radiation therapy, they should be asked to inform the maxillofacial prosthodontist of any future oral treatment proposal to include a tooth extraction, the surgical placement of an endosseous titanium implant, or periodontal or endodontic flap surgery in advance so that an estimation of dosimetry can be provided to the surgeon. When these estimates indicate that a bone-exposing violation of mucosa could occur in an area that received more than 5000 cGy of radiation, the Marx hyperbaric oxygen protocol should be considered as an adjunct to the surgical procedure.[3,6,7,9,12,27,28,32] Marx's hyperbaric oxygen regimen involves 90-minute dives at a barometric pressure of 2.4 atmospheres while breathing 100% oxygen. Twenty dives are undertaken preoperatively, and 10 dives are completed postoperatively in the interest of stimulating an angioneogenesis that partially and irreversibly[32] counteracts the hypovascularity caused by radiation therapy that is responsible for the increased risk of osteoradionecrosis.

Because dosimetry is highly variable depending on primary tumor sites, regional metastases, radiation oncology philosophy, and available technology, patients and their dental caregivers cannot be expected to routinely know whether it is safe to go forward with bone-exposing oral surgical interventions after radiation therapy. Consequently, it is incumbent on the maxillofacial prosthodontist to assist this determination whether the prosthodontist personally accepts this responsibility or shares it with radiation oncology personnel. When patients have been treated with conventional 3D conformal radiation therapy, possession of simulation and portal radiographs, as well as radiation oncology records, sometimes allows the prosthodontist to establish a relative risk for surgically precipitated osteoradionecrosis without the assistance of a physician or a physicist. On the other hand, when intensity-

modulated radiation therapy, the latest 3D conformal radiation modality, is used, a greater reliance on the radiation oncologist or radiation physicist, or both, may be necessary.

Oral surgical planning after conventional 3D conformal radiation therapy first involves the acquisition of simulation and portal radiographs, as well as a complete description of the radiation oncologist's dosimetric and clinical assessments.[3,6,19] Although the possession of simulation and portal radiographs provides the dental team a mere 2D perception of the fields prescribed by the radiation oncologist, their value in determining whether dentoalveolar structures of interest lie within or without treatment fields allows for surgical treatment planning often without the need for further conference with radiation oncology personnel. When parallel opposed field simulation and portal radiographs are shown to encompass dentoalveolar structures, the dental team must take for granted the fact that an invasive procedure within that field will place the patient at risk for osteoradionecrosis if

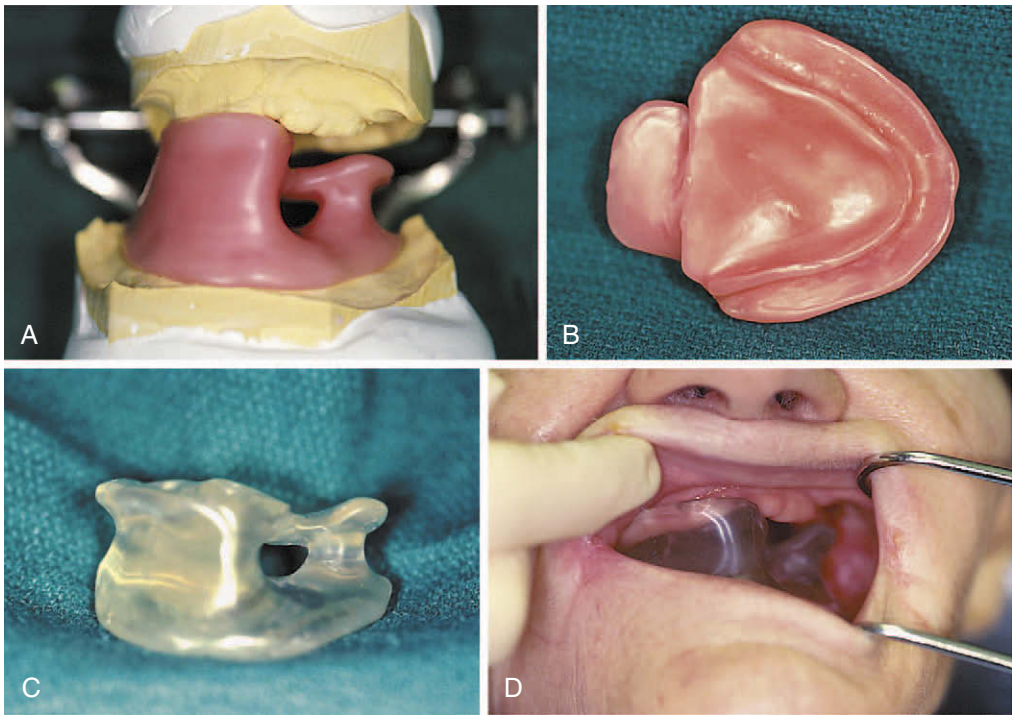

Figure 98-6. **A,** Anterior view of articulated maxillary and mandibular models and the wax pattern used to generate an intraoral device that serves to repetitively position the mandible and oral tongue and support a diaphragm to be filled with water during radiation fractionation. The water-containing diaphragm thus occludes maxillectomy defects and serves as a tissue-equivalent material. **B,** Inferior view of the wax pattern demonstrating an axial shelf to inferiorly confine and exclude the oral tongue from the radiation fields. **C,** Anterior view of the finished intraoral device. **D,** Anterior view of the positioned intraoral device demonstrating the diaphragm-supporting shelf situated immediately inferior to the maxillectomy defect.

the prescribed dose to that field surpassed 5000 cGy. However, as is frequently the case in head and neck radiation oncology, the exclusion of dentoalveolar structures anterior, superior, or inferior to a field boundary allows surgical intervention in the excluded area without risking osteoradionecrosis (Fig. 98-8) because osteoradionecrosis by definition comprises a volume of necrotic bone within a radiation therapy field.[30] Uncertainty can arise, however, when treatment field borders bisect or tangentially appose dentoalveolar structures to be included in a proposed surgical intervention. Although dosages at the borders of conventional 3D conformal radiation therapy fields approximate only 50% of the prescribed dose, patient positioning can vary by as much as 5 mm in any given dimension despite exceptional efforts on the part of radiation oncology teams to reproducibly orient their patients on a daily basis. Considering the possibility of positioning errors during the course of daily radiation therapy sessions, such scenarios warrant erring on the side of caution with the assumption that affected field border areas could become osteoradionecrotic after a surgical insult.

Likewise, when ipsilateral dentoalveolar structures are found within unilateral treatment fields where photon doses exceeded 5000 cGy, it can be assumed that ipsilateral oral surgical procedures within that field would place a patient at great risk for osteoradionecrosis. Conversely, the risk for contralateral, oral, surgically induced osteoradionecrosis can be relatively low for such a patient considering the fact that only about one third of a conventionally prescribed photon dose would reach contralateral dentoalveolar structures. However, because the use of electron beams; uniform, oblique, or wedged pair multiple fields; or appositional fields can complicate dosimetric deductions made with the use of simulation and portal radiographs and a medical record narrative, it is always reasonable to confer with the radiation oncologist or physicist when questions arise before invasive oral surgical procedures. The potential debility associated with the precipitation of osteoradionecrosis merits such caution.

In contrast to conventional 3D conformal radiation therapy, in which gantry positions are limited and static, intensity-modulated radiation therapy can be delivered by way of a mobile collimator. The

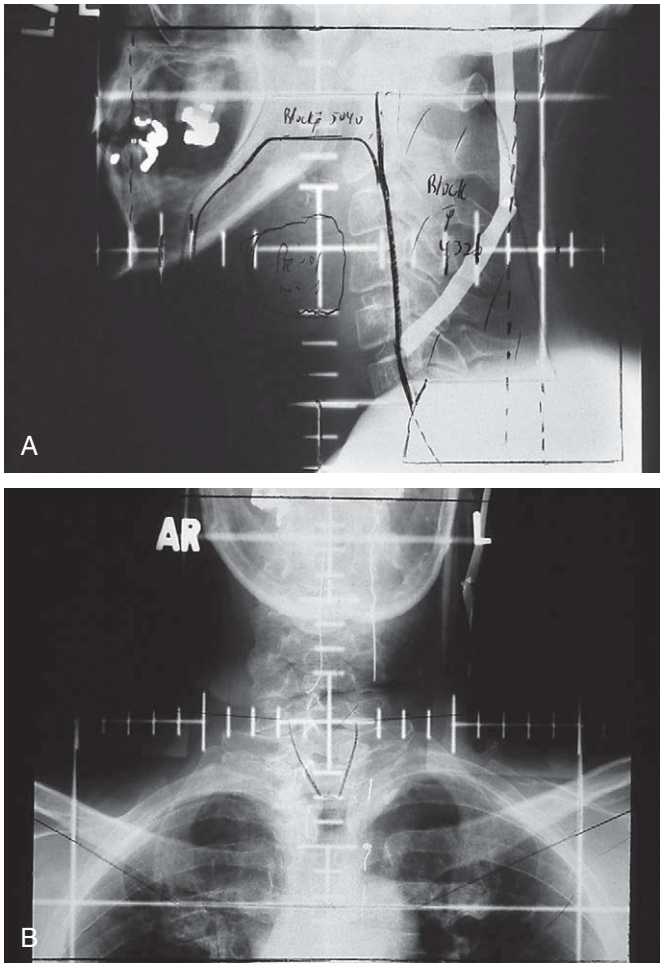

Figure 98-8. **A,** Bilateral parallel opposed simulation radiograph for a patient who undertook radiation therapy after a total laryngectomy for a squamous cell carcinoma. The exclusion of dentoalveolar structures anterior to the field boundaries allowed for the safe extraction of the remaining carious dentition without adjuvant hyperbaric oxygen therapy. collimator arcs across several swaths of parallel appositional fields while two rows of tungsten leaves within the collimator (Fig. 98-9) concentrically open and close to strategically deliver radiation to targeted tissues while sparing normal structures of the highest radiation burdens.[22,35-38] In another technique that has come to be known as *step and shoot intensity-modulated radiation therapy,* radiation is directed from multiple stationary gantry positions that are each uniquely and statically collimated through the use of multiple layers of tungsten leaves capable of converging from the periphery of the linear accelerator's nonadjustable port to fashion customized portal shapes in accord with the radiation oncologist's or physicist's treatment prescription (Fig. 98-10). In either scenario, intensity-modulated radiation therapy simulation is based on an interface between computed tomography imaging and dosimetric treatment planning software such as the CORVUS system. As such, intensity-modulated radiation therapy simulation and portal radiographs offer limited or no value for establishing surgically induced osteoradionecrosis risks after radiation therapy, and intensity-modulated radiation therapy dosimetry must be evaluated using software that is at this time almost universally unavailable to any dental team. This software, however, offers an evaluation of each computer-generated tomographic slice that is so detailed in its resolution that

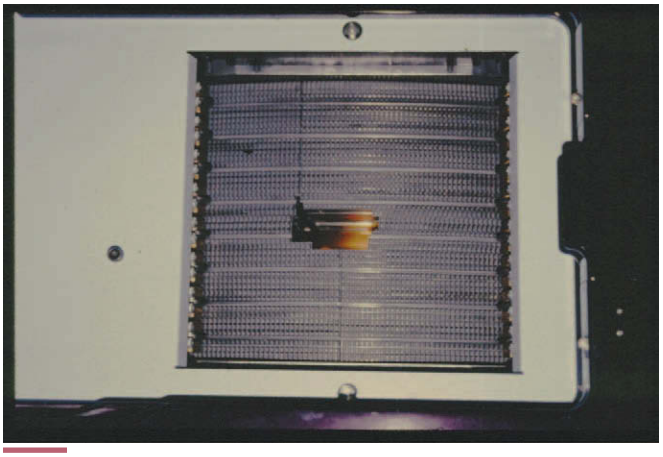

Figure 98-10. Step and shoot intensity-modulated radiation therapy collimator.

anatomic structures as small as individual tooth roots can be identified and dosages can be estimated at the pinpoint level of a computer mouse cursor superimposed over the area of dosimetric interest. Because CORVUS and other intensity-modulated radiation therapy software firms offer axial, sagittal, and coronal tomography sections, a comprehensive 3D depiction of dosimetry can be achieved by means of a review of computer records. This can be done without the need for assessing multiple simulation and portal radiographs that may be geometrically confusing, tattered from age, untidily drawn, of poor radiographic quality, or entirely lost or discarded.

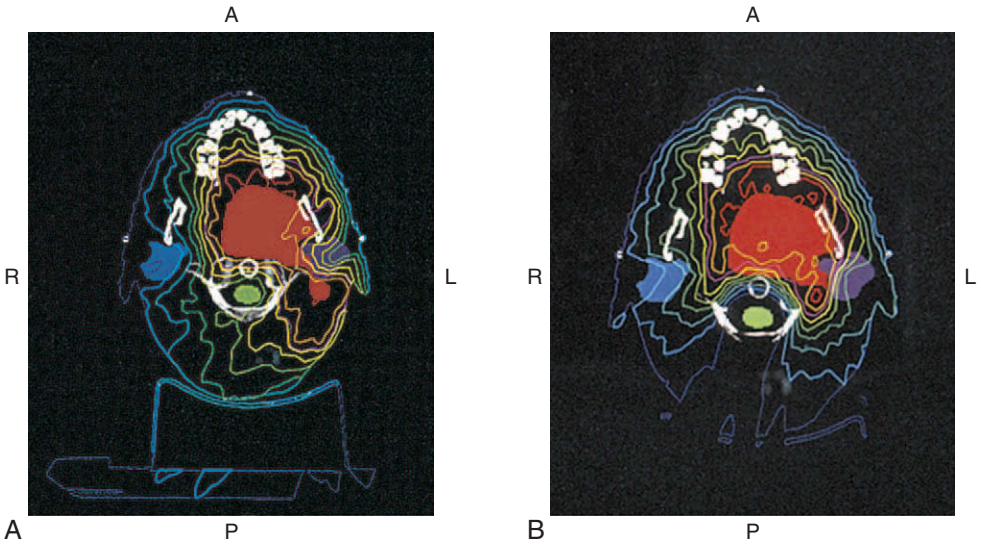

Figure 98-11. **A,** Computed tomography illustration of intensity-modulated radiation therapy isodose lines for a patient treated for a left tonsillar squamous cell carcinoma. The development of a second primary squamous cell carcinoma in the area of the right maxillary palatal mucosa after intensity-modulated radiation therapy necessitated a right inferior maxillectomy. The subsequent development of osteoradionecrosis in the area of the maxillectomy is substantiated by the cumulative dose of radiation in the area of the posterior right maxilla. The axial image demonstrates dosages delivered to the dentoalveolar structures at a level midway between the crestal alveolar bone and the periapices of the right maxillary molars. **B,** The patient's left tonsillar tumor bed was boosted during the administration of intensity-modulated radiation therapy. The computed tomography axial image delineates the additional dosages that were received during the boost in the area of the right posterior maxilla. The collective dose to the right posterior maxilla in the area of subsequent postoperative osteoradionecrosis approximated 7000 cGy and warranted a hyperbaric oxygen therapy regimen that indeed mitigated the osteoradionecrosis.

Although intensity-modulated radiation therapy dosimetric evaluations performed in the interest of establishing the relative safety of proposed dental interventions are readily achieved by way of the dental team's access to computer records when maxillofacial prosthodontic support is found in the facility in which a patient's therapy was delivered, communicative problems can arise between dental and radiation oncology personnel when they are separated geographically. Radiation oncology personnel are not always familiar with dental anatomy and terminology or oral surgical procedures, and dental personnel are not generally knowledgeable of intensity-modulated radiation therapy computer simulation packages or the general delivery of intensity-modulated radiation therapy. It can thus benefit dental practitioners routinely involved in invasive oral procedures to personally meet a radiation oncology team involved in the delivery of intensity-modulated radiation therapy before encountering their first head and neck intensity-modulated radiation therapy patient. Conversely, dental personnel can share an oral surgical treatment plan with a patient's radiation oncology team face-to-face when they first encounter a patient treated by way of intensity-modulated radiation therapy. Either way, an initial interdisciplinary conference at the intensity-modulated radiation therapy facility could lend clarification to each team's needs and concerns when future patients are shared and fiscal, travel, and time constraints make it impractical or impossible to convene personally. Once dental and intensity-modulated radiation therapy providers possess a working knowledge of one another's methodology and concerns, distant communication can be assisted. The most convenient means by which to request dosimetric data from a remote intensity-modulated radiation therapy center involves obtaining printed colorized serial computed tomograms displaying isodose information that is superimposed over imaged anatomy (Fig. 98-11). These images are generated by all intensity-modulated radiation therapy computer packages and offer a reasonable representation of dosages delivered in three dimensions. A common impediment to dental teams' treatment planning efforts involves their receipt of black-and-white photocopied computerized tomography isodose images that are essentially illegible by virtue of the fact that intensity-modulated radiation therapy computer packages routinely rely on the use of color for the assignment of dosimetric values.

Overview of Maxillofacial Prosthodontic and Radiation Oncology Interactions

The maxillofacial prosthodontic team's involvement in the care of head and neck cancer patients who will receive radiation therapy is initially focused on treatment planning in the interest of preventing osteoradionecrosis and the preparation for any prosthetic rehabilitation necessitated by that treatment planning or a patient's comprehensive oncologic management. The maxillofacial prosthodontist also participates in decision making intended to diminish the risk of osteoradionecrosis for patients obliged to undertake oral or maxillofacial surgical procedures after radiation therapy. Because these efforts are usually multidisciplinary to the extent that decisions made by any of those involved in the treatment of an oncology patient could affect the maxillofacial prosthodontic team's treatment options, participation in multidisciplinary head and neck tumor board conferences is constructive. Additionally, with support from the general dental and oral hygiene communities, the maxillofacial prosthodontist contributes to preventive dental health education and care from the outset of the oncologic experience through what should become a lifelong follow-up relationship. Furthermore, maxillofacial prosthodontic personnel can assist the radiation oncology team with intraoral and extraoral devices that repeatedly position and shield anatomy, serve as tissue-equivalent material to allow a more even dose distribution of external radiation beams, or situate radioisotopic sources for intracavitary brachytherapy. Finally, the participation of maxillofacial prosthodontic team members at the commencement of any head and neck oncologic treatment is meritorious in that the often complex intraoral and extraoral rehabilitation of anatomic deficits acquired before, during, or after that treatment is germane to the traditional role of maxillofacial prosthodontists.

Intraoral Rehabilitation of Tumor-Ablative Surgical Defects

The incidence of oral cancer approaches about 5% of all new cancers diagnosed in the general population of the United States.[21] A significant number of head and neck oncology patients are treated for neoplasms of the lip, tongue, oropharynx, mandible, maxilla, soft palate, larynx, external ear, orbit, and external nose. The highest incidence of onco-

logic disease afflicts those persons with significant risk factors such as an excessive use of alcohol and tobacco or exposure to ultraviolet light and human papillomaviruses. To successfully eradicate disease, these tumors are treated with multimodal therapy including tumor-ablative surgery, radiotherapy, and chemotherapy. Patients treated for tumor-ablative surgery of the oral and pharyngeal areas may have significant anatomic deficits compromising speech, swallowing, and mastication.

Prosthetic Maxillary Obturation

The maxilla may require resection for tumor control that may create a host of problems related to speech, swallowing, and aesthetics. Traditional resection of the maxilla involves an infrastructure, medial, or total maxillectomy to include the infraorbital rim. The maxillectomy procedure used to control incipient disease of the oral cavity has been classified by Aramany[39] on the basis of frequency of occurrence. As with other anatomic defects, tumor surveillance dictates keeping these areas clearly visible to detect recurrences, should they arise. Obviously, the more teeth, bone, and soft tissue available, the more easily prosthetic rehabilitation can be achieved. However, edentulous and some partially dentate patients requiring a maxillectomy may have significant difficulty in obtaining stability with prostheses, and in these cases a consideration for the use of dental implants may be warranted.

Surgical Obturation

Resection of maxillary tumors that involve the oral cavity is dedicated to total eradication of disease. Similarly, preservation of anatomy conducive to prosthetic rehabilitation should be considered. Preoperative assessment of the patient by the maxillofacial prosthodontist is integral to overall treatment success by the head and neck treatment team (Fig. 98-12). Clinical examination with panoramic radiography may assist with decisions to extract diseased teeth at the time of surgical resection (Fig. 98-13). In this way, if adjunctive radiotherapy is necessary, a 4- to 6-week healing time offers a distinct advantage (Fig. 98-14). Preoperative assessment also aids to plan osteotomy planes through the existing tooth sockets in dentate patients to preserve the support of adjacent teeth.[40] These teeth, also called *abutments,* may be strategic for retention of a prosthesis. In fact, the more arch curvature formed by remaining teeth, the more favorable retention may be for a prosthesis of this type.

Arches planned for maxillectomy should be approached with the thought of disease eradication. As a secondary thought, preservation of structures vital for support should be kept in mind for maximum potential of successful rehabilitation. The first of these preserves as much of the hard palate as possible, which is the primary stabilizing structure of a maxillary prosthesis. Second is grafting of the cheek flap with epidermis or split-thickness skin (discussed further later). Third comes removal of the inferior conchae, which, if not eliminated, frequently obstruct proper obturation. This is most evident with posterior and some lateral resections that involve the oral cavity. Finally, the sinus walls should be grafted, if possible. Again, split-thickness skin will limit polypoid tissue formation and keep mucus formation to a minimum.[41] The roof of a sinus grafted with skin will allow its use as a supporting wall for the prosthesis.

Impressions can be made before surgery to provide diagnostic casts (Fig. 98-15). These casts will aid in fabrication of a prosthesis to be inserted at the time of surgery. These prostheses are usually made from polymethylmethacrylate resin and can be made with or without pros-

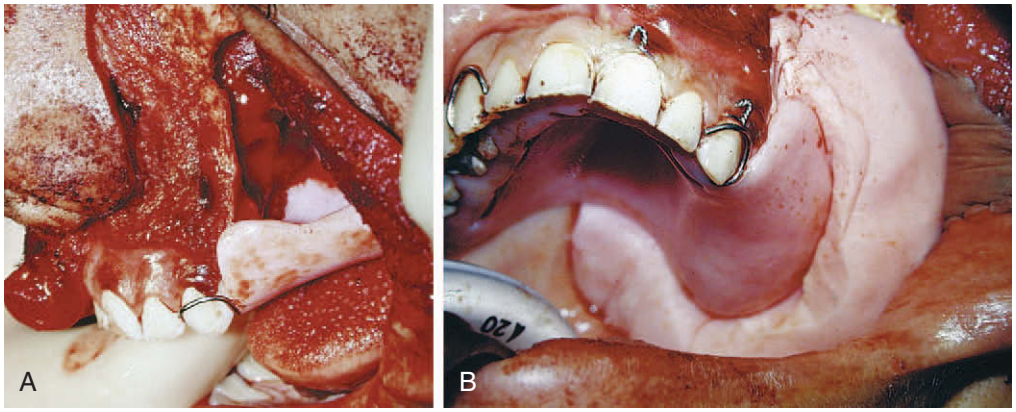

Figure 98-16. **A,** Surgical prosthesis is tried for proper fit. **B,** A surgical bolster is added with xeroform gauze, denture-conditioning material, and stainless steel ligatures securing in place for 5 to 7 days. Note split-thickness skin graft sewn in lateral cheek flap. *(Surgery performed by Gary Clayman, DDS, MS.)*

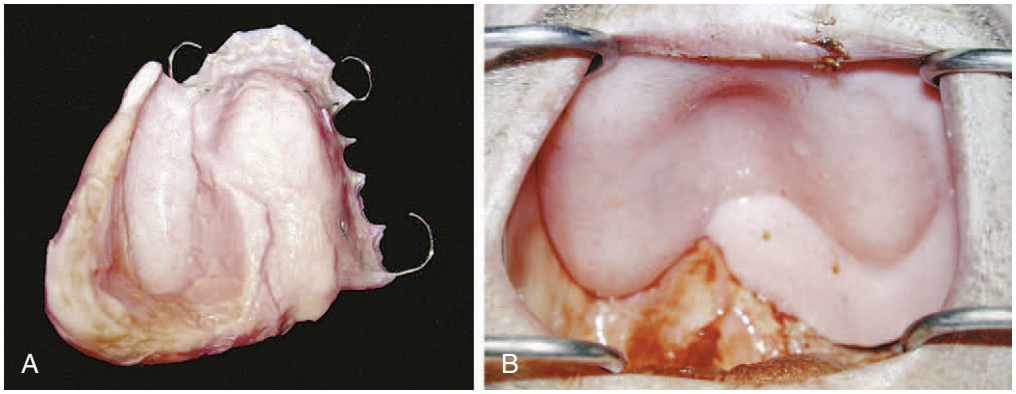

Figure 98-17. **A,** At pack removal, interim obturators made from modification of surgical prosthesis. **B,** Photograph of an edentulous patient's interim obturator. Patients are instructed on defect hygiene and placement/removal of prosthesis.

thetic teeth. The advantage of having no functioning dental components to these prostheses is that occlusal forces are left off the wound to allow for efficient healing. A surgical prosthesis offers advantages relating to speech, swallowing, and psychological well-being. Also, the prosthesis is helpful in securing a surgical bolster and aids the patient in acclimating to wearing a removable prosthesis. Because respiratory epithelium may remain within a sinus defect, prosthetic loading of this area can be problematic. The ability to clean the defect also becomes a concern, with hardened mucus being a particular obstacle for placement of a prosthesis. Grafting of the defect with split-thickness skin can create a more comfortable surface with fewer mucus secretions. As with any skin graft, positive pressure with a surgical bolster can aid with providing this type of surface. Perforating the graft with dispersed small incisions can minimize the likelihood of hematoma formation, thus improving take of the skin graft. In partially dentate patients, securing the prosthesis can be accomplished by incorporating stainless steel wrought wires in the prosthesis that encircle the most terminal teeth (also called *abutments*) (Fig. 98-16). In addition, the prosthesis can be wired to the abutment tooth closest to the defect using 25-gauge stainless steel wires. In edentulous patients, the prosthesis can be held in place using sutures, circum-zygomatic wiring, or several titanium screws (2.7, 10 mm) into the remaining hard palate. Care should be taken to ensure that the screws are placed in an angled fashion so as to allow screwdriver insertion at pack removal. In most cases the surgical prosthesis should be kept in place between 5 and 7 days.

After this time, removal of the packing material and prosthesis should ideally be undertaken by the surgeon and prosthodontist. Removal of the packing material can precipitate a hemorrhage, and preparations with oxidized cellulose, gelatin foam, or microfibrillar collagen can be invaluable. At this time, transitioning the prosthesis by addition of tissue-conditioning material assists patients in becoming accustomed to placement and removal (Fig. 98-17). The patient is also instructed on how to cleanse the defect twice daily with a dilute solution of baking soda and salt. This can best be accomplished using an irrigation syringe and a dispersion attachment head. The patient returns weekly during the following month for changing of the material on the prosthesis as the defect continues to change shape.

Interim Obturation

At the time of pack removal, it is beneficial to have the patient place and remove the prosthesis so that the defect can be lavaged and allowed to heal appropriately. The patient should be seen weekly for the first month after resection. Maximum changes will occur during this time and may be accommodated in the shape of the defect portion of the prosthesis. The original acrylic resin portion of the prosthesis can still be used at this stage to provide a stable anchorage for the changing defect. Other soft acrylic resins can be attached to it and can be changed to a solid acrylic resin prosthesis before radiation therapy, if indicated. If necessary, prolonged use of the interim obturator can assist further surgery or other significant modification. Occasionally, a new impression procedure shortly after packing removal will obtain an improved adaptation of the interim prosthesis. During times of radiation to the area of the defect, it is desirable to have a solid acrylic resin structure that is more resistant to the effect of opportunistic *Candida* colonization.

Definitive Obturation

After an extended period of healing (i.e., 6 weeks) following surgery and/or radiation therapy fabrication of a definitive prosthesis may take

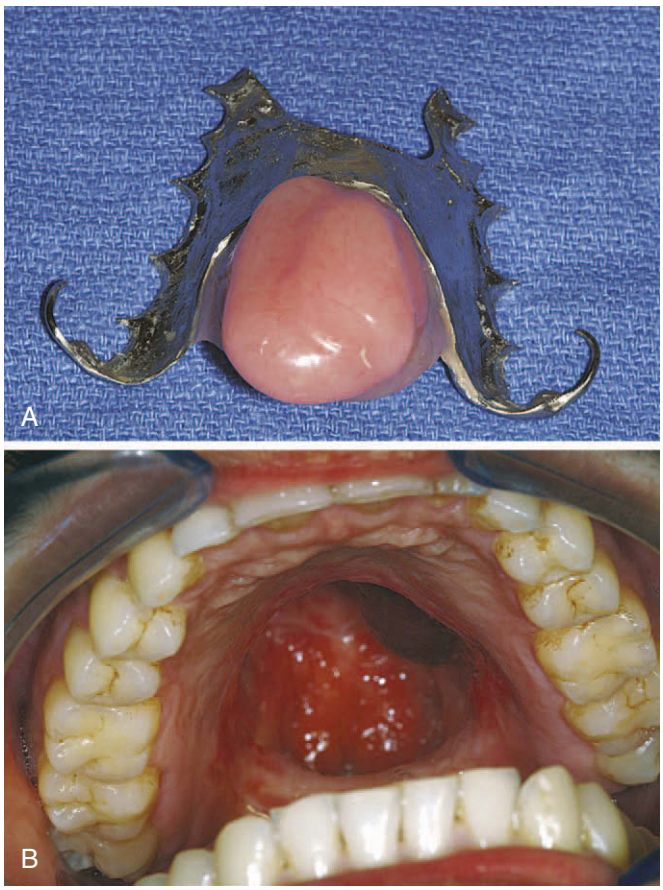

Figure 98-18. Definitive obturator made with cast chrome base **(A)** for resection defect of pleomorphic adenoma **(B).**

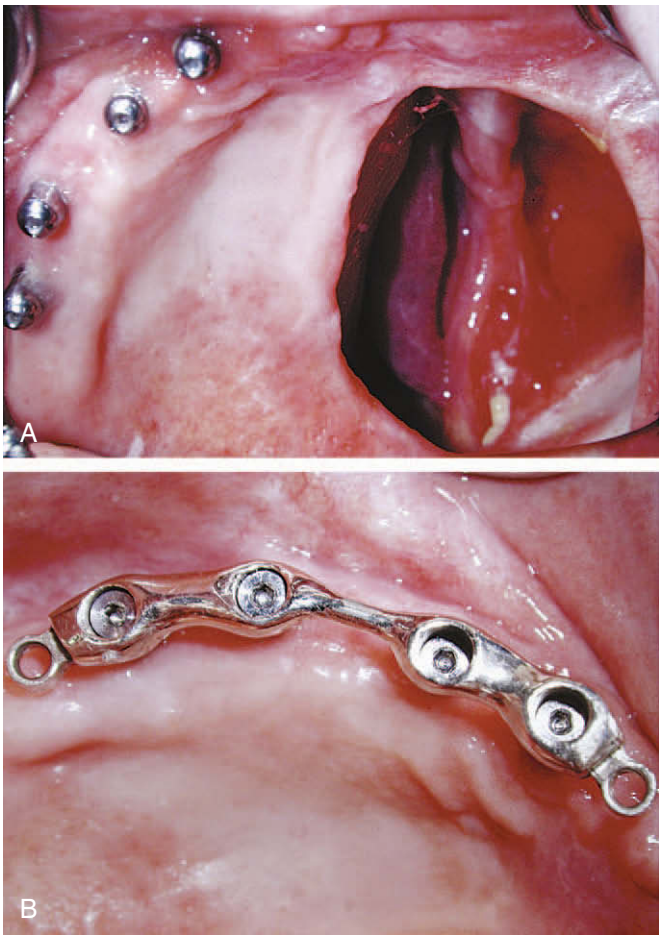

Figure 98-19. **A,** Implant-retained obturator with sinus augmentation and, **B,** stress-breaking bar attachment of nondefect side.

place. For dentate patients, this prosthesis can be made of either acrylic resin and stainless steel wrought wire clasps or a cast chromium framework that supports a bulb extension made of polymethylmethacrylate (Fig. 98-18). Specific recommendations for design have been well published.[26] Prostheses with masses of less than 45 g may remain solid, but prostheses of greater masses should be hollowed.[16,42] Edentulous patients are treated with prostheses made entirely of acrylic resin, the bulbs of which can be hollowed similarly. Teeth placed in the area of the defect serve as aesthetic replacements and prevent opposing tooth supraeruption but are of limited functional value.

Many edentulous or partially edentulous patients have difficulty with retention and, in some cases, difficulty with support as well. In these cases, osseointegrated implants can anchor and support the obturator prosthesis. Although long-term follow-up studies of patients possessing implants in irradiated bone warrants their cautious use, implants remain potentially advantageous.[43] Because maxillary sinuses may be extensively pneumatized following tooth extractions, installation of implants into this area can be problematic unless bone is grafted into the sinuses. This use of sinus augmentation has been well documented and deemed to be successful with the use of implants.[44] This technique can be used on a nondefect side where a unilateral or posterolateral defect of the opposite side is present. Splinting of approximately four to five implants with a stress-breaking bar is generally suggested and provides the patient with a retentive, stable prosthesis that may offer improved support as well (Fig. 98-19). Recently, the use of zygomatic implants (extended length) has been suggested as an alternative to sinus augmentation.[20,45] The implant protocol for zygomatic implants mandates bilateral placement, and preservation of the infraorbital rim on the defect side may improve surgical stability. Both techniques require a screw-retained bar attachment to be made with the obturator (Fig. 98-20).[46] Remote anchorage sites have been suggested as a means of stabilizing prostheses rehabilitating maxillary defects.[46,47]

Mandibular Resection Prostheses

Resection of a portion of the mandible may be necessary to control disease and may or may not create a discontinuity defect. Because the mandible is so integral to oral and respiratory physiology, it is desirable to preserve function as much as possible.

If a marginal mandibulectomy is performed, a general guideline is to surgically preserve about 1 cm of vertical mandibular height for integrity. Subsequently, the remaining mandible can be rehabilitated with a split-thickness skin graft and removable tissue-borne prostheses, or alternatively it can be reconstructed with osseointegrated dental implants. In the dentate patient, preservation of the inferior alveolar nerve in the posterior mandible may preclude placement of implants if there is minimal bone available above the canal position to stabilize implants. In these cases, either nerve transposition[48] (Fig. 98-21) or onlay bone grafting can serve to provide an osseointegrated rehabilitation (Fig. 98-22).

In edentulous patients, placement of either conventional prosthetics or implant supported/retained prosthetics may be desirable. Often, prosthetics can rely on select placement of implants in the anterior mandible with specified posterior occlusal cantilevering (Fig. 98-23). This procedure is well documented, with recent evidence indicating immediate functionality when implants are placed in the native mandible.[49,50]

Discontinuity Defects

If a discontinuity defect is created by composite resection, it may be feasible to collapse the defect and not reconstruct mandibular continuity. This becomes more feasible if the patient is edentulous because

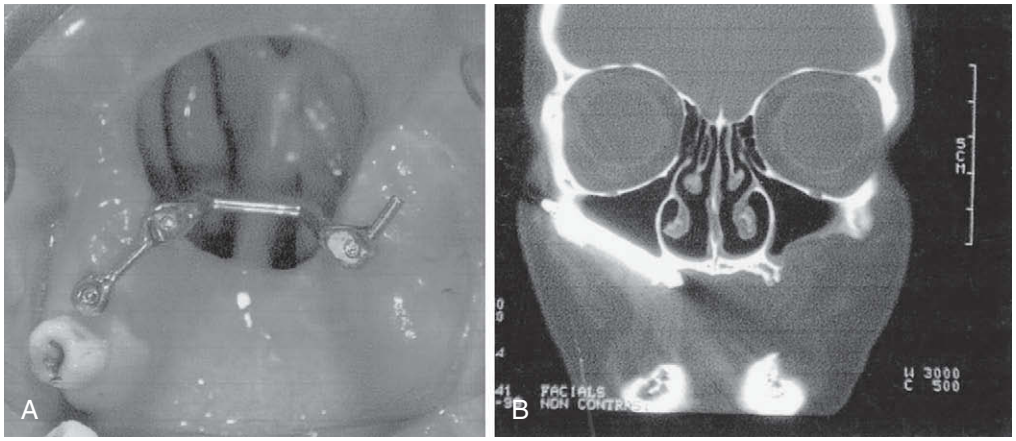

Figure 98-20. Use of extended-length implants **(A)** that traverse lateral aspect of maxillary sinus and engage dense zygoma **(B)**. Such implants obviate the necessity for sinus augmentation for installation of conventional endosseous implants. *(Courtesy of Samuel Zwectchenbaum, DDS.)*

dentate patients will have significant occlusal discrepancies that make postoperative rehabilitation difficult to impossible. In these cases a significant cosmetic deformity may result because the lower third of the face is asymmetric (Fig. 98-24). Also, disability of the tongue usually results because portions of the tongue may be used to close the wound, making swallowing problems inevitable. Additional consideration is given to the fate of the proximal resection segment of the mandible after the resection. Reconstruction bars may create additional backscatter radiation if adjunctive radiation is used for tumor control (Fig. 98-25).

The key to functioning in these cases lies with preservation of the ramus, for which attachment of the muscles of mastication is preserved. Through removal of the ramus, less function is evident without balance of contralateral pull of pterygoid, temporal, and masseter muscles. If more of the ramus is retained and not maintained in its preoperative position, it may collapse on the maxillary buccal vestibule and obstruct maxillary dental hygiene procedures or the fabrication of a maxillary prosthesis. Furthermore, the ramal segment could be sequestered into the oral cavity. Reconstruction in these cases is the wiser choice and does not advocate joining the plate to small condylar remnants.[51] If mandibular continuity is not preserved after resection, it may be desirable to reconstruct the area with an autogenous or alloplastic graft. Location of the resection may be indicative of the relative success of the reconstruction. Anterior reconstructions that cross the midline with a plate system alone may be less successful than those with an osseous reconstruction as well.[52] Cosmetic and functional deformities are also more of a consideration in the anterior mandibular areas. This is perhaps due to the influence of the suprahyoid musculature on swallowing and respiration. Concurrently, it is considerably difficult to conform an osseous graft to an arch form in this area. Posterior or lateral resections appear to be less debilitating and problematic because a linear replacement of bone is frequently sufficient to reconstruct this area. A reconstruction with pedicled soft tissue may serve to deviate the remaining mandibular segments to the affected side. Osteomyocutaneous flaps are superior in reconstructing mandibular discontinuity to avoid this deviation and preserve maxillomandibular relationships vital to rehabilitation.

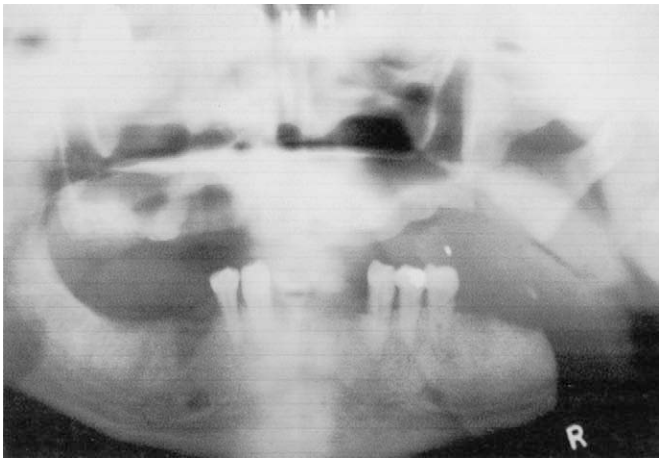

Figure 98-25. Proximal segment without reconstruction results in deviation and displacement against maxillary posterior ridge.

In some cases, autologous grafts offer a greater volume of viable bone with progenitor cells capable of creating a more favorable environment for osseointegration.[36] Nonvascularized or vascularized osteomyocutaneous flaps can also be used for reconstruction. It may be preferable to use vascularized flaps in previous operative beds or in areas that have been or will be irradiated, because the provision of a blood supply may offer a more predictable opportunity for the graft to remain viable. Vascularized iliac crest has been used with some degree of success for mandibular defects and some maxillary defects. Introduced by Hidalgo,[53,54] the use of vascularized fibular grafts has also shown a promising degree of success in the reconstruction of these complex mandibular defects.[55] Being a non-weight-bearing bone, the fibula is of reasonable dimension to functionally and cosmetically reconstruct the mandible. Additional phases of rehabilitation with titanium implants have been demonstrated to be uniquely applicable to these cases. Bicortical stability is typically well obtained at surgical installation, and long-term success has been favorable (Fig. 98-26). The choice of using either a sectional overdenture design or a screw-retained fixed prosthesis may be predicated on the amount of tissue missing, the function of the tongue, perioral scarring, and adjacent/opposing occlusion (Fig. 98-27). Frequently, the restoration to implant height ratio is seen to be greater than 1:1. Passive splinting of these implants is crucial to their long-term success, and close attention should be paid to the development of the occlusal scheme. Occasionally, it may be necessary to perform soft tissue revision procedures if the skin pedicle is thick or if a greater vestibular depth is necessary. This ensures soft tissue health and visibility for hygiene procedures.

Tongue Resection

Resection of the oral or pharyngeal tongue is occasionally necessary to control disease. Integral to swallowing, speech, and mastication, the tongue is often treated aggressively for tumor control. Centrally located malignant lesions have a propensity to metastasize bilaterally to the neck and may require extensive resection for tumor control. As a result of large resections of tongue muscle, wound closure becomes a concern for postoperative healing. Vascularized myocutaneous or fasciocutaneous flaps may be a valuable adjunct for reconstruction of these resections. However, these flaps are generally insensate and do not provide tissue conducive for normal swallowing and speech production. Physiology of swallowing has been described and is divided into three main

Figure 98-27. Screw-retained ceramometal prosthesis used for patient in Figure 98-26.

phases: oral, pharyngeal, and esophageal. The voluntary oral phase can be further subdivided into two phases of oral preparatory and mastication.

The competency of the lips is mandatory for the oral phase to function effectively because a lip seal will create a boundary for bolus transportation. Mastication is an independent function of the tongue for tougher-consistency foods, and efficiency is also dependent on dental status of the patient. The time taken for the bolus to be transported to the posterior oral cavity past the anterior faucial arch demarcates the oral transit time. In healthy adults, the oral transit time can be about 1 to 2 seconds. After tumor-ablative surgery of the tongue or mandible, the range of motion needed for swallowing and speech production may not be sufficient. In these cases the height of the palatal vault may not allow appositional contact of the remaining tongue tissue to propel the bolus of food or liquid into the pharyngeal area where the involuntary phase of the swallowing reflex is initiated. Consequently, lowering of the palatal surface prosthetically can aid in providing a surface that approximates the extent of the tongue's range of motion postsurgically. This prosthesis, known as a *palatal augmentation prosthesis,* can be used in dentate or edentulous patients (Fig. 98-28).[56,57] In patients with dysphagia, palatal augmentation prostheses have been shown to decrease oral transit times, thereby increasing swallowing efficiency.[58]

Articulatory speech debility is dependent on the area(s) of the tongue that are resected. For instance, resection of the anterior or tip of the tongue may not allow articulation of linguoalveolar sounds such as /t/, /d/, /n/, or /s/. In other cases the base or sides of the tongue may be resected to create deficiencies in /g/, /ng/, /k/, or /c/. In these cases a prosthesis may serve to better aid production of these sounds. Because the shape needed for swallowing may be markedly different from that which is necessary for speech production, a prosthesis with interchangeable surfaces being incorporated into a palatal augmentation or a mandibular "tongue" prosthesis has been advocated. Each respective surface is used specifically for speech or swallowing.[51,59] Regardless of the type of prosthesis being constructed, involvement of a speech pathologist can be quite instructive to patients and the maxillofacial prosthodontist.

Soft Palate Resection

As a component of Waldeyer's ring, the soft palate is occasionally included in resection of tumors of squamous cell origin. Because of its dynamic nature, the soft palate, like the tongue, is integral to swallowing and speech. The anterior faucial arch serves as a landmark for the involuntary phase of swallowing and, if included in resection, can predispose the patient to aspiration. An anatomic deficit of the soft palate can also create velopharyngeal insufficiency, which may result in nasal regurgitation of swallowed matter and nasal speech production. Replacement of velar function with pharyngeal flaps is reserved for conservative soft palatal defects that may be acquired or congenital. A prosthesis (known as a *speech aid*) replacing soft palate function should obturate the pharyngeal recess at the level of the first cervical vertebra or Passavant's pad, frequently seen as a conglomeration of muscular tissue in the superior pharyngeal constrictor (Fig. 98-29). At this level, the extension of the prosthesis should serve to partially fill the pharyngeal recess while providing room for the dynamic nature of the pharyngeal and tongue musculature. A stable reference for the prosthesis starts with assessment of the oral cavity. Anchorage for the prosthesis can be tooth borne or partially or completely tissue borne. For tooth-borne prostheses, anchorage with molar teeth becomes advantageous because anchorage closer to the vectors of dislodging forces discourages premature loosening with function.

Soft palate function can also be affected by cerebrovascular accidents, demyelination diseases, or surgical procedures. The anatomic structures, in these cases, may be incompetent in performing velopha-

ryngeal closure. A palatal lift prosthesis may serve to provide the patient also with better speech production and improved swallowing patterns and it may stimulate the musculature to perform at increased functional levels.[60-62] For the palatal lift prosthesis to be effective, some pharyngeal muscular movement must be present. To effectively evaluate the closure of the soft palate, a nasal endoscope can aid in directly identifying deficiencies.

Intraoral rehabilitation of congenital and acquired defects has historical roots in traditional restorative dentistry. It is within this literature that restoring a patient's preoperative level of function has proved essential. Quality-of-life and clinical outcome studies have been shown to validate these goals and objectives. These achievements have been taken to a higher level with our knowledge of osseointegration, tissue physiology, and technology. Continued developments in tissue engineering and other related technology will continually explore and improve outcomes in this complex area of clinical treatment.

Prosthetic Management of Acquired Facial Defects

Facial defects acquired from trauma or surgery can be devastating and among the most socially crippling for the patient. There is a tremendous emphasis on perfection and beauty in today's society. The prosthetic restoration of patients who are not surgical reconstruction candidates can lead to their return to active, productive lives and complete social acceptance.

The decision of whether to manage a facial defect surgically or prosthetically is often a difficult one. Most patients would rather have surgical reconstruction. However, the advantages and disadvantages of each method must be considered as the decision is made. The patient's functional status and overall health are concerns. Radiation treatment to the defect area results in a reduced blood supply and can prevent some surgical procedures. The texture, contour, and color of the surrounding tissue must also be considered, as well as the need to examine the surgical area for an extended period after the original intervention. Achieving the correct shape to restore contour can be difficult with living tissue, and large defects may require staged procedures. If all of these factors can be managed positively and there are no other contraindications, the patient and surgeon may opt for surgical reconstruction. If the defect can be successfully managed with the patient's own tissues in an aesthetically acceptable fashion, this may be the first choice. Otherwise, a prosthesis is required.

Prosthetic management of facial defects has its disadvantages as well. Although excellent contour and color are attainable, the prosthetic materials used have fairly limited life spans—usually 18 to 24 months. The prosthesis may have to be retinted during that time, depending on

Table 98-1

Prosthetic Management of Facial Defects

	Advantages	Disadvantages	Ideal Defect
Nasal	Postoperative inspection; color; contour	Longevity; daily removal; retention without implants; hygiene dependent	Total rhinectomy including nasal bones; central location; nasolabial fold intact; STSG in anterior floor, implants
Orbital			
Scleral shell	Postoperative inspection; longevity; color, contour, no surgical equivalent	Daily removal; small space, thin; hygiene dependent	Scleral contents removed; implant
Custom ocular	Postoperative inspection; longevity; color, contour, no surgical equivalent	Periodic removal; hygiene dependent	Total globe removal; implant posteriorly
Oculofacial	Postoperative inspection; color, contour; no surgical equivalent	Longevity; daily removal; retention without implants; hygiene dependent	Confined to orbit; no irregular margins; brow in normal location; STSG, implants
Auricular	Postoperative inspection; color, contour	Longevity, retention without implants; hygiene dependent	Total removal; minimal extension, implants; tragus intact

STSG, split-thickness skin graft.

its environment. Craniofacial implants or adhesives must be used to retain the prosthesis, and it should be removed for a few hours regularly each day to maintain the underlying tissues in a healthy state. Various masking techniques such as large-framed glasses or cosmetics are often used to hide margins. Some patients develop chronic mechanical tissue irritation from wearing prostheses, and allergic responses, though not common, may affect prosthesis use. Despite this, excellent cosmetic results and patient acceptance are obtainable in the vast majority of cases (Table 98-1).

Prosthesis retention can be managed in several ways. Where possible, tissue undercuts should be used. Tissue "pockets," particularly those that have been lined with split-thickness skin grafts, can be effective as retentive aids. The most common of the retentive aids used are the skin adhesives. These have been effective, and there are several kinds in use. Mechanical aids such as glasses frames, double-faced tape, or straps are also used where appropriate. Craniofacial implants can be used and have several distinct advantages over the other types of retention. With several strategically placed implants, connecting bars can be used, with corresponding clips or other types of attachments that are bonded to the tissue side of the prosthesis. These hold the prosthesis securely, adding a measure of confidence for the patient and allowing him or her to accurately place it without the sometimes irritating effects of an adhesive. Where possible, this is the retention of choice, particularly for large facial prostheses.

Previously irradiated patients may not be good candidates for craniofacial implants due to compromised blood supply to the supporting bone. However, implant placement within the first 3 months after radiation is possible due to the delayed tissue response. Use of hyperbaric oxygen treatments in irradiated patients also improves the bone and soft tissue response to implant placement. Patients with facial prostheses must have good manual dexterity and the ability to keep the prosthesis and defect clean.

A psychosocial support system of family or friends helps to ensure success in dealing with a facial prosthesis, especially for older patients. Those without this support and the dexterity required may have difficulty and cease wearing the prosthesis. The patient's willingness to accept the defect and cope with it, as well as having reasonable expectations, are of paramount importance. The most cosmetic and retentive prosthesis is still a failure if the patient cannot deal with it. Interdisciplinary discussions between the surgeon and the maxillofacial prosthodontist before or during surgery will be helpful in the management of the primary disease and the postoperative rehabilitation of the patient.

Although the eradication of disease and the preservation of the patient's life are the first priority, there are intraoperative procedures the surgeon can complete that will greatly enhance the tissues surrounding the defect for support and retention of a prosthesis. These procedures are best discussed according to the type of facial defect involved. The most common types of facial surgical defects are the nasal, auricular, and orbital.

Nasal Defects

Many variations of acquired defects are caused by ablative surgery involving the nose. Where there is a relatively small, isolated defect, a split- or full-thickness skin graft can be used if primary closure is not feasible. In these cases, prosthetic management need not be considered unless the surgeon wishes to observe the defect for an extended period of time. Defects involving greater areas including not only skin but bone, subcutaneous tissues, and mucosal lining can be reconstructed using various flap procedures with or without autogenous support. If more than half the nose is resected, a complete rhinectomy should be considered. Alar tabs or unsupported tissue surrounding the defect do nothing for prosthetic support and, in fact, hinder the fabrication of a cosmetic prosthesis. Although it may be possible for the patient to wear a prosthesis, more margins will be visible, thus compromising the aesthetic value. Centrally located defects, leaving the nasolabial folds intact with surrounding supported tissue, provide the best base for restoration (Fig. 98-30). Those defects that extend beyond the nose laterally or toward the upper lip are more difficult to restore due to greater tissue mobility in these areas; they therefore require greater exposure of margins. Placement of split-thickness skin grafts, particularly at those margins extending toward the lip, will be beneficial in preventing scar contraction of the lip and will provide a firm, immobile base for the inferior margin of the prosthesis. Craniofacial implants are useful in the retention of a nasal prosthesis and should be placed in the anterior floor of the nose where there is sufficient bony support. They are best used in conjunction with split-thickness skin grafts, and their position should be such that the abutments will extend into the greatest thickness of the subsequent nasal prosthesis (Fig. 98-31).

Auricular Defects

As with nasal defects, flexible remnants of the ear such as the lobe and helix should be removed unless surgical reconstruction of the ear is anticipated. The tragus, however, should be retained because part of

Figure 98-30. Small, centrally located nasal defect with nasolabial folds intact and no involvement of the upper lip.

Figure 98-32. Auriculectomy defect with split-thickness skin graft in place and a bar splint supported by craniofacial implants. Notice the presence of the tragus.

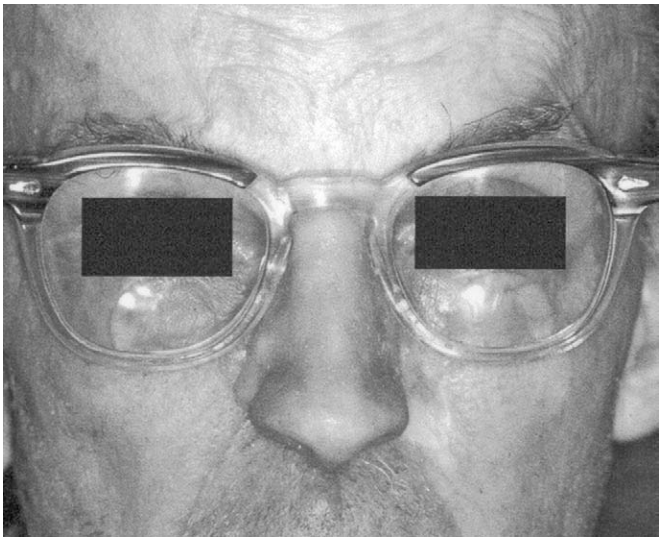

Figure 98-31. Nasal defect restored with a prosthetic nose.

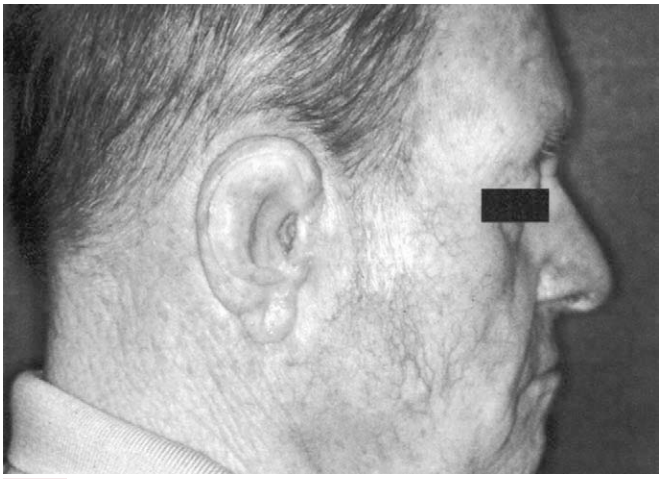

Figure 98-33. Prosthetic ear in place with the tragus masking the anterior margin.

the anterior margin of the prosthesis can be hidden behind it. A defect that results from a partial resection is much more difficult to restore prosthetically than that of a total auriculectomy. If an attempt at surgical reconstruction has been made and has failed, the tissue should be completely removed (Fig. 98-32). A split-thickness skin graft will provide a firm, immobile tissue bed for the prosthesis. Full-thickness or hair-bearing skin grafts should not be used. It should be remembered that prosthesis margins that must overlay the condylar area can loosen during function if they rely on adhesive for retention. If implants can be placed in a position such that they will be in the thickest part of the auricular prosthesis, usually close to the helix, they will provide maximum retention and patient confidence.

The auricular prosthesis has two major advantages over the nasal or midface prosthesis; the viewer cannot focus on both ears at the same time because they are located laterally, and the patient's hair can be used to hide a portion of the margin (Fig. 98-33).

Ocular Defects

Evisceration, enucleation, or exenteration of the eye requires, more than any other, the combined efforts of the surgeon and maxillofacial prosthodontist for a successful restoration. After evisceration, or removal of the global contents, a spherical implant is placed within the scleral space. A thin, custom ocular prosthesis or scleral shell is fabricated to fit over the implanted sclera and reproduce the contour and aesthetics of the original eye. Because the muscles controlling globe movement are left intact, movement of the prosthesis should be relatively good. This prosthesis must be thin to keep the eye from appearing exophthalmic and to accommodate the potential movement.

Enucleation is the total removal of the eye after severing the optic nerve and detaching the ocular muscles. The space provided by the procedure, along with placement of an implant in the posterior wall associated with the muscles, makes it possible to provide an aesthetic, mobile, custom ocular prosthesis.

The aesthetic and functional restoration of the orbital exenteration defect, where all the contents of the orbit are removed, is a difficult one. Its success usually depends on the amount of tissue that must be removed beyond the orbit. It is unique among the types of facial prostheses in that the eye within the prosthesis has no movement and the normal eye presents itself for easy comparison, unlike the ears (which are located laterally) or the nose (which has no basis for comparison on the face). During socialization, the eyes are usually focal points. In defects that extend beyond the orbit

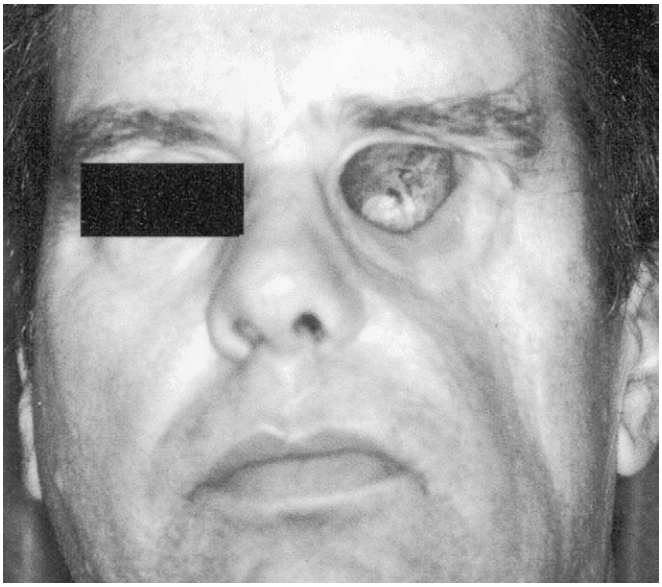

Figure 98-34. Orbital exenteration defect lined with a split-thickness skin graft that does not extend beyond the orbital rim.

into the more mobile tissues of the face, the margin of the prosthesis can loosen during facial expressions if it relies solely on adhesive to retain it.

An ideal defect is one that is within the orbital boundaries with no marginal irregularities, lined with a split-thickness skin graft, and having sufficient depth to recreate normal anatomy with the oculofacial prosthesis (Fig. 98-34). Without the skin graft, the tissues are much more sensitive and difficult to manage hygienically. If the eyebrow cannot be kept in normal position, it is best to remove it and include it in the area of the skin graft. Where possible, placement of implants in the lateral or superior orbital rims is a great advantage for retention of the prosthesis. As with placement for other types of facial prostheses, location of the implants and their angulation should be such that they will be in the thickest portion of the prosthesis. If these requirements can be met without compromising the patient's cure, it will be possible to provide a defect that the patient can manage hygienically and one for which the most aesthetically pleasing and retentive prosthesis can be made (Fig. 98-35).

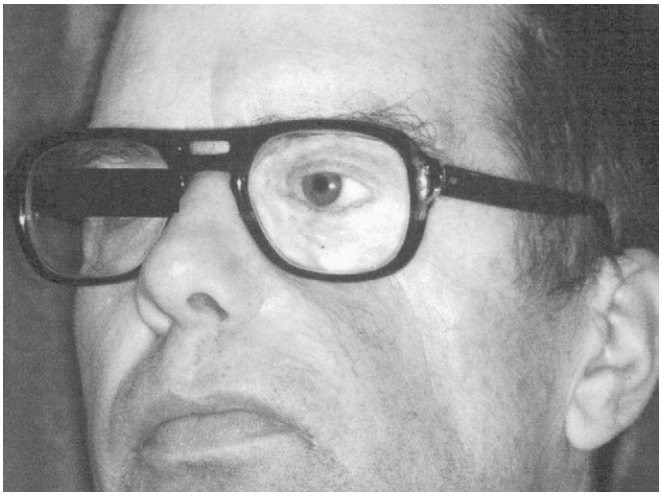

Figure 98-35. Oculofacial prosthesis in place with margins masked by glasses.

SUGGESTED READINGS

Readers interested in the discipline of maxillofacial prosthetics should be abreast of current literature associated with the many disciplines with which maxillofacial prosthodontists interact. Several recent textbooks offer a comprehensive overview of the topic.

CHAPTER NINETY-NINE

Benign and Malignant Tumors of the Nasopharynx

Luke Tan

Thomas Loh

Key Points

- A large number of different tumors can arise in the nasopharynx (NP) (see Table 99-1).
- Juvenile angiofibroma (JNA) is the commonest tumor in the male adolescent and can extend into the paranasal sinuses, infratemporal fossa, and skull base, as well as intracranially.
- The mainstay of JNA management is surgical and the endoscopic route is being used more frequently.
- Recurrence rates can be up to 33%.
- Nasopharyngeal carcinoma (NPC) is the commonest malignancy in the NP. It has strong correlation to (1) ethnicity, (2) Epstein-Barr virus infection, and (3) dietary habits.
- NPC presents with nodal metastasis in more than half of cases at presentation.
- Early-stage NPC is treated by radiation. Stages 3 and 4 are treated with chemoradiation.
- Surgery is reserved for salvage. A radical neck dissection is the preferred mode of treatment. At the primary site, surgical approach depends on the extent of tumor. Endoscopic resection is reserved for small, localized lesions.

The nasopharynx (NP) is an embryologic confluence of the end of the nasal structures and the beginning of the pharynx. It is also bounded superiorly by the ectodermal origins of the cranial base and upper cervical spines posteriorly. For this reason, a large range of pathologies occur in this small confine (Table 99-1). Because of the NP capacity for tumor growth and expansion, the symptoms in general arise late. Thus they can reach significant sizes before presentation because of the diagnostic inaccessibility of the NP area.

The learning points in this chapter are (1) to know the range of tumors (benign and malignant) that can occur in this region and (2) to have a comprehensive understanding of the most common benign and malignant tumors in the NP, which are juvenile angiofibroma (JNA) and nasopharyngeal carcinoma (NPC).

Diagnostic Approach for Nasopharyngeal Masses

The presentation of an NP tumor is variable ranging from ear, nasal, and throat symptoms to neck masses and cranial nerves palsies. The age and sex of the patient is important in the differential diagnosis of an NP mass. Although it is usually due to adenoidal hypertrophy in the pediatric age group, JNA should be strongly considered in teenage males having a NP mass. In adults, NP malignancy should be the default diagnosis for masses in this area as adenoid hypertrophy would have usually regressed. In certain regions of the United States (California, Alaska) and in several Asian regions (Singapore, Hong Kong, Guangzhou province of China) NP malignancy is common and usually of the Epstein-Barr virus–related, undifferentiated type of carcinoma.

As a diagnostic approach, it is reasonable to proceed to imaging studies before biopsy of the mass. Both computed tomography (CT) and magnetic resonance imaging (MRI) have their benefits. Radiologic studies in cases where extension from an intracranial lesion is suspected are particularly important. Outpatient clinic–based transnasal biopsy for patients with suspected malignancy is commonly practiced in areas where NPC is endemic. However, in patients where JNA is suspected, this should be done under conditions where hemostasis of significant bleeding is available, usually in the operating suite.

The histology of the NP mass dictates the management. For benign lesions, surgical removal is commonly required. The most common benign lesion is JNA, which is discussed in detail in this chapter. NP malignancy is usually treated with radiation and chemotherapy.

Thornwaldt's Cyst/Bursa

This is the commonest epithelial growth next to adenoidal hypertrophy in the NP. The cyst is a result of cleavage line between the nasal and pharyngeal embryologic processes (Rathke's pouch). This lesion is usually asymptomatic, although some patients may present with post-nasal drip due to the extrusion of the contents of the cyst occasionally. The diagnosis of this mass is usually incidental as part of a nasal endoscopic examination. The findings are that of a smooth, usually centrally located mass with a yellow hue due to the cystic contents. The differential diagnosis here should include a meningocele or meningoencephalocele. Occasionally, the lesion can be darker colored due to a hemorrhage or hemosiderin content. In such a situation the lesion should be removed or at least biopsied to exclude a melanoma. However,

Table 99-1

Benign and Malignant Tumors of the Nasopharynx

    - Adenoid cystic carcinoma
    - Mucoepidermoid carcinoma
    - Acinic cell carcinoma
    - Adenocarcinoma
  - Metastatic Tumors
    - Adenocarcinoma
    - Papillary carcinoma

in general, Thornwaldt's cyst need not be removed or biopsied if the diagnosis is apparent. The root of the cyst can be adherent to the underlining prevertebral fascial and complete exenteration would best be done under general anesthesia. The wound after resection heals well, as in a case of adenoidectomy.

Squamous Papilloma

This benign epithelial tumor is common in the anterior and posterior nasal space. The epithelial changes of such a tumor may be inverting at the basal membrane, whence they are termed "Schneiderian" or "inverting" papilloma. The presentation is unusually incidental for lesions of the nasopharynx (which is not common), and diagnosis should be done with a biopsy. The base of the lesion should be completely removed with a margin of normal tissue. The use of powered instrumentation is helpful in difficult recesses of the nasopharynx. Further detail on the management of inverting papilloma of the nose and paranasal sinuses is available in Chapters 49 and 99.

Craniopharyngioma

Craniopharyngiomas are histologically benign tumors that arise developmentally from Rathke's pouch. They usually present with symptoms similar to pituitary tumors (endocrine and visual disturbances), but occasionally they may present with nasal symptoms such as nasal obstruction due to extension into the nasopharynx. In children, these lesions have been known to mimic presentation similar to adenoidal hypertrophy.[14] Treatment is surgical excision with or without radiation therapy. The gamma knife has been used as the primary treatment.

Angiofibroma

Angiofibroma usually occurs in adolescent males and is thus commonly called JNA. It accounts for less than 1% of all head and neck tumors. The peculiar vascular nature of this mass and difficulty in accessing the deep-seated tumor mass for diagnosis provide the basis for abundant published literature regarding this disease.

Growth Patterns

The tumor mass is locally infiltrative and usually has a wide-based attachment to the NP and to its surrounding related anatomy. JNA is a slow-growing vascular tumor arising in the area of the sphenopalatine foramen at the root of the pterygoid process on the lateral nasal wall. The tumor expands laterally via the pterygopalatine fossa to the infratemporal fossa but has no resistance to growth into the NP and choanal space and thereby may expand into the anterior nasal cavity and all the related sinuses. It can have intracranial extensions into the middle and anterior cranial fossae, although this is uncommon. It can also extend bilaterally to the maxillary sinuses and superiorly to the cranial skull base. Because JNA commonly occurs in young males, this has prompted studies related to the androgen receptor (AR) and estrogen receptor (ER) in the tumor tissue. A recent study suggests a stronger relationship to ER positivity, which may provide a platform for ER modulators in the management of JNA.[1]

Pathologic Features

The gross pathology usually shows a sessile, lobulated, rubbery dark red to tan gray mass that can be large in size. Mucosal ulceration is uncommonly seen and the tumor is unencapsulated and composed of an admixture of vascular tissue and fibrous stroma. The vessel walls lack elastic fibers and have incomplete or absent smooth muscle that will account for their tendency to bleed.[2]

Clinical Features

Although JNA is typically diagnosed between the ages of 10 and 25 in males, many case reports exist for female patients and also in patients who are in the later decades of life. JNA patients present with nasal obstruction (usually unilateral), epistaxis, blood-stained sputum, and serous otitis media. Less common symptoms include nasal discharge, facial swelling, proptosis, sinusitis, and anosmia. The duration of symptoms is usually long and often mild and innocuous. JNA cases occurring in sites other than the NP have been reported. The next commonest site, the maxillary sinuses, is associated with a greater proportion of females.[3]

Diagnosis

On endoscopic examination, JNA presents as a rubbery vascular mass protruding into the anterior nasal space and may have excessive bleeding on contact. A CT scan with contrast will show an enhancing soft tissue mass arising from the NP or lateral wall of the nose. Although the pterygopalatine fossa may be widened by the tumor (Fig. 99-1), bone erosion is not present in general. MRI will show a vascular tumor with flow voids within the mass and enhances on gadolinium. MR angiography will be the least invasive form of vascular imaging that will show the feeding vessels arising from the branches of the external carotid system. The authors have found the MRI with contrast to be more useful for follow-up evaluation (Fig. 99-2). The use of ^{99m}Tc-RBC single photon emission computed tomography has been suggested to

Figure 99-1. Computed tomography showing the widening of the left sphenopalatine foramen from a juvenile angiofibroma.

Figure 99-2. Magnetic resonance imaging showing the follow-up of the same JNA patient with no recurrence at 3 years.

be accurate in the diagnosis of JNA.[4] However, final proof of diagnosis is histologic.

Staging

In 1984 Chandler and colleagues[5] proposed a staging system (Table 99-2) on the basis of clinical and CT assessment. This staging system is logical and easy to understand and it is useful for reporting. Due to the large anatomic region of stage 3, Sessions and Radkowshi have suggested refining stage 3. However, none of the systems has been used extensively for comparing outcomes because published case series have usually been of small numbers.

Chandler's Staging of JNA

Stage 1 Tumor confined to nasopharynx

Stage 2 Tumor extends into nasal cavity or sphenoid

Table 99-2

The 2002 UICC TNM Staging of Nasopharyngeal Carcinoma

T Classification	
Tx	Primary tumor unable to be assessed
T0	No evidence of tumor
T1	Confined to nasopharynx
T2a	Extends to nasal cavity, oropharynx
T2b	Tumor extends to parapharyngeal space
T3	Tumor involves sinuses, orbit, skull base, hypopharynx
T4	Intracranial or infratemporal involvement
N Classification	
N0	No nodal involvement
N1	Ipsilateral lymph nodes < 6 cm
N2	Bilateral lymph nodes < 6 cm
N3	Lymph node > 6 cm; supraclavicular node
M Classification	
M0	No distant metastasis
M1	Distant metastasis (includes mediastinal nodes)
Stage Classification	
Stage I	T1N0M0
Stage II	T1N1M0, T2N0M0, T2N1M0
Stage III	T3N0-2M0, T1-2N2M0
Stage IVa	T4, any NM0
Stage IVb	any TN3M0
Stage IVc	any T, any N, M1

TNM, tumor node metastasis; UICC, Union Internationale Contre Cancre.

Stage 3 Tumor involves the maxillary, ethmoids, infratemporal fossa, orbit, cheek, and cavernous sinus

Stage 4 Tumor is intracranial

Management

The primary treatment is surgical extirpation. Due to the infrequency of the disease, most of the experience for managing this disease is limited to case series based on institutional practice gleaned over a period of time. For the patient diagnosed with histologically proven JNA, the initial relevance would be to assess for fitness for surgery. Although this is usually not an issue with young adult males, intracranial lesions can be associated with long surgeries and comorbidities. With intracranial masses, a team of skull base surgeons (head and neck and neurosurgeon) would be necessary for joint management.

Although the traditional method of surgery has been the open approach, recent interest surrounds the use of the exclusively endoscopic techniques for removal of such vascular tumors. The open approach, however, remains an important method for tumors that may not be fully accessible endoscopically. For small lesions, an intraoral transpalatal approach allows for access to the nasopharynx. This approach will likely be replaced by the endoscopic route. The more commonly employed medial maxillectomy approach can be done via a lateral rhinotomy or preferably a midfacial degloving incision, which affords reasonably good access to the NP and eliminates facial scars.

For extension outside the NP into the paranasal sinuses, a Le Fort type 1 osteotomy will allow an inferior approach to the maxillary and ethmoid sinuses as well as the pterygopalatine canal. For lesions involving the infratemporal fossa or large lesions involving the majority of the sinuses, a facial translocation approach affords a large window of access. The facial translocation involves the rotation of the facial cheek flap as a single osteoplastic unit with the underlying maxilla rotated

laterally after osteotomies to the maxillary nasal, orbital maxillary, and zygomatic arches. The senior author has also incorporated the entire nose and cheek as a single rotation based laterally. This allows for excellent access to the infratemporal fossa and hemostatic options in the event of bleeding. A lateral infratemporal fossa approach has been recently used as reported by Tyagi and colleagues.[6]

Endoscopic sinus surgery techniques have advanced significantly over the past 2 decades and have allowed the intranasal access and nasal anatomy to be approached in an extremely competent fashion. Several authors have published their experience of successful endoscopic resection of such tumors. Several reports of endoscopic resection have reasonable follow-up durations (13 patients in 23 months) and low recurrence rates (8%).[7] Combination approaches of type 3 JNA with open and endoscopic approaches have also reported good success but of shorter-term results.[8] For larger lesions such as stage 3A disease, Hofmann and colleagues have reported successful endoscopic resection with long-term results (52 months) in a series of 21 patients and have reported that extension to the medial aspect of infratemporal fossa and retromaxillary space was not a contraindication to an endonasal endoscopic approach.

Preoperative embolization of the tumor mass is used by some to reduce intraoperative bleeding. However, the risk of recurrence has been highlighted with the use of preoperative embolization.[9] In extensive tumors where the feeding vessels come from the internal carotid system, a laser-assisted extracranial-intracranial bypass has been used before the definite surgery in order to prevent neurologic deficits.[10]

Recurrence rates have been reported to be as high as 35% depending on the length of follow-up. For patients with recurrent disease, the options remain for observation alone, revision surgery, or radiation. Radiation has been used for treatment of JNA, especially those that recur after surgery and those with intracranial extension where clearance of margins may be difficult. Cummings and colleagues[11] reported a series of 56 patients treated with 3000 cGY. However, issues of impact on growth centers, cataract formation, and osteoradionecrosis have been reported, as have cases of malignant transformation.[12] For these various reasons, observation, sometimes followed by involution with aging or repeat surgery, is an option in the presence of recurrence. In patients who cannot undergo surgery, recalcitrant cases of tumor recurrence despite several repeat resections and inaccessible recurrences may be considered for radiation therapy with full disclosure of possible long-term, late effects (e.g., radiation-induced malignancy, carotid artery damage). Park[13] recently reported using the gamma knife with good success for a case of recurrent intraorbital JNA.

Chordoma

Chordoma is a locally aggressive malignancy that may arise from bone of the basisphenoid and erode through the bony skull base to appear through the sphenoid and into the nasopharynx. These tumors arise from notochord remnants and can present with cranial nerve deficits including hoarseness, swallowing difficulties, or diplopia. They may also present in asymptomatic patients when identified incidentally by CT or MRI of the head and neck. The definitive diagnosis of these tumors may be accomplished by transnasal endoscopic biopsy, but it is also frequently made at the time of surgery, which will require a team effort including a neurosurgeon and skull base surgeon. An anterior midline subfrontal approach, or more recently an expanded endonasal approach, may be employed for exposure. Cranial nerve deficits and even long tract deficits may ensue after surgery due to the need to work around the brainstem and vertebrobasilar system of vessels on the dorsal extent of these tumors. The use of postoperative radiotherapy is necessary in patients who do not have complete removal of these lesions due to the complicated anatomy and risk of neurologic or vascular trauma. Proton beam therapy is recommended.

Adenoid Cystic Carcinoma of the Nasopharynx

Adenocystic carcinoma of the sinonasal tract constitutes 20% of all adenoid cystic carcinomas of the head and neck. They, along with other tumors of salivary gland origin, arise from the minor salivary glands in this region. Those of the NP are not common but can be insidious and slow growing.[14] The lesion can extend from the nasopharynx into the anterior skull base and can present as bilateral nasal lesions. In the latter, there is a need to differentiate this from simple bilateral nasal polyps. Patients with either condition may present with simple nasal obstruction with hyposmia. Other accompanying symptoms do not usually occur, unless palpable neck metastasis is detectable at presentation. Otitis media with effusion may exist if the eustachian tube is involved. These tumors have the propensity for perineural spread and thus MR imaging is important in the pretreatment evaluation. The primary treatment of such lesions is surgical resection. However, proximity of the nasopharynx to the sphenoid, and, hence, the internal carotid arteries and intracranial structures, plus their propensity for centrifugal spread along nerves, may preclude complete removal. Postoperative radiotherapy is important in local control of such lesions.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) is unique in its epidemiologic pattern. It is common in certain ethnic groups, with the highest incidence in southern China, Hong Kong, and southeast Asia. The majority of patients with NPC are diagnosed with advanced disease. However, over the past 20 years, the survivals of these patients have improved.[15] This has been attributed to the combined use of chemotherapy and radiation to treat the patients with advanced disease.[16] Furthermore, with the advent of improved techniques in radiation, the side effects, which plagued long-term survivors in the past, may be reduced.[17,18] The strategy in the management of NPC is to find novel methods of early detection and develop improved techniques of effective primary treatment with the focus on reducing morbidity from the treatment. In this chapter we describe the epidemiology, etiology, pathology, clinical features, staging, treatment, and prognosis of NPC.

Epidemiology

The highest incidence of NPC is recorded in Guangzhou, China, where the age-adjusted incidence rate is reported to be more than 30 per 100,000.[19] Hong Kong has a rate of 20.2 per 100,000 in males and 7.8 per 100,000 in females.[15] Patients who are affected by NPC are ethnic Chinese with an ancestry from the southern part of China. In southern China the two main ethnic subgroups are the Cantonese and the Fujians. In Hong Kong the vast majority of the population is Cantonese. In Singapore the overall incidence in males from 1998 to 2002 was 10.8 per 100,000.[20] This lower rate may be in part accounted for by the demographics of Singapore, which unlike China, Hong Kong, and Taiwan, has a more heterogeneous population. The population in Singapore is approximately 70% Chinese, with the remaining major ethnic groups being Malays and Indians. The majority of the NPC patients in Singapore are Chinese (Fujians and Cantonese).[21] The incidence of NPC in Singaporean male Chinese is 12.5 per 100,000. These incidence rates in southern China, Hong Kong, and southeast Asia are among the highest in the world and have remained stable for many years. However, in the most recent review of the latest trend in the incidence of NPC, both Singapore and Hong Kong have reported a significant decrease for the first time after many years of stable rates.[15] Why there was a fall in incidence is unclear, but one theory advanced to account for this is the change in dietary habits.[22,23] Other ethnic groups, with rates that are reported to be intermediate to high, include the Eskimos,[24,25] Polynesians, and indigenous Mediterranean population.[26] NPC is not common in whites. In North America the highest incidences are seen in the ethnic Chinese who are first-generation immigrants.[23] Subsequent-generation immigrants have a lower incidence, although it is still higher than the other ethnic groups. Overall, these incidence rates are lower than those in southern China and southeast Asia. This pattern of decreasing incidence rates seen in emigrant Chinese is a well-known phenomenon. It is likely that with migration, there is over time a greater variation in the gene pool arising from factors such as intermarriage, although the adoption of different dietary habits cannot be discounted. The epidemiologic pattern indicates that NPC occurs commonly in Chinese. This will suggest the possibility of a genetic link or a shared habit such as dietary intake.

Etiology

Three main factors are believed to be associated with the development of NPC.[27] These are genetic and environmental factors, as well as EBV. The knowledge relating to these factors that are associated with NPC has been advanced over the past 20 years. However, we are still unable to assimilate the information in an orderly fashion to translate the knowledge into prevention, early detection, or markedly improved survivals. Nevertheless, the current school of thought among those involved in NPC research believes that this cancer is probably a result of interaction among the three main factors.

Genetic Factors and Nasopharyngeal Carcinoma

A large body of evidence indicates that genetic factors play a significant role in NPC. Family clusters with NPC are not uncommon. Ung and colleagues[28] had reported that the risk of NPC in a first-degree family member could be as high as eight times. Reports from Hong Kong and Guangzhou have also estimated this risk to be as high as 20 times when compared with the general population. We had reported that 15.5% of all NPC patients have had a first-degree relative with NPC.[29] The majority of first-degree family members who are affected are usually siblings (70%) rather than parents and children (30%).[29] The mean duration between two siblings who are affected within a family is 5.3 years, whereas that between a parent and child is 25 years.[29] Experts also believe that the risk for a first-degree relative also developing NPC is higher if the index NPC patient is diagnosed at age younger than 40 years.[30] The presence of such family clusters may indeed be due to common genetic factors, but it can also be argued that shared environmental factors may play a role.

The association of HLA alleles with NPC was established in 1975.[31] These alleles are the HLA class I alleles belonging to the HLA A, B, and D groups in chromosome 6. HLA A2, Bw46, B 17, Bw58, DR3, and DR9 have been consistently found to be significantly more prevalent in NPC patients in contrast to the general population.[31-35] These haplotypes are associated with increased risks for NPC. Further refinements in establishing these haplotypes have been reported with the highest risks established consistently for patients with the haplotypes A2 and B46.[34,36] It has also been found that multiple alleles confer protective effects. The evidence suggests it is likely that the tumor susceptibility gene has a recessive mode of inheritance because an NPC-linked gene with a dominant mode will not be associated with such wide allelic variations in protective effects.[37] It has also been established that most Chinese patients with NPC have the HLA-A0207 haplotype in contrast to the HLA-A0201 found in whites.[38] Microsatellite instability in the nearby region of the HLA loci has been described, suggesting the possibility of tumor susceptibility factors.[39] NPC patients may have alleles in these loci that may contain genes that contribute to the oncogenesis of normal nasopharynx cells. However, linkage analysis has shown that the tumor susceptibility gene is not likely to be at the position of the high-risk A2 B46 haplotypes.

Chromosome changes that have been described include deletions in chromosomes 3, 9, and 11.[40-43] The significance of these chromosomal changes is the implied loss of function of known specific factors: for example, chromosome 9p21 region codes for known cell cycle regulators such as p15 and p16. The protein p16 has been reported to be inactivated in NPC patients.[44,45] Other chromosomal changes have been sporadically reported. Each of these genetic deletions has also been associated with an implied tumor suppressor gene. Novel markers have also been reported to suggest the possibility of other tumor suppressor gene candidates.[46] Despite this wealth of information, it is difficult to determine if these changes are downstream events rather than early changes. What will be helpful will be genome-wide scans of NPC tumor samples and normal tissues, as well as using techniques such as comparative genomic hybridization to narrow in on the true early changes.

Environmental Factors and Nasopharyngeal Carcinoma

The most common environmental factor associated with NPC is diet. It has been suggested that certain diets high in preservatives are associated with NPC. These include salted fish, eggs, and vegetables.[47-51] The origin of these associations is traced to the epidemiologic studies performed on a group of high-incidence NPC patients, the "boat people" of Hong Kong. These people had originated from a common region in China many years ago and had settled into a life based largely on living in boats. The diets are necessarily based on preserving the food from the sea (e.g., salted fish). Subsequently large epidemiologic studies have suggested similar findings, too.[52] It is believed that the risk is associated with early exposure or during weaning period.[50,53] The carcinogen believed to be the inciting factor is nitrosamines. Other environmental causes that have been thought to be associated include chemical fumes and wood dust.[54] Smoking is not an associated factor unlike squamous cell carcinoma of the aerodigestive tract. However, it is always difficult to attribute food alone as the factor that leads to oncogenesis because many confounding factors are also often present.

Epstein-Barr Virus and Nasopharyngeal Carcinoma

EBV is a ubiquitous virus. The vast majority of the population in the world have been infected with EBV. It is a herpes virus, with a central core of DNA and an envelope known as the *capsid.* Infection with the virus occurs in early childhood or as young adolescents. Those infected in early childhood tend to be asymptomatic, whereas young adolescents will be symptomatic, often resulting in a clinical syndrome that is consistent with infectious mononucleosis. Once a person is infected with EBV, he or she develops immunity. However, EBV is present for the remaining life of the person within specific circulating B lymphocytes or shed through saliva. The latter route is believed to account for the horizontal transmission typical of this infection.

The IgM and IgG class of antibodies to antigens on the EBV are raised in acute and convalescent phases of infection. The antigens on the EBV are either the nuclear core early antigen (Ea) or the viral capsid antigen (VCA). Hence in the majority of any population, the IgG VCA and Ea will be raised. In NPC, however, the IgA VCA and Ea are raised.[55] This is used as a marker, with laboratories using immunofluorescence to detect these antibodies. The sensitivity and specificity of these two antibodies are high.

EBV antigens are also found on NPC cells. EBV expresses both lytic and nuclear antigens. Lytic antigens include latent membrane proteins 1, 2, and 3 (LMP-1, -2, -3). Nuclear antigens include the Epstein-Barr nuclear antigens 1 to 6 (EBNA-1 to 6). In NPC, EBNA-1 is always expressed, whereas LMP-1 is consistently expressed in significant levels. Both of these are latent proteins. EBNA-1 is believed to be responsible for maintaining the viral episomes in the tumor cells. LMP-1 has been shown to induce cellular growth by inducing epithelial hyperplasia and altered keratin gene expression.[56,57] It reduces cytokeratin expression and inhibits squamous cell differentiation. It has been shown to up-regulate epidermal growth factor receptors. NPC also expresses Epstein-Barr encoded ribonucleic acids (EBERs) within the cytoplasm. These EBV antigens and EBERs are not present in normal nasopharynx cells.

The vast majority of the people infected with EBV do not develop NPC. In addition, the expression of latent proteins EBNA-1 and LMP-1 are not seen in normal nasopharynx cells. Therefore it is believed that EBV is not the initiating event in NPC and that its role in the development of NPC is a result of latent infection of the genetically susceptible and environmentally transformed epithelial cells of the nasopharynx.

Clinical Presentation

Virtually all NPC patients are symptomatic at the time of diagnosis. Less than 1% of NPC patients are asymptomatic and diagnosed incidentally. This may occur because of imaging performed for some other indications or an abnormal EBV serology is detected because of health screening. Three quarters of NPC patients are males. More than 80% are diagnosed between 30 and 60 years of age with more than 50% diagnosed between 30 and 50 years. The proportion of NPC patients diagnosed at a relatively young age has a significant socioeconomic impact on these patients and their families. Approximately 15% to 20% of NPC patients will also report a first-degree relative who was similarly affected.[29]

The most common presentation in NPC is the presence of a neck lump (Fig. 99-3). About 60% of our patients presented with a neck lump. These neck lumps are due to metastatic disease in the cervical

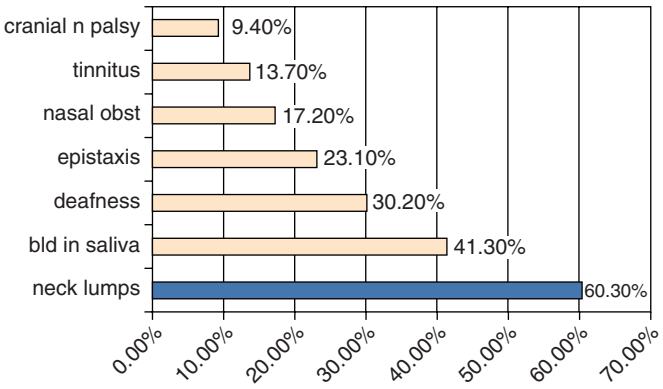

Figure 99-3. Clinical presentation of nasopharyngeal carcinoma patients.

Figure 99-4. Bulky bilateral cervical lymph nodes in levels II, III, IV, and V.

lymph nodes. It is not uncommon for the enlarged nodes to be matted. The nodal metastasis is usually located in the superior aspect of the neck (Fig. 99-4), corresponding to high level V and level II. The first echelon of nodal metastasis is in the retropharyngeal nodes. These retropharyngeal nodes may be so bulky that they can be visualized on physical examination as nodular swellings in the posterior pharyngeal wall. Occasionally NPC patients may present with enlarged level III nodes (Fig. 99-5) and less commonly level IV. Enlarged submental lymph nodes at the time of diagnosis are rare and not encountered in our series. Some patients may present with a parotid swelling due to metastatic parotid lymph nodes, although these are also uncommon. Metastatic NPC nodes are usually firm. If left for a significant duration of time, a node may enlarge to such an extent that central necrosis occurs, followed by abscess formation. In endemic regions such as China, Hong Kong, and Singapore, a Chinese adult male presenting with large bulky bilateral nodes is usually either NPC or lymphoma. Although 60% of NPC patients present with a neck lump due to nodal metastasis, at least 80% of NPC will be classified as N1. This is because even in the NPC patients without palpable nodes, imaging will show metastatic nodes in at least another 20%.

The next most common presenting symptom or sign is that of blood-stained saliva or sputum (41.3%). The patient usually reports a persistent production of blood in the saliva without any other symptom. Epistaxis is not common in NPC because the tumor is located in the postnasal space. The natural tendency is for blood from the tumor to gravitate and hence mix with saliva or sputum. Indeed, epistaxis was reported in only 23.1% of our patients. Frank epistaxis, however, is not typical of NPC. Deafness was more commonly reported (30.2%). This is due to otitis media with effusion, which is believed to be secondary to eustachian tube dysfunction. The hearing loss is therefore conductive in nature and impedance tympanometry corresponds to the type b pattern. Other presenting complaints include nasal obstruction and

Figure 99-5. Right level III nodes in nasopharyngeal carcinoma.

unilateral tinnitus. Persistent headaches are also common in patients with intracranial extension or clival erosion. Cranial nerve palsies are encountered in about 10% of the patients. The most common nerves affected in descending order of frequency are the sixth, fifth, twelfth, and ninth/tenth nerves. In the endemic regions, isolated sixth nerve palsy, caused by cephalad extension through the foramen lacerum, is an indication to have the nasopharynx examined and the skull base imaged for possible NPC. Some of these patients with cranial nerve palsies at the time of diagnosis may show resolution following treatment with radiation. The most likely explanation for this is that the tumor had caused surrounding edema near the cranial nerves, resulting in deficits such as diplopia. Also, some syndromes are associated with NPC. Patients with dermatomyositis are at high risk for developing this cancer and should be screened regularly because approximately 10% of these patients can be at risk for developing the cancer.

Examination of the nasopharynx in NPC patients usually reveals an exophytic mass that may occupy the whole postnasal space (Fig. 99-6). This may be ulcerated and contact bleeding is usually encountered. However, in about 10% of NPC patients the lesion is submucosal. In these cases the mucosal surface of the nasopharynx is normal in appearance. Occasionally, only a slight irregular mucosa is detected. This may consist of a small area of heaped-up mucosa or just an erythematous change, both of which could be passed off as normal. The significance of submucosal NPC in a patient is unclear, although a review of our patients suggested that this group might have more aggressive disease.

In the endemic regions the axioms are that a Chinese adult male presenting with a neck lump needs to be investigated for NPC and that a Chinese adult male presenting with a neck lump, blood-stained sputum, and unilateral deafness has NPC until proven otherwise.

Diagnosis of Nasopharyngeal Carcinoma

The gold standard in the diagnosis of NPC is histologic confirmation by nasopharynx biopsy. This is performed transnasally under local anesthesia using rigid endoscopy. The biopsy of the tumor is thereby performed under direct visualization. In rare instances patients suspected of NPC will have the biopsy performed under general anesthesia. An example of such a situation is when the fine-needle aspirate cytology of a metastatic node confirms undifferentiated carcinoma but the nasopharyngeal biopsies remain negative for malignancy. In these patients a deep nasopharynx biopsy under general anesthesia including Rosenmüller's fossa and the vault of the nasopharynx is indicated. A nasopharyngeal biopsy may also be performed under general anesthesia if previous biopsies in a patient highly suspected of having NPC were negative and a diagnosis is imperative before treatment is instituted.

The classification of NPC[58,59] is shown in Table 99-3. The vast majority of patients with NPC—at least 90%—in the endemic region

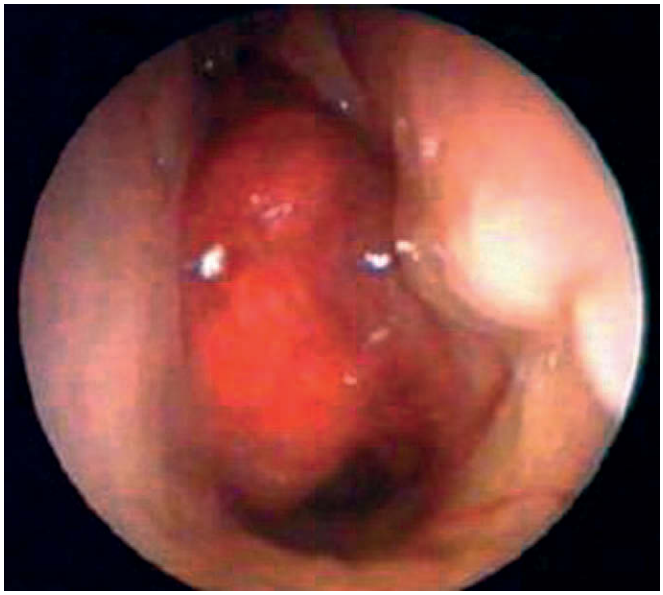

Figure 99-6. Nasopharyngeal mass occupying the whole of the post-nasal space.

Table 99-3

World Health Organization (WHO) Classification of Nasopharyngeal Carcinoma

Type 1 (I)	Squamous cell carcinoma
Type 2a (II)	Keratinizing undifferentiated carcinoma
Type 2b (III)	Nonkeratinizing undifferentiated carcinoma

Types 1, 2a, and 2b correspond to WHO types I, II, and III, respectively, and are used interchangeably.

have a histologic pattern termed as *nonkeratinizing undifferentiated carcinoma (type 2b or type III).* Squamous cell carcinoma is uncommon in endemic regions.

Staging of Nasopharyngeal Carcinoma

The TNM staging system is shown in Table 99-2. This staging system is based on clinical and radiologic examination. In general, two thirds of NPC patients are classified as stage III or IV at the time of diagnosis. Only about 10% of newly diagnosed NPC patients have stage I disease.

Computed Tomography Scan/Magnetic Resonance Imaging

CT scan had been for many years the essential staging investigation for assessing the primary tumor, as well as regional disease. The soft tissue of the nasopharynx is shown well and CT is particularly useful in delineating clival and skull base erosion.[60] It has been the cornerstone of radiologic staging of NPC for many years. However, MRI has been used increasingly in many centers. This is because of the superior definition afforded by MRI in detecting soft tissue changes and intracranial involvement. It is not uncommon for MRI to show features consistent with disease that is not shown on a CT scan.[61]

Other Staging Investigations

These include chest radiograph, ultrasound of liver, and bone scans. Alternatively, CT scans of the lungs and liver may be performed. The main purpose is to locate distant metastasis. Of these the highest pick-up rate appears to be the bone scan. This is consistent with the skeleton being the most common distant site of metastasis in NPC. In the past 5 years, PET scans have come into more prominent use. Much of the information in the literature on the use of PET CT in NPC is with regard to detecting local and regional recurrences or residual disease, as well as in the detection of distant metastasis.[62] It is a useful imaging tool for patients with indeterminate CT or MRI abnormalities that may represent local, regional, or distant recurrences. Enhancement will suggest a higher possibility of recurrences in such indeterminate imaging abnormalities. However, caution has to be advised in the interpretation of current data on PET CT, especially as a tool for staging newly diagnosed NPC patients. The main criticisms of these reports have been the lack of a standardized methodology to determine the histopathology of the tissues that have high uptake of agents like 18-fluoro-2-deoxyglucose (FDG). Oftentimes these reports will include any form of enhancement on PET CT to represent metastasis without confirmation of the pathology. Inflammatory reactions and radiation necrosis, without malignancy, can lead to high uptake.[63] Literature on the efficacy and cost-effectiveness of using PET CT as a staging tool in newly diagnosed NPC patients to assess the primary tumor and regional metastasis is scant.

Other Investigations

An audiogram and tympanogram are performed to obtain a baseline level. This is crucial as the patient undergoes radiation that might worsen the hearing. Indeed, with increasing use of combined chemotherapy and radiation, certain chemotherapy agents like cisplatin might give rise to idiosyncratic sensorineural hearing loss.

EBV serology titers are performed. These include IgA VCA (viral capsid antigen) and IgA Ea. The former is highly sensitive and the latter specific. The main usefulness of this test is in assisting diagnosis of new NPC patients. In particular, a negative IgA Ea likely will indicate that the patient has no NPC. It has to be emphasized that the diagnosis of NPC is histologic proof on biopsy of the nasopharynx, therefore, these titers are not a substitute for diagnosis.

Treatment of Nasopharyngeal Carcinoma

Pretreatment Planning

The treatment of a newly diagnosed NPC patient is best served by a multidisciplinary team of head and neck surgeon, radiation oncologist, medical oncologist, pathologist, and radiologist. This includes audiological investigations and dental clearance. In addition, if chemotherapy is part of the treatment, hematologic and biochemical investigations are performed including creatinine clearance. Dental clearance involves ensuring that oral hygiene is maintained because the oral cavity will inevitably be in the radiation field. The decaying, unhealthy tooth is extracted to prevent osteomyelitis from setting in during the postradiation period. However, there is no evidence that prophylactic extraction will reduce osteoradionecrosis in patients undergoing radiation of the head and neck.[64,65] Allowing such prophylactic extractions will potentially delay treatment and increase costs for the patient.

Treatment

NPC is treated by radiation. In general, patients with stage I and II NPC are treated by radiation only, whereas stage III and stage IV patients are treated by concurrent chemotherapy and radiation. In addition, there is evidence that patients diagnosed with stage IV NPC with locally advanced disease may be better controlled by neoadjuvant cisplatin followed by chemoradiation.[66] Radiation is administered by linear accelerator, and the dose reaches 60 to 70 Gy in the nasopharynx and both necks. This is given daily at up to 2 Gy in 35 to 40 fractions. The main side effects include mucositis and xerostomia. The former may take up to 3 months after the last day of treatment to heal. Xerostomia affects every patient and can be permanent, although the younger patients show much better improvement with time. Other side effects include sinusitis, crusting, and blood-stained nasal discharge. Otitis media with effusion can develop or be worsened with radiation. Sensorineural hearing loss has been attributed to radiation, although the cochlea is resistant and it has been shown that this may be due to other causes such as infiltration by tumor cells.[67] Trismus is particularly more

severe in those treated for skull base involvement. It may take several years for trismus to develop. Late side effects include cranial nerve palsies, which may give rise to difficulties in distinguishing trismus from recurrent disease. The most common cranial nerve to be affected post-radiation, other than the cochlear-vestibular nerve, is the hypoglossal nerve. In the past 5 to 10 years, data have emerged to confirm the efficacy of using intensity-modulated radiation therapy (IMRT) to treat NPC patients. This has resulted in control rates similar to conventional radiation.[68] It has also resulted in better treatment outcomes, especially xerostomia[17] and skin burns.

The use of concurrent chemotherapy and radiation to effectively treat local and regionally advanced NPC patients was reported by Al-Sarraf.[69] There is compelling evidence for using concurrent chemotherapy and radiation in advanced stage NPC.[70] The concurrent chemotherapy regimen includes cisplatin and 5-fluorouracil (5-FU). We had found this to give good local and regional control, but it increases both acute and late toxicities. Two of the significant toxicities associated with cisplatin are idiosyncratic sensorineural hearing loss and peripheral neuropathy. To avoid these toxicities, other agents such as Taxol combined with 5-FU and hydroxyurea are alternatives that can be considered.[71]

Surgery is reserved for recurrent local and regional disease. Although recurrent local disease may be treated by brachytherapy, localized recurrent tumor may be considered for resection. The three contraindicating factors are internal carotid artery involvement, skull base erosion, and intracranial involvement. The surgical approaches use either one or a combination of transnasal, transmaxillary, midfacial degloving, or transpalatal approach. Regional disease in general is dealt with by neck dissection. This will usually take the form of a radical neck dissection or a modified neck dissection. Usually the spinal accessory nerve and the sternocleidomastoid muscle are not spared and the internal jugular vein is not commonly preserved. If brachytherapy is considered, a pectoralis major myocutaneous flap is harvested to reduce the likelihood of cutaneous necrosis and to protect the carotid artery. A second course of radiation to treat regional recurrences may be considered, albeit with its attendant risks.

Surgical Treatment of Nasopharyngeal Carcinoma

The indications for surgical treatment of NPC are currently for local and regional recurrences.

Surgical Treatment of Local Recurrences

Approximately 5% to 10% of all newly diagnosed NPC patients will develop local recurrences. Up to 50% of these patients will be amenable to salvage by surgery. The remaining 50% are usually too far advanced for surgical intervention. This may be due to intracranial invasion or carotid artery encasement. In some patients this may be due to concomitant distant metastasis. The surgical treatment of locally recurrent or residual NPC is nasopharyngectomy. In those who can be salvaged surgically, the recurrent T (rT) classification is often rT1 to rT3.[72] The success of surgical intervention in recurrent NPC is strongly correlated with T classification. The best results are obtained with rT1 patients. Patients with rT3 recurrences are considered by some to be not salvageable. In particular if there is clival erosion, some surgeons consider this to be a situation in which complete tumor extirpation is not possible. Hence careful and diligent follow-up coupled with biopsies of any suspicious areas of the nasopharynx are crucial factors that allow for early detection of recurrences or residual tumor.

The local recurrences may be dealt with by either another course of radiation or by surgery. Treatment by a second dose of radiation will carry with it the risk of complications such as transverse myelitis, leading to weakness and numbness of the limbs. The risks of temporal lobe necrosis, severe trismus, severe sensorineural hearing loss, choanal stenosis, palatal dysfunction, and lower cranial nerve palsies are increased by a second course of radiation. These effects may be reduced by the use of IMRT. Radiation is generally reserved for patients with a large recurrence such as when there is skull base erosion or intracranial extension or when tumor tissue surrounds the carotid arteries.

All patients with local recurrences are assessed with a CT scan or MRI. The thorax, liver, and bones are also assessed for possible metastasis. In the past 3 years, the use of PET scan has been found to be a useful tool for staging recurrent patients. The depth of invasion of the local recurrences can be assessed by a PET CT and allows us to plan our resection approaches.

Figure 99-7. Magnetic resonance imaging showing a small recurrence on the left side of the nasopharynx.

When faced with a local recurrence that can be salvaged, the head and neck surgeon will have to decide the surgical approach. The factors that govern the chosen approach and access to tumor resection are usually the surgeon's preference and expertise, as well as the extent of the tumor recurrence. Many surgical approaches have been reported. This is a testament to the difficult access to the nasopharynx. The anterior-posterior distance from the nasal vestibule to the nasopharynx is about 10 cm, and open approaches mean that the surgeon is operating through a narrow and deep window. In addition, the internal carotid artery lies just posterior and lateral to the eustachian tube cushion. These considerations, as well as possible intracranial extension and operating in a previously radiated or chemoradiated field, are the main issues in nasopharyngectomy. All the approaches give adequate visualization.

Endoscopic Approach

This approach is clearly possible for small recurrences.[73] It is best limited to recurrences that are centrally placed on the posterior wall of the nasopharynx (Fig. 99-7). Recurrences that extend out to the pterygopalatine fossa, the soft palate, and beyond may be too large for endoscopic nasopharyngectomy, although experienced endoscopic skull base surgeons may not necessarily consider this an absolute contraindication. The success of this approach lies in being able to choose the patients well. Besides proper instruments, the key to being able to have excellent visualization and control of the surgical approach lies in resection of the posterior nasal septum. Depending on the site and size of the recurrences, the medial maxillary wall may have to be resected. It is also important to remember to resect adequately the roof of the nasopharynx and drilling down the vomer. The depth of resection should include at least the prevertebral muscles. Once the resection and frozen sections are completed, the wound in the resected nasopharynx is packed with antiseptic gauze and left for at least 1 week.

Lateral Rhinotomy and Medial Maxillectomy Approach

This approach can be used for tumors slightly larger than those indicated for endoscopic approach. It may be used for recurrent or residual tumors limited to the nasopharynx or with extension out to the pterygopalatine fossa. It may also be combined with a transoral approach to resect tumors with oropharyngeal extension. Alternatively it may be extended for tumors that invade the orbit. After completion of the lateral rhinotomy, the medial wall of the maxilla is removed as far out laterally as possible while preserving the infraorbital nerve. The naso-

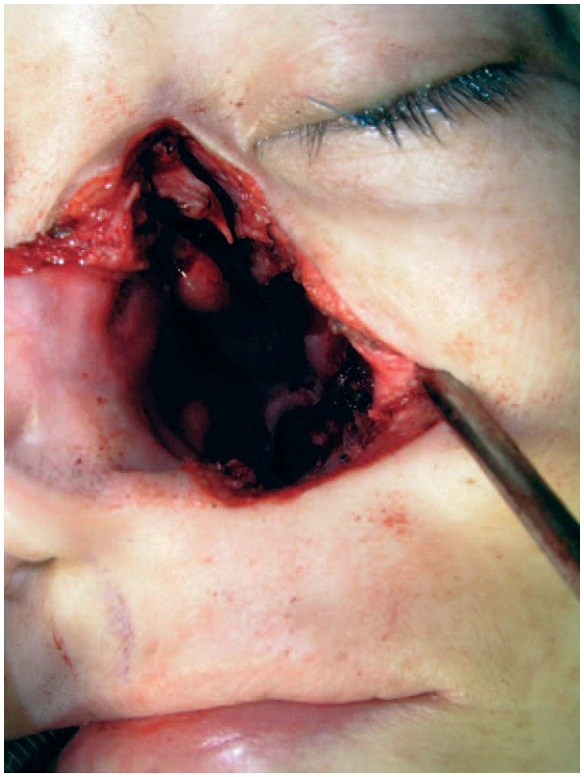

Figure 99-8. Lateral rhinotomy approach with resection of medial maxilla and posterior nasal septum completed, exposing the whole nasopharynx.

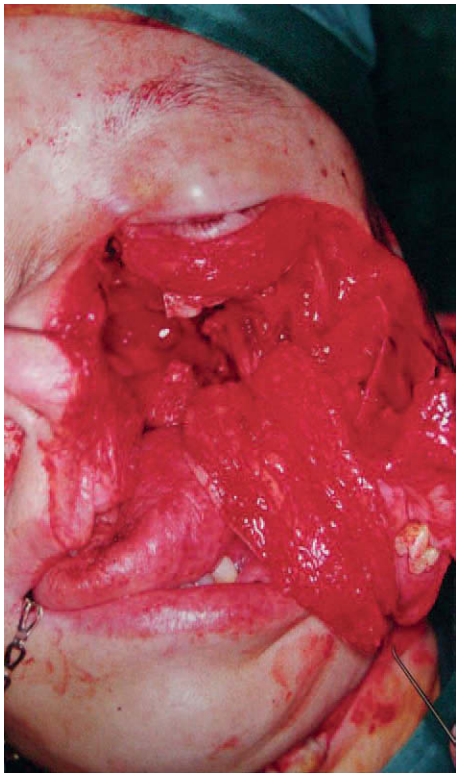

Figure 99-9. Left maxillary swing approach. The skin, subcutaneous tissue, left maxilla, and hard palate are rotated laterally en bloc to expose the nasopharynx.

lacrimal duct is marsupialized. Resecting the inferior half of the middle turbinate will also help with surgical access. The key to visualizing the entire nasopharynx well is in resecting the posterior nasal septum (Fig. 99-8). The surgical access is adequate but not as wide as the view afforded by the maxillary swing approach. It does not require any palatal split. The wound almost always heals well and cosmetically it is not an issue with the patient. Trismus is uncommon and palatal fistula does not exist. However, postoperatively these patients often complain of headaches, which usually take about a month to settle. The problem is the prolonged period of nasal clearance required to rid the crusts that develop. Exposed bone may lead to localized osteoradionecrosis.

Maxillary Swing

This is an elegant operation described by Wei in 1991.[74] It provides a wide access for resecting nasopharyngeal tumors. The procedure involves a Weber-Ferguson incision. The maxilla is exposed, and osteotomies are made such that the maxilla will be rotated laterally but the skin and subcutaneous tissues continue to provide the blood supply to the maxilla because it is not dissected off the anterior wall of the bone (Fig. 99-9). The medial maxillary wall is removed. This is an approach that provides excellent access to remove tumors that have infiltrated the pterygopalatine space. It is also argued that the internal carotid artery may be controlled should there be tumor extension laterally. It does, however, require a palatal split and this can lead to palatal fistulas.

Other Surgical Approaches

Lateral infratemporal and Le Fort 1 drop-down approaches have been described. These are not common approaches used to perform nasopharyngectomy for recurrent NPC and are used by surgeons familiar and comfortable with the respective surgical approaches.

Surgical Treatment of Regional Recurrences

Regional recurrences or residual regional disease occur in about 10% of patients. These patients commonly also have local disease or distant metastasis. Which factors are associated with regional recurrences is unclear. It is also difficult to detect regional recurrences because it may be difficult to elicit signs on palpation of the fibrotic neck after radiation. In fact, it is not uncommon to be able to palpate an obvious mass in the neck and yet the fine-needle aspirate cytology to be negative. A CT scan or MRI of the neck is useful. Once regional recurrence is detected, metastatic workup should be performed and the primary site should be cleared before setting off on a treatment plan for the patient.

The treatment of regional recurrence and residual regional disease is by neck dissection (Fig. 99-10). The evidence clearly indicates that a radical neck dissection should be performed.[75] This is because regional disease is often along the chain of nodes of the upper internal jugular vein, as well as the accessory nerve. Furthermore, the metastatic node, unlike similar nodes in squamous cell carcinoma of the head and neck, tends to have a propensity for extracapsular spread. Hence the internal jugular vein, accessory nerve, and sternocleidomastoid muscle should be sacrificed. In fact, it is not uncommon to perform an extended radical neck dissection involving resection of the skin. Levels I to V nodes are removed. Although retropharyngeal nodes are said to be the first echelon of nodes in NPC, these do not need to be removed because oftentimes the radiation will have encompassed the retropharyngeal nodes. The main problems with performing a radical neck dissection for recurrent NPC are related to bleeding and wound infection, because a good proportion of these patients will have had radiation with or without chemotherapy. The risk of carotid blowout is higher if the wound breaks down and the carotids are exposed. This may be prevented by the use of a pedicled flap such as the pectoralis major (see Fig. 99-10) or latissimus dorsi flap. The effectiveness of the treatment is good, with overall survival after radical neck dissection reaching above 50%.[76] Regional control is often achieved and further recurrences are often at distant sites.

Prognosis

The poor prognostic factor in NPC is stage IV disease. In particular, N3 disease is associated with poorer survival and higher rates of distant metastasis. Patients with stage III or IV disease who have had concur-

Figure 99-10. Left radical neck dissection and left myocutaneous pedicled pectoralis major flap to cover skin defect, as well as protect the carotid artery.

rent chemoradiation have a 5-year overall survival rate of about 70%.[77] Stage I and II NPC patients treated by radiation alone have 5-year overall survival rates of 80% and higher. The use of chemoradiation for stage III and IV patients has seen improvements in local and regional control, but distant metastasis remains the main failure leading to death in NPC patients.[78]

CHAPTER ONE HUNDRED

Malignant Neoplasms of the Oropharynx

Uli Harréus

Key Points

- About 10% to 12% of all head and neck malignancies are oropharyngeal tumors, more than 90% of which are histopathologically squamous cell carcinoma (SCC).
- On the basis of different diagnostic, therapeutic, and outcome characteristics, the oropharynx should be subdivided into soft palate, tonsillar fossae, base of tongue, and oropharyngeal wall.
- The invasive cell grading system by Bryne and colleagues is a significant predictor for the outcome and survival of cancer patients using degree of keratinization, nuclear polymorphism, number of mitoses, pattern of invasion, and lymphoplasmacytic infiltration.
- In addition to SCC, the most frequent malignancies of the oropharynx are lymphoepithelial carcinoma, salivary gland tumors (adenoid cystic carcinoma, mucoepidermoid carcinoma), soft tissue tumors, hematolymphoid tumors, and mucosal malignant melanoma.
- Diagnostic evaluation includes thorough history taking, physical examination, imaging (e.g., ultrasound, MRI, CT, PET-CT), endoscopy, and biopsy of the tumor.
- Therapeutic management of oropharyngeal cancer depends on staging, tumor location, post-treatment function, and the patient's preference after thorough information.
- Endoscopic or transoral laser surgery has become an important tool in the surgical treatment of oropharyngeal cancers with good functional and prognostic outcome.
- Early-stage lesions can be treated surgically with or without postoperative radiation.
- Advanced-stage lesions can be treated surgically with or without reconstructive surgery and postoperative chemoradiation therapy or with definitive chemoradiation therapy in case of inoperability.
- Most oropharyngeal cancers can be approached transorally. However, lateral and transhyoid pharyngotomy, as well as mandibular swing approaches, can be necessary for selected tumors on the basis of location and tumor size.
- As for other malignancies of the head and neck region, a thorough follow-up enables early detection of possible recurrence and timely intervention for improved disease control.
- In addition to locoregional control and patient survival, quality of life is a key factor in the judgment of therapeutic success. The International Classification of Functioning, Disability and Health (ICF) core set by the World Health Organization enables standardized quality-of-life assessments for head and neck cancer patients.

About 10% to 12% of all malignancies of the upper aerodigestive tract occur in the oropharynx. Approximately 130,000 new cases were detected worldwide in 2002.[1] Histopathologically, most malignancies found in the oropharynx (>90%) are squamous cell carcinomas (SCCs) with an incidence of 1 to 3/100,000 in the United States and Europe per year. Although the male population has a higher prevalence of oropharyngeal cancer, future counts will depend on tobacco and alcohol consumption behavior, which is the major risk factor for oropharyngeal carcinoma, followed by occupational and environmental pollutants and endogenous risks.

The prognostic outcome for patients with oropharyngeal malignancies strongly depends on the primary location within the oropharynx and the initial staging and grading of the disease. Survival is based on locoregional recurrence, its prevention, early detection, and treatment. Moreover, all head and neck cancer patients are at risk for second malignancies of the upper aerodigestive tract. However, one has to consider persisting mortality counts despite improved therapeutic options in recent years. Therefore intensive knowledge of existing treatment plans is required, and new treatment strategies based on latest studies and research must be aimed for in the future.

Anatomy of the Oropharynx

The structure of the oropharynx is complex and can be subdivided into the soft palate, tonsils, and base of tongue respecting different site-specific characteristics. The oropharyngeal borders are the soft palate superiorly and the hyoid bone and the vallecula inferiorly. The ventral border is the base of tongue, which ends at the circumvallate papilla. Laterally and dorsally the oropharynx contains the tonsillar region and

the lateral and dorsal pharyngeal wall, respectively. In the following sections, the anatomic sites are described separately, accounting for their specific characteristics (Fig. 100-1).

Soft Palate

The soft palate incompletely separates the nasopharynx and oral cavity from the oropharynx. It is built by the palatopharyngeal arch and the uvula containing the levator and tensor muscle of the palate, the uvular muscle, and laterally the palatopharyngeal and constrictor muscles. Small salivary glands exist within the soft palate tissue. The blood supply is based on the palatine arteries accompanied by palatine sensory nerves.

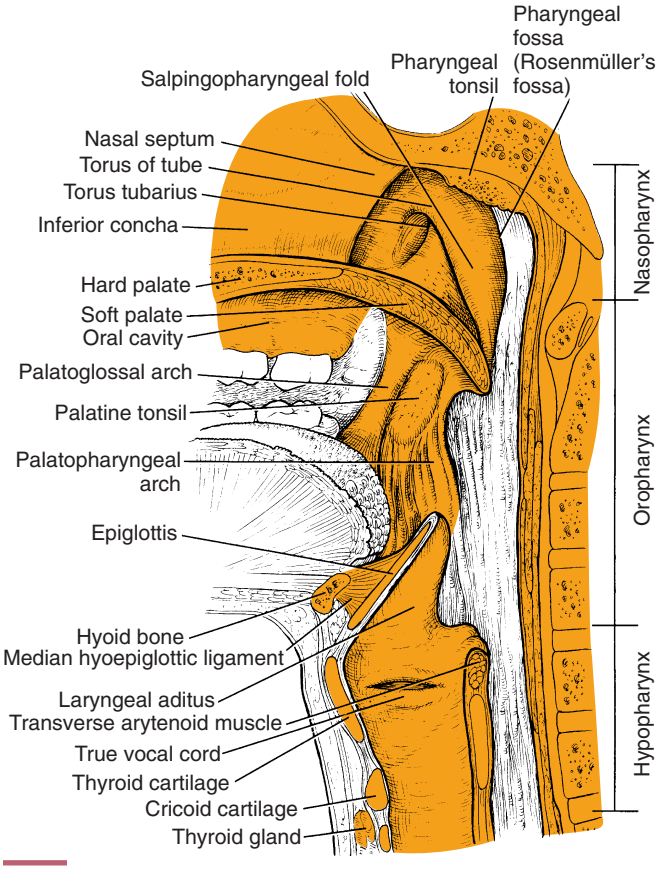

Figure 100-1. Surface anatomy of the oropharynx.

Tonsillar Fossae

The tonsillar region contains the lymphoid tissue of the palatine tonsil, located on the lateral pharyngeal wall. The vascular supply of the palatine tonsils is covered by posterior branches of the lingual artery, the ascending pharyngeal artery, branches of the facial artery, and palatine branches of the internal maxillary artery. The tonsils are embedded in the anterior and posterior pillar, formed by the palatoglossus and the palatopharyngeal muscle, respectively.

Base of Tongue

The base of tongue reaches from the circumvallate papilla to the vallecula and to the glossopalatine sulci laterally. The tongue base is rich in lymphatics and contains part of Waldeyer's ring. The blood supply is covered by the lingual arteries. Innervation of the tongue musculature is provided by the hypoglossal nerve (Fig. 100-2).

Oropharyngeal Wall

The posterior pharyngeal wall of the oropharynx reaches from the region of the soft palate to the epiglottis and borders the tonsillar fossae and the lateral aspect of the piriform sinuses laterally. The wall is composed of superior constrictor muscle and the buccopharyngeal and pharyngobasilar fascia covered by the pharyngeal mucosa (Fig. 100-3).

Lymphatics

The lymphatic pattern of the oropharynx is complex, and lymphatic spread from malignant lesions depends on size and location of the primary malignancy. Its understanding is of high importance for the outcome of surgical and/or radiotherapy treatment of oropharyngeal lesions. A number of previous studies have defined the routes of lymphatic spread in the head and neck.[2-4] The clinical neck levels are defined by levels I to VI with subdivisions A and B for levels I, II, and V (Fig. 100-4).[5]

Oropharyngeal carcinoma is predisposed to drain to levels II, III, and IV with possible further spread to other regions in extensive disease.[6] However, primary drainage is to the jugulodigastric nodes in the upper deep jugular chain (level II) and to the retropharyngeal and parapharyngeal nodes in the retropharyngeal and parapharyngeal space, respectively. Other metastatic spread may involve midcervical (level III) and lower cervical nodes (level IV). Skip metastases to other clinical levels are extremely rare. Shah described in a retrospective study of 1119 radical neck dissection specimens that tumors of the oropharynx characteristically metastasized to lymph node levels II to IV. There was no positive node involvement of level V when levels II to IV were negative.[7]

Please refer to the printed publication.

Figure 100-4. Lymph node chains of the neck that may be involved with cervical metastatic spread from oropharyngeal tumors. **A,** Superficial cervical and facial nodes. **B,** Deep cervical and intraparotid lymph nodes.

Attention should be spent on the location of the primary malignancy near the midline. Tumors of the base of tongue, the soft palate, and the posterior pharyngeal wall have a higher incidence of bilateral lymphadenopathy. These considerations should influence therapeutic planning to optimize therapy and minimize patient morbidity (Figs. 100-5 and 100-6, Table 100-1).

Pathology

SCC is the most common malignancy of the oropharynx, comprising more than 90% of all malignant tumors of that origin. Other malignant transformations are lymphomas, lymphoepithelial carcinoma, minor salivary gland tumors, malignant melanomas, and other rare malignancies. The World Health Organization Classification of Tumours outlines the presently known malignancies of the oropharynx (Table 100-2).[8]

Epithelial Precursor Lesions

In general, precursor lesions of the oropharynx clinically present as white patches (leukoplakia) (Fig. 100-7) or red patches (erythroplakia). Some lesions appear as mixed variants with white and red components. Most white lesions do not show dysplastic cells and relate to hyperplasia. However, erythroplakia or mixed lesions frequently display dysplasia. Whereas leukoplakia rarely undergoes malignant transformation and may even regress after elimination of underlying etiologic factors, erythroplakia can often lead to malignancy.

Hyperplasia describes increased cell counts in the spinous layer (acanthosis) or in the basal/parabasal layers. The cells are free of atypia and tissue architecture is regular.

In case of changes in architecture and in the presence of atypia in cells, we speak of dysplasia. Dysplasia is considered a range and it is somewhat challenging to divide the dysplastic spectrum into mild, moderate, and severe.

Mild dysplasia is described as mild cell atypia with architectural changes limited to the lower third of the epithelium.

Moderate dysplasia shows architectural changes up to the middle third of the epithelium and cytologic atypia.

Severe dysplasia begins with architectural changes over two thirds of the epithelium and atypic cells. Again, there is no definite division

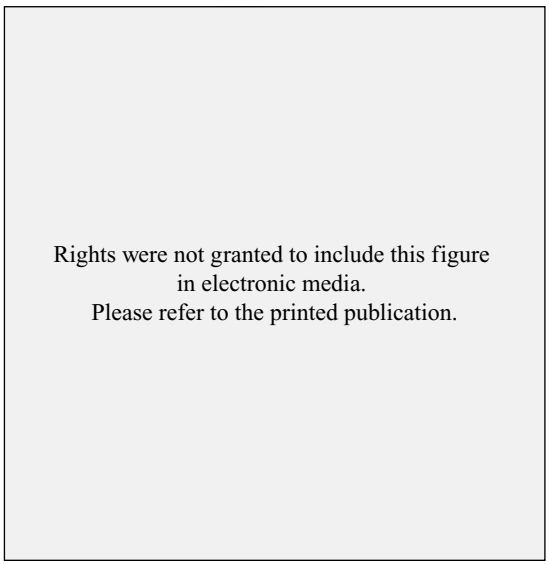

Figure 100-5. Lymphatics of the base of the tongue, with jugulodigastric node involved first.

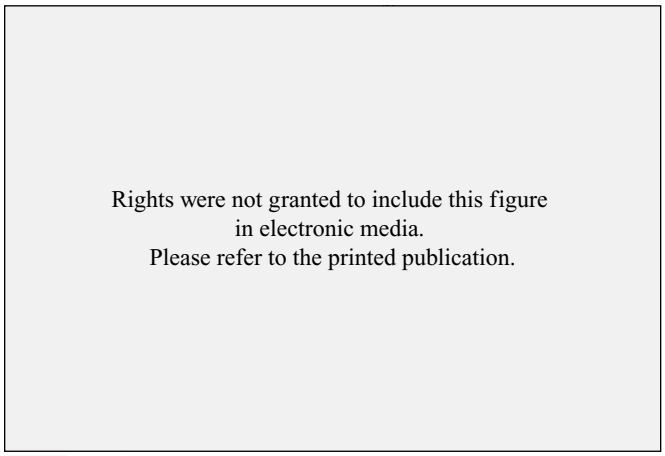

Figure 100-6. Bilateral base of tongue lymphatic drainage.

of dysplastic variants and, depending on the degree of cell atypia, upgrading of dysplasia categories might have to be considered.

Carcinoma in situ is described as malignant transformation without invasion, which is difficult to distinguish morphologically. WHO experts recommend that CIS be diagnosed when full-thickness architectural abnormality and severe cytologic atypia is found.[9]

Squamous Cell Carcinoma

SCC is defined as an invasive epithelial neoplasm with varying degrees of squamous differentiation and a propensity to early and extensive lymph node metastases, occurring predominantly in alcohol- and tobacco-using adults in the fifth and sixth decades of life.[10] The clinical appearance varies and presents as exophytic, flat, ulcerated, verrucoid, or papillary in growth (Fig. 100-8). Independent from the gross appearance, histopathologic patterns of invasion demonstrate multiple variations as well. SCC can vary from keratinizing to nonkeratinizing and well differentiated to poorly differentiated. Severe dysplasia and CIS are common elements found in association with invasive SCC. Invasive carcinoma eliminates the regular architecture and can include lymphovascular space invasion, neurotropism, and infiltration of other tissue components such as muscle or cartilage, demonstrating aggressive behavior of the tumor.

From Lindberg R: Distribution of cervical lymph node metastases from squamous cell carcinoma of the upper respiratory and digestive tracts. *Cancer.* 1972;29:1446. By permission of the American Cancer Society.

Most invasive SCC can easily be identified by experienced pathologists. However, early clinical stages might significantly complicate the diagnosis of invasive patterns. Inflammation can make detailed analysis of the deep epithelial layers and the lamina propria difficult. Presence of cytologic atypia and mitotic features can lead to the correct diagnosis, although they cannot be found in all cases of early SCC pathology. Borderline cases without unambiguous evidence of invasion might still be called early invasive carcinoma after communication between clinician and pathologist.

Malignancy grading can be a prognostic marker, although different grading systems have been proposed with diverse impact on prognosis. Broders suggested a four-tiered grading system for carcinoma of the lip in 1929.[11] His grading system allows assessment of tumor differentiation with some predictability of prognosis because poorly differentiated tumors are more likely to recur.[12,13] However, the grading system has also been shown to lack consistent prediction of prognosis using multivariate analyses.[14,15] A subsequent multivariate analysis on 77 patients with oropharyngeal cancer unveiled only the invasive pattern of the tumor to be an independent predictor for patients' survival.[16] Anneroth and colleagues[17] proposed that grading should include six morphologic features: degree of keratinization, nuclear polymorphism, number of mitoses, pattern of invasion, stage of invasion, and lymphoplasmacytic infiltration. Bryne and colleagues[18] revised this grading method, applying Anneroth's criteria to the most anaplastic fields in the areas of highest infiltration. This invasive cell grading was demonstrated to be a highly significant predictor for oral SCC patients' outcome and survival.[18-20] Table 100-3 summarizes the invasive cell grading system (ICG) by Bryne and colleagues.

Table 100-2

World Health Organization Classification of Malignant Tumors of the Oropharynx

- Malignant epithelial tumors
  - Squamous cell carcinoma
    - Verrucous carcinoma
    - Basaloid squamous cell carcinoma
    - Papillary squamous cell carcinoma
    - Spindle cell carcinoma
    - Acantholytic squamous cell carcinoma
    - Adenosquamous cell carcinoma
    - Carcinoma cuniculatum
  - Lymphoepithelial carcinoma
- Salivary gland tumors
  - Salivary gland carcinoma
    - Acinic cell carcinoma
    - Mucoepidermoid carcinoma
    - Adenoid cystic carcinoma
    - Polymorphous low-grade adenocarcinoma
    - Basal cell adenocarcinoma
    - Epithelial-myoepithelial carcinoma
    - Clear cell carcinoma, not otherwise specified
    - Cystadenocarcinoma
    - Mucinous adenocarcinoma
    - Oncocytic carcinoma
    - Salivary duct carcinoma
- Myoepithelial carcinoma
- Carcinoma ex pleomorphic adenoma
- Soft tissue tumor
  - Kaposi's sarcoma
- Hematolymphoid tumors
  - Diffuse large B-cell lymphoma (DLBCL)
  - Mantle cell lymphoma
  - Follicular lymphoma
  - Extranodal marginal zone B-cell lymphoma of MALT type
  - Burkitt's lymphoma
  - T-cell lymphoma
  - Extramedullary plasmocytoma
  - Langerhans cell histiocytosis
  - Extramedullary myeloid sarcoma
  - Follicular dendritic cell sarcoma/tumor
- Mucosal malignant melanoma
- Secondary tumors

The present WHO grading system has been recommended for histopathologic typing of oropharyngeal cancers by the American Joint Committee on Cancer (AJCC).[21] This grading system is based on Broders' system and includes three grades, which are described in Table 100-4.

Lymphoepithelial Carcinoma

The lymphoepithelial carcinoma is defined as a poorly differentiated SCC or undifferentiated carcinoma, accompanied by a prominent reactive lymphoplasmacytic infiltration. The lymphoepithelial carcinoma is rare and diagnosed in 0.8% to 2% of all oral and oropharyngeal malignancies.[22] More than 90% of all lymphoepithelial carcinoma in the oral and oropharyngeal region is found in the tonsils and the base of tongue. Some are found in the buccal mucosa and the palate.

The histopathologic pattern is described as invasive, comprising syncytial sheets and clusters of carcinoma cells with prominent nucleoli, ill-defined cell borders, and often intact surface. The tumor sites are accompanied by rich lymphoplasmacytic infiltrate. These tumors are radiosensitive and local control can be achieved in a high percentage of cases.[23]

Figure 100-7. Leukoplakia of the tongue.

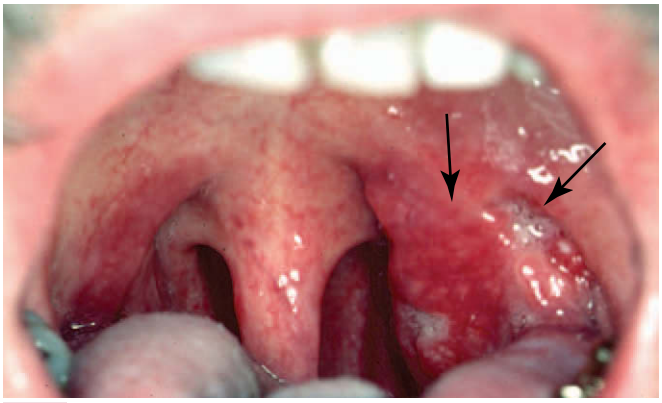

Figure 100-8. Squamous cell carcinoma of the left tonsil (*arrows*).

Salivary Gland Tumors

Among malignant salivary gland tumors, 9% to 23% are found in the oral cavity and oropharynx.[24-26] Nearly half of the salivary gland tumors in the oral cavity and oropharynx are malignant.[24] However, most neoplasms of minor salivary glands arise in the oral cavity. The most common oropharyngeal sites are the (soft) palate, the tonsillar fossa, and base of tongue. Oropharyngeal salivary gland tumors are rare with only 1.1% to 3.3% of all minor salivary gland tumors.[24,25,27] All malignant salivary gland tumors that can possibly arise in the oropharynx are listed in Table 100-2. Among those, adenoid cystic carcinoma and the mucoepidermoid carcinoma are most frequent.

The *adenoid cystic carcinoma* is relatively common in minor salivary glands. A large series describes 42.5% of this lesion to be found in minor glands and 20.5% of minor salivary gland adenoid cystic carcinoma in the oral/oropharyngeal space.[28] They usually present as slow-growing masses, sometimes with ulceration of the palate. Symptoms like pain, signaling nerve invasion, suggest progressive disease. The histopathologic pattern is cylindromatous or cribriform, although some can show tubular areas or appear solid.[29] Cribriform lesions have a more favorable prognosis than solid tumors. The spread of adenoid-cystic lesions is commonly hematogenous, typically in the lung and bones, and lymph node involvement is rather rare. Therefore neck dissection is generally reserved for patients with palpable disease.[30] In case of radiation therapy for these rather moderately radiosensitive

Table 100-3

Invasive Cell Grading System (ICG)

Morphologic Feature	1	2	3	4
Degree of keratinization	Highly keratinized (>50% of cells)	Moderately keratinized (20-50% of cells)	Minimal keratinized (5-20% of cells)	No keratinization (0-5% of cells)
Nuclear polymorphism	Little nuclear polymorphism (>75% mature cells)	Moderately abundant nuclear polymorphism (50-75% mature cells)	Abundant nuclear polymorphism (25-50% mature cells)	Extreme nuclear polymorphism (0-25% mature cells)
Number of mitoses (high-power field)	0-1	2-3	4-5	>5
Pattern of invasion	Pushing, well-delineated infiltrating borders	Infiltrating solid cords/bands/strands	Small groups/cords of infiltrating cells	Marked and widespread cellular dissociation in small groups or in single cells (n <15)
Lymphoplasmacytic infiltration	Marked	Moderate	Slight	None

From Bryne M, Koppang HS, Lilleng R, et al. New malignancy grading is a better prognostic indicator than Broders' grading in oral squamous cell carcinomas. *J Oral Pathol Med.* 1989;18:432-437.

Table 100-4

World Health Organization Grading System for Oral Squamous Cell Carcinoma

Grade	Description
1	Well differentiated. Histologic and cytologic features closely resemble those of the squamous epithelial lining of the oral mucosa. There are varying proportions of basal and squamous cells with intercellular bridges; keratinization is a prominent feature; few mitotic figures are seen and atypical mitoses or multinucleated epithelial cells are extremely rare; nuclear and cellular polymorphism is minimal.
2	Moderately differentiated. This is a neoplasm with features intermediate between well differentiated and poorly differentiated. Compared with well-differentiated squamous cell carcinoma, these tumors have less keratinization and more nuclear and cellular pleomorphism; there are mitotic figures and some are abnormal in form; intercellular bridges are less conspicuous.
3	Poorly differentiated. Histologically and cytologically there is only a slight resemblance to the normal stratified squamous epithelium of the oral mucosa. Keratinization is rarely present, and intercellular bridges are extremely scarce; mitotic activity is frequent and atypical mitoses can readily be found; cellular and nuclear pleomorphism are obvious and multinucleated cells may be frequent.

From Pindborg JJ, Reichert PA, Smith CJ, et al, eds. *Histological Typing of Cancer and Precancer of the Oral Mucosa.* 2nd ed. Berlin: Springer-Verlag; 1997:11. By permission of the publisher.

tumors, neutron beam radiation is recommended.[31] Prognosis is negatively influenced by minor salivary gland as origin, tumor size greater than 4 cm, osseous invasion, advanced stage, and local recurrence.[32,33]

Mucoepidermoid carcinoma is the most common salivary gland malignancy and accounts for 9.5% to 23% of all minor salivary gland tumors.[25,34,35] Half of the often asymptomatic cases arise in the palate, whereas the base of tongue and other oropharyngeal locations are rare.[36] They are commonly well differentiated and appear as a bluish swelling. Some show granulation or a papillary surface. Oropharyngeal tumors can cause symptoms of dysphagia. Histopathologically, a mixture of epidermal epithelium and mucous membrane-producing cells is found. Treatment usually includes wide surgical excision, and neck dissection appears to be beneficial in patients with suspected or clinically obvious metastases. Olsen and colleagues reported on a series of oropharyngeal mucoepidermoid carcinoma at Mayo Clinic. Based on a follow-up of at least 10 years, recurrence rate was significantly reduced after wide local excision, including bone if necessary compared with simple excision with closer margins. Of the patients in the series, 24% presented with positive lymph nodes.[37] Patients treated with primary radiation or postoperative radiation did not profit in terms of local control or survival in this evaluation; however, numbers might be too small to draw final conclusions and radiotherapy might be beneficial in case of adverse effects in those patients.

Soft Tissue Tumors

Kaposi's sarcoma is a locally aggressive growing neoplasm, which might present as cutaneous but also as mucosal lesion, showing multiple patches and nodules (Fig. 100-9). It can also affect lymph nodes and visceral organs. It rarely metastasizes and is a member of intermediate-type vascular tumors. It is associated with human herpes virus 8 (HHV 8) infections. Kaposi's sarcoma occurs as an indolent variant in elderly men in the Mediterranean and Eastern Europe, as endemic disease in equatorial Africa, and in immunosuppressed patients after organ transplantation or in case of human immunodeficiency virus (HIV) infection.[38]

Oral Kaposi's sarcoma is found predominantly on the palate, the gingiva, and the tongue. It clinically presents as reddish blue or brown nodules or plaques with possible ulceration. The AIDS-related form of Kaposi's sarcoma is the most aggressive form. There are three histopathologic stages of Kaposi's sarcoma: the patch stage in early lesions, the plaque stage, and the nodular stage. Stages can be considered a spectrum and they blend into another. Early lesions are uncharacteris-

tic, showing vascular proliferation, collagen fibers, hyaline globules, endothelial cell lining, and cells with some atypia and infiltration of inflammatory cells as they grow.

Patients might be treated with surgery, radiation, and chemotherapy, depending on the epidemiology of the disease. The incidence and course of the disease has improved with antiretroviral therapy in HIV-infected patients.[38]

Hematolymphoid Tumors

On the basis of the complex and widespread lymphatic tissue in the oropharynx, lymphoid malignancies often occur in this area. *Non-Hodgkin's lymphomas* (NHLs) are found in the palatine tonsils, palate, base of tongue, and other oropharyngeal sites. Etiologic factors are yet unknown in most patients, although some lymphoma patients might suffer from an immunodeficiency. Clinical symptoms can be fullness of the throat, dysphagia, snoring, and pain. Systemic symptoms are rare.[39] The lesions present as exophytic mass, submucosal swelling, and sometimes ulcerations (Figs. 100-10 and 100-11).

Most NHLs in the oropharynx are B-cell lymphomas, with diffuse large B-cell lymphoma being the predominant type. Histopathologically the stroma is densely infiltrated with lymphoma cells, which vary depending on the histologic type. Treatment is based on radiotherapy and/or chemotherapy depending on the histologic type and stage. Studies have demonstrated a benefit for adjuvant chemotherapy along with radiation compared with radiation treatment only.[40,41] The 5-year survival rate for localized disease has been reported from 50% to more than 80%.[41-45]

Mucosal Malignant Melanoma

Although malignant melanoma (MM) most commonly manifests as skin lesions, it may also arise from melanocytes in the mucosa, but only 1.3% of all melanomas are mucosal melanomas (Figs. 100-12 and 100-13). Of those, 55.4% are mucosal MMs of the head and neck.[46] They are characterized as malignant transformed melanocytes at the epithelial–connective tissue interface with migration into the epithelium and the connective tissue, respectively. Oropharyngeal mucosal melanoma is exceedingly rare, with more mucosal MM of the head and neck occurring in the oral cavity (50%).[46,47]

No known etiologic factors exist for mucosal MM of the head and neck. Clinically they can present as black, gray, or reddish, and they are rarely amelanotic. They typically consist of widespread, multiple, pigmented lesions with or without nodules. Ulcerations and bone infiltration are common and oral bleeding, dysphagia, and sensations of pain can be symptoms before diagnosis. Mucosal MM is usually diagnosed in an advanced stage with most tumors showing invasive character. However, 20% are in situ lesions.[47] Aggressive surgical resection is still the primary treatment of choice, although many adjuvant modalities including different chemotherapy regimens and radiotherapy have been applied. Despite surgically achieved possible local control, 5-year survival of pharyngeal melanoma is only 13%.[46,48,49] Developments for improved treatment options are limited because mucosal MM is a rare disease lacking clinical treatment trials. By early detection, melanoma

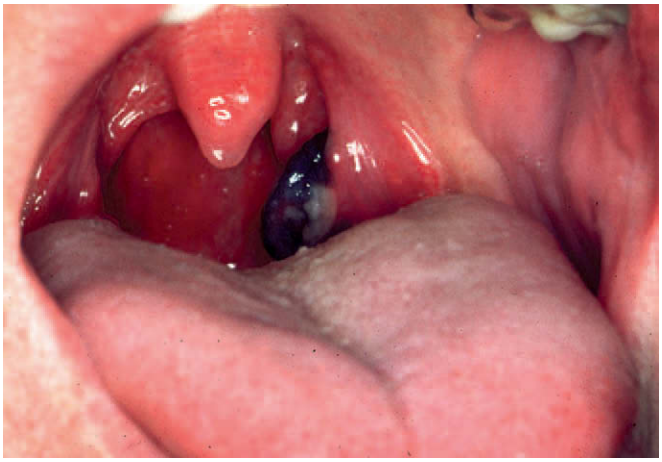

Figure 100-13. Malignant melanoma of the left tonsillar fossa.

patients have the best chance for cure and physician's threshold for biopsy of a suspected lesion should be low.

Squamous Cell Carcinoma

Etiology

Predominant and synergistic acting risk factors for SCC of the oropharynx are tobacco and alcohol consumption.[50] These factors account for about 75% of oral and oropharyngeal carcinoma in Western countries.[50,51] For the highest consumption levels, relative risks from 70 to 100 have been reported compared with lowest consumption levels. A super-multiplicative effect in case of contact with tobacco and alcohol substances has been shown for oral and oropharyngeal cancers in case-control studies.[52]

Tobacco chewing is a common habit, particularly in India, parts of Southeast Asia, the Middle East, China, and Taiwan. Tobacco is often consumed in betel quids containing areca nut, which has been classified as human carcinogen by the IARC in 2003. Smokeless tobacco is a major risk factor for oropharyngeal cancer in these parts of the world.[53] In India about 50% of oropharyngeal cancers in male and 90% in female are caused by chewing.[54]

Human papillomavirus (HPV) infection is another well-established cancer risk factor. Genotypes HPV 16 and 18, known causes for uterine cervix and skin cancer, are found in 50% of tonsillar and oropharyngeal SCC, and studies suggest that up to 40% of oropharyngeal cancer cases may be due to HPV infection.[55] The incidence of HPV-associated oropharyngeal primaries is rising according to recent reports—up to 70% of all presenting cases in some series. The cohort of patients harboring this form of the disease is younger by approximately 10 years and has a distinctly favorable prognosis. Epidemiologic studies propose that having multiple sexual partners is significantly associated with HPV-related tumors.[1]

In addition to exogenic risk factors, multiple endogenic risks have been identified and associated with head and neck cancer.[56] DNA repair, differences in mutagen sensitivity, and alteration of genes such as epidermal growth factor receptor (EGFR) have shown their impact on head and neck cancer and influenced modern therapy and prevention strategies.

Clinical Presentation, Patterns of Spread

Patients with SCC of the oropharynx often present at advanced stages III and IV. Despite psychologic and social factors, late symptoms might cause prolonged und undiscovered tumor growth. First symptoms may be dysphagia, pain, feel of throat mass, oral bleeding, otalgia (involvement of cranial nerves IX and X), or presentation of a neck mass. Oropharyngeal regions can vary in clinical presentation and pattern of spread, causing different considerations for diagnostics and treatment.

Cancers of the *soft palate* present almost always on the anterior oropharyngeal portion. They are well detectable and can in most cases be biopsied in the office. Primary lymphatics involved are commonly level II nodes, with other levels involved depending on the clinical stage. Whereas midline and paramedian lesions have a tendency for bilateral lymphatic spread, this becomes more unlikely the more lateral the tumor growth is located.

The most frequent location for oropharyngeal tumors is the *tonsillar fossa,* with the palatine tonsil and the anterior tonsillar pillar. They commonly present as foreign body, dysphagia, otalgia, or impeded jaw mobility caused by infiltration of the periosteum or bone of the mandible or the pterygoid muscles in extended cases. Physical examination can show exophytic or ulcerated lesions, dysplasia, and/or inflammation reaction. Extension into the base of tongue inferiorly and the soft palate superiorly is common, with 55% and 60% in a study by Perez and colleagues, respectively.[57] Lymphatic drainage is directed primarily to level II nodes but can involve level III parapharyngeal and retropharyngeal nodes level I, IV, and V, depending on stage of presentation.[58-60] Lindberg described nodal metastasis for cancer of the tonsil in 76% of cases compared with 45% in patients with cancer of the tonsillar pillar, with most common node involvement in level II for both locations. Contralateral nodal disease was found in 11% of patients with cancer of the tonsil and 5% with primary malignancy of the pillar.[61] However, in these studies no mention is given of proximity to the midline, which is the most frequent reason a lateralized tumor epicenter in the oropharynx would present with "contralateral" neck metastasis. Differences might be based on higher-staged groups with tonsillar lesions, and likelihood of contralateral lymphatic spread is less than 5% for T1 and T2 cancers.

Cancer of the *base of tongue* is particularly difficult to detect and often becomes clinically evident in an advanced stage. This is due to relatively late clinical symptoms because the base of tongue is nearly without pain fibers. Moreover, the assessment of the base of tongue can be more difficult during physical examination due to prominent lingual tonsils or submucosal location, and deep basal areas might not completely present even using operative endoscopy. As in the palatine tonsil, occult carcinoma with clinically prominent metastatic disease, typically in neck level II, is often found in the base of tongue and is often the presenting feature of this disease. As with neck metastases primarily clerived from tonsils, some of these neck masses can be misdiagnosed as branchial cleft cysts or, on biopsy, as branchiogenic carcinomas.[62] To rule out such findings, meticulous microendoscopic examination (see Fig. 100-12) and biopsy of suspected lesions are mandatory. Base of tongue cancer has a higher frequency of bilateral metastases (up to 20%), which is mainly due to proximity to the midline but enhanced by a rich lymphatic drainage of the base of tongue and tendency to late clinical presentation with upstaging. Ipsilateral node involvement can be detected in more than 70% of cases.[63]

Prolonged diagnosis is also common in *oropharyngeal wall* tumors. Symptoms can be pain, dysphagia, and bleeding. Infiltration of the prevertebral fascia posteriorly and deep cervical structures and vessels laterally negatively affect therapeutic options and prognosis. Lymphatic spread is found in about 25% of T1 and in 75% or more of T4 cancers. Most pharyngeal wall tumors come close or past the midline with frequent bilateral lymphatic spread. Microscopic parapharyngeal and retropharyngeal lymphatic spread has to be considered even in small lesions without palpable cervical nodes.

Diagnostic Evaluation

Anamnesis

A thorough anamnesis is part of any comprehensive evaluation of head and neck cancer patients. Symptoms at first presentation of oropharyngeal cancer patients are commonly dysphagia and/or odynophagia, oral bleeding, otalgia, or changes in speech. In addition to the history of risk factors such as alcohol and tobacco consumption, xenobiotic exposure at working places and in the environment should be evaluated. Dietary and social habits are also worthwhile to evaluate. Knowing about possible risk factors for head and neck cancer in individual patients enables for future elimination and enlarges the chances for prevention of recurrent disease. Also, better results and improved treatment tolerance are obtained for patients who quit smoking.[64] Other

factors such as social aspects, family support, and general health status have great impacts on treatment and outcome and should therefore be consequently evaluated.

Physical Examination

Physical examination is one of the initial keys for cancer diagnosis, selection of further diagnostics, and treatment plan. In case of suspicion for oropharyngeal cancer, patients should carefully be investigated with focus on the tongue (appearance and movement), tonsillar fossae, retromolar trigone, soft palate (appearance and mobility), base of tongue, vallecula, and pharyngeal walls. Inspection should include a close endoscopy (flexible or rigid) and palpation, especially of the tongue base and sensate testing. Examination can unveil local tumor extension and nerve infiltration. Video endoscopy and documentation of findings are helpful tools for teaching reasons and future comparisons.

All cancer patients need to undergo a complete head and neck investigation to exclude secondary cancers. Bimanual palpation of the neck is mandatory in order to assess lymph node status and possible regional tumor spread.

Imaging

For most head and neck malignancies, imaging is an important and recommended tool for diagnostics and clinical staging. Oropharyngeal malignancies, especially with their close anatomic relationship to important soft tissue and bony structures, require further imaging studies for precise evaluation and treatment plans.

Gray-scale and Doppler ultrasonography of the neck have proven to be valuable methods to evaluate lymphadenopathy of the neck. Using ultrasound for cervical assessment has advantages. It is a relatively inexpensive procedure with real-time imaging and can be frequently performed without radiation exposure. However, there is limitation to ultrasonography in patients with head and neck malignancies. Retropharyngeal nodes and deep structures are not accessible using ultrasound. Furthermore, ultrasound has deficits describing extracapsular spread and infiltration of soft tissue and bone. Moreover, the oropharyngeal primary usually cannot be detected using ultrasonography.[65]

Most oropharyngeal malignancies today are evaluated using computed tomography (CT) or magnetic resonance imaging (MRI). Sometimes the imaging technique preferred simply depends on its availability. Each has its advantages and disadvantages. Some oropharyngeal malignancies involve bony structures such as the maxilla, mandible, cervical spine, and skull base, and a CT scan might be helpful in interpretation of bone infiltration, although modern MRI precisely demonstrates infiltration of the periosseous membrane and allows for exact interpretation of bone involvement. In some cases panoramic x-ray views of the mandible can support identification of mandibular infiltration. Especially in deep invasive malignancies, MRI is helpful, although it can lead to false-negative results regarding superficial lesions. Although magnetic resonance scanning is generally the most recommended imaging method for the evaluation of the oropharynx and the neck, both CT and MRI have been used in such determinations.[66] Positron emission tomography (PET)/CT plays an increasing role for the management of head and neck SCC. It can unveil unknown primary tumor sites and synchronous primary tumors, regional lymph node metastases, and distant metastases. It plays a lesser role for T-staging of a known primary based on decreased anatomic definition compared with MRI and contrast-enhanced CT.[67] Its reliability may be limited by previous surgical or radiation therapy. Recent studies suggest that PET/CT is more accurate 2 to 3 months after completion of radiation therapy.[68-70] Whereas a negative PET/CT is found to be highly reliable, positive results must be correlated with findings in physical examination and cross-sectional imaging modalities because nonspecific inflammation may cause false-positive results.[71]

In addition to evaluation of locoregional tumor spread, imaging systems are used to screen for distant metastatic spread in organs such as the lung, liver, skeletal system, and brain. On the basis of the primary malignancy and the accompanying likelihood of distant metastases, regular chest radiographs and ultrasonography of the abdomen might be sufficient staging methods. In many cases, CT scanning of the lung and CT and/or MRI for the abdomen are recommended. In recent years, FDG PET/CT showed growing importance for the detection of distant metastatic spread.[71]

Endoscopy, Biopsy, and Frozen Section

To further diagnose oropharyngeal lesions, a biopsy and histopathologic examination must be performed. Biopsies of oropharyngeal tumors might be taken under local anesthesia. Lymphadenopathy without perceptible primary lesion can be evaluated using fine-needle aspiration (FNA). Best diagnostic results are found for FNA using ultrasound of the neck.[72]

Some oropharyngeal lesions are not sufficiently accessible in the office setting and may require general anesthesia to biopsy an adequate-sized specimen. Occasionally small oropharyngeal malignancies can be difficult to detect in physical examination, as well as in imaging systems, and demand further diagnostics (e.g., using endoscopes with or without microscopic assistance) (Fig. 100-14). Microscopic evaluation is a sensitive procedure for the identification of unknown primary lesions, which can often be detected in the base of tongue or tonsillar fossa, respectively. The panendoscopy in general anesthesia is an important tool not only to detect and biopsy such lesions and to define tumor extension but also to rule out any secondary malignancy, which can be found in head and neck cancer patients and includes endoscopy of the bronchi and esophagus.

Frozen sections as confirmation of a suspected malignancy and as criteria for tumor-free margins have been critically evaluated in the past.[73] The reliability of frozen sections depends on the experience and technique of the pathologist and requires close interdisciplinary communication. The accuracy of frozen sections is close to the final diagnosis (>90%).[74] Considering the possibility of false-positive results, depending on the examiner's expertise, frozen sections cannot be generally recommended as a basis for final treatment, however. The final treatment should be based on standard histopathology.

Staging

The Union Internationale Contre Cancer (UICC) and the American Joint Committee on Cancer (AJCC) in its *Cancer Staging Manual* (sixth edition) have defined the current staging system for oropharyngeal cancer.[75,76] Both classifications correspond exactly. Tables 100-5 and 100-6 present an overview of the present oropharyngeal staging system.

Experts have debated and evaluated the clinical use of the staging system.[77] The fifth edition of the tumor node metastasis (TNM) classification divided stage IV tumors into three subcategories (IVA, IVB, and IVC), which already caused relevant changes to the fourth edition.[78] The sixth edition of the TNM classification introduced a subdivision of advanced tumors of group T4 into T4a (lower risk) and T4b (higher risk), which describes the risk of uncontrolled disease in patients with

Table 100-5

Definition of the Tumor Node Metastasis Staging System

Primary Tumor (T)

T_X	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_{is}	Carcinoma in situ
Oropharynx	
T_1	Tumor ≤ 2 cm in greatest dimension
T_2	Tumor > 2 cm but ≤ 4 cm in greatest dimension
T_3	Tumor > 4 cm in greatest dimension
T_{4a}	Tumor invades the larynx, deep or extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible
T_{4b}	Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery

Regional Lymph Nodes (N)

Oropharynx and Hypopharynx	
N_X	Regional lymph nodes cannot be assessed
N_0	No regional lymph node metastasis
N_1	Metastasis in a single ipsilateral lymph node ≤ 3 cm in greatest dimension
N_2	Metastasis in a single ipsilateral lymph node > 3 cm but ≤ 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension
N_{2a}	Metastasis in a single ipsilateral lymph node > 3 cm but ≤ 6 cm in greatest dimension
N_{2b}	Metastasis in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension
N_{2c}	Metastasis in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension
N_3	Metastasis in a lymph node > 6 cm in greatest dimension

Distant Metastasis (M)

M_X	Distant metastasis cannot be assessed
M_0	No distant metastasis
M_1	Distant metastasis

tumor extension beyond the site of origin. T4a disease describes tumors with reasonable opportunity for disease control on the basis of the resectability of structures involved such as larynx, deep/extrinsic muscles of the tongue, medial pterygoid, mandible, and hard palate. T4b describes tumors with certainty of poor outcome showing involvement of the lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, skull base, or carotid artery. O'Sullivan and Shah[79] suggested invasion of the prevertebral fascia to be classified as high risk and therefore included into subgroup T4b. T4a and T4b in combination with categories for N (regional lymph node disease) and M (distant metastasis) assist the classification of the advanced tumor stage IV into the subgroups with advanced lower-risk stage IVA (potentially curable), advanced higher-risk IVB (of dubious curability), and stage IVC with distant metastatic disease (undoubtedly incurable). Despite some suggested additions, the sixth edition of TNM classification offers valuable assistance in clinical management and research. Changes in the staging system over the past decades and improvements of staging tools such as modern imaging systems must be taken into consideration when former clinical studies about outcome and prognosis are evaluated.

Despite the importance of therapeutic management, outcome, and prognosis, clinical staging remains strongly dependent on the examiner's skills, the imaging system and its quality, and the excellence of surgical and pathologic assessment.

Oropharyngeal cancer is usually amenable to direct or endoscopic visualization and palpation, which in combination with imaging assessment enables a thorough clinical evaluation. Reasons for misjudgment remain. The examiner's evaluation does not unveil microscopic and deep infiltration. Using MRI and CT scanning for further information results might be limited when examining superficial smaller lesions.[62] Additionally, poor demarcation and accompanying inflammatory tissue reaction may affect interpretation of the images. Tumor size can be overestimated or underestimated by these factors and misjudged, and it can strongly influence therapeutic planning. Not only clinical but also postoperative staging might be affected (e.g., by shrinkage of the specimen and lack of clinical and surgical information). Moreover, large tumor extension might lead to difficulties about classification of the site of origin (e.g., whether a lesion derived from the oropharynx, hypopharynx, or supraglottic region). Because those tumor extensions commonly accompany high staging and comparably worse prognosis, there is less influence concerning management strategies but concerning scientific studies and statistical evaluation. Nevertheless, correspondence between the clinician and the pathologist is the key for best postoperative staging.

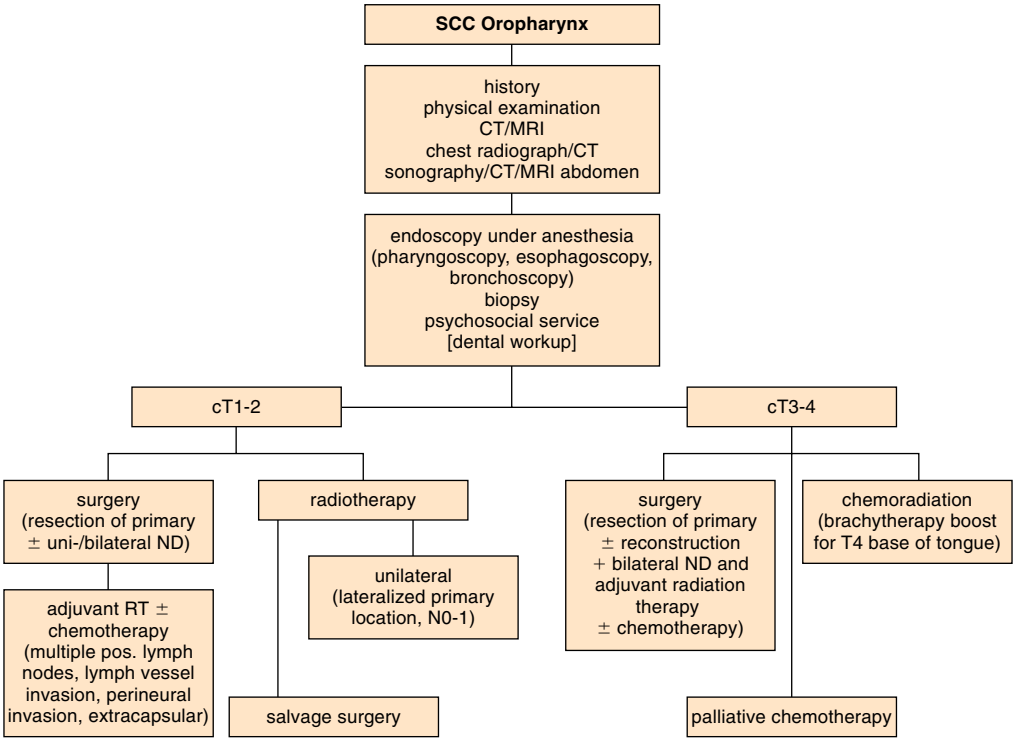

Figure 100-15. Management algorithm for squamous cell carcinoma of the oropharynx.

Therapeutic Management and Outcome

The main criterion for a successful treatment is locoregional control of the primary tumor. The choice of treatment modality depends on the location of the primary and the ability to control the primary and the regional node involvement. Figure 100-15 presents an informing algorithm for oropharyngeal cancer treatment. With improvements in locoregional control, distant metastases are a growing issue in the treatment of oropharyngeal cancers. To achieve this goal, surgery, radiotherapy, and chemotherapy can be administered alone or in combinations. In case of an early tumor stage, surgery and radiation therapy can be used for primary treatment. In later stages of oropharyngeal cancer, combinations of surgery, radiation therapy, and chemotherapy are recommended in most cases. The impact of additional therapies such as immunotherapy/biotherapy (e.g., epidermal growth factor receptor [EGFR] inhibitor) is currently investigated and their significance has yet to be evaluated. The decision-making process for treatment modality should include information from the latest review of the Cochrane Collaboration on the treatment on oral and oropharyngeal cancer. Only one study by Robertson (1998) compared surgery plus adjuvant radiotherapy and radiotherapy alone, fitting their criteria and therefore being included. The trial was prematurely stopped because of the unacceptably high number of deaths in the radiotherapy arm.[80,81] However, in addition to outcome, post-therapeutic function associated with the patient's quality of life must be considered in the decision about treatment.

With the use of modern free tissue transfer techniques, patients' quality of life and functions like speech and swallowing have considerably improved after surgery with ablative defects.[82] Patients should be thoroughly informed about possible treatment options to be included in the decision-making process. Complications and long-term effects possibly arising from surgical interventions or toxicity of chemoradiation therapy must be clearly assessed. As for all head and neck cancers, the clinician's experience, the options given by the institution, and the patient's individual reliability should be accounted for in order to achieve the optimal cancer treatment.

Soft Palate

Early disease of the soft palate (Fig. 100-16) shows favorable results for local control using surgery and using radiation therapy. Considering possible long-term side effects caused by radiation therapy and good reconstructive options with positive functional outcome, surgery (conventional or laser surgery) might be preferred. Some studies have been performed using radiation in combination with brachytherapy (Iridium-192 implant), without any proof of significant benefit.[83-86]

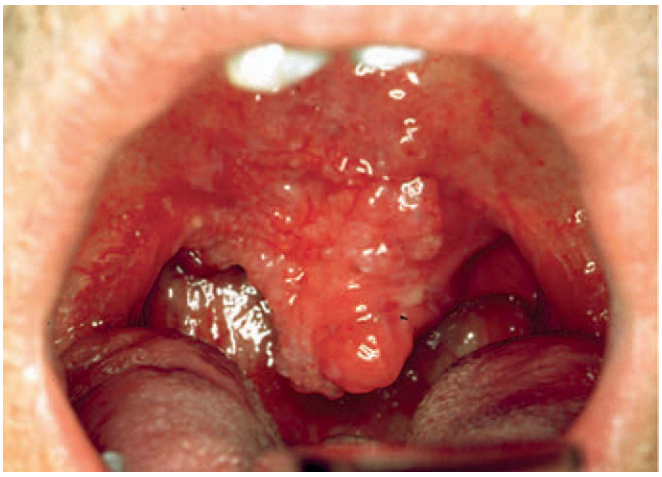

Figure 100-16. Squamous cell carcinoma of the uvula.

Advanced disease is commonly treated with surgery and adjuvant radiotherapy with or without chemotherapy. Radiation therapy did not demonstrate convincing results.[87] However, Calais and colleagues[88] showed more favorable results using radiation therapy with concomitant chemotherapy compared with radiation therapy alone as an alternative therapeutic modality for stage III and IV cancers.

The decision for performing a *neck dissection* is led by the propensity of soft palate cancers to metastasize even in early stages. Har-El and colleagues[89] showed that more than 48% of patients with soft palate cancers present with clinical evidence of neck disease, and even in patients with no palpable or radiographic proof, more than 40% of

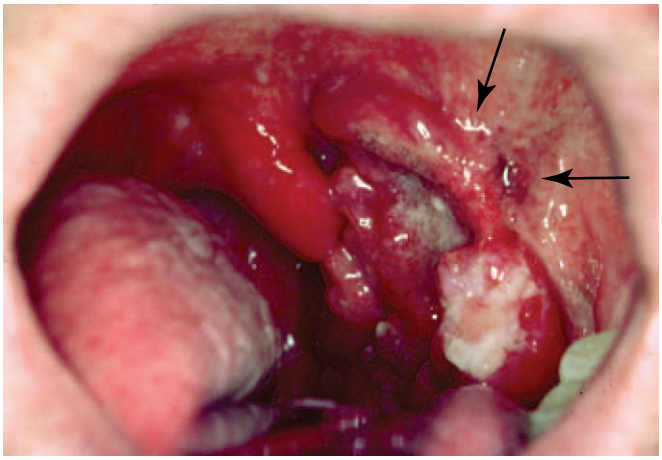

Figure 100-17. Advanced squamous cell carcinoma of the tonsil.

their patients eventually had neck disease. As a consequence, patients with positive nodes should be treated with neck dissection (e.g., followed by radiation therapy). Also, patients with clinically negative neck should either receive elective neck dissection or radiation therapy. Some authors describe radiation therapy followed by neck dissection in clinically positive nodes as well.[81] Yet higher complication rates have been found for neck dissection following radiation therapy in several studies, suggesting surgery as primary treatment.[90] The closer the lesion is positioned toward the midline, the higher the likelihood for bilateral lymphatic spread and the necessity to perform bilateral neck dissection.[91]

Tonsillar Fossae

Early lesions of the tonsillar region can be treated with surgery or radiation. Both modalities offer good outcome and functional results. In most cases modern surgical techniques and instruments allow good transoral access to the tumor site without comorbidity worth mentioning. Procedures including mandibulotomy are rarely necessary and used only in some cases of extensive disease and reconstruction. Also, laser techniques add to the advancements of surgical precision and reduced morbidity.[92,93] Local control rates up to 90% after surgery have been described.[94,95] Comparing external radiation beam therapy (EBRT) with surgery, no differences in locoregional control or overall survival have been unveiled. However, complications based on high dosage for primary treatment and the effect on the patient's quality of life must be considered and compared with those resulting from surgery.

Advanced lesions (Fig. 100-17) are commonly treated with surgery and postoperative radiotherapy ± chemotherapy). One study was performed using single-modality (surgery vs. radiotherapy) treatments for stage III and IV cancers, with significantly better 5-year survival rates using surgery, even though more patients were stage IV in the radiated group.[96] Foote and colleagues evaluated advanced cases treated with surgery ± adjuvant radiotherapy. After surgery with postoperative radiation, their overall survival rate was found to be 100% for stage III and 78% for stage IV cases, whereas patients who underwent solely surgery showed 56% and 43% survival, respectively.[97] Another study from the Memorial Sloan-Kettering Cancer Center demonstrated favorable local control rates (T3 94%, T4 75%) and 64% disease-free survival. In case of positive or close surgical margins, 60 Gy or higher was administered and followed by a 93% local control rate.[98]

Spiro and Spiro compared radiation therapy and combined therapy with surgery followed by radiation retrospectively from 1969 until 1983. They found 3-year local control rates comparable with other investigators but for stage IV disease, although possibly biased against the combined treatment by preselection of high-staged cases.[99] Recently, concomitant chemoradiation following surgery compared with postoperative radiation was investigated for head and neck cancers in Europe and the United States in two multicenter studies. For oropharyngeal tumors, the evidence for a benefit using concomitant chemoradiation therapy remains somewhat weak, although much stronger in patients with additional features such as extracapsular spread of lymph nodes.[100,101] Parsons and colleagues presented a review of several studies comparing surgery ± radiation therapy with radiation ± neck dissection for tonsillar carcinoma. Despite comparable counts for 5-year survival and locoregional control, they criticize higher complication rates in the surgery group, although the data indicate that almost all fatal complications resulted in studies with radiation therapy performed before the surgery.[102] Salvage surgery in the tonsillar region after primary radiation is accompanied by high mortality and low 5-year survival rates. One investigation by Gehanno and colleagues[103] showed a 5-year survival of 24% and a mortality rate as high as 8% in 120 patients. Two investigations support the idea of brachytherapy salvage in this area with 5-year survival rate of 64% and a 2-year survival rate of 42%, respectively.[104,105]

In general, the clinically negative neck should be treated in case of an incidence of occult metastasis of 20% or higher.[106] In patients with carcinoma of the tonsillar region, ipsilateral elective *neck dissection* is commonly performed even for small lesions and clinically negative necks. The latest considerations about neck dissections in clinically negative necks and the more selective surgery (e.g., sparing level IIb) have significantly reduced comorbidity and improved patients' outcome.[107] Postoperative radiation is often recommended in case of positive nodes, although prospective randomized trials exploring the role of radiation therapy after selective neck dissection are necessary.[107] On the basis of the size and location of the primary metastasis and the ongoing higher likelihood of bilateral metastases, bilateral neck dissection or radiation treatment should be considered. This is true for T3 and T4 lesions, involvement of the tongue base, and neck findings greater than or equal to cN2. However, patients with T1-2 lesions and N0/N1 might be adequately treated with ipsilateral surgery/radiation.

Base of Tongue

As with other locations of the oropharynx, *early lesions* might be treated with surgery and/or radiation therapy according to the literature. Published study results show that local control and survival do not significantly differ between the two modalities. Again, the functional outcome is an important factor to be considered in the decision-making process. Modern surgical applications such as transoral laser surgery have significantly improved surgical treatment and reduced morbidity.[108] Latest investigations demonstrate highly effective surgical treatments with good functional outcome using transoral laser techniques. Grant and colleagues treated 59 patients with primary cancer of the base of tongue, among whom 11 had stage I and II disease. Their locoregional control for the entire patient collective was as high as 88%, and their recurrence-free survival was 84% with excellent postoperative function results measured.[109] Steiner and colleagues reviewed 48 patients, 94% of whom were in stage III and IVA. The Kaplan-Meier 5-year recurrence rate was 20% and overall survival was 52% for T3 and T4 lesions. For T1 and T2 lesions, however, there was no local recurrence after 5 years and overall survival was 73%.[110] New operative systems with even further chances of improvement like the transoral robotic surgery have been shown to be suitable and are under further evaluation.[111] More extensive surgical procedures like transhyoid pharyngotomy or mandibulotomy are commonly reserved for patients with larger lesions. Radiation therapy is often performed as combination of external beam radiation therapy and brachytherapy with an interstitial 192-Iridium implant.[63] Primary radiation therapy ± neck dissection without brachytherapy implant showed varying local control rates between 78% and 96% for T1 and 47% and 88% for T2 lesions.[112-115] Others used external beam radiation in combination with brachytherapy implants and reported local control rates between 71% and 100% for T1 and T2 lesions.[116-118] Houssett and colleagues compared surgery plus adjuvant radiation therapy, external beam radiation therapy plus 192-Iridium implant, and external beam radiation alone on stage T1 and T2 base of tongue carcinoma. They found comparable results for surgery plus adjuvant radiation and external beam radiation plus implant, although external beam radiation therapy alone showed an unacceptable failure rate twice as high as in the other two groups.[113]

Advanced disease of the base of tongue can be managed with two therapeutic strategies, one of which is resection with adjuvant radiation ± concomitant chemotherapy. Advances in oropharyngeal reconstruction in the past 2 decades can ensure good function and improved quality of life even when ending up with large defects of the tongue base and surrounding tissues.[119] Zelefsky and colleagues performed a 7-year follow-up on 51 patients with carcinoma of the tongue base who received surgery and postoperative radiation therapy, most of those with T3 and T4 cancers. Their local control rate was as high as 94% and 75% in patients with T3 and T4 lesions, respectively. The disease-free survival for all patients was 64% after 7 years and the likelihood for distant metastases was 30%.[117,120] Concurrent chemoradiation therapy has been shown to significantly improve local control and disease-free (59% vs. 41%) and overall survival (65% vs. 49%) compared with conventional radiation in a study by the European Organization for the Research and Treatment of Cancer (EORTC) reported by Bernier and colleagues in 2001. Acute toxicity (e.g., mucositis) was higher in the chemoradiation group, although chronic toxicity was comparable.[101] In case of persistent or recurrent disease, surgical and radiotherapeutic modalities were evaluated. One study from 1980 performed by Pradhan and colleagues[121] reported unsatisfying results after aggressive salvage surgery in most cases. However, on the basis of when the study was performed, this investigation contains many negatively affecting components that must be considered. Encouraging results were published by Grant and colleagues in 2006. They investigated patients with recurrent and residual disease showing local control rates of 75% and an overall survival of 54% after 2 years.[122] Other groups have performed after-loading techniques with Iridium-192 in patients treated with radiation therapy ± surgery earlier. One group achieved local control in 59% and actuarial survival of 48%,[123] and others achieved local control of 61% in base of tongue cancer patients.[124] However, residual or recurrent disease of the tongue base remains a demanding therapeutic problem.

As for tonsillar carcinoma, tongue base lesions should be treated with elective, selective, modified radical, or radical *neck dissection,* depending on their clinical stage due to the high propensity of such cancers to lymphatic spread. Clinically negative necks should be treated less extensively to achieve reduced morbidity. Levels considered are II to V for base of tongue SCC. In case of primary chemoradiation therapy the neck is included in the planning, depending on the neck stage. In N2 to N3 disease some authors discuss planned neck dissection after surgery on the basis of the risk for residual occult disease.[125] Cupino and colleagues favored neck dissection before definite primary chemoradiation in stage IV oropharyngeal cancer patients. Their small population of 25 patients had an actuarial locoregional control rate of 88% and an actuarial overall survival rate of 92% after 3 years.[126] Independent from the modality used, the high incidence for bilateral occult or evident lymphatic disease commonly demands bilateral neck treatment.

Oropharyngeal Wall

Early lesions of the oropharyngeal wall can be treated with surgery and/or radiation therapy. Transoral conventional or laser surgery ± radiation therapy has shown to be a valid therapeutic option with low morbidity to the patients. In case of positive nodes surgery is commonly followed by radiation therapy ± chemotherapy. However, definitive radiation therapy is also sometimes used for small oropharyngeal lesions. An early analysis performed at M. D. Anderson Cancer Center showed survival rates of 71% (T1) and 73% (T2) using radiation therapy.[127] In another early study from 1978, Marks and colleagues[128] compared results for patients treated with radiation followed by surgery and those treated with definite radiation alone and found discouraging 17% survival for both groups and high complication rates for the group receiving surgery after radiation.

Most *advanced lesions* of the oropharyngeal wall are treated with surgical resection of the primary, bilateral neck dissection, and postoperative radiation therapy ± chemotherapy. Using modern reconstructive options, acceptable function often can be achieved. A retrospective analysis of posterior pharyngeal wall cancers by Spiro and colleagues[129] showed 5-year survival rates ranging from 15% to 44% depending on tumor staging after surgical treatment with or without radiation therapy. However, in some cases resectability is not given and definitive chemoradiation therapy is applied. Some might use definitive radiation with addition of neck dissection. For posterior wall lesions the close proximity to the spinal cord is challenging for radiation planning and application.[63]

In oropharyngeal wall cancers, lymphatic distribution and spread of disease is of particular concern for the treating physician. Retropharyngeal and parapharyngeal nodes can be difficult to access and likelihood of bilateral spread is high. Therefore in those cancers adjuvant radiation therapy after bilateral *neck dissection* is often indicated. As with all oropharyngeal cancers, the neck should be addressed by neck dissection bilaterally in case of clinically evident disease. In case of a high propensity of contralateral lymphatic spread and clinically negative nodes on this side, radiation therapy without surgery can be considered.

Surgical Approaches

The choice of the adequate surgical approach depends on the location and size of the lesion to be resected. Whereas most oropharyngeal lesions can be approached transorally using adequate surgical devices, some larger lesions or tumors located close to the supraglottic and hypopharyngeal area might require wider exposure using lateral or transhyoid pharyngotomy, mandibula swing, or split approaches. Especially large cancer resections with following flap reconstruction might call for open approaches. In case of neck dissection, the approach selected must be considered when planning the neck incision. However, the surgical approach chosen also depends on the surgeon's experience and preference.

Transoral Approach

Most oropharyngeal lesions can be removed transorally. This is a minimally invasive approach, suitable for most small- and medium-sized lesions and even larger lesions in the upper part of the oropharynx. Necessary exposure can be achieved using the Stierlen (Fig. 100-18), McIver, Kastenbauer (Fig. 100-19), or Dingman mouth gag or endoscopes such as the Kleinsasser or Steiner for laser surgery of tongue base or deeply located lesions (Fig. 100-20).

The laser surgical approach either via microendoscopy or using a laser hand device is an excellent tool for oropharyngeal cancer resection

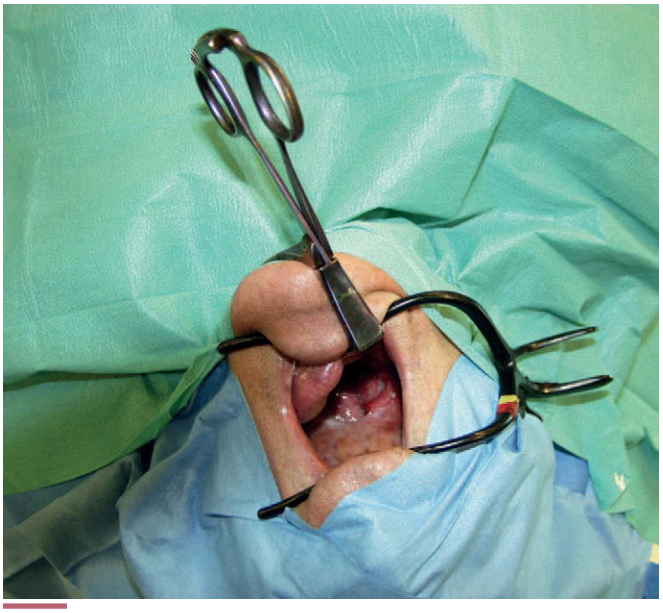

Figure 100-18. Exposure of a recurrent carcinoma of the left soft palate and tonsil using the *Stierlen* mouth gag. Tumor resection was performed, as well as implantation of a radial forearm flap for reconstruction, via this access.

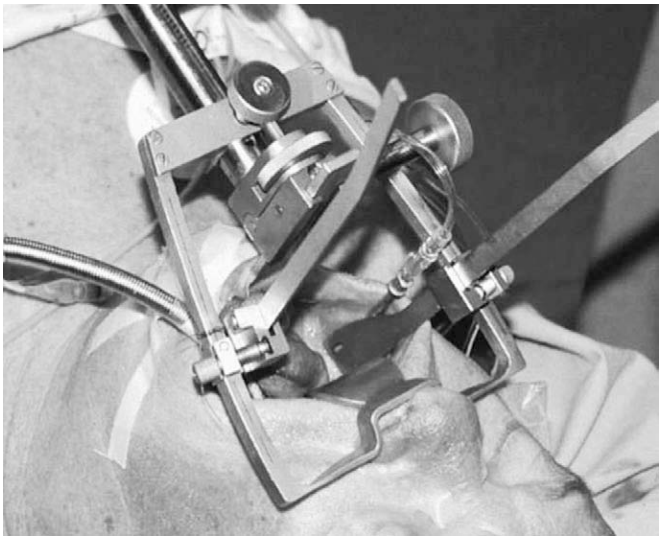

Figure 100-19. Transoral exposure using the *Kastenbauer* mouth gag.

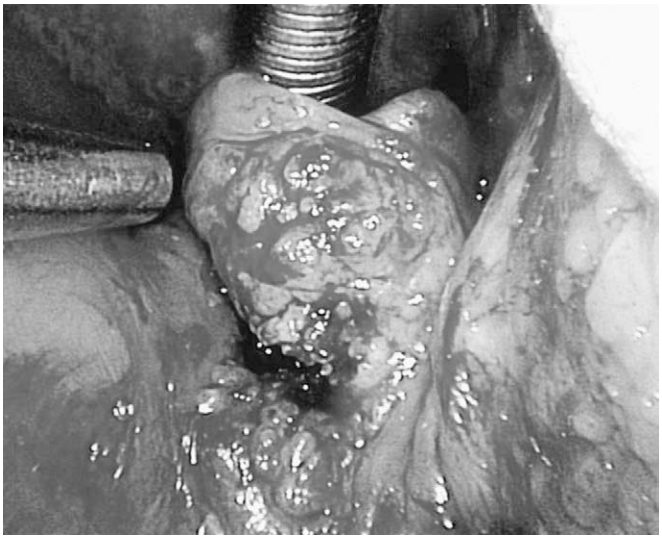

Figure 100-20. Transoral laser resection of a tongue base and epiglottic tumor.

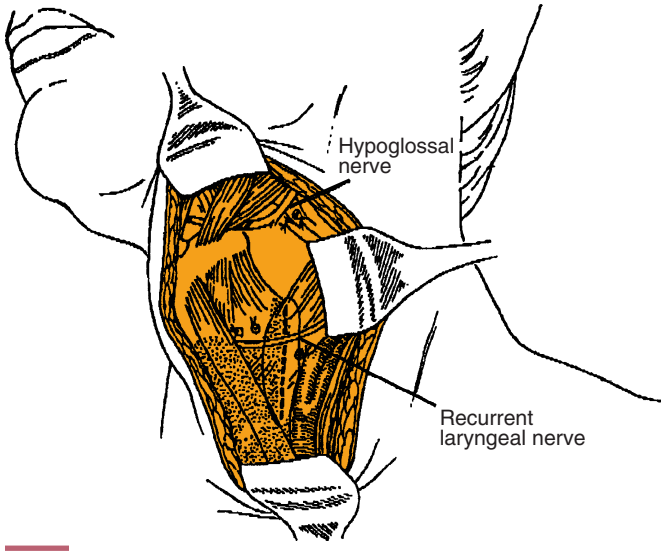

Figure 100-21. The epiglottis and tongue base are exposed through a lateral pharyngotomy approach. *(From Carrau RS. Lateral pharyngotomy. In: Myers EN, ed.* Operative Otolaryngology: Head and Neck Surgery. *Philadelphia: WB Saunders; 1997:242. Used with permission.)*

with minimized morbidity to the patient.[130] Other adequate options are electrocautery and cold knife or scissor. Using the CO_2 laser, lesions of the soft palate, tonsil, pharyngeal wall, and tongue base can be resected (see Fig. 100-20). Depending on the individual skills of each surgeon, larger lesions involving more than one subsite can be resected with the laser. In case of involvement of the lateral pharyngeal wall/tonsillar fossa, depending on the depth of tumor growth, neck dissection should be addressed first. The medial portion of vessels such as the carotid can be easily protected with sponges before transoral laser resection. Laser surgery requirements such as adequate surgical training and local precautions in the entire operating room must be met. Today's laser procedures enable minimal invasive access, reduced blood loss and morbidity, rapid secondary wound healing, and rehabilitation. Yet using electrocautery and scissors might be more suitable in selected cases.

Outcomes using the transoral laser microsurgical approach, both oncologic and functional, have proven to be excellent, even for advanced stage III and IV disease. Haughey and Rich (personal communication) have analyzed a large prospectively registered and followed group of patients (N = 84) presenting at their institution with stage III and IV oropharyngeal cancer. They found 95% locoregional control, 86% disease-free survival at 5 years (with a minimum follow-up of 2 years), and a mean functional outcome swallowing score of 1.4 (0 [best] to 5 [worst]). Feeding tubes were necessary in only six cases, five of which were introduced during postoperative adjuvant radiotherapy.

Lateral and Transhyoid Pharyngotomy

Some inferior lesions might not be accessible transorally or the patient's neck mobility might not allow for reflexion and adequate vision of the lesion. In such cases lateral or transhyoid pharyngotomy can be performed. Those approaches can be combined and variations depend on the location and size of the tumor to be resected. The conventional lateral approach would leave the hypoglossal nerve cranially and the superior laryngeal bundle inferiorly (Fig. 100-21). Attention has to be spent on where to enter the pharynx in order not to cut into tumor tissue. In those cases, preliminary endoscopy can be recommended.

Transhyoid pharyngotomy is achieved by freeing the hyoid from supraglottic musculature and entering the vallecula medially (Fig. 100-22). Again, tumor location has to be considered before entering the pharynx. The lesion is then visualized and thorough resection with adequate distance to the tumor can be performed. Separation of muscle structures like the stylohyoid or digastric muscle can further improve access to the surgical field. Using these approaches, there is no additional skin incision than that for the neck dissection and proper exposure in most cases in avoidance of lip and mandibular splitting. Yet the pharyngotomy can result in fistulas and closure of the pharynx has to be performed thoroughly inverting the mucosa using absorbable sutures.

Mandibular Swing Approach

The mandibular swing approach is commonly reserved for extensive lesions, which also often require reconstructive surgery. The incision of the skin is usually performed through the midline of the lip, followed by a zigzag-shaped line down to the mental fold, around the mentum, and continuing into the neck incision submentally (Fig. 100-23).

The soft tissue and gingiva, as well as the periosteum, are cut and the latter released from the bone only in the area of the mandibular split. Tissue must be handled carefully and later closure of the oral vestibule must be considered. A plate must be prepared to fit the contour of the mandible, and holes should be drilled and sized before mandibular splitting. The course of the dental roots must be considered before positioning the plate. The osteotomy is performed in the midline using an electric saw, although the cranial part of the mandible should be handled with an osteotomy in order of preservation of the roots of

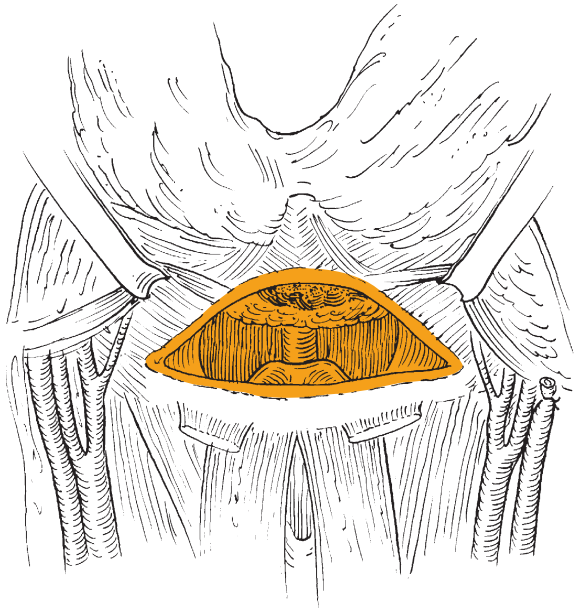

Figure 100-22. The suprahyoid musculature is released from the hyoid bone, and the vallecula is entered.

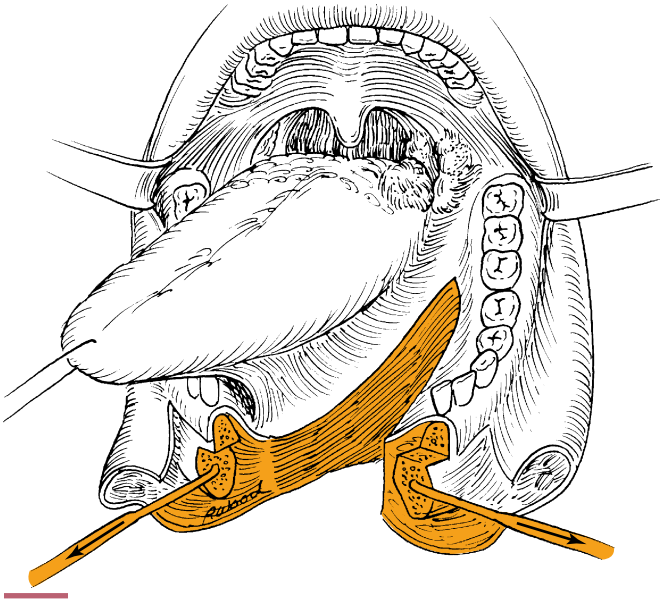

Figure 100-24. Anterior mandibulotomy may be used to expose the oropharynx. Incision along the medial aspect of the mandible is made to obtain posterior exposure. Arrows indicate direction of tissue retraction.

incisor teeth. The osteotomy can also be performed in a stair-step-like fashion. Then the floor-of-mouth soft tissues are divided and enough tissue must be left laterally toward the mandible for sufficient soft tissue closure with or without tissue transfer for reconstruction (Fig. 100-24). This approach allows the widest access to the oropharynx, although it is the most invasive. However, it might be necessary for extensive tumors and adequate exposure for resection and reconstruction. Other procedures for oropharyngeal access without mandibulotomy via the floor of mouth have been described, although indication seems limited and transoral approach might have been sufficient in the cases described.[131]

Follow-up

As with other head and neck tumors, the impact of follow-up on survival is controversial. However, it seems obvious that thorough follow-up enables early detection of possible recurrence and timely intervention with chances of further disease control. Figure 100-25 presents a suggested concept for the follow-up of oropharyngeal cancer patients. Follow-up schedules should always include the treating physician's judgment about each individual patient's compliance.

Special Treatment Considerations

Data on oropharyngeal cancer treatment remain controversial. The Scottish Intercollegiate Guidelines Network (SIGN) found that randomized controlled trials comparing surgery versus radiotherapy ± chemotherapy for the treatment of primary lesions were unavailable for both early and advanced lesions. This is also true for the treatment of the neck.[132] Although more studies were included in their analysis, the Cochrane Collaboration also criticized the lack of valid evidence for one modality or the other.[77] The assessment of existing literature must include the time frame of the investigation because many surgical and radiotherapeutic, as well as chemotherapeutic applications, have been tremendously modified in the past.

Quality of life has been hardly addressed in the Cochrane literature despite being one of the most important factors for decision making concerning therapy.[77] Selective studies offer quality-of-life assessments, yet scaling systems differ significantly and results are not comparable. Moreover, upcoming investigations should include adverse events and morbidity caused by the applied therapy. It is recommended to clearly separate studies on therapy and outcome on the basis of the exact tumor location respecting the complexity of the different head and neck subsites. Finally, treatment regimen might also be influenced by socioeconomic factors; thus elements such as length of hospital stay and costs should, ideally, be integrated in future studies.

Complications

Complications related to *surgery* may be divided into perioperative and postoperative. Possible perioperative complications include damage to blood vessels and nerves (e.g., cranial nerves V, VII, IX, X, XI, XII). Complications after surgery include fistulas, trismus, aspiration, mus-

cular dysfunction (e.g., shoulder mobility), bleeding, pain, dysphagia, and dysarthria, as well as flap loss after reconstruction. Using modern surgical approaches for the primary malignancy, employing laser techniques for selected cases and current free tissue transfer techniques for reconstruction, complications could be strongly reduced compared with earlier studies.

Complications of *radiation therapy* can be acute or chronic in nature and are influenced by concomitant therapy such as surgery and/or chemotherapy, fraction size, and way of fractionation and total dose applied. Acute side effects are commonly mucositis, dysphagia, xerostomia, loss of taste, dental impairment such as caries, pain, skin affections, hair loss, and loss of sebaceous gland functions. Additional late complications may include osteoradionecrosis and affected ability of wound healing in radiated fields. Modern applications such as intensity-modulated radiation therapy (IMRT) and improved technique resulted in reduced complications after radiation, although patients are frequently affected by lasting dysphagia, xerostomia, and altered sense of taste or recurrent mucositis, especially after doses exceeding 60 Gy for definitive treatment.

Prognostic Factors

TNM status, general performance, and gender are known influential factors for prognosis in oropharyngeal cancer patients.[91,133] Aebersold and colleagues[134] found intratumoral microvessel distribution to effect local control and overall survival using definitive radiation therapy with unfavorable high microvessel density. In case of proliferating cell nuclear antigen (PCNA) and vascular endothelial growth factor (VEGF) receptor, no predictive effect was investigated in patients with oropharyngeal cancer independent from the treatment modality used. A high Ki-67 labeling index was found to be linked to a reduced time interval until relapse of disease after surgery and adjuvant radiation.[134-136] Several studies have analyzed the negative impact of anemia on radiation therapy.[133,137] Also, hypoxia measured in lymph node metastases from head and neck cancers reduced the response rate for radiation and chemoradiation therapy.[138-140] Many other molecular markers such as EGFR and DNA-repair enzymes are currently under investigation. Regardless of these tested markers, one of the most important predictive factors seems to be the exposure to exogenous risk factors such as tobacco and alcohol, before and following treatment. Patient compliance must also be considered for future outcome. Different reviews have been performed to explore the effect of delay in commencing postoperative radiotherapy on patient's outcome. Although it remains vague whether outcome is significantly impaired by a delayed postoperative radiotherapy, there is some evidence supporting time intervals between surgery and radiotherapy not to exceed 6 to 8 weeks.[141,142] However, such prognostic factors are important for the evaluation of the ideal treatment modality and must be taken into account in the judgment of outcome in existing clinical studies.

Quality of Life

Quality of life is the major key for judgment of therapeutic success besides evaluation of locoregional control and survival. As mentioned earlier, multiple variants for life quality assessment exist and comparability is low. However, the importance of the issue has tremendously grown for head and neck cancer patients in the past and studies including objective criteria are necessary in order to compare the impact of different treatment modalities on patients' quality of life. In acknowledgement of the problem, the International Classification of Functioning, Disability and Health (ICF) supported by the World Health Organization in 2007 initiated an international consensus meeting on head and neck cancer and developed a core set for this patient group. In future studies, this core set will enable a standardized quality of life assessment for head and neck cancer patients.[143]

CHAPTER ONE HUNDRED AND ONE

Reconstruction of the Oropharynx

S. Mark Taylor

Bruce H. Haughey

Key Points

- Oropharyngeal reconstruction is complex, but an organized systematic approach using the reconstructive ladder aids the surgeon in the decision-making process. The simplest reconstruction that results in the highest level of function should be chosen.
- The size and location of the oropharyngeal defect combined with patient-related factors such as age and comorbid status determine the reconstructive technique appropriate for each patient.
- Extensive defects of the oropharynx are best reconstructed with a free tissue transfer. The neurotized radial forearm flap remains the flap of choice for these defects.
- Oropharyngeal defects involving 50% or more of the soft palate will result in velopharyngeal insufficiency. The reconstruction should address this by narrowing the caliber of the velopharyngeal aperture.

The complexity of the human upper aerodigestive tract renders oropharyngeal reconstruction one of the most challenging tasks in the field of head and neck surgery. Successful reconstruction requires detailed knowledge of the normal anatomic and physiologic mechanisms of swallowing and velopharyngeal competence that exist in this area, in combination with the surgical expertise and insight to execute various techniques for a multitude of defects. This chapter discusses the various options for reconstruction of oropharyngeal defects and the decision-making process the surgeon must go through when encountering specific defects in this area.

Oropharyngeal reconstruction has gone through several stages in the past 25 years. Reconstruction of this area before the advent of the pectoralis major flap proved difficult and was commonly complicated by wound infection and breakdown. First described in 1979 by Ariyan[1] and Baek,[2] the pectoralis major myocutaneous flap revolutionized head and neck reconstruction at that time and added a new dimension to our reconstructive capability. This was soon followed by the introduction of free tissue transfer with the belief that reconstructions that rendered the patient functionally and esthetically superior could now be performed. These effective reconstructions are even more important as the prognosis for advanced oropharyngeal cancer has improved.[3]

Several factors influence reconstructive decision making. First, one must consider the overall medical condition of the patient, with particular emphasis on comorbidities such as peripheral vascular disease, diabetes, previous radiotherapy, and nutritional insufficiency, because these conditions may adversely affect postoperative wound healing. A detailed medical history should be obtained to determine the patient's ability to tolerate extensive surgery. Severe coronary artery disease, chronic obstructive pulmonary disease, or poor overall functional status or prognosis may preclude a complicated time-consuming reconstruction. Instead, a reliable and more expedient reconstructive technique should be considered. The reconstructive surgeon should have a detailed preoperative discussion with the patient to determine which donor site would be most appropriate given the patient's lifestyle and expectations.

Careful three-dimensional (3D) analysis of the defect is critical at the conclusion of the ablative portion of the case. The size of the primary tumor, specifically the T stage, has been shown to directly correlate with the functional status of the patient in the postoperative period.[4,5] The soft tissue and the bony defect should be determined. The purpose of the soft-tissue reconstruction is to re-establish bulk, sensation, and a re-epithelialized passageway for respiration and deglutination. The dimensions of the defect should be measured with a ruler, or a template of the defect can be fabricated with Esmarch (Microtek Medical, The Netherlands). The subsites of the oropharynx involved should be determined. Although this chapter focuses on oropharyngeal reconstruction, these defects do not exist in isolation. Factors such as laryngeal and mandibular arch preservation must be taken into account before determining the reconstruction of choice. For example, a base of tongue defect in combination with a supraglottic laryngectomy may be best reconstructed with a sensate fasciocutaneous free flap, as opposed to a musculocutaneous flap that cannot be reinnervated. Also, surgeon and hospital factors come into play in the decision-making process. A surgeon will decide on a reconstructive technique on the basis of his or her experience and level of training. Hospital factors include the availability of an intensive care unit experienced in monitoring head and neck patients with free flaps, microsurgical instrumentation, and appropriate paramedical staff for rehabilitation.

Cost has also become a factor in recent times. Managed care has affected most American centers, and more cost-effective methods of reconstruction are often stressed elsewhere. The use of free tissue transfer for oropharyngeal reconstruction has been compared with pedicled soft tissue transfer. These studies have demonstrated that the operative costs are higher in the free flap group; however, the overall costs are lower compared with the pectoralis major flap.[6,7] A more recent study, however, showed no evidence that cost or morbidity differed in the two groups.[8] In other areas where universal health care systems are in place, operative time and long waiting lists may dictate which form of reconstruction is used. All things being equal, however, the most important determining factor should be the resultant quality of life for the patient. The method of reconstruction chosen must give the patient the best chance of re-establishing an oral diet, intelligible speech, and a stable airway without cannulation. It has been shown that quality of life and

functional status can be restored at 6 months after microvascular reconstruction for advanced (T3, T4) oropharyngeal cancers, and most have improved post-treatment scores at 1 year.[9]

Options for Reconstruction

Various reconstructive options are available for defects of the oropharynx. It is helpful for the surgeon to consider the reconstructive ladder and to work through the possible techniques for a given defect (e.g., soft palate versus base of tongue, starting with the simplest and progressing to the more complicated) (Fig. 101-1). The simplest method of reconstruction that achieves the highest level of function should be chosen.

No reconstruction by tissue graft or transfer, i.e., healing by secondary intention, is the simplest form of reconstruction. This is not commonly used for open approaches, given the size and complexity of most oropharyngeal defects; however, both authors have used this as their method of first choice after transoral laser resections of the tonsil and base of tongue, as well as smaller soft palate defects. It is successful even for deep resections extending into the parapharyngeal space. Healing by secondary intention can be used for small defects typically less than 4 to 5 cm, although it is not advisable when the oropharyngeal wound communicates with the neck. The advantage of this method is in its simplicity and the tendency of the granulating bed to mimic the native tissue when fully healed. The main disadvantages are the contracture and tethering that can occur when unopposed surfaces heal. This can be particularly a problem when used for larger resections of the tonsil that are taken down to the parapharyngeal fat pad, and/or forward into the retromolar trigone, mainly because of anterior displacement of the soft palate, resulting in velopharyngeal incompetence. Healing by secondary intention can also be supplemented by the use of a prosthesis for obturating defects of the palate.

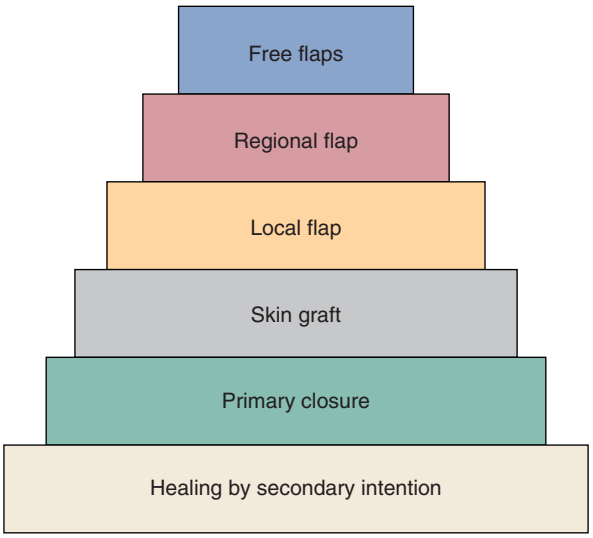

Figure 101-1. A reconstructive ladder is an organized method of working through the various options of reconstructing a defect starting with the simplest and working through to the most sophisticated. Routine use of the ladder will ensure that no possible reconstructive modalities are overlooked.

Primary closure is sometimes possible after surgical ablation of an oropharyngeal tumor. It should only be considered when a tension-free closure is obtained without distortion of the normal anatomy of the region. A prospective case-comparison study by McConnel and colleagues challenged the idea of free and pedicled flap reconstruction of the oral cavity and base of tongue. They concluded that speech and swallowing are superior with primary closure for defects of 60% or less of the tongue base.[10] Although there are inherent flaws in the study and the defects addressed were small, their findings bring to light the need for objective research on reconstructive efforts of the oropharynx and its effect on speech and swallowing.

Skin grafts can be used effectively for small defects of the posterior pharyngeal wall that are not amenable to primary closure. A bolster dressing is used to decrease shearing forces on the graft, and a tracheotomy should usually be performed in conjunction with this. Skin grafting can also be used in combination with healing by secondary intention. The graft is used in critical areas such as the glossotonsillar sulcus to decrease contracture formation and to maintain tongue mobility.

Local Flaps

Local flaps have not gained popularity for oropharyngeal reconstruction. Tongue flaps are of historical interest and are mentioned here only to be discouraged. The flap is performed by dividing the anterior tongue and then rotating it posteriorly into the surgical defect. It is clear that the use of this flap leads to restriction in the mobility of the remaining tongue and leads to impaired oral and oropharyngeal function.[11,12]

By comparison, the palatal island flap does have a role in oropharyngeal reconstruction.[13] The flap is composed of hard palatal mucoperiosteum and is based on a single greater palatine artery (Fig. 101-2). It is performed by sharply incising the mucoperiosteum of the hard palate approximately 1 cm medial to the maxillary alveolus. A periosteal

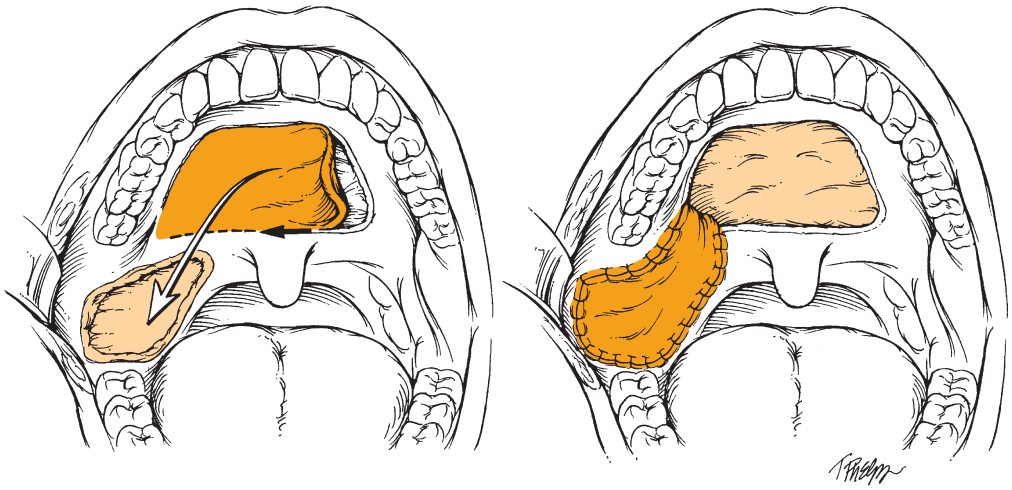

Figure 101-2. The palatal island flap consists of hard palatal mucoperiosteum pedicled on a single greater palatine pedicle. It is ideal for reconstructing limited defects of the soft palate, tonsil, and retromolar trigone. *(Adapted from Gullane PJ, Arena S. Palatal island flap for reconstruction of oral defects.* Arch Otolaryngol. *1977;103:598.)*

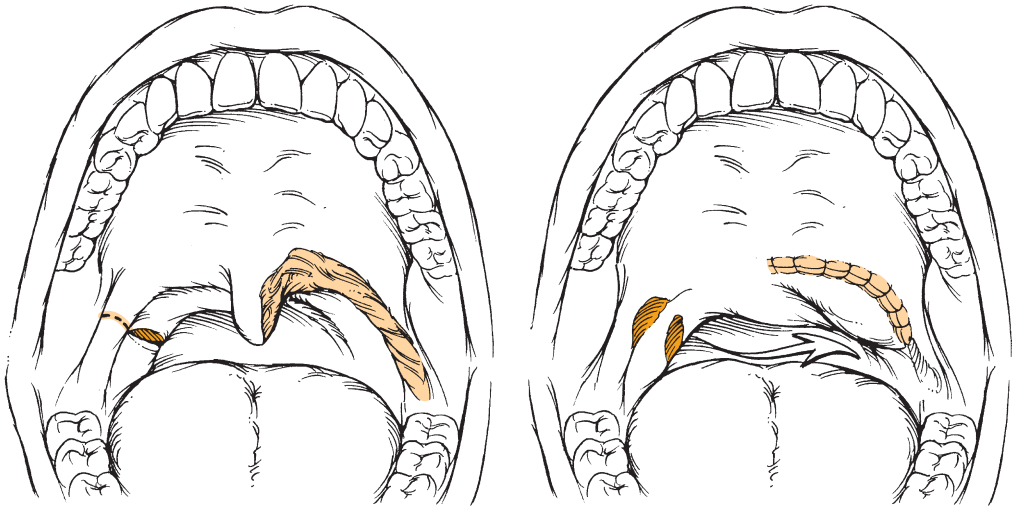

Figure 101-3. Uvulopalatal flap. Lateral defects of the soft palate are amenable to reconstruction with this technique. The flap consists of the uvular remnant that is transposed into the defect after a releasing incision is made in the contralateral tonsillar pillars. Most of the uvula and the contralateral soft palate must be intact for this flap to be used. *(Adapted from Gillespie MR, Eisele DW. The uvulopalatal flap for reconstruction of the soft palate.* Laryngoscope. *2000;110:613.)*

elevator is then used to elevate the flap, and the base is narrowed accordingly. The hard palate is left to remucosalize. The flap provides thin but relatively nonpliable tissue for reconstruction.

The uvulopalatal flap can be used for limited lateral soft palatal defects.[14] Most of the uvula and the contralateral soft palate must be intact for this flap to be used. The uvula is denuded of its mucosa and is then rotated into the defect (Fig. 101-3). A releasing incision is made in the contralateral anterior and posterior tonsillar pillars to increase the arc of rotation. Other local flaps such as inferior and superior pharyngeal flaps, the superior-constrictor advancement-rotation flap (SCARF), and the buccinator myomucosal flap, should also be considered as local flap options for palatal defects,[15,16] but all must be measured against the gold standard procedure for through-and-through defects, which is the folded radial forearm flap.

Regional Flaps

Before the advent of free tissue transfer, oropharyngeal reconstruction was most commonly performed with regional flaps. Currently, these flaps remain an excellent option for selected defects of the oropharynx because they are reliable and relatively easy to harvest. The pectoralis major flap has served as the workhorse of head and neck reconstruction for more than 2 decades (Fig. 101-4). The flap is based on the thoracoacromial artery, which originates from the second part of the axillary artery. It passes medial to the pectoralis minor and courses on the undersurface of the pectoralis major muscle. The lateral thoracic artery may contribute to the blood supply of the flap as well.[17] The flap can be used as a myocutaneous or a myofascial transfer.[18] The bulk of the flap can make it difficult to fold into a complex oropharyngeal defect, and this flap is therefore not the technique of choice at most centers.

The platysma myocutaneous flap was initially proposed for oropharyngeal reconstruction in 1978.[19] The flap has not gained wide acceptance in the literature, and many believe it is an underused technique for head and neck reconstruction (Fig. 101-5). Koch[20] reported on 34 patients who had this flap performed for head and neck defects. Postoperative fistula formation was noted in five patients (15%), and flap desquamation was seen in six cases (18%). Donor site complications were rare, with two cases developing distal skin loss at the closure site. Complications were not related to previous radiation. The platysma myocutaneous flap is based on the submental branch of the facial artery. Ligation of the facial artery during neck dissection does not compromise the blood supply to the flap.[12,21] The flap can be harvested in 20 to 30 minutes and can be done with or without a neck dissection. It provides a thin, pliable skin paddle that is ideal for oropharyngeal reconstruction. The main disadvantage cited in the literature is the

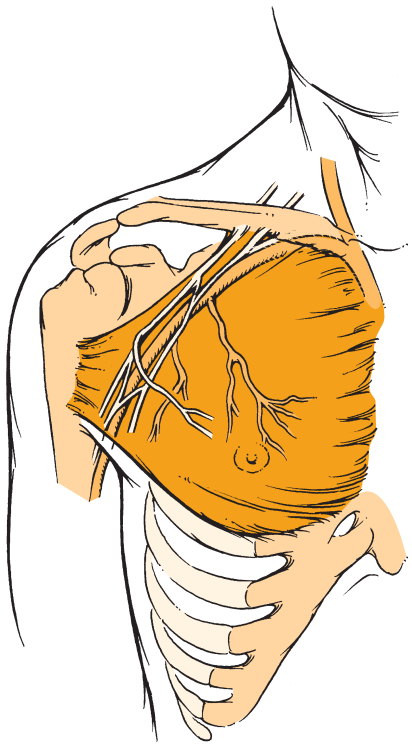

Figure 101-4. Pectoralis major flap. This flap is supplied mainly by the thoracoacromial artery, but the lateral thoracic artery also contributes to the blood supply. The lateral and medial pectoral nerves provide motor supply to the muscle. The flap has been described as the "workhorse" flap in head and neck reconstruction because of its reliability, hardiness, and versatility. *(Adapted from Urken ML, Cheney ML, Sullivan MJ, et al.* Atlas of Regional and Free Flaps for Head and Neck Reconstruction. *New York: Raven Press; 1995:16.)*

reliability of the flap because flap-related complication rates have been reported to be as high as 40%.[22]

The temporal area provides two regional flaps for oropharyngeal reconstruction. The temporoparietal fascial flap provides thin, highly vascular tissue for reconstruction.[23] Its blood supply is based on the superficial temporal artery and vein. It can be used either as a pedicled

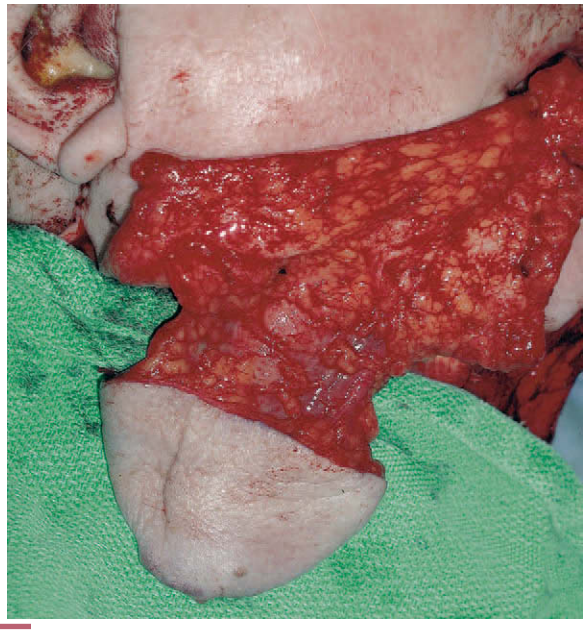

Figure 101-5. Elevation of a platysma myocutaneous flap. Note the presence of subcutaneous fat on the anterior surface of the platysma muscle in keeping with meticulous elevation of a subdermal/supraplatysmal superior skin flap. This is done along with a standard subplatysmal dissection to free the muscle and allow transposition into the defect.

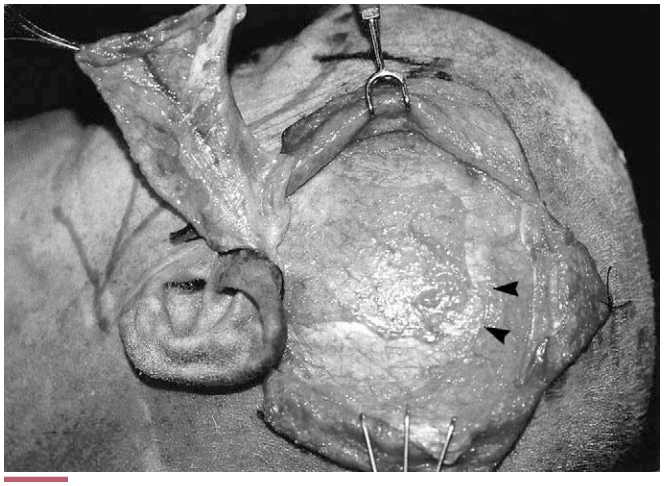

Figure 101-6. Temporoparietal flap. This flap provides thin highly vascularized tissue for reconstruction of defects of the superior oropharynx. The harvest may be extended to the vertex of the scalp or carried to the contralateral side if needed to increase flap length. It may also be used as a free tissue transfer if required. *(From Urken ML, Cheney ML, Sullivan MI, et al.* Atlas of Regional and Free Flaps for Head and Neck Reconstruction. *New York: Raven Press; 1995:207).*

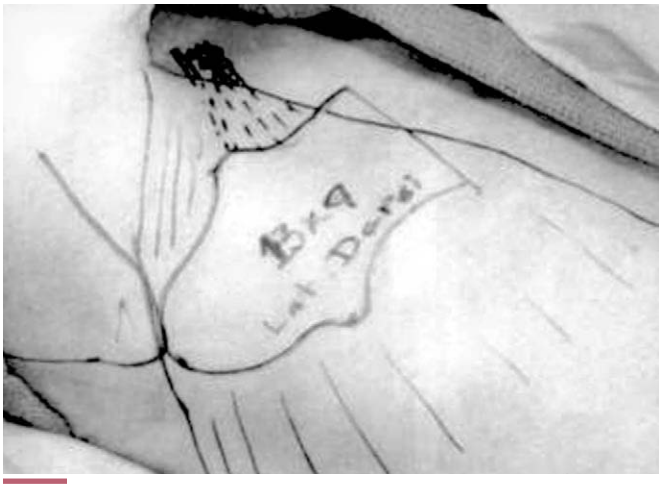

Figure 101-7. The anatomy of the latissimus dorsi muscle is shown in this patient who is in the right lateral decubitus position. The anterior limit of the muscle extends from the midaxillary line to the anterior superior iliac spine, whereas the posterior limit extends approximately 2 cm above the scapular tip. The neurovascular pedicle is shown and is usually located 8 to 10 cm from the midaxilla along the anterior border of the muscle. The skin paddle depicted demonstrates our flap design for total glossectomy defects where the skin paddle is oriented transverse to the underlying muscle. *(From Haughey B. Tongue reconstruction: concepts and practice.* Laryngoscope. *1993;103:1133.)*

or free tissue transfer if this is required to enhance inset of the flap. An outer table calvarial bone graft superior to the temporal line may also be harvested with the flap.[24] Identification of the vascular pedicle by Doppler ultrasonography is done at the initiation of the harvest. A preauricular incision is then made and is carried superiorly through the temporal scalp and can be extended to or above the vertex if necessary (Fig. 101-6). The dissection is begun superiorly just deep to the hair follicles. Care must be taken when dissecting the anterior branch of the artery because this is accompanied by the frontal branch of the facial nerve. The fascia is then divided by carrying the dissection to the level of the superficial layer of the deep temporal fascia. It is then narrowed inferiorly; at this point the anterior branch of the artery is divided close to the origin of the posterior branch of the superficial temporal artery, being aware of the facial nerve. The flap is then tunneled into the oropharynx and is sutured into the defect. A skin graft may be used on the flap but is not necessary because the surface of the flap will remucosalize. Similarly, the temporalis muscle can be tunneled into the oropharynx after removal of the zygomatic arch, which is later replaced. It is less commonly used than the temporoparietal flap because of its added bulk, limited arc of rotation, and difficult tunneling into the defect, although in experienced hands and with a fascial extension it has proved useful in soft palate and pharyngeal wall defects.[25]

The latissimus dorsi musculocutaneous flap is another viable option for reconstructing oropharyngeal defects.[26,27] It can be used either as a pedicled or free flap, especially for total glossectomy defects (Fig. 101-7). The flap is based on the thoracodorsal artery, which is a branch of the subscapular system of vessels. The subscapular artery arises from the third part of the axillary artery. The latissimus muscle arises from the thoracolumbar fascia, the lower six thoracic vertebrae, and the iliac crest and inserts onto the medial surface of the humerus. Several musculocutaneous perforators supply the overlying skin and are more abundant in the upper two thirds of the muscle. The flap is harvested by first incising the lateral aspect of the skin paddle and then extending this superiorly following the lateral border of the muscle into an axillary crease. The pedicle is found along the lateral border of the muscle 8 to 10 cm from the midpoint of the axilla. The medial skin paddle incision is next fashioned, and tacking sutures are placed between the skin and underlying muscle. The muscle is then divided distally and medially, and the pedicle is traced into the axilla after identifying and dividing the branch to the serratus anterior. Finally, the superior muscle cut is made protecting the vascular pedicle. If the flap is to be used as a pedicled transfer, a tunnel is made above or below the pectoralis major muscle. We have had success with a tunnel above the muscle in combination with a partial-thickness myotomy of the lateral aspect of the pectoralis major.

Less commonly, the trapezius musculocutaneous flap may be used. It is generally not a good option because trapezius muscle sacrifice leads to significant shoulder dysfunction and chronic pain. Other factors that make it an unpopular choice are the flap's limited arc of rotation and

Figure 101-8. The forearm flap is the most commonly used free flap for oropharyngeal reconstruction. The flap provides thin pliable tissue that is ideal for this purpose. We harvest the flap with a cuff of soft tissue around the pedicle to prevent kinking and also routinely incorporate the deep and superficial venous systems by preserving the communicating branch between the two.

need for patient repositioning in the lateral decubitus position. By comparison, the longus colli muscle flap can be used to reconstruct defects of the lateral and posterior pharyngeal wall.[28] There have been reports on 13 patients who had pharyngeal reconstruction with this regional technique with no postoperative fistulas. The flap is reported to have minimal, if any, donor site complications; however, three patients had postoperative Horner's syndrome, and there is a question as to whether this was related to the ablation of high pharyngeal wall tumors as opposed to a flap-related problem. Experience with the longus colli flap is limited, and more evidence is necessary before the flap can be championed for oropharyngeal reconstruction.

Free Tissue Transfer

The introduction of free tissue transfer has been the greatest advance in the area of oropharyngeal reconstruction. This technique is available at most tertiary care centers. As stated previously, reconstructive advances have not changed the prognosis for oropharyngeal cancer.[3] Quality of life and postoperative function are then paramount when deciding on reconstructive efforts. Free flap reconstruction has been found to be superior from a functional standpoint in both prospective and retrospective studies.[7,9] In the following sections, commonly used free flaps from their respective donor tissues are outlined, and details of their use are addressed.

Fasciocutaneous

The radial forearm flap is the most commonly used free flap for oropharyngeal reconstruction (Fig. 101-8). The flap was initially described in the Chinese literature. The flap is based on the radial artery and the accompanying paired venae comitantes. The cephalic vein is also routinely incorporated into the flap and serves as the superficial venous drainage system. The lateral antebrachial cutaneous nerve provides sensation to the forearm skin, and the flap can be successfully neurotized to improve pharyngeal sensation.[29] Sensory recovery is also present in most patients even when a neural anastomosis is not performed, and more commonly occurs in fasciocutaneous flaps than musculocutaneous flaps.[30] This reinnervation is, however, often incomplete and unpredictable, and it is not valid to rely on spontaneous sensory recovery of free flaps in oral and oropharyngeal reconstruction.[31] The skin paddle of the forearm flap is thin and pliable and thus makes it ideal for a variety of oropharyngeal defects. In fact, because of its thinness it can be used for reconstruction of large defects after transoral resections, inset through the mouth albeit with greater technical difficulty. It can be elevated either deep or superficial to the investing fascia of the forearm, depending on the bulk required. A preoperative Allen test should be performed on all patients. The flap is elevated under tourniquet control. The skin paddle is incised along its ulnar, distal, and radial aspect. The flap is then elevated at the desired level, preserving the sensory branches of the radial nerve. The level of dissection is taken to the subfascial level as the pedicle is approached. The pedicle is then identified between the medial head of the brachioradialis and the flexor carpi radialis and is then divided. A lazy S-shaped incision is fashioned into the antecubital fossa, and the cephalic vein is incorporated into the flap, leaving a generous cuff of fat and fascia to prevent kinking. An external skin monitor can be incorporated into the flap proximally if the main skin paddle is not visible for evaluation.[32] The radial artery is dissected to its origin and is divided distal to the radial recurrent artery. We routinely incorporate the deep and superficial venous systems and generally have two veins for performing venous anastomoses. The donor site is covered with a split-thickness skin graft, and a bolster and cast is left in place for 1 week.

The lateral thigh free flap is another commonly used fasciocutaneous flap for oropharyngeal reconstruction. It was first described by Baek[33] in 1983 and has since been used extensively in the head and neck with excellent results. Hayden[34] reported a 98% success rate in 43 pharyngeal reconstructions, of which 11 were used in the oropharynx. The flap is usually based on the third perforator of the profunda femoris artery, which terminates in the intermuscular septum between the long head of the biceps femoris and the vastus lateralis. Occasionally, the second or fourth perforator will serve as the dominant blood supply to the flap. The lateral femoral cutaneous nerve provides sensation to the skin of the lateral thigh and may be incorporated into the flap. The flap is typically harvested as an ellipse of skin whose epicenter is based on the midpoint of the intermuscular septum between the greater trochanter and the lateral epicondyle of the femur. The dominant perforator is identified in the subcutaneous plane and is then traced through the biceps femoris to the main pedicle. Release of the adductor magnus from the linea aspera assists dissection of the main pedicle, which is divided distal to the origin of the dominant perforator and is then dissected proximally, where its diameter is usually 2 to 5 mm. Paired venae comitantes serve as the venous drainage of the flap. These veins typically converge before entering the deep femoral vein, and this vein ranges in size from 3 to 5 mm. The advantages of this flap are the ability to close the donor site primarily and the relative separation between the ablative site and the donor site, which tends to assist a simultaneous harvest. The disadvantages of the flap are the prevalence of atherosclerosis in the donor artery and the variability of the donor perforators to the skin paddle.

The anterolateral thigh flap has gained recent popularity in head and neck reconstruction and is now more commonly used than the lateral thigh flap. It was first described by Song and colleagues in 1984 and has been used extensively in Asia ever since.[35] The flap is most often supplied by perforating vessels arising from the descending branch of the lateral circumflex femoral artery. This artery courses in the intramuscular space between the vastus lateralis and rectus femoris muscles and provides musculocutaneous and septocutaneous perforators to the overlying skin of the anterolateral thigh. The flap can be harvested as a subcutaneous, fasciocutaneous, myocutaneous (a portion of the vastus lateralis muscle may be incorporated for ease of harvest or to increase bulk), or adipofascial flap, giving this flap the required versatility for reconstructing a variety of head and neck defects.[36] The advantages of this flap are its versatility, as mentioned previously, a potentially long vascular pedicle (16 cm) of excellent caliber (2 to 3 mm), low donor site morbidity, and the ability to harvest the flap simultaneously with an ablative team. The main disadvantage relates to the variations in the vascular pedicle, which may exist at the time of harvest.[36] Also, with the incidence of obesity in Western countries the flap donor is bulkier; thus the flap has not gained widespread use in North America[37] and is usually too thick for base of tongue or palatal reconstruction. Wei and colleagues reported on their experience with 475 anterolateral thigh free flaps used for defects of the head and neck.[38] The overall flap survival rate was approximately 95%. The authors concluded that the thigh flap has potential in many Asian patients because it is as thin as the forearm flap and has essentially replaced the forearm flap at their center.

The lateral arm flap was described by Song in 1982 and was specifically applied to head and neck reconstruction by Sullivan 1 decade later.[39,40] Civantos[41] reported on the use of this flap in 28 head and neck defects, of which 14 encompassed the oropharynx. The flap success rate in this series was 100%. The authors concluded that this

flap is ideal for oropharyngeal reconstruction because it incorporates thin skin from the proximal forearm, which is ideal for reconstructing the pharyngeal wall, and thick skin from the upper arm, which can be used in the tongue base where additional bulk is sometimes required. The flap is supplied by the posterior radial collateral artery, which is a terminal branch of the profunda brachi artery. It courses in the lateral intermuscular septum between the triceps posteriorly and the brachialis and brachioradialis anteriorly. Sensation to the flap is provided by the posterior cutaneous nerve of the arm. The flap is harvested from the nondominant arm without the use of a tourniquet. The desired skin paddle is based on the lateral intermuscular septum that topographically is located between the lateral epicondyle and the V-shaped insertion of the deltoid on the humerus. The flap can also be extended distally over the upper forearm to achieve additional pedicle length. The pedicle is identified between the previously described muscles and is divided distally. The radial nerve is identified along the anterior aspect of the pedicle and is preserved, dissecting free the posterior cutaneous nerve of the arm. The deltoid is released, and the radial nerve and pedicle are followed into the spiral groove. The pedicle is then divided at this point. Wide undermining of the skin is performed, allowing for primary closure of the donor site in most cases. The main advantage of this flap is that the feeding vessels are terminal and nonessential for perfusion of the arm. Also, the donor site may be closed primarily and may be more aesthetically pleasing than the forearm flap. The disadvantages of the lateral arm flap are the risk to the radial nerve and the relatively small caliber of the donor vessels.

Visceral Tissue Free Flaps

Jejunum, gastric wall, and colon are sources of free tissue that have been described in oropharyngeal reconstruction. The jejunum and colon segments are split along their antimesenteric borders to form a flat patch. Examples of split jejunum used for palatal reconstruction are seen in Figures 101-9 and 101-10.

Musculocutaneous Flaps

The latissimus dorsi myocutaneous free flap is our flap of choice in this category. The anatomy of the flap and the technique of harvest have been described previously in the regional flap section. The authors have found this flap most useful after total glossectomy. One of the authors (BHH) has described a useful technique of using an innervated latissimus myocutaneous free flap for reconstructing total glossectomy defects.[42] The skin paddle is designed at a right angle to the course of the underlying muscle (see Fig. 101-7). The muscle is inset as a transverse sling on the undersurface of the mandible by suturing it to the remnant of the pterygoid, masseter, or superior constrictor, depending on what is available. The thoracodorsal nerve is then anastomosed to a suitable hypoglossal nerve, usually ipsilateral to the microvascular anastomoses. This gives the reconstructed tongue the ability to elevate superiorly toward the palate, thus enhancing the swallowing mechanism.

The rectus abdominis free flap is another viable option for selected defects of the oropharynx. It, too, has been used extensively for total glossectomy defects,[43-45] although it lacks the potential for convenient motor reinnervation. The flap is based on the deep inferior epigastric artery and vein, which provide several myocutaneous perforators that traverse the rectus muscle and terminate in the periumbilical skin. The skin paddle is designed with its epicenter above and lateral to the umbilicus because myocutaneous perforators are more abundant in this area. The superior portion of the skin paddle is incised, and the dissection is taken through the anterior rectus sheath to the underlying muscle. The fascia is then split vertically above the skin paddle to the costal margin. The lateral and inferior portions of the skin paddle are next incised, and the dissection is once again taken to the fascial level. A small cuff of anterior rectus fascia is preserved medially and laterally, taking care not to disrupt the cutaneous perforators. The fascia is then split vertically down to the pubic region. The rectus muscle is divided superiorly, taking care to ligate the superior pedicle. The muscle is then dissected free from the posterior rectus sheath, and the dissection is then taken below the arcuate line, noting that the posterior rectus sheath is absent below this level. The vascular pedicle is identified below the arcuate line along the lateral deep aspect of the muscle. The inferior portion of the muscle is divided after a tunnel is made between the pedicle and the overlying muscle. The pedicle is then dissected inferiorly to its origin off the external iliac system. The anterior rectus sheath is reconstructed with a patch of Gore-Tex or Mersilene mesh, whereas the cutaneous defect is closed primarily after wide undermining of the abdominal skin. The flap is highly reliable in the head and neck. A review of 73 flaps used in the head and neck revealed only one flap failure.[46] The vascular pedicle is long and of excellent caliber. The flap can be easily harvested and can be performed simultaneously with the ablative team. The main disadvantage of this flap is the donor site morbidity, progressive flap muscle atrophy, and the chance of abdominal wall herniation.

Osteocutaneous

Free osteocutaneous flaps are not generally used in isolated defects of the oropharynx. However, as stated previously, these defects often accompany other sites in the head and neck. These flaps are commonly used for extensive mandibular defects that extend to the central segment of the mandible or that portion anterior to the mental foramen. Our flap of choice for anterior mandibular defects has been the fibular osteocutaneous flap. Other widely used flaps for this purpose are the iliac crest and scapular flap. These defects are not addressed in this chapter. Lateral mandibular defects, however, are commonly found in combination with oropharyngeal defects, particularly in the case of retromolar trigone primary tumors. These mandibular defects are effectively reconstructed with a soft tissue flap with or without a mandibular reconstruction plate. A recent study at the M. D. Anderson Cancer Center specifically addressed posterior mandibular defects reconstructed with vascularized bone compared with those reconstructed with a free soft-tissue flap.[47] They report that vascularized bony reconstruction of posterior mandibular defects results in superior speech, diet, and midline symmetry. The rectus abdominis free flap was used in 75% of the soft tissue reconstructions, which may have provided too

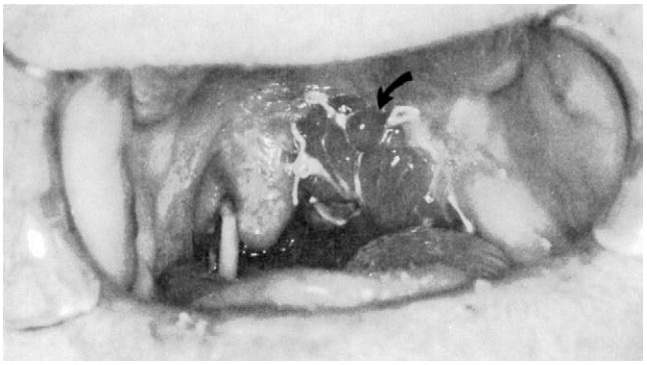

Figure 101-10. Palate and pharyngeal wall reconstruction 2 days postoperatively. *Arrow* depicts jejunal tissue. (From Haughey BH. The jejunal free flap in oral cavity and pharyngeal reconstruction. *Otolaryngol Clin North Am.* 1994;27:1159-1170.)

much bulk for adequate function. Also, the group failed to perform detailed analysis of the oropharyngeal portion of the defect and the radiation protocols used on the cohort of patients. The authors' preference has been to reconstruct all defects of the pharynx with a single flap.[48] Several others, however, recommend using a free bone flap for mandibular reconstruction in combination with a soft tissue flap for reconstructing the remainder of the defect.

Site-Specific Defects

Soft Palate

The soft palate is critical for velopharyngeal competence because it serves as a dynamic muscular structure to effectively separate the oral and nasal passageways. Ablative surgery to the area may result in hypernasal speech, with obvious air escape or nasal regurgitation of food with swallowing. These problems can be greatly improved with functional palatal reconstruction. The goals of palatal reconstruction are to recreate a functional myomucosal velum and to establish closure of the oronasal communication.[49] Several options are available for palatal reconstruction including the use of local, regional, and free flaps. Also, more conservative methods such as the use of a palatal prosthesis may be considered. Primary closure and healing by secondary intention are rarely indicated but may be considered when a marginal resection of the soft palate is performed and the muscular raphe of the palate is not violated. Skin grafting of soft palatal defects is of little use because it does not adequately reestablish the bulk necessary for through-and-through palatal defects, therefore leading to contracture and palatal dysfunction. We suggest referring to the reconstructive ladder for all defects of the oropharynx.

Prosthetic obturation is the traditional means of reconstructing palatal defects. It is available at most academic centers and is usually performed by a maxillofacial prosthodontist. It remains the method of choice for defects of the hard palate.[50] A prosthesis can also be used effectively to obturate a combined defect of the hard and soft palate or a total soft palate defect. Isolated defects of the soft palate, however, are among the most difficult to treat with a prosthesis.[51] Prosthetic rehabilitation of soft palatal defects is often functionally inferior because the prosthesis lacks the dynamic capability of the native palate.[52] Also, the prosthesis may irritate the remnant palate and result in patient discomfort and the need for multiple adjustments. Yoshida and colleagues[53] compared surgical and prosthetic reconstruction for speech disorders after ablative surgery of the soft palate. All surgical reconstructions were performed with a free radial forearm flap. They concluded that defects extending into the posterior edge of the soft palate are best reconstructed surgically because they believe patients achieve better restoration of speech and function. In cases in which a posterior band of soft palate remained, half of the patients reconstructed with an obturator had excellent restoration as tested by a standard speech intelligibility score.

If the decision is made to obturate a defect, preoperative impressions of the palate are made and the initial obturator is fabricated on the basis of the planned area of resection. The obturator is positioned in the operating room with the patient under general anesthesia after frozen section analysis of the margins has been completed, and negative margins are confirmed. The obturator can be fixated to existing teeth if available. Edentulous patients can have an upper denture made with a palatal extension to fill the defect. Patients can resume an oral diet immediately after surgery, and hospital stay is generally short. Often a subsequent interim prosthesis and finally a permanent prosthesis must be made to maximize function as the wound contracts.

Local flaps are an excellent option for reconstructing soft palatal defects in cases in which less than 50% of the palate has been resected. The uvulopalatal flap has been used successfully for marginal defects of the posterior soft palate. The uvula and contralateral soft palate must be intact for this flap to be used (see Fig. 101-3). Zohar and colleagues[49] first reported on the use of this flap in five patients to close small to moderate defects of the lateral soft palate. None of the patients had evidence of velopharyngeal insufficiency postoperatively. Zohar and colleagues concluded that the uvulopalatal flap is a technically simple technique without significant donor site morbidity and satisfies the two goals of soft palatal reconstruction. More recently, Gillespie and Eisele[14] reported on 18 patients in whom the uvulopalatal flap was used for soft palatal reconstruction. A total of 11 patients had the flap used alone, whereas the flap was used in combination with a free radial forearm flap, pectoralis major flap, and a skin graft in four, two, and one patients, respectively. All flaps survived. One flap partially dehisced but healed uneventfully. Of the 11 patients who had reconstructions with the flap alone, nine had normal speech, whereas two had mild hypernasal speech. All patients with T1 tumors had normal speech (six of six). The remaining five patients had T2 lesions. By comparison, all six patients with T1 tumors had no evidence of dysphagia, whereas 40% (two of five) of the patients with T2 tumors had dysphagia requiring G-tube alimentation. The authors concluded that postoperative speech and swallowing function depends on initial tumor stage and the extent of the resection and that the uvulopalatal flap is an effective method of soft palate reconstruction either alone or in combination with other methods of reconstruction for selected oropharyngeal defects. We have used the uvulopalatal flap successfully in our practices. One of the authors (SMT) has used this flap in combination with the platysmal myocutaneous flap for tumors of the retromolar trigone. The uvulopalatal flap is used for the soft palatal defect, and the platysmal flap is used for the lateral pharyngeal and retromolar trigone reconstruction.

The buccinator musculomucosal flap is another option for limited defects of the soft palate. Originally used in cleft palate repair and for closure of septal perforations, the buccinator musculomucosal flap has been relatively overlooked in the otolaryngologic literature. The flap was originally described by Bozola and colleagues,[54] and the vascularity of the flap was defined. The maximal flap size available is 7 cm in length by 4 cm in width. The flap is elevated in an anterior to posterior direction. Care is taken to stay 3 to 5 mm below the opening of Stensen's duct and 1 cm posterior to the oral commissure. The buccal mucosa and the buccinator muscle are incised, and the dissection is taken to the level of the buccopharyngeal fascia. Posteriorly the buccal artery, which serves as the feeding vessel, and buccinator nerve are identified and preserved (Fig. 101-11). The flap is transposed into the defect, and the donor site is closed primarily. A recent article reported on eight patients who had this flap used for reconstructing defects of the soft palate, retromolar trigone, and oral cavity.[15] The distal 3 mm of one flap underwent necrosis; however, this patient had had previous surgery at the site and was treated with radiotherapy after the initial surgery. The wound was débrided and healed uneventfully by secondary intention. Two of the eight patients had soft palatal reconstructions, and

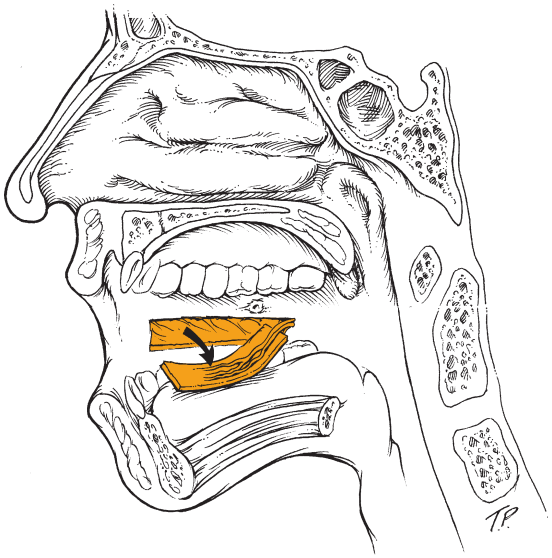

Figure 101-11. Buccinator musculomucosal flap. This demonstrates the design and anatomy of the flap. Note the proximity of the flap to the parotid duct and the oral commissure. *(Adapted from Licameli GR, Dolan R. Buccinator musculomucosal flap: applications in intraoral reconstruction.* Arch Otolaryngol Head Neck Surg. *1998;124:72.)*

both were staged as T1 tumors. The two patients had no problems with swallowing. Speech results were not reported. All patients reported light single-point touch sensation over the flap 2 weeks after surgery. The authors concluded that the flap is dependable, sensate, and has a well-defined neurovascular pedicle, which can be readily used for intraoral reconstructions. Our experience with this flap has been limited, and further studies are necessary to determine the usefulness of the flap for palatal reconstruction. A sound anatomic basis for the flap has been demonstrated by Licameli and Dolan,[15] which makes the flap somewhat promising. The main problem with the flap, however, is the limited amount of tissue available for transfer and the thinness of the flap. The main advantage of the flap is the defined sensory nerve supply to the flap, which may aid in oropharyngeal rehabilitation. Also, the flap is relatively easy and quick to harvest, with minimal donor site morbidity, and eliminates the need for extraoral reconstructions when a transoral resection has been performed.

The Superior Constrictor Advancement-Rotation Flap (SCARF) is another local flap that has been used for semisoft palate defects. The basic approach of flap design and use was initially described by Strong and colleagues[55] and Healy and colleagues.[56] More recently, Zeitels and Kim[16] have reported on the use of this flap to reconstruct defects of 35% to 65% of the soft palate. They state that the use of this flap achieves circumferential closure of the velopharynx, which reestablishes its valvular sphincteric function. The flap was used to reconstruct 10 patients with transmural defects from the paramidline posterior pharyngeal wall to the soft palate. Two cases had temporalis flaps transposed into the lateral pharyngeal wall defect in combination with the SCARF. The SCARF reestablished velopharyngeal competence in all 10 patients. Two patients required secondary procedures because of partial dehiscence of the flap. Both subsequently healed uneventfully. All patients were able to resume a normal oral diet without significant nasopharyngeal regurgitation. Three patients had evidence of mild hypernasality, but these patients were not dissatisfied with their voice quality.

The SCARF is elevated by first transecting the anterior and posterior tonsillar pillars of the residual soft palate as low as possible without violating the tongue. The lateral oropharyngeal musculature is transected as the dissection is carried toward the mandibular ramus, therefore dividing the palatoglossus, the palatopharyngeus, and the superior constrictor. A stab incision is then made in the remnant of the soft palate just medial to the pterygoid hamulus. Dissection is performed bluntly with a Kelly clamp or a hemostat deep to the superior constrictor, and finger dissection is then used posteriorly until the cervical spine is palpable and the retropharynx is reached. These maneuvers effectively mobilize the soft palate, and the cut surface of the soft palate can then be rotated superolaterally and sutured to the exposed superior constrictor on the posterior pharyngeal wall (Fig. 101-12). The remainder of the wound including the stab incision on the soft palate is left open to heal by secondary intention. A pedicled muscle flap can be used to augment the lateral pharyngeal wall if necessary. Patients are started on an oral diet in approximately 7 days. The neovelopharyngeal aperture is narrow initially but widens as the lateral pharyngeal wall heals by secondary intention. Also, the neovelopharynx is sensate and has dynamic capability. This reconstructive approach may be feasible in cases in which the resection has been performed by way of a transoral technique and no communication with the neck exists. However, it necessitates surgical interruption of adjacent, normal palate and pharynx. The authors have had limited experience with this method of reconstruction and have favored the use of free fasciocutaneous flaps to reconstruct large defects of the soft palate, tonsil, and lateral pharyngeal wall.

The palatal island mucosal flap may be considered for lateral defects of the soft palate in combination with tonsillar and retromolar trigone defects. The authors address this local flap option in "Tonsil and Pharyngeal Wall" later. Similarly, the authors would not recommend regional flap reconstruction of isolated soft palate defects, but these often occur in combination with defects of the tonsil and pharyngeal wall that are amenable to regional flap reconstruction. Because of this, they, too, are addressed later in "Tonsil and Pharyngeal Wall."

Free flap reconstruction of the soft palate has become the most common method of reconstruction at our institutions (Halifax, Nova Scotia, Canada, and St. Louis). The authors most commonly encounter these defects after extensive resections of the oropharynx for tonsillar carcinomas. The radial forearm flap has become our flap of choice for this, although other flaps that may be considered are the anterolateral thigh and lateral arm free flap. The anatomy and technique of harvest for the radial forearm flap was described earlier in the chapter. The palatal defect is measured from the nasopharyngeal resection margin to the proposed neopalatal margin and is then doubled to take into account our folding technique. The flap is designed with the distal aspect of the forearm flap used for the palatal reconstruction. The width of the distal flap is determined by the preceding measurement, and the remainder of the flap is planned accordingly. The distal portion of the flap is inset first, with the distal midpoint of the flap sutured to the inferior remnant of the soft palate (Fig. 101-13). The nasopharyngeal surface is then reconstituted by folding the flap on itself. The oral surface of the palate is then reconstructed. The authors do not routinely perform a pharyngoplasty to create an adhesion between the flap and the posterior pharyngeal wall but consider this in cases where greater than 50% of the soft palate has been resected. This method nicely reestablishes the velopharynx, but it does lack dynamic capability.

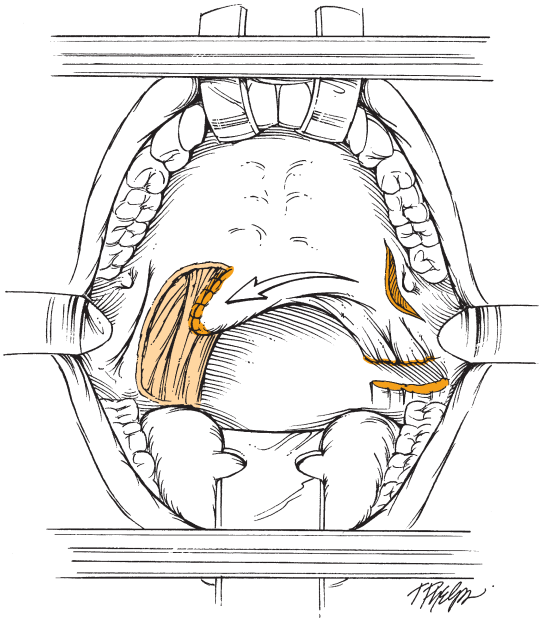

Figure 101-12. The superior constrictor advancement rotation flap is used for soft palatal reconstruction and leaves the pharyngeal wall defect to heal secondarily. Releasing incisions are made low on the contralateral tonsillar pillars and are carried through the underlying superior constrictor. A stab incision is then made just medial to the pterygoid hamulus, and further mobilization of the superior constrictor is performed through this incision. The superior constrictor is then advanced and sutured to the transected edge of the soft palate. *(Adapted from Zeitels SM, Kim J. Soft-palate reconstruction with a "SCARF" superior-constrictor advancement-rotation flap.* Laryngoscope. *1998;108:1138.)*

Another option is to use the Gehanno method in combination with a free tissue transfer as suggested by Kimata and colleagues.[57] In the Gehanno method the lateral and posterior pharyngeal wall is mobilized, and this advancement flap is turned inside out and sutured to the posterior surface of the remaining soft palate, thus reconstituting a mobile neovelopharynx.[58] The free flap is then used to patch the anterior aspect of the soft palate and lateral pharyngeal wall. Kimata recommends the use of the Gehanno method in combination with a free flap (they used the rectus abdominis musculocutaneous flap in 26 of 40 reconstructions) for defects that extend to the contralateral soft palate because velopharyngeal function is superior due to a decreased incidence of wound dehiscence.[57]

Lacombe and Blackwell[59] have reported their results with a folding technique similar to ours with a radial forearm flap. However, they

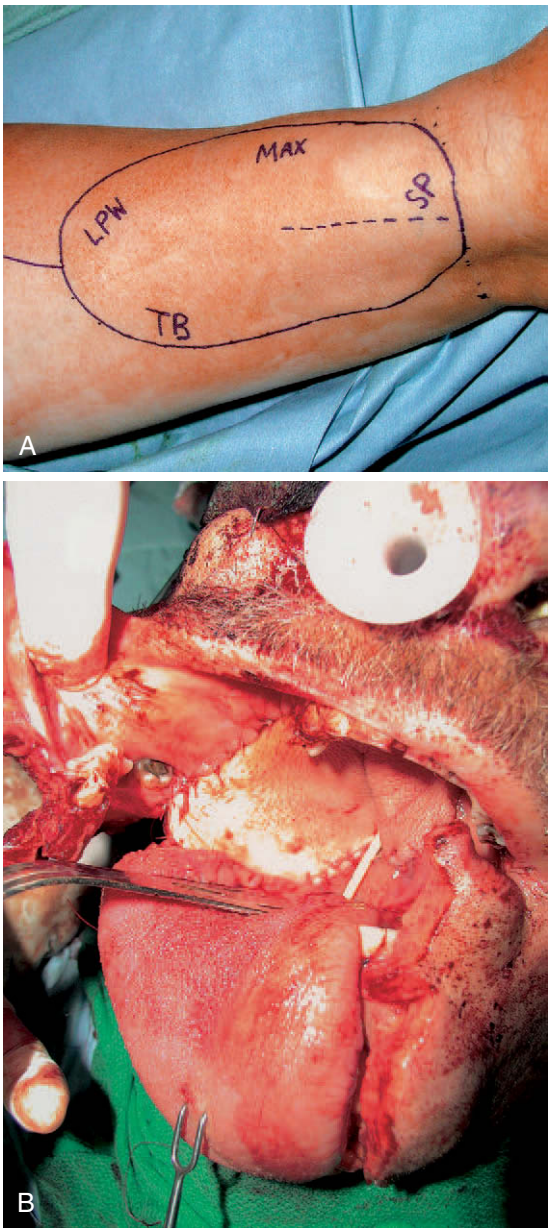

Figure 101-13. These photographs demonstrate our design for folding the forearm flap into the soft palatal defect. In **A**, note the distal aspect of the flap is used for this purpose, and the proximal flap is used for the pharyngeal and tongue base component if present. The flap was used in this case to reconstruct a 70% defect of the soft palate, as shown in **B**.

routinely perform a midline adhesion in cases in which more than one third of the soft palate is reconstructed. They accomplish this by deepithelializing a portion of the forearm flap and suturing it to a denuded area on the posterior pharyngeal wall. Red rubber catheters (16 F) are used to establish lateral ports, essentially converting the result to look and function like a pharyngeal flap. Their study reviewed 15 patients who had soft palatal reconstruction with the free radial forearm flap. Thirteen of 15 patients achieved an oral diet, whereas two were dependent on enteral feeding. Similarly, 13 patients were reported as having good velopharyngeal function without revision surgery or use of a prosthesis. One patient required a palatal-lift prosthesis for nasal regurgitation, and another patient had a secondary pharyngeal flap to decrease the size of one lateral velopharyngeal port. As with pharyngeal flaps, judgment of the size of the velopharyngeal ports needs to be correct in order to avoid nasal obstruction and sleep apnea.

Several other groups have reported on their experience with soft palate reconstruction with a free radial forearm flap. Two used a forearm flap in conjunction with a superiorly based pharyngeal flap. Brown and colleagues[60] and Penfold and collegues[61] used this approach in 11 and 3 patients, respectively. They noted good functional results for swallowing, speech intelligibility, and velopharyngeal sufficiency. The larger of the two studies done by Brown used objective measures of function such as videofluoroscopy, voice intelligibility recordings, and functional outcome evaluation by means of a questionnaire. We would caution the use of the pharyngeal flap in cases in which a significant volume of the pharynx has already been resected, and further sacrifice with the pharyngeal flap may further compromise swallowing.

Speech function after palatal reconstruction was specifically addressed by Yoshida and colleagues,[53] who reported on five patients who had soft palate reconstructions with a free radial forearm flap. Three of the five patients reconstructed with forearm flaps had a speech intelligibility score greater than 70%. The other two patients had scores of 40.8% and 57.8%. Two patients had a slight improvement of their intelligibility scores with placement of a special prosthesis. Eighty percent (four of five) of the patients were endoscopically and aerodynamically shown to have evidence of velopharyngeal incompetence. McCombe[62] reported on velopharyngeal function in patients following reconstruction of defects between 50% and 100% of the soft palate. All patients were reconstructed with a free radial forearm flap. Results were disappointing and the authors recommend a reduction of the velopharyngeal aperture to compensate for the lack of mobility in the soft tissue reconstruction. This had been scientifically previously shown by Seikaly and colleagues,[63] who found that patients with 50% or more of the soft palate resected and reconstructed with a radial forearm flap had significantly higher nasalance values and velopharyngeal orifice areas. Another recent report by Sinha and colleagues[64] on 16 folded forearm flap reconstructions for soft palatal defects found that all patients had intelligible speech and 14 of the 16 patients were able to tolerate a normal or soft diet within 6 weeks. Figure 101-14 presents an algorithm for reconstruction of defects of the soft palate.

Tonsil and Pharyngeal Wall

The extent of tonsillar and pharyngeal wall defects encountered is dependent on the approach to the primary tumor. In centers where radiotherapy is used as the primary modality of treatment, the reconstructive surgeon will be faced with extensive defects of the region because of the aggressive nature of the resection required for surgical salvage. These defects generally require a free or pedicled flap reconstruction because of the size of the defect and the compromised blood supply of the local tissue as a result of radiation. By comparison, centers that treat these tumors with primary surgery will be faced with a multitude of defects that may be reconstructed in a variety of ways, depending of the location and stage of the tumor. The same issue arises for tumors located in the tongue base.

Early tonsillar cancers can be easily resected transorally with the use of the carbon dioxide laser and the wound left to heal by secondary intention.[65] The authors have used this technique for T1 lesions of the tonsil and lateral pharyngeal wall, thereby leaving defects of up to 4 cm. The resection is taken down through the superior constrictor to the parapharyngeal fat pad. It is important to leave the fat undisturbed if possible because this serves to protect the carotid artery from intraoral contents. Patients can be started on an oral diet the same day of surgery. The authors have found that this technique is well tolerated, and patients heal well with little if any distortion of native tissue. Close examination of the healed defect usually reveals slight inferior displacement of the soft palate on the side of the resection, but velopharyngeal insufficiency is rare. This has been exemplified in cases reconstructed with the SCARF because the entire basis of its use is to reconstruct the soft palate with local tissue while allowing the lateral pharyngeal wall to heal secondarily. Healing by secondary intention is also possible for posterior pharyngeal wall defects. This is usually accomplished by suturing the margins of the defect to the prevertebral fascia and allowing the defect to remucosalize over the exposed fascia.

Primary closure is another option for reconstructing defects of the tonsil or pharyngeal wall. No specific guidelines apply for defects that

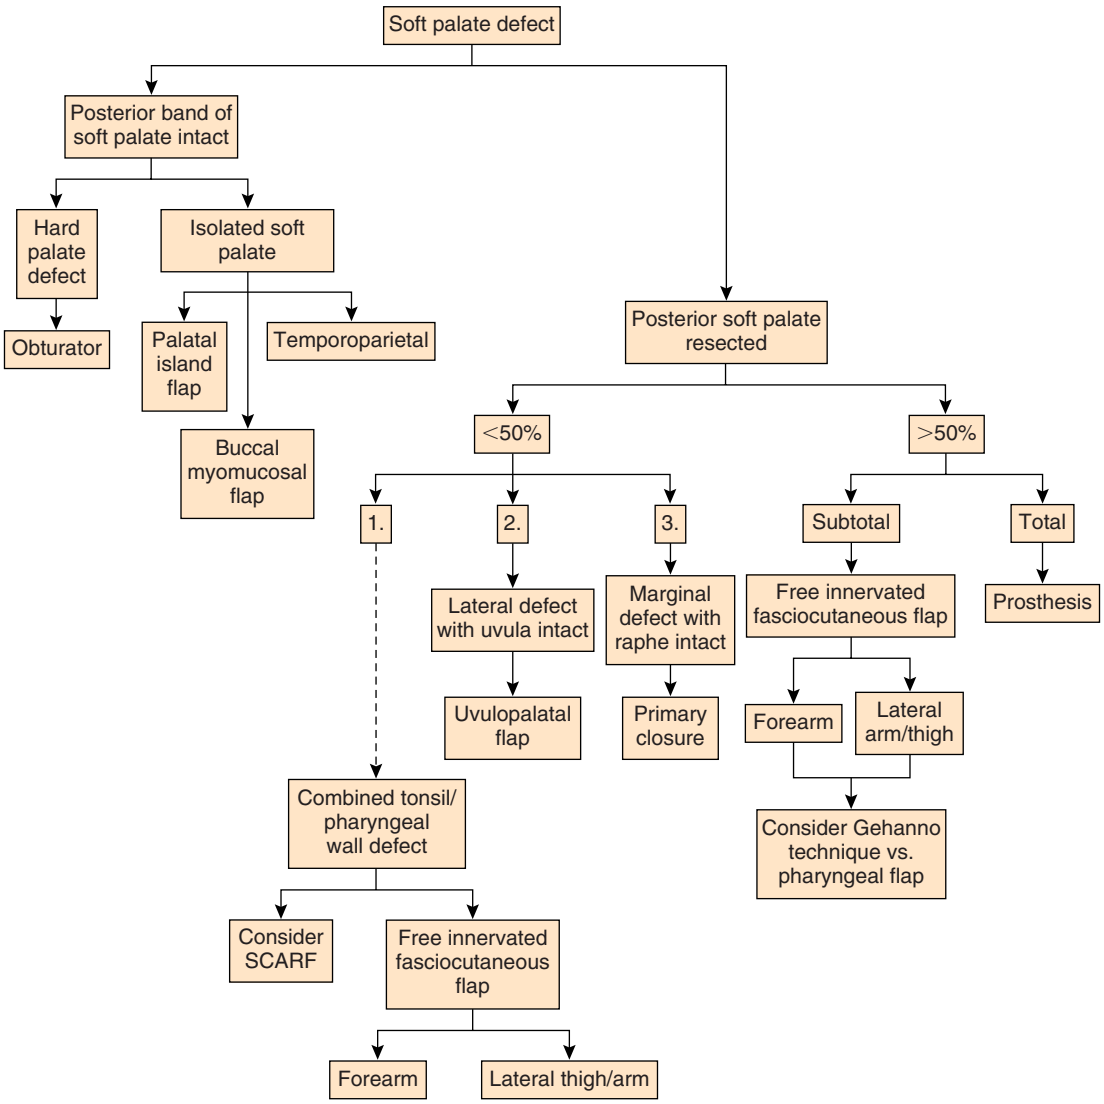

Figure 101-14. An algorithm for reconstructing defects of the soft palate.

are amenable to primary closure. The general principles include the absence of tension on the pharyngeal wound closure and lack of distortion of the normal anatomy of the region. As stated previously, this technique must be used with caution in patients who have been previously radiated. McConnel and colleagues[66] studied the functional results of primary closure versus flap reconstruction of the oropharynx. This was a prospective case-comparison study drawing from a database of 284 patients treated at four head and neck cancer institutions. Patients were matched for tumor location and the extent of resection. Speech and swallowing function was assessed preoperatively and 3 months after healing. They report that patients who had primary closure had less pharyngeal residue, were more efficient at swallowing liquids, and had higher conversational intelligibility than patients who had reconstruction with a distal flap. The primary closure patients had a longer oral transit time than the distal flap group. Compared with the free flap cohort, the primary closure patients had more efficient swallowing of liquids, less pharyngeal residual, and shorter pharyngeal delay times with paste. The authors did not find any difference in speech and swallowing function between the distal myocutaneous flap and the free flap groups. They conclude that primary closure results are equal or better in function than the use of flap reconstruction. This article is particularly controversial because it goes against most of our current trends in oropharyngeal reconstruction. Several questions have been raised about this study, and the authors of this chapter suggest reviewing the letter to the editor submitted by Reece and colleagues[67] with regard to this. A more recent study by Zuydam and colleagues showed improved speech and swallowing in patients closed primarily as compared with those reconstructed with free flaps.[68] Other published studies, however, support the use of primary closure for selected defects of the tonsil, pharyngeal wall, and tongue base.[11,69] These studies do highlight the importance of considering this modality for selected cases and the need to objectively study speech and swallowing results achieved with the various means of reconstruction.

Skin grafting of tonsil/pharyngeal wall defects is another uncomplicated method of reconstruction available to the surgeon. Pauloski and colleagues[69] described this technique in 14 patients with tonsillar defects in combination with varying defects of the tongue base and soft palate. The study specifically addressed variables affecting speech in patients with oral and oropharyngeal cancer including methods of reconstruction. Results were favorable for those reconstructed with a skin graft because they had more limited defects than the flap reconstruction group. Skin grafting may also be used to reconstruct defects of the posterior pharyngeal wall. The skin graft is sutured to the margins of the defect, and a bolster dressing is used to decrease the shearing forces on the graft. This technique can be used after a transoral or transcervical approach. A tracheotomy is recommended for airway protection in cases in which a skin graft is used.

Local flap reconstruction of tonsil and pharyngeal wall defects is uncommon. The longus coli muscle flap has been reported to be useful for defects of the lateral pharyngeal wall.[28] The longus colli muscles

arise from the anterior tubercles and transverse processes of the vertebral column from the arch of the atlas to the third thoracic vertebra and lie deep to the prevertebral fascia but anterior to the ligaments of the cervical spine. The muscle extends inferiorly to the level of the cervical esophagus. Innervation is from the cervical plexus (C2-C7), whereas the blood supply arises from muscular perforators of the vertebral artery. The muscle is thicker laterally, measuring approximately 0.5 to 1 cm in thickness. The flap is mobilized by dissecting free the lateral border of the muscle and then bluntly dissecting dorsal to the muscle. The muscle is rotated anteriorly into the defect without transecting it. Collins[28] reports that up to 4 to 5 cm of flap width is available for use, and the procedure takes from 5 to 10 minutes. She reported on 16 patients who were reconstructed with this flap. A total of 13 had primary tumors of the pharyngeal wall. Eighty-eight percent of patients had stage 3 or 4 disease, and 50% had T3 or T4 primary tumors. She reports that there were no wound infections or fistulas, although one of two previously radiated patients had a transient wound-healing problem. Two thirds of patients achieved an oral diet, and 58% (7 of 12) of patients who had laryngeal preservation procedures were decannulated. The author concludes that the longus colli muscle flap is useful for defects of the lateral pharyngeal wall on the basis of the reliability of wound healing and the absence of a negative impact on oncologic and functional results.

The palatal island flap is another local flap option appropriate for limited defects of the tonsil and pharyngeal wall. The entire hard palate mucoperiosteum based on a single greater palatine neurovascular pedicle is available to be transferred with this technique (see Fig. 101-2). The flap is ideal for defects less than 5 cm involving the upper tonsil/pharyngeal wall and retromolar trigone. Gullane and Arena[13] reported a 5% failure rate in a series of 53 palatal island flaps. They caution the use of this flap after irradiation, previous palatal surgery, or ligation of the external carotid or internal maxillary artery. Care must be taken to inset the flap without tension. The donor site is left open, and remucosalization occurs rapidly with little morbidity.

Regional flap reconstruction of the tonsil and pharyngeal wall remains a common reconstructive technique. The pectoralis major flap is without question the most commonly used regional flap for this purpose. This flap was first described by Ariyan[1] in 1979 for head and neck reconstruction and revolutionized the field. It can be used as a musculocutaneous, myofascial, or myogenous transfer and may be tailored to fit almost any defect of the head and neck. The anatomy of the flap has been outlined previously with the pectoral branch of the thoracoacromial artery serving as the flap's main blood supply. The flap is simple to harvest, and some surgeons prefer to do this through a deltopectoral-sparing incision starting in the axilla and coursing along the lateral border of the muscle inferiorly. If a cutaneous paddle is to be included, the lateral component is first incised, confirming correct planning of the skin paddle over the distal muscle. An avascular plane exists between the pectoralis major and the underlying pectoralis minor. The muscle is divided medially and laterally from its sternal and humeral attachments, respectively, after completing incision of the skin paddle. The skin paddle is then sutured to the underlying muscle to prevent shearing on the musculocutaneous perforators. The pedicle is identified medial and anterior to the pectoralis minor, and the flap can be narrowed superiorly or completely skeletonized on the pedicle alone, as the clavicle is approached. This assists tunneling into the neck.

Baek[2] first reported on the use of the pectoralis major flap for oropharyngeal reconstruction. Since then, several groups have reported their experience with this flap. The largest study to date was a series of 371 patients who had pectoralis major myocutaneous flaps performed for head and neck defects. The overall complication rate was 36% with a 2.4% incidence of total flap necrosis.[70] Koh has also recently reported on the use of this flap for oropharyngeal reconstruction and concluded that the pectoralis major flap is not only an alternative to a free flap but in fact may be a better choice for patients because the complication rates at their institution were lower in the pectoralis cohort compared with the free flap group.[71] One of the limiting factors of the flap for pharyngeal wall reconstruction is its excessive bulk. For this reason, we have preferred to use this flap as a myofascial transfer because it can be easily molded to the pharyngeal defect and the accompanying fascia is useful for suture placement.[72] Righi and colleagues[73] reported a flap complication rate of 22% with their series of myofascial flaps. We have used this flap primarily in tonsillar/pharyngeal wall defects in combination with lateral oromandibular defects in patients believed to be poor candidates for free tissue transfer (Fig. 101-15).

Figure 101-15. A pectoralis major myofascial flap was used to reconstruct the lateral pharyngeal wall in combination with a posterior mandibular defect. The patient had significant comorbidities and was felt to be a poor candidate for a free tissue transfer. Despite this, he was decannulated and is tolerating a normal diet.

The platysmal myocutaneous flap is another viable option for tonsillar/pharyngeal wall reconstruction. It is ideal for this purpose because of the thinness and pliability of the flap. It can be harvested in 20 to 30 minutes with little, if any, donor site morbidity. No special skills or equipment is necessary. The flap is designed low in the neck, with the skin paddle planned over the midportion of the platysma muscle. The upper skin paddle incision is made first, and a subcutaneous flap is raised to the level of the mandible. Next, the inferior portion of the skin paddle is incised and carried through the platysma. A subplatysmal flap is then elevated to the level of the mandible, which essentially frees the muscle and the overlying skin paddle (see Fig. 101-5). The flap has been used mostly for intraoral reconstruction; however, most series include patients in whom the flap has been used in the oropharynx. Ruark and colleagues[21] reported on 13 of a total of 41 patients who had primary tumors of the oropharynx reconstructed with this technique. This is the largest series of platysmal flaps reported in the literature for oropharyngeal reconstruction. They did not specifically analyze the subsites reconstructed, but the flap was used for tonsil, lateral pharyngeal wall, and soft palate defects. Other than this report, a total of 29 myocutaneous oropharyngeal reconstructions are reported in the literature.[19-22] Twelve were used for tonsil/pharyngeal wall reconstruction, whereas 17 were used in the tongue base. The complication rate for the tonsil/pharyngeal wall reconstructions was 67% (8 of 12). A more recent study by Jackel[74] reported on six patients reconstructed with a platysmal myofascial flap. These patients had tonsillar primaries resected with transoral laser microsurgery and all were free of complications.

The sternocleidomastoid myocutaneous flap may also be used for tonsil/pharyngeal wall reconstruction. The flap can be used either as a superiorly or inferiorly based flap based, respectively, on the occipital and transverse cervical arteries. The superior thyroid artery supplies the midportion of the muscle. Ariyan[75] reported on 31 consecutive reconstructions using this flap, of which 6 were used for the tonsil or pharyngeal wall. The remainder were used for defects of the oral cavity. Superiorly based flaps were used in two thirds of the cases. Fourteen patients had previous radiotherapy, and 17 had concomitant modified neck dissections. The complication rate in his series was 52%. Thirteen of 31 had partial loss of the skin paddle develop, whereas one was lost completely. Two patients had fistulas develop, despite no loss of the

skin paddle. All healed without additional surgery. There was no difference in complication rates for patients who had neck dissections or previous radiation. The location of the blood supply (inferior vs. superior) was not found to be significant. Significant concerns exist with regard to the use of this flap. First, the reliability of the skin paddle is questionable on the basis of the preceding and other studies. The vascularity of the skin paddle may be enhanced by preserving the superior thyroid pedicle.[76] One other major criticism of the use of this flap is its intimate relationship with potential nodal metastasis in the neck. The largest published study in the literature addresses these two issues. Sebastian and colleagues[77] reported on 121 superiorly based flaps for oral reconstruction in patients with clinically N0 necks. Total flap loss occurred in 7% of cases, whereas superficial skin loss was seen in 23%. The fistula rate in the series was 12%. Radiation was found to increase the incidence of flap complications. Pathologically N0 necks had a recurrence rate of 6% compared with 17% in necks that were pathologically positive.

The temporal system of flaps may be useful for reconstructing tonsil/pharyngeal wall defects as well. The techniques of harvesting the temporalis and the temporoparietal fascia flap have been outlined previously in "Regional Flaps." The flap's ease of harvest and proximity to the defect make it a viable option. It may be particularly useful in cases in which the coronoid process of the mandible has been resected, leaving the muscle functionless. We have tended not to use this flap routinely for oropharyngeal defects given its bulk, difficulty of inset, and donor site morbidity. We previously discussed the use of this flap in conjunction with the SCARF, where the flap was used to augment the lateral pharyngeal wall defect in two cases.[16] Huttenbrink[78] reported on the use of this flap specifically for oropharyngeal reconstruction, and this represents the only dedicated article to this in the English literature. The transfer used by Huttenbrink consisted of muscle, fascia, and periosteum. He stresses the importance of subperiosteal dissection along the deep aspect of the flap to protect the deep temporal vascular pedicle. A total of 11 patients with oropharyngeal defects were reconstructed with the temporalis flap. One flap developed partial necrosis of the fascial layer, but the muscle healed uneventfully. There were no problems with the other 10 flaps. No fistulas or flap dehiscence occurred. The author was nonspecific with reporting of functional outcomes and simply reported that nearly all patients could swallow and speak without restraint. A subsequent article by Huttenbrink in the German literature expanded on his experience and reported on 26 patients in whom the flap was used.[79] A more recent study by Smith and colleagues[80] reported on 26 temporalis flaps used for oropharyngeal and nasopharyngeal reconstruction. They reported two cases of minor flap loss and two cases of transient frontal nerve weakness. More than 50% of patients were able to tolerate a normal diet, and 8% were G-tube dependent.

The temporoparietal fascial flap may be used in a similar fashion. The thinness, pliability, and vascularity make it ideal for this purpose. Flap harvest is relatively simple and was described in detail previously in this chapter. Donor site morbidity is rare, with frontal nerve injury and alopecia being the most significant. Cheney and colleagues[23] have nicely outlined the application of this flap in head and neck reconstruction. They report on the variety of defects that can be reconstructed with this flap including the pharyngeal wall. The flap can be used either as a pedicled or free tissue transfer. Most defects of the pharyngeal wall should be amenable to pedicled flap reconstruction because of the proximity of the donor site and the thinness of the flap to be tunneled into the defect. Objective measures of functional outcomes that use this method of reconstruction are lacking.

Free flap reconstruction is now the gold standard reconstructive modality for extensive defects of the tonsil and pharyngeal wall. Usually, these defects occur in combination with defects of the soft palate and tongue base, and we focus on these two subsites in this section because published data on free flap reconstruction for isolated defects of the pharyngeal wall are scant. The radial forearm flap is the "workhorse" free flap in this area and has gained widespread popularity because of its thinness and pliability, ease of harvest, and minimal donor site morbidity. The forearm flap has become the most common free flap used in oral and pharyngeal reconstruction. Compared with the jejunum and gastro-omental free flaps for this purpose, there was no difference in speech, swallowing, or control of saliva between the different reconstructive modalities.[81] The gastro-omental cohort, however, was found to have a higher complication rate. The authors make no reference as to whether the forearm flaps were neurotized at the time of surgery. We prefer the use of the forearm flap over the jejunum and gastro-omental flaps because the forearm flap may be reinnervated, which may improve pharyngeal sensation, thus preventing aspiration. Also, the forearm flap avoids the laparotomy required for harvest of the other two flaps.

A recent Finnish study addressed free flap reconstruction in the management of oral and pharyngeal cancer.[82] Of the 50 patients included in the study, seven had defects of the tonsil and pharyngeal wall. All seven patients were reconstructed with a free radial forearm flap. Twenty percent of the flaps required reexploration, and the overall flap success rate was 96%. Patients who had primary tumors of the tonsil had the best 3- and 5-year survival rates at 85% and 57%, respectively. This point stresses the need for functional reconstruction because prognosis at this subsite tends to be good compared with the hypopharynx and oral cavity. Schwager[83] reported the use of the forearm flap in reconstructing 62 patients with pharyngeal carcinoma. A regular diet was achieved an average of 14 days postoperatively. All patients had a tracheotomy performed at the time of surgery, and 90% were decannulated at 1 year. Another European article by Barzan[84] reported on four patients with isolated posterior pharyngeal wall defects. All patients were reconstructed with a free radial forearm flap. No flap problems, fistulas, or donor site morbidity was noted. Speech and swallowing function was not noted.

Combined defects of the lateral and superior (soft palate) pharyngeal wall have been addressed by Kimata and colleagues.[57] All 40 patients had extensive defects of the lateral pharyngeal wall combined with varying defects of the soft palate. They classified the defects as follows: type 1, localized in the lateral pharyngeal wall and including palatopharyngeal, palatoglossal, and superior pharyngeal muscles; type 2, extending to the soft palate and including the tensor veli palatini and levator palatini muscles; and type 3, extending to the contralateral soft palate. Free flap reconstructions were performed on all patients. The rectus abdominis flap was used in 26 patients, an anterolateral thigh flap in 7 patients, and a forearm flap in 5 patients. Jejunum and superior iliac crest flaps were used in one patient each. Six flaps underwent partial necrosis, and 34 survived completely. The authors describe four different methods of reconstructing these defects, namely the patch, jump, denude, and Gehanno methods (Fig. 101-16). Wound dehiscence between the remnant soft palate and flap developed in 7 of the 40 patients. This occurred in 4 of 8 (50%) patients treated with the denude method and 3 of 10 (30%) patients treated with the Jump method. Of the seven patients with wound dehiscence, five had a wide fissure develop between the flap and the soft palate that resulted in postoperative hypernasality. As expected, patients with type 1 defects had the best overall velopharyngeal function. All 10 patients in this group had satisfactory postoperative function. Sixteen patients had type 2 defects. The authors report that most of these patients showed satisfactory function. Five of these patients had mild or severe nasal emission during soft blowing, and seven had mild nasal regurgitation with eating. Fourteen patients had type 3 pharyngeal defects. Of these, five patients had satisfactory function without nasal emission with soft blowing. The five patients who had flap dehiscence had severe velopharyngeal incompetence. The remaining four patients initially had intact velopharynges, but as the rectus free flap atrophied, they had progressive incompetence develop. Overall, patients with type 3 defects had low speech intelligibility scores, and 9 of 14 patients had evidence of hypernasality. The authors conclude that flap dehiscence was directly correlated to poor speech intelligibility, hypernasality, and nasal emission. The rates of wound dehiscence were lower with the patch and Gehanno methods. They suggest the use of the Gehanno method for extensive defects of the oropharynx and for all type 3 defects of the soft palate.

The lateral arm and thigh free flaps are other options for reconstructing defects of the tonsil and pharyngeal wall. Civantos[41] reported on 28 patients who had the lateral arm flap used in head and neck

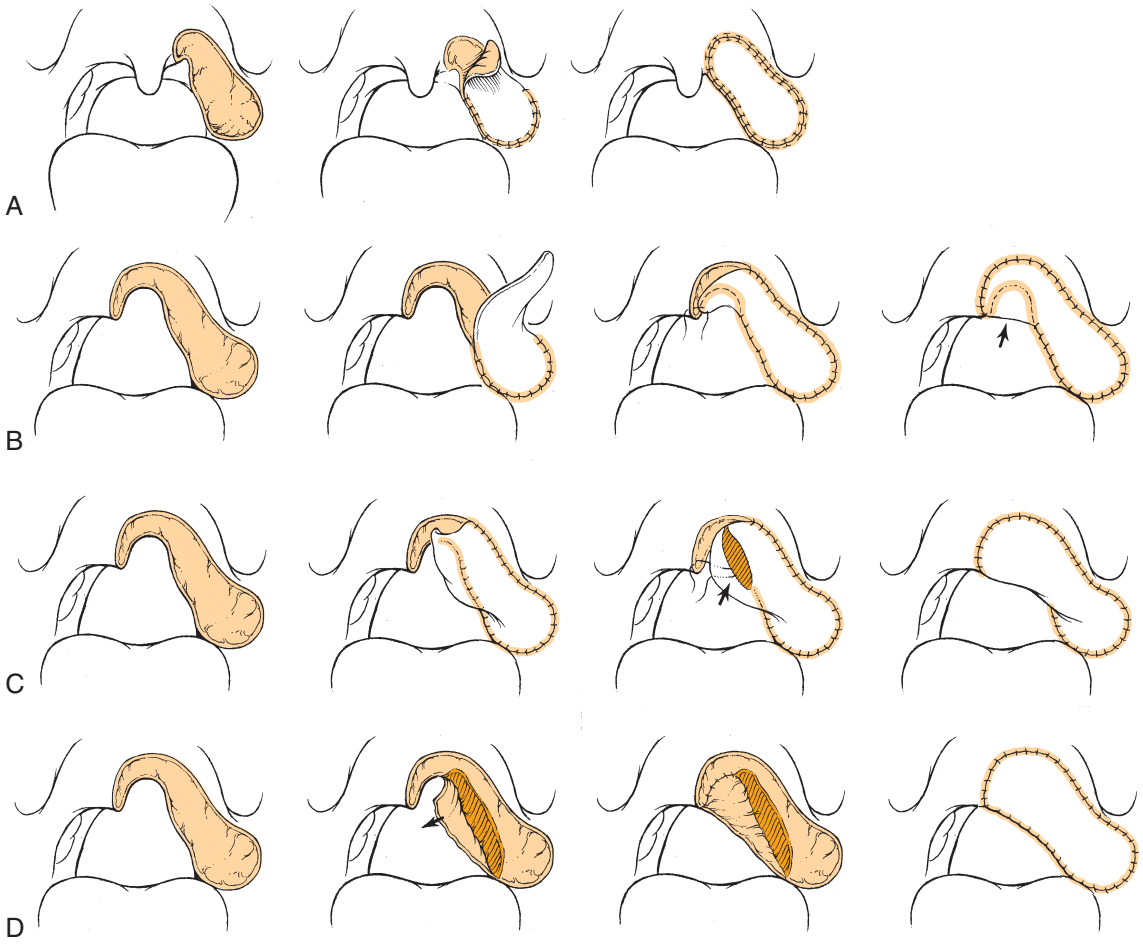

Figure 101-16. **A,** Patch method: The flap is simply sutured into the defect. **B,** Jump method: The inferior portion of the free flap is left unsutured to the posterior pharyngeal wall and soft palate, therefore jumping directly to the anterior soft palate. **C,** Denude method: The flap is used to reconstitute the posterior pharyngeal wall, and the portion of the flap adjacent to the cut end of the soft palate is deepithelialized and sutured to the remaining soft palate. **D,** Gehanno method: The posterior and lateral pharyngeal wall is advanced and sutured to the posterior surface of the soft palate remnant. The flap is then used as a patch for the anterior portion of the defect. *(Adapted from Kimata Y, Uchiyama K, Sakuraba M, et al. Velopharyngeal function after microsurgical reconstruction of lateral and superior oropharyngeal defects.* Laryngoscope. *2002;112:1037-1042.)*

reconstruction. Of these, 14 patients had large oropharyngeal defects, four of which involved the tonsil and pharyngeal wall. Eight of the 14 patients resumed early oral feeding, and all eventually were able to obtain nutrition orally. Swallowing was compared with a simultaneous control group that was reconstructed with pectoralis major flaps. The swallowing ability of the lateral arm cohort was found to be superior to the group reconstructed with the pectoralis flaps. The authors concluded that the lateral arm free flap is ideal for oropharyngeal reconstruction because the flap incorporates thin skin from the proximal forearm and thicker skin from the upper arm. They suggest that the thin forearm skin may be used in the lateral pharyngeal wall, whereas the thicker upper arm skin may be used to reconstruct the tongue base. Also, the flap is amenable to neurotization. Hayden and Deschler[34] make similar recommendations with regard to the use of the free lateral thigh flap. They reported their experience with the lateral thigh flap in 58 cases. Most flaps were used for pharyngoesophageal reconstruction, but two involved the pharyngeal wall. The authors of this chapter have used the lateral thigh flap in the past as their second line flap but now prefer the anterolateral thigh flap in patients who are not candidates for radial forearm flap reconstruction or have very thin lower extremities. Figure 101-17 reviews an algorithmic approach to defects of the tonsil and pharyngeal wall.

Tongue Base

Reconstruction of the tongue base is challenging because of its proximity to the larynx and the resultant risk of aspiration. These defects may occur as an isolated entity but also may occur in combination with defects of the anterior tongue, with the extreme being the total glossectomy defect with or without laryngeal preservation. The goals of tongue base reconstruction in order of importance are (1) maintenance of the airway; (2) swallowing; and (3) articulation. The tongue base is critical for the first and second goals, with the anterior tongue being more significant with regard to articulation. The ideal tongue base reconstruction provides the necessary bulk to create a shelf above the laryngeal inlet. This serves to better direct the oral bolus down the posterior pharyngeal wall and away from the larynx. The form of reconstruction chosen should provide pliable tissue that has dynamic capability, which is required for adequate speech and swallowing. Last, reinnervation of the flap from both a sensory and motor standpoint would be ideal because this would improve pharyngeal sensation, thus decreasing the risk of aspiration, whereas motor function would enhance tongue and laryngeal elevation, resulting in a more physiologic swallow. These factors are critical in cases in which partial laryngectomy is performed because the risk of aspiration is increased.[84]

With the growing popularity of minimally invasive techniques, endoscopic resection of tongue base tumors with the use of the CO_2 laser has emerged in selected centers. We have performed endoscopic resections of T1 to T3 carcinomas of the tongue base, leaving up to 6 cm to heal by secondary intention. With time, the surgical bed granulates in and forms a neotongue that closely resembles and functions like the native tongue base. This form of reconstruction is simple and reliable in the nonirradiated patient, although it may also be used as a

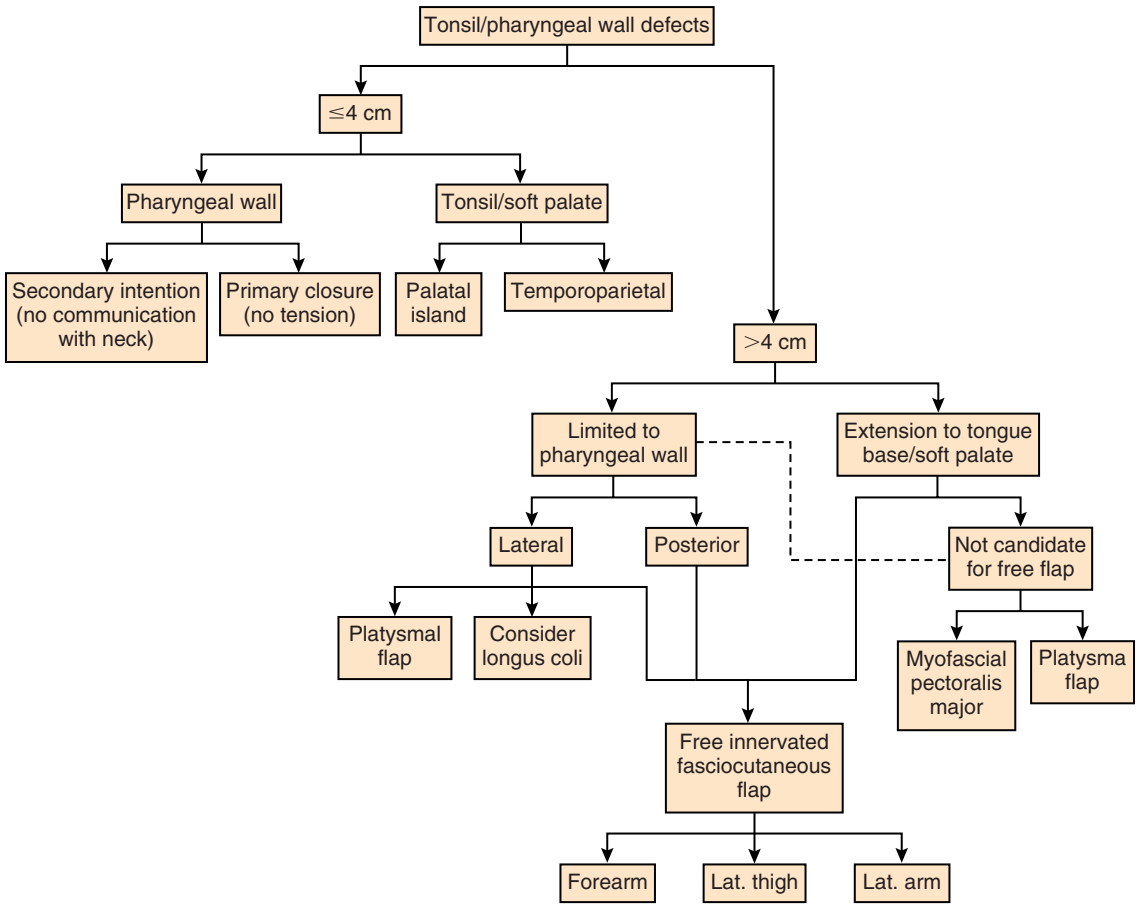

Figure 101-17. Reconstructive algorithm for the tonsil and pharyngeal wall.

salvage technique, with healing and local control being less predictable. Overall patient functioning is generally directly related to the extent of the resection performed.[69] Primary closure is an excellent option for reconstructing selected defects of the tongue base. This approach has been championed by McConnel and colleagues.[10,66] We have previously addressed this study in detail in "Tonsil and Pharyngeal Wall." Tongue base defects of up to 60% were closed primarily, and these were matched against similar defects reconstructed with free and pedicled flaps. They report that there is no significant improvement in swallowing efficiency between patients having flaps and patients with primary closure. Conversely, patients with primary closure had better swallowing efficiency than both the free flap and pedicled flap groups. This report is controversial because it represents a paradigm shift in conventional reconstructive ideals. Currently, most would recommend flap reconstruction for defects involving far less than 60%, with one group suggesting flaps are necessary in cases where more than 20% of the tongue base is resected.[67] Clearly, there are no definite guidelines to follow, and much is based on surgeon preference and experience. As a general rule, we have tended to use free tissue transfer in cases in which a mandibulotomy was performed for exposure, while reserving consideration of primary closure for transoral, transhyoid, or pharyngotomy approaches. Basic principles still apply for the use of primary closure because the wound must be free of tension, and there should be minimal or no distortion of the native anatomy. We have used primary closure for tongue base defects of 30% or less and favor the use of free flaps for more extensive defects.

Skin grafting and local flaps are not recommended in isolation for reconstructing defects of the tongue base. Local flaps are mentioned only for completeness sake and are not appropriate in the tongue base because of the resultant deformation and tethering of the tongue that occurs. Similarly, we have not used skin grafting alone for defects of the base of tongue because immobilization of the skin graft is difficult and lacks the volume of tissue required for adequate reconstruction. A skin graft may be considered in combination with other forms of reconstruction, particularly in key areas such as the glossotonsillar sulcus, if insufficient flap is available to fully cover the wound.

Regional flap reconstruction of the base of tongue remains an option. The pectoralis major myocutaneous flap is the tried, tested, and true regional flap used for this purpose. Soon after the description of this flap, Conley and colleagues[86] reported their experience with reinnervated pectoralis myocutaneous flaps for reconstructing total glossectomy defects. The pectoral nerves were anastomosed to the stump of the hypoglossal nerve in all cases. Electromyographic recordings confirmed that reinnervation had occurred. Although flap atrophy was prevented with the reinnervation of the muscle, coordinated contraction and movement of the neotongue was not observed. Even if muscular contraction had been observed, this would result in inferior movement of the flap, which is opposite to the desired upward movement seen in normal swallowing. Sultan and Coleman[87] reported on a group of 11 patients who were reconstructed with pedicled pectoralis flaps. They proposed that delayed sagging of the flap leads to decreased laryngeal mobility. There is a scarcity of functional outcomes reported with this form of reconstruction. Weber and colleagues[88] reported on swallowing results in 27 patients who had subtotal or total glossectomies with laryngeal preservation. All patients were reconstructed with a pectoralis major flap. Of the 27 patients, 18 (67%) were able to obtain an oral diet; however, with time, this number decreased to 12 (45%), thus confirming the subjective observations of Sultan and Coleman. Gehanno[85] reported his experience with 80 patients with advanced carcinoma of the tongue who were treated with total glossectomy. Reconstruction was performed with a pedicled musculocutaneous flap in 75 patients (64 pectoralis major, 8 trapezius, and 3 latissimus) and a gastro-omental free flap in 5 patients. Twenty-six (32%) patients had a pharyngocutaneous fistula develop, and half of these patients required

further surgery. Half of the patients were decannulated within 30 days of their initial surgery. At 3 months, 41 (53%) patients were able to eat soft food, and speech was intelligible in 49 (63%) patients. Five-year survival of the study patients was a dismal 12%.

Another regional musculocutaneous flap that may be used for total and subtotal glossectomy defects is the latissimus dorsi. This is our flap of choice for this defect. However, we have abandoned its use as a pedicled transfer and use it solely as a free flap for this purpose. Haughey[42] has reported his initial experience with this flap as a pedicled transfer in tongue reconstruction. Of his first four latissimus flaps for tongue reconstruction, three were used as pedicled transaxillary transfers. Two of these three flaps failed, and both were salvaged with pectoralis major myocutaneous flaps. We have abandoned the pedicled transfer for tongue reconstruction because of the unreliability of the flap for this purpose and the potential limitations of neotongue mobility caused by pedicle tethering.

The platysmal myocutaneous flap has recently been reported to be appropriate for use in the tongue base. Koch[20] reported on nine patients with base of tongue defects that were reconstructed with the platysma flap. Despite the high rate of complications reported with this flap by some, all nine flaps survived entirely. One patient had a pharyngocutaneous fistula develop that healed uneventfully with conservative measures. Eight of the nine patients were able to achieve an oral diet. The one patient unable to do so had a resection of a T3 tumor of the tongue base after failure of radiation and chemotherapy. None of the patients had evidence of aspiration. The flap was used for tongue base primary tumors in approximately 25% of the reported cases (9 of 34) in this series. A review of other published data on the platysma flap revealed only eight other cases in which this flap was used for tongue base reconstruction.[12,22,89] Seven of the eight flaps survived entirely, and one flap developed partial necrosis of the skin paddle. Functional results for these patients are not apparent. The overall flap survival rate for the platysmal flap for tongue base reconstruction is 94% (17 of 18). The advantages of this flap for tongue base reconstruction are the flap's simplicity and proximity to the defect, thus allowing a tension-free closure. Disadvantages of this technique are the lack of flap bulk and sensory potential.

Free tissue transfer has become the "go to" method of reconstruction for defects of the tongue base. Fasciocutaneous and musculocutaneous flaps are most commonly used for this purpose. Sensory recovery has been documented with fasciocutaneous flaps in tongue reconstruction.[90] Seventeen patients who underwent reconstruction of glossectomy defects with reinnervated forearm flaps were studied 8 months after surgery. Sensory recovery occurred in all 17 patients. The free flap reconstructions had superior sensation compared with the contralateral forearm donor site and approached that of the native tongue. Despite this, no direct link between sensory recovery and functional recovery has been conclusively shown.[90,91] We also published our experience with fasciocutaneous flaps for tongue and floor of mouth reconstruction.[92] Forty-three reconstructions were performed, of which 13 were centered in the tongue base and did not extend into the oral tongue or floor of mouth for more than 2 cm. The defects were reconstructed with a planar inset of a forearm flap between the hyoid inferiorly and the oral tongue superiorly. No patients had a supraglottic laryngectomy or a delayed total laryngectomy for aspiration. In the presence of a contiguous pharyngeal wall defect, the flap was folded 90 degrees from the plane of the tongue base to provide coverage of the pharyngeal component. One lingual artery and hypoglossal nerve were preserved in all cases. Laryngeal suspensions were performed in all cases. All patients were decannulated at an average of 14.6 days. The Functional Outcomes Swallowing Score was used to assess swallowing outcomes.[93] The tongue base cohort had a mean score of 1.6, which was superior to the oral tongue group at 2.4, but this was not statistically significant. Finally, speech intelligibility was greater than 90% in all patients, with a mean score of 98%. We believe this was partially due to the flap's allowing for excellent anterior tongue remnant mobility.

Urken[94] contended for the importance of reconstructing isolated base of tongue defects with tissue that provides both bulk and sensation. His flap of choice for this defect is also the radial forearm flap because it can be harvested with large amounts of additional vascularized subcutaneous fat to impart the necessary bulk while also providing sensation. He has described a tripartite subcutaneous extension from the body of the flap to reconstruct these defects. The bulk that is provided with these extensions does not diminish as is seen in vascularized muscle. All forearm flaps were sensate in his series. The earliest signs of sensation were noted after 4 months in most patients. The degree of discrimination did not seem to be age dependent. Improvements that suggested a role for sensory recovery were a reduction or disappearance in coughing and decreased use of adaptive techniques for aspiration during the time when sensation returned in the neotongue. However, no swallowing measures or quality of life instruments were used to support the contention that bulk or sensation was helpful, and the absence of a control group further confuses the reinnervation issue.[11] Rieger and colleagues[95] reported on their functional results on 32 patients following reconstruction of the base of tongue with a free radial forearm flap. Speech intelligibility was above 90% for most patients. Only five patients required a feeding tube at some point over the year of postoperative evaluation, and one patient used a tube as the primary source of nutrition. These results contrast with those of Borggreven,[5] which found that patients with advanced tumors (T3-T4 vs. T2) and combined base of tongue and soft palate reconstructions were associated with profound swallowing problems. Despite giving details of sensory reinnervation, swallowing and rates of decannulation were not reported. Urken[96] expanded the use of the sensate forearm flap and has described its use in combination with the iliac crest free flap for reconstruction of significant glossectomy-mandibulectomy defects.

The lateral arm free flap may also be used for base of tongue defects. Civantos[41] reported on 17 patients who underwent major oropharyngeal resections, of whom 12 had more than half of the tongue base removed. Thirteen of these patients had reinnervation of their lateral arm flaps. Three patients had a total laryngectomy for oncologic reasons, and all were able to swallow. Of the remaining 14 patients, 12 could be evaluated between 6 months and 1 year postoperatively. Eight patients (67%) were able to swallow within 2 months, and 11 patients (92%) were able to feed orally by 8 months. All surviving patients were eventually able to achieve an oral diet. Salibian and colleagues[97] reported on seven patients who had ulnar forearm flaps for reconstruction of subtotal glossectomy defects. All patients were able to feed orally. Four patients were able to resume a normal diet, whereas the remaining three were tolerating a soft diet.

Total or subtotal glossectomy defects are a particularly challenging problem for the reconstructive surgeon. The complexity of the reconstruction is due to the multitude of functions provided by the native tongue. These functions are possible because of the array of intrinsic and extrinsic musculature along with the strategic position of the tongue above the larynx. Our flap of choice when faced with these defects is the innervated free latissimus dorsi musculocutaneous flap. Haughey[42] has reported on a design for latissimus dorsi flaps in tongue reconstruction. The flap is designed in such a fashion that the skin paddle is oriented perpendicular to the underlying muscle. The dimensions of the skin paddle are obtained by measuring the distance from the mandibular symphysis to the inferior extent of the resection in the base of tongue, vallecula, or supraglottic larynx. Allowance is made dorsally so that the flap will contact the palate once inset, and lateral wings are added to the skin paddle if a tonsillar defect is present. Also, a triangular wedge of anterior skin is deepithelialized, imbricated, and repaired to create a "cupula," which rises from the anterior neotongue. An allowance is then required anteriorly in the skin paddle design to provide sufficient tissue for this maneuver. The key to this technique is in the inset of the flap. The flap is inset from an inferior to superior direction. If the epiglottis is preserved, the flap is sutured as close to its base as possible. The flap is then suspended from the skull base bilaterally to form a sling under the mandible. This is performed by suturing the latissimus muscle to the pharyngeal constrictors, medial pterygoids, or the masseter if the mandibular ramus was resected (Fig. 101-18). The thoracodorsal nerve was anastomosed to the hypoglossal nerve in all free flap cases. Postoperative superior movement of the flap was observed presumably from reinnervation of the latissimus muscle and was documented by video-oropharyngography in two patients. Fifteen cases were included in the study including three pedicled flaps and one

free innervated radial forearm flap. Two of the three pedicled flaps and one of the 12 free flaps failed. Pedicled flap reconstruction with this technique is no longer recommended by the author. Four patients underwent a laryngectomy or laryngeal closure, and one died perioperatively. Of the 10 remaining patients, 8 were decannulated at a median interval of 3.2 weeks. An oral diet was obtained in 10 patients. Two patients in the series were G-tube dependent including one patient whose flap failed and was salvaged with a pectoralis major flap. Three patients who had died did not have swallowing results available. Speech intelligibility was not formally studied but was estimated by a speech language pathologist to be in the range of 85% to 90% on the basis of observations made in three patients. Videos of active, voluntary movement in the flap initiated by the patient are available from the author (BHH) upon request.

Kimata and colleagues[43] reported on functional results and complications after total glossectomy with microvascular reconstruction. Thirty patients were included in the study, all of whom had a total glossectomy with laryngeal preservation. The rectus abdominis musculocutaneous flap was the authors' flap of choice, and this was used in 23 patients. Other flaps used include combinations of the latissimus dorsi, serratus anterior, anterolateral thigh, and radial forearm flaps. Flaps were designed as wide and thick as possible while still allowing for primary closure of the donor site. The flaps were inset from an inferior to superior fashion, with slight anterior and superior traction in an attempt to elevate the larynx. A formal laryngeal suspension to the mandible was performed on four patients. There was one flap failure, and marginal necrosis occurred in five flaps. Orocutaneous fistulas developed in nine patients (27%), and two of these required additional surgery. Of the 30 patients in the study, 21 (70%) were decannulated with laryngeal preservation, and all of these patients were able to achieve an oral diet. In 9 of 30 patients, laryngeal function could not be preserved. Preoperative cerebral dysfunction, resection of the epiglottis, and postoperative orocutaneous fistulas were found to be statistically significant with regard to failure of laryngeal preservation. Speech was judged to be intelligible in 16 of 19 patients evaluated. At the conclusion of follow-up at a mean duration of 29 months, 10 patients were alive without disease. Similarly, Lyos and colleagues[45] reported their experience with the rectus abdominis flap for tongue reconstruction. This was a retrospective outcomes analysis of 14 patients who had a minimum of 75% of the tongue resected with preservation of the mandible and larynx. Eight patients had a total glossectomy, whereas six had subtotal resections. Decannulation was possible in 12 patients (86%) at an average interval of 3.5 months postoperatively. One patient required a laryngectomy for intractable aspiration, and three patients required G-tubes for severe dysphagia. Eleven of 14 patients (81%) were able to tolerate an oral diet of some variety. A palatal augmentation device was found to be of benefit in eight patients because of insufficient vertical height of the free flap reconstruction. This is due to the atrophy of the rectus muscle and subsequent displacement of the skin paddle inferiorly. Speech was judged as being acceptable in nine patients (64%).

A money pouch–like reconstructive method after total glossectomy without laryngectomy has been described with a free rectus abdominis myocutaneous flap.[44] With this technique, the authors established a money pouch–like neotongue by harvesting a skin paddle that is 20% larger than the defect in both width and length. When the skin paddle is sutured to the defect, the excess skin and fat fold into the shape of a money pouch, thus establishing the vertical height needed for successful tongue reconstruction (Fig. 101-19). They report on only three patients in this study; however, a normal swallow was achieved in all patients by 6 weeks with the assistance of oral ingestion training. Speech intelligibility was about 50% to 60% in the patients. Although this seems to be a novel technique, other descriptions of the rectus flap for tongue reconstruction have attempted to overcorrect to achieve this vertical height of the reconstruction.[43] The rectus flap may also be inset as a sling under the mandible to support the overlying position of the skin paddle. Urken[46] has preferred the use of the rectus flap over the latissimus for this purpose because of the tendinous inscriptions, which are able to hold sutures. He also advocates the use of drill holes in the mandible for suspension of the rectus flap. Atrophy of the rectus is inevitable, but this may be reduced by reinnervating the muscle with a hypoglossal nerve stump, although meaningful movement of the muscle has not been documented.[94]

Hayden[34] reported on the use of the lateral thigh flap for reconstructing nine patients with total or near-total glossectomy defects. All flaps survived completely, and no patients had postoperative fistulas develop. Functional results in this cohort of patients are not reported. The author states that the flap is ideal for this purpose (in selected cases with appropriately fat thighs) because the distal portion of the flap can be deepithelialized and used as a platform under the mandible, while the proximal thicker portion of the flap is used for reconstruction of the neotongue.[34] The free anterolateral thigh flap has been reported for total and near-total glossectomy defects. The flap is useful for this purpose because it provides significant bulk and also the possibility of sensory reinnervation. Yu[98] reported on 13 patients

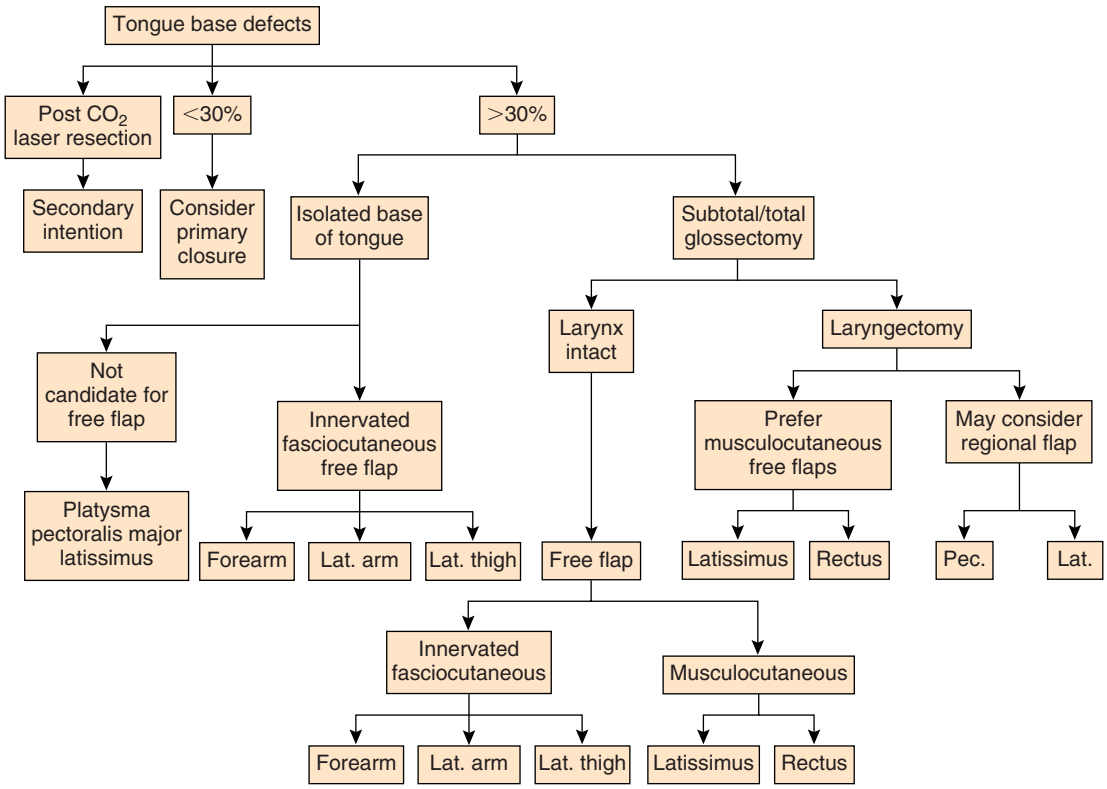

Figure 101-20. Algorithm for tongue base reconstruction.

reconstructed with this flap, 8 of which were reinnervated. Innervated flaps were found to have superior sensory recovery, which resulted in improved swallowing function and patient satisfaction. Figure 101-20 presents an algorithm for reconstructing defects of the tongue base.

CHAPTER ONE HUNDRED AND TWO

Diagnostic Imaging of the Pharynx and Esophagus

Barton F. Branstetter, IV

Key Points

- Esophagram (sometimes called *barium swallow*) should be used to evaluate pharyngeal mucosa, whereas modified barium swallow should be used to assess deglutition.
- PET/CT has become an essential modality for the staging, monitoring, and surveillance of pharyngeal and esophageal carcinomas.
- Although endoscopy has replaced fluoroscopy for many pharyngoesophageal diagnoses, diseases of peristalsis, fistulas, and diverticula are still best evaluated radiographically.
- Nasopharyngeal carcinoma is best staged with a combination of MRI and PET/CT.
- Esophageal carcinoma is best staged with a combination of endoscopic ultrasound and PET/CT.
- Oropharyngeal and hypopharyngeal carcinoma is best staged with endoscopy and PET/CT.

As the diversity of radiologic examinations continues to grow, it is increasingly important for referring clinicians to understand the arsenal of tests offered by radiologists. The improved quality and availability of cross-sectional imaging, along with advances in endoscopic techniques, have contributed to a decline in fluoroscopy. However, many disorders of the pharynx and esophagus still are best evaluated with fluoroscopic techniques. In particular, patients who have pain, trismus, a hyperactive gag reflex, or bulky disease are often not optimally evaluated with direct inspection or endoscopy, and mucosal lesions may not be evident on cross-sectional modalities. This chapter discusses the basics of radiographic technique and anatomy, with a focus on the appropriate choice of imaging modality for evaluation of the pharynx and esophagus. The radiographic appearance of specific disorders is then discussed.

Techniques

Conventional Radiography

Conventional radiographs (plain films) of the neck are economical and readily available. They are particularly useful in pediatric patients with airway distress. The lateral projection provides the most information, and it will often be obtained without the frontal projection (Fig. 102-1). If the examination is performed to evaluate a radiopaque foreign body, the frontal projection should be included. Patients are instructed to say the letter "e" during exposure to bring the tongue forward and better demonstrate the oropharynx.[1] If a hypopharyngeal lesion is being evaluated, the patient should blow through compressed lips to distend the hypopharynx. In children, the lateral radiograph should be obtained during peak inspiration to prevent redundancy of the prevertebral soft tissues that may simulate pathology.

Chest radiographs occasionally reveal advanced esophageal abnormalities or pneumomediastinum, but fluoroscopy and cross-sectional imaging are preferred for evaluation of the thoracic esophagus.

Computed radiography and digital radiography are the modern counterparts to screen-film techniques. Instead of exposing a piece of film, the technologist captures an image on a reusable array of digital elements and reads the image directly into a computer. One advantage of these techniques is the ability to emphasize subtle soft tissue differences, even in suboptimally exposed images.[2]

Xeroradiography is a historical technique that clearly delineated the soft tissues of the neck.[3] However, xeroradiography had a narrow range of applications, and it is no longer available at most institutions.

Linear and complex-motion tomography improve on conventional radiographs by blurring the soft tissues that obscure the pharyngeal walls. Small mucosal lesions can sometimes be distinguished, but conventional tomography has been replaced almost universally by computed tomography (CT).

Fluoroscopy

Motion capture techniques with intraluminal contrast are invaluable when studying the functional dynamics of the pharynx and esophagus. Although endoscopy provides direct visualization of the mucosa, radiographic techniques provide a more physiologic examination. Both cineradiography (high-resolution images obtained at a low frame rate) and video capture (low-resolution images obtained at a high frame rate) are used in each examination. Cineradiography provides better spatial resolution for mucosal detail, whereas video capture allows more dynamic evaluation with less radiation. At most institutions, the video capture is not permanently stored, so it may be cumbersome or impossible to review these data after the examination is completed.

On traditional film, radiodense elements appear whiter than radiolucent elements. This convention has not persisted in the age of digital imaging; some aspects of anatomy and pathology are visualized better when the image is inverted. The images in this chapter follow the traditional convention.

The term "esophagram" is slowly replacing the ambiguous term "barium swallow." Note that an esophagram, which is designed to evaluate the pharyngeal and esophageal mucosa, is distinct from a "modified barium swallow," which evaluates laryngotracheal aspiration and is usually performed in conjunction with a speech pathologist. At some institutions, an esophagram includes a complete evaluation of the pharynx, but at other institutions, a "cervical esophagram," "pharyngoesophagram," or "pharyngography" must be specifically requested. Note that the nasopharynx is not evaluated with fluoroscopic techniques; cross-sectional imaging is required.

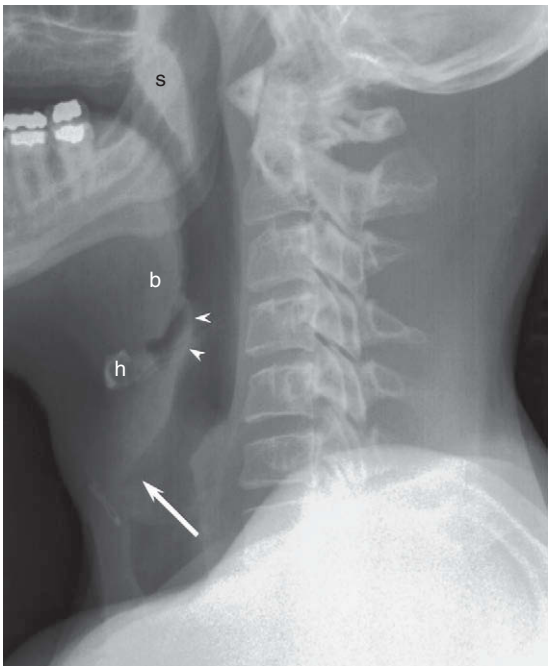

Figure 102-1. Lateral radiograph of the neck emphasizing soft tissues. The soft palate *(s),* tongue base *(b),* hyoid bone *(h),* and epiglottis *(arrowheads)* are marked. The laryngeal ventricle is barely visible as a dark wedge *(arrow).*

Pharyngoesophagram

A complete esophagram has three phases: full-column (single contrast), air-contrast (double contrast), and mucosal relief.[4] To obtain full-column images, the patient is given a thin suspension of barium by mouth. The pharynx is best imaged in the standing position, with rapid cineradiography (four to six images per second) in several projections (Fig. 102-2). In the frontal projection, the patient's neck is extended to prevent the jaw from obscuring the pharynx. When digitally displayed, cine images reveal much of the swallowing dynamics. Video capture is still useful, however, to evaluate equivocal filling defects.

Full-column images of the esophagus (Fig. 102-3) are obtained in a prone oblique position, with the patient drinking barium suspension from a straw. There are two objectives to this portion of the examination: evaluate esophageal peristalsis and maximally dilate the esophagus to identify contour abnormalities. Peristalsis is evaluated with videotaped single swallows. Maximum dilatation is achieved with rapid swallows followed by a Valsalva maneuver. The prone position eliminates gravity as a factor in peristalsis.

Air-contrast images of the esophagus (see Fig. 102-3) are obtained with the patient upright and in slightly left anterior obliquity. An effervescent agent is first administered, followed by a thick barium suspension. The barium coats the mucosal surface, whereas the gas from the effervescent agent distends the lumen. This provides exquisite mucosal detail and is most useful for the evaluation of small plaquelike mucosal tumors and the mucosal irregularities of esophagitis.[5] If the patient is unable to undergo the air-contrast portion of the thoracic esophagram, prone full-column imaging should be obtained in two orthogonal planes as an alternative.

Air-contrast images of the pharynx are not always necessary because this region is amenable to direct inspection. However, in some cases, such as tumors arising in the hypopharynx, air-contrast images are of use. After the administration of thick barium suspension, phonation and a modified Valsalva maneuver are used to distend the pharynx (Fig. 102-4).

Mucosal-relief images of the esophagus (Fig. 102-5) are obtained after the administration of thick barium suspension, but without air distention. Esophageal varices and some mucosal lesions are best seen with mucosal relief. Only the distal esophagus and gastroesophageal junction need to be imaged in this phase of the examination.

At the conclusion of an esophagram, after the esophagus has completely cleared all contrast, Valsalva and modified Valsalva maneuvers should be performed to document gastroesophageal reflux. It is important to realize, however, that these maneuvers are insensitive for the diagnosis of intermittent gastroesophageal reflux.

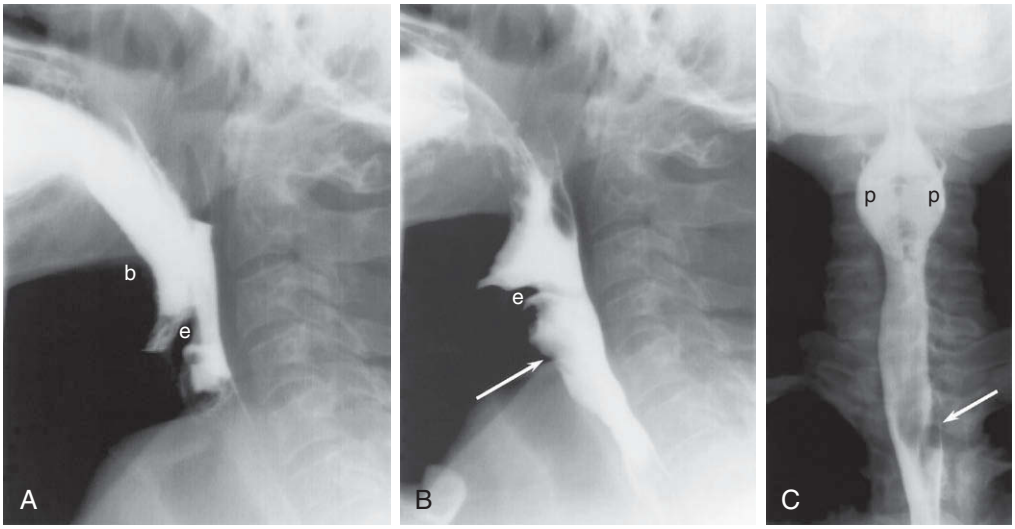

Figure 102-2. Normal pharyngogram. **A,** Lateral projection, early phase. The epiglottis *(e)* is upright, and the base of tongue *(b)* is well evaluated. **B,** Lateral projection, late phase. The epiglottis *(e)* has inverted. Note the normal anterior venous plexus *(arrow),* which mimics a mucosal lesion. **C,** Frontal projection, late phase. The pyriform sinuses *(p)* are well seen. Dynamic flow *(arrow)* can mimic a filling defect.

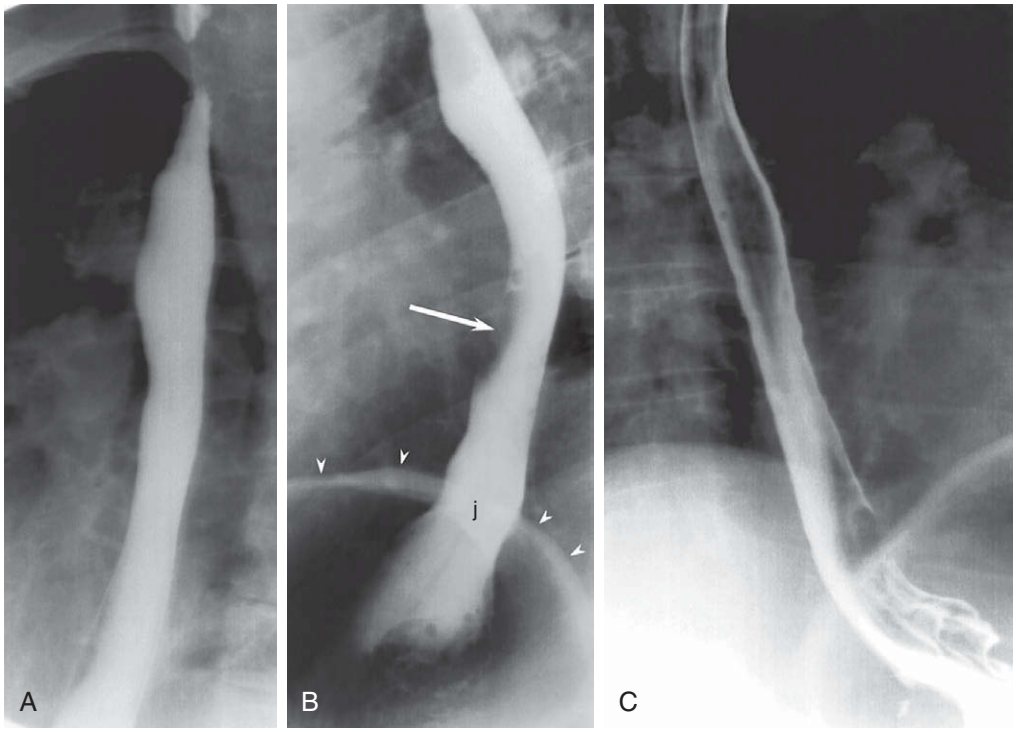

Figure 102-3. Normal esophagram. **A,** Full-column prone oblique image of the upper thoracic esophagus. Note the featureless mucosa. **B,** Full-column prone oblique image of the distal esophagus. Contrast spills past the gastroesophageal junction *(j)* into the air-filled stomach. The diaphragm is marked by *arrowheads.* An air bubble *(arrow)* can be distinguished from a true lesion because the air bubble moves during the examination. **C,** Normal air-contrast upright oblique image of the distal esophagus.

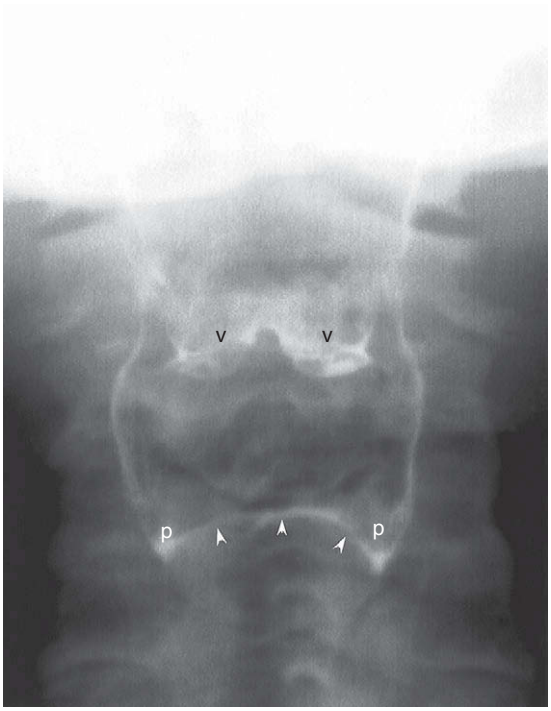

Figure 102-4. Normal air-contrast pharyngogram, frontal projection. Barium outlines the valleculae *(v)* and pyriform sinuses *(p).* The pyriform sinuses are connected by the smooth, arcuate postcricoid line *(arrowheads).*

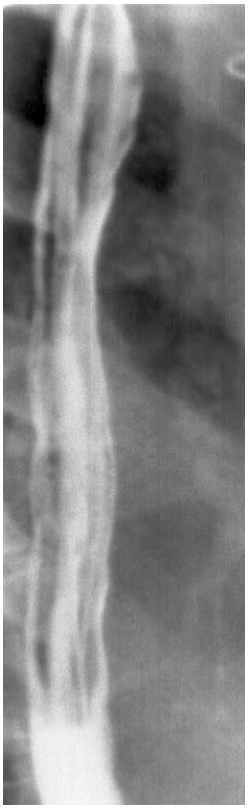

Figure 102-5. Normal mucosal-relief esophagram, oblique projection. Thick barium coats the undistended midthoracic esophagus. The normal longitudinal mucosal folds are easily identified.

Modified Barium Swallow

A modified barium swallow evaluates the coordination of the swallow reflex. It is most often used to determine a cause for, and evaluate the severity of, tracheal aspiration. The speech pathologist, using appropriate radiation safety precautions, administers barium suspensions of varying thickness while the radiologist observes fluoroscopically in the lateral projection. The entire examination is videotaped.[6,7]

The patient is given barium suspension of several consistencies (e.g., thin liquid, thick liquid, nectar, paste, solid). The various barium suspensions are intended to mimic different food consistencies and provide a more complete assessment of aspiration risk. If tracheal aspiration or laryngeal penetration is identified with the head in a neutral position, the speech pathologist may direct the patient to perform protective maneuvers during deglutition. Such maneuvers include varying the head position (chin tuck) and postprandial forced cough. The examination can be supplemented with images in the frontal projection to evaluate symmetry of the pyriform sinuses.

Oral Contrast Agents

Barium suspension is the best-known fluoroscopic contrast agent, but some patients are not appropriate candidates for oral barium administration. Patients who may have a perforated pharynx or esophagus are at risk for barium extravasation into the soft tissues of the neck or chest. Extravasated barium may incite an inflammatory reaction or may become inspissated and fail to resorb.[8] Water-soluble contrast agents (such as those used for intravenous CT contrast) may be used as an alternative. Unfortunately, water-soluble agents are not as dense as the barium suspension, so they are less sensitive to small leaks. If no leak is detected after the administration of a water-soluble agent, the examination should be repeated with barium.[9]

Ionic contrast agents have another disadvantage: if they are aspirated into the lungs, they may cause a chemical pneumonitis and pulmonary edema.[10] Nonionic water-soluble agents are presumed to be safer and thus should be used if there is a risk of aspiration or tracheoesophageal fistula.

Oil-based contrast agents for the evaluation of the larynx and pharynx are of historical interest only.

Computed Tomography

At most institutions, CT is the modality of choice for evaluating masses in the neck and chest. Two recent advances have dramatically changed the quality of CT imaging: multidetector scanners and helical acquisition. Multidetector scanners have several rows of photoreceptors, allowing the simultaneous acquisition of several slices. Helical techniques allow patients to move continuously through the scanner instead of stopping for each slice. These advances have dramatically decreased scan times and radiation doses while improving spatial resolution.[11] This improved resolution allows multiplanar and three-dimensional reconstructions that rival magnetic resonance (MR) for clarity and diagnostic accuracy. The rapid scan times permit dynamic CT imaging, which can assess vascularity and other physiologic properties.[12]

CT is readily available and provides critical information about the extent and character of mass lesions. In known tumors, CT is used to determine the degree of invasion into surrounding deep tissues, the relationship of the neoplasm to critical structures such as the vocal cords and arteries, and the involvement of regional lymph nodes.[13] CT is comparable to magnetic resonance imaging (MRI) for the evaluation of bone invasion,[14] but MRI is preferred for the evaluation of soft tissue extent, particularly at the skull base.[15] Disadvantages of CT include artifacts from dental amalgam and from patient body habitus, particularly at the shoulders.

Intravenous contrast is of particular importance in the neck because enlarged lymph nodes may be difficult to distinguish from unenhanced vessels. Allergies to contrast material and renal dysfunction are relative contraindications to intravenous contrast. Some practitioners avoid intravenous contrast in patients who may require radioablation of thyroid neoplasms because the contrast can impede iodine uptake for an indeterminate amount of time after the examination.

Ionic contrast media are more prone to allergic reactions than the more expensive nonionic media. For this reason, some institutions have abandoned ionic contrast media. Ionic contrast should be avoided in patients with airway pathology because a mild allergic reaction could precipitate severe airway compromise.

Helical neck CT should be performed with a maximum slice thickness of 3 mm. Thinner slices may be required to delineate the extent of pathology, particularly in tumors near the larynx. A contrast bolus of 75 to 125 mL is used, with a delay of 30 to 60 seconds.[16] Faster scanners require longer contrast delays, so revised protocols are required when equipment is upgraded. CT of the chest is performed with a thickness of 5 to 7 mm; additional intravenous contrast is usually not required. CT of the neck and chest should not be performed as a continuous acquisition because the arms are positioned differently for the two scans.

Magnetic Resonance Imaging

Unlike CT, which relies on ionizing radiation to create images, MRI uses a strong magnetic field and radiofrequency pulses to interrogate the patient's tissues. It is particularly useful for evaluating tumors of the pharynx and larynx, but it is less useful in the thorax, where motion artifact and field distortions prevent a thorough evaluation of the mediastinum.[17]

MRI has the substantial advantage of multiple pulse sequences, which allows more precise characterization of pathologic tissue. The most frequently used sequences are T1-weighted and T2-weighted sequences. Postcontrast images are exclusively T1 weighted. T1-weighted images demonstrate anatomic relationships, whereas T2-weighted images are sensitive for pathology. Many additional sequences and modifications (e.g., inversion recovery, fat suppression, magnetization transfer, and diffusion weighting) can more precisely determine tissue characteristics and extent of pathology.

Advantages of MRI include reduced artifacts from dental amalgam and body habitus, as well as the ability to directly image in any plane including oblique planes. The gadolinium-based intravenous contrast agents used in MRI have a substantially lower risk of allergic reaction than CT agents do.[18] Disadvantages of MRI include the long duration of MRI studies, which sometimes results in motion artifact, especially in debilitated patients or patients with respiratory compromise. The small bore of the MRI magnet often induces claustrophobia. Many patients cannot go near the MRI magnet because of metallic or electronic implants that might be displaced or triggered by the rapid changes in the magnetic field.[19] In particular, cardiac pacemakers/defibrillators, cochlear implants, and ferromagnetic aneurysm clips are relative contraindications to MRI.[20] Metallic foreign bodies may also be of concern, depending on their location.[21]

Different receiving coils are available for MRI, with characteristics tailored to different body parts. It is critical for head and neck patients to be imaged with a surface coil, which allows for improved spatial resolution and higher signal-to-noise ratios. Low-field "open" MRI magnets do not have the spatial resolution or signal-to-noise characteristics to evaluate the intricate anatomy of the skull base or larynx and are not recommended for imaging of the head and neck.

Ultrasound

Transcutaneous sonographic evaluation of the neck[22] has undergone a resurgence in popularity in patients with thyroid cancer and for guidance in interventional procedures. Although ultrasound can be used to evaluate superficial lymph nodes in the neck, it may overlook deep nodes and cannot be relied on for a complete evaluation of cervical tissues. Transesophageal echosonography provides information that is complimentary to CT and invaluable for the evaluation of the extent of esophageal lesions across tissue planes.[23] All sonographic techniques are highly operator dependent, so experienced technologists and appropriately trained physicians are necessary to produce diagnostic-quality examinations.

Positron Emission Tomography-Computed Tomography

Combined 18F-fluorodeoxyglucose positron emission tomography and CT scanning (PET/CT) has revolutionized the care of head and neck cancer patients.[24] PET is a functional imaging technique that relies on the increased metabolic uptake of glucose in tumors to identify

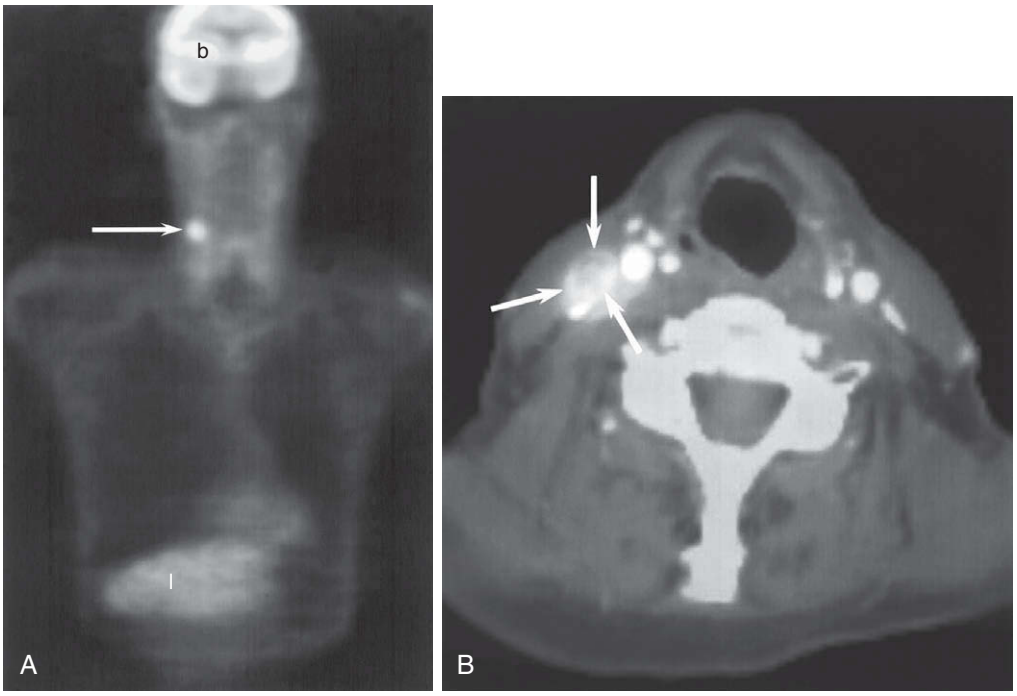

Figure 102-6. Positron emission tomography (PET)-computed tomography identifies a metastatic cervical node. **A,** Coronal PET image shows focal uptake in the lower neck *(arrow),* but the precise anatomic location is uncertain. Brain *(b)* and liver *(l)* are marked. **B,** Fused axial image localizes the uptake to a level III lymph node.

unknown primary tumors, stage malignancies, search for metastatic disease, and evaluate recurrences.[25,26] The major limitation of PET imaging is its poor spatial resolution, which is particularly significant in the head and neck. Combined PET/CT scanners use the high spatial resolution of CT with the functional information of PET to produce fused images that overcome this difficulty (Fig. 102-6). For the evaluation of head and neck cancers, PET/CT is superior to either PET or CT alone.[27]

PET/CT is used in the staging of cancer, the monitoring of treatment response, and the surveillance of treated patients.[28] Optimal monitoring and surveillance schemata have not yet been established, but it is known that PET/CT should not be performed until at least 8 weeks after the conclusion of therapy to avoid both false-positive and false-negative results.[29] Surveillance with PET/CT is particularly useful because of the low rate of false-negative studies.

The analysis of PET/CT scans is complicated and requires a radiologist with experience in both PET/CT and head and neck imaging. Physiologic uptake of FDG is prevalent in the head and neck, especially during contraction of muscles (e.g., neck and thyroarytenoid muscles), and may therefore be confused with tumor uptake.[30] Inflammation, either postoperative or from infectious sources such as the teeth, palatine, or lingual tonsils, may also obscure the interpretation, resulting in false-positive reads and unnecessary clinic evaluations and biopsies.

Future trends in PET/CT will likely include combined PET-MR scanners, the development of novel ligands to supplement or replace fluorodeoxyglucose, and guidance for optimizing the utilization of this relatively new modality.

Other Nuclear Medicine

Although PET/CT is the most commonly used nuclear medicine examination in the head and neck, other nuclear medicine tests are sometimes of use. Esophageal transit, gastroesophageal reflux, and gastric emptying can be studied with conventional nuclear medicine techniques.[31,32] These studies are more sensitive than fluoroscopy for the presence of reflux, but the quantitative degree of reflux does not correlate well with symptoms. Radionuclide swallowing studies are used predominantly in the pediatric population.

Radiographic Anatomy

Pharynx

The radiographic anatomy of the pharyngeal lumen is best visualized with air-contrast fluoroscopic images (see Fig. 102-4). The mucosal surfaces of the epiglottis, vallecula, and pyriform sinuses are easily identified. Normal asymmetry of the lingual tonsils should not be confused with a vallecular mass. The epiglottis is best evaluated in the lateral projection, where its thickness can be directly assessed. The pyriform sinuses may be asymmetric, but a complete lack of filling is suspicious for tumor. Barium pooled between the posterior margin of the larynx and the posterior wall of the hypopharynx forms the postcricoid line (see Fig. 102-4). Disruption or irregularity of this line is a sign of tumor invasion. The cricopharyngeus muscle lies anterior to the sixth cervical vertebra. It may be seen as a slight indentation on the posterior wall of the hypopharynx, but it is often not visualized in normal individuals. The normal cross-sectional anatomy of the upper aerodigestive tract is demonstrated in Figures 102-7 and 102-8.[33]

Esophagus

The esophagus begins at the level of the sixth cervical vertebra. The cervical esophagus lies posterior to, and slightly to the left of, the trachea (see Fig. 102-7). Surrounding structures that may affect the cervical esophagus include the trachea, cervical spine, thyroid and parathyroid gland, and cervical lymph nodes. On CT, the anteroposterior diameter of the collapsed cervical esophagus should not exceed 16 mm, and its lateral dimension should not exceed 24 mm, except at the esophageal verge, where it may be more prominent.[34] On full-column lateral projections, there is a normal mucosal irregularity of the anterior esophagus just below the cricoid cartilage (see Fig. 102-2). This is caused by lax mucosal folds overlying the ventral submucosal venous plexus, and it should not be mistaken for tumor invasion or a web.[35] Unlike webs and tumors, the venous plexus changes shape during swallowing.

The thoracic esophagus lies anterior to the spine, anteromedial to the descending aorta (see Fig. 102-7). The phrenic ampulla, which is a normal widening of the esophageal lumen, is seen just above the gastroesophageal junction (Fig. 102-9). There are three normal inden-

tations on the anterolateral esophagus: aortic arch, left mainstem bronchus, and left atrium (see Fig. 102-3). Other nearby structures include the descending aorta, aortic arch and great vessels, carina, mediastinal lymph nodes, and spine.

When the esophagus is filled with contrast, it is a featureless tube. When the esophagus is collapsed, longitudinal mucosal folds appear along the entire length of the organ. Occasional transverse folds are normal.

Motility Disorders

Pharynx

The modified barium swallow is the most appropriate radiologic test to evaluate swallowing dysfunction.[7] Although an esophagram provides some information about deglutition, the modified swallow uses barium of several different consistencies, which provides a more detailed evaluation. Functional endoscopic evaluation of swallowing, with or without sensory testing, has been proposed as an alternative to the modified swallow.[36] However, the modified swallow provides a more physiologic environment because there is no endoscope to interfere with motility. During a modified swallow, patients can use protective maneuvers such as chin tuck and forced cough, which are not available during endoscopy. Furthermore, the modified swallow evaluates the upper phases of swallowing in more detail.[37] Endoscopy and modified swallow are considered complementary examinations at most institutions.

The modified barium swallow can evaluate all phases of the swallow reflex.[1,6,38] The tongue forms the oral bolus and then transports it from the oral cavity to the oropharynx. The soft palate elevates and approximates the posterior pharynx to prevent velopharyngeal reflux. The entire larynx elevates, followed by a peristaltic wave through the pharynx. The epiglottis inverts to deflect the bolus into the pyriform sinuses and protect the laryngeal vestibule. At the bottom of the hypopharynx, the cricopharyngeus muscle relaxes to permit the passage of the food bolus.

Velopharyngeal occlusion can be observed directly. Elevation of the larynx is best visualized by observing the hyoid bone. Epiglottic inversion is fast, and confirmation of this event may require review of the video images. Brief episodes of contrast penetration may be seen in the laryngeal vestibule. If the contrast clears rapidly and without cough, this finding does not indicate a risk of tracheal aspiration. A small amount of barium may pool in the valleculae or the pyriform sinuses in normal patients, but the peristaltic wave should strip the contrast from the remainder of the pharynx. The cricopharyngeus muscle lies at the level of the C6 vertebral body, and it is not normally visualized.

Abnormal Deglutition

Aspiration can occur in any phase of deglutition. During the oral phase, incomplete control of the oral bolus allows contrast to spill over the base of the tongue into the vallecula. In severe cases, the vallecula will fill completely, and contrast will spill over the epiglottis into the larynx. During peristalsis, failure of epiglottic inversion allows contrast to enter the larynx. After the swallow, incomplete clearance of contrast leads to postprandial aspiration when the patient resumes breathing.

Abnormal pharyngeal motility is caused by disorders of the brainstem, cranial nerves IX and X, the myoneural junction, or the pharyngeal musculature. Myasthenia gravis is a disorder of the myoneural junction that produces hesitancy in swallow initiation, nasopharyngeal reflux, enlargement of the pharynx, tracheal aspiration, and incomplete clearance. The findings worsen over consecutive swallows and improve after neostigmine administration. Diseases that affect the pharyngeal muscles such as dermatomyositis, systemic lupus erythematosus, myotonic dystrophy, systemic sclerosis, and oculopharyngeal myopathy produce weakened pharyngeal contractility with incomplete clearance.

Unilateral pharyngeal palsy causes an asymmetry in the pyriform sinuses because the contrast is thrown to the palsied side by the functioning pharyngeal constrictors.[39] This asymmetry should not be misinterpreted as a filling defect from carcinoma in the unaffected side. A careful dynamic examination of several swallows may be necessary to prevent this diagnostic error.

Cricopharyngeal Dysfunction

Unlike the other muscles of pharyngeal constriction, the cricopharyngeus remains contracted between swallows, acting as an upper esophageal sphincter. It normally relaxes during deglutition to allow the

The arytenoid cartilages *(arrow)* are also seen.

passage of the food bolus. When the muscle fails to completely relax (cricopharyngeal achalasia), there is a smooth posterior impression on the hypopharynx at the level of the C6 vertebra (Fig. 102-10). Unlike most retropharyngeal masses, the cricopharyngeus does not exceed 1 cm in vertical dimension. The most frequent cause of cricopharyngeal achalasia is cerebrovascular disease. Other causes include pseudobulbar palsy, nasopharyngeal carcinoma, poliomyelitis, thyroid myopathy, cervical vagotomy, polymyositis, dermatomyositis, oculopharyngeal syndrome, amyotrophic lateral sclerosis, and hiatus hernia, but many cases are idiopathic. Cricopharyngeal achalasia has been implicated in the development of Zenker's diverticula.[40]

Incompetence of the upper esophageal sphincter is called cricopharyngeal chalasia. It manifests radiographically as a lack of cricopharyngeal impression between swallows. Cricopharyngeal chalasia is specific for myotonic dystrophy, although most patients with myotonic dystrophy have cricopharyngeal achalasia instead.[41]

Delayed opening of the cricopharyngeus, seen in familial dysautonomia, results in aspiration and recurrent pulmonary infections. This disorder is distinct from cricopharyngeal achalasia in that the muscle relaxes completely after a delay.

Esophagus

Manometry is considered the reference standard for evaluation of esophageal dysmotility. The relative sensitivity of fluoroscopy, radionuclide scans, and manometry is controversial.[31,32,42,43] However, radiographic techniques are less invasive and elicit less patient discomfort. Fluoroscopy has the additional advantage of identifying structural abnormalities.

A normal (primary) peristaltic wave is initiated by a swallow. The wave passes uninterrupted to the lower esophageal sphincter (LES). The contrast bolus should remain intact during a primary wave; contrast that escapes proximally is the earliest sign of weakened peristalsis. Secondary peristaltic waves are initiated in the midesophagus by local irritation such as from gastroesophageal reflux or retained food. Tertiary contractions are nonperistaltic local contractions, a contributing factor in dysmotility.

Diminished Peristalsis

Achalasia is a neuromuscular disorder caused by degeneration of Auerbach's plexus.[44] Peristalsis fails, but the LES remains tight, so the esophagus progressively dilates. In severe cases a dilated esophagus with

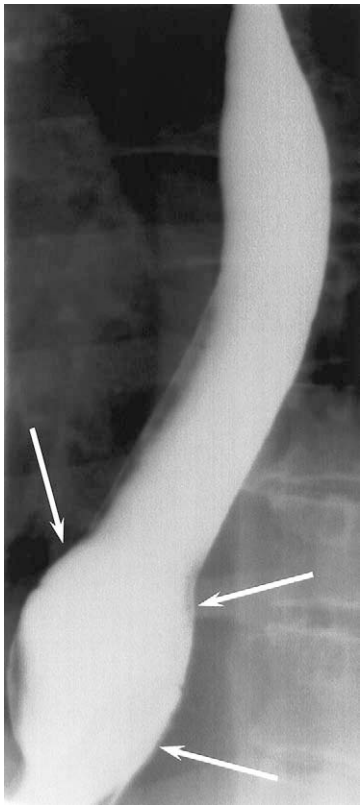

Figure 102-9. The phrenic ampulla is a normal widening of the distal esophagus just above the diaphragm.

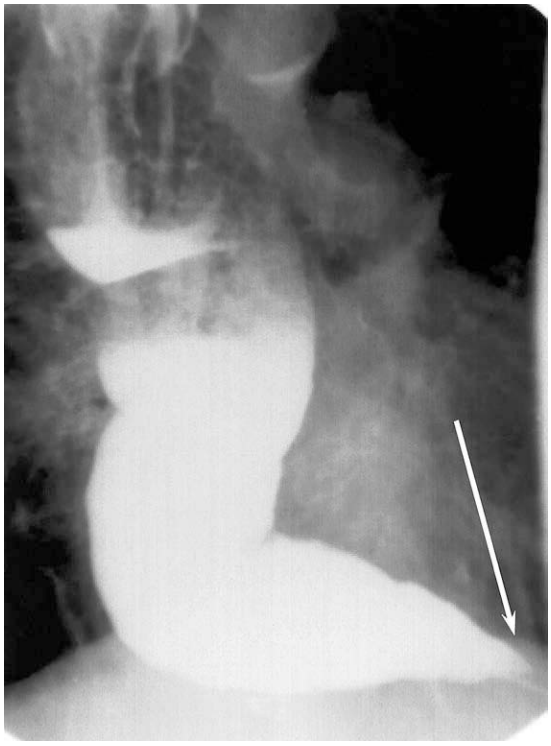

Figure 102-11. Achalasia. Oblique image of the lower mediastinum reveals a patulous esophagus with beaking of the gastroesophageal junction *(arrow)*.

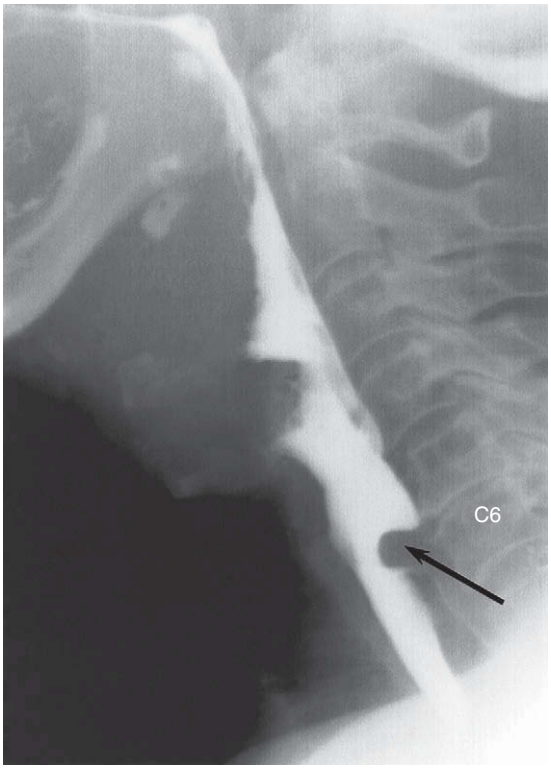

Figure 102-10. Cricopharyngeal achalasia. Lateral view from an esophagram reveals a smooth, rounded impression *(arrow)* on the posterior esophagus at the level of the sixth cervical vertebra *(C6)*.

retained food can be appreciated on a chest film. On fluoroscopy, the distal esophagus has a conical (beaked) shape (Fig. 102-11). In early stages of the disease, the esophagus may be only minimally dilated, with dominant tertiary contractions. This is called vigorous achalasia, and it may mimic esophageal spasm (Fig. 102-12).[45] Patients with achalasia are at increased risk of esophageal carcinoma, and radiographic screening may be indicated.[46,47]

Impairment of the LES is a constant feature of achalasia, but it is not pathognomonic. Patients with diffuse esophageal spasm, presbyesophagus, or connective tissue diseases may also have impaired relaxation of the LES. Carcinoma of the distal esophagus or gastric cardia can mimic achalasia.[48] Chagas' disease, in which the parasite *Trypanosoma cruzi* affects the ganglion cells of the esophagus, may appear identical to achalasia on an esophagram.[49] Other mimics of achalasia include central and peripheral neuropathies such as stroke, diabetes mellitus, and amyloidosis, and strictures from reflux esophagitis.[40]

Presbyesophagus is a failure of peristalsis associated with aging. It is frequently observed in older patients with dysphagia, but the relationships among reflux esophagitis, presbyesophagus, and dysphagia remain unclear.[50] Presbyesophagus manifests as failure of the primary peristaltic wave with intermittent tertiary contractions.

Many other diseases can cause diminished peristalsis including severe esophagitis, diabetes, alcoholism, hyperthyroidism, anticholinergic medications, and surgical vagotomy.[40]

Connective Tissue Diseases

Scleroderma is the prototype for a connective tissue disease with esophageal manifestations. Peristalsis is absent in the distal two thirds of the esophagus (the portion with smooth muscle rather than striated muscle). This usually results in mild dilation of the distal esophagus. In contrast to achalasia, the LES becomes incompetent, allowing reflux (Fig. 102-13). Scleroderma has been associated with hiatus hernia, *Candida* esophagitis,[51] aspiration pneumonia, esophageal adenocarcinoma,[52] and reflux esophagitis with Barrett's esophagus.[53]

Systemic lupus erythematosus, rheumatoid arthritis, and polymyositis have radiographic manifestations similar to scleroderma. Der-

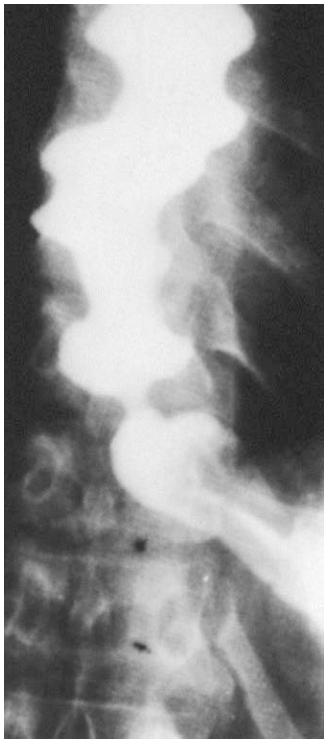

Figure 102-12. Vigorous achalasia. Barium esophagram shows dilation of the esophagus with multiple nonperistaltic contractions.

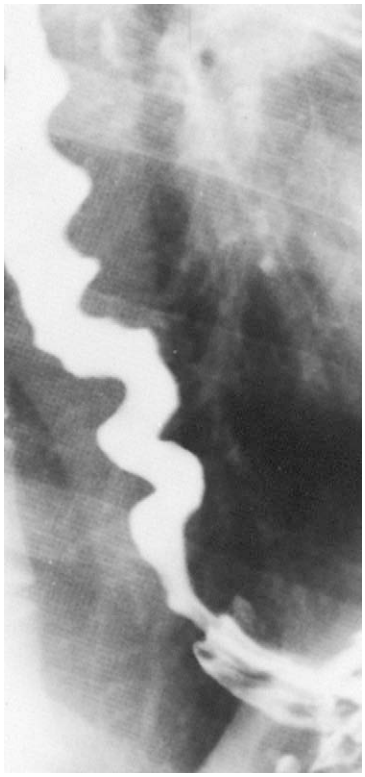

Figure 102-14. Diffuse esophageal spasm. Barium esophagram demonstrates a corkscrew appearance of the esophagus produced by nonperistaltic contractions in a patient with chest pain.

matomyositis, in contrast, predominantly affects the striated muscle of the pharynx and upper esophagus.[40] Fluoroscopy and manometry are more useful than endoscopy in the evaluation of connective tissue disorders.[54]

Esophageal Spasm

Patients with diffuse esophageal spasm have normal peristalsis in the proximal third of the esophagus, but contractions in the distal two thirds are uncoordinated and nonperistaltic. Possible radiographic manifestations include the corkscrew esophagus (a spiral column of contrast, Fig. 102-14), the rosary or shish-kebob (pouches separated by tight contractions), and diffuse narrowing. The diagnosis of diffuse esophageal spasm is made only when these radiographic findings are accompanied by substernal chest pain.

Nutcracker esophagus, also known as symptomatic esophageal spasm or hypertensive peristaltic esophagus, is characterized by high-contractility peristaltic waves causing chest pain. The esophagram is usually normal; this diagnosis is made with manometry.[55,56]

Diverticula

Zenker's Diverticula

Zenker's diverticulum is the most prevalent of the pharyngeal diverticula. It is a true diverticulum of the posterior pharyngeal wall, arising through Killian's dehiscence just above the cricopharyngeus muscle. Patients generally present with halitosis and food regurgitation. Zenker's diverticulum is best imaged fluoroscopically in the lateral projection (Fig. 102-15). Contrast is seen filling the diverticulum during swallowing, with variable retention between swallows. Large diverticula may compress the hypopharynx. Fluoroscopy is useful to delineate the size of the pouch and the diameter of its neck.

Pharyngeal Pouches

The pharyngeal wall may protrude out of its normal contour at the levels of the tonsillar pillar or thyrohyoid membrane. This "pharyngeal

Figure 102-15. Zenker's diverticulum. Oblique image from an esophagram shows a barium-filled pouch extending posteriorly from the hypopharynx, displacing and compressing the upper esophagus. The neck of the diverticulum is denoted by *arrowheads.*

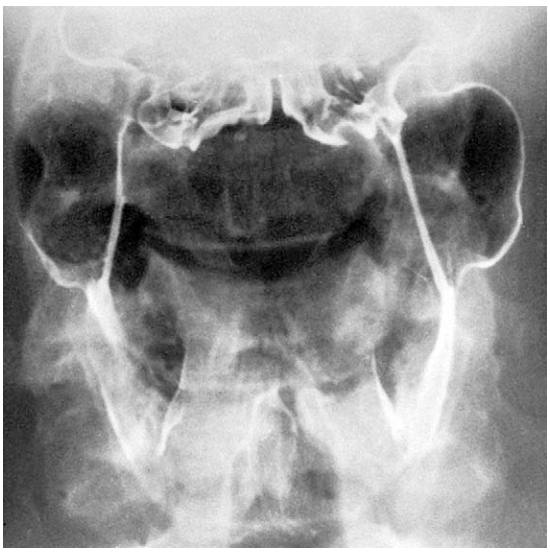

Figure 102-16. Lateral pharyngeal pouches. Frontal view from an air-contrast pharyngogram shows bilateral bulging of the lateral pharyngeal walls as the patient performs a modified Valsalva maneuver. These pouches are not true diverticula.

pouch" is usually asymptomatic, but patients may complain of dysphagia or regurgitation of food in severe cases. Pharyngeal pouches are best viewed in frontal projection, where they fill transiently (Fig. 102-16). Pouches should be distinguished from true pharyngeal diverticula, which present as persistent outpouchings of pharyngeal mucosa

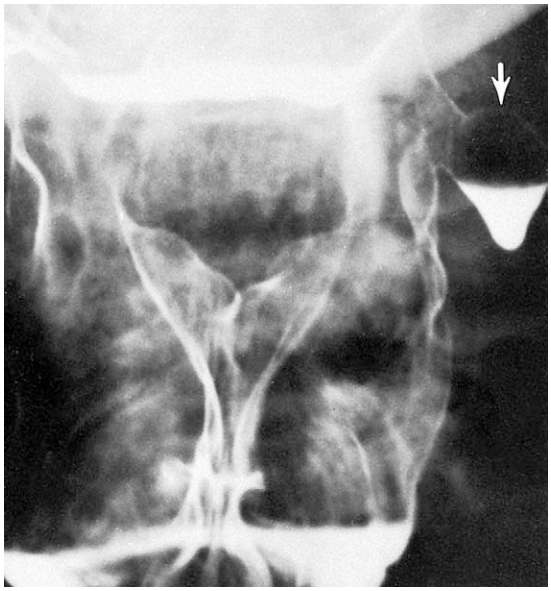

Figure 102-17. Acquired lateral pharyngeal diverticulum. Frontal view from an air-contrast pharyngogram shows persistent focal outpouching *(arrow)* of the lateral pharyngeal wall. This outpouching represents protrusion of the hypopharyngeal mucosa through the thyrohyoid membrane.

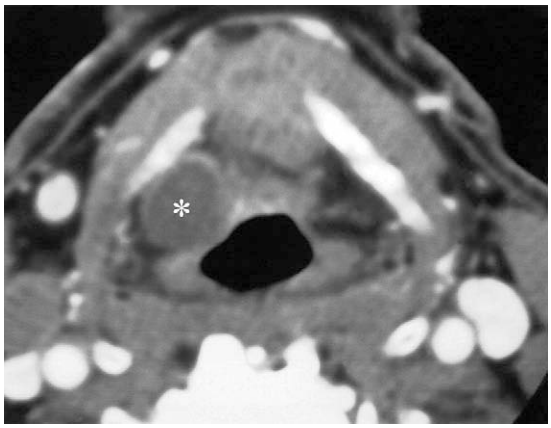

Figure 102-18. Intrinsic laryngocele. Enhanced computed tomography of the larynx reveals a fluid-filled mass *(*)* in the paraglottic fat. Laryngoceles may be filled with air or fluid.

(Fig. 102-17).[57] Pharyngeal diverticula are seen with chronically increased pharyngeal pressure, as in trumpet players and glass blowers.

Laryngoceles

A laryngocele is a diverticulum of the saccule of the laryngeal ventricle. Laryngoceles are classified as internal, external, or mixed, depending on whether they traverse the thyrohyoid membrane. Esophagram is usually normal, but the aryepiglottic folds may be displaced by the underlying mass. Laryngocele is best evaluated with CT or MR, where it appears as a well-defined, air-filled or fluid-filled mass in or around the larynx (Fig. 102-18).[58] The density or signal of the mass varies with the degree of proteinaceous debris.

Midesophageal Diverticula

Esophageal diverticula arise at the level of the carina or in the epiphrenic region. They are formed by pulsion rather than traction.[59] Fluoroscopically, esophageal diverticula present as smooth outpouchings that expand and contract with peristalsis (Fig. 102-19). These diverticula are usually seen in the setting of esophageal dysmotility.

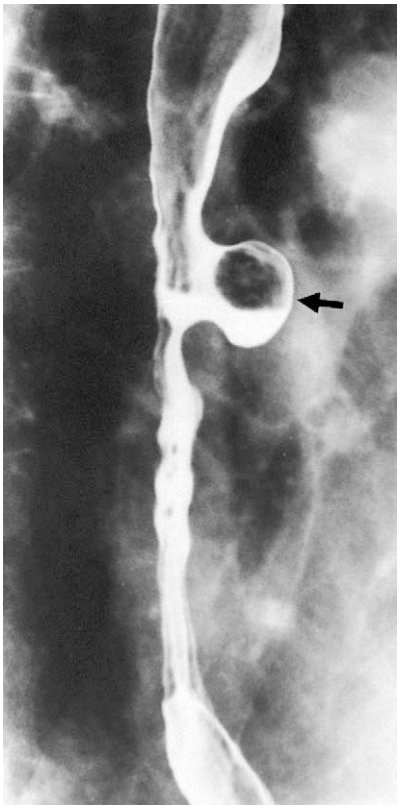

Figure 102-19. Midesophageal diverticulum. Air-contrast esophagram shows a smooth, round diverticulum *(arrow)* at the subcarinal level in a partially collapsed esophagus.

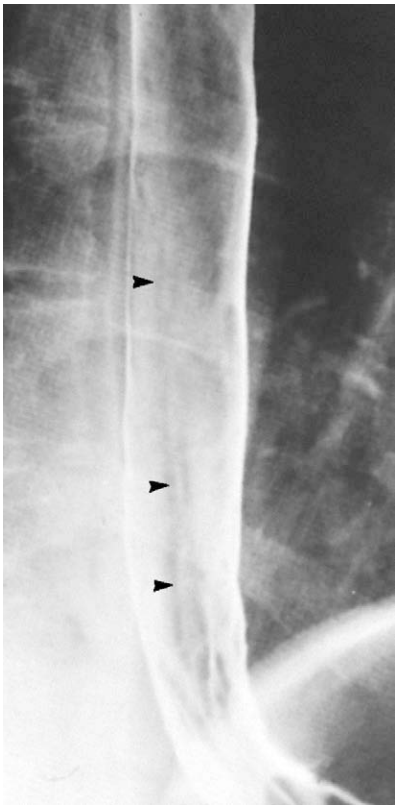

Figure 102-20. Reflux esophagitis. Air-contrast esophagram demonstrates several linear ulcerations *(arrowheads)* in a patient with reflux esophagitis.

Infection/Inflammation

The radiographic hallmark of esophageal inflammation is an altered mucosal pattern. The mucosa is best evaluated fluoroscopically by use of both full-column and air-contrast techniques.[60] Thickening of the esophageal folds and a lack of normal distensibility can be seen in all forms of esophagitis. The abnormal folds may have a transverse orientation and are often fixed during peristalsis. A variety of chemical, physical, and infectious agents cause esophageal inflammation, but gastroesophageal reflux is by far the most prevalent.

Reflux Esophagitis

The radiologist uses a variety of evocative maneuvers to elicit gastroesophageal reflux (GER) during an esophagram. These include coughing, Valsalva maneuver, leg raising, Trendelenburg position, epigastric compression, and the water-siphon test, in which the patient swallows water when contrast is already in the stomach. Despite these maneuvers, radiographic evidence of GER is present in only half the patients who have endoscopic evidence of reflux esophagitis.[61] Endoscopy itself is insensitive for the diagnosis of GER, and 24-hour pH monitoring remains the best diagnostic test.[62]

The earliest radiographic manifestations of GER are subtle: diminished contractility of the distal esophagus, granular mucosa, and tiny superficial erosions. As the disease progresses, frank ulcerations can appear, with either linear or round configurations (Fig. 102-20). Advanced GER results in deep ulceration (Fig. 102-21). These ulcerations heal with a variable degree of scarring, and strictures may result (Fig. 102-22). Although most patients with GER have a hiatus hernia, the relationship between these diagnoses is not completely understood.[63]

The esophagus is normally covered by squamous epithelium and the stomach by columnar epithelium. Patients with severe GER may transform the normal squamous epithelium of the distal esophagus into a columnar epithelium, thus changing the location of the squamoco-

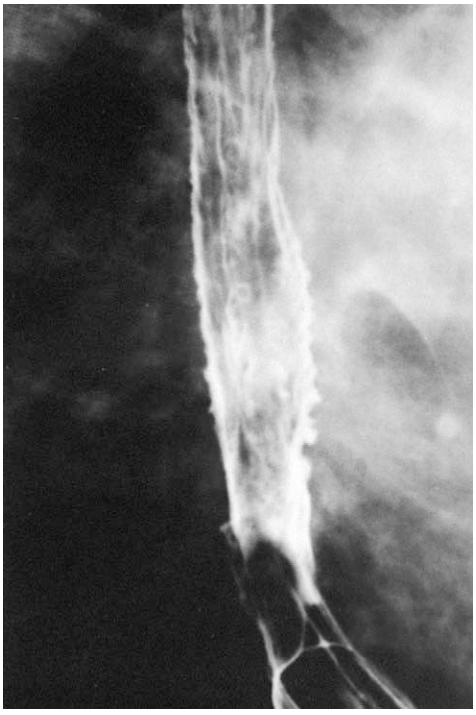

Figure 102-21. Severe reflux esophagitis. Air-contrast esophagram shows marked irregularity of the mucosa with multiple ulcerations.

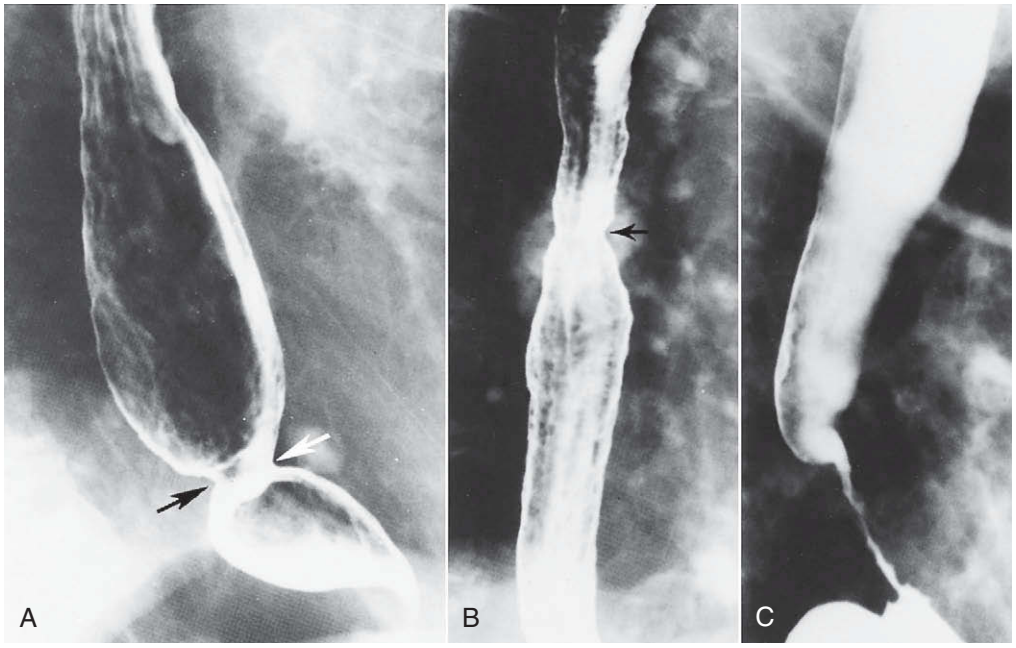

Figure 102-22. Peptic strictures. **A,** Smooth symmetric focal stricture of the distal esophagus *(arrows)* secondary to reflux esophagitis. **B,** Mildly irregular midesophageal stricture *(arrow)* in a patient with severe reflux esophagitis. Note the irregularity of the esophageal mucosa. **C,** Long narrow stricture of the distal esophagus with irregular margins secondary to severe reflux esophagitis.

lumnar junction. This is called Barrett's esophagus. Patients with Barrett's esophagus have a dramatically increased risk of esophageal carcinoma (incidence of 0.5% per year).[64]

There are no radiographic findings specific to Barrett's esophagus, but strictures or ulcers in the mid to upper esophagus suggest the diagnosis (Fig. 102-23). A fine reticular pattern in the mucosa adjacent to a stricture is also suggestive.[63] However, endoscopy with biopsy is preferable to fluoroscopy for the diagnosis and surveillance of Barrett's esophagus.[64]

Infectious Esophagitis

Infectious esophagitis is seen predominantly in immunosuppressed patients such as those with AIDS, cancer, diabetes mellitus, or organ transplants. Long segments of esophagus are usually involved. Odynophagia is the most frequent presentation. The radiographic findings in early esophagitis are easily overlooked on single-contrast examinations; air-contrast techniques are recommended.[65]

Candida albicans is the most frequent organism to cause esophagitis. It is seen not only in immunocompromised patients but also in the setting of esophageal stasis (e.g., achalasia or stricture).[66] Radiographic findings in early disease include abnormal motility and longitudinal mucosal plaques. As the disease progresses, these plaques coalesce and the mucosa acquires a "shaggy" appearance (Fig. 102-24). The mucosal abnormalities resolve after treatment.

Herpes simplex virus is the second most common organism to cause esophagitis. Fluoroscopy reveals discrete ulcers in the midesophagus (Fig. 102-25). Strictures and giant ulcers are less frequently seen.[67] The mucosal vesicles seen endoscopically precede the ulcerations visible on fluoroscopy. Cytomegalovirus, another member of the herpes family, can have radiographic manifestations that mimic *Candida* esophagitis, herpes esophagitis, or reflux esophagitis.[65]

Esophagitis has been reported from bacteria, fungi, mycobacteria, and from HIV itself.[68-71]

Caustic Esophagitis

Caustic esophagitis is the result of ingestion of corrosive materials. The most common caustic agent seen in the United States is lye (sodium hydroxide), which is commercially available in drain cleaners. The radiographic appearance of caustic esophagitis depends on the corrosive agent. For example, acids cause coagulation necrosis, which limits their penetration, whereas alkali causes liquefaction necrosis and penetrates deeply.[72] Endoscopy has become the predominant modality for evaluation and treatment of caustic injuries,[73] but radiology provides useful information in both the acute and chronic stages of the disease.[74]

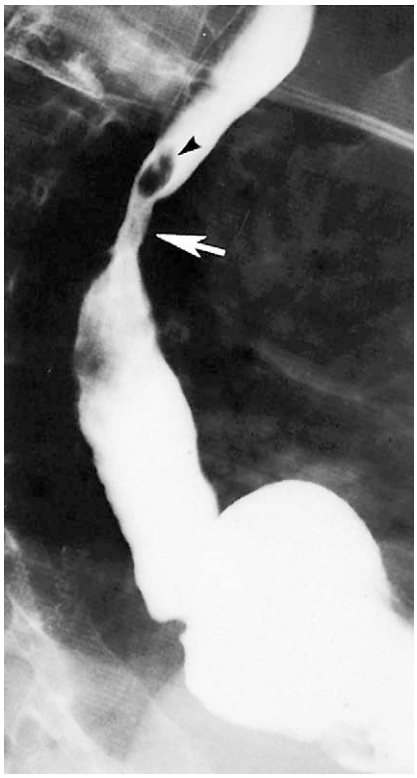

Figure 102-23. Barrett's esophagus with stricture. Left posterior oblique view from an upper gastrointestinal examination demonstrates a midesophageal stricture *(arrow)* in a patient with chronic gastroesophageal reflux. Note the pill *(arrowhead)* lodged above the stricture.

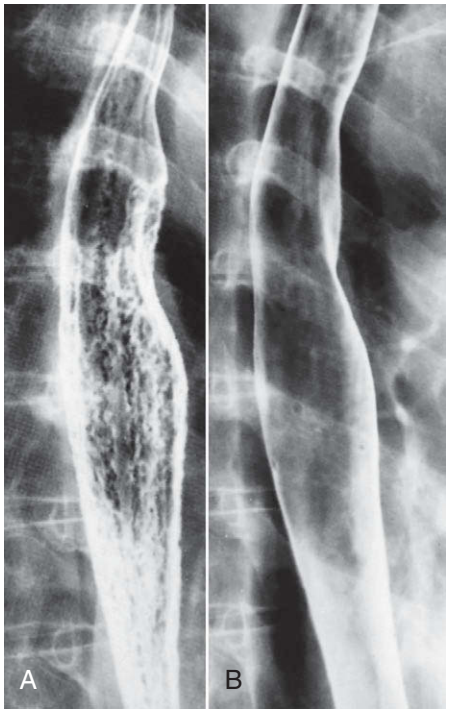

Figure 102-24. *Candida* esophagitis. **A,** Air-contrast esophagram demonstrates shaggy mucosa with irregular, longitudinal plaquelike filling defects involving most of esophagus. **B,** Repeat air-contrast esophagram after treatment with amphotericin-B shows complete resolution of the esophagitis. *(Courtesy of Dr. Marvin Lindell, Houston.)*

Figure 102-26. Lye stricture. Barium esophagram shows a long, smooth midesophageal narrowing in a patient who had ingested lye many years previously.

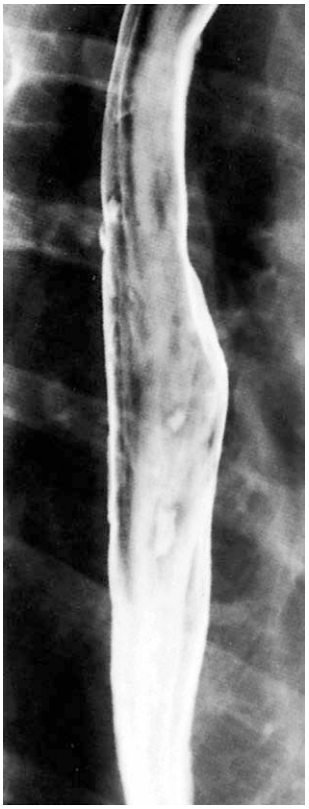

Figure 102-25. Herpes esophagitis. Air-contrast esophagram demonstrates multiple discrete mucosal ulcerations characteristic of viral esophagitis.

In the acute stage, there is mucosal irregularity, ulceration, fold thickening, and weakened peristalsis. Sloughed mucosa may produce filling defects. Thickening of the esophageal wall may result in luminal narrowing.[75] Lye ingestion may result in esophageal perforation, so patients should be given water-soluble agents before barium is administered.

Esophageal strictures develop 1 to 3 months after the injury. These appear as long segments of esophageal narrowing (Fig. 102-26). The strictures usually have smooth contours, but submucosal fibrosis occasionally causes nodular defects or scalloping. Concomitant gastric injuries occur in 25% of patients with lye ingestion, so a complete upper gastrointestinal series is warranted in these patients.[75]

Patients with caustic strictures are at risk for esophageal carcinoma approximately 30 years after the initial injury.[76] Nodularity or ulceration in the region of a previously smooth stricture suggests malignant transformation.

Although caustic ingestion most commonly affects the esophagus, pharyngeal strictures and gastric injury are also seen.[75,77]

Granulomatous Esophagitides

Tuberculous esophagitis is usually caused by direct extension from adjacent lymph nodes. Swallowed sputum is causative only when there is an underlying structural abnormality of the esophagus.[65] Immunocompromised patients are more prone to tuberculous esophagitis.[78] The radiographic findings are nonspecific and include stricture, fistula, and mucosal irregularity.[79]

Crohn's disease may affect the esophagus. The earliest finding is aphthous ulcers, which increase in size and number as the disease advances. Cobblestoning, fistulas, and strictures are late findings.[80] Early Crohn's disease may be mistaken for drug-induced esophagitis.

Behçet's disease is a multisystem disorder that may show ulcerations on esophagram. Histoplasmosis is a granulomatous infection that may cause ulcers or fistulas.

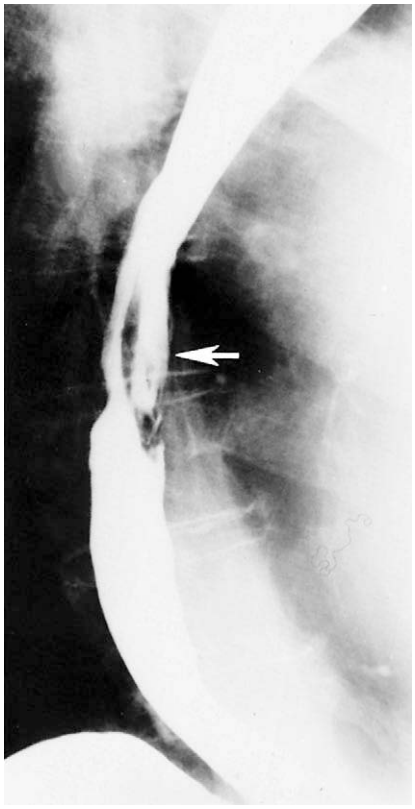

Figure 102-27. Drug-induced esophagitis. Left posterior oblique view from a barium esophagram demonstrates a large ulcer *(arrow)* in the midesophagus caused by potassium tablets in a patient with massive cardiomegaly. Note the posterior displacement of the esophagus by enlarged heart.

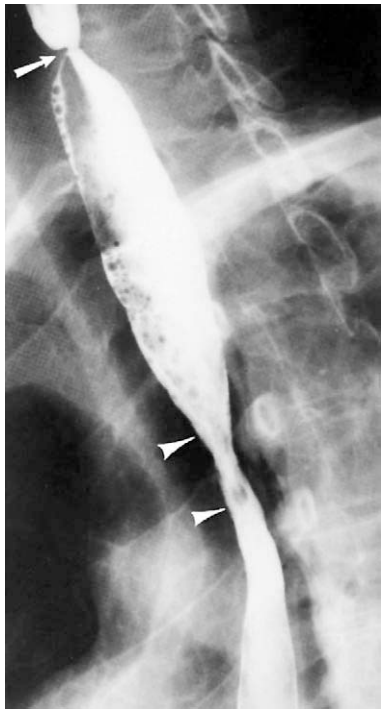

Figure 102-28. Epidermolysis bullosa. Esophagram demonstrates cervical esophageal web *(arrow)* and midesophageal stricture *(arrowheads)*.

Other Esophagitides

Many medications can irritate the esophagus with prolonged contact. Antibiotics such as tetracycline and doxycycline, quinidine, potassium chloride, iron sulfate, and vitamin C are among the offending agents.[40] Most patients do not have underlying esophageal pathology, but bedtime dosing, a tortuous esophagus, and medication taken with no water can predispose to drug-induced esophagitis. Radiographic abnormalities include a solitary ulcer (or small cluster of ulcers) in the midesophagus, with or without focal esophageal spasm (Fig. 102-27). These abnormalities generally resolve within 2 weeks of medication withdrawal. The major differential consideration is herpes esophagitis.[81]

Radiation esophagitis manifests as superficial ulcerations in the mucosa 7 to 10 days after radiation therapy. Another appearance is granular mucosa with spasm. After several months, dysmotility with normal morphology is the most common presentation, but smooth strictures or longstanding ulcers may also be seen.[82]

Severe peptic esophagitis may develop in patients with prolonged nasogastric intubation because the LES is rendered incompetent. Strictures in these patients tend to be long and tapered.

Epidermolysis bullosa is a hereditary skin disorder with recurrent blisters that rupture and scar. Only the recessive form, epidermolysis bullosa dystrophica, has esophageal manifestations.[83] Early disease presents as ulcers, dysmotility, spasm, or edema. Small, nodular filling defects represent bullae.[84] Extensive bulla formation leads to a serrated or spiculated mucosa. Advanced disease has scarring or stricture in the upper thoracic esophagus (Fig. 102-28). Radiography plays an important role in the assessment of patients with epidermolysis bullosa because the esophageal mucosa is prone to injury from endoscopy.

Pemphigoid is another disorder of the skin and mucous membranes with chronic bulla formation and rupture. Early disease is manifested by edema, spasm, and ulceration.[85] The bullae themselves are rarely visualized. Late disease has strictures and webs in the upper thoracic esophagus. Early radiographic diagnosis of esophageal involvement is important because adhesions can be lysed before strictures form.[86]

Intramural pseudodiverticulosis is ectasia of the esophageal mucous ducts. It is associated with many types of esophagitis, and *C. albicans* is frequently cultured from affected patients, but no definite cause has been established. The radiographic appearance is dramatic, with innumerable small outpouchings in linear rows (Fig. 102-29). Strictures are frequently identified in association with the pseudodiverticula. Radiographic studies are more sensitive than endoscopy for the diagnosis of intramural pseudodiverticulosis.[87]

Alcohol-induced esophagitis, graft-versus-host disease, and eosinophilic esophagitis all share the nonspecific radiographic finding of mucosal irregularity. In these diseases the diagnosis is suggested by the clinical history.[81]

Epiglottitis

Epiglottitis is a fulminant infection of the supraglottis that usually affects children 3 to 6 years old. *Haemophilus influenzae* is the most frequent infectious agent. The clinical presentation of drooling, fever, and sore throat is similar to that of viral laryngotracheobronchitis (croup) or retropharyngeal abscess; lateral radiographs of the neck help to distinguish these entities.

The typical plain film findings in epiglottitis are thickening of the epiglottis (thumb sign) and thickening of the aryepiglottic folds (Fig. 102-30).[88,89] The hypopharynx may distend as airway compromise progresses. Diseases such as angioneurotic edema, caustic burns, and radiation therapy have the same radiographic appearance, but they can be distinguished clinically. It is important to recognize the involvement of the aryepiglottic folds because this may distinguish epiglottitis from epiglottic abscess, cyst, or hematoma. The term "supraglottitis" has begun to replace "epiglottitis" to emphasize the involvement of the aryepiglottic folds.

Although thickening of the supraglottic tissues can be easily appreciated on CT, and CT can more completely evaluate differential possibilities such as retropharyngeal abscess, patients with epiglottitis have a tenuous airway, and the recumbent positioning of CT may provoke abrupt airway occlusion. Thus conventional radiographs are preferred for the initial evaluation.

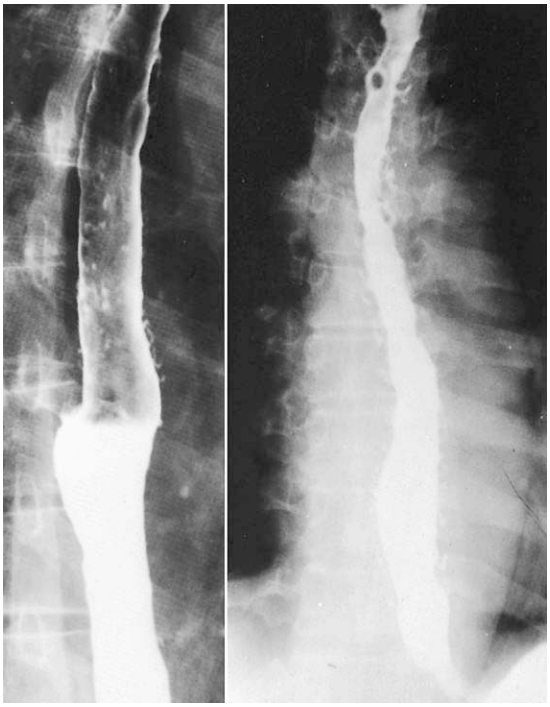

Figure 102-29. Intramural pseudodiverticulosis. Esophagrams from two patients show multiple irregular linear collections of barium outside the esophageal lumen, representing dilated excretory ducts of mucous glands.

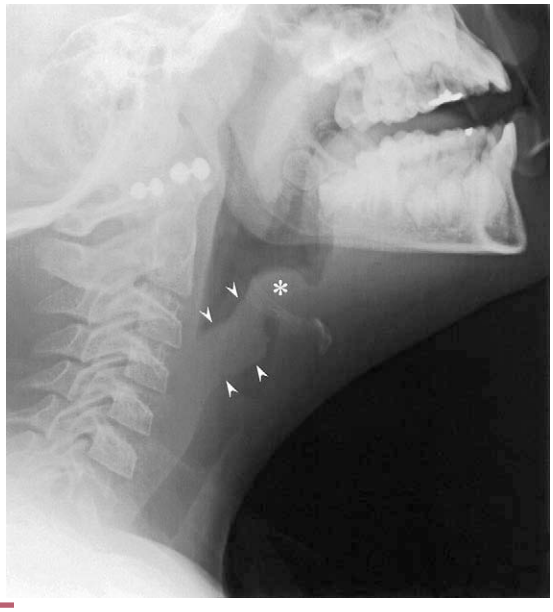

Figure 102-30. Epiglottitis. Lateral plain film of the neck reveals thickening of the epiglottis *(*)* and the aryepiglottic folds *(arrowheads)*. The pharynx is expanded.

Patients with epiglottitis can have rapid clinical deterioration with airway obstruction. If epiglottitis is suspected clinically, personnel experienced with emergent intubation should accompany the patient to the radiology suite.[90]

Abscess

Common sources of neck infection include the teeth, salivary glands, and palatine tonsils. However, a definite source of infection is found in only 50% of neck infections.[91]

Figure 102-31. Peritonsillar abscess. Enhanced computed tomography through the upper neck reveals a low-density mass *(*)* with a thick, enhancing rim, in the expected location of the tonsillar pillar. The oropharynx and tongue are displaced.

An abscess is a drainable collection of infected fluid, whereas a phlegmon is infected, edematous tissue. The differentiation between phlegmon and abscess is critical for surgical planning. The usual CT appearance of an abscess is a fluid-attenuation mass with a rim of enhancing tissue (Fig. 102-31). This rim of enhancement is initially thick and irregular but progresses to a well-defined thin rim over several days.[91] Phlegmon appears as a low-density region of soft tissue with a poorly defined margin and little surrounding enhancement. Unfortunately, these findings lack specificity and phlegmon is difficult to reliably distinguish from abscess on cross-sectional imaging.[92] Surgeons should expect a high false-positive rate for the diagnosis of neck abscess on CT.

CT and MR are excellent at determining the extent of neck infections. Retropharyngeal and peritonsillar abscesses frequently extend into the parapharyngeal space. Patients with retropharyngeal disease are at risk for spread into the mediastinum by way of the danger space, so imaging of patients with retropharyngeal infection should include the thorax.[33]

Esophageal Narrowing

Webs

A pharyngoesophageal web is a thin membrane extending horizontally from the anterior mucosal surface, usually within 2 cm of the pharyngoesophageal junction (Fig. 102-32). Circumferential webs are unusual. Webs are covered with normal mucosa and will often reduce with a large bolus of barium. Thus they are identified less frequently on radiographic studies than on autopsy series.[93] Webs in the pharynx and cervical esophagus are usually idiopathic and asymptomatic, but a fixed stenosis of less than 13 mm can result in dysphagia.

Webs will occasionally arise from longstanding inflammation (epidermolysis bullosa, pemphigoid, reflux esophagitis), but most are incidental findings. Pharyngoesophageal webs are best visualized fluoroscopically in the lateral projection (see Fig. 102-32). Webs are not generally seen on cross-sectional imaging.

Strictures

Inflammatory strictures are the end result of many forms of esophagitis. Iatrogenic strictures form after surgical resection, usually at the site of an anastomosis. Therapeutic radiation may also result in alimentary strictures.

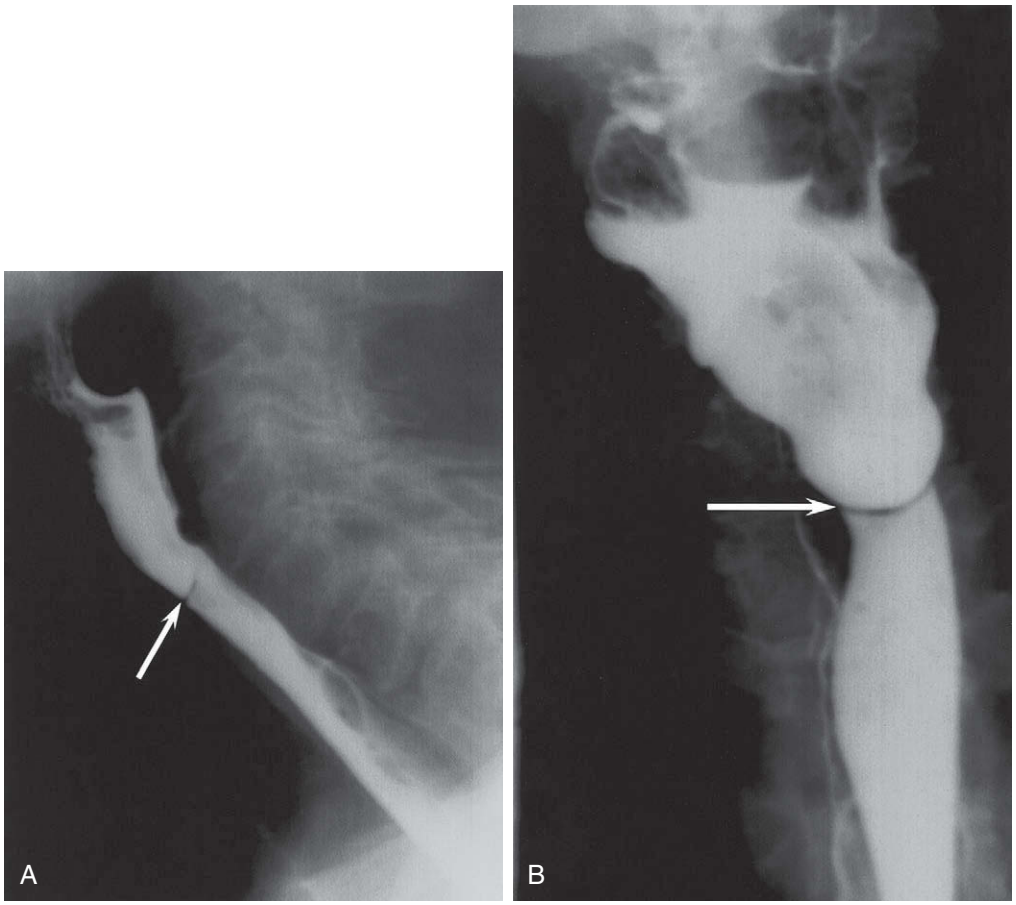

Figure 102-32. Esophageal web. Lateral **(A)** and frontal **(B)** projections show a thin filling defect (*arrows*) extending from the anterior esophageal wall.

In the setting of an esophageal stricture, the most important determination is whether the lesion represents a cancer or is the result of a benign process. In general, malignancies produce a discrete area of irregular mucosa with overhanging borders (Fig. 102-33). The esophagus may be fixed to surrounding structures at the level of a malignant stricture. Asymmetry favors a malignant process. Absence of these findings, however, is not sufficient to exclude malignancy. In the setting of a stricture without a definite benign etiology, endoscopy with biopsy is indicated. CT is often useful to exclude a surrounding mass.

Extrinsic Compression

The most frequent source of external compression of the pharynx and esophagus is degenerative disease of the spine. Anterior vertebral osteophytes create an undulating posterior impression on fluoroscopy (Fig. 102-34). In severe cases, cervical osteophytes may cause dysphagia or may interfere with inversion of the epiglottis and cause aspiration.[94,95]

Infection is another frequent cause of extrinsic compression. A peritonsillar or retropharyngeal abscess can displace or compress the oropharynx and hypopharynx (see Fig. 102-31). Although retropharyngeal soft tissue swelling can be seen on lateral plain films of the neck, CT is the preferred modality to evaluate the extent of disease and to distinguish abscess from phlegmon.[91]

Foregut duplication cysts are an unusual cause of esophageal compression. Three types of duplication cyst exist: esophageal cyst, bronchogenic cyst, and neurenteric cyst. All three present as well-defined cervical or mediastinal masses. The three types are distinguished by location. On cross-sectional imaging, foregut duplication cysts usually mimic water (Fig. 102-35), but inspissated secretions can change the CT and MR characteristics.[96] On fluoroscopy, foregut duplication cysts can mildly displace or compress the esophagus. When an esophageal cyst communicates with the true esophagus, it is called an esophageal duplication, and it appears as a double-barreled esophagus (Fig.

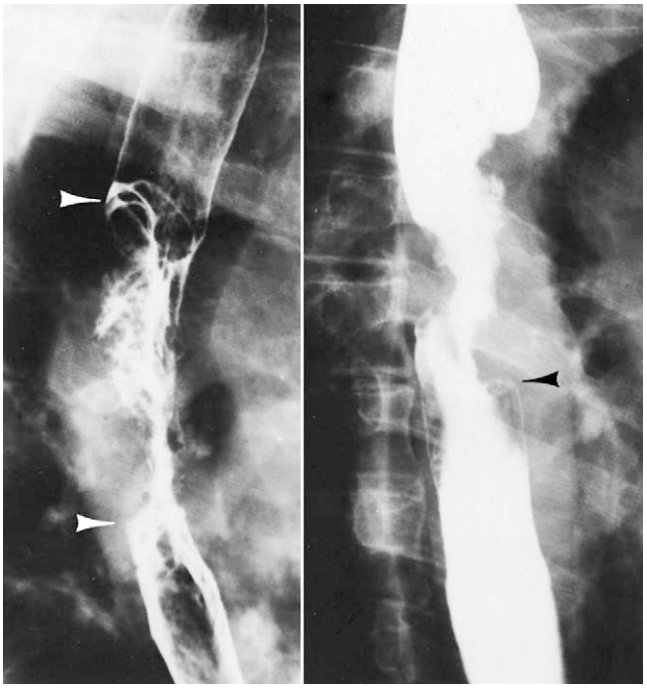

Figure 102-33. Esophageal carcinoma. Two examples of squamous cell carcinoma producing irregular segmental constriction of the esophageal lumen by large ulcerated masses. Note the sharp overhanging edges produced by the mass in each case *(arrowheads)*.

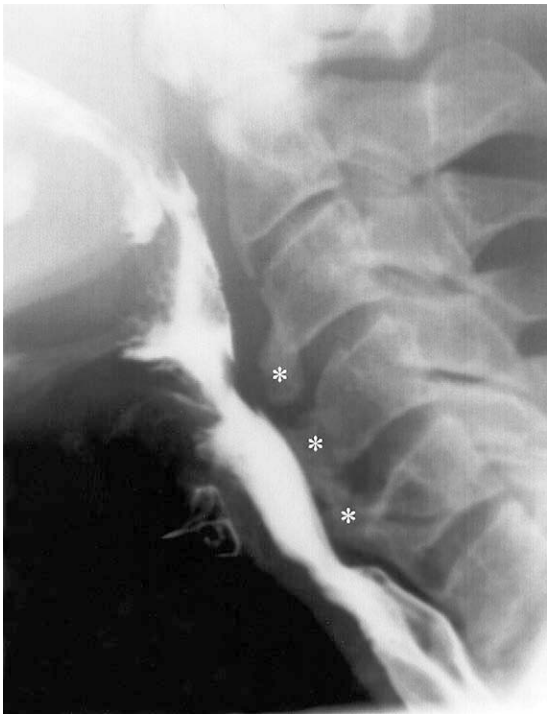

Figure 102-34. Vertebral osteophytes. Lateral esophagram shows large bridging osteophytes *(*)* creating an undulating impression on the posterior hypopharynx.

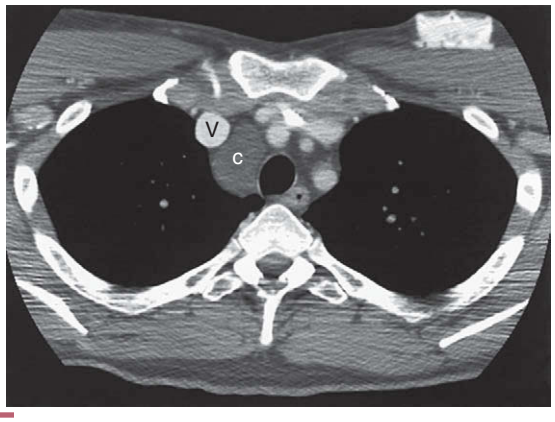

Figure 102-35. Bronchogenic duplication cyst. Computed tomography through the upper thorax reveals a cystic mass *(c)* between the trachea and the right brachiocephalic vein *(v)*. This is a frequent location for bronchogenic duplication cysts.

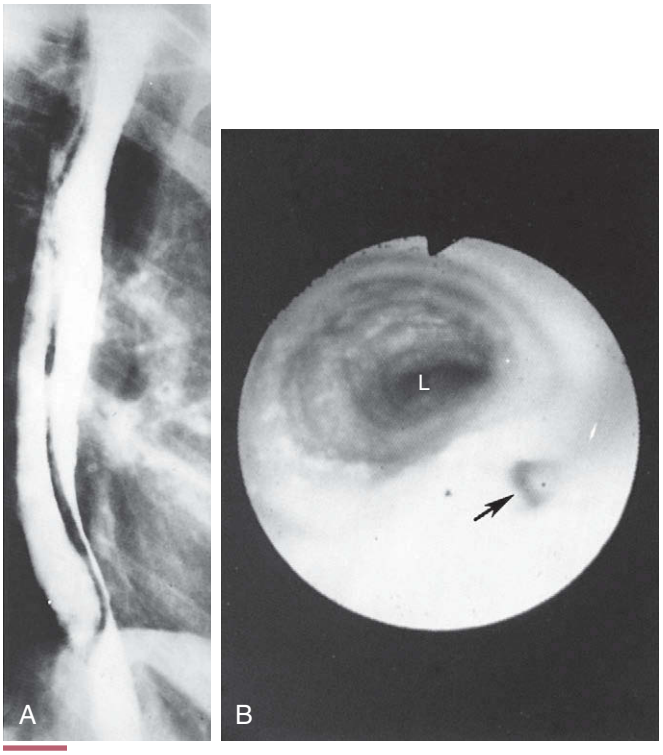

Figure 102-36. Communicating esophageal duplication. **A,** Barium esophagram demonstrates near-complete esophageal duplication communicating with the esophageal lumen. **B,** Photograph taken during endoscopy shows the duplication cyst *(arrow)* communicating with esophageal lumen *(L)*.

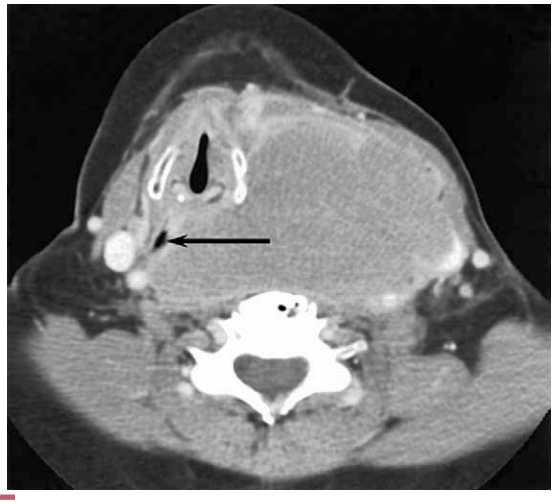

Figure 102-37. Thyroid goiter. Enhanced computed tomography through the larynx. A large mass replaces the left thyroid gland, displacing the larynx and esophagus *(arrow)*.

102-36).[40] If solid elements are identified in conjunction with a duplication cyst, metastatic degeneration should be considered.[97]

Vascular abnormalities that compress the esophagus include left atrial enlargement, aortic ectasia, aberrant subclavian artery, pulmonary sling, and double aortic arch.[98] Benign or malignant masses may displace the esophagus and pharynx; thyroid goiter is the most familiar example (Fig. 102-37). In the setting of trauma, hematoma may displace the tissues of the neck. If displacement is noted on an esophagram, the patient should undergo CT to identify any adjacent mass and evaluate the extent of disease.

Retraction of the esophagus in the setting of pleural, pulmonary, or mediastinal scarring can be mistaken for esophageal deviation from a mass. This is an important distinction because retraction is generally benign and requires only a chest x-ray to confirm the presence of scar. Displacement, on the other hand, requires CT evaluation. On fluoroscopy, a retracted esophagus is widened, whereas a displaced esophagus is narrowed.[98]

Fistulas

Congenital

Tracheoesophageal Fistula

Tracheoesophageal fistula (TEF) results from an incomplete separation of the trachea and alimentary tract. Among the four classes of TEF,

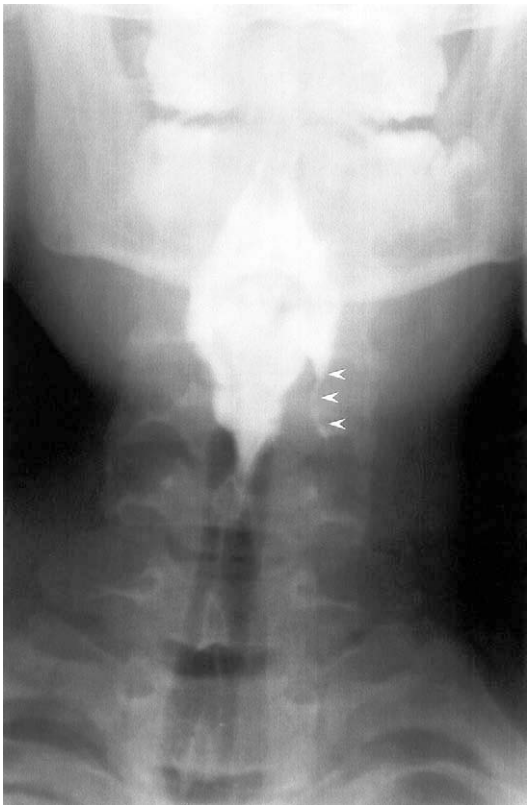

Figure 102-38. Fourth branchial cleft fistula. Frontal esophagram shows a thin line of barium (*arrowheads*) extending from the apex of the left pyriform sinus. On later images, contrast continued to the skin surface.

type 3 (esophageal atresia with distal fistula) is by far the most common. The diagnosis of type 3 fistula is usually clinical. If fluoroscopic confirmation is necessary, contrast should be introduced through a catheter so that the radiologist can control the amount of contrast and remove the contrast after the procedure.[40] Clinically, type 1 TEF (esophageal atresia without fistula) is difficult to distinguish from type 3 TEF (esophageal atresia with fistula). An abdominal plain film helps; if there is gas in the stomach, a fistula is present, so the anomaly must be type 3.

Type 2 TEF (esophageal atresia with proximal fistula) is diagnosed when oral contrast enters the bronchial tree, and the abdomen is gasless. Type 4 TEF has two subtypes: H-type TEF (fistula without atresia) and atresia with proximal and distal fistulae. It may be difficult to demonstrate an H-type fistula radiographically because the fistula slopes upward from the esophagus to the trachea. Prone positioning helps to delineate the abnormality.

Branchial Cleft Anomaly

Branchial cleft anomalies are remnants of the fetal communication between the alimentary tract and the skin of the lateral neck.[99] The most frequent remnant is a branchial cleft cyst, but sinuses and fistulae may also remain. Although a branchial cleft cyst is best imaged with CT or MRI, a branchial cleft sinus or fistula is best imaged fluoroscopically. CT performed after infusion of a contrast agent into the fistula provides more precise delineation of the path of the fistula.[100] A thin line of contrast extending from the pyriform sinus is the classic appearance for a third or fourth branchial cleft fistula (Fig. 102-38).

Perforation

Iatrogenic trauma, as from intubation, endoscopy, or dilation, is the most frequent cause of esophageal perforation.[59] Other causes include blunt trauma, penetrating trauma, and foreign body penetration. Prompt diagnosis is essential because complications such as fasciitis and mediastinitis can be fatal.

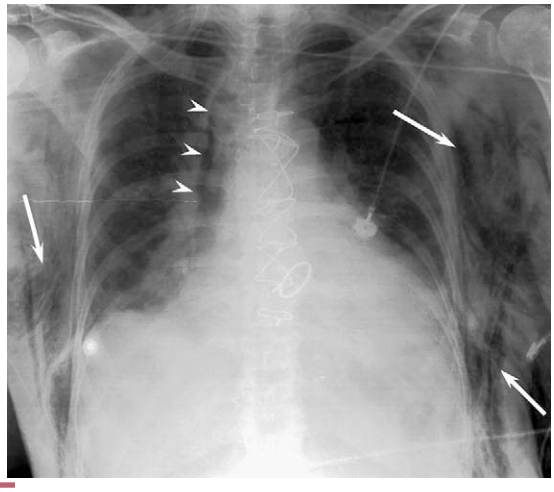

Figure 102-39. Pneumomediastinum. Chest x-ray reveals extensive gas in the subcutaneous tissues *(arrows)* and outlining the mediastinal structures *(arrowheads).*

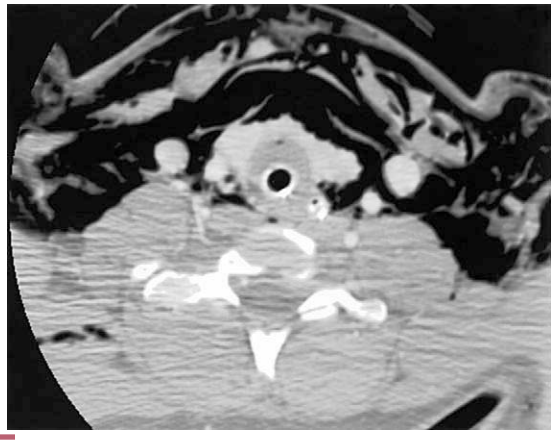

Figure 102-40. Subcutaneous emphysema of the neck. Enhanced computed tomography through the thyroid bed reveals extensive gas within the deep fascial planes of the neck, the result of pharyngeal perforation.

Plain films of the neck and chest are appropriate screening tools to assess for cervical emphysema or pneumomediastinum (Fig. 102-39). However, only half of patients with esophageal rupture will demonstrate abnormalities on conventional radiographs.[101]

Esophagography should be performed first with water-soluble contrast material to avoid inspissation of extravasated barium. If no leak is identified with water-soluble agents, the examination should be repeated with barium, which is more sensitive for small leaks.[9] If a nasogastric tube is already in place, an esophagram may be performed with the patient in the recumbent position by slowly retracting the tube while infusing contrast. The contrast bolus will extend superior to the tip of the nasogastric tube, and leaks may be identified before the tip of the tube reaches the site of perforation. This technique is useful in patients who are unable to cooperate with standard esophagography.

CT may also be used to evaluate perforation in patients who are unable to cooperate with esophagography. Extravasated oral contrast and gas within the soft tissues are indicators of alimentary perforation (Fig. 102-40).[101] Gas is also seen in the soft tissues with laryngeal or tracheal injuries or as an extension of pneumomediastinum.

Mallory-Weiss syndrome is a mucosal tear of the distal esophagus, usually caused by forceful vomiting. Esophagography is insensitive for this diagnosis; endoscopy is the preferred examination. Although many

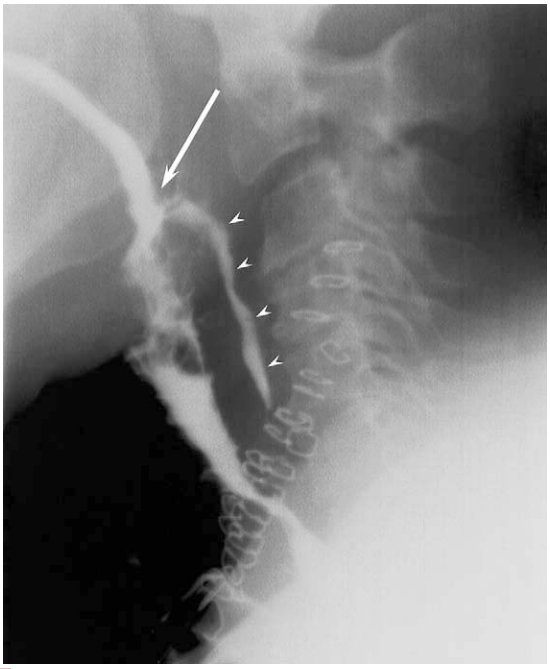

Figure 102-41. Postoperative pharyngeal leak. Two days after total laryngectomy, lateral esophagram reveals barium extravasating from the posterior pharynx. The point of origin is marked with an *arrow,* and the sinus tract is marked with *arrowheads.*

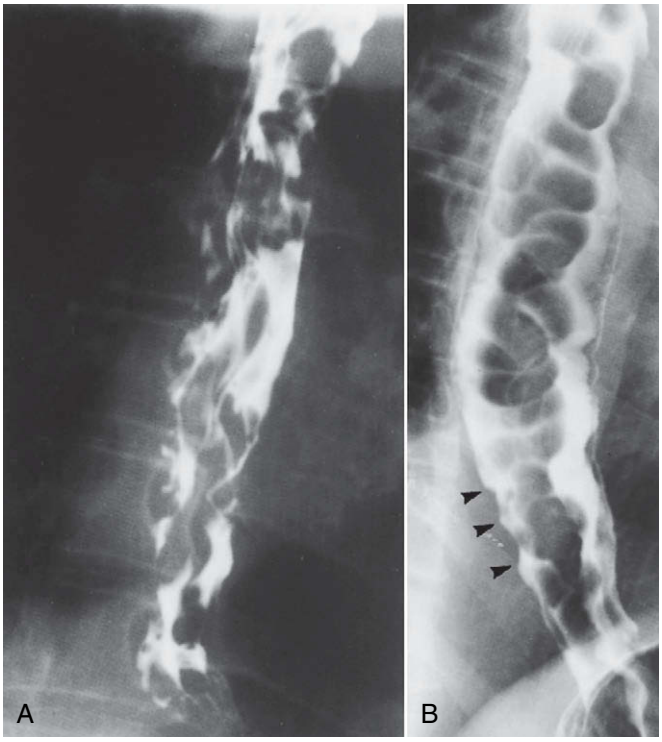

Figure 102-42. Varices. **A,** Mucosal relief radiograph of the esophagus demonstrates multiple serpiginous filling defects. **B,** Full-column esophagram from another patient shows multiple ovoid filling defects with scalloping of the distal esophageal contour *(arrowheads).*

patients with Mallory-Weiss syndrome may be treated conservatively, persistent bleeding can be addressed with angiographic infusion of vasospastics or catheter embolization.[102]

Patients who are at risk for perforation are also at risk for esophageal hematoma. On an esophagram, an esophageal hematoma usually appears as a broad submucosal mass and may be indistinguishable from benign masses, such as leiomyomas.[98]

Other Fistulas

After pharyngoesophageal surgery, a fistula may form between the alimentary tract and the skin surface, or a sinus tract may form within the deep soft tissues of the neck. These complications are best evaluated with a pharyngoesophagram (Fig. 102-41). Fistulous communication between the esophagus and the trachea, pericardium, aorta, or pleura is usually iatrogenic, but trauma, infection, and tumor erosion should also be considered.

Varices

Esophageal varices are enlarged veins in the submucosa of the esophagus. "Uphill" varices have cephalad flow, are located in the lower esophagus, and are usually the result of portal hypertension. "Downhill" varices have caudal flow, are located in the upper esophagus, and are usually the result of superior vena cava obstruction. Endoscopy is the most appropriate test for screening and treatment of esophageal varices.[103] Emergent transhepatic portosystemic shunt placement is the preferred treatment for patients who have acute variceal bleeding when endoscopic treatment fails.[104]

On esophagogram, varices are best visualized with mucosal relief techniques.[105] Varices appear as thickened longitudinal folds or serpentine filling defects (Fig. 102-42). Respiration, peristalsis, and Valsalva maneuvers change the size and configuration of the varices. Most varices are seen best when the patient is recumbent, but some are better visualized when the patient is upright. Both positions should be used. Anticholinergic agents can be used to prevent the varices from collapsing during esophageal peristalsis. Varices can be distinguished from tumors and extrinsic masses because the varices change configuration during the examination.

Foreign Body

Pieces of food, such as small bones or an unchewed bolus of meat, are the most frequent source of impacted foreign bodies in the pharynx and esophagus. The initial evaluation is frontal and lateral plain films of the neck with a technique that emphasizes soft tissues instead of the vertebral bodies (Fig. 102-43). Plain films are particularly useful for depicting the three-dimensional structure of the foreign body. However, CT better identifies foreign bodies that are near soft tissue density, so CT should be used if plain films are negative. An esophagram will show bulky foreign bodies as filling defects but may fail to identify smaller foreign bodies such as bones. Because foreign body impaction carries a risk of perforation, initial esophagography should be performed with water-soluble media. Secondary signs of perforation (pneumomediastinum, prevertebral swelling, and gas within the fascial planes of the neck) should be sought on conventional radiographs or cross-sectional imaging.

Spicules of bone most commonly lodge in the inferior tonsil, tongue base, or vallecula. Larger objects get stuck at pathologic strictures (Fig. 102-44) or areas of anatomic narrowing: the cricopharyngeus muscle, the thoracic inlet, the aortic arch, or the diaphragmatic hiatus. Because many foreign bodies lodge below the level of the larynx, cross-sectional imaging should include the entire neck and chest.

Ossification of the laryngeal cartilages can be confused with radiopaque foreign bodies.[106] The cricoid cartilage, in particular, ossifies along the posterior margin and superior tip, which can mimic a swallowed bone. The posterior lamina and inferior horn of the thyroid cartilage can also ossify in a manner suggestive of a foreign body. Postinflammatory tonsillar calcifications have a characteristic appearance on CT (Fig. 102-45); they should not be mistaken for foreign bodies.[107]

Up to 20% of ingested foreign bodies require intervention. Although balloon and magnet techniques have been used by radiologists to extract foreign bodies, endoscopy has become the treatment of choice at most institutions.[108]

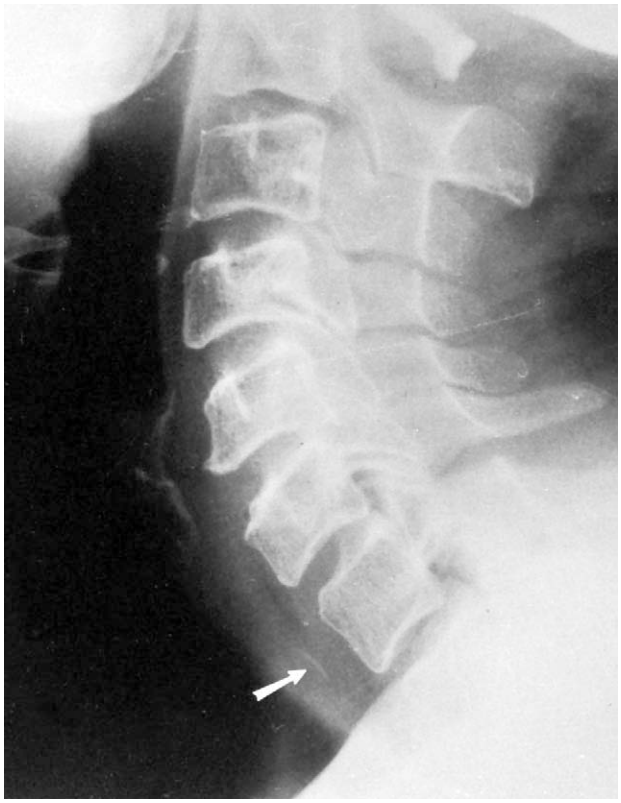

Figure 102-43. Foreign body. Lateral soft-tissue radiography of the neck shows a chicken bone *(arrow)* lodged near the pharyngoesophageal junction.

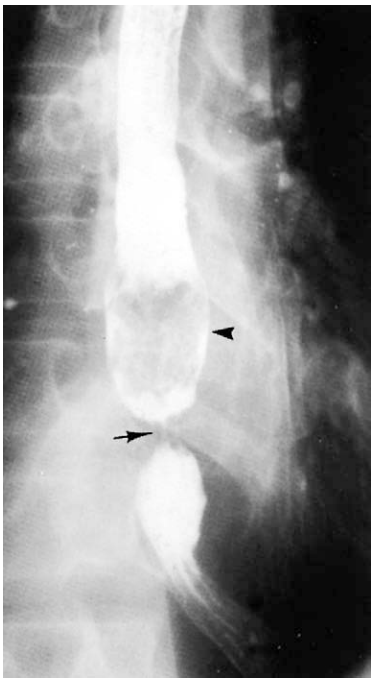

Figure 102-44. Foreign body. Barium esophagram shows a large piece of meat *(arrowhead)* lodged above a focal peptic stricture *(arrow)*.

Mass Lesions

Pharyngoesophageal filling defects are categorized as mucosal, submucosal, or extrinsic on the basis of their radiographic appearance.[59] Mucosal lesions are irregular, with abrupt, well-delineated borders. Submucosal lesions are broad based with smooth borders. Extrinsic masses displace the esophagus. These distinctions drastically shorten the differential diagnosis of pharyngoesophageal lesions. Mucosal lesions are usually sarcomas or carcinomas, whereas submucosal lesions are almost always benign. Extrinsic masses are usually not of esophageal origin.

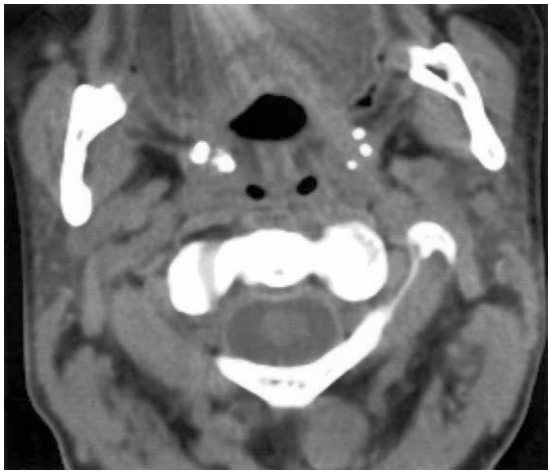

Figure 102-45. Tonsillar calcifications. Unenhanced computed tomography demonstrates coarse calcifications in both tonsillar pillars. These benign calcifications are the result of chronic inflammation.

Malignant Neoplasms

Squamous cell carcinoma accounts for most tumors in the pharynx and esophagus. Although most patients are initially seen with advanced disease, the radiologist must give particular attention to the tonsillar pillars, tongue base, nasopharynx, and pyriform sinuses to avoid overlooking early tumors in these frequently affected areas. Furthermore, patients with cancer of the head and neck are prone to second primary tumors, which are often discovered by the radiologist.

Esophagography is used to exclude carcinoma in patients who have dysphagia. Although esophagography has a low yield in this setting, it is relatively inexpensive and may provide an alternate explanation for the dysphagia. Precise evaluation of a lesion's mucosal extent is usually left to endoscopy. CT, MR, or PET/CT is necessary to assess the submucosal extent of a carcinoma and to stage the tumor.

No imaging findings reliably distinguish squamous cell carcinoma from the less common malignancies of the pharynx and esophagus, but there are some features that may be suggestive. Adenoid cystic carcinoma and lymphoma are prone to perineural invasion, which may be evident only on MRI. Esophageal adenocarcinomas arise primarily in the distal esophagus, often in the setting of Barrett's esophagus. Esophageal carcinosarcomas and spindle cell sarcomas are frequently polypoid.[109]

Nasopharynx

Nasopharyngeal carcinomas are mostly squamous cell carcinomas, lymphomas, and lymphoepitheliomas. Imaging is used to define the extent of disease, particularly in the skull base (Fig. 102-46). MRI is the preferred modality for the evaluation of skull base invasion and perineural spread, whereas PET/CT is preferred to identify nodal and distant disease.[110,111] Common pathways of intracranial spread include direct invasion through the clivus and extension into the foramen lacerum. In either case, the tumor may spread to the cavernous sinus and Meckel's cave. The clivus, jugular foramen, and hypoglossal canal should be carefully evaluated, especially in patients with cranial nerve dysfunction. The dural extent of disease is best identified on coronal postcontrast images. Invasion of the brain parenchyma is seen as edema on T2 and fluid attenuated inversion recovery images.

Evaluation of nasopharyngeal tumors must include evaluation of the neck because 90% of patients have nodal spread at diagnosis.[110] Retropharyngeal lymphadenopathy, in particular, may be clinically occult. PET/CT is the most sensitive modality for this evaluation.

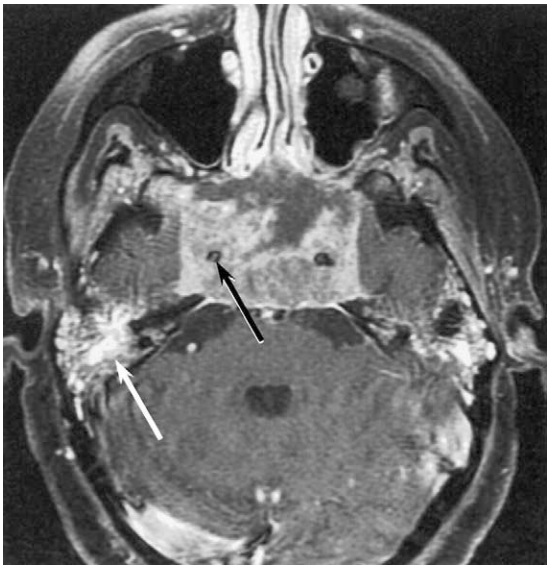

Figure 102-46. Nasopharyngeal carcinoma. Enhanced, fat-suppressed, T1-weighted axial magnetic resonance imaging demonstrates a large, partially necrotic mass replacing the clivus and surrounding structures. The internal carotid arteries *(black arrow)* are encased. Mastoiditis *(white arrow)* can be the earliest radiographic sign of nasopharyngeal carcinoma.

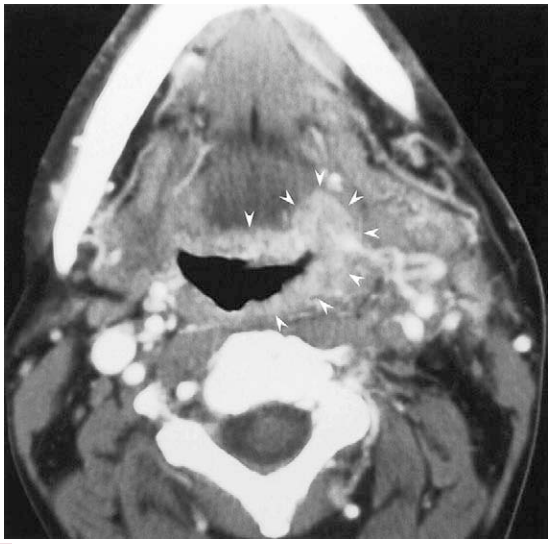

Figure 102-47. Oropharyngeal squamous cell carcinoma. Enhanced computed tomography reveals submucosal spread of tumor *(arrowheads)* from the inferior tonsil to the tongue base and posterior oropharynx.

All patients with incidentally noted mastoid effusions should be carefully evaluated for small tumors in the nasopharynx that have obstructed the eustachian tube.

Oropharynx

Oropharyngeal carcinomas most frequently arise in the tonsillar pillars, soft palate, or tongue base. They may be clinically occult and present with nodal metastases, usually in level 2. Cross-sectional imaging is useful in the search for a primary lesion, but small cancers are often indistinguishable from the surrounding gland and soft tissues. Even PET/CT has difficulty distinguishing tumor uptake from uptake in an asymmetrically hyperplastic gland.[112] Tonsillectomy is often necessary to exclude a primary tumor in this location.

Either CT or MRI may be used to assess the local extent of oropharyngeal carcinomas. MRI may be advantageous in patients with extensive dental amalgam that would obscure CT images. The extent of disease from the palatine tonsils into the tongue base, oral floor, parapharyngeal space, and mandible can be evaluated with CT or MRI (Fig. 102-47).[113]

Mandibular invasion is of particular importance in the preoperative planning of advanced oropharyngeal carcinomas. Although MRI is more sensitive for mandibular invasion, it is less specific than CT. Recent advances in CT techniques have improved the sensitivity, so CT is the preferred modality at many institutions.[14] A dental CT scan, in which thin axial images are reconstructed into a curved paracoronal plane, may be particularly useful.

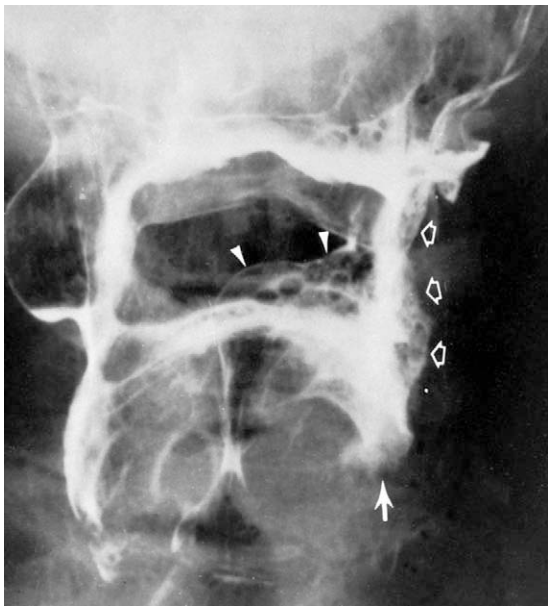

Figure 102-48. Left pyriform sinus carcinoma. Frontal view from air-contrast pharyngography shows a mass *(arrowheads)* arising from the left pyriform sinus, causing irregularity and amputation of the pyriform sinus *(arrow)* and loss of the normal contour of the lateral pyriform sinus wall *(open arrows)*.

Hypopharynx

Hypopharyngeal carcinomas may arise in the pyriform sinus, posterior pharyngeal wall, or postcricoid region.[114] Because the pyriform sinus is often collapsed during cross-sectional imaging and the apex can be difficult to evaluate endoscopically, barium studies are particularly useful for pyriform sinus tumors. Findings include filling defects, rigidity of the sinus walls, mucosal irregularity, and elevation of the postcricoid line. Involvement of the apex can usually be demonstrated or excluded (Fig. 102-48).[114] Lesions arising in the medial pyriform sinus can usually be distinguished from lesions arising within the larynx on cross-sectional imaging.

Tumors of the posterior hypopharyngeal wall extend predominantly along the mucosa, but posterior spread to the prevertebral tissues has a dramatic effect on prognosis and treatment. Invasion of the prevertebral tissues is best assessed with an esophagram because the radiologist can evaluate motion of the larynx relative to the vertebral column during deglutition. Decreased motion suggests invasion.[114]

Postcricoid hypopharyngeal tumors are rare. They can be difficult to demonstrate radiographically. The most frequent appearance is stricture or contour abnormality on full-column esophagography.

Cross-sectional imaging (CT or MRI) is necessary in all patients with hypopharyngeal tumors to assess the extent of tumor into surrounding structures such as the larynx, supraglottis, esophagus, and thyroid gland, as well as to evaluate nodal metastases (Fig. 102-49).[115]

Esophagus

Both fluoroscopy and CT have traditionally played important roles in the diagnosis of esophageal carcinoma, but PET/CT and endoscopic ultrasound now represent the standard of care for staging of this disease. Fluoroscopy or endoscopy may be used for detection; endoscopic ultrasound and PET/CT are used for staging.[116,117] MRI has limited usefulness in the chest, but it is sometimes used to precisely define local spread of tumor.

Esophageal carcinoma has a varied appearance on fluoroscopy. Early disease may be only a flat plaque, whereas advanced disease can present as an annular mass, a large ulceration, an irregular segmental narrowing, or an exophytic mass (see Fig. 102-33). Submucosal spread of tumor may simulate varices (Fig. 102-50).[118]

On CT, esophageal carcinoma appears as focal enlargement of the esophagus. The collapsed cervical esophagus should not exceed 16 mm by 24 mm, and the collapsed thoracic esophagus should be of constant diameter.[34] PET/CT provides valuable information about the local extent of tumor to aorta or lung; nodal metastases in the thorax and upper abdomen (Fig. 102-51); and distant metastases to the liver, lung, or adrenal glands.

Figure 102-49. Hypopharyngeal squamous cell carcinoma. The tumor involves all walls of the right pyriform sinus *(*).*

Lymphadenopathy

CT and MRI are more sensitive than physical examination for cervical lymph node metastases.[119] The radiologic classification of lymph nodes in the neck mirrors the American Academy of Otolaryngology–Head and Neck Surgery classification system, with radiologic landmarks substituted for surgical landmarks.[120,121] The hyoid bone separates levels II and III; the inferior cricoid cartilage separates levels III and IV; and the posterior margin of the sternocleidomastoid muscle is the anterior boundary of level V. Cross-sectional imaging is particularly important for identifying retropharyngeal nodes (Fig. 102-52), which are not included in the classification system and are not readily assessed clinically.

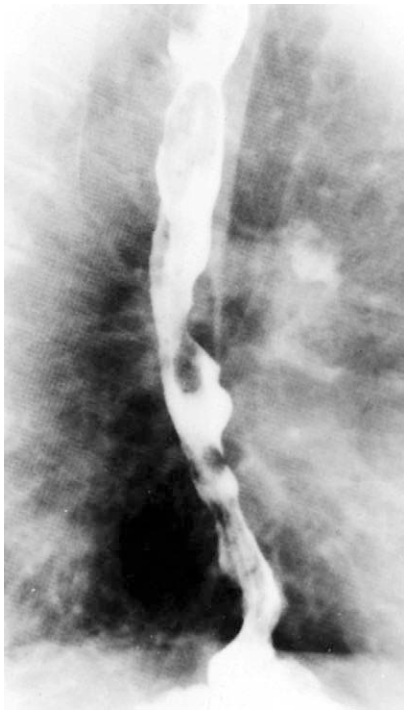

Figure 102-50. Varicoid carcinoma of esophagus. Barium esophagram demonstrates multiple, smooth, elongated filling defects in the esophagus, simulating varices.

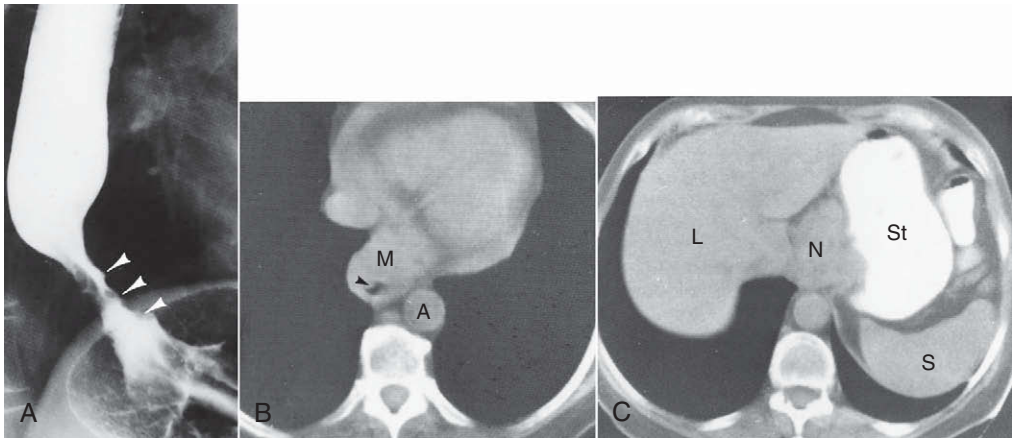

Figure 102-51. Computed tomography (CT) staging of esophageal carcinoma. **A,** Radiograph from an upper gastrointestinal examination shows irregular narrowing of the distal esophagus *(arrowheads),* consistent with esophageal carcinoma. However, the barium study gives no information about local spread of disease. **B,** CT scan demonstrates distal esophageal mass (*M*) with an eccentric narrowed lumen (*arrowhead*). **C,** CT scan at a more caudal level shows a large lymph node mass *(N)* in the region of the gastrohepatic ligament, making carcinoma unresectable for cure. A, aorta; L, liver; St, stomach; S, spleen. *(From Mauro MA, Lee JK, Heiken JP, Balfe DM. Radiologic staging of gastrointestinal neoplasms.* Surg Clin North Am. *1984;64:67.)*

The radiologic diagnosis of lymphadenopathy is based on the size, shape, enhancement, and homogeneity of the nodes. No single feature is sufficient to confidently diagnose or exclude metastatic disease; the diagnosis is based on a combination of the preceding criteria. Lymph nodes greater than1 cm (>1.5 cm for the jugulodigastric node) are considered abnormal. Nodes with central hypodensity or fluid signal are necrotic, unless the central hypodensity represents the fatty hilum of the node. Reniform or oval nodes are usually normal or hyperplastic, whereas spherical nodes are more likely malignant (Fig. 102-53). Ill-defined nodal margins and obliteration of surrounding fat planes are suggestive of extracapsular spread of tumor.

CT and MRI are useful for detecting vascular invasion from malignant lymph nodes.[122] Nodes that are adjacent to the carotid greater than 4 cm in length or approximately 270 degrees of circumference are likely invading. Nodes that are adjacent for less than 180 degrees are likely not invading. When carotid sacrifice is contemplated, balloon catheter occlusion with brain perfusion imaging can predict postoperative morbidity.[123]

In the chest, CT is insensitive for the spread of esophageal carcinoma to periesophageal nodes because unenlarged nodes often contain tumor. PET/CT is a more sensitive means of evaluating these lymph nodes.[124,125]

MRI and CT have comparable sensitivity for the detection of cervical lymph node metastases.[126] Recent advances in MR imaging such as T1-rho and magnetization transfer may provide additional benefit but are as yet unproven in large clinical trials.[127] PET/CT, however, is superior to either CT or MRI in the evaluation of nodal and distant metastatic disease.

Benign Neoplasms

Benign esophageal neoplasms present as submucosal masses (Fig. 102-54). They are usually asymptomatic and incidental. Leiomyomas are the

Figure 102-52. Retropharyngeal lymphadenopathy. Even large retropharyngeal lymph nodes *(*)* may not be clinically evident.

Figure 102-53. Reactive lymph nodes. Size alone does not indicate the presence of tumor. Enhanced axial computed tomography demonstrates a 28-mm jugulodigastric node *(*)* that retains its reniform configuration, suggesting a benign etiology. The patient had a peritonsillar abscess.

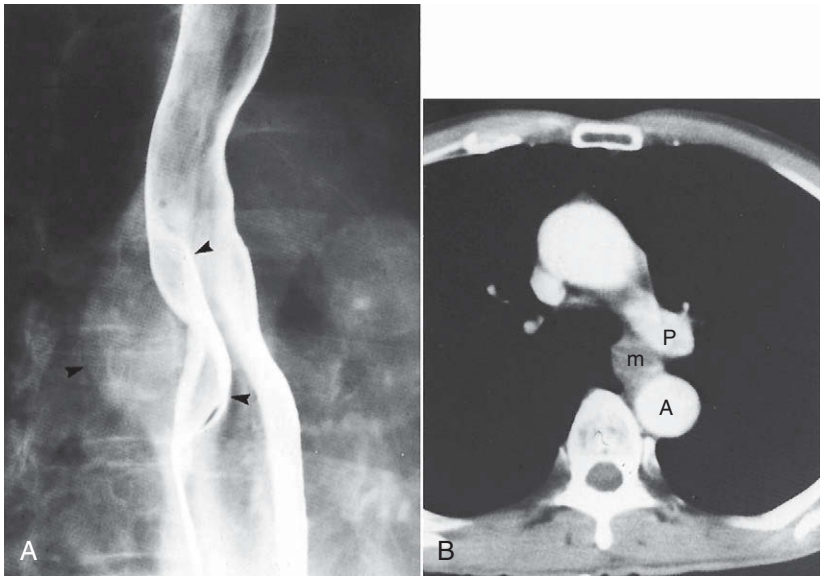

Figure 102-54. Esophageal leiomyoma. **A,** Air-contrast esophagram demonstrates a smooth soft tissue mass *(arrowheads)* arising in the wall of esophagus. **B,** Computed tomography scan shows a round soft tissue attenuation mass *(m)* between the descending aorta *(A)* and the left pulmonary artery *(P)*.

Figure 102-55. Vallecular cyst. Enhanced computed tomography reveals a large cystic mass filling the left vallecula, displacing the epiglottis to the right and compromising the airway.

Figure 102-56. Tornwaldt cyst. Enhanced computed tomography reveals a complex cystic mass in the midline of the upper nasopharynx.

most common benign esophageal neoplasm, but lipomas, neurofibromas, hemangiomas, fibromas, and granular cell tumors have been reported.

Papillomas appear as sessile mucosal masses that may extend into the larynx. Adenomas are mucosal masses that should be surgically removed because of their malignant potential. Benign extra-alimentary tumors such as schwannomas and hemangiomas may become large enough to displace the pharynx or esophagus.

Non-neoplastic Mucosal Masses

A retention cyst, the result of a single obstructed mucous duct, can be seen anywhere in the pharynx or esophagus. The most familiar locations are the adenoids, vallecula, lingual tonsil, and distal esophagus. Retention cysts appear as submucosal masses on fluoroscopy. On cross-sectional imaging, retention cysts are usually fluid-filled, but longstanding cysts may become dense on CT and have high signal on T1-weighted MRI (Fig. 102-55).

A Tornwaldt cyst is an embryologic remnant found in the midline of the nasopharynx (Fig. 102-56). It is indistinguishable from a retention cyst, except by location. Fibrovascular polyps are pedunculated masses projecting into the lumen of the cervical esophagus. Inflammatory esophageal polyps are actually rugal folds, enlarged by reflux disease, extending into the distal esophagus.

A tortuous internal carotid artery may simulate a submucosal or extrinsic mass behind the pharynx. A definitive diagnosis can be made with contrast-enhanced CT (Fig. 102-57).

Esophageal hematoma may appear as a mucosal or submucosal mass; the history is usually suggestive.

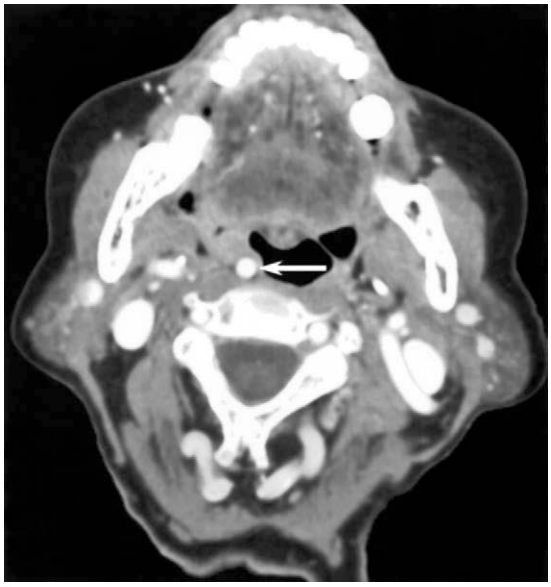

Figure 102-57. Retropharyngeal carotid artery. Enhanced computed tomography reveals a tortuous right internal carotid artery *(arrow),* which may simulate a submucosal mass.

Post-treatment Appearance

Total Laryngectomy

The postlaryngectomy neopharynx looks like a featureless tube on esophagography (Fig. 102-58). It is normal for a small pouch to form along the anterior surgical bed. The ridge of tissue between the anterior pouch and the neopharynx is called a *pseudoepiglottis* because of its fluoroscopic appearance (Fig. 102-59). Residual cricopharyngeal fibers, although they lack an anterior attachment, may form a smooth posterior impression on the esophagus, similar in appearance to cricopharyngeal achalasia.

Benign strictures can have one of two configurations: a focal stricture at the distal surgical closure or a long tapered stricture throughout the neopharynx.[128] These strictures, as well as fistulas and leaks, are best assessed with esophagography.

Recurrent tumor may be seen on an esophagram as mucosal irregularity, a mass displacing the neopharynx, or circumferential narrowing (Fig. 102-60). Nonmucosal recurrences are frequently not evident on an esophagram, so cross-sectional imaging (CT, MRI, or preferably PET/CT) should be used for surveillance. Esophagography is reserved for patients with delayed postoperative dysphagia.

Laryngopharyngectomy

Patients who undergo laryngopharyngectomy may be reconstructed with a primary closure, a jejunal interposition, or various flaps. These reconstructions have different radiographic appearances. Flap reconstructions and primary closures result in a smooth, tubular neopharynx with only mild surrounding soft tissue on CT. Jejunal interpositions have a more confusing appearance.

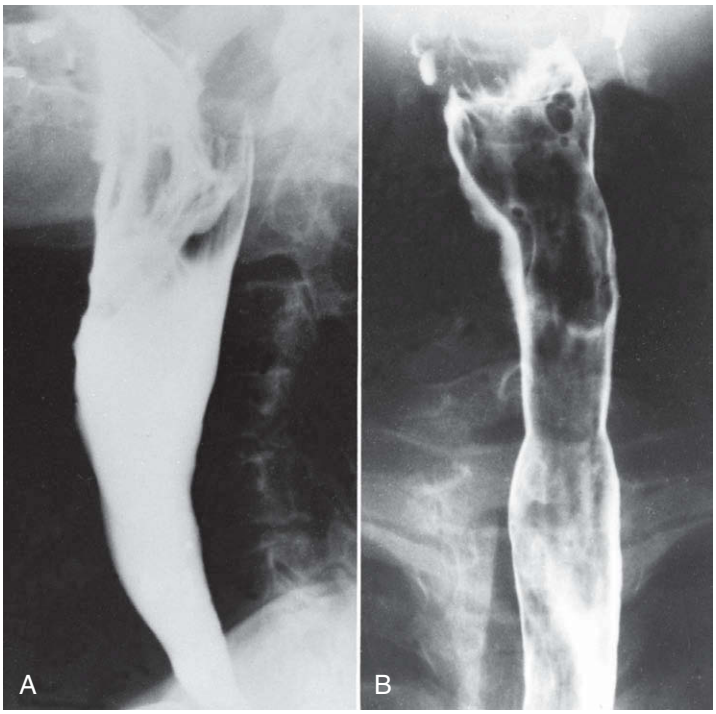

Figure 102-58. Normal postlaryngectomy pharyngoesophagography. **A,** Frontal projection. **B,** Lateral projection. The neopharynx is essentially a featureless tube.

Figure 102-59. Pseudoepiglottis. Lateral esophagram in a laryngectomy patient demonstrates a ridge of tissue mimicking the epiglottis. This is a normal postoperative appearance.

Figure 102-60. Tumor recurrence after total laryngectomy. Frontal view from an esophagram shows a 3-cm mass indenting the right side of the neopharynx *(arrows).*

On CT, the jejunal mucosa enhances briskly and may simulate recurrent tumor (Fig. 102-61). The interposed jejunum may have a tortuous course within the neck, further complicating the radiographic evaluation.[129] On an esophagram, the plicae circulares of the jejunum have a characteristic appearance (Fig. 102-62). Longstanding jejunal grafts may show evidence of peristalsis. Because jejunal peristalsis is much slower than normal pharyngeal peristalsis, these patients may present with dysphagia.

All laryngopharyngectomy reconstructions share characteristic sites of stenosis. Short-segment strictures most frequently involve the proximal or distal anastomosis. Long, tapered strictures affect the midneopharynx, particularly in patients who undergo radiation therapy.

Radiotherapy

Motility disorders are often identified in patients who have received therapeutic radiation to the neck. The most common dysfunction is failure of epiglottic inversion,[130] but hypocontractility, tracheal aspiration, and failure of cricopharyngeal relaxation are also seen.

On cross-sectional imaging, prior radiation therapy is evidenced by stranding of the cervical fat, thickening of the platysma muscle, increased density of the salivary glands, and persistent edema of the laryngeal mucosa (Fig. 102-63). This mucosal swelling is less pronounced, and less persistent, in the pharynx.

Monitoring and Surveillance

Combined PET/CT scanning has dramatically changed the assessment of recurrent tumor in the head and neck.[131,132] Traditional surveillance with CT or MRI relies on morphologic changes over the course of many months to distinguish postoperative scar from recurrent or residual tumor. PET/CT can detect residual disease as soon as 8 weeks after therapy and may be useful during chemoradiation to assess response to therapy (Fig. 102-64). Appropriate screening regimens for postoperative surveillance with PET/CT have yet to be established.[133]

PET/CT is also able to detect second primary tumors, either in the head and neck or elsewhere in the body (Fig. 102-65). This is particularly important because of the high rate of synchronous and metachronous tumors in patients with carcinomas of the pharynx and esophagus.

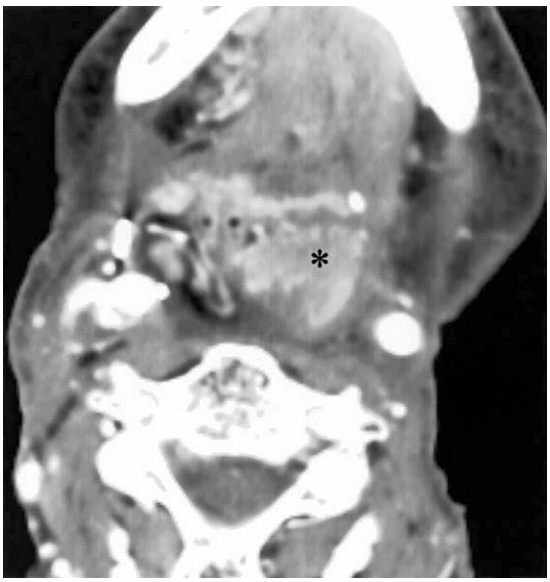

Figure 102-61. Jejunal interposition graft. Enhanced CT reveals an irregular, enhancing mass *(*)* in the surgical bed. This is the normal appearance of the transposed jejunum and should not be confused with tumor recurrence.

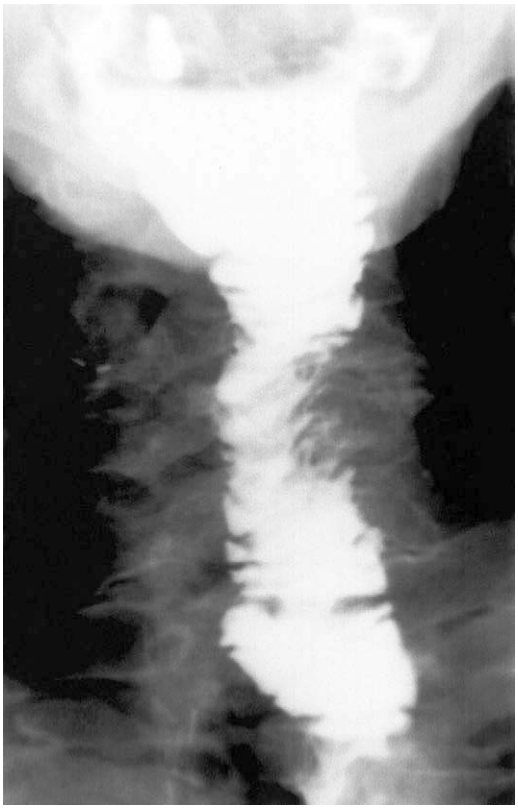

Figure 102-62. Jejunal interposition graft. Frontal esophagram demonstrates normal jejunal folds in the neopharynx.

Figure 102-63. Effects of radiotherapy. Enhanced computed tomography reveals extensive edema *(*)* lining the larynx. The submandibular glands *(g)* are dense. The platysma muscle *(arrow)* is thickened.

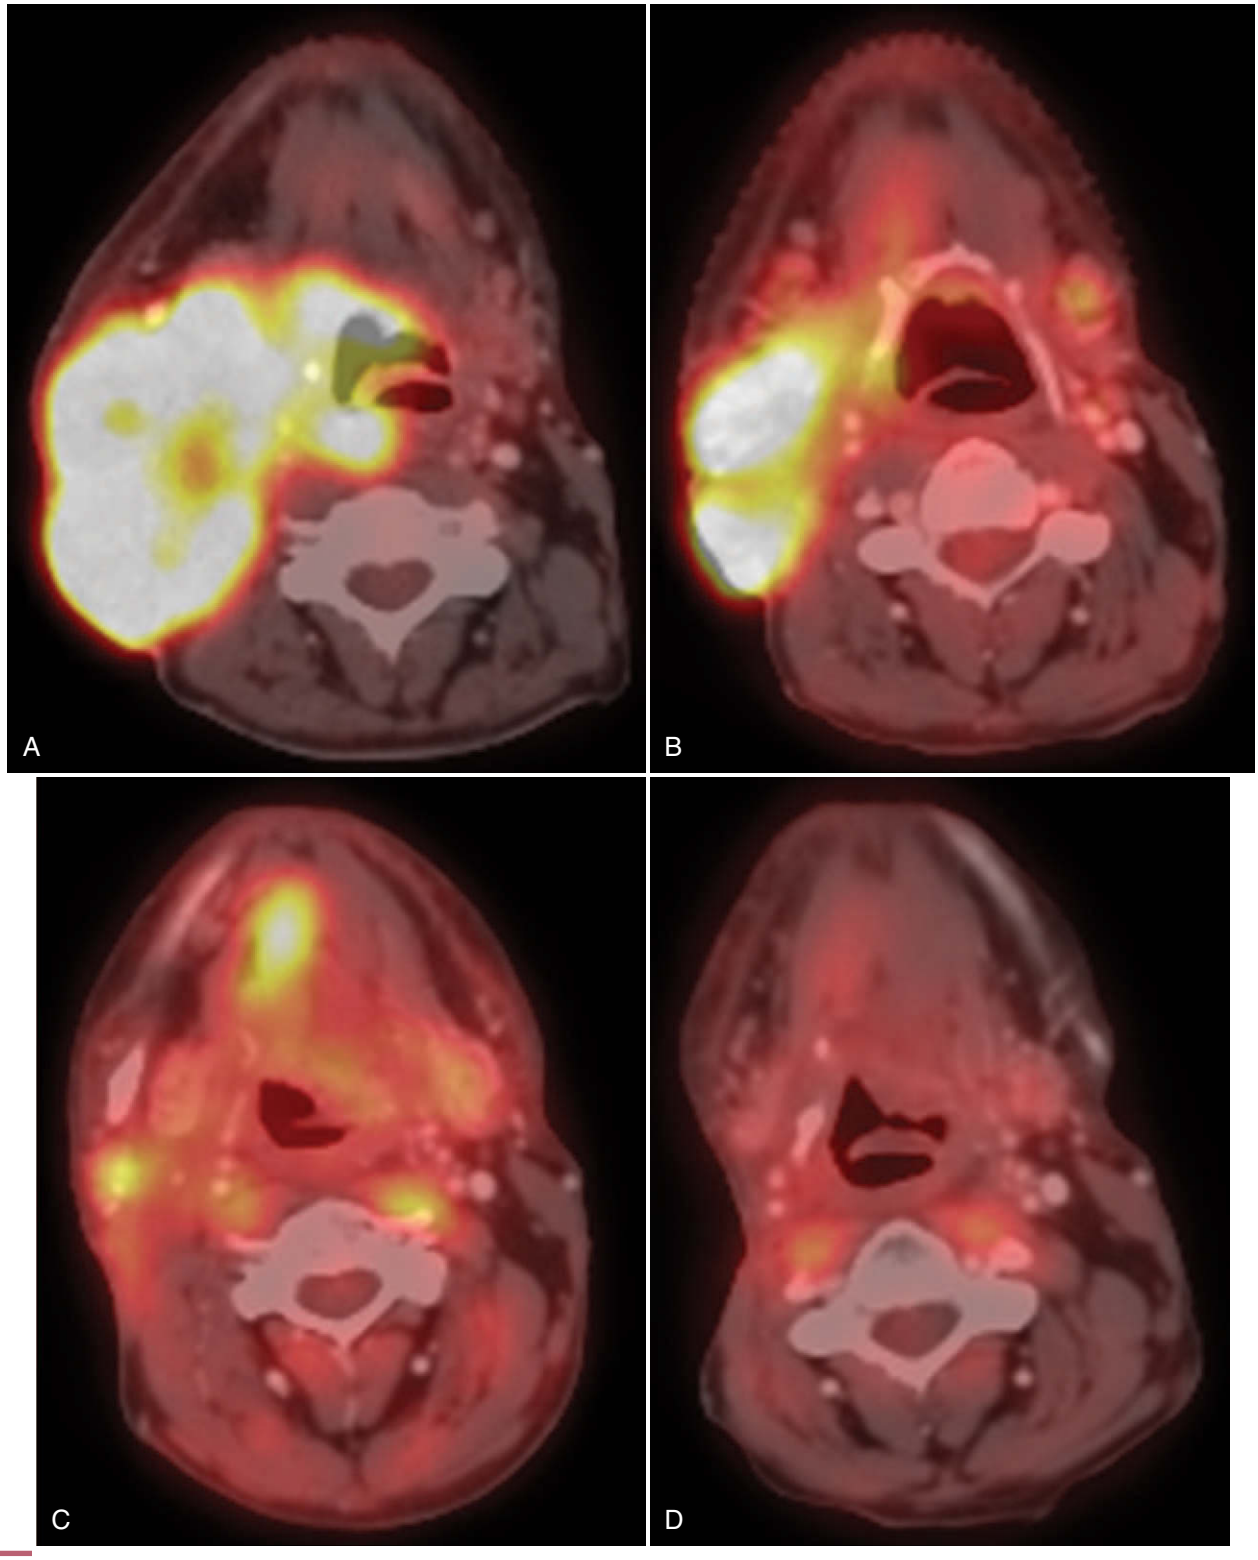

Figure 102-64. Monitoring tumor response with positron emission tomography-computed tomography. Sequential fused axial images through the oropharynx show large tumor at presentation **(A),** improved after 2 months of therapy **(B),** further regressed 4 months later **(C),** and completely resolved 3 months later **(D).**

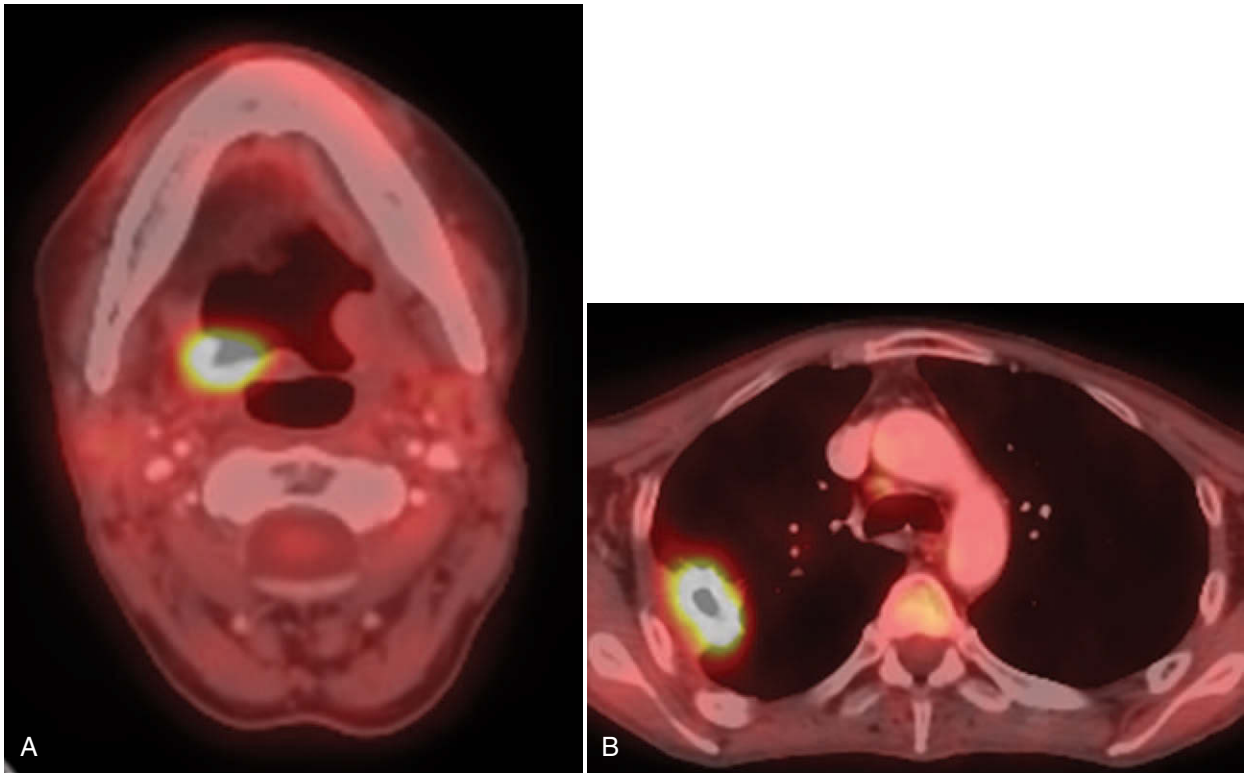

Figure 102-65. Detecting second primary tumors with positron emission tomography-computed tomography (PET/CT). **A,** Fused axial PET/CT image through the oral cavity demonstrates recurrent squamous cell carcinoma in the right tonsillar pillar and soft palate. **B,** On the same scan, an unsuspected second primary lung cancer is revealed.

CHAPTER ONE HUNDRED AND THREE

Neoplasms of the Hypopharynx and Cervical Esophagus

Ravindra Uppaluri

John B. Sunwoo

Key Points

- Of all subsites of head and neck squamous cell carcinoma, patients with hypopharyngeal carcinomas as a group fare the worst in terms of oncologic outcome.
- Hypopharyngeal carcinomas tend to have significant submucosal extent, especially inferiorly, but according to one study, this does not worsen locoregional recurrence nor does it affect 5-year survival.
- Organ-preserving therapy for hypopharyngeal lesions includes nonsurgical concurrent or induction chemotherapy and radiation or surgical options including transoral laser microsurgery and supracricoid hemilaryngopharyngectomy.
- Combined chemotherapy and radiotherapy for hypopharyngeal carcinomas leads to a higher rate of stricture and gastrostomy tube dependence compared with other subsites of the head and neck.
- Advanced hypopharyngeal tumors requiring surgery routinely involve reconstruction with either microvascular free flaps (fasciocutaneous or jejunum interposition) or gastric pull-ups.

Neoplasms of the hypopharynx and cervical esophagus are some of the most challenging diseases managed by the head and neck surgeon. Pathologically the vast majority of these lesions are squamous cell carcinomas, which usually present at an advanced stage and thus pose several challenges to the managing physician. As with all advanced head and neck cancers, a multidisciplinary approach involving head and neck surgeons, radiation therapists, and medical oncologists is used in formulating a treatment plan. Unfortunately, the available modalities of treatment yield a similar poor prognosis for patients with hypopharyngeal and cervical esophageal cancer. When primary surgical-based approaches are used, a careful assessment of the tumor extent is critical because hypopharyngeal tumors often have significant submucosal extension, which can significantly affect the planned resection. Furthermore, the surgeon must consider the reconstructive challenges of the surgical defect, which affects swallowing, speech, and respiration. When radiation and chemotherapy are used as initial modalities of therapy, great care must be taken to follow patients because the ability to surgically salvage treatment failures is an integral part of the therapeutic regimen. The goal of this chapter is to provide a comprehensive review of cancers of the hypopharynx and cervical esophagus that have such devastating effects on the patients who develop them.

Anatomy of the Hypopharynx and Cervical Esophagus

The hypopharynx is the region of the pharynx that extends from the oropharynx superiorly to the cervical esophagus inferiorly. The cervical esophagus is that portion of the esophagus that extends to the thoracic inlet. The superior extent of the hypopharynx is approximately at the level of the hyoid bone or at the level of the pharyngoepiglottic folds. Inferiorly, the hypopharynx tapers to the esophageal introitus at the cricopharyngeus muscle. It is bordered anteriorly by the larynx and posteriorly by the retropharyngeal space. It is subdivided into three regions: the pyriform sinuses, the postcricoid region, and the posterior pharyngeal wall (Fig. 103-1).

The pyriform sinuses (one on each side) are composed of anterior, medial, and lateral walls that form an inverted pyramid with the base of the pyramid at the level of the pharyngoepiglottic fold and the apex extending to just below the cricoid cartilage. This lower region is lateral to the aryepiglottic folds and medial to the thyroid lamina. Because of this close relationship, tumors of the hypopharynx often extend to invade the larynx.[1] The medial pyriform mucosa forms the posterior wall of the paraglottic space and is separated from the endolarynx by the aryepiglottic folds and the lateral cricoarytenoid muscles. Hypopharyngeal tumors extending medially from the medial wall of the pyriform sinus can, therefore, invade into the larynx.

The postcricoid region is the anterior wall of the hypopharynx, extending from just below the posterior aspect of the arytenoid cartilages to the esophageal introitus. Postcricoid tumors commonly invade the cricoid cartilage and the posterior cricoarytenoid muscle. Because the postcricoid region lies just medial to the tracheoesophageal groove, tumors arising from this area can involve the recurrent laryngeal nerve, paratracheal nodes, and thyroid gland.

The third region of the hypopharynx, the posterior hypopharyngeal wall, is separated from the vertebral and paravertebral structures by the potential retropharyngeal space. Tumors can easily cross this space to invade prevertebral tissues. The posterior wall extends from the level of the hyoid bone to the superior aspect of the cricopharyngeus muscle.

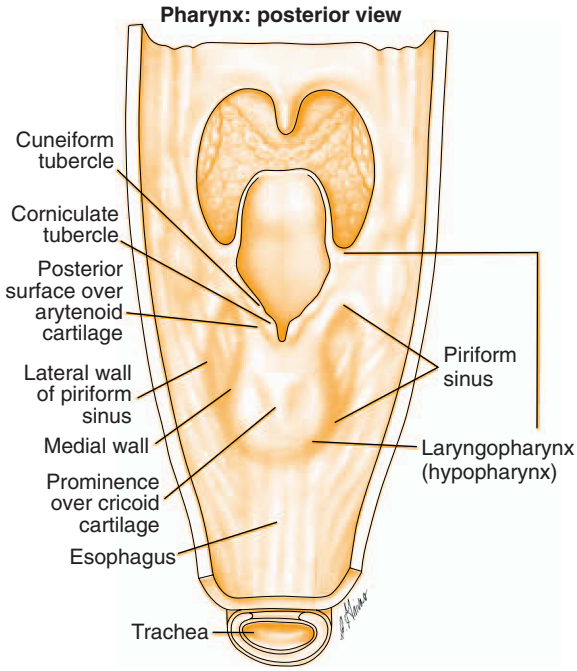

Figure 103-1. Anatomic regions of the hypopharynx.

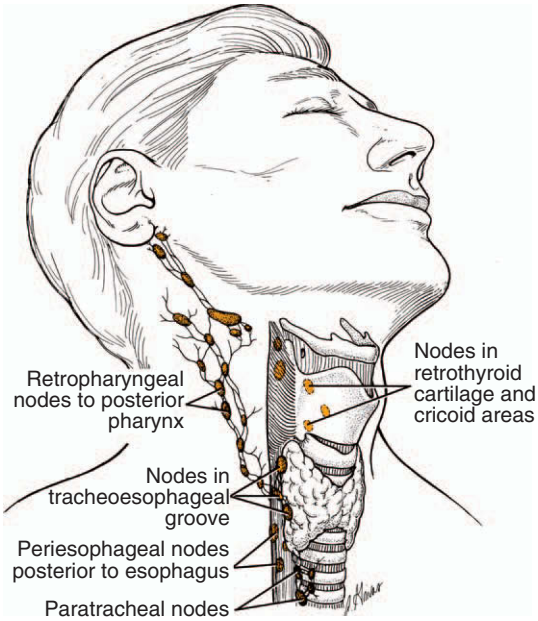

Figure 103-2. Hypopharyngeal carcinomas metastasize primarily to the superior jugular and midjugular nodes. However, metastasis to the retropharyngeal nodes, paratracheal nodes, paraesophageal nodes, and parapharyngeal space nodes may be present.

The aryepiglottic folds separate the endolarynx from the medial wall of the pyriform sinus bilaterally and form what has been termed the "marginal area." Although the aryepiglottic folds are actually part of the supraglottic larynx, tumors arising at this site behave aggressively like hypopharyngeal cancers and not supraglottic carcinomas.[2]

The cross-sectional anatomy of the hypopharynx reveals that it is composed of four layers: a mucosal lining formed by stratified squamous epithelium over loose stroma; a fibrous layer formed by the pharyngeal aponeurosis; a muscular layer; and a fascial layer arising from the buccopharyngeal fascia. The muscular layer is composed of the posterior cricoarytenoid muscles anteriorly and the middle/inferior constrictor muscles posteriorly. The inferior constrictor condenses into the cricopharyngeus muscle distally, and just superior to this junction is a potential area of weakness, known as *Killian's triangle,* through which posterior pharyngeal wall tumors can extend outside the hypopharynx. Just inferior to the hyoid bone at the thyrohyoid membrane, there is another potential area of weakness through which hypopharyngeal tumors may extend laterally along the vascular pedicle and the superior laryngeal nerve.

The arterial blood supply to the hypopharynx is primarily through the superior thyroid arteries. Branches from the lingual and ascending pharyngeal arteries also form collaterals supplying this area. The venous drainage mirrors the arterial blood supply.

Sensory innervation from the hypopharynx that assists in swallowing passes through the glossopharyngeal (cranial nerve IX) and the vagus (cranial nerve X) nerves to the nucleus solitarius in the brainstem. The sensory input is connected to the nearby cranial nerve motor nuclei by interneurons and assists in the coordination of deglutition. The internal branch of the superior laryngeal nerve passes through the superior portion of the lateral wall of the pyriform sinus and through the thyrohyoid membrane to join the vagus nerve. These sensory fibers then synapse in the jugular ganglion within the jugular foramen along with sensory fibers of Arnold's nerve from the external auditory canal. This juxtaposition accounts for the referred otalgia that is often experienced by patients with tumors of the pyriform sinus.

Lymphatic drainage from the pyriform sinuses passes through the thyrohyoid membrane primarily to the jugulodigastric lymph node and to the midjugular and spinal accessory chains (Fig. 103-2). Lymphatic vessels from the inferior portion of the hypopharynx and from the postcricoid region also drain to the paratracheal and paraesophageal nodes and to nodes in the supraclavicular fossa. Lymphatic drainage from the posterior hypopharyngeal wall is to the retropharyngeal nodes and to the midjugular chain. The retropharyngeal nodes are divided into a medial and lateral group. Lateral retropharyngeal nodes, also known as the *nodes of Rouvière,* are present at the level of the skull base.

The cricopharyngeus muscle represents the transition between the hypopharynx and cervical esophagus. The cervical esophagus is also a muscular tube that has a squamous epithelial layer, a submucosa rich in lymphatics, a muscular layer, and an adventitial layer. The muscular layer is divided into an inner circular and outer longitudinal layer. The trachea and thyroid are anterior to the cervical esophagus with the lobes of the thyroid also extending laterally. The retroesophageal space is contiguous with the retropharyngeal space above and the posterior mediastinum below. The lymphatics of the cervical esophagus are almost coincident with the hypopharyngeal lymphatics and include drainage to the recurrent laryngeal, paratracheal, and jugular chain nodes. The only difference in lymphatic drainage may involve some drainage of the cervical esophagus to the superior mediastinal lymph nodes. The vascular supply is derived from the inferior thyroid arteries with some contribution from the high thoracic vasculature. Finally, innervation to the cervical esophagus is provided by sympathetics, parasympathetics, and cranial nerves IX, X, and XI (the spinal accessory nerve). The recurrent laryngeal nerve and the pharyngeal plexus provide innervation to the cricopharyngeus.

Incidence

The incidence of cancer of the hypopharynx varies depending on worldwide geographic location. In addition, the incidence of cancer arising from specific subsites within the hypopharynx may also vary by geographic location. In the United States, three large database reviews shed light on the epidemiology of hypopharyngeal carcinoma. Neoplasms specific to the cervical esophagus are not mentioned in the first two of these three studies. Canto and Devesa[3] analyzed data from 1975 to 1988 in nine registries of the Surveillance, Epidemiology, and End Results (SEER) database. Although these data are not a random sample because each registry is from a specific geographic location, they represent approximately 10% of the U.S. population. The rates of cancer per 100,000 person-years vary with race and sex. It is also not clear from this study why the sites are listed separately as hypopharynx and pyriform. Whether there is overlap in these numbers is not stated in

this study. For white males the rate is 0.4 and 0.9 for the hypopharynx and pyriform sinus, respectively. For African American males the rate is 0.8 and 2.3 for the hypopharynx and pyriform sinus, respectively. For white females the rate is 0.2 for both the hypopharynx and pyriform sinus. For African American females the rate is 0.2 and 0.5 for the hypopharynx and pyriform sinus, respectively.

Hoffman and colleagues[4] conducted a second major database review of the National Cancer Data Base (NCDB) report, which is a comprehensive hospital-based registry of all cancer cases encountered. The data cover the years 1985 to 1994 and reveal that hypopharyngeal malignancy comprised 4.3% of all head and neck cancers, which included salivary gland and thyroid tumors in this study. Ninety-five percent of the hypopharyngeal tumors were squamous cell carcinomas with the remainder being adenocarcinomas, lymphoma, and other pathologies. Stage III and IV tumors comprised 77.3% of cancers, demonstrating the advanced stage of hypopharyngeal tumors at presentation. The survival data in this study were noteworthy in that hypopharyngeal cancers had the worst 5-year survival compared with any other primary site in the head and neck. The 5-year disease-specific survival was 31.4%.

Finally, Davies and Welch[5] analyzed the updated SEER database for the years 1999 to 2001 and found an average of 75,000 new cases of head and neck cancer. Interestingly, compared with the average 1975 statistics, this study found that incidence and mortality rates for hypopharyngeal and cervical esophageal cancer were decreasing. The one caveat to consider in saying that this trend was a definitive finding is that the rates of these tumors were below 1 per 100,000. Notwithstanding this statistic, this study shows a continued significant incidence of these deadly cancers within all head and neck squamous cell carcinomas.

The statistics outside of the United States reveal similar epidemiologic data. Wahlberg and colleagues[6] analyzed the comprehensive Swedish databases, covering 1960 to 1989, and found rates of 1.22/100,000 for men and 0.45/100,000 for women, similar to rates described by Canto and Devesa.[3] During this time the rates for men increased, but the rates for women decreased. The authors suggest that this may reflect a decrease in Plummer-Vinson syndrome, the sideropenic anemia common in Northern Sweden that predisposes to development of postcricoid carcinoma.

The data on cervical esophageal carcinoma are much more limited. Esophageal carcinoma causes approximately 12,000 deaths per year in the United States.[7,8] In one series, cervical esophageal carcinoma represented only 5.3% (9/168 patients) of all esophageal cancers.[9] Given this low frequency, the data are limited on the incidence and optimal treatment of this cancer. Additionally, these tumors are often included in statistics regarding all esophageal cancers.

Clinical Evaluation

PATIENT SYMPTOMS. Patients with lesions in the hypopharynx and cervical esophagus usually present at an advanced stage of disease. Lesions in this area can grow unabated to a size larger than most other head and neck sites because the anatomic boundaries of neighboring structures are not as limiting as for other sites (e.g., the larynx). Thus a disturbance of function is not seen until the disease is advanced. Because this area also has a rich lymphatic drainage, a neck mass is not an uncommon finding, especially in the advanced-stage disease. Hoffman and colleagues[10] analyzed presenting symptoms in 2939 cases from the Patient Care Evaluation study of the American College of Surgeons Commission on Cancer (Table 103-1). For stage I/II disease, gastroesophageal reflux, a common and nonspecific symptom, was most common (30.5%) followed closely by sore throat (28.1%). Importantly, 37.3% of patients with early-stage disease were asymptomatic at presentation. For stage III/IV disease, the most common symptom was a neck mass (92.3%) followed by shortness of breath (87.9%). Dysphagia occurred in 21.6% of early-stage and 78.4% of advanced-stage lesions. Additionally, referred otalgia was present in 25.1% of early-stage and 74.9% of advanced-stage lesions.

PHYSICAL FINDINGS. The overall appearance of these patients will likely reveal a malnourished individual. A complete examination of the head and neck should be performed with a focus on the mucosa of the upper aerodigestive tract to evaluate the extent of the primary tumor and to assess for second primaries. Synchronous tumors were present in a significant proportion of asymptomatic stage I/II patients in the Hoffman and colleagues' study.[10] In the same study a significant portion of patients presented with a neck mass; thus clinical staging of the neck to define the nodal stage is also critical. In the clinic, fiberoptic laryngoscopy should be used to evaluate the airway because impending airway distress is a possibility with advanced tumors. Immobility of the vocal cord(s) may reveal whether the larynx has been invaded.

In defining the options for managing a patient with hypopharyngeal and cervical esophageal cancer, the following must be addressed. The extent of tumor and lymph node involvement must be defined by office examination, operative endoscopy, and imaging. For tumors involving the posterior pharyngeal wall, invasion of the prevertebral fascia needs to be assessed clinically and radiographically to ensure an adequate surgical margin. Because distant metastases in certain series are the highest for hypopharyngeal cancers,[11] a metastatic workup by imaging and laboratory testing should also be completed. Comorbidities of the patient are also a significant contributing factor in managing these patients. For example, if a conservation surgical procedure is planned, the pulmonary function status of the patient needs to be evaluated because these patients are at significant risk for aspiration and must have adequate pulmonary reserve.

Table 103-1

Presenting Symptoms of Lesions

Symptoms*	All Cases	Clinical Stage I/II	Clinical Stage III/IV
Dysphagia	48.0	21.6	78.4
Neck mass	45.1	7.7	92.3
Sore throat	43.0	28.1	71.9
Hoarseness	35.6	18.7	81.3
Otalgia	17.5	25.1	74.9
Shortness of breath	11.8	12.1	87.9
Hemoptysis	8.1	18.0	82.0
Gastroesophageal reflux	3.0	30.5	69.5
Asymptomatic	1.9	37.3	62.7

*Numbers are percentages. Note the columns do not total 100% because single patients may have had more than one symptom. Adapted from Hoffman HT, Karnell LH, Shah JP. Hypopharyngeal cancer patient care evaluation. *Laryngoscope.* 1997;107:1005-1017.

Imaging

In the treatment of hypopharyngeal malignancies, the role of imaging involves the pretreatment evaluation of the extent of the primary tumor and possible metastases, as well as the evaluation of the patient following treatment. Hypopharyngeal tumors have a propensity for submucosal spread that may be undetectable on clinical or radiographic examination.[12] Causes for surgical failure include submucosal extension, involvement of the thyroid gland, and metastasis to paratracheal and upper mediastinal lymph nodes.[13] Thus imaging is essential to assess tumor extent or recurrence.

Although the barium swallow has been historically used to identify malignancies in this region,[14] its use is now more limited. Some centers continue to use the swallow to evaluate for second primaries in the esophagus. In the case of a cervical esophageal cancer where an endoscope cannot be passed distally, the barium swallow can be used for

Figure 103-3. Axial computed tomography scan of a patient with a left pyriform squamous cell carcinoma invading the arytenoids cartilage and the thyroid lamina.

imaging the distal extent of disease. Another use of the barium swallow study is in the postoperative setting to examine the deglutition process or to identify anastomotic problems such as stricture or fistula.

The primary imaging modality for pretreatment evaluation of the hypopharynx is cross-sectional imaging with computed tomography (CT) or magnetic resonance (MRI). In multiple studies examining the impact of cross-sectional imaging on the staging of hypopharyngeal and/or esophageal cancer, the clinical tumor stage was upstaged in up to 90% of patients.[15] Accuracy of tumor staging, determined by comparison to pathologic findings, is 58% for clinical examination, 80% for CT, and 85% for MRI.[16] CT is often preferred to MRI to assess cartilage invasion; however, an experienced radiologist looking for an increased T2 and decreased T1 signal intensity on MRI, which indicates cartilage involvement, can achieve a high degree of sensitivity (89% to 100%).[15] The specificity of MRI for cartilage invasion, however, is inferior to CT (62% vs. 84%).[17] A wide variability in specificity reflects the variability in ossification and the degree of inflammation, edema, and/or fibrosis at the tumor site. The specificity for cartilage invasion is lowest for the thyroid cartilage (57%), highest for the arytenoid cartilages (95%), and intermediate for the cricoid cartilage (87%).[16] Figure 103-3 demonstrates a T4 left pyriform sinus squamous cell cancer that has invaded the arytenoid cartilage and the thyroid lamina. The incidence of a second neoplasm of the aerodigestive tract, either synchronous or metachronous to an index tumor of the hypopharynx, has been reported to be 16% to 18%[11]; therefore a thorough radiographic evaluation of the entire aerodigestive tract including the esophagus is necessary.[18,19]

There are no available data supporting the routine use of imaging with CT or MRI in the post-treatment period to follow disease-free status. Typically patient symptoms or clinical endoscopic findings will dictate the utilization of specific imaging. The role of positron emission tomography (PET) has been explored as a modality to assist in the detection of locoregional recurrence and/or persistent disease. Several studies have reported on the improved sensitivity of PET over MRI in the evaluation of response to therapy.[20,21] Although this modality appears to have an increased sensitivity (86%) for recurrence over CT/MRI (57%), there is a lower measured specificity with PET (75% vs. 92% for CT/MRI).[21] An improvement in specificity with PET may be achieved as newer tracers are studied. For example, Chesnay and colleagues[22] described the successful use of ^{11}C-methionine to follow post-chemotherapy tumor response. The combination of PET and CT scans (PET/CT) provides significant advantages due to the ability to correlate fluorodeoxyglucose (FDG) avid lesions with anatomic findings and is increasingly used in all phases of hypopharyngeal tumor management.[23] Figure 103-4 illustrates the use of PET/CT in a patient with an advanced left pyriform sinus squamous cell carcinoma with cervical lymphadenopathy. The fused scan not only shows the primary FDG avid lesion but also highlights the left cervical lymph node with obvious tumor involvement. Thus the combination of CT, MRI, and PET scanning can be used in all phases of the management of hypopharyngeal and cervical esophageal carcinoma.

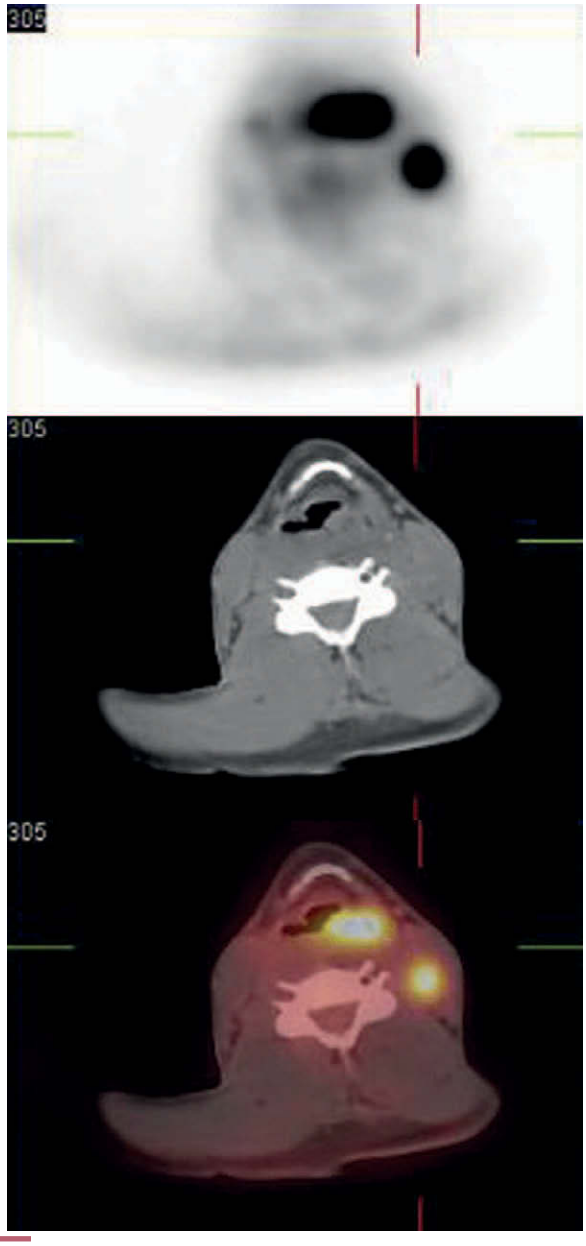

Figure 103-4. The bottom panel shows the positron emission tomography/computed tomography (PET/CT) fused image of a left pyriform sinus carcinoma with regional lymph node metastasis. The top panel shows the PET image alone, and the middle panel shows the CT alone.

Pathology

Although the vast majority (95% in the Hoffman and colleagues' study[10]) of neoplasms of the hypopharynx and cervical esophagus are squamous cell carcinomas, other rare pathologic entities have been described (Fig. 103-5). In addition, variants of squamous cell carcinoma have also been described.

Unusual malignant lesions include lymphomas, which can present in the hypopharynx as the primary site or can secondarily involve the hypopharynx and cervical esophagus after systemic presentation. Some of the subtypes include angiocentric T cell lymphomas, non-Hodgkin's extranodal lymphomas, and mucosa-associated lymphoid tissue (MALT) lymphomas.[24] A high index of suspicion for lymphoma should

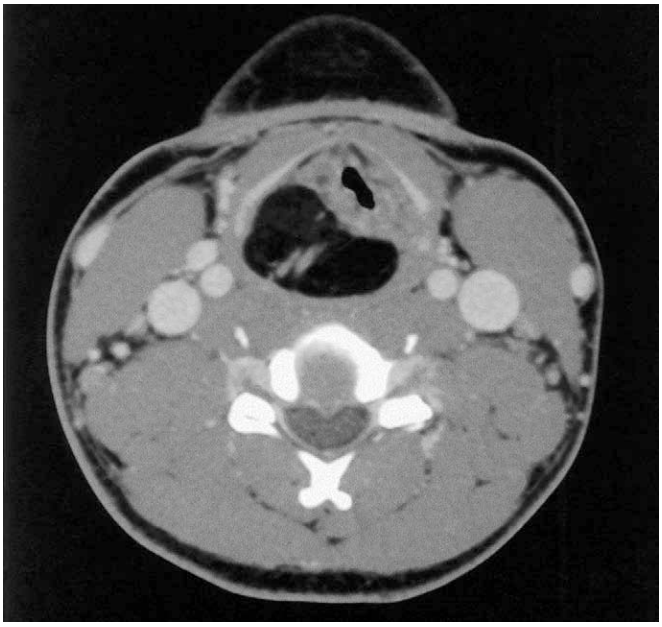

Figure 103-5. Axial computed tomography scan of a patient with a hypopharyngeal lipoma displacing the larynx.

be maintained in patients with AIDS and a hypopharyngeal mass.[25] Lymphomas need to be extensively staged and, depending on subtype, are treated with a combination of radiation and/or chemotherapy. The neuroendocrine tumors of the larynx and hypopharynx are a diverse subset of small cell tumors.[26] Depending on the histologic subtype, treatment varies from chemotherapy and radiation to surgical therapy.

Adenocarcinomas are another rare malignant entity seen in the hypopharynx and cervical esophagus. These lesions may initiate in the minor salivary glands within the hypopharynx or ectopic gastric mucosa in the cervical esophagus. The outgrowth of adenocarcinomas from ectopic gastric mucosa is a rare event.[27] Thyroid malignancies may secondarily involve the hypopharynx or cervical esophagus via direct invasion.[28] Other extremely rare malignancies include sarcomas[29] such as liposarcomas,[30] angiosarcomas,[31] and synovial sarcomas.[32]

Of the squamous cell cancers, there are three histologic subtypes that deserve special attention. First is basaloid squamous cell carcinoma,[33] which is a bimorphic variant of squamous cell carcinoma that has distinct pathologic features. Clinically, these lesions appear primarily in the supraglottis, pyriform sinus, and tongue base and have a distinctly more aggressive clinical course.[34] Second, lymphoepitheliomas are the hypopharyngeal counterpart of nasopharyngeal cancers.[35,36] These tumors are treated with radiation and chemotherapy, similar to nasopharyngeal carcinoma. Finally, the adenosquamous carcinoma is another rare variant, which also behaves clinically in an aggressive manner.[37]

Location of Tumors and Patterns of Spread

An understanding of the site of initiation and patterns of spread of hypopharyngeal carcinoma is critical in the management of these tumors. Substantial data exist regarding the origin of the carcinoma within specific subsites of the hypopharynx. Kirchner[1] described experience at the Yale University hospitals in managing hypopharyngeal carcinoma. In their patient population, 152 (86%) carcinomas arose in the pyriform sinus, 17 (10%) were in the posterior pharyngeal wall, and 8 (4%) were located in the postcricoid region. In the series of Carpenter and colleagues,[38] 117 (72%) carcinomas arose in the pyriform sinus, 37 (23%) in the posterior pharyngeal wall, and 8 (5%) were located in the postcricoid region. Saleh and colleagues[39] described their series of patients from Egypt and found that postcricoid cancers were the majority of presenting lesions (50.1%) followed by pyriform sinus (26.5%) and finally posterior pharyngeal wall tumors (23.4%). A European cancer registry review[40] demonstrated highest rates of pyriform sinus cancer in France (78%) and lowest rates in Sweden (5%). Although difficult to identify the precise reason for these subsite differences, one explanation is the possibility that an assignment of the exact origin of these tumors may be difficult except in the earliest stages.

Regarding the histologic spread of tumor, Kirchner[1] performed whole organ serial sections on 51 surgically resected pyriform sinus carcinoma specimens and described several interesting findings. Tumors were able to infiltrate the larynx and behave as transglottic cancers. They may invade the lateral and posterior pharyngeal walls and they may spread into the supraglottis and base of tongue. Invasion inferiorly into the cervical esophagus was not a common finding in these specimens. Twenty-two specimens invaded the thyroid cartilage at its posterior border, and all were found to have lateral pharyngeal wall involvement. Kirchner demonstrated in this study that the exclusion of tumors with pyriform apex involvement from conservation surgery was indeed appropriate because all of these tumors had laryngeal framework invasion.

A distinct feature of hypopharyngeal carcinoma that was noted early in the surgical treatment of this disease was its tendency to spread in a submucosal fashion.[13,41] This is an often-cited feature of hypopharyngeal cancer, especially in discussing its poor prognosis. Ho and colleagues[12] performed a detailed analysis of submucosal extension by serial sectioning of 57 specimens of hypopharyngeal cancer. Three classes of submucosal extension were identified: type 1 was a direct submucosal extension visible on gross inspection as elevated mucosa, type 2 was direct submucosal extension that was only visible on histologic examination, and type 3 was a true "skip" lesion with no connection to the primary. Only 1 of 57 specimens had type 3 extension; however, 33 (58%) patients did have submucosal extension of some type. In contradiction to the findings of Harrison,[13] significant inferior extension toward the cervical esophagus was observed. Patients treated with preoperative radiotherapy had significantly increased amounts of type 2 extension. Interestingly, in comparing overall 5-year survival, no differences were found between the group that had submucosal extension and the one that did not. Additionally, submucosal extension was not associated with increased locoregional recurrences. Thus although it is true that submucosal extension occurs in a significant number of patients with hypopharyngeal cancer, most of it is detectable clinically and a poorer prognosis is not seen in patients with submucosal extension of tumor.

Included in the data from serial sectioning by Ho and colleagues and Wei[12,42] was the finding that submucosal extension was greatest in the inferior direction, followed by lateral extension, and finally superior extension. On the basis of these data, they recommended that resection margins should be 3 cm inferiorly, 2 cm laterally, and 1.5 cm superiorly in patients who have not received previous radiation. For those with previous radiation, these margins were recommended to be 4 cm, 3 cm, and 2 cm, respectively. The deep margin was recommended to be greater than 1 mm in all patients.[43]

Etiology and Biology

The causal relationships among alcohol and tobacco intake, genetic predisposition, diet, and socioeconomic conditions in the development of squamous cell cancers of the head and neck apply as well to hypopharyngeal cancer.[44-46] In examining these factors, two specific components appear to be more closely associated with hypopharyngeal cancer. The first is alcohol intake, which appears to be more common in patients with hypopharyngeal cancer, at least when compared with laryngeal cancer.[10,47-49] What the specific effect of alcohol may be in hypopharyngeal cancer development is unclear. Alcohol may have direct carcinogenic effects, may be more of a promoter of tobacco's carcinogenic effects, or may have both functions. Two recent studies found that specific chewing tobacco products or exposure to wood smoke were associated with hypopharyngeal cancers in India.[50,51]

A condition specifically associated with postcricoid carcinoma is the Plummer-Vinson or Paterson-Brown-Kelly syndrome, which primarily affects women (85% of the cases).[52] This syndrome represents the combination of dysphagia, iron deficiency anemia, and hypopharyngeal and esophageal webs. It is hypothesized that chronic irritation results in the hypopharyngeal webs that then progress to carcinoma.

The syndrome is also geographically biased in that patients are predominantly located in the United States, Wales, and Sweden. The etiology is believed to be due to nutritional deficiency and since these issues have been addressed, the incidence of postcricoid carcinomas has declined in Sweden.[6]

The elucidation of the molecular genetic events underlying the development of squamous cell carcinoma of the head and neck has progressed rapidly over the past decade. A separate chapter in this text reviews the relevant molecular biology in detail.

Staging

The TNM system continues to be the standard by which the morphologic extent of the tumor is described. The American Joint Commission on Cancer updated the TNM staging in 2002, and the relevant hypopharyngeal and cervical esophageal system is listed in Tables 103-2 and 103-3.[53] The TNM system's major advantages are that it allows for comparing end results, communicating about patients, determining prognosis, and selecting treatments.[54] However, it is also acknowledged to have deficiencies due to inconsistencies; inaccuracies; observer variability; problems with various T, N, and M classification criteria; and exclusion of host factors. Piccirillo and colleagues from our institution have examined the role of host factors including patient symptom severity and comorbidities on outcomes of treatment. Piccirillo and colleagues[55,56] demonstrated that comorbidities are an independent prognostic factor in outcomes of patients with head and neck cancer. The most recent AJCC Cancer Staging Manual[53] recommends comorbidity assessment but does not yet incorporate these factors into staging.

Available Modalities for Management

The evolution of the management of hypopharyngeal and cervical esophageal carcinoma has paralleled that of management of cancer of other sites within the head and neck. From the early part of the century through the 1980s, the standard therapy focused on radical surgery followed by radiation or radiation alone. More conservative procedures for early lesions became possible with the introduction of conservation laryngeal procedures in the 1960s. There is no standard of care for these lesions because some institutions use combination chemotherapy and radiation protocols as primary treatment, whereas others continue to use surgery followed by radiation alone or with chemotherapy as the primary modality.

Therapeutic Modalities—Surgical Options Including Techniques

An understanding of the technical aspects of surgical management is amplified in the context of the historical experience. In addition, an appreciation of the pathologic behavior in the context of the anatomic boundaries of a hypopharyngeal or cervical esophageal carcinoma allows one to appreciate the extent and limitations of these procedures.

Cheever[57] first described the lateral pharyngotomy in combination with a mandibulotomy approach in 1878. Resection of a large tonsil tumor and a node plucking were performed; however, the patient recurred with local and regional metastases. With no anesthesia, attempts at control of the local recurrence were made with 18 applications of white-hot irons. Not surprisingly, the patient's tumor continued to grow. Other highlights in the development of hypopharyngeal cancer treatment include Sebileau's (1904) description of the lateral retrothyroid pharyngectomy; Trotter's (1913) development of the lateral pharyngectomy; the supracricoid hemilaryngopharyngectomy (SCHLP) described by Andre, Pinel, and Laccourreye (1962); and Ogura's (1965) development of the extended supraglottic laryngectomy. Many other surgeons contributed to the development of other techniques including Orton, Alonso, and Harrison.

The available surgical options can be divided among the organ-preservation procedures and more radical operations (Table 103-4). The conservation surgical procedures are limited to T1, T2, or highly selected T3 lesions, except for the endoscopic approach used by Steiner and colleagues.[58] The more radical operations typically require extensive reconstruction of the alimentary tract. The options and the algorithm for deciding on a specific reconstruction are discussed in a separate section.

Table 103-2

Tumor and Lymph Node Staging

Primary Tumor (T)	
Hypopharynx	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor limited to one subsite of hypopharynx and ≤ 2 cm in greatest dimension
T2	Tumor invades more than one subsite of hypopharynx or an adjacent site, or measures > 2 cm but not > 4 cm in greatest dimension without fixation of hemilarynx
T3	Tumor > 4 cm in greatest dimension or with fixation of hemilarynx
T4a	Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, esophagus, or central compartment soft tissue (including prelaryngeal strap muscles and subcutaneous fat)
T4b	Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures
Cervical Esophagus	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades lamina propria or submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
Regional Lymph Nodes (N)	
Hypopharynx	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, ≤ 3 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node > 3 cm but not > 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none > 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none > 6 cm in greatest dimension
N3	Metastasis in a lymph node > 6 cm in greatest dimension
Cervical Esophagus	
NX	Regional lymph nodes cannot be assessed
N1	No regional lymph node metastasis
N2	Regional lymph node metastasis
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

PARTIAL PHARYNGECTOMY. This option is considered when tumors are staged as T1 or T2 and are limited to the posterior or the lateral wall of the pyriform sinus. Contraindications to this technique include extension of the tumor to more than one wall of the pyriform, extension to the pyriform apex, and involvement of the larynx in any fashion. Four surgical approaches can be taken to approach these lesions to perform a partial pharyngectomy.

The first technique is a standard *lateral pharyngotomy* and involves a collar incision, which can be extended to address the cervical lymphat-

Table 103-3

Stage Groupings

Hypopharynx

Stage	T	N	M

ics. A neck dissection is first performed if indicated for the lesion. A tracheotomy is a standard part of the operation because significant pharyngeal edema may compromise the airway postoperatively. After this the carotid sheath and its contents are identified and gently dissected away from the posterior thyroid ala. This maneuver exposes the inferior constrictor muscle and the superior thyroid neurovascular pedicle. Transection of the inferior constrictor muscle identifies the pyriform sinus mucosa, which is then sharply divided, ideally at a resection margin, to enter the hypopharynx. The tumor in the posterior or lateral wall is then extirpated. After tumor removal, the defect is examined and a reconstruction plan is devised. If adequate mucosa is present, a two-layer primary closure can be performed. However, a skin graft or flap patch may be necessary (see reconstruction section later).

A tumor that more extensively involves the lateral hypopharyngeal wall needs to be addressed by wider margin. This can be accomplished with a *lateral transthyroid pharyngotomy* (Fig. 103-6) by a wider resection that involves the posterior portions of the thyroid cartilage and the hyoid bone.[59] In this variation, instead of approaching the tumor through the pyriform, an entry through the vallecula is chosen. Once the neck dissection is completed, a medial and inferiorly based perichondrial flap is elevated off the thyroid cartilage. The hyoid bone is exposed from lesser cornu extending laterally. The hyoid bone is then cut through the lesser cornu, and cartilage cuts are made in a vertical fashion at the junction of the anterior two thirds and posterior one third of the thyroid cartilage. The hypopharynx is then visualized by entering through the vallecula. A blunt retractor placed into the vallecula assists entry. The incision is then carried laterally and inferiorly through the cartilage cuts. As these cuts are made, visualization through the initial incision ensures a safe margin around the tumor. The lesion is reflected laterally and the other required circumferential cuts are completed. Frozen sections for control of the margins are obtained. Reapproximating the mucosa and suturing the perichondrial flap as a second layer closes the defect.

With both these approaches, complications include pharyngocutaneous fistula with wound breakdown and dysphagia. Fistula problems are addressed by attempting to decrease or divert salivary contamination, meticulous wound care, and the possibility of secondary flap closure. A cricopharyngeal myotomy performed intraoperatively is one prophylactic measure to address possible dysphagia, although one study has shown no benefit of this maneuver in head and neck cancer patients.[60]

The *anterior transhyoid pharyngotomy* (Fig. 103-7) is another approach for lesions that primarily involve the posterior pharyngeal wall. Thus T1 or T2 lesions are good candidates for this approach. A tracheotomy is first performed. Again, a collar incision is used to identify the hyoid bone. The hyoid may be resected or the approach may be above or below the hyoid. The vallecula is identified, and sharp dissection through this mucosa with subsequent tongue base retraction

Table 103-4

Surgical Options

Procedure	T Stage	Reconstruction
Partial pharyngectomy	T1, T2	Primary closure
Partial laryngopharyngectomy	T1, T2, T3	Regional or free flap
Supracricoid hemilaryngectomy	T1, T2, T3	Primary closure
Endoscopic CO_2 laser resection	T1, T2 (possible T3, T4)	Secondary intention
Total laryngectomy with partial/total pharyngectomy	T3, T4	Primary closure vs. regional or free flap
Total pharyngo-laryngo-esophagectomy	T4	Gastric pull-up

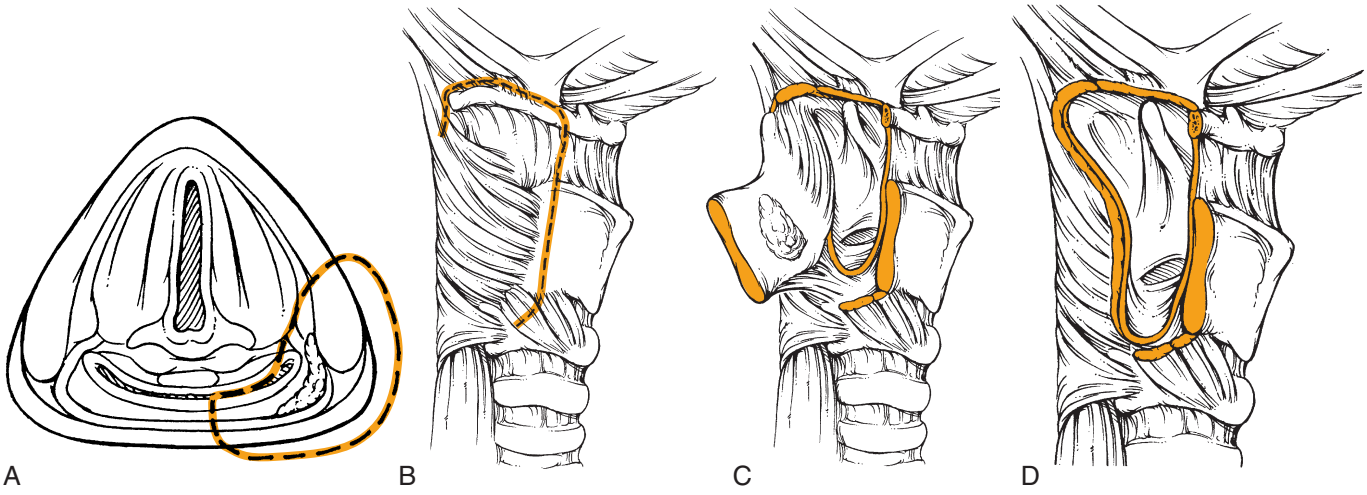

Figure 103-6. Partial pharyngectomy via the lateral pharyngotomy. **A,** Area removed, including the posterolateral hypopharyngeal wall and a portion of the thyroid ala. **B,** *Dotted lines* show cuts on the thyroid cartilage, hyoid, and vallecula. **C,** After entry into the hypopharynx, the specimen is reflected laterally and final cuts are made. **D,** Defect following excision of the posterolateral hypopharyngeal tumor.

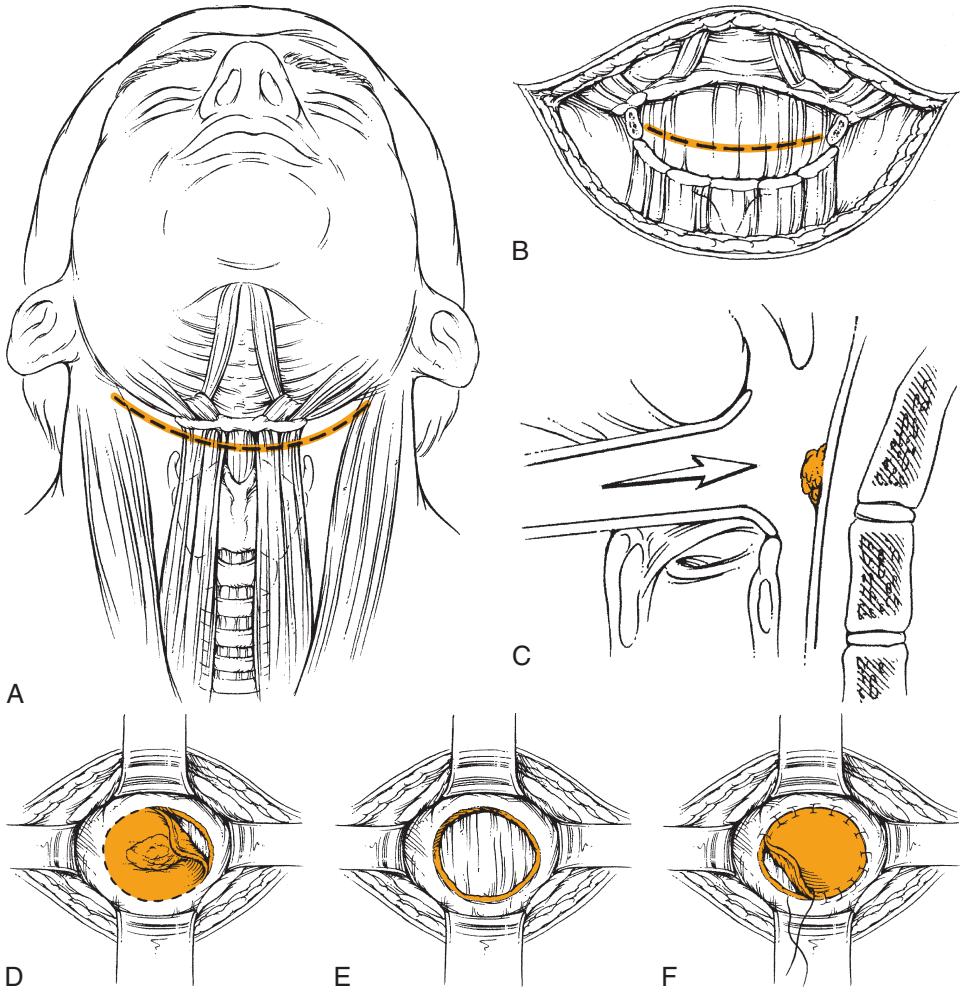

Figure 103-7. **A,** The anterior transhyoid approach is begun by transecting the musculature above (as shown) or below the hyoid bone. **B,** After removal of the hyoid, the vallecular incision is made to enter the pharynx. **C,** Inferior retraction of the pharynx and superior retraction of the base of the tongue exposes the posterior pharyngeal wall tumor. **D** and **E,** Tumor resection margin and defect. **F,** A skin graft is sutured to the posterior pharyngeal wall.

provides access to the posterior hypopharyngeal wall. The tumor is removed with the prevertebral fascia as the deep margin. After all margins are assessed by frozen section, a split-thickness skin graft can be used to cover the defect. The wound is closed by reapproximating the vallecular mucosa. The primary limitation to this procedure is that there is limited visualization of the full hypopharynx. Thus choosing the appropriate tumor for this approach is critical. Complications of this approach include pharyngocutaneous fistula and dysphagia.

The *median labiomandibular glossotomy* can be used to treat limited T1 and T2 lesions of the posterior hypopharyngeal wall. The procedure uses a mandible and tongue-splitting approach to gain access to the hypopharynx. The procedure is begun by creating a lip-splitting incision that is designed to prevent scar contracture over the chin. The incision is carried down to the mandible and inferiorly to the level of the hyoid. Holes for a reconstruction plate are drilled into the mandible and then a bone cut is made in the midline. The tongue is then split in the avascular midline plane and each segment is retracted laterally. Once the tumor is identified and resected in the posterior wall of the hypopharynx, a skin graft can be sutured onto the prevertebral fascia. The tongue is then reapproximated in several layers, and finally the mandible is reduced using the predrilled holes. Meticulous closure of the skin is the final step. Its major advantage is the wide exposure that can be achieved. This has to be balanced with the possible morbidity of the procedure, which includes malunion of the mandible, contracture in the chin skin incision, and dysphagia.

PARTIAL LARYNGOPHARYNGECTOMY. This operation combines the classic hemilaryngectomy operation with a partial pharyngectomy.[61] In certain cases the laryngeal remnant is still able to maintain speech, swallowing, and airway protection. The tumor must fit strict criteria including involvement of the medial pyriform sinus. The lesion may be a marginal aryepiglottic fold tumor. Extension into the base of tongue, lateral pyriform sinus, and vallecula can potentially be included in the resected specimen. Contraindications include (1) involvement of the pyriform apex, (2) extension to the postcricoid region, (3) ipsilateral true vocal cord paralysis, or (4) encroachment into the cricopharyngeus.

The procedure (Fig. 103-8) is begun after the completion of the tracheotomy and the neck dissection(s). For a lesion involving the medial wall of the pyriform sinus, minimal extension onto the epiglottis, and encroachment onto the arytenoid, the final resected specimen will contain the tumor on the medial wall, a portion of the epiglottis, the ipsilateral arytenoid, the ipsilateral half of the hyoid bone and the superior two thirds of the ipsilateral thyroid cartilage. After transection of the suprahyoid musculature, a superiorly based perichondrial flap is elevated off the thyroid cartilage. The thyroid cartilage is cut in the midline in an incision extending approximately two thirds of its height. This cut is then extended horizontally to the posterior border of the cartilage. The ipsilateral hyoid is freed and the vallecula is entered. Extension of this incision along with visualization of the epiglottis allows better exposure. At this point the epiglottis is grasped and retracted, providing visualization of the tumor. The epiglottis is then divided with a safe margin around the tumor and this cut is brought to, but does not include, the anterior commissure. One blade of the scissors is placed into the ventricle, and the other blade approximates the horizontal thyroid cartilage cut. This incision is made to the arytenoid, which is spared only if there is no involvement; however, it has to be sacrificed with tumor involvement. The vallecular incision is extended inferiorly with a good margin around the tumor. This is where a portion of the lateral pyriform/pharyngeal wall can be included in the resection if involved with tumor. The medial and lateral cuts meet at the arytenoid. If tumor involves more of the supraglottic area, a standard supraglottic laryngectomy can be performed to resect the entire epiglottis, pre-epiglottic space, and/or a portion of the base of tongue.

After clear margins are obtained on frozen section, closure of the wound is completed. With resection of the arytenoid, the ipsilateral true vocal cord must be sutured in the midline to the cricoid to prevent aspiration. A cricopharyngeal myotomy is performed, and for small lesions primary closure may be possible. However, myocutaneous flap closure or a microvascular free flap should be considered to avoid postoperative complications of wound breakdown. The complications include fistula formation and the possibility of aspiration. Meticulous postoperative care followed by eventual decannulation and attempts at oral feeding follow.

SUPRACRICOID HEMILARYNGOPHARYNGECTOMY. The major proponent of this technique is the French group of Laccourreye.[62-65] This procedure extends the partial laryngopharyngectomy procedure to include the entire ipsilateral supracricoid hemilarynx along with the pyriform sinus. Thus contraindications to this approach include involvement of the pyriform apex, ipsilateral cord fixation, postcricoid involvement, or posterior pharyngeal wall invasion.

The technique begins with appropriate neck dissections followed by a hemithyroidectomy and node dissection of the recurrent laryngeal nerve groups. The posterior border of the strap muscles is retracted to identify the posterior thyroid cartilage border. A musculoperichondrial flap is then elevated off the cartilage just past the midline. The ipsilateral half of the hyoid bone can be resected by cutting it at the lesser cornu. At this point the cricothyroid joint is identified and disarticulated. The airway access is then converted to a tracheotomy. The entrance into the hypopharynx is begun by incising the cricothyroid membrane vertically in the midline and connecting this to the midline vertical thyrotomy. The incision is extended superiorly through the epiglottis and the pre-epiglottic fat, where the contralateral fat is incorporated into the resection, and finally this incision ends in the vallecula. The specimen is then rotated open visualizing the tumor within the hypopharynx. A horizontal incision, on the superior surface of the cricoid from the midline extending to the cricoarytenoid joint, is then completed. The incision from the vallecula is then brought down inferiorly and connected to the interarytenoid incision, releasing the entire specimen. After clear margins are obtained, the contralateral arytenoid is covered with surrounding mucosa. A buttress using any remaining ipsilateral true vocal cord needs to be created for good apposition of the remaining functional vocal cord. The musculoperichondrial flap is then closed to the lateral pharyngeal wall.

Postoperatively, because these patients are at significant risk for aspiration, aggressive pulmonary toilet is critical and highlights the need for careful preoperative selection of patients with adequate pulmonary function. Fistula formation is a theoretic possibility but is not seen in Laccourreye's series.

ENDOSCOPIC CO_2 LASER RESECTION. The discussion of the endoscopic approach to management of hypopharyngeal tumors represents a transition from conservation laryngeal procedures to more radical extirpations. For more than 3 decades, Steiner and colleagues have been performing transoral laser microsurgery (TLM), which is an endoscopic resection of carcinomas of the upper aerodigestive tract. The cited advantages to this procedure are that (1) no tracheotomy is required, (2) the preservation of the suprahyoid musculature allows more normal swallowing, (3) not reconstructing is often the rule, and (4) hospital stay is decreased with patients returning to an oral diet as early as postoperative day 1. This approach has yielded remarkable results for all areas in which it has been applied. Certainly the full validation of these results awaits a prospective trial, but anecdotal experience at our own institution has been excellent (B.H. Haughey, personal communication, September, 2008).

The technique for all tumors involves use of a bivalved laryngopharyngoscope, an operating microscope, and a CO_2 laser as the dissecting instrument. As opposed to conventional open procedures, the tumor is often cut through during endoscopic approaches to provide a direct view of tumor depth and/or to assess cartilage invasion. Under microscopic vision, tumor margins are taken up to 10 mm and in this fashion the entire tumor is removed. The specimen is usually resected in multiple pieces, which are all oriented appropriately by the surgeon. A typical sequence of resection for a pyriform sinus primary is an initial cut through medial tumor, transverse to the plane of the aryepiglottic fold to assess extent of laryngeal extension, followed by posterior ± arytenoid, anterior, inferior posterolateral, and then superior posterolateral excisions. Margins are checked by frozen sections and a step serial technique.[66] Cartilage may be exposed or resected during the surgery and to avoid perichondritis antibiotics are given prophylactically. The wound bed is allowed to heal by secondary intention. In Steiner's management, delayed neck dissections are performed as indi-

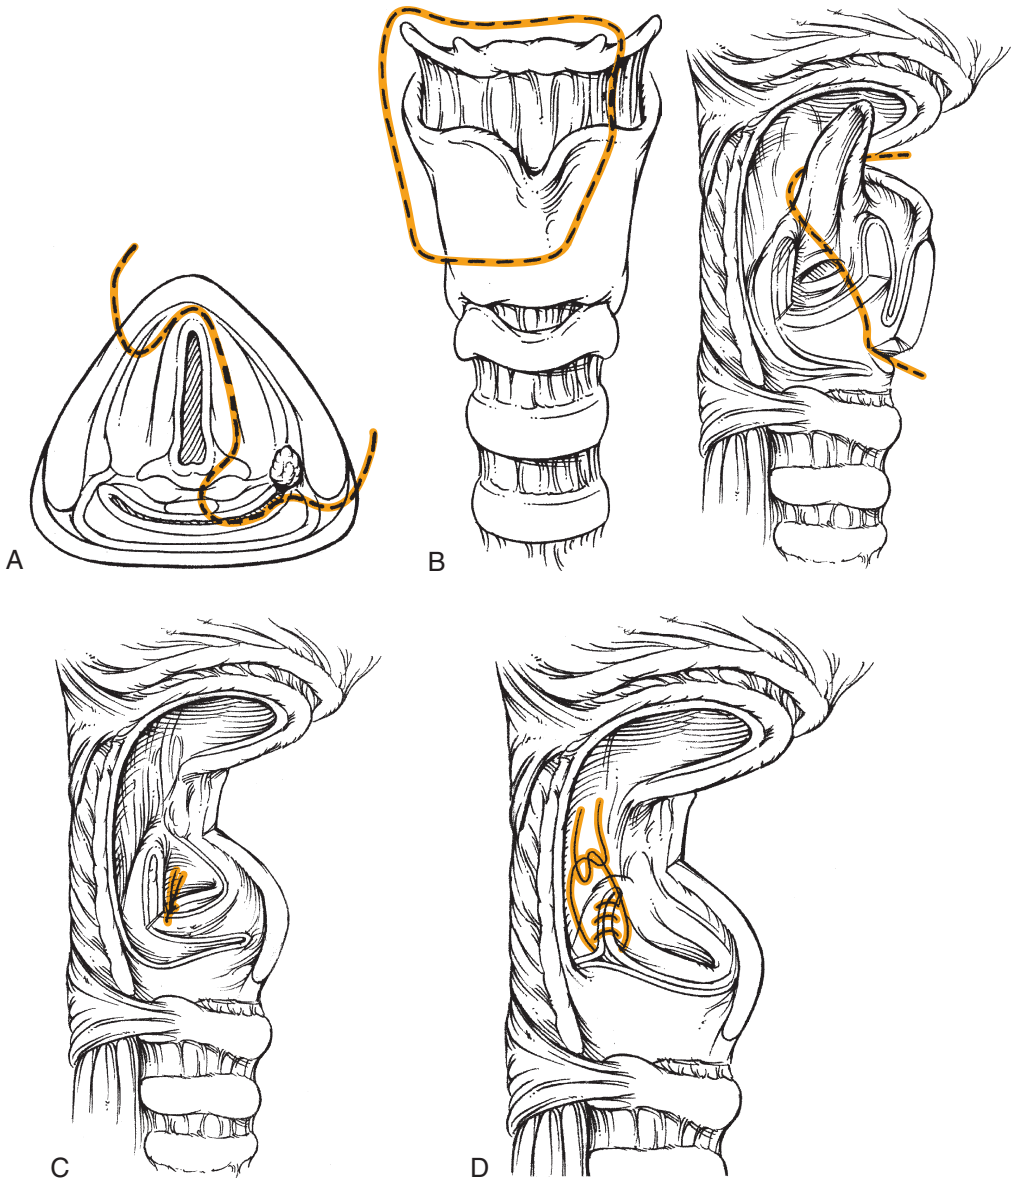

Figure 103-8. **A,** The resection margin after a partial laryngopharyngectomy for a medial pyriform tumor is shown in the superior view. **B,** This view demonstrates the bone and cartilage cuts for a partial laryngopharyngectomy. **C,** The completed resection of the medial pyriform tumor is shown. The epiglottis may be divided (as described in the text) or removed completely as shown here. **D,** With resection of the arytenoid, the ipsilateral true vocal cord must be sutured in the midline to the cricoid to prevent aspiration. The laryngeal mucosa is reapproximated as much as possible as shown.

cated by the tumor size, location, and lymph node status. Postoperatively the patients are started on an oral diet, as early as day 1, unless extensive resections are undertaken.

TOTAL LARYNGECTOMY WITH PARTIAL/TOTAL PHARYNGECTOMY. For T3 (those that are judged inappropriate for conservation therapy) and T4 lesions of the hypopharynx, combining a standard laryngectomy with excision of the involved pyriform walls completes this operation. In addition, total laryngopharyngectomy (TLP) is increasingly used as a salvage procedure for failures of chemoradiation protocols. Figure 103-9 shows a TLP of the patient whose PET/CT is shown in Figure 103-4 after failed chemoradiation. Reconstruction of these defects with primary closure can be accomplished if an adequate remnant of pharyngeal mucosa remains. Myocutaneous or free flap coverage may be required. Postoperative complications can include pharyngocutaneous fistulas with rates as high as 40% in patients previously treated with chemotherapy and/or radiation.[67]

Tumors with significant inferior extension may require a circumferential resection of the hypopharynx. This resection in addition to the laryngectomy encompasses this operation. The remaining defect will require re-establishment of the continuity between the oropharynx and the cervical esophagus. Again, some of the complications include fistula and dysphagia.

TOTAL PHARYNGO-LARYNGO-ESOPHAGECTOMY. This procedure is indicated for patients with involvement of the cervical esophagus due to either primary involvement or regional extension from the hypopharyngeal subsites. As for the TLP, this procedure is also used in cases of chemoradiation failure. Harrison recommended this operation for patients with postcricoid carcinoma because of the possibility of skip lesions.[68]

The procedure is begun after completion of bilateral neck dissections including paratracheal lymph node dissections and a total thyroidectomy with parathyroid autotransplantation. A total laryngopharyngectomy is performed as described earlier. A transhiatal pull-through esophagectomy is then performed to complete the inferior resection. Reconstruction is performed with the gastric pull-up technique as described later. The morbidity (20% to 60%) and mortality

(5% to 20%) rates are significant with this combined procedure.[69] Larynx-sparing esophagectomy has been described in certain case reports for lesions limited to the cervical esophagus.[70,71]

Therapeutic Modalities—Options for Reconstruction

Although briefly mentioned earlier, the spectrum of reconstructive options available for hypopharyngeal reconstruction is discussed here. The only situation where closure is not routinely performed is with the endoscopic excision of hypopharyngeal carcinoma, where healing by secondary intention is the rule. In addition to the brief discussion here, a separate chapter in this text discusses reconstruction of the pharynx and esophagus.

The principles of reconstruction that are used for hypopharyngeal reconstruction are the same as elsewhere in the head and neck region. These include the restoration of form and function with minimal donor site morbidity. In addition, to be able to achieve these goals in a single setting without need for secondary procedures is ideal. For the conservation procedures, a primary closure can be performed so long as there is no compromise of the pharyngeal lumen that could result in significant dysphagia. Primary closure can be performed safely when the pharyngeal lumen measures between 28 and 32 French. Skin grafts are the next available alternatives and are primarily used in the posterior pharyngeal wall resections. In addition, mucosal and dermal grafts, local rotation flaps, and tongue flaps have been described for closure.[72] Regional flaps that have been described include the platysma, deltopectoral, and latissimus dorsi flaps.[73] These flaps are typically used in the event of failure of the more popular options discussed later.

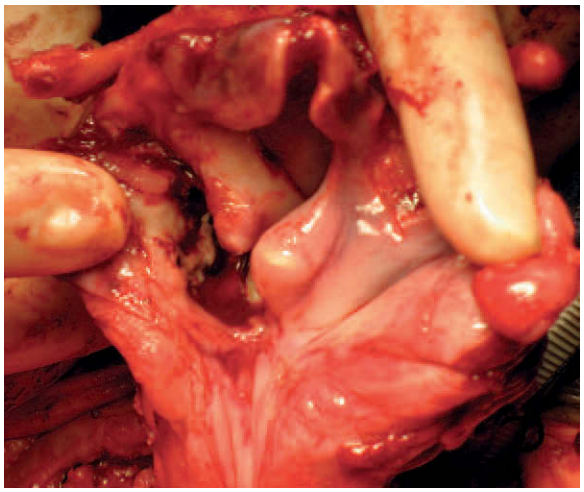

Figure 103-9. Total laryngopharyngectomy of a pyriform sinus carcinoma after failed chemotherapy and radiation. The ulcer crater in the left pyriform sinus is visible.

Ideally the head and neck/reconstructive surgeon has the full armamentarium of available surgical techniques for more extensive surgical defects. This not only provides the surgeon with multiple options for any given defect, but also ultimately provides the patient with the best possible functional outcome. In practice, the surgeon's level of comfort with a particular technique dictates the reconstructive option that is chosen. This bias is reflected in the literature where multiple case series from various groups describe their particular technique and its functional outcomes. For these reasons and also because of the limitation in number of extensive hypopharyngeal defects, no prospective, randomized studies exist comparing various reconstructive techniques.

PECTORALIS MYOCUTANEOUS FLAP. The pectoralis major myocutaneous flap has been the "work-horse" pedicled flap for head and neck reconstruction since its introduction by Ariyan in 1979.[74] The advantages of its use to close partial defects of the hypopharynx include its reliability and ease of harvest (Fig. 103-10). Disadvantages include the bulky nature of the flap, which can lead to postoperative stenosis, fistula problems, dysphagia, and difficulties of harvest in women with pendulous breasts. Partial defects are best closed with this flap when there is a strip of pharyngeal mucosa available for direct suturing. Although possible, tubing of this flap is not facile and should be avoided. Fabian described use of this flap for repair of partial defects[73,75] and others have extended his earlier reports.[76,77]

CIRCUMFERENTIAL DEFECTS. The reconstruction of circumferential defects of the hypopharynx and cervical esophagus is a controversial topic because a single flap has not been identified that necessarily gives the best functional outcome with the least morbidity. The choice of reconstruction is also limited by the surgeon's experience and availability of options at a particular institution. The literature on reconstruction in the 1980s and 1990s primarily focused on the jejunal free flap or the gastric pull-up as viable options. More recently, fasciocutaneous flaps that are tubed around a salivary stent have gained favor.[78-80]

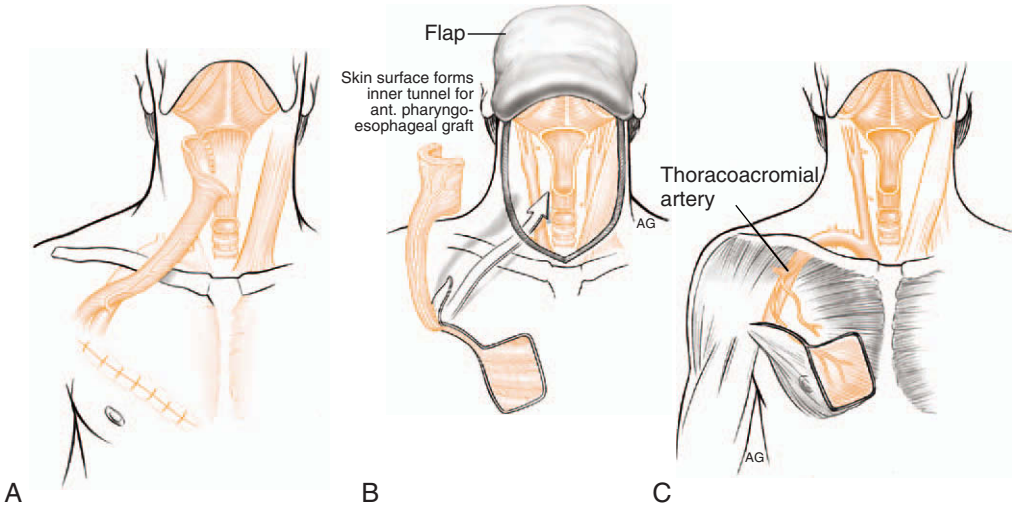

Figure 103-10. **A,** Rolling of the pectoralis major mucocutaneous flap to reconstruct the hypopharynx. The lower anastomosis should be carefully performed to reduce the likelihood of stricture. **B,** In this pectoralis major mucocutaneous flap, an 8-cm × 10-cm skin paddle is outlined and raised on the long axis of the pectoral branch of the thoracoacromial artery. **C,** Outline of the skin paddle over the pectoralis major for hypopharyngeal reconstruction. When soft tissue is excessive, a split-thickness skin graft can be applied directly to the muscle to reduce the bulk of the flap.

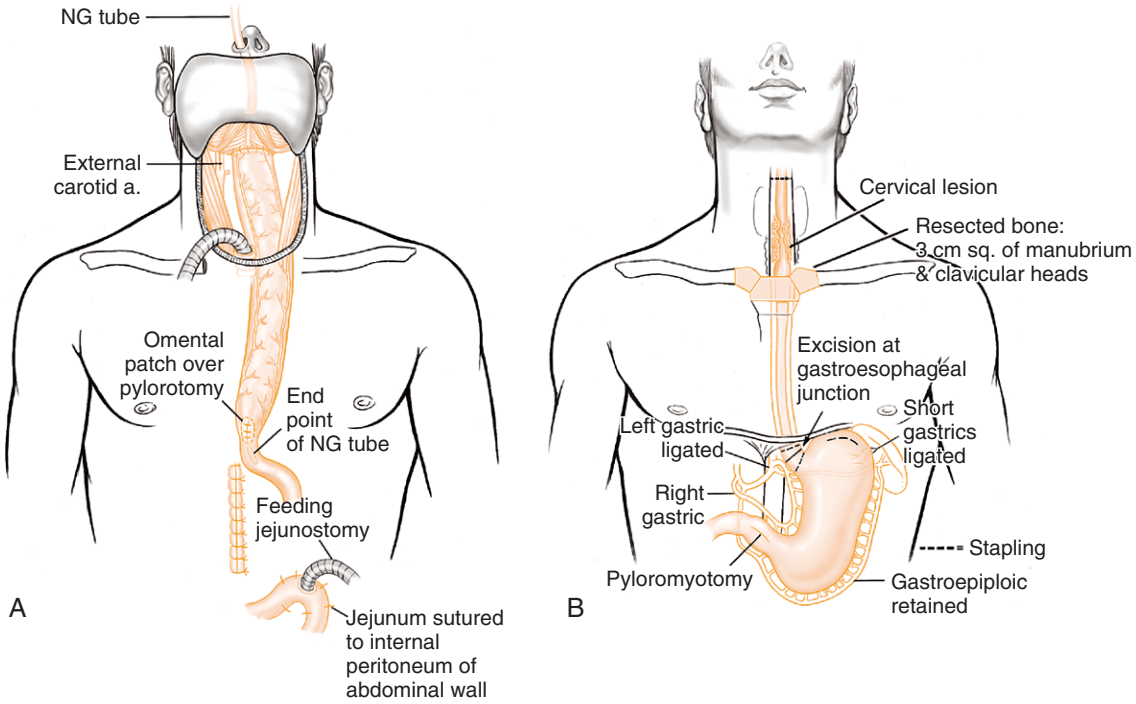

Figure 103-11. **A,** Gastric transposition. The stomach is passed through the posterior mediastinum. Pyloromyotomy enhances food passage. A jejunostomy will be used for decompression and for temporary feeding. Jejunostomy may be retained when postoperative radiation is planned. **B,** The advantage of the gastric pull-up procedure is no anastomosis within the abdomen or mediastinum. The single anastomosis occurs near the thoracic inlet. Ligation of the short gastric vessels and left gastric artery permits rotation of the greater curvature of the stomach upward through the funnel created at the time of resection of the esophagus. The stomach is placed in a plastic bag, which allows gentle passage through the posterior mediastinum to the neck.

Reconstruction options for circumferential defects that result after TPL include a regional flap, jejunal interposition, a tubed fasciocutaneous flap, a gastro-omental flap, and a gastric pull-up. A gastric pull-up or colon interposition can be used for total pharyngo-laryngo-esophagectomy defects. The regional flap as described earlier is the pectoralis myocutaneous flap.

GASTRIC PULL-UP. This option can be used when the inferior margin of tumor ablation extends past the cervical-thoracic junction of the esophagus or when a safe margin requires total esophagectomy. One school of thought advocates a complete esophagectomy along with the hypopharyngeal resection to address possible second primary malignancies for all hypopharyngeal cancer. Harrison, who originally advocated this concept, stated: "Total removal of the esophagus not only ensures complete resection of the lower limits of the tumor but also areas of potential malignancy and unexpected, undiagnosed second tumors."[68] He based these comments on whole-organ serial sections, which showed second primaries in the esophagus consistent with the field cancerization idea of Slaughter and coworkers.[81] Most recently, Martins made a similar case for total laryngo-pharyngo-esophagectomy in patients with advanced-stage hypopharyngeal cancer.[82]

Turner originally described this operation for esophagectomy using stomach as the reconstruction (Fig. 103-11).[83] However, it was Ong and Lee[84] who popularized this reconstructive method for laryngo-pharyngo-esophagectomy defects. The operation is carried across three compartments: neck, thorax, and abdomen. After completion of the laryngo-pharyngo-esophagectomy, the stomach is mobilized on the basis of the right gastric and right gastroepiploic artery. A pyloromyotomy is performed, and the stomach is then passed to the neck through the posterior mediastinum. A pharyngogastric anastomosis is then completed. As described earlier, the combination of total laryngo-pharyngo-esophagectomy with gastric pull-up is associated with high morbidity and mortality.[69]

JEJUNAL FREE FLAP. Seidenberg and colleagues first described the jejunal free flap in 1959 (Fig. 103-12).[85] The advantages to this procedure are that a large segment can be harvested for anastomosis as high as the nasopharynx. Concomitantly with the harvest, the primary tumor resection can be performed in the neck. Additionally, the intrinsic mucus production of the jejunum is hypothesized to assist in swallowing. The disadvantages are poor donor vessels, a short ischemia time, dysphagia from the intrinsic peristalsis of the jejunum,[86] poor vocal rehabilitation using a tracheoesophageal puncture, and morbidity from the abdominal surgery. Despite these potential problems, the jejunal free flap is a popular method of reconstruction for these defects.

While tumor resection is being performed in the neck, a second team performs the harvest. A segment of jejunum is harvested with associated vessels. Typically the second vascular arcade of vessels after the ligament of Treitz has a caliber that matches those of donor vessels in the neck. An exteriorized segment can be used to monitor flap viability. The jejunum usually matches the lumen on the side of the cervical esophagus. The flap is oriented such that isoperistaltic contraction will aid normal swallowing. At the proximal anatomosis, cutting the antimesenteric border to provide a better match with the oropharynx or nasopharynx expands the jejunum. A jejunostomy distal to the bowel anastomosis is then placed. The major disadvantage to this procedure is the requirement for a laparotomy, which can lead to complications in the debilitated and malnutritioned cancer patient. Recent efforts with minimally invasive laparoscopic harvest may revitalize the interest of surgeons who may have turned away from this option.[87,88] Two studies described successful harvest of the required jejunal segment. Gherardini and colleagues[87] performed the bowel anastomosis via a mini-laparotomy, whereas all patients in the study by Wadsworth and colleagues[88] underwent laparoscopic bowel anastomosis. The laparoscopic approach avoids the complications of postoperative ileus and other abdominal complications.

Although early case series using this technique reported poor results,[89,90] more recent and larger series have shown flap success rates between 95% and 97%.[91-93] Complications included flap failure, fistula, stricture, and abdominal complications. Detailed description of these complications is described by Reece and colleagues,[92] who found that flap failure caused by arterial thrombosis occurred in 7 of 93 patients.

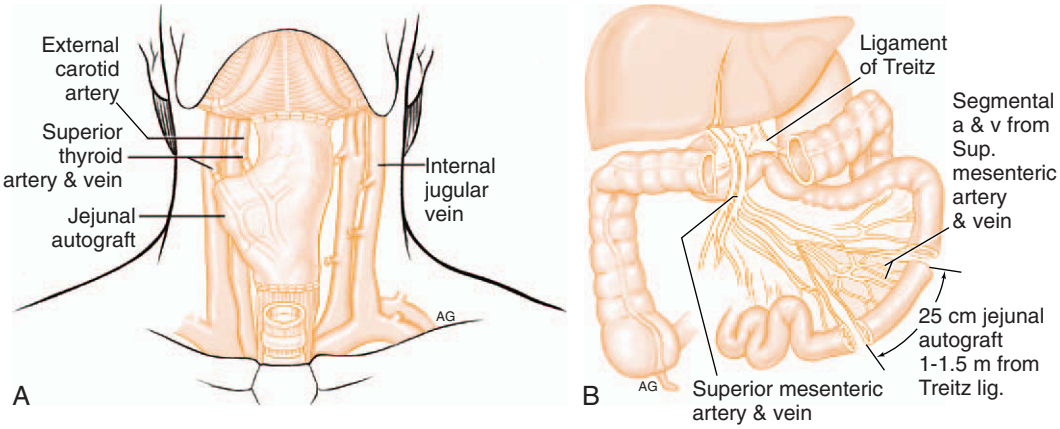

Figure 103-12. **A,** Free jejunal segment reconstruction. The mesenteric artery is anastomosed to the superior thyroid or external carotid artery. Vein anastomosis to the facial thyroid or end-to-side to the jugular vein is another option. Preservation of a jugular vein is required. Vein is anastomosed to the superior thyroid (facial). **B,** A segment of jejunum is isolated with complete arcade and an adequate length of the mesenteric artery and vein.

Postoperative fistulas, which delay oral alimentation and initiation of adjuvant therapy, have been reported to be high for jejunal flaps. Fistula rates were reported as 10% by Disa and colleagues[94] and 19% by Reece and colleagues.[92] Strictures as a cause of dysphagia were reported to occur in 4% to 15% of patients. Donor site morbidity consisting of dehiscence, small bowel obstruction, and infection occurred in only 1 of 90 patients in the Memorial Sloan-Kettering series and in 9 of 93 patients in the M.D. Anderson group of patients. Postoperative oral alimentation began between 11 and 14 days after surgery in two large case series. An unrestricted diet was tolerated between 53% and 92% of patients in three large case series.[91-93]

Although animal studies suggested that the jejunal autograft was poorly tolerant of radiation,[89] patients with jejunal grafts have tolerated postoperative radiation with minimal complications.[94-97] Wei and colleagues[97] performed biopsies at defined intervals over a 2-year period on either cohorts of patients receiving radiation or controls who did not receive radiation after jejunal free tissue transfer. Although microscopic changes were identified, no clinically significant symptoms or signs were observed consistent with previous observations.

Vocal rehabilitation using a TEP in these patients has been described as worse compared with patients who have undergone total laryngectomy alone.[98] The patients are described as having a "wet" voice. Most patients in the study by Reece and colleagues used an electrolarynx for communication with only 12 of 93 patients using a TEP.

FASCIOCUTANEOUS FREE FLAPS. Although the literature regarding hypopharyngeal reconstruction primarily discusses the jejunal free flap or gastric pull-up techniques, fasciocutaneous free flap techniques are being used more frequently. The popularity of these flaps has increased within the past decade.[78] This method was first described by Harii and associates in 1985 as an alternative reconstructive option; however, the early experience with fasciocutaneous flaps showed fistula rates as high as 67%.[99-101] One possible reason for strictures is that granulation tissue that forms at the fistula site ultimately may lead to stenosis at the anastomosis. However, more recent studies with modified techniques have shown more positive results.

Varvares and colleagues[80] and Scharpf and Esclamado[79] reported on their series of 20 and 25 patients, respectively, who underwent radial forearm free flap reconstruction of pharyngoesophageal defects. Both authors used surgical modifications to attempt improvements on past reported data on fistulae and stenosis. In seven patients of the Varvares series, the flap was completely tubed around a Montgomery salivary bypass tube and one patient developed a fistula. In Esclamado's report a "lock and key" design at the distal anastomotic site, a slightly larger flap than the actual defect (to allow for contraction) and minimal stretching prior to inset yielded a 28% (7/25) total fistula rate and a 36% (9/25) stenosis rate. Of the fistulas, five occurred greater than 4 weeks after surgery and all healed spontaneously. The stenosis was treated satisfactorily in 5/9 patients. Recently, Rosenthal and colleagues[102] reviewed their experience with 104 patients who underwent radial forearm free flap reconstruction for hypopharyngeal reconstruction. Similar to other studies, a fistula rate of 28.8% was noted in this series, which was associated with longer hospital stays and other complications. The anterolateral thigh is another effective donor site for circumferential defects and results in acceptable postoperative speech and swallowing.[103,104]

Therapeutic Modalities—Radiation Therapy

Although these modalities are discussed briefly here, a separate chapter in this text discusses in further detail chemotherapy, radiation therapy, and concurrent chemoradiation. The use of radiation as a single-modality therapy for hypopharyngeal carcinoma is limited to early lesions such as T1 cancers and selected T2 lesions. Favorable lesions are considered to be those that are exophytic in appearance and those lesions limited to the medial wall of the pyriform. The neck is included in the radiation field, although surgical salvage for bulky neck disease may be required.[105] Additional contexts in which this modality may be used are for elderly, debilitated patients; patients with advanced lesions who refuse surgical treatment; or palliative treatment. Complications associated with radiation include mucositis, stricture, airway compromise caused by laryngeal edema, chondronecrosis, and dysphagia.

In addition to the standard delivery of the radiation dose, altered fractionation schemes have been shown to achieve improved locoregional control in patients with head and neck cancer.[106] This was demonstrated in the large Radiation Therapy Oncology Group (RTOG) trial, in which different schemes were used in a randomized trial.[107] Two general types of altered fractionation schemes exist. The first is hyperfractionation, which results in a higher total dose by delivering smaller fractions more frequently (typically twice a day) without causing more late complications. The second is accelerated fractionation, which shortens the overall treatment time and attempts to achieve the same overall dose as standard fractionation. In the study by Fu and colleagues,[107] both hyperfractionation and accelerated fractionation with a concomitant boost showed significantly improved locoregional control but showed no difference in overall survival compared with standard treatment. Depending on the arm, between 11% and 15% of the patients in this trial had hypopharyngeal primary tumors. Acute reactions were increased in all accelerated fractionation schemes. Thus incorporation of these techniques in the use of radiation for cure or as postoperative treatment is a further advance for treating head and neck cancer patients.

Therapeutic Modalities—Chemotherapy

Chemotherapy is not used to treat hypopharyngeal and cervical esophageal carcinoma as single-modality treatment except in palliative treat-

ment cases. For all squamous cell carcinomas of the head and neck, the best responses are to platinum-based compounds such as cisplatin or carboplatin. In addition, 5-fluorouracil (5-FU), methotrexate, leukovorin, mitomycin C, and the taxanes have been used.[108] Some of the major complications of the commonly used 5-FU and cisplatin include hearing loss, mucositis, myelosuppression, and peripheral neuropathy.

LeFebvre and colleagues[109] published the first prospective, randomized study evaluating laryngeal preservation for hypopharynx carcinoma. Their protocol involved infusional chemotherapy consisting of cisplatin and 5-FU followed by endoscopy to assess tumor response. After two or three cycles, complete responders went on to receive definitive radiation and the remaining patients underwent conventional surgery.

Therapeutic Modalities—Concomitant Chemoradiotherapy

This combination modality attempts to combine the toxic effects of both agents on cancer cells to achieve therapeutic benefit. Concurrent chemotherapy also potentially radiosensitizes tumor cells in addition to direct toxic effects. These approaches use various combinations of cisplatin, 5-FU, taxanes/taxol, or hydroxyurea in conjunction with radiation. Obviously, one untoward effect of concurrent therapy is a significant increase in toxicity to patients. These toxicities are the same as those seen in patients being treated with the individual modality alone but are much more severe. Again, these include neutropenia, thrombocytopenia, mucositis, nausea, dysphagia with the need for a feeding tube, renal failure, cutaneous reactions, chondronecrosis, airway compromise, and death. Lee and colleagues[110] found that hypopharyngeal or upper esophageal strictures occurred in 21% of patients (41/222) undergoing concurrent chemoradiation and that a hypopharyngeal primary was a significant risk factor for developing this complication. A separate chapter in this text provides further details on chemoradiotherapy for hypopharyngeal and cervical esophageal malignancies.

Management of the Neck

The control of regional metastasis is a critical component of the management of hypopharyngeal and cervical esophageal tumors. Although this statement can be generalized to all other head and neck tumor sites, it is particularly important in this region due to the rich lymphatic drainage and the high percentage of tumors that have regionally metastatic disease (see Fig. 103-2). As for other sites, the discussion of neck management can be divided between elective neck dissection (for N0 stage necks) and therapeutic neck dissection (for N+ necks). For necks with positive nodes, the current management is to treat both necks, either with radiation followed by salvage surgery if necessary or surgery followed by radiation. For the ipsilateral neck that is staged N0, there is compelling evidence to treat both necks for all but the very early lesions where a unilateral neck dissection alone may be adequate. The types of neck dissections are discussed in a separate chapter in this text.

Many studies demonstrate the prognostic significance of lymph node metastasis in hypopharyngeal carcinoma. We focus on two early studies that demonstrate this finding. Shah and colleagues[111] observed that positive neck node(s) were a poor prognostic indicator in patients with hypopharyngeal carcinoma. In their series of 104 patients who were N0 at presentation, 61 underwent radical neck dissection and 36 did not. Nodes were positive in 25 (41%) patients who underwent neck dissection. In comparing survival with those patients whose nodes were negative after neck dissection, the 5-year survival was significantly better in the pathologically N0 group (50% vs. 32%). It is unclear whether the tumor stage was controlled for these groups (i.e., it is possible that the node-negative group involved early stages, whereas the node-positive group involved advanced stages). However, it is apparent from this overall study that positive nodes in hypopharyngeal cancer do not indicate a good prognosis. LeFebvre and colleagues[112] confirmed these data by examining lymph node status in a large series of patients treated at the Centre Oscar Lambret from 1974 to 1983. Almost 70% of these patients presented with palpable cervical metastasis. Again, a significant correlation between prognosis and lymph node status (N0 vs. N+) was established.

Given this prognostic significance, what are the draining lymph node basins for hypopharyngeal carcinoma? To understand the drainage patterns, Shah[113] reviewed the records of 1081 patients, 126 of whom had hypopharyngeal primaries, who underwent radical neck dissections. All the occult positive nodes in this study were in levels II and III. Interestingly, in the therapeutic neck dissection group, all five levels were found to have lymph nodes involved with tumor. On the basis of these studies, Shah recommended levels II, III, and IV neck dissection for N0 patients and comprehensive levels I to V neck dissection for node-positive patients. Shah and colleagues[114] confirmed these findings on a larger group of hypopharyngeal cancer patients and again came to the conclusion that N0 necks should be treated electively removing levels II to IV and N+ necks should undergo comprehensive neck dissection.

These studies provide support for the prognostic value of neck dissections and detail the nodal basins that need to be addressed. We next address the rates of lymphatic metastasis in patients with N0 necks to describe a rationale for ipsilateral neck treatment. Multiple studies demonstrate that patients of stage N0 will have occult lymph node metastasis. In some of these studies a comparison of N0 necks in T1/T2 tumors to N0 necks in T3/T4 tumors was not performed. Clearly, one problem in attempting this comparison is the relatively few T1/T2 tumors that are encountered compared with T3/T4 tumors. Byers and colleagues[115] reported on the occurrence of occult metastasis in elective neck dissections from patients with cancers at various sites in the head and neck. There were only three N0 patients with T1/T2 pyriform sinus tumors and two of these had occult metastasis. The T3/T4 group had 16 of 29 (55.2%) patients with occult metastasis. Buckley and MacLennan[116] prospectively examined 16 neck dissection specimens that were N0 from primary hypopharyngeal tumors with a careful sampling technique of all nodal levels. This subset of tumors was part of a larger series of cancers examined similarly. They found 9 of 16 (56%) of the hypopharyngeal neck dissection specimens to harbor occult metastatic deposits, although the T stages were not specifically given for the positive necks. Some of these occult tumor deposits were in nodes as small as 3 mm. Both the Byers and Buckley studies illustrate the high occult metastatic rate of hypopharyngeal carcinoma. These studies in combination with the studies of Shah and colleagues support the idea of selective level II/III/IV dissections in patients with N0 neck stage.

The retropharyngeal and paratracheal level VI nodes also form part of the draining echelon of nodes for these tumors. The studies discussed earlier do not discuss these nodal basins in detail. The removal of these nodes in conjunction with the jugular chain nodes is supported by the following studies. The study of Buckley and MacLennan[116] mentions that there were positive nodes in N0 necks in level VI, but no detail is given as to what primaries are or what tumor stage yielded these nodes. Harrison[117] performed serial sections of laryngopharyngectomy specimens and showed that lymphatic channels pierce through the cricothyroid membrane and drain into the paratracheal lymph nodes. Thus he argued that a total thyroidectomy with paratracheal node dissection was critical in the management of these tumors. Weber and colleagues[118] analyzed 141 patients from the M.D. Anderson Cancer Center who underwent paratracheal lymph node dissections for laryngeal, hypopharyngeal, or cervical esophageal cancer. Of the patients with a cervical esophageal primary, 10 of 14 (71.4%) had metastases in these nodes and 3 of 36 (8.3%) of hypopharynx primaries had positive nodes. Survival was significantly reduced in patients with positive paratracheal nodes. On the basis of these findings, the authors recommend paratracheal node dissection in all patients with primaries in these locations.

The retropharyngeal lymph nodes are not commonly addressed in hypopharyngeal and cervical esophageal squamous cell cancers and few studies have discussed management of these nodes. McLaughlin and colleagues[119] analyzed pretreatment CTs or MRIs for retropharyngeal adenopathy in patients with head and neck cancers. Pharyngeal wall tumors had 19% incidence of adenopathy in this area. As a group, rates of regional relapse were highest in those patients with retropharyngeal adenopathy. Hasegawa and Matsuura[120] found that 8 of 13 (62%) hypopharynx cancer patients had retropharyngeal lymphatic metastasis.

Amatsu and colleagues[121] performed retropharyngeal node dissections in 82 patients with hypopharyngeal and cervical esophageal carcinoma. Twenty percent (16/82) of patients had positive lymph nodes identified in the retropharynx. Thus these authors recommend bilateral retropharyngeal node dissection in all patients with hypopharyngeal and cervical esophageal cancer. Despite this data, the standard approach does not include dissection of these nodes. A recent case report highlights the involvement of retropharyngeal lymph nodes in hypopharyngeal cancer and the use of fused PET/CT in the pretreatment evaluation.[122]

The treatment of the N0 contralateral neck in hypopharyngeal carcinoma has been addressed by few studies. Marks and colleagues[122a] studied this question in a diverse group of head and neck cancer patients. Their conclusions were that (1) the risk of developing contralateral metastasis was unrelated to the size of the tumor, (2) the contralateral metastasis existed or developed in 13% of pyriform sinus tumors, and (3) the risk of contralateral metastasis was higher in patients with ipsilateral palpable disease. However, Johnson and colleagues[123] compared regional nodal metastases in medial versus lateral pyriform wall tumors and found significantly higher rates of contralateral metastases in the medially based tumors. These authors recommend bilateral neck dissections for medial pyriform wall tumors and unilateral neck dissections for lateral pyriform wall tumors.[123] Buckley and MacLennan[116] further examined this question in their study. For N+ necks, 3 of 3 patients had positive nodes in contralateral necks. Interestingly, in the N0 cases, 7 of 15 (47%) contralateral necks were positive for occult carcinoma in the lymph nodes. The disease was always in levels II to IV or VI, and never in level I or V. Except for these studies, there are limited other data on the treatment of the contralateral neck in hypopharyngeal carcinoma. The choice to treat the contralateral neck in the majority of cases will be straightforward because so many patients present with advanced disease. Postoperative radiation is routinely administered to treat the necks if there is extracapsular spread or if more than one lymph node is involved.

Therapeutic Outcomes

There are currently no prospective, randomized reports comparing the modalities available for the management of cervical esophageal or hypopharyngeal squamous cell carcinoma. Thus no clear evidence exists for the superiority of one strategy versus the next. It appears in reviewing the literature that individual preference of the physician in charge of the patient's care directs the therapeutic modality that is chosen. In summary, options for tumors that are staged T1 or select T2 tumors include surgery followed by radiation or radiation followed by salvage neck surgery for residual nodal disease. For any other lesions radical surgery followed by postoperative radiation is the standard practice. Laryngeal preservation, using induction chemotherapy followed by radiation, is supported by the study of Lefebvre and coworkers.[109] This protocol requires an understanding by the patient that surgical salvage is part of the protocol. Also, it is incumbent on the treating physician to closely follow the patient's tumor because prompt surgical salvage will ensure survival similar to conventional treatment.

A review of the literature reveals multiple series with various algorithms for management of this disease. These studies are confounded by several factors, which make comparing separate series difficult, including that they (1) are retrospective, (2) are nonrandomized, (3) represent a heterogeneous population of patients, (4) use techniques that evolved over the course of a study, (5) in some instances used preoperative radiation, (6) used different staging systems, (7) failed to include comorbidities, and (8) used different statistical techniques. However, despite these caveats some conclusions can be drawn from them and these are presented in the following sections. In this section we first discuss the results of large reviews of databases that reveal overall survival when analyzed retrospectively, without regard to actual surgical techniques or heterogeneity in radiation treatment. Then, we review the studies that use different modalities with a view to presenting a comprehensive picture of the current management of hypopharyngeal and cervical esophageal carcinoma.

Pingree and colleagues[124] completed a review of 1362 cases of hypopharyngeal cancer contained in the Rocky Mountain database that covered the periods 1973 to 1983. Of these, 239 (17.5%) were stage I and II and 966 (71%) were stage III and IV. Of the advanced stages 231 (23.9%) had distant metastatic disease at presentation. The hypopharyngeal tumors were predominantly located in the pyriform sinus. On the basis of treatment data, 695 of these patients who were followed for 5 years were available for analysis. The therapeutic modalities used were radiation alone, surgery alone, or combined surgery and radiation. The overall survival for all groups of patients was 25% at 5 years. The authors provide further data on stage-specific survival and therapeutic modality specific survival for all stages. Surprisingly, for all stages examined, the surgery alone or the combined modality groups had equivalent survival at 1-, 3-, and 5-year points and these were always better than radiation alone. The 5-year survival of the radiation-only group was 11.5% versus 39% for surgery only and 31.8% for combined therapy. Clearly, these data confirm that hypopharyngeal cancer has a poor prognosis. However, there are several confounding aspects of this retrospective review that must be appreciated in examining the data. First, the results against radiation in advanced-stage tumors is likely subject to selection bias because the radiation-only group likely had a significant number of advanced, inoperable patients, whereas the surgery or combined-modality therapy groups likely had patients felt to be operative candidates. Other uncontrolled or unclear variables in these analyses are what types of surgery were used, the doses of radiation, and the cause of death.

A decade later Hoffman and colleagues[10] published their retrospective review of the Patient Care Evaluation (PCE) study of the American College of Surgeons. This database was subdivided between two periods, 1980 to 1985 and 1990 to 1992. There were 1317 cases in the first set of years and 1622 in the second set. Again, the majority of these were located in the pyriform sinus (64.4%) and the advanced stages (III and IV) comprised approximately 75% of the cases in both situations. A stage migration effect was clearly seen as the pathologic stage advanced a significant number of patients to stage IV disease. As 5-year survival was available only for the 1980 to 1985 cohort, an analysis of outcomes for this group was presented. Overall, disease-specific survival was 69.6% at 1 year, 39% at 3 years, and 33.4% at 5 years. Analysis of stage-specific survival revealed a gradual decrease as stage increased from 63.1% for stage I to 22% for stage IV. When analyzed for therapeutic modality, a conclusion similar to that of Pingree and colleagues[124] was reached. Those patients who had surgery alone had a 50.4% five-year survival, those with combined modality had a 48% survival, and the radiation-alone group had a 14.9% survival. However, Hoffman and colleagues went on to correct for possible selection bias by matching tumors with the TNM classification and found the same pattern. The greatest difference was noted in the T3/T4N0M0 groups, in which surgery alone produced a 34.6% five-year survival and radiation alone had a 3.2% five-year survival. This would suggest that for advanced tumors radiation alone is not an adequate modality.

Wahlberg and colleagues[6] addressed overall survival of patients with hypopharyngeal tumors in a retrospective review of a 30-year (1960-1989) experience. Data were analyzed from the Swedish Cancer Registry, which is a compilation with a completeness of more than 95% of all tumors in Sweden. There were 2012 total cases that not only included squamous cell carcinomas but also adenocarcinomas, malignant salivary gland tumors, and other rare tumors (these accounted for 5% to 10% of all the tumors). This study primarily examined overall survival rates, but no data describing tumor stage, actual cause of death, details of therapy, recurrences, second primaries, or status of neck disease were presented. The treatment of these patients was heterogeneous, but in general in the early years radiation was used primarily and in the 1980 to 1989 period evolved to include combined surgery followed by radiation. Incidence of cancer decreased in women at an average of 2% per year, and although not clear, may be explained by better treatment of Plummer-Vinson syndrome. The 2-year and 5-year overall survival rates were 25% and 13%, respectively. The overall survival for nonsquamous cell cancers was slightly better at 5 years.

Thus in these large retrospective reviews, it is clear that carcinoma of the hypopharynx has a poor outcome relative to other sites in the head and neck. These studies have their deficits as discussed earlier, but they allow physicians to discuss the outcomes of overall therapy with their patients. No surveys addressing cervical esophageal carcinoma

alone have been reported likely due to the limited numbers of primaries in this region and variation in reporting these cancers. In the following sections, we focus further on specific modalities as used at different institutions and their respective outcomes.

Therapeutic Outcomes—Primary Radiation Therapy

Although outcomes of radiation are discussed in brief here, Jean Louis LeFebvre describes more extensively the use of radiation therapy in a separate chapter. The best evidence for the use of therapeutic radiation as the primary modality is for T1 and selected T2 cancers. Overall, these lesions constitute a low number of cancers from the hypopharynx. These favorable lesions are exophytic in nature, are high in the pyriform (i.e., not involving the apex), and have a low volume by CT scan measurement.[125] Multiple groups have shown that actuarial survival using radiation followed by neck dissection for bulky neck disease is equivalent to conservation surgery with postoperative radiation for T1 and select T2 tumors.

The M.D. Anderson experience was first described by El-Badawi and colleagues[126] and later expanded by Garden and colleagues.[105] In a 1996 report, Garden and colleagues retrospectively reviewed 82 patients with T1 (19 patients) and T2 (63 patients) tumors of the hypopharynx who were treated between 1976 and 1992 with definitive radiation.[105] Fifty-two percent (43/82) were node positive at the start of radiation, and of these 23 of 43 had a neck dissection performed after radiation. Radiation itself was given in a single daily dose or in divided daily doses to 40 and 42 patients, respectively. The 2- and 5-year actuarial survival rates were 72% and 52%, respectively, and overall the altered fractionation scheme gave better results. The preference of this group is to use single-modality therapy whenever possible. Thus for early tumors, the M.D. Anderson experience has been to radiate and then perform neck dissections only on those patients who still have cervical lymphadenopathy. This strategy spares a subset of patients from having surgery. Other studies that used radiation as the primary modality include the Institut Gustave-Roussy,[127] which noted a 40% five-year survival of selected T1 and T2 tumors. All other tumor stages in their study of radiation as the primary modality did poorly at 5 years.

The experience of Mendenhall and colleagues at the University of Florida has been described in several reports.[128-130] As opposed to the other available studies on radiation as primary treatment, Mendenhall and colleagues analyzed their data using overall stages rather than tumor stage (i.e., T1 or T2). Patients either received twice-daily fractionated therapy or daily treatments. The overall absolute and cause-specific survival rates at 5 years were 43% and 58%, respectively. A stage-specific analysis showed that the probability of cause-specific survival was 100% for stages I and II, 62% for stage III, 43% for stage IVA, and 25% for stage IVB. Acute complications occurred in two patients and included severe mucositis and hospitalization for dehydration. Complications included chondronecrosis leading to total laryngectomy in one patient. Six others had aspiration, dysphagia, or laryngeal edema leading to tracheostomy. Five of 10 patients who had to undergo total laryngectomy had significant postoperative complications including wound breakdown with fatal carotid rupture, a separate death, and fistulas.

In summary, although the caveats listed earlier apply to all these studies, the basic premise from all of them is that early lesions can be treated with radiation as the primary modality. The data on survival are similar to that achieved with conservation surgery from other studies. As a reminder, again, this subset of patients is a small portion of all hypopharynx carcinoma patients. Despite this limitation, a future prospective trial designed to randomize patients to radiation with surgery if necessary or conservation surgery with postoperative radiation may ultimately answer the question of superiority of either approach. Until then, clinical practice will be dictated by the treating physician's preferences in the context of these retrospective studies.

Several groups have described radiation as primary therapy for cervical esophageal carcinoma. Mendenhall and colleagues[131] described 34 patients treated in this fashion and reported a 14% five-year overall survival. Jones and colleagues[132] reported on a series of 12 patients who underwent radical radiation therapy and 14 patients treated with surgery. The overall 3-year survival was 18%. Although it is difficult to draw a definitive conclusion from these small series, radiation as primary therapy appears to achieve poor control of cervical esophageal carcinoma.

Therapeutic Outcomes—Primary Surgical Therapy

Conservation surgery for hypopharyngeal cancer became possible because of contributions from Trotter, Orton, and Alonso. In the 1960s, Ogura and associates applied lessons learned from conservation laryngeal surgery to hypopharyngeal cancers. They reported on the development of the partial laryngopharyngectomy operation and described the results of this operation.[61,133] *Preoperative* radiation was routinely administered during this period. A summary of the major surgically oriented studies reported in the literature is shown in Table 103-5.

Holsinger and coworkers reviewed the experience of the Laccourreye group for patients with T1 or T2 lateral wall pyriform tumors that were resected using a lateral pharyngectomy with primary closure.[134] A subset of these patients was treated with preoperative chemotherapy and some patients received postoperative radiation. Three postoperative deaths occurred (one related to surgery), but all patients were eventually decannulated. Surprisingly for these small tumors, this series found that the 5-year survival rate was 23.3% with four patients (13%) having local recurrences.

In addition to the lateral pharyngectomy, Laccourreye and colleagues[63] used the supracricoid hemilaryngopharyngectomy (SCHLP) to treat cancers primarily of T1 to T3 staging (one patient who was a T4 was included in the series). In their retrospective review, 240 patients were treated with an ipsilateral neck dissection and the SCHLP. Deglutition was recovered in 204 of 233 patients with a 17-day average time to removal of the nasogastric tube, although the authors state that "recovery of satisfactory deglutition may take up to 1 year." A thorough evaluation of survival data on all 192 patients was not discussed in this study. A detailed analysis of 34 selected T2 pyriform cancers was published in 1993.[65] Prior to operation, most patients received chemotherapy consisting of either bleomycin (7 patients); vincristine, methotrexate, and bleomycin (14 patients); or cisplatin and 5-FU (10 patients). Postoperatively 31 of 34 patients received radiation. Of the 34 patients, 33 were decannulated and 31 of 34 patients were able to swallow after 1 month (range 13 to 26 days). Aspiration pneumonia occurred in 7 of 34 patients (20%). A completion laryngectomy was eventually performed in 3 of 34 patients due to intractable aspiration. Voice quality was initially judged as good to satisfactory in 32 of 34 patients. The 5-year actuarial survival rate was 55.8% with only one patient developing a local recurrence and two patients (one was the same, who developed local recurrence) developing neck recurrences. Cause of death was intercurrent disease in 7 of 34, second primary in 6 of 34, nodal recurrences in 1 of 34 and primary recurrence in 1 of 34. One patient died from chondroradionecrosis of the larynx, and two deaths were from unknown causes. Compared with the results with radiotherapy alone or other conservation surgical methods, these data produce similar actuarial results but appear to have a significant associated complication rate including aspiration pneumonia. However, of the several confounding factors cautioning against direct comparisons with other methods is the routine use of preoperative chemotherapy. It is unclear whether this treatment predisposed patients to the various complications described. In addition, the chemotherapy itself was given in three different regimens. An updated review of this group's experience with SCHLP on 147 patients has been reported[62,64] and demonstrates actuarial 5-year survival rates of 96.2% for T1, 91.1% for T2, 92.9% for T3, and 62.6% for T4 lesions. These rates and the functional outcomes described compare favorably with other organ-preserving approaches.

Steiner and colleagues have been strong proponents of the TLM CO_2 laser endoscopic approach to excision of tumors of pharyngeal, supraglottic, glottic, and hypopharyngeal origin. The postoperative course and survival data of their group of patients are impressive and are briefly reviewed.[58] Between 1981 and 1996, 129 cases of hypopharyngeal cancer underwent endoscopic excision and can be subdivided as follows: pT1:24, pT2:74, pT3:17, and pT4:14. Of these patients 68% were node positive and 75% were stage III/IV. Surgery as sole modality was used in 42% of patients, and the remainder had surgery followed by radiation. The overall survival rates were 71% and 47%

Table 103-5

*Disease burden was determined as described by the authors. Comparisons across studies are not possible because various American Joint Commission for Cancer criteria were used.

CO_2, carbon dioxide laser; PLE/pull-up, total pharyngo-laryngo-esophagectomy with gastric pull-up reconstruction; RT, radiation therapy; SCHLP +C, supracricoid hemilaryngopharyngectomy with chemotherapy; Surg., surgery; EBM grade # (evidence-based medicine grade) based on the definitions from the Centre for Evidence Based Medicine (as described in Sackett DL, Straus SE, Richardson SW, et al. *Evidence-Based Medicine: How to Practice and Teach EBM.* 2nd ed. Edinburgh: Churchill Livingstone; 2000). All studies are grade C because they are retrospective reviews without internal control groups.

for stages I/II and III/IV, respectively. These data compare favorably with outcomes using conventional treatment of these tumors. The most impressive aspect, however, of this technique is the perioperative management. Only 5 of 129 cases underwent tracheotomy during surgery and 1 required tracheotomy postoperatively due to hemorrhage. Thirty-five patients were taking an oral diet on the first postoperative day and all but two patients eventually achieved oral feeding. Only one patient developed a hypopharyngeal stenosis and was dependent on gastrostomy tube feeding. Thus although technically challenging, this procedure appears to be oncologically sound and has the significant added advantage of no tracheotomy, no reconstruction, voice preservation, and a quick return to an oral diet. For advanced-stage tumors, a defini-

tion of the inferior extent of the tumor is required because extension into the cervical esophagus would clearly limit the ability of the endoscopic surgeon.

Rudert and Hoft[135] described their experience managing 29 patients with hypopharyngeal carcinoma using the endoscopic approach. Except for two patients (one T3 and one T4), the remaining 27 patients had T1 and T2 tumors. Of these patients, 9 were stage I/II and 20 were stage III/IV. No patients underwent tracheotomy at operation; however, the authors do not report on whether any required it in the postoperative period. Functionally, no surviving patients had speech or swallowing problems at 5-year follow-up. The 5-year survival rates for stage I/II were 78% and 35% for stage III/IV. Not surprisingly, node status was a significant predictor of outcome with N0 patients having 74% and node-positive patients having 34% overall survival. Locoregional recurrences occurred in 8 of 29 (27.6%) patients each. Interestingly, 7 of 8 of the local recurrences occurred below an arbitrary line drawn at the interarytenoid line. Distant metastases and second primaries occurred in 8 of 29 (27.6%) and 12 of 29 (41%) patients, respectively. These authors found the best local control with tumors of the pharyngeal walls.

Recently, Steiner and colleagues[136] reported the outcomes analysis of 172 patients with hypopharyngeal tumors treated with TLM. Although the relationship between this cohort and the one reported previously is not clear from the publication, the time period of the two cohorts shows some overlap. The 5-year recurrence-free survival in this study was reported to be 73% for stages I and II, 59% for stage III, and 49% for stage IVa. These numbers compare favorably with other modalities with the major reported benefits as described earlier. Again, the outcomes of this technique need broader evaluation but deserve closer attention because of the apparent superior functional outcome and our patients' demands of more minimally invasive techniques to handle even advanced cancers.

ADVANCED LARYNGOPHARYNGEAL CANCER. Multiple groups have published their retrospective series of patients treated with partial laryngopharyngectomy, total laryngopharyngectomy, or laryngo-pharyngo-esophagectomy. In this section we review a select set of the series with large groups of patients with adequate follow-up.

Goepfert and colleagues[126] reported the M.D. Anderson experience in treating squamous cell carcinoma of the pyriform sinus from 1949 to 1976. An evolution in techniques affected the specific procedures used to treat patients, but the majority of lesions were treated with surgery and postoperative radiation. This factor clearly affects the analysis of the outcomes data. The major subdivisions in the treatment groups were between those patients who underwent surgery alone and those who underwent surgery and planned postoperative radiation.[31] Each group had approximately equivalent numbers of patients in each T category but the nodal status was not described for each individual group. Locoregional control was superior in the combined therapy group (39% vs. 11% in the surgery-only group). The 5-year survival (not adjusted for any other factors) was 25% for the surgery-only group and 40% for the combined-therapy group. Thus as opposed to the study of Pingree and colleagues[124] and Hoffman and colleagues,[10] Goepfert and colleagues found that combined therapy was superior to surgery alone.

Vandenbrouck and colleagues[127] described the Institut Gustave-Roussy's experience with radical surgery followed by radiotherapy in 181 cases from 1968 to 1978. The overall 5-year survival in these patients was 39% and was not broken down by further staging or node status. Consistent with all other head and neck sites, node positivity and extracapsular spread resulted in poorer outcome. The distant metastatic rate was 27.6% and was the most common cause of failure.

Kraus and colleagues described the Memorial Sloan-Kettering experience[138] in managing 132 patients with hypopharyngeal squamous cell carcinoma. Of these patients, most (78%) had advanced disease; however, none had distant metastasis at presentation. These patients were all treated by surgery and 80% then received postoperative radiation. Radiation in 76 of 106 patients was given at various outside institutions due to logistical considerations, which may be one variable in understanding the outcomes. Surgery consisted of partial laryngo-pharyngectomy, total laryngectomy with partial pharyngectomy, or total laryngopharyngectomy. The 5-year overall survival was 30% and disease-specific survival was 41%. Although T stage was not significant in outcome, the following factors were all significant: N0/N1 was better than N2/N3, stages I/II/III did better than stage IV, patients who underwent laryngectomy did worse than those who did not need one, and finally positive margins portended a poor prognosis.

Elias and colleagues[139] reported their analysis of 101 patients with pyriform sinus cancer. Over a 20-year period, treatment evolved from radiation as primary therapy to surgery with postoperative radiation therapy. They reported a 5-year overall survival of 27% and a 5-year disease-free survival of 37%. Survival correlated with stage of the patient, and disease-free survival was significantly better in the combined surgery and radiation group.

Spector and colleagues[140] reported a 30-year experience from our institution on 408 patients with pyriform sinus cancers. These patients were treated with a heterogeneous group of modalities: 95 patients were treated with a single modality (either radiation or surgery) and 302 were treated with preoperative radiation and then surgery or surgery followed by postoperative radiation. Survival was described by grouping these lesions into specific anatomic locations in the hypopharynx. At 5-year follow-up, survival for one-wall lesions was 73%; medial-wall lesions, 63%; and 2- or 3-wall lesions, 49%. Distant metastasis and second primary tumors occurred in 17.7% and 6.2% of patients, respectively. Interpretation of these data is complicated by the fact that there was such a diversity in therapeutic modalities. The broad experience at Washington University does, however, give an overview of survival rates in these patients.

Harrison and Thompson[141]reported on their series of 101 patients who underwent total pharyngolaryngectomy and esophagectomy from 1965 to 1983. They reported an 11% mortality rate and a 33% morbidity rate. The morbidities included 15 patients with pneumonia and 2 with abdominal dehiscence. Actuarial survival of 58% was achieved at a 5-year follow-up. Second primaries or distant metastasis accounted for 18 of 101 (15%) patient deaths. Harrison clearly acknowledged the contribution of comorbidities in these patients as he stated, "In comparing the relative success of the various operations … one must consider not only the intrinsic risks of the actual procedure but the age and general condition of the patients."

Triboulet and colleagues[142] performed a retrospective review of 209 patients treated from 1982 to 1999 who underwent total laryngo-pharyngectomy that in some cases included a cervical or total esophagectomy followed by reconstruction with either jejunal free flap (77 patients), gastric pull-up,[92] or pharyngocolic anastamosis.[121] Nearly all of these patients presented at an advanced stage or had multiple small tumors distributed between the hypopharynx and cervical esophagus, thus requiring a more radical operation. Forty-two patients were failures of preoperative treatment consisting of chemotherapy, radiation, or both. At 3- and 5-year follow-up, the overall actuarial survival rates were 32% and 24%, respectively. Survival was unrelated to the reconstruction technique used, but negative factors included positive margins, advanced primary tumor in the cervical esophagus, and not receiving postoperative radiation therapy. The mortality rate was 4.8% and the morbidity rate was 38.3%. Interestingly, patients who underwent free jejunal transfer had more complications including flap necrosis and fistulas, leading to delayed feeding. Thus these authors favor gastric pull-up over jejunum for reconstruction of the alimentary tube. Two more recent studies[143,144] show similar low 5-year survival rates of approximately 30% using TLP with esophagectomy.

The group of William Wei at the University of Hong Kong has extensive experience in managing these difficult tumors.[69,145] Wei and colleagues[69] analyzed outcomes of 317 patients treated at the University of Hong Kong from 1966-1995. The goal of their 1998 study was to compare a group of 69 patients undergoing operations from 1986 to 1995 with earlier groups they had treated to evaluate changes in survival and morbidity and mortality of treatments. These authors exclusively used a total laryngopharyngectomy and esophagectomy for advanced tumors of the hypopharynx and cervical esophagus. In their earlier experience, this operation was also applied to advanced tumors of the larynx but was not used for these tumors from 1986 to 1995. The hospital mortality for this operation declined from 31% to 9% over 3

decades. The 5-year actuarial survival rate improved from 18% in the 1970s to 24.5% for the subset of patients from 1986 to 1995.

Data on the outcomes of cervical esophageal cancer are more limited due to the lack of experience at most centers and due to clustering of these lesions with the esophagus as a whole.

Laterza and colleagues[146] reported their 20-year experience with the surgical management of carcinoma involving the cervical esophagus. Of 167 patients, 37 had primary cervical esophageal involvement with the others extending superiorly to involve the hypopharynx or inferiorly to involve the thoracic esophagus. The overall 5-year survival rate was only 16.6% with a mortality rate of 8.8%. Kelley and colleagues[147] examined the management of 67 patients seen at the Memorial Sloan-Kettering Cancer Center from 1980 to 1993. A diverse set of protocols was used to manage these patients. Of these, 22 patients were treated with surgery with curative intent and other subsets were treated with radiation or chemotherapy in various combinations. Survival was poor in all groups (mean survival for entire group was 17 months and cumulative 5-year survival was 12%), although the surgery group had the best outcome. It is difficult in this study to compare specific treatments because of heterogeneity in therapy and the small numbers. However, Kelley and colleagues concluded that surgical therapy provided the best outcome.

THE ROLE OF CHEMOTHERAPY. Chemotherapy regimens for advanced unresectable head and neck cancers were begun in the 1970s. In the 1980s it was described that cisplatin and 5-FU were able to produce a significant number of partial and complete responders.[148] These data were augmented by the interesting description of Ensley and colleagues[149] that chemosensitivity was a predictor of radiosensitivity. Ultimately, this led to the landmark Veterans Affairs study on laryngeal preservation.[150]

In the meta-analysis reported by Pignon and colleagues[151] a significant benefit of concomitant chemoradiation was observed; however, a significant confounding factor was the heterogeneity between the trials. Multiple phase III trials have attempted to use concomitant chemoradiation in the treatment of locally advanced head and neck cancers.[108,152] Typically the hypopharyngeal and cervical esophageal cancers have been grouped with other subsites.[153,154] In addition to concurrent protocols, some investigators have expanded on induction chemotherapy protocols for advanced head and neck cancers.[155] These findings now form some of the key bases for combined chemotherapy and radiotherapy protocols for hypopharyngeal cancers. Again, the data on concomitant chemoradiotherapy application in advanced head and neck cancers are discussed in a separate chapter.

QUALITY OF LIFE STUDIES. Although survival is a critical measure of the success of therapy for all head and neck cancers, the patient's perception of his or her quality of life (QOL) after therapy is also an important measure. As chemotherapy, radiation, and reconstructive options have advanced the management of these diseases, the question of patient perception of their lives post-treatment is one that is addressed by QOL studies. Several validated measurement tools exist for the evaluation of quality of life.[156] Studies limited to QOL in patients with hypopharyngeal or cervical esophageal carcinomas are not available. However, several studies have reported QOL in patients with advanced head and neck cancers, subsets of which include hypopharyngeal carcinomas.[157-159] The major limitation in these studies is the patient numbers that impede extrapolation. For example, in a large prospective evaluation of all sites for QOL, Weymuller and colleagues[160] had 14 patients pretreatment and 4 post-treatment with primaries in the hypopharynx. They concluded that it is difficult to perform these types of studies from a single institution because statistical significance cannot be reached on the basis of limited numbers and because there is selection bias.[160,161]

Studies on QOL in laryngeal cancer patients treated with organ-sparing protocols yielded results that may be applicable to hypopharyngeal cancer patients. Terrell and colleagues[162] evaluated QOL in surviving patients from the Veterans Affairs Laryngeal Cancer Study. Four different measures were used to examine patients from the surgery/radiation group or the chemotherapy/radiation group. The differences identified include better scores for the chemoradiation group in the bodily pain scores and in the mental health domain. All other scores were equivalent. Surprisingly, comparing speech domain scores in patients who underwent laryngectomy versus those with intact larynges demonstrated no significant differences and Weymuller and colleagues and Deleyiannis and colleagues[161,163] confirmed these data and reported that the functional limitation imposed by a laryngectomy did not affect overall quality of life. Thus although organ-sparing protocols may appear intuitively to be superior in terms of patient QOL, these data indicate that overall QOL may not be affected by laryngectomy.

Although the frequency of QOL studies has increased in the past few years, reflecting an acknowledgement of the importance of this component of postmanagement patient care, no broad studies have emerged specifically dealing with hypopharyngeal or cervical esophageal carcinoma. Incorporating QOL instruments in future prospective trials in patients either treated with conventional therapy or organ-preservation therapy is necessary.

Conclusion

Taken together, this chapter summarizes the complexities in the management of patients with hypopharyngeal and cervical esophageal neoplasms. Clearly, the survival of these patients is poor compared with all other sites in the head and neck. However, with advances in reconstructive techniques and organ-preservation protocols, improved options are available for patients. Ultimately, prospective, multi-institutional trials together with biomarkers are necessary to delineate the "best" therapy for individual patients. Progress in outcomes research will continue to add data on tumor staging and yield a better understanding of QOL and survival figures. These studies in combination with novel molecular approaches for treating head and neck malignancies will ultimately improve on the current poor prognosis of patients with hypopharyngeal and cervical esophageal malignancies.

Acknowledgments

We apologize in advance if we have not mentioned specific studies either due to oversight or space limitations. We thank B.H. Haughey, B.N. Nussenbaum, and R.C. Paniello for insightful comments during the preparation of this chapter.

CHAPTER ONE HUNDRED AND FOUR

Radiotherapy and Chemotherapy of Squamous Cell Carcinomas of the Hypopharynx and Esophagus

Jean-Louis Lefebvre

Antoine Adenis

Key Points

- Hypopharynx cancers occur in heavy drinkers and long-term smokers. As a result, most of the time hypopharynx patients present with notable comorbid illness.
- Hypopharynx cancers carry a particular high risk to metastasizing to the neck or distant sites.
- The vast majority of hypopharynx cancers are diagnosed at an advanced stage, often at a metastatic stage.
- The overall prognosis remains poor because of local, regional, and distant failures and undercurrent diseases as well.
- Early diseases may be treated by partial surgery or irradiation, or both.
- Advanced diseases, as long as there is no extension to the esopharyngeal junction or to the soft tissues of the neck, may be treated by chemotherapy/radiotherapy-based larynx preservation protocols.
- More intensive chemoradiation regimens including taxanes, sequential chemoradiation, concurrent chemoradiation, as well as molecular targeted therapies (in particular targeting the epidermal growth factor receptor [EGFR] pathway), are under evaluation.

The treatment of squamous cell carcinomas (SCCs) of hypopharyngeal and esophageal malignancies remains a real challenge. These tumors are most often diagnosed at advanced stages in rather debilitated patients. They have high locoregional aggressiveness, as well as a high metastatic propensity. Treatment planning must take into account both the locoregional extension and the frequent comorbid illnesses and is too often considered with palliative intent. Surgery with postoperative irradiation has long been the only one treatment performed with curative intent. This surgery was in the vast majority of the cases rather mutilating and had, in particular for esophageal cancer, a notable morbidity. The development of the use of a combination of irradiation and chemotherapy has somewhat modified these therapeutic approaches. If globally, the outcome in terms of disease control and survival has not been tremendously improved, the organ-preserving strategies have allowed, in selected cases, to improve the quality of life without jeopardizing survival. A multidisciplinary decision-making approach that includes the surgeon, medical oncologist, radiation therapist, imaging specialist, and general practitioner is mandatory to better treat these patients.

Hypopharynx Cancers

Background

The hypopharynx is most certainly the worst primary site when considering the different cancers of the upper aerodigestive tract. This was clearly seen in two studies from Centre Oscar Lambret.

The first study was a prospective epidemiologic analysis carried out on 339 new successive hypopharynx patients. This population consisted of 329 males (97%) with a mean age of 57 years and 10 females (3%) with a mean age of 55 years. Of the patients, 114 (34%) lived alone at time of diagnosis. Only 95 patients (28%) were employed, 38% were retired, 20% were disabled, 13% were unemployed, and 1% (all females) had never had any occupation. Of the patients, 330 (97%) acknowledged they had both used tobacco and abused alcohol. The mean lifelong consumption of tobacco was 317 kg of tobacco smoked before diagnosis, ranging between 13 and 998 kg. The mean lifelong consumption of alcohol was as high as 1654 kg of equivalent of pure ethanol, ranging between 55 and 6074 kg. Such impressive data explained why more than half the patients presented with comorbid illnesses.

The second study was a retrospective review of the clinical charts of 652 new successive hypopharynx patients. Again, 97% of patients were males. All tumors were SCC. Of the patients, 346 had at least one comorbid illness (e.g., liver cirrhosis in 11% of the patients). Stage I included only 4% of the cases, with a similar figure (3%) for stage II, while stages III and IV made up 40% and 53%, respectively. Metastatic cervical lymph nodes were found on either palpation or computed tomography (CT) scan in 78% of patients.

Conventional Treatment Modalities

Surgery, combined with postoperative irradiation, and definitive irradiation (with surgery in reserve for salvage in case of local failure) have long been the only two options for treatment of hypopharyngeal cancers. As for larynx cancers, no randomized comparison of both approaches has been carried out. Comparison of these two approaches

is particularly inappropriate for hypopharynx cancers. As most of the patients present with locoregionally advanced diseases and notable comorbidities, surgical series are assessed on the basis of selected cases (resectable diseases in operable patients); however, radiotherapeutic series include cases that are expected to conclude with much more unfavorable results.

Early Diseases

Partial surgery of the hypopharynx has been proposed for early diseases. This surgery may consist of partial lateral or posterior hypopharyngectomy or of supraglottic hemilaryngopharyngectomy. The indication of such a surgery is rare because it requires a thorough assessment of patients' local extension and performance status. When indicated, this surgery is given a local control as high as 90%.[1,2] Laser CO_2 surgery has also been advocated with similar results.[3] This surgery may generate laryngopharyngeal dyssynergia with frequent aspirations, particularly when postoperative irradiation is delivered or when a cricoid resection has been necessary. Adjuvant irradiation is most often required because of the risk of submucosal spread and the frequent nodal involvement. The reported 5-year survival rates range around 50%.

Definitive radiation therapy has also been proposed. Several series have shown similar results, with probably slightly better functional results,[4-6] but, in case of failure in about all resectable local recurrences, salvage surgery resulted in a total laryngectomy.

No straightforward rule exists for selection of either partial surgery or irradiation. In general radiation is proposed for exophytic tumors located in the "membranous part" of the hypopharynx (i.e., behind the thyrohyoid membrane). For more infiltrating tumors and tumors located in the "cartilaginous part" of the hypopharynx (i.e., behind the thyroid ala), surgery is the preferable treatment. When irradiation is proposed, a radical neck dissection followed by radiotherapy to the primary tumor and to the neck seemed to improve the outcome in case of T_1T_2 with enlarged metastatic lymph nodes.[7]

Advanced Diseases

The majority of hypopharynx cancers, when resectable, are only able to endure a total laryngectomy with a partial pharyngectomy performed with a radical neck dissection. Postoperative irradiation improves the results of surgery.[8] This surgery is able to control 85% of the cancers above the clavicles in French series.[9-11] Despite this advantageous local control rate, the 5-year survival rate does not exceed 35%, most of deaths being attributed to distant metastases, intercurrent diseases, or, to a lesser extent, second primary tumors. In addition, a major structural and functional alteration to the patient's upper aerodigestive tract is incurred. All previously untreated patients must receive postoperative irradiation to the surgical bed and both sides of the neck. Comparison between preoperative and postoperative irradiation showed that the postoperative results were superior.[12]

Endoscopic laser CO_2 surgery has also been advocated by some teams for advanced diseases of the hypopharynx. A recent retrospective study reported (5-year local control as high as 75% for pT3 and 57% for pT4a, while 5-year recurrence-free survival was of 59% for stage III and 47% for stage IVa.[13] This surgery is indicated for selected cases, although its application widens in the hands of experienced surgeons.

Conventional irradiation often gives poor results in T_3 and T_4 diseases both in terms of local control and survival far under the locoregional control rates seen after surgery and postoperative irradiation.[4,5,14]

New Modalities

For a long time, chemotherapy was used primarily for palliative purposes because of its poor outcomes in the treatment of cancer of the head and neck. A new era in the management of cancer of the head and neck was initiated in the early 1980s with the introduction of platinum-based chemotherapeutic regimens. Actually, clinical studies using cisplatin as a single agent or more often in combination with other drugs have demonstrated partial response rates of 40% to 50% and complete response rates of 26% to 50%, for an overall response rate ranging between 78% and 94%.[15,16] In the early 1990s it appeared obvious that this approach had not provided any improvement in survival benefit for most patients. This was clearly demonstrated by the major meta-analysis carried out at the Institute Gustave Roussy (MACH-NC analysis)[17] including more than 10,000 patients enrolled in randomized trials comparing conventional treatment with the same treatment with chemotherapy (either adjuvant or induction or concomitant chemotherapy). The conclusion of this meta-analysis was that adjuvant chemotherapy, as well as induction chemotherapy (4%), produced an insignificant increase in survival (1%). But when induction chemotherapy consisted of cisplatin and fluorouracil, a significant 5% benefit in survival was achieved. On the contrary, concomitant chemoradiotherapy resulted in a significant increase in survival to 8%, but this group had a mixture of definitive and postoperative radiation trials. However, additional trials of chemoradiation as the first line of treatment, which were published after this meta-analysis, confirmed the trend toward an improved outcome.[18-20] This meta-analysis was updated in 2007[21] including 16,665 patients and confirmed that concurrent chemoradiation provided the highest benefit in survival (hazard ratio: 0.81), particularly for platinum-based chemotherapy (hazard ratio: 0.75), but the effects of chemotherapy decreased with increasing age. It must be underscored that these trials did not address hypopharynx cancers specifically. As a result, chemoradiation remains an important treatment that is still under evaluation for this primary site.

Radiation therapy has also been subject to intensive clinical research, particularly regarding fractionation and overall treatment time (discussed later in this chapter).

Chemotherapy to Improve the Outcome after Total Laryngectomy

In an attempt to improve the results of radical surgery with postoperative irradiation, chemotherapy has been evaluated. In 1990 the European Organization for Research and Treatment of Cancer (EORTC) Head and Neck Group reported a randomized trial[22] comparing this approach with the same treatment preceded by one course of vincristine with bleomycin and methotrexate. No difference was shown for locoregional control, distant metastases, and metachronous cancers. In 1996 the Institute Gustave Roussy[23] reported on perioperative chemotherapy in which patients received three cycles of cisplatin-fluorouracil before surgery and two additional cycles between surgery and postoperative irradiation without any improvement in outcome when compared with historical controls without chemotherapy.

A French trial[24] assessed the role of induction chemotherapy consisting of three cycles of the conventional regimen cisplatinum-fluorouracil. In one arm this chemotherapy was followed—whatever the response to chemotherapy—by a total laryngectomy with a radical neck dissection and postoperative irradiation. The other arm consisted of the same chemotherapy protocol followed again—whatever the response—by definitive irradiation, keeping the surgery in reserve for salvage. The aim of this trial, to evaluate a larynx preservation approach, is discussed later in this chapter, but the "surgical" arm may be analyzed separately in regard to the impact of chemotherapy. In this arm the 5-year survival was 37%. The fact that induction chemotherapy has not tremendously improved survival has been often underscored, whatever the primary site.

Another way to try to improve the results of radio-surgical protocols is to deliver postoperative concurrent chemotherapy and irradiation[25-28] in high-risk patients (e.g., positive margins, extracapsular spread, multiple nodal involvement, perineural invasion). One of these situations is often encountered after hypopharynx resection. Two recent randomized trials (RTOG 95-01 and EORTC 22-981) have explored the same protocol consisting of conventional 70 Gy external beam irradiation with cisplatin on days 1, 22, and 43 at a dosage of 100 mg/m^2. Randomized or not, none of these studies have focused on hypopharynx cancer only.

The Radiation Therapy Oncology Group RTOG 95-01 trial[29] randomized patients with two or more positive lymph nodes or extracapsular spread or positive margins. This trial failed to find a significant difference. A trend appeared for a slight difference in 2-year estimates for locoregional control in the experimental arm (79% vs. 74%, $P = 0.16$) and in 2-year estimates for overall survival (63% vs. 57%, $P = 0.51$), while a borderline significant difference appeared for

disease-free survival (54% vs. 43%, $P = 0.049$). The EORTC 22-951 trial[30] included many more clinical situations (stage III and IV or two or more positive lymph nodes or extracapsular spread or positive margins or vascular embolisms or perineural invasion or positive lymph nodes in levels 4 or 5). The interim analysis demonstrated a significant increase in 3-year estimates for disease-free survival (59% vs. 41%, $P = 0.0096$), for overall survival (65% vs. 49%, $P = 0.0057$), for time to progression (56% vs. 44%, $P = 0.0016$), and for local control (83% vs. 64%). Longer-term results and detailed comparison of both trials should help in the future understanding of this discrepancy.

Radiation Therapy

Altered fractionation has been explored in advanced head and neck cancers. The largest randomized trial was a four-arm trial[31] carried out by the RTOG (RTOG 90-03) that compared (1) conventional irradiation with (2) a split course accelerated fractionation with (3) a delayed concomitant boost and with (4) a hyperfractionated irradiation. Previously untreated advanced head and neck carcinomas were eligible for this study. Of the 1073 patients enrolled in the study, 13% had hypopharyngeal cancers. Both hyperfractionated irradiation and concomitant boost showed significantly better locoregional control, disease-free survival, disease-specific survival, and overall survival, but also a higher rate of acute and, to a lesser extent, late toxicities. No data specifically studying the hypopharynx have been published. Another large meta-analysis[32] pooled together updated individual patient data from randomized trials comparing conventional irradiation with unconventional radiotherapy schedules (hyperfractionation, acceleration, acceleration with dose reduction). A total of 6515 patients had been randomized in 15 trials. With a median follow-up of 6 years there was a significant survival benefit with altered fractionated radiotherapy (+3.4% survival at 5 years); the highest benefit (+8% at 5 years) was achieved with hyperfractionated irradiation. Again, few patients had hypopharyngeal diseases.

Combined Chemotherapy and Irradiation for Larynx Preservation

Induction Chemotherapy

As discussed earlier in this chapter, induction chemotherapy using cisplatin and fluorouracil provided impressive response rates.[33] Chemosensitive tumors' radiosensitivity was confirmed in a number of cases and suggested the ability of induction chemotherapy to predict radiosensitivity.[34] This led some teams to use a scheme of induction chemotherapy as a selective test for two groups of patients: good responders are candidates for subsequent radiation therapy and poor responders are still candidates for subsequent surgery. The larynx has been the most investigated primary site for this new approach, most often in noncontrolled trials using historical comparisons with surgical series.

Many published series have assessed in a nonrandomized fashion the reliability of induction chemotherapy–based protocols. They usually reported small series of cases mixing laryngeal, hypopharyngeal, and oropharyngeal tumors or tumors amenable to partial surgery and to radical surgery. In addition, the concept of organ preservation or preservation of function was unclear. Finally, larynx preservation rates were presented under different forms: for the overall population at a precise follow-up time, in survivors at that time, or according to a median follow-up. All in all, larynx preservation could be achieved in one third to one half of patients according to the patient selection.

Only two randomized trials focused on cancer of the hypopharynx. The first trial was conducted by the EORTC[35] on cancer of the hypopharynx eligible for total laryngectomy with partial pharyngectomy. In this study 202 patients were enrolled in which the standard treatment (surgery and postoperative radiation) was compared with two or three cycles of chemotherapy, followed in clinically complete responders at the primary site by irradiation, or, for other patients, by the conventional treatment. A notable difference appeared in the median survival, favoring the experimental arm (44 months) when compared with the surgery arm (25 months). This difference in median survival was only explained by the fact that distant metastases appeared later after chemotherapy, leading to a better survival at 3 years, which was not shown at 5 years. There was no significant difference in locoregional control or in second primaries' appearance. However, at 3 and 5 years, half the survivors in the chemotherapy arm had retained their larynx.

The second trial[24] compared 92 patients with resectable cancer of the hypopharynx (only amenable to total laryngectomy-pharyngectomy) with the outcome of patients randomly assigned to receive induction chemotherapy. In one arm, chemotherapy was followed by surgery and postoperative radiation therapy. In the other arm, chemotherapy was followed by radiation, with surgery reserved for salvage. In this trial chemosensitivity was not taken into consideration for deciding a subsequent treatment. With a median follow-up of 92 months, researchers observed a better 5-year survival (37%) and a better local control (63%) in the surgery arm when compared with the radiotherapy arm (19% and 39%, respectively). The comparison of this trial with the EORTC trial suggests that the cancer's sensitivity to chemotherapy must be taken into account before deciding a subsequent radiation therapy instead of surgery.

In 2000 the previously mentioned meta-analysis[17] assessed separately three randomized trials on larynx preservation based on induction chemotherapy. There was an insignificant 6% better survival in the surgical arm, but it was balanced by a 56% larynx preservation rate in the induction arm.

Induction chemotherapy has once again gained interest after the publication of two randomized trials comparing the conventional cisplatin 5-fluorouracil regimen with a triplet mixing cisplatin, fluorouracil, and docetaxel either in nonresectable diseases followed by irradiation alone[36] or in resectable/nonresectable diseases followed by concurrent chemoradiotherapy.[37] In both trials the triplet arm achieved significantly better overall and progression-free survivals.

In 2009 the Groupe d'Oncologie Radiothérapie Tête Et Cou (GORTEC)[38] published the results of their induction chemotherapy–based larynx preservation trial for larynx and hypopharynx cancer candidates for a total laryngectomy. Eligible patients were randomly assigned to receive either three cycles of cisplatin and fluorouracil in one arm or, in the other arm, three cycles of cisplatin with 5-fluorouracil and docetaxel. In both arms, following this induction chemotherapy, responders over 50% went to radiation therapy while other patients went to radical surgery and postoperative irradiation. The larynx preservation rate was significantly higher in the triplet chemotherapy arm but without significant difference in survival.

Concurrent Chemoradiotherapy

As discussed earlier in this chapter, there are promising data on concurrent chemoradiation. The questions are (1) how many patients in daily community practice are able to undergo such toxic treatments? (2) what is the largest disease stage amenable to larynx-preserving strategies? (are clinically defined T_4 or large necrotic lymph nodes acceptable?) (3) what are the most appropriate tools used to detect as soon as possible residual diseases to be treated by salvage surgery? and (4) what would be the postoperative morbidity of this salvage surgery? These concerns are of the utmost importance if the cancer is initially operable.

As far as cancer of the hypopharynx is concerned, it must be underscored that (1) this site is rarely studied separately; (2) in case of mixed sites, the hypopharynx represents just a few cases; (3) little is known about the selection of patients with cancer of the hypopharynx (detailed locoregional extension, performance status); and (4) no information is provided about the possibilities of surgical salvage.

The first randomized trial issuing larynx preservation with concurrent chemoradiotherapy to be published was the RTOG 91-11 trial.[39] But it concerned only laryngeal sites. Preliminary results suggested that concurrent chemotherapy was able to significantly increase the rate of larynx preservation when compared with induction chemotherapy and with radiotherapy alone. However, there was no difference in survival (the 5-year, disease-free survival was 39%) and, in particular, there was no difference in laryngectomy-free survival, which was 46% at 5 years.[40]

In 2007 the EORTC head and neck and radiotherapy groups published the second trial on larynx preservation comparing larynx and hypopharynx cancers candidates for radical surgery including a total

laryngectomy. This trial compared the sequential administration of induction chemotherapy and irradiation versus their alternating administration (EORTC 24954 trial).[41] No significant difference was found between both arms for either the primary end point survival with a functional larynx in place) or the secondary end points (overall survival, progression-free survival, and larynx preservation) whatever the primary site (larynx or hypopharynx).

Finally a randomized trial[42] compared radiotherapy with radiotherapy and cetuximab, a monoclonal antibody binding the extracellular receptor of the epidermal growth factor, in advanced, previously untreated head and neck cancer. Both locoregional control and overall survival were significantly higher in the cetuximab arm. In the subset of patients with larynx and hypopharynx cancers, the larynx preservation rate was also higher in the cetuximab arm.[43]

The next step could be to mix both approaches with induction chemotherapy followed, in case of chemosensitivity, by concurrent chemoradiotherapy. The potential role of the adjunct of targeted therapies (e.g., EGFR, angiogenesis, cyclin D1) must also be taken into account. A randomized phase II is currently ongoing in France under the responsibility of the GORTEC-Groupe d'Etude des Tumeurs de la Tête et du Cou (GETTEC) groups. After three cycles of induction chemotherapy (cisplatin, fluorouracil, and docetaxel), responders with at least 50% reduction of tumor volume and larynx mobility recovery are randomized between concurrent administration of radiotherapy and, at a 3-week interval, cisplatin versus radiotherapy and weekly cetuximab.

Localized Squamous Cell Carcinoma of the Esophagus

In most countries the standard of care for limited esophageal cancer (AJCC stage I and II) is surgery alone. Because most of the patients have local and distant recurrences, many cancer centers worldwide have favored a multimodality preoperative approach, although the evidence supporting this practice is inconsistent with no survival advantage seen in randomized studies. For patients who are not suitable candidates for surgery (AJCC stage III) or who refuse it, the current standard of care is radiotherapy in conjunction with chemotherapy.

Postoperative Therapy

A total of 8 randomized trials have examined the role of post-operative radiotherapy[43-47] or postoperative chemotherapy.[49-51] None of these studies has observed a survival benefit for patients receiving adjuvant treatment,[44-51] although Japanese investigators showed that disease-free survival for adjuvant chemotherapy was superior to surgery alone.[50]

Preoperative Therapy

Based on the five existing trials, there is no clear evidence that preoperative radiotherapy improves the survival of patients with potentially resectable SCC.[52-56] Results from clinical trials have been confirmed on 1147 patients by a meta-analysis on updated individual patient data that showed an insignificant reduction in the risk of death of 11%.[57]

Until recently, published studies that have examined the role of preoperative chemotherapy have failed to demonstrate any improvement in overall or relapse-free survival.[56,58-66] Moreover, some data suggested a reduced resectability rate[51,60] and a higher treatment-related mortality rate.[60,66] All these negative studies but one[63,64] involved a small number of patients. Conversely, a survival benefit was noted in two studies.[67,68] One small trial, published in an abstract form,[67] reported a significant increase in median survival in favor of a preoperative regimen with cisplatin and etoposide. The European OE02 study included a majority of adenocarcinomas and showed a significant improvement in survival and disease-free survival favoring the preoperative chemotherapy. A microscopically complete resection was significantly more often achieved in the preoperative chemotherapy arm (60% vs. 53%, $P < 0.0001$). In that trial, 802 patients (SCC: 31%, adenocarcinoma: 66%) were randomly assigned to surgery alone or two cycles of cisplatin (80 mg/m^2) and fluorouracil (1000 mg/m^2) daily for 4 days every 3 weeks followed by surgical resection.[68] In a large Japanese study reported at the 2008 Gastrointestinal Oncology symposium, 330 patients with clinical stage II/III (excluding T4) SCC of the thoracic esophagus were randomized to two courses of chemotherapy (cisplatin, fluorouracil) followed by surgery and surgery followed by two courses of chemotherapy. With a median follow-up time of 22.6 months, this study did not reach its primary end point to detect a difference in terms of disease-free survival. Surprisingly, the Japanese investigators showed a significant survival benefit favoring preoperative chemotherapy over postoperative chemotherapy (hazard ratio: 0.64, two-sided $P = 0.014$).[69] More mature and detailed results are awaited before considering neoadjuvant chemotherapy as a new standard of care for resectable, localized SCC of the thoracic esophagus. Finally, Thirion and colleagues[70] showed, with an individual patient data-based meta-analysis (9 trials, 2102 patients), a statistically significant survival benefit favoring preoperative chemotherapy (hazard ratio: 0.87, $P = 0.003$) over surgery alone. This 13% relative survival benefit translated into a 5-year absolute survival increase of 4% (from 16% to 20%).[70]

Ten randomized trials have compared chemoradiation and surgery with surgery alone in operable SCC of the esophagus (Table 104-1).[56-79] Two of these trials contained a substantial number of adenocarcinomas.[72,76] All these studies but two, only published as abstracts,[75,78] have failed to show any survival advantage favoring the neoadjuvant approach. However, some of these studies,[72-74,76] as well as retrospective studies,[80,81] have reported the prognostic value of pathologic complete response on overall survival. In fact, most of these trials recruited a small number of patients and were not statistically powered to detect any realistic difference between the different strategies. One of the largest studies has been conducted by the French Foundation of Digestive Cancer (FFCD) and the EORTC.[74] A total of 282 patients with resectable (stages I and II) SCC were randomized to preoperative chemoradiation versus surgery alone. The chemoradiation regimen consisted of a sequential perfusion of cisplatin (80 mg/m^2, 0 to 2 days) followed by an unusual split-course radiation therapy (3.5 Gy × 5, then a 2-week rest and another 3.5 Gy × 5). With a median follow-up of 55 months, patients who were allocated to the multimodality regimen had a significant greater 3-year, disease-free survival (40% vs. 28%, $P = 0.003$) and a higher rate of microscopically complete resection (81% vs. 69%, $P = 0.02$). It is worth noting that these patients also had a higher rate of postoperative death (12% vs. 4%, $P = 0.02$) along with a lack of advantage in terms of survival (median survival: 19 months).[74] A more recent trial with protracted radiation therapy (35 Gy/15 fractions over 3 weeks) combined with a single course of chemotherapy (cisplatin 80 mg/m^2 on day 1 followed by fluorouracil 800 mg/m^2/day on days 1 to 4) also failed to detect a better outcome for patients with resectable esophageal cancer.[76] Even subgroup analysis showed that patients with SCC had better progression-free survival with chemoradiotherapy followed by surgery than with surgery alone (hazard ratio: 0.47 $P = 0.014$). In addition, the trimodality group had more complete resections than did the surgery-only group (R0 resection: 80% vs. 29%, $P = 0.0002$).[76] Two trials have reported a survival benefit from neoadjuvant chemoradiotherapy.[75,78] Walsh and colleagues[75] showed on a small series of 98 SCCs of the esophagus a better median survival for patients treated by chemoradiotherapy followed by surgery (12 m vs. 8 m, $P < 0.02$). These results have to be tempered by the unusually high rate of operative mortality (>17% in both therapeutic arms). Five hundred patients were targeted for enrollment in the Cancer and Leukemia Group B 9781 trial.[78] However, this trial was closed due to poor accrual after a total of 56 patients had entered the study over a 2.5-year period.[78] In this underpowered study the statistical difference, favoring the trimodality therapy group (54 m vs. 22 m, $P = 0.02$) reported by Tepper and colleagues,[78] applied to differences between median survival and was not based on the areas between the two survival curves. Finally, a recent meta-analysis (1209 patients, nine trials) suggested a survival benefit of 19% (OR: 0.81; 95% CI: 0.7-0.93; $P = 0.002$) for concomitant chemoradiotherapy followed by surgery compared with surgery alone. The hazard ratio for death by any cause was 0.84 ($P = 0.04$) for patients with SCC.[82]

Finally, on the basis of the fully published and adequately powered randomized trial, there is little evidence that preoperative chemoradiation may improve survival. On the other hand, preoperative chemoradiation improves resectability (R0 resection) and locoregional control,

well-conducted meta-analysis supports improved survival, and neoadjuvant chemoradiation is a commonly used therapeutic approach worldwide. Therefore chemoradiation followed by surgery may be a reasonable alternative to surgery alone in the management of resectable esophageal cancer.

Definitive Chemoradiation

Because several uncontrolled studies on primary unresectable cancer have shown promising activity with chemoradiation with or without subsequent surgery, this procedure has been applied to potentially curable tumors without surgical resection. Seven randomized trials have compared definitive radiation therapy alone with definitive chemoradiation for operable or inoperable esophageal cancer (Table 104-2).[83-91] The RTOG 85-01 study was the only trial realistically designed to deliver adequate doses of systemic chemotherapy (fluorouracil: 1000 mg/m^2 as a continuous infusion × 4 days + cisplatin: 75 mg/m^2 at day 1, every 3 weeks, 4 cycles) with concurrent radiation therapy (50 Gy, 2 Gy/day).[83] At the 5-year follow-up, the latter trial showed a clear survival advantage favoring the combined therapy (26% vs. 0%, $P < 0.001$).[85] These long-term survival data have been confirmed in a subsequent study by the RTOG.[92] Therefore this RTOG 85-01 chemoradiation regimen is currently considered the standard of care for the nonsurgical management of esophageal cancer. However, it is also associated with increased morbidity rates. Compared with radiation therapy alone, patients who received combined modality therapy had a higher incidence of severe toxic events (23% vs. 66%), and chemotherapy could not be completed in more than 40% of the patients.[83,84] A trial from the Eastern Cooperative Oncology Group confirmed this survival benefit when chemotherapy was added to radiotherapy (median survival: 9 m vs. 14.9 m for radiation and chemoradiation, respectively; $P = 0.03$).[89] Because patients were treated according to their physicians' choices (surgery or continued radiation ± chemotherapy) after 40 Gy (± chemotherapy), the results of that pragmatic study are somewhat difficult to interpret. The EORTC trial included 221 patients. Any patients considered inoperable because of general physic condition or because they refused surgery and who fulfilled other classic eligibility criteria including localized SCC entered the study.[91] The chemoradiation regimen consisted of a perfusion of cisplatin (100 mg/m^2) followed 3 or 4 days later by a split-course radiation therapy (4 Gy × 5, then a 2-week rest and another 4 Gy × 5). After a post hoc stratification for clinical stage at entry, the investigators reported a significant difference favoring the combination arm for progression-free survival ($P = 0.048$) and overall survival ($P = 0.028$).[91] On the basis of the available randomized studies and results favoring chemoradiation over radiation therapy alone, it is not surprising that a recent meta-analysis confirmed that chemoradiation over radiation alone provided a significant reduction in local recurrence rate and in mortality (hazard ratio: 0.73).[93] The combined treatment was also associated with a significant risk of severe and life-threatening toxicities.[93]

Investigators have also addressed questions on the intensification of radiation dose (50.4 Gy vs. 64.8 Gy),[92] the scheme of radiation regimen (protracted vs. split),[94] and the optimal chemotherapy regimen (fluorouracil and cisplatin vs. fluorouracil, folinic acid, and oxiliplatin).[95] The RTOG 01-22 (Table 104-3) showed that increasing radiation dose (64.8 Gy vs. 50.4 Gy) with concurrent chemotherapy did not translate into enhanced survival or local control but increased morbidity and mortality rates.[92] The randomized study ($n = 202$ inoperable stage I to III SCC) by Jacob and colleagues[94] reported a significantly better 2-year, disease-free survival with conventional protracted radiation over split-course radiation scheme. Conroy and colleagues[95] investigated the role of a new chemoradiotherapy regimen that includes protracted standard radiation therapy (50 Gy, 25 fractions, 5 weeks)

combined with concurrent and sequential fluorouracil, folinic acid, and oxiliplatin courses (Folfox 4 regimen) (see Table 104-3). The primary end point of this trial was to assess the feasibility and the complete endoscopic response rate of the Folfox 4/radiation combination. Ninety-seven patients with inoperable esophageal cancer (82% of SCC) were randomized to receive either the experimental therapy or the standard treatment, which was the RTOG 85-01 schedule (fluorouracil, cisplatin, and radiation therapy). Definitive chemoradiotherapy with Folfox 4 was found feasible because 75% of the patients completed the planned treatment, whereas 70% of the patients completed the RTOG 85-01 schedule. Of 47 patients, 21 (45%, 95% CI: 30% to 60%) achieved an endoscopic complete response with Folfox 4 compared with 12 of 20 patients (30%, 95% CI: 17% to 46%) with the fluorouracil-cisplatin regimen. Median survival was 22.7 and 14.9 months for the Folfox 4 and the RTOG 85-01 groups, respectively.[95]

Is surgery necessary as part of local therapy in patients with locally advanced esophageal carcinoma?

A series of randomized trials,[75,78,85] as well as uncontrolled studies[96,97] and meta-analyses,[93,98] have confirmed that chemoradiation allows a certain proportion of complete clinical and pathologic responses and long-term survival. These features led researchers to investigate whether surgery is necessary after neoadjuvant chemoradiation.[99,100] The FFCD 9102 trial[99] (Table 104-4) compared chemoradiation alone with chemoradiation followed by surgery in patients with operable T3N0-1M0 thoracic esophageal cancer who responded to a first course of chemoradiation. Four hundred and fifty-five patients (SCC: 89%) received radiation therapy (either conventional 46 Gy in 4.5 weeks or

split-course 15 Gy × 2, days 1 to 5 and days 22 to 26) in conjunction with two cycles of fluorouracil and cisplatin. The 259 responding and still operable patients were randomly assigned to surgery or continuation of chemoradiation (conventional or split-course radiation) with three further courses of chemotherapy. The 2-year local control rate was 66.4% in the surgery arm compared with 57% in the chemoradiation arm. A 2 years the survival rate was 34% for the surgery arm versus 40% for the chemoradiation arm.[99] The quality-of-life study did not show any difference between the two arms.[101] Indeed, hospital stay was shorter in the chemoradiation arm. Conversely, patients in the surgery arm had fewer needs in esophageal stenting (13% vs. 27%, P = 0.005).[99] According to the authors, chemoradiation with or without surgery resulted in similar survival rates for locally advanced thoracic esophageal cancer patients responding to chemoradiation.[99] One hundred and seventy-seven patients with locally advanced SCC (T3-4, N0-1, M0) have been randomized in a German study[100] (see Table 104-4) in order to compare sequential and concurrent chemoradiation only with sequential and concurrent chemoradiation followed by surgery. The chemoradiation-only group of patients received three courses of sequential fluorouracil, folinic acid, cisplatin, and etoposide followed by one course of cisplatin and etoposide combined with radiation (50 to 65 Gy, 2 Gy per fraction, 5 to 6 weeks, plus a boost with either bifractioned external-beam radiation or high-dose rate brachytherapy). In another group, patients received the same neoadjuvant chemotherapy, followed by one course of cisplatin and etoposide with concurrent radiation (40 Gy, 2 Gy per fraction, 4 weeks), followed by surgery. Two toxic deaths in each arm were attributed to chemotherapy, but no fatalities related to chemoradiation occurred. Postoperative deaths occurred in 62 patients who underwent surgery. Despite improved local control (2-year freedom from local progression: 64% vs. 41%, P = 0.003), surgery after radiotherapy and sequential and concurrent chemotherapy resulted in equivalent survival (intent-to-treat analysis) compared with chemoradiation alone. Median survival was 16 and 15 months for the multimodality treatment and chemoradiation alone, respectively. Cox regression analysis revealed that response to induction chemotherapy was the single independent prognostic factor (hazard ratio: 0.30, P < 0.0001), regardless of the group of treatment.[100] From these results[100] and those from the FFCD[99] group, there is now a body of evidence suggesting that in patients with locally advanced SCC there is no survival benefit for adding surgery to chemoradiation. However, local control still represents an issue; persistent local disease is present in about 40% of the patients treated with chemoradiation only,[83,84] and median time to locoregional recurrence after sequential and concurrent chemoradiotherapy is about 14 months.[100] Whether or not salvage surgery should be offered to nonresponding patients is still a matter of clinical research.

Metastatic Squamous Cell Carcinoma of the Esophagus

The amount of chemotherapeutic agents with activity against advanced squamous cell esophageal cancer is rather limited, but responses have been documented using cisplatin, fluorouracil, vindesine, mitomycin, irinotecan, oxiliplatin, paclitaxel, and vinorelbine. Various combinations of these molecules were shown to be associated with higher response rates but also higher morbidity and in some cases with 10% to 14% of toxic deaths. Among the available regimens, the cisplatin-vinorelbine combination seems to fit the best therapeutic ratio in metastatic SCC.[102] However, we still do not know if chemotherapy provides any benefit in terms of survival versus best supportive care.[103] One randomized trial from the EORTC gastrointestinal group has examined the activity of cisplatin (100 mg/m^2, q 3 weeks) versus cisplatin (same dosage) plus fluorouracil (1000 mg/m^2 as a continuous infusion from day 1 to day 5, q 3 weeks) in 88 evaluable patients with advanced SCC. Although greater activity was demonstrated for the cisplatin-fluorouracil combination (response rate: 35% vs. 19%, median survival: 33 vs. 28 weeks), this was achieved at the expense of substantially increased toxicity. The randomized phase II study concluded that neither arm could be recommended as the standard chemotherapy for patients with advanced SCC.[104] Another randomized study compared cisplatin-fluorouracil with no chemotherapy in 156 patients. Again, there was no difference in survival but an increase of adverse events in the chemotherapy arm, which resulted in toxic deaths in 6% of this frail population.[105]

CHAPTER ONE HUNDRED AND FIVE

Reconstruction of the Hypopharynx and Esophagus

Douglas B. Chepeha

Key Points

- To obtain the best outcome for the patient, perform pharyngoesophageal reconstruction as part of a knowledgeable multidisciplinary team.
- Hypopharyngeal defects are associated with the highest surgical complication rates in the head and neck.
- Careful monitoring of thyroid-stimulating hormone and optimization of nutritional status improve wound healing outcomes.
- Use of the salivary bypass tube reduces the incidence of stenosis and helps reduce the impact of fistula.
- Careful defect assessment before surgery is important for planning the appropriate reconstructive approach.
- In patients with a history of chemoradiation therapy, vascularized tissue is useful for reducing complications even if a primary pharyngeal closure is performed.
- If a fistula develops and the great vessels are exposed, creation of a controlled fistula is the best way to make the wound safe.
- A pedicle monitoring plan should be integrated into revascularized free tissue transfer for reconstruction of pharyngeal defects.

Many technical advances in conservation surgery of the larynx and pharynx have occurred, and new treatment protocols for organ preservation with chemotherapy and radiation have developed. Current management of advanced-stage laryngopharyngeal and esophageal cancers generally involves multiple modalities to optimize outcomes. At present, there is a trend toward reserving surgery as a salvage procedure after failure of other modalities for advanced laryngeal and hypopharyngeal cancers (Fig. 105-1).[1-5] The adverse effects of radiation therapy on wound healing have been well documented.[6] Salvage surgery in patients exposed to previous radiotherapy and/or chemotherapy is associated with a higher incidence of wound complications, with overall complication rates ranging from 37% to 100%.[7] For example, postoperative salivary fistula rates as high as 50% have been reported after surgical salvage for persistent disease after chemoradiation therapy.[8] Therefore prior treatment must be taken into consideration when choosing a reconstructive method for patients who undergo salvage surgery. Given the high complication rate with surgical salvage, treatment selection may be a better choice to reduce the incidence of surgical complications.[9] Treatment selection makes use of induction chemotherapy to determine the responsiveness of a tumor. If the tumor responds (shrinks) by more than 50% to one or two doses of chemotherapy, then the patient undergoes chemoradiation therapy. If the tumor does not respond, the patient undergoes surgery followed by radiation therapy (Fig. 105-2). The possible advantage of treatment section is customization of therapy and avoidance of surgical salvage with its attendant complications. Reconstruction of the hypopharynx and esophagus is largely being shaped by the current trend toward primary concurrent chemoradiation therapy. The surgeon is most commonly involved in salvage of treatment failure, which is resulting in new approaches that attempt to reduce complications and improve function in this compromised patient group.

Patient Population at Presentation

Most patients who require reconstruction of the hypopharynx and esophagus harbor a malignancy at those sites. At the University of Michigan, patients present for reconstruction of their hypopharynx or cervical esophagus after failure of chemoradiation for advanced-stage squamous cell carcinoma of the larynx, pharynx, or trachea. Primary resection is reserved for patients who present with laryngeal cartilage invasion or those who do not respond to induction chemotherapy. Patients who undergo surgical resection and pharyngeal reconstruction have the highest postsurgical complication rate when compared with any other site in the upper aerodigestive tract.[10] Carcinomas of the larynx tend to be less aggressive than carcinomas of the hypopharynx. Hypopharyngeal carcinomas are known to demonstrate aggressive behavior, with a high incidence of submucosal spread, satellite lesions, and subsequent invasion of adjacent structures. Careful assessment of the lungs is also important. A solitary focus of disease in the lung can be resected, but more extensive metastatic disease or mediastinal disease would make the patient incurable and a palliative approach would be taken. This patient population has a high prevalence of tobacco and alcohol abuse and often has related comorbidities such as cardiovascular disease, hypertension, chronic obstructive pulmonary disease, peripheral vascular disease, and nutritional deficiency. Because of these underlying comorbidities and the disease process, treatment of this patient population is more difficult. Trauma from explosive devices or accidents, previous radiation or chemoradiation resulting in stenosis, or chemicals (e.g., lye ingestion injury) is another possible cause for reconstruction of the hypopharynx and esophagus.

Perioperative Counseling

Nursing, social work, speech pathology, dentistry, cessation counseling, nutrition, and appointment scheduling are all part of the pretreatment

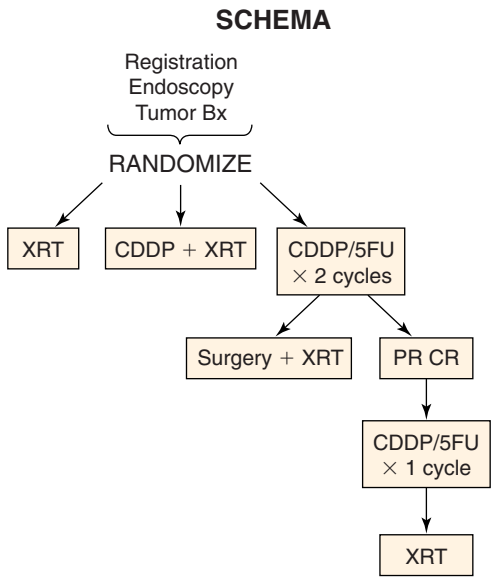

Figure 105-1. Schema of 91-11, 3-arm, randomized, multi-institutional phase III trial for the treatment of advanced laryngeal cancer. The 5-year overall survival of the chemoradiation arm was the best. As the trial progresses through 5- to 10-year follow-up, the treatment selection arm has, nonstatistically significant, better overall survival than the chemoradiation arm. If laryngeal resection can be performed before chemoradiation, the surgical reconstruction will be more straightforward. Note that this trial excluded patients with cartilage invasion. Bx, biopsy; CDDP, cisplatinum; CR, complete response; 5FU, 5 fluorouracil; PR, partial response; XRT, external beam radiation therapy.

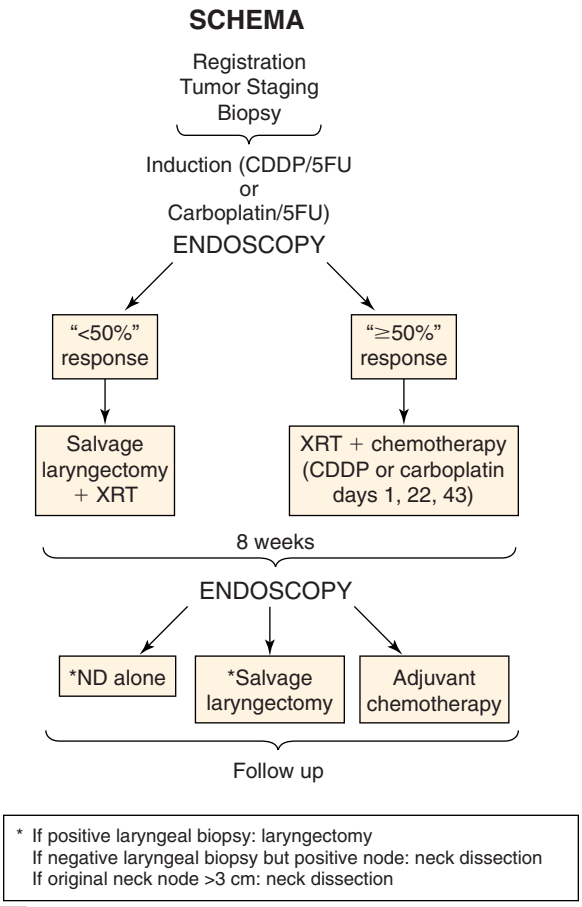

Figure 105-2. Schema of UMMC 9520, single-arm, single institution, phase II selection trial for the treament of stage III to IV laryngeal cancer. The 5-year survival was better than any arm in the 91-11 study. The selection arm in 9520 used concomitant chemoradiation therapy for responders and surgery with radiation therapy for nonresponders. The goal was to customize therapy and avoid surgical salvage after chemoradiation therapy. Note that the trial included patients with cartilage invasion. CDDP, cisplatinum; 5FU, 5 flourouracil; ND, neck dissection; XRT, external beam radiation therapy.

workup. Because of the many disciplines involved, the treatment and rehabilitation experience can be bewildering for the patient. This has put the nurse clinical coordinator at the core of the patient care experience. It is not uncommon for these patients to have a poor predisease diet that, when coupled with a painful obstructive disease process involving the upper aerodigestive tract, can lead to significant malnutrition. Preoperative counseling with the speech pathologist is an essential part of patient education and shaping expectations. The speech pathologist is often regarded by the patient as the individual who will restore function post treatment. The greatest counseling challenge in this patient group is overcoming poor coping skills.[11] The speech pathologist must contend with the patient's coping mechanisms in order to assist rehabilitation. Psychosocial counseling, which speech pathologists often do on an "ad hoc" basis, has been shown to benefit head and neck cancer patients when compared with controls.[12] The speech pathologist must describe the expected long-term functional outcomes, identify the communicative and swallowing strategies that will be necessary, and indicate his or her interest in supporting the patient throughout treatment and rehabilitation. An addicted patient is unlikely to be effectively rehabilitated. Smoking is highly correlated with alcohol intake and depression. Smoking cessation interventions, particularly those that take into consideration alcohol intake and depression, have been shown to be efficacious for this patient population.[13] The patient must understand that continuation of addictive behaviors represents the greatest risk to survival and future functioning. It is important to emphasize that there are many different ways to quit smoking, that alcohol is a facilitator, and that nicotine is not a carcinogen. Use of patient volunteers who have completed treatment are an important resource. They provide education and experience with regard to post-treatment recuperation and long-term quality of life to patients who are preparing for treatment.

For rehabilitation to be effective, the patient's social, psychologic, and addictive behaviors must be assessed and treated. Many of these patients have addictions to tobacco and alcohol at presentation and may lack social support. All these issues should be comprehensively addressed, and in so doing, providers and patients are often rewarded by the productive role the patients assume for themselves, for their families, and in the workplace.

Preoperative Evaluation

A thorough preoperative evaluation including endoscopy and radiographic studies must be performed to assess the extent of the primary tumor and to detect the presence of regional or distant metastasis. Particular attention must be given to a complete esophagoscopy. The degree of involvement of the cervical esophagus should be assessed carefully, keeping in mind the propensity for submucosal spread and skip lesions. The presence of a tumor in the esophagus must be ruled out because it may necessitate a total esophagectomy. It is generally not possible to preserve the larynx with advanced lesions, although laryngeal-sparing surgery may be an option for a select few patients. Partial laryngeal procedures and the associated reconstructive approaches are discussed in another chapter. The ideal margin for hypopharyngeal lesions is still controversial. Some authors advocate distal margins of up to 3 to 6 cm as long as there is no evidence of disease in the remaining esophagus.[14-17] Although routine total esophagectomy had been recommended in the past for management of carcinoma involving the hypopharynx, this approach is no longer the standard of care.[18] The esophagus is removed only for adequate margin or direct involvement. If the patient has been previously treated with chemotherapy and radiation therapy, the quality of the cervical skin can be poor. The skin may need to be replaced as part of the reconstructive procedure. It is also

important to assess thyroid function preoperatively because the patient can be hypothyroid due to prior radiation. Hypothyroidism causes delayed healing and contributes to postoperative wound complications.

Goals and Principles of Reconstruction

The goals of reconstruction are a healed wound with protection of the great vessels, restoration of a pharyngeal conduit, protection of the airway, and rehabilitation of the voice. The principles of pharyngeal reconstruction are (1) if the area has undergone prior chemoradiation therapy, vascularized tissue from outside of the radiation field should be used to close or re-enforce the pharyngeal closure; (2) if the pharyngeal reconstruction needs to be tubed, the thickness of the tissue should be less than or equal to 2 cm; (3) if aspiration pneumonia is affecting the patient's quality of life, the trachea has to be separated from the aerodigestive tract; (4) if the patient is going to be fitted with a tracheoesophageal speech prosthesis, a cricopharyngeal myotomy needs to be performed; (5) if there is risk for stenosis after reconstruction, then a salivary bypass tube needs to be inserted; and (6) if there is concern about pharyngocutaneous fistula, then a salivary bypass tube should be inserted.

Defect Classification

Pharyngoesophageal defects are classified according to the amount of pharyngeal (partial, near total, and total), oropharyngeal (base of tongue, lateral pharyngeal wall, posterior pharyngeal wall, soft palate), esophageal, and skin involvement. Partial pharyngeal defects are those arising from the extirpation of a larynx that may include some pharyngeal mucosa and can be closed primarily without stenosis or require a small graft to reconstruct less than 50% of the circumference of the pharynx. Near-total pharyngeal defects are defects in which only a thin strip of pharynx (≈1 cm) remains and requires a graft to reconstruct more than 50% of the circumference of the pharynx. Total pharyngeal defects are those in which there is complete absence of a segment of the pharynx. For the purposes of this chapter, we do not discuss partial laryngeal defects or reconstruction of hypopharyngeal defects with an intact larynx because this topic is covered elsewhere. Anecdotally, there have been numerous attempts to reconstruct hypopharyngeal defects with an intact larynx. Interestingly, there are no published case series. Drawing from the author's experience and discussions with colleagues, there does not seem to be a reliable and reproducible technique. This reconstructive issue needs more investigation. Defects that extend into the oropharynx may need additional reconstructive planning. Particularly those defects that involve the soft palate will require a pharyngoplasty and additional tissue to resurface the palate and tonsil.[19] Defects of the tonsil can generally be closed primarily. Associated defects of the tongue base can be partial or total. Partial defects that involve up to 50% of the tongue base do not require reconstruction. Primary closure of these defects is achieved by advancing the tongue base across the defect and suturing it to the resected edge of the oropharynx. This approach results in a sensate, functional tongue base reconstruction. Defects of the entire tongue base are more concerning and may require reconstruction with a graft, particularly if the patient has a near total or total pharyngeal defect and is post chemoradiation therapy. Although it has been suggested that patients who have undergone hemilaryngectomy do not require reconstruction of the base of the tongue, loss of the entire tongue base diminishes the ability of the patient to propel the bolus through the pharyngeal segment and can limit dietary intake to thin liquids. If the resection of the pharynx extends into the mediastinum and a reliable distal anatomosis cannot be sutured, then a visceral transposition is the reconstruction of choice. For a visceral transposition, the patient will undergo a complete esophagectomy, dissection of the mediastinum, and an open abdominal approach. The cervical skin needs to be assessed for tumor involvement and viability. A cervical skin defect in combination with a pharyngeal defect significantly affects reconstructive decision making.

Reconstructive Decision Making

Reconstruction of the hypopharynx and cervical esophagus is associated with a high risk of morbidity and mortality. A wound at this site can expose the carotid and internal jugular vein, which can lead to life-threatening hemorrhages. Wound breakdown of the common wall between the trachea and esophagus usually results in aspiration pneumonia and is associated with a high mortality rate. Hypopharyngeal reconstruction should be designed to make a wound safe and provide a pharyngeal conduit that assists swallowing and speech. If the only priority of the reconstructive surgeon was a safe wound, then exteriorization of the upper aerodigestive tract with a pharyngostome, esophagostome, and tracheostome would ameliorate nearly all of the associated wound complications. The patient is interested in more than a safe wound and wants to return to pretreatment levels of social interaction and occupation. For this reason, reconstructive surgeons reconstruct the pharynx despite the attendant risk and measurable mortality. Fortunately, there are many reconstructive options for hypopharyngeal reconstruction (Fig. 105-3A and B). These options include local and regional cervical skin flaps, deltopectoral flap, pectoralis flap, latissimus flap, gastric transposition, colonic interposition, revascularized fascial flaps, and the gastro-omental flap. The following factors must be considered when choosing a reconstructive option:

1. The condition of the local tissue, which includes the pharynx and the overlying cervical skin. If the local tissue is compromised by chemoradiation therapy or the patient has radiation chondritis, then nonradiated vascularized tissue should be used in the wound.[20,21]

2. The likelihood of a total versus a partial versus a primary hypopharyngeal closure.

3. The likelihood of extension into the esophagus.

4. The likelihood of oropharyngeal extension.

5. The vascular access in the cervical region.

6. The overall comorbid status of the patient.

7. The thickness of the donor site. Patients who present for hypopharyngeal reconstruction are rarely obese, but if they are, adjustments in donor site choice must be made. Thick cutaneous tissue will not make a good tube. If the patient does not have a good cutaneous donor site, the jejunum can be considered if there are not other comorbid conditions.

Voice rehabilitation also needs to be addressed with respect to primary versus secondary tracheoesophageal puncture (TEP). If the patient is high risk or the reconstructive plan was not appropriate given the intraoperative findings, the patient can be closed with a pharyngostomy, an esophagostomy, and a tracheostomy. This is a safe, staged approach.

Local and Regional Skin Flaps

From 1877 through 1904 Czerny, Mikulicz, and Trotter[22,23,24] described the first techniques to restore continuity to the pharynx. These procedures were multiple-stage procedures that used cervical skin flaps for reconstruction. In the 1940s Wookey improved on these techniques when he used a two-stage repair for pharyngoesophageal defects with a laterally based rectangular cervical flap. In the first stage the cervical skin was redraped over the prevertebral fascia and was interposed between the pharyngeal and cervical esophageal stomas to create the posterior wall of the pharyngeal reconstruction.[25,26] The approach exteriorized salivary and gastric secretion, protected the vascular sheath, and controlled infection. The continuity of the pharynx and cervical esophagus was returned at a second stage, usually 2 or 3 months later. Rectangular skin flaps with a base along the reconstructed posterior pharyngeal wall were fashioned from the cervical skin, on the right and left sides. These flaps were tubed and closed vertically in the midline to create a skin-lined pharyngoesophageal segment. A skin graft was placed on the reconstructed pharynx and the donor sites of the rotated cervical flaps. All these methods that used local skin flaps required multiple steps and were associated with a high frequency of complications. Although this approach created a safe wound, the functional outcomes of speech and swallowing were compromised because of the

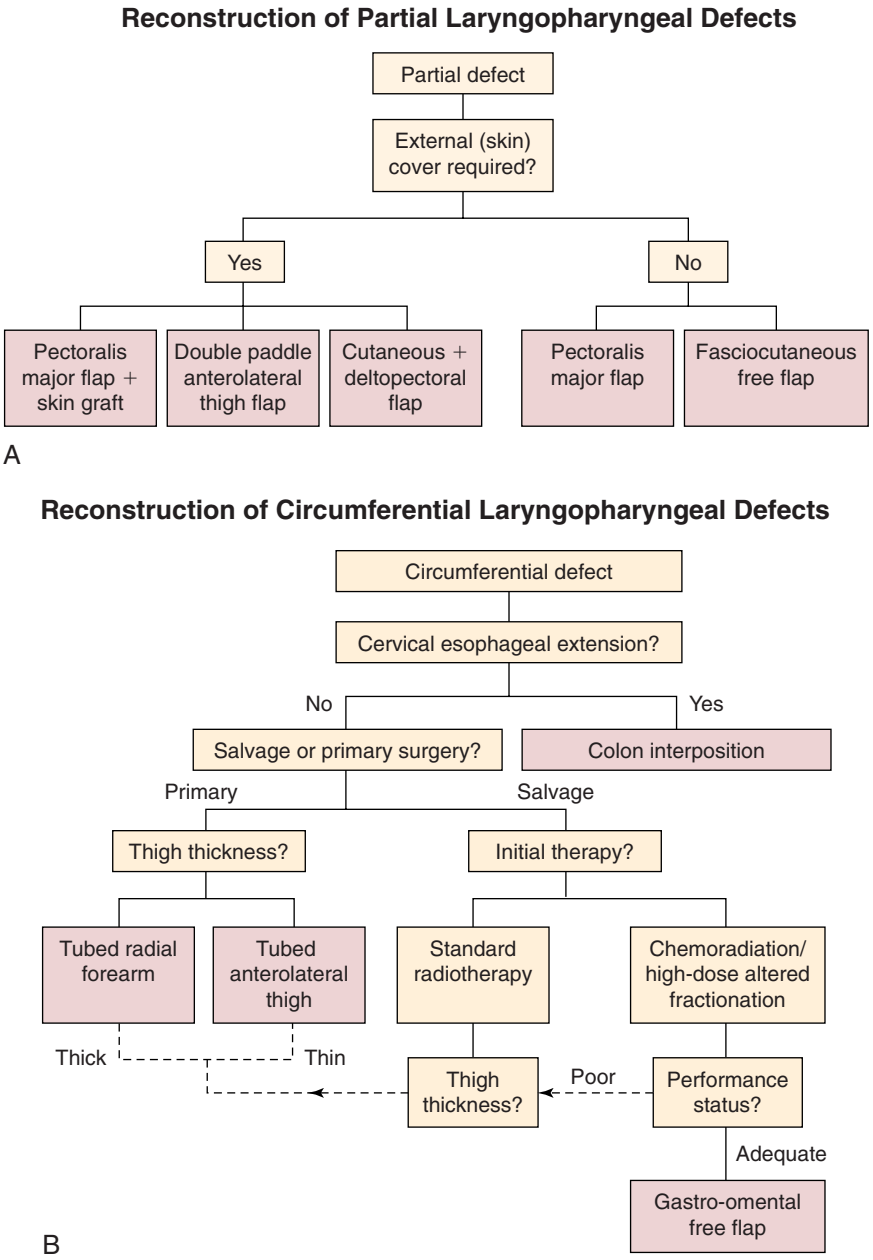

Figure 105-3. **A,** Decision tree for partial pharyngeal defects. Note that the decision tree does not include a decision point for patients who have salvage surgery after chemoradiation therapy and undergo primary closure of the pharynx. For these patients, a vascularized pharyngeal interposition graft is suggested to support the primary pharyngeal closure. **B,** Decision tree for total pharyngeal defects. *(**A** and **B** adapted from Clark JR, Gilbert R, Irish J, et al. Morbidity after flap reconstruction of hypopharyngeal defects.* Laryngoscope. *2006;116(2):173-181.)*

difficulty of reconstructing a pharynx that would not fistulize or stenose. The use of radiation increases the complication rate of this reconstructive approach. Although it is important to be aware of this approach, it is largely of historical interest. The concept of a two-layer closure, one for the pharynx and one for neck cervical skin, using local flaps for mature pharyngocutaneous fistula has its conceptual roots in this approach. To improve the success rate of pharyngeal closure, nonradiated tissue with an axial blood supply was necessary.

The description of the deltopectoral flap by Bakamjian in 1965 represented a significant advance over previous methods.[27] Unlike local flaps that rely on a random blood supply, this regional chest skin flap is based on a more reliable axial-pattern blood supply through the perforating branches of the internal mammary artery. It provides well-vascularized tissue from a donor site that lies outside of the typical radiation fields used for head and neck cancer. The deltopectoral flap has a consistent vascular supply and can be reliably used without the need for surgical delay of the flap if limited to the area medial to the deltopectoral groove. This donor site continues to evolve. New approaches involve mobilizing the internal mammary artery by removing the costochondral junction to improve the mobility and transposability of the flap.

Like the Wookey approach, the deltopectoral flap is a multistage procedure requiring the initial creation of a controlled fistula. In the case of the deltopectoral flap, it is used to form the pharyngeal tube and the cervical skin is draped over the deltopectoral inset. At the first stage, a medially based skin flap is elevated and tubed to the superior cut edge of the pharyngeal resection. The posterior wall of the inferior cut edge was sutured to the deltopectoral flap, and a controlled fistula was fashioned with the anterior wall of the inferior edge of pharyngeal resection. The flap pedicle was divided at least 6 weeks later, along with closure of the fistula and skin grafting to the donor site. The deltopectoral flap was an improvement, but there remained an unacceptably

Figure 105-4. A right deltopectoral flap rotated into ipsilateral neck as a second-layer closure for repair of a pharyngeal cutaneous fistula, which occurred after a total laryngectomy. The stoma seen in the photo is the tracheostoma, and the deltopectoral flap is shown after transposition and inset into the recipient bed.

high rate of fistula formation, flap necrosis, and stenosis. Given these limitations, this approach is not commonly used, although these techniques may still occasionally be useful in certain patients who have failed or are unable to undergo alternative reconstructive approaches. At present, this donor site is most commonly used for the closure of a fistula after hypopharyngeal reconstruction (Fig. 105-4).

Myocutaneous Flaps

The development of regional myocutaneous flaps such as the pectoralis flap and the latissimus flap decreased surgical complications, improved outcomes, and introduced single-stage reconstruction of hypopharyngeal defects. The myocutaneous flaps were described for head and neck reconstruction in the early 1970s by Ariyan, Baek, and other researchers. The use of these flaps for hypopharyngeal reconstruction became the treatment of choice by the 1980s. The pectoralis and latissimus myocutaneous flap allows immediate, single-stage reconstruction of hypopharyngeal defects that would previously have required multiple stages and an extended wound healing period. However, these myocutaneous flaps are thick and are difficult to form into a tube. This characteristic makes them a good alternative for partial pharyngeal defects but not as effective an alternative for total or near total hypopharyngeal defects. The myocutaneous flaps made hypopharyngeal reconstruction less difficult for the surgeon and the patient. They reduced wound complications, but the wound healing and functional results were not satisfactory in total and near total defects.

The pectoralis major muscle primary blood supply derives from the perforating vessels from the pectoral branch of the thoracoacromial artery, with secondary contributions from the lateral thoracic artery and parasternal perforators from the internal mammary artery. A skin paddle of sufficient size to close the pharyngeal defect is designed over the inferior medial portion of the muscle. The pectoralis major muscle with its investing fascia is elevated, and the flap is then transposed over the clavicle into the neck through a widely undermined subcutaneous tunnel. Closure of the donor site can often be accomplished primarily, although a skin graft may be required for larger defects. An inframammary incision with a lateral approach will reduce deformity and preserve the deltopectoral flap. A lateral approach allows for identification of the lateral edge of the pectoral muscle. A subpectoral pocket can be fashioned similar to the approach for placement of breast implants. Once a subpectoral pocket is created, the origin of pectoral muscle can be directly visualized and the skin paddle can be positioned in an optimal location to maximize vascularity. The pectoralis myocutaneous flap had adequate pedicle length to rotate into pharyngeal and adjacent tonsil and base of tongue defects. It is important to cut the lateral pectoral nerve, which is adjacent to the pedicle, and the medial pectoral nerve, which is more lateral and closer to the humeral insertion. The maneuver prevents volitional contraction of the muscle once it has been positioned in the defect.

The latissimus dorsi myocutaneous flap is a larger, thinner, more reliable flap than the pectoralis myocutaneous flap. It is used less frequently because it is located laterally on the thoracic cage, requires semi-decubitus patient positioning on the operative bed, and requires pedicle dissection. The same vessel dissection is performed for the elevation of the rotational flap and the free revascularized transfer. When rotating a latissimus flap, the following advice can prevent kinking or traction, or both, of the pedicle.

1. The pedicle needs to be dissected to the axillary artery and vein.
2. The subscapular artery and vein need to be ligated.
3. The tunnel needs to be deep to the sternal head of the pectoralis muscle.
4. The tunnel goes through the superior aspect of the clavicular head of the pectoralis muscle.
5. The pedicle needs to have a gentle curve as it branches from the axillary vessels.
6. The branches of the pedicle need to be ligated with suture to minimize the likelihood of a hemorrhage from the pedicle in the tunnel because Ligaclips can be torn or cause kinking of the pedicle in the tunnel.
7. The flap should be placed in a plastic bag used for visceral transposition to assist with transposition through the tunnel.
8. The latissimus muscle in the flap should not be innervated once the flap has been interposed.
9. The humeral head should be sutured to the clavicle to prevent excessive traction on the pedicle during inset.
10. Postoperatively, the patient's arm should be elevated on a pillow to prevent compression of the pedicle.

The primary use of the myocutaneous flap is for reconstruction of partial pharyngoesophageal defects. A strip of pharyngeal mucosa is left so that a complete tubing of the myocutaneous flap may be avoided.[28] However, it may be the only option for patients with poor cardiopulmonary status who cannot tolerate prolonged surgery or the combined violation of thoracic and abdominal cavities. It is also a good option for those who do not have suitable recipient vessels for free tissue transfer because of previous radical surgery. The pectoralis flap may be most useful as a salvage flap for extra soft tissue, for carotid protection as a myofascial flap, or as a reinforcing layer in previously irradiated patients to minimize the chance of fistula formation.[29] Voice can be successfully restored in patients reconstructed with pectoralis myocutaneous flaps.[30]

Many modifications have been proposed to maximize the usefulness of the pectoralis myocutaneous flap for near total or total pharyngoesophageal reconstruction. Due to newer reconstructive techniques, these modifications have less clinical utility. However, they are important to know as alternatives to conventional reconstructive approaches. These modifications include harvest of the flap as a myofascial flap, thereby avoiding the often excessively bulky subcutaneous tissue that makes tubing of the myocutaneous flap difficult. The difficulty with this approach is stenosis. To our knowledge this approach is no longer used. Alternately, the pectoralis flap can be partially tubed 270 degrees around and closed to prevertebral fascia that has been grafted.[31] When the pectoralis flap is used for reconstruction of circumferential defects, it is associated with stricture formation at the distal anatomosis. Stricture formation after pharyngoesophageal reconstruction with the pectoralis flap has been reported in 35% of patients.

Some surgeons have suggested that a disadvantage of myocutaneous flaps is a relatively high rate of fistula formation. Fistula formation in hypopharyngeal reconstruction is more likely to be related to the history of prior chemoradiation therapy or use of the myocutaneous flap in a defect that is too large for the primary angiosome. Myocutaneous flaps are ideal for defects limited to the hypopharynx. It can also be useful if there is a combined cervical defect because the muscle can be skin grafted to resurface the cervical skin and the cutaneous portion of the flap can be used to resurface the hypopharynx.[32] The pectoralis flap is also useful in chemoradiation patients for the reinforcement of the primary closure to reduce fistula formation. A pectoralis flap is often inadequate at closing a defect extending into the superior-lateral oropharynx or nasopharynx. Other potential disadvantages of the pectoralis flap include the risk of shoulder dysfunction, particularly in patients who have undergone neck dissection.

Visceral Transposition

Visceral transposition is reserved for the reconstruction of lesions that extend past the cervical esophagus. Because of morbidity and mortality associated with laparotomy, dissection of the mediastinum, and resection of the esophagus, these procedures are only performed when necessary. Colon transposition has likely surpassed gastric transposition as the most frequently performed visceral transposition procedure for lesions extending into the thoracic esophagus. Because these procedures are infrequently performed, there is limited reporting on current treatment paradigms. Colon interposition is a more desirable technique because it is reliable and leaves the stomach in its anatomic position, which reduces regurgitation and eliminates gastric dumping. Both the colon and stomach are patulous, which leads to difficulty with restoration of voice with a tracheal esophageal puncture prosthesis. In this patient group an artificial electric larynx is more frequently necessary for effective voice production.

Gastric Transposition

In 1960 Ong and Lee[33] were the first to describe gastric transposition with pharyngogastric reconstruction. They used a transthoracic approach for the single-stage reconstruction after pharyngoesophagectomy. At present, the "gastric pull-up" technique is performed without thoracotomy in favor of blunt esophageal dissection to reduce the high morbidity and mortality associated with simultaneous violation of the thorax and abdomen.

Gastric transposition offers many of the ideal elements for pharyngoesophageal reconstruction: It provides a reliable, single-stage restoration of alimentary continuity by use of well-vascularized tissue from a donor site that is remote from the field of radiation. Significantly, it allows complete removal of the esophagus, thereby eliminating the dangers of unappreciated submucosal extension or a synchronous tumor in the distal esophagus. There is only one visceral anastomosis, which is generally located in the neck, thereby decreasing the possibility of stricture, fistula, and postoperative mediastinitis. Before the mastery of microvascular techniques, gastric transposition was regarded as the procedure of choice for hypopharyngeal lesions because it was a relatively simple and reliable technique that allowed most patients to swallow with timely healing and reasonable morbidity.

Gastric transposition (gastric "pull-up") is performed with a two-team approach. The stomach is approached through an upper midline laparotomy incision. Blood supply to the stomach is maintained through the right gastric artery and its gastroepiploic arcade. A pyloroplasty and a vagotomy are also often performed to promote gastric emptying postoperatively. The entire esophagus is then mobilized by blunt bimanual dissection. Great care must be taken to avoid injuring the posterior membranous tracheal wall during this maneuver. Next, the proximal stomach is transposed into the neck through the posterior mediastinum. The pharyngogastric anastomosis is sutured in a two-layered fashion. A feeding jejunostomy tube is commonly placed to allow for enteric alimentation until oral feeding can be started. Oral intake can usually begin within 10 to 14 days.

The major disadvantage to gastric transposition is the relatively high rate of morbidity and mortality associated with a procedure that involves three surgical fields. Wei and colleagues[17] recently reviewed the trends in gastric transposition surgery in their series of 317 patients operated on over a 30-year period. There was a significant reduction in their perioperative mortality from 31% to 9%, as well as a decrease in fistula rates from 23% to 9%. Their review of the literature demonstrated a 16% overall mortality rate in studies reporting on series of 10 or more patients. They also reported an overall complication rate of approximately 50%, of which most were minor. Pulmonary complications are common including pulmonary effusion, pneumothorax, and pneumonia. Permanent hypoparathyroidism is often unavoidable, necessitating chronic calcium replacement. Previous gastric surgery, peptic ulcer disease, significant cardiopulmonary disease, and cirrhosis are contraindications to this technique. Occasionally, the stomach cannot be mobilized sufficiently to bridge a defect extending superiorly into the oropharynx or nasopharynx.

Other disadvantages to gastric pull-up include frequent abdominal discomfort and dysfunction in the immediate postoperative period including regurgitation of bile and/or food, distention, and diarrhea. Both gastric dumping and gastric outlet obstruction have also been observed. Many of these symptoms will subside over time; regurgitation can be minimized if the patient eats small, frequent meals in an upright position.

Successful voice rehabilitation has been reported in patients with pharyngogastric repair after pharyngolaryngoesophagectomy. Voice quality after gastric pull-up tends to have a wet or gurgling quality.

Colonic Transposition

Goligher and Robin[34] detailed their use of a pedicled segment of colon to reconstruct a defect after pharyngolaryngectomy and cervical esophagectomy in 1954. This technique provides a single-stage method of reconstruction with a smooth, mucosa-lined tube. A section of colon is mobilized in the abdomen, and this can be performed at the same time as the resection in the head and neck. The colon is pedicled on the inferior mesenteric artery. After a section of colon has been mobilized, the remaining colon is closed primarily. The colon is transposed and one end is anastomosed to the fundus of the stomach, while the other end is anastomosed to the remnant of the upper aerodigestive tract. The colon is brought from the abdominal cavity to the upper aerodigestive tract along the path of the esophagus. The esophagus is dissected bluntly just as with the esophagectomy performed for a gastric transposition. By using this technique, a thoracotomy is avoided. If the colon appears to be poorly vascularized when it is transposed into the neck, the associated artery and vein can be anastomosed to a recipient artery and vein in the neck, which is rarely necessary.

The advantages of the colon are its ability to extend easily to the oropharynx, which reduces tension on the anastomosis (Fig. 105-5). The result is a lower rate of dehiscence when compared with the gastric transposition. When the colon is transposed, distal anastomosis is performed to the fundus of the stomach. This leaves the stomach in situ, which resolves the issues of regurgitation and gastric dumping. The colon is able to tolerate radiation therapy as with other visceral grafts. The colon is also an ideal reconstruction for patients who have severe stenosis of the pharynx and esophagus after caustic ingestion.[35] If the pharynx and larynx have been spared, the colonic anastomosis can be performed at the level of the cricopharyngeus, thus preserving the larynx. With this approach, the risks for recurrent laryngeal nerve paralysis and future aspiration are high. But if the larynx can be preserved, the risks of these complications are worthwhile.

As with other procedures that require a laparotomy, colonic grafts have a risk of possible abdominal complications, as well as graft necrosis and fistula formation at the cervical anastomosis. At present, colon transposition is more reliable and flexible than gastric transposition. The symptoms of regurgitation and gastric dumping associated with gastric transposition are so distressing to patients that colon transposition is the reconstruction of choice for total pharyngoesophagectomy. The patients are still challenged with speech and swallowing. The peristaltic movements of the colon do not impair swallowing or speech, but due to the colon's patulous anatomy, any solid oral intake needs copious liquid wash to move the food bolus into the stomach. With respect to voice, many patients use an electric artificial larynx because the colon can lack a vibratory segment to generate voice.

Revascularized Free Tissue Transplantation

Microvascular free tissue transfer surgery has advanced hypopharyngeal reconstruction, particularly for patients with near total and total hypopharyngeal defects. Autogenous tissue transplantation represented an improvement because the donor tissue was not radiated, the reconstruction could be performed in a single stage, circumferential defects could be addressed, and the complication rate was lower when compared with alternative approaches. Revascularized free tissue transfer is the most reliable reconstructive technique in the head and neck.[16] When revascularized free tissue transfer replaced other approaches, the pectoralis myocutaneous flap was the most common approach for partial, near-total, and full-thickness defects including the cervical skin. For total pharyngeal defects, gastric transposition was the reconstruction of choice. At present, the pectoralis myocutaneous flap remains a reasonable option for partial pharyngeal reconstruction. Visceral transposition (colon and gastric transposition) is now limited to defects that include the thoracic esophagus.

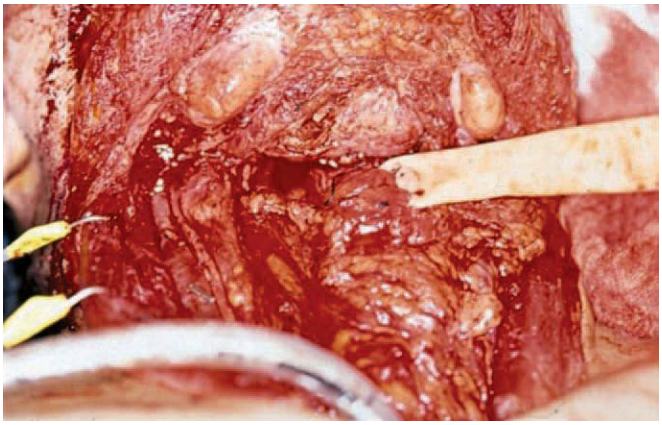

Figure 105-5. A colon interposition in place after a total laryngopharyngectomy and esophagectomy. The patient's head is to the upper part of the figure and the thorax is to the lower part. The colon is shown reconstructing the pharyngeal segment. The patient presented with a leiomyosarcoma of the cricopharyngeus, which was treated with radiation, chemotherapy, and surgical excision. The patient consumed a normal diet, which was taken in many small meals each day, and used an artificial electronic larynx for communication.

The jejunum was the first revascularized free tissue transfer used for hypopharyngeal and cervical esophageal reconstruction. This flap was reliable and well suited to defects that were near total, were total, and/or included the skin. This approach was slowly replaced by fasciocutaneous revascularized free tissue transfer primarily because an abdominal incision was avoided, and speech and swallowing were improved.[36,37] Revascularized free tissue transfer is the current approach of choice for the reconstruction of pharyngoesophageal defects that do not extend below the thoracic inlet. Distal anastomosis of the revascularized free tissue transfer in the mediastinum is not recommended because wound breakdown is likely to result in a life-threatening infection.

An additional level of complexity with revascularized free tissue transfer is the location of appropriate recipient vessels in the head and neck, particularly if the patient has undergone prior laryngectomy and bilateral neck dissection. For patients who have had a bilateral neck dissection, a preoperative computed tomography (CT) scan is useful to determine the patency of the internal jugular veins. A CT angio can be performed simultaneously and is useful for guiding the dissection for the recipient artery. If the patient has poor vascular access, a latissimus rotation flap with staging or a colon interposition is an alternative. The right internal mammary artery can also be flipped in to the neck after removing the second or third distal rib, or both. Monitoring of the transplant also merits consideration when the reconstruction is covered by the cervical skin. Monitoring can be customized to the individual patient in several ways. A monitoring segment can be left externally.[38] This could be a small skin paddle in patients who have undergone transplant of a radial forearm or an anterolateral thigh flap. A monitoring segment could also be a piece of jejunum or a portion of omentum that is left externally from a jejunum or a gastro-omental revascularized free tissue transfer. Monitoring can also be performed with oxygen saturation sensors placed around the venous anastomosis. Monitoring can be performed with Doppler scanning after appropriate planning in the operating room. The cervical skin must be scanned separately to ensure that the Doppler signal is not from the overlying skin. Next, the pedicle of the tissue transfer can be placed in a midline position, which is away from the carotids. The midline Doppler site can be a reliable monitoring option if these steps are followed (Fig. 105-6A).

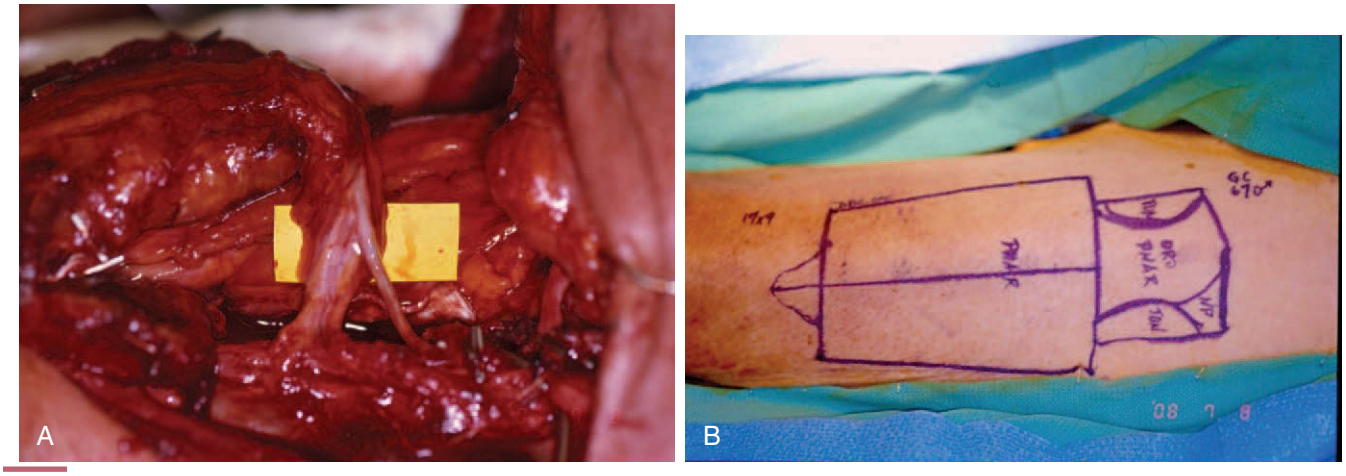

Figure 105-6. **A,** The donor artery and vein are shown crossing the yellow background, which was placed for emphasis of the pedicle but will be removed before closure. The patient is in a supine position with the head on the right side of the figure and the thorax on the left. The figure shows the pedicle in a paramedian position that allows for Doppler monitoring without an external skin paddle. **B,** The template for the same patient is shown before elevation. The donor site is the left anterolateral thigh. The donor site skin is thin, which makes it desirable for a total pharyngeal reconstruction. The pelvis is to the right of the figure and the foot is to the left. The reconstruction will be sutured into a tube along the long axis of the template. The distal or inferior aspect of the template shows a tab that will be inset into the esophagus to reduce the likelihood of stricture. The proximal or superior aspect of the template shows a large square tab that was added to reconstruct a large oropharyngeal extension of the defect.

Fasciocutaneous Transplantation

Radial Forearm Donor Site

The radial forearm flap was introduced into the Chinese literature in China by Yang in 1981 and has since become the commonly used free flap for soft tissue defects in the head and neck because of its versatility and dependability. Harii and colleagues[39] first described the use of a tubed fasciocutaneous radial forearm free flap for pharyngoesophageal reconstruction in 1985. It is currently used to reconstruct partial, subtotal, and total pharyngoesophageal defects. It is also useful for reconstruction of persistent fistula and hypopharyngeal stenosis. It is important to perform a workup for recurrence, which should include tissue biopsy and CT imaging of the neck and chest to ensure the stenosis or persistent fistula is not secondary to a tumor recurrence. The major functional advantage of the radial forearm is speech quality after total laryngopharyngectomy reconstruction.[37,40]

The major disadvantage of the radial forearm flap is the high fistula rate (42% to 59%), particularly when used for total pharyngeal defects.[32,39] Creation of a controlled fistula or use of a salivary bypass stent can decrease fistulization and stricture.[41]

The primary angiosome of the radial forearm site is approximately 150 to 250 cm^2, which is thin, pliable, and well suited for single-stage reconstruction of the pharynx and cervical esophagus. Harvest is straightforward because the pedicle is anatomically consistent, the anatomy is superficial, and the pedicle is large. Blood supply to this flap derives from the radial artery and its fascial plexus. Venous drainage is through paired venae comitantes and the superficial system of subcutaneous veins. There are usually numerous connections between the deep and superficial venous systems, providing excellent drainage of the flap. Preoperative confirmation of adequate collateral ulnar circulation to the hand is essential to avoid postoperative ischemia. Allen's test is the most commonly used and consists of digital occlusion of the radial artery for assessment of blood flow through the palmar arches to the thumb. This is a simple and reliable indicator of postharvest blood flow. Due to the superficial nature of the dissection, the donor site morbidity is low. Donor site morbidity can include injury of the superficial sensory branch of the radial nerve. Overly tight closure of the wound or placement of tight dressings can lead to a compartment syndrome. The hand needs to be monitored along with the transplant to prevent complications secondary to limb ischemia. Closure of the donor site defect requires a split-thickness skin graft. Functional loss of the hand is limited to minor loss of grip strength.

The location of the forearm relative to the head and neck allows for two surgical teams to operate simultaneously. Several points should be considered when designing the template for a total pharyngeal defect. The inferior aspect of the reconstruction should include a small triangle of skin, approximately 2 × 2 cm. This triangle is interdigitated into a 2-cm longitudinal incision into the esophagus, which is placed at a right angle to the edge of the esophagus. This approach was first taught by Hayden and is universally used to reduce the likelihood of distal anastomotic stricture (Fig. 105-6B).[39,40] A monitoring segment can be designed from the skin of the proximal aspect of the flap (i.e., separated from the skin paddle by a subcutaneous fascial segment).[42] The monitoring segment is exteriorized by incorporating the skin island into the closure of the neck flaps and is an indicator of the viability of the buried flap. The flap can be fashioned into a tube while still vascularized in the forearm, which saves additional time with an approach that involves two surgical teams. Successful oral intake is seen in 75% to 88% of patients.[39,43]

Anterolateral Thigh Donor Site

The anterolateral thigh has become the fasciocutaneous flap of choice for thin patients who have near-total and total pharyngeal defects including those defects involving skin. This flap is harvested as an ellipse on the anterolateral thigh. The advantages of this flap are ample skin, primary closure, opportunity to harvest a distal monitoring segment, and new reports of lower fistula rate when compared with the forearm site.[32] The disadvantages are the variable blood supply that may require harvesting a portion of the vastus lateralis and the thickness of the flap, particularly in North American patients.[44]

The anterolateral thigh flap receives its blood supply from the descending branch of the lateral femoral circumflex artery and the associated venae comitantes. The pedicle can pass in between the rectus femoris and the vastus lateralis, or it can pass through the vastus lateralis muscle. The pedicle is situated at the midpoint of a line drawn from the anterior superior iliac spine to the lateral aspect of the patella. It is best to position the template over the middle third of this line. Due to the variability of the pedicle anatomy, the medial incision can be made first, the perforators located, and the flap designed depending on the perforator location. It is important to place the medial incision in a near-midline location to ensure incorporation of the pedicle. The principles of inset described earlier for the radial forearm site are similar for all fasciocutaneous flap types and can be applied to the anterolateral thigh flap. A monitoring segment or a paddle for cutaneous reconstruction can be designed on a distal perforator that is found at the junction of the middle and distal third of the line from the anterior superior iliac spine to the lateral aspect of the patella. Approximately 300 cm^2 are available for reconstruction. The available skin at this site makes the anterolateral thigh a good choice for defects that extend to the tonsil or base of tongue or include the cervical skin.

Other Fasciocutaneous Donor Sites

The lateral thigh was used by Western Hemisphere surgeons before the anterolateral thigh flap because the anterolateral thigh had not been published and Western surgeons lacked experience with this site. The lateral thigh had many similar reconstructive advantages, particularly for total pharyngeal defects. The lateral thigh was used by select surgeons with extensive reconstructive experience because the pedicle was short and its harvest was difficult. The pedicle of the anterolateral thigh is much longer and the harvest is much more straightforward. Hayden described the use of the lateral thigh site for total pharyngoesophageal reconstruction.[45] This flap is harvested as an elliptically shaped skin paddle over the lateral aspect of the thigh. Its blood supply comes primarily from the third cutaneous perforator off the profunda femoris artery. Two venae comitantes accompany the arterial perforator, joining proximally and entering the profunda femoris vein.

The advantages to the lateral thigh flap are minimal donor site morbidity and thin, pliable tissue. Usually the donor site can be closed primarily, which avoids the need for a skin graft, yielding a more cosmetic scar. Like other fasciocutaneous flaps, the skin can be easily tubed for total pharyngeal defects. Unlike enteric flaps, no laparotomy incision is necessary. Dissection of the lateral thigh flap can be difficult, however, which may explain its less common use compared with the anterolateral thigh site or the radial forearm site. It is not advised for use in obese individuals or in those with previous surgery or trauma to the thigh. Excessive hair growth on the thigh may also be a relative contraindication to this flap.

The lateral arm and scapular flaps have also been described for pharyngoesophageal reconstruction. They have disadvantages including a limited amount of available tissue (lateral arm) and the need for patient repositioning for flap harvest, which results in a longer operative time (scapula). In addition, these flaps are usually not as thin as the radial forearm or the anterolateral thigh sites. Use of the ulnar flap has also been reported, with similar advantages and disadvantages as the radial forearm flap.[43]

Enteric Transplantation

Jejunal Donor Site

Seidenberg was the first to report successful transfer of a free vascularized segment of jejunum in 1959.[46] Microvascular techniques were not yet perfected at that time, but as microvascular techniques improved, interest in the free jejunal autograft was reinvigorated.

The major advantage of the jejunal free flap is that it provides a moist, mucosa-lined tube for single-stage reconstruction of pharyngoesophageal defects. The jejunum is a good size match for the cervical esophagus and is ideally suited for circumferential defects. Because it is already a tube, there are only two anastomotic suture lines in the neck,

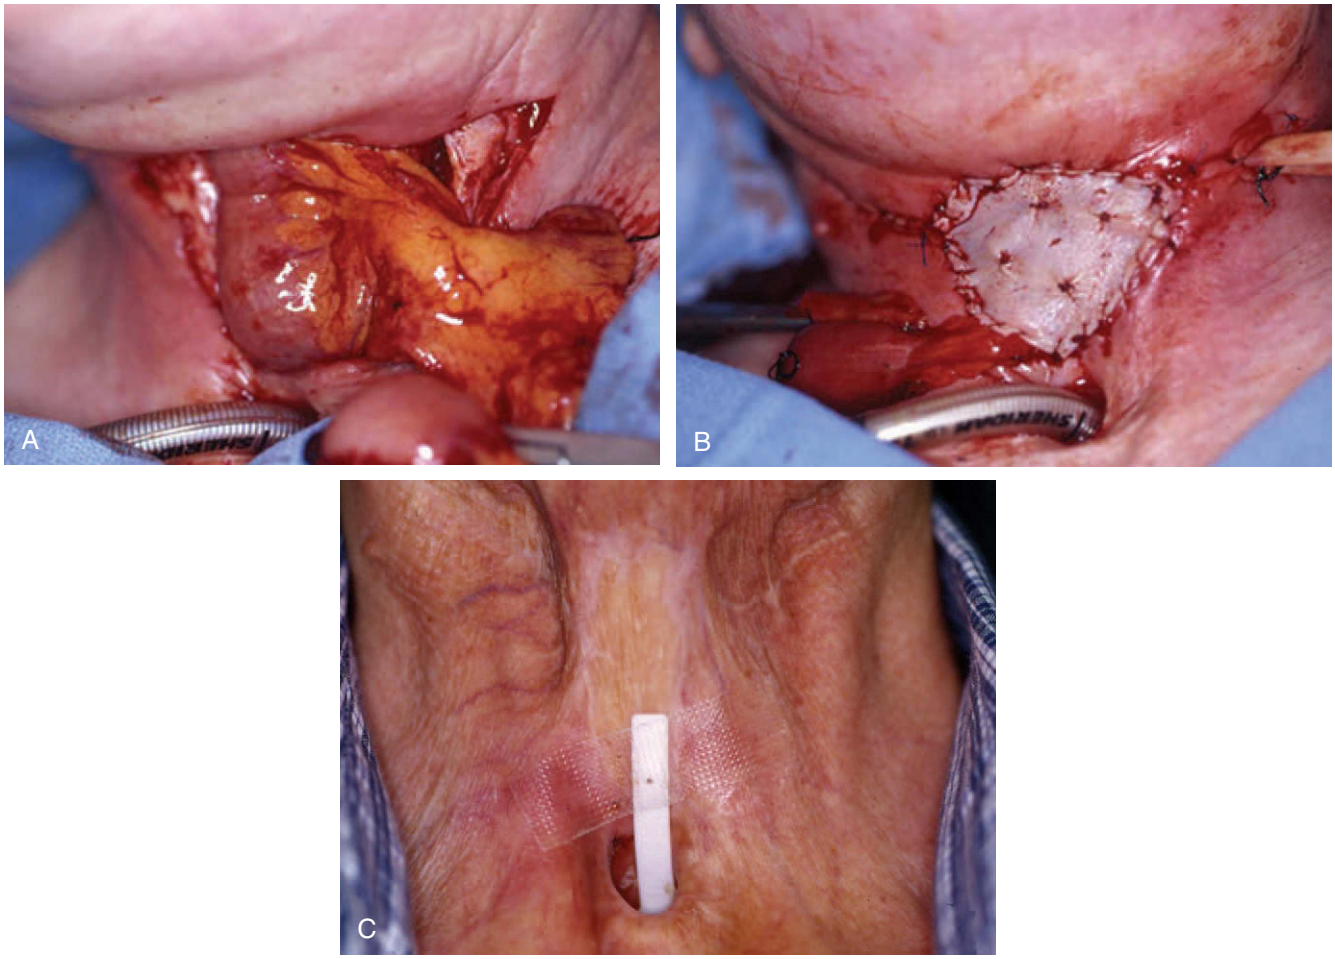

Figure 105-7. **A,** The jejunum is shown reconstructing a total pharyngeal defect. The patient's head is at the top of the figure, and the tracheal stoma can be seen at the inferior aspect of the figure with an endotracheal tube in place. The mesentery is seen to the right of the figure and will be used for the external, cutaneous reconstruction. This patient had a laryngectomy many years before this procedure and developed pharyngeal stenosis. The patient was referred following a dilation, which resulted in necrosis of the cervical skin and the anterior aspect of the pharynx. **B,** The patient is in the same orientation. The figure shows the patient after the mesentery has been draped over the jejunum and a skin graft has been applied as an epithelial reconstruction. On the left of the figure a small segment of jejunum is shown. It was used as an external monitoring segment. **C,** The patient is shown approximately 1 year after treatment. The tracheal stoma is shown with an indwelling tracheal-esophageal speech prosthesis. The skin graft is well healed just above the stoma and the patient is eating and phonating well. The reconstruction has been stable without further intervention for the past 9 years.

which potentially decreases fistula and stricture formation. The vascular arcade supplies a longer segment of jejunum than is required for pharyngeal reconstruction. The additional mesentery can be used to reconstruct an associated cervical skin defect (Fig. 105-7A). The jejunum is also easily used as a patch graft for subtotal defects. If the jejunum is opened, it is important to open the jejunum along its antimesenteric border. A free jejunal segment can be tailored to fit defects of varying lengths. In addition, the jejunum tolerates radical doses of radiotherapy.[47]

Jejunal reconstruction of the pharyngoesophagus requires a two-team approach. An appropriately sized segment of jejunum is harvested after the abdomen has been entered by way of a standard laparotomy incision. The jejunal segment is usually selected from the bowel distal to the ligament of Treitz on the basis of the second jejunal branch of the superior mesenteric artery. An intestinal segment of up to 20 cm can be harvested. Transillumination of the bowel is performed to allow identification of the best arteriovenous pedicle, which is confirmed by palpation of the vessels through the mesentery. An extra length of jejunum based on the same mesenteric arcade as the graft can be harvested to serve as an external monitoring loop (Fig. 105-7B). The additional mesentery can also be used to reconstruct the cervical skin (Fig. 105-7C). The proximal end of the graft should be marked with a suture to ensure isoperistaltic insetting of the jejunum into the pharyngoesophageal defect. The jejunum has to be inset under moderate tension. A kink or loop will functionally obstruct, making postoperative speech and swallowing more difficult. A feeding jejunostomy tube is placed after harvest of the graft. Revascularization of the jejunum does not need to be performed before insetting, but the ischemia time should be minimized. Both pharyngeal and esophageal anastomoses should be hand-sutured in a two-layered closure because a higher rate of stenosis formation has been reported with stapling.[28,48] The external monitor loop can be excised on postoperative day 7.

Reconstruction with the jejunal free flap does have several potential disadvantages. Laparotomy, with its accompanying abdominal complications, is cause for morbidity in these patients. Recent advances in laparoscopic harvest of the jejunal segment have helped to decrease donor site morbidity.[49] Ascites and Crohn's disease are absolute contraindications to the jejunal flap. Previous abdominal surgery may be a relative contraindication, as is a debilitated patient either from other medical comorbidities or age.

The key disadvantage of the jejunum relates to postoperative speech and swallowing function. This is the key reason that it is not commonly used. The intrinsic peristalsis of the jejunum remains after transplantation and often causes significant early postoperative dys-

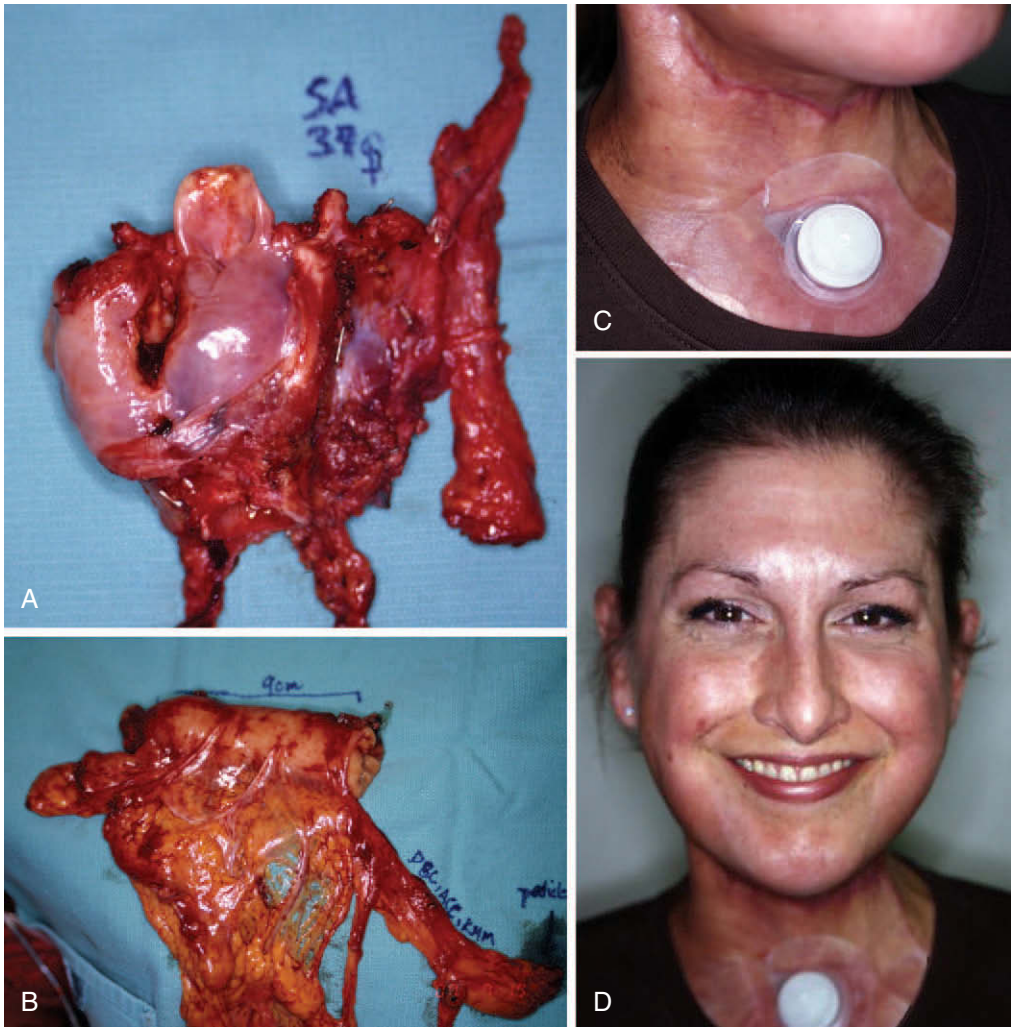

Figure 105-8. **A,** Laryngopharyngectomy specimen with the pharynx bisected to assist a view of the postcricoid and pyriform sinus sites. The posterior surface of the larynx is shown facing toward the camera with the epiglottis facing superiorly. The patient was referred with a recurrent piriform sinus cancer, seen on the left side of the figure, that underwent prior treatment with laser excision, ipsilateral neck dissection chemotherapy, and radiation therapy. **B,** A gastro-omental flap is shown after elevation. The stomach tube is shown in the upper part of the figure, and the omentum is shown in the lower part of the figure. The pedicle can be seen on the right side of the figure. The stomach tube is sized with two 30-French chest tubes along the greater curvature, taking care to preserve the gastric antrum. Note the rugae seen on the right side of the figure running along the length of the gastric tube. A portion of the omentum is harvested and can easily cover all the dissected areas of the wound. **C,** Close-up of the cervical skin of the same patient 3 months following the operation. The skin was not closed primarily in this case. Omentum was left exposed in the open wound, covered with Iodoform-Vaseline gauze as a bolster, in a defect that was 60 cm^2. The patient had a methicillin-resistent *Staphylococcus* wound infection postoperatively, which required intravenous antibiotics. No skin grafting or further reconstruction was required. **D,** A hands-free stoma cover is in place for this patient, who is communicating with tracheal esophageal speech, consuming a soft, solid diet, and working.

phagia because jejunal peristalsis is not coordinated with the pharyngeal swallow. In addition, mucous production by the jejunal mucosa can impair speech intelligibility and cause a coarse vocal quality in patients who undergo speech rehabilitation with a tracheoesophageal puncture and voice prosthesis after jejunal flap reconstruction.

Gastro-omental Donor Site

The first successful transfer of a segment of gastric antrum for reconstruction of the pharyngoesophagus was reported by Hiebert and Cummings in 1961.[50] The gastric mucosa is smooth and flexible tissue, similar in texture to the rest of the alimentary tract. This may assist the transit of food through this adynamic segment and possibly be a better vibratory segment for voice when compared with a reconstruction that uses skin. The gastro-omental graft may also be advantageous in hirsute patients, although hair on a cutaneous flap rarely causes problems by trapping food. The omentum is thin and well vascularized, offering excellent coverage of the great vessels. It can also be used to fill soft tissue defects of varying sizes and shapes because of its plasticity. The omentum also has the unique ability to form adhesions to tissues that are inflamed, ischemic, or necrotic, thereby encapsulating them and separating them from the surrounding tissues. The rich vascularity of the omentum is beneficial for healing in surgical fields that have poor tissue quality. These qualities make the gastro-omental flap a good choice for complicated wounds that are prone to infection developing or for closure of persistent fistulae. At present, the most common indication for total laryngopharyngectomy is treatment failure after chemoradiation therapy (Fig. 105-8A). The fistula and wound complication rate is higher in this patient group, and the gastro-omental flap is an ideal choice to ameliorate some of these wound-healing complications. The research challenge will be determining whether the complications resulting from a laparotomy will offset the reduction of wound complications and improvement of functional results in the head and neck.

The greater omentum is a double-layer of peritoneum attached to the greater curvature of the stomach and the transverse colon. The

gastro-omental free flap consists of a segment of gastric antrum that is harvested in continuity with its attached omentum (Fig. 105-8B). A laparotomy incision is used, allowing simultaneous harvest with the ablative procedure. The blood supply for the omentum and greater curvature of the stomach arises from the right and left gastroepiploic arteries. The right gastroepiploic artery is used for the anastomosis because it is usually the dominant vessel. The gastric segment is harvested with an enteric stapler that both separates the flap and closes the remaining stomach. Depending on the patient, the mucosal graft can either be tubed to reconstruct a circumferential defect or used as a patch graft in a partial pharyngeal defect. The omentum is used to cover the great vessels and envelop the reconstruction, which should reduce the complication rate. If there is a large cervical soft tissue defect, the omentum can be easily contoured to fill the defect and can also be skin grafted in a second stage. The option to easily reconstruct a cervical defect adds great value to a salvage reconstruction for a patient who has failed chemoradiation (Fig. 105-8C). In many chemoradiated patients, the skin is stiff, edematous, and contracted. At the completion of the pharyngeal reconstruction, primary closure of the skin can be difficult. Because of the condition of the skin, it tolerates a closure with tension poorly. To reduce tissue tension with the cervical closure, it is valuable to be able to interpose tissue above the tracheal stoma. If this reconstructive approach is taken, then there is no additional design required for the gastro-omental flap because the omentum is well suited to reconstruct above the tracheal stoma (Fig. 105-8D).

Disadvantages to the gastro-omental flap largely stem from the potential abdominal complications. These include possible gastric leak with subsequent peritonitis or abscess formation, gastric outlet obstruction, or volvulus. Peptic ulcer disease or a history of gastric outlet obstruction precludes the use of a gastro-omental flap. In addition, previous abdominal surgery or infection may be a relative contraindication to its use. Also, a history of a gastric tube may make the harvest of the gastro-omental flap more difficult.

Only small series of gastro-omental reconstructions of pharyngoesophageal defects have been reported in the literature. Guedon and colleagues[51] demonstrated successful oral intake in 18 patients reconstructed with either a patch graft (10 patients) or with a tubed gastro-omental flap (8 patients). Fistulae occurred in three patients (17%), but all resolved spontaneously. Genden and colleagues[52] illustrated the usefulness of the gastro-omental flap in patients previously exposed to multimodality therapy, who are at a high risk of fistulae and other complications developing. They reported on five patients reconstructed with a tubed gastro-omental flap; there were no fistulae or flap complications. Three patients had strictures develop that were successfully treated with dilation, and 80% ultimately achieved oral intake.

Management of Postsurgical Complications

Historically, complications of hypopharyngeal reconstruction are more frequent and more serious than other sites in the upper aerodigestive tract.[10] A number of strategies have reduced the incidence of wound complications. The salivary bypass tube seems to reduce the incidence and severity of pharyngocutaneous fistula.[41] The combination of salivary bypass tube and anterolateral thigh flap has reduced the overall complication rate at this site.[53] Should a fistula arise, determine if the carotid needs to be protected from salivary contamination. Check the thyroid-stimulating hormone (TSH) and free T4 to ensure that the patient does not have iatrogenic hypothyroidism. If the carotid is not at risk and there is nonradiated, vascularized tissue around the pharyngeal reconstruction, then these cases can be managed with regular wound irrigation, antibiotics, and thyroid replacement. If the carotid is at risk, it may need to be covered with vascularized tissue from outside the radiation field such as the pectoralis or latissimus muscle. A revascularized free tissue transfer can also be used to repair a fistula and protect the great vessels.[54] Should the patient not be able to undergo flap surgery at the time of fistula, then the fistula can be exteriorized. Exteriorization of the pharynx is effective, creates a safe wound, and involves the least tissue dissection when compared with any other approach. If the pharynx is intact, a pharyngostomy can be fashioned in the midline of the neck (Fig. 105-9). If there is no pharynx, exteriorization is accomplished by creating a pharyngostomy and an esophagostomy. The pharyngostomy is fashioned by making a transverse incision in the neck skin at the cervical-mental angle approximately 5 cm long. The superior aspect of the incision is sutured to the base of the tongue, and the inferior aspect of the incision is sutured to the posterior pharyngeal wall. The esophagus is sutured to the left of the tracheostoma. The neck skin is draped over the deep cervical fascia and carotid sheath. With the saliva diverted, the carotid is safe and the patient can undergo a secondary reconstruction in the future.

Calcium levels need to be monitored in the perioperative period. Extension of pharyngeal resection, dissection of the mediastinum, paratracheal node dissection, and use of a jejunostomy tube can all increase the likelihood of postoperative hypocalcemia.[32] The more dissection that occurs around the parathyroid gland, the more likely the parathyroid glands are to be partially or completely devascularized. If a parathyroid is detached, it should be morselized and reimplanted into muscle. Before reimplantation, it should be confirmed that it is parathyroid tissue with a frozen section histology. Feeding through a jejunostomy can exacerbate calcium absorption issues if the parathyroids are unable to produce large amounts of parathyroid hormone. The exposure of calcium to the acidic pH of the stomach assists absorption. If the enteral feeding regimen is bypassing the stomach, intravenous calcium may be a better route. Whenever hypocalcemia is noted in this patient group, administering both dihydroxy vitamin D and calcium is advisable.

Stenosis is a common postoperative problem. It typically presents with increased difficulty eating solid foods. It can present with increased difficulty producing speech. Careful attention to changes in swallowing function and patient education can assist early intervention. Stenosis rates are higher in patients who have undergone fasciocutaneous reconstruction versus visceral reconstruction. The stenosis rate is reduced substantially by the insertion of the salivary bypass tube at the time of initial surgery.[41] The effectiveness of the salivary bypass for reducing stenosis is one of the reasons that fasciocutaneous flaps have become more popular. Stenosis had been one of the major limitations to using these flaps. If a patient does develop stenosis, dilation is required.

Stenosis can present as soon as 6 weeks postoperatively despite prophylaxis. Cancer recurrence should always be considered and ruled out. Dysphagia secondary to malignancy tends to be associated with otalgia and odynophagia. If the patient is pain free, it is less likely that the dysphagia is secondary to recurrence. In this case a swallow study can be helpful to differentiate a cicatricial stenosis versus a functional stenosis secondary to cricopharyngeal spasm. Cicatricial stenosis is treated with dilation, which can be difficult due to inability to extend the neck. For these cases, dilation over a guidewire is advisable. If there is concern about distal placement of the guidewire, a small flexible scope such as a choledochoscope can be inserted over the guidewire to verify distal placement. Patients who suffer from functional stenosis secondary to spasm of the cricopharyngeus can be helped with dilation with the first occurrence. At the same time, or with second occurrence, the cricopharyngeal spasm should be treated with botulinum toxin injection. The injection can be performed endoscopically or percutaneously.

A subset of patients require frequent dilations. Awake, self-dilation is an option. After several teaching sessions, self-dilation can be a favored option for patients. For the first several awake dilations, the patient should have the oropharynx anesthetized with a topical spray to reduce the involuntary gag reflex. The patient should also swallow a small quantity of 4% lidocaine based on body weight for topical anesthesia of the dilation site. This increases the comfort of the dilation. With each session, the patient can perform more of the procedure until he or she becomes adept and self-sufficient.

Voice Rehabilitation

After laryngopharyngectomy the patient has a tracheostoma in the lower neck and a separated digestive tract. The stoma requires management to prevent stomal stenosis and prevent stomal trauma. The lungs require humidification and control of tracheal crusting. Various products prevent tracheostomal stenosis, protect the stoma from digital trauma, and enhance pulmonary humidification. Many of these tra-

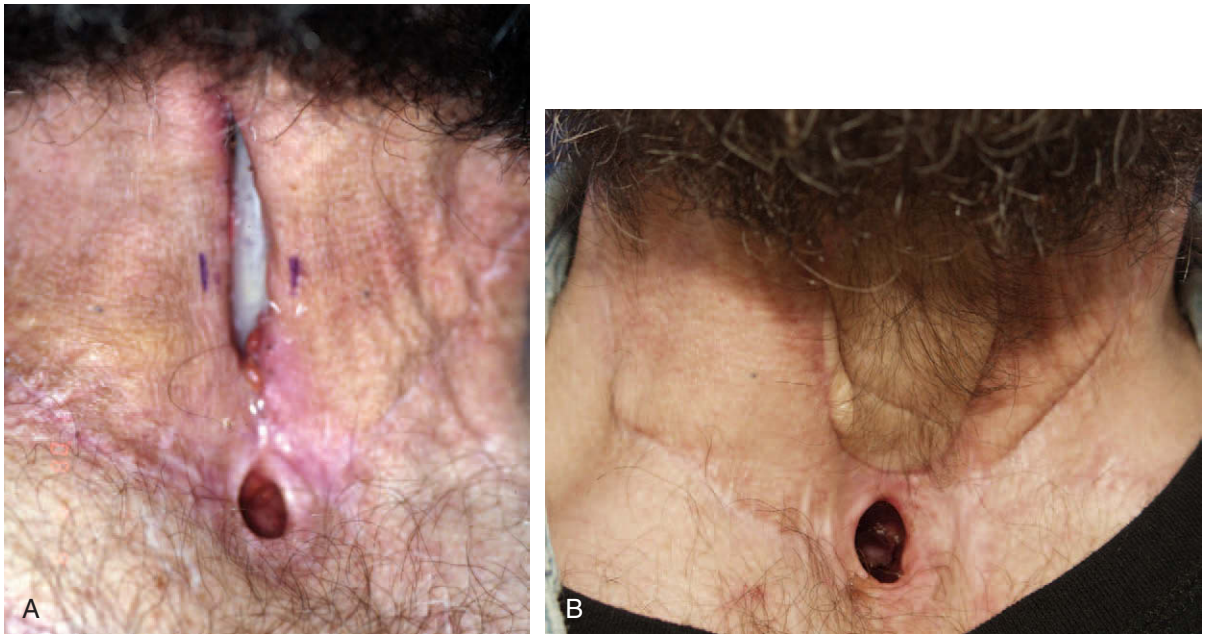

Figure 105-9. **A,** Midline pharyngostomy. The patient had an intact pharynx. The head is at the top of the figure and the tracheostoma is at the bottom of the figure. A salivary bypass tube that is in the pharynx can be seen through the pharyngostoma. The patient was treated with radiation therapy, failed, was treated with a laryngectomy and bilateral neck dissection, developed a fistula involving the carotid, and underwent a pectoralis flap, which failed to separate the fistula from the carotid. The patient was referred for definitive management and a controlled fistula was created as a first stage. **B,** A radial forearm revascularized transplant forming the external layer of a two-layer closure of the controlled pharyngostomy. The inner layer was reconstructed with advancement rotation flaps, which were pedicled on the pharyngostomy. The patient is communicating with tracheoesophageal speech, consuming a normal diet, and working.

cheal stomal prosthetics are designed to be used with or without tracheoesophageal prostheses.

Rehabilitation of speech after laryngopharyngectomy has improved with the use of tracheoesophageal prosthetic devices. Options for speech rehabilitation after laryngectomy include tracheoesophageal voice, voice generated by an artificial larynx, and esophageal voice. Use of tracheoesophageal voice has become the gold standard for voice rehabilitation after total laryngectomy. A surgical tract needs to be made for the tracheoesophageal voice prosthesis. The tract is called a *tracheoesophageal fistula* or *puncture.* The tracheoesophageal puncture can be created at the time of the resection or as a secondary procedure. If a laryngectomy with a partial pharyngectomy has been performed and wound healing problems are not expected, then a puncture with placement of a red rubber tube at the time of surgery is a common approach. If a total laryngopharyngectomy has been performed, then it may be a good idea to perform the puncture as a second procedure approximately 4 weeks after the resection. The reason for delay of the puncture is to maximize the healing of the pharyngeal reconstruction before any additional surgical wounding. A cricopharyngeal myotomy should be performed at the time of the pharyngeal resection. This will decrease the likelihood of cricopharyngeal spasm, which could impair sound production. Placement of secondary tracheoesophageal puncture can be difficult if the head does not extend. One option is to insert an endotracheal tube into the pharynx while the patient is under general anesthesia. The tip of the tube is inserted to the planned tracheoesophageal puncture site. A fiberoptic scope is inserted into the endotracheal tube so that the puncture site can be visualized from the esophageal lumen. Under direct endoscopic vision, a needle from a central line kit can be inserted through the common tracheal wall approximately 1.5 cm distal to the stomal opening. The needle should be visualized in the esophageal lumen. A guidewire is passed and the central line is inserted. The patient can be dilated over a guidewire in 2 weeks in the clinic, and a prosthesis can be placed.

The challenge with prosthetic rehabilitation is a customized solution because "one size does not fit all." An experienced speech pathologist is essential for long-term patient compliance. The electric artificial larynx may be used as a long-term means of alaryngeal communication in a selected number of patients. Additionally, it is often used during postoperative recovery until functional tracheoesophageal voice is achieved. Another alaryngeal speech option is esophageal speech, which does not use devices or implants. It involves trapping air in the pharynx distal to the cricopharyngeus with subsequent controlled release of air to produce a voice. Learning esophageal speech is time intensive and can take up to a year to achieve a functional result, whereas voice production with a tracheoesophageal voice prosthesis, in many instances, can be achieved on the day of insertion. As a result, esophageal speech is not commonly used.

As with swallowing, cricopharyngeal spasm can affect fluency of alaryngeal voice production. Botulinum toxin can be beneficial in improving fluency. Before the decision to inject botulinum toxin, the patient can undergo local infiltration of 1% lidocaine in the peristomal region in the area of the cricopharyngeus to determine if voice fluency can be improved. This approach also helps determine the most effective location for percutaneous injection of botulinum toxin.

Post-treatment Speech and Swallowing Outcomes

There is a wide variation in the reported speech and swallowing outcomes in head and neck cancer patients who have undergone partial or total pharyngeal reconstruction. Most reports have focused on reconstructive approach to reduce complication rate and maintain an open conduit from the oropharynx to the distal aerodigestive tract. The data are difficult to interpret because of survivor bias, historical bias, the changes in cancer treatment approaches, the lack of sample size to compare two different approaches, the variety of reconstructions, the variation of measurement, the availability of a trained rehabilitation team, the variety of options for postoperative speech, and particularly the motivation of the patient. More outcome data exist for patients who have undergone laryngectomy, but relatively less on patients who have undergone pharyngolaryngectomy. Risk factors for poor outcomes after pharyngolaryngectomy are total pharyngectomy, preoperative

radiation therapy, preoperative chemoradiation therapy, history of fistula, and resection of oropharyngeal structures. Factors that affect swallowing outcomes are the caliber of the pharyngeal lumen, propulsive force of the base of the tongue, and lubrication of the reconstructed segment and the closure of the velopharynx. Factors that affect speech outcomes are a poor vibratory segment, cricopharyngeal spasm, and accumulated secretions, which give the voice a wet quality. A way to understand this is to think of the oropharynx creating a seal and a propulsive force to push food through the pharynx. A patient will swallow well if the base of the tongue is of adequate volume and has good innervation, if the pharynx is large, and if the palate can seal well. For a patient to speak well, there must be a vibratory segment. The patient is more likely to have a good vibratory segment if he or she has some native pharyngeal mucosa. For speech, the pharynx cannot be obstructed with a stenosis or cricopharyngeal spasm, but it must be small enough to have a vibratory segment. Most patients can swallow and speak, but the degree to which they are successful depends on the factors discussed earlier. Specific outcome data with respect to these issues are sparse. At the University of California, San Francisco, a small group of laryngectomized patients was evaluated and compared with patients who underwent pharyngolaryngectomy, which was reconstructed with a vascularized forearm flap. Although the range of pitch was slightly greater in the laryngectomized patients, both groups were rated as "good" or "excellent" by untrained listeners.[55]

Summary

Hypopharyngeal and esophageal reconstruction is most commonly performed in patients who have failed prior radiation or chemoradiation therapy. If treatment selection protocols are used, primary surgery or alternative treatment approaches may reduce the frequency of salvage surgery. This patient population frequently has advanced disease and comorbid conditions, which require workup before surgery. To obtain a good postsurgical result, a team approach that includes nursing, speech pathology, dietician, cessation counseling, and social work is necessary. Presurgical assessment is important for appropriate reconstructive planning. Assessment of the distal resection margin is necessary to appropriately plan for esophagectomy. It is important to determine if the defect will include a total versus partial pharyngectomy, resection of components of the oropharynx, and resection of cervical skin. Also of importance is vascular access for free tissue transfer and the quality of the local tissues.

The goals of hypopharyngeal and esophageal reconstruction are protection of the great vessels, restoration of a pharyngeal conduit, protection of the airway, and rehabilitation of the voice. Pharyngoesophageal defects are classified as partial, near total, and total, whether the oropharynx, esophagus, or cervical skin is included. When making reconstructive decisions it is important for the surgeon to be aware of the high complication rate associated with hypopharyngeal reconstruction and to develop a plan that maximizes the safety of the wound.

Patients who have undergone prior chemoradiation therapy benefit from reinforcement of primary hypopharyngeal closure with vascularized tissue. Patients with partial pharyngeal defects can be reconstructed with rotational flaps such as pectoralis or latissimus dorsi flaps. Near-total, total, and extended hypopharyngeal defects are reconstructed with revascularized free tissue transfer. Fasciocutaneous free tissue transfer, particularly anterolateral thigh flap, has become the most commonly used flap due to the area of available donor skin, minimal donor site morbidity, reliability, two-team surgery, and good functional results with respect to speech and swallowing. The pharyngeal bypass tube is a critical part of the success of fasciocutaneous reconstruction as it reduces the incidence of stenosis. Visceral transposition is reserved for defects that include the esophagus. Colon interposition has become the reconstruction of choice due to lower rates of distal necrosis and better swallowing results. Gastric transposition is being evaluated for reduction of complications in patients who have failed chemoradiation therapy and require a laryngopharyngectomy. This approach may also result in improved speech and swallowing results.

Should a fistula occur after reconstruction, protection of the great vessels is the most important wound care issue. A controlled fistula is one of the best approaches available to create a safe wound. TSH levels should be checked to ensure that there is metabolic support for wound healing. After initial wound healing, difficulty with voice or difficulty swallowing can mean functional or cicatricial stenosis. Recurrence must be ruled out and the stenotic segment treated. Tracheal esophageal speech prostheses and stomal prostheses have undergone many improvements and are effective for most patients. Overall, pharyngoesophageal reconstruction can be effectively performed with careful preoperative planning, defect assessment, control of complications, and an effective multidisciplinary rehabilitative team.
