Treatment of bacterial meningitis with appropriate antibiotics is essential. Broad-spectrum antibiotics should be given early and modified when bacteria are isolated and antibiotic sensitivities are determined. Evidence that administration of corticosteroids reduces the incidence of hearing loss in children and adults is accumulating.[72,166,175-177] A more recent MEDLINE survey concluded, however, that the benefit of corticosteroids remains unclear.[178] Maximal benefit occurs when the corticosteroids are given early in the course of meningitis in individuals from developed countries.[179]

When hearing loss has developed, no management modifies its severity or permanency. Because hearing deficits are common in patients with bacterial meningitis, a hearing evaluation of all patients during recovery is recommended. If the child is young or uncooperative, evoked-response audiometry should be used.[154]

Vaccines to Prevent Hearing Loss

Bacterial and viral vaccines are playing an increasing role in prevention of hearing loss in adults and children through prevention of meningitis and acute otitis media. The pneumococcal vaccines have significantly reduced the incidence of invasive pneumococcal disease, including pneumococcal meningitis in elderly individuals[180] and children.[180,181] *H. influenzae* type B used to be the most common cause of bacterial meningitis in children.[182] Since the introduction of *H. influenzae* type B vaccine for children, the incidence of *H. influenzae* meningitis has dramatically decreased.[182] Several studies have recommended the administration of these vaccines to children receiving cochlear implants to reduce to risk of bacterial meningitis.[183,184]

Acute otitis media is responsible for conductive hearing loss and SNHL in children. Bacteria are responsible for about 70% of cases of acute otitis media, with *S. pneumoniae,* nontypable *H. influenzae,* and *Moraxella catarrhalis* as the most common causes.[185] Viruses including influenza, respiratory syncytial, rhinovirus, and parainfluenza account for the remaining 30%. Immunization of young children with vaccines that contain *S. pneumoniae*[181,186] or killed influenza virus[187,188] have been shown in some studies to reduce the incidence of acute otitis media. Other studies report less benefit, however.[189,190] The creation of specific childhood vaccines to prevent otitis media are being considered.[185]

Cochlear Implant Infections

Placement of cochlear implants is associated with several types of infections involving the inner ear or meninges. Since 2003, an average of 4% of cochlear implants develop a delayed major infectious complication requiring hospitalization, intravenous antibiotics, and often removal of the device.[191] The risk of infectious complications does not vary whether the cause was congenital or postmeningitis, and cochlear implants seem to improve patient communication equally.[192] Studies have varied regarding whether children or adults are more prone to device infections. The most common bacteria encountered are *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Repeated episodes of otitis media and poor chronic health conditions increase the risk of infection. Some cochlear implant infections are associated with *S. aureus* biofilms on the implanted device that are difficult to cure with antibiotics.[193]

Bacterial meningitis from *S. pneumoniae* and *H. influenzae* occurs about 30 times more often in children with cochlear implants than in normal children.[194,195] About half the infections have been associated with a device positioner that has been discontinued. The risk of meningitis continues for many years, however, and argues that these children should receive the pneumococcal and *H. influenzae* B vaccines repeatedly.[196]

Congenital and Acquired Syphilitic Deafness

Clinical Features

SNHL can be a complication of congenital and acquired syphilis.[197] Hearing loss from congenital syphilis can occur early (birth to 3 years old) or late (8 to 20 years old). In 2002, 450 cases of congenital syphilis were reported to the Centers for Disease Control and Prevention, an incidence of 11 cases per 100,000 live births.[198] Extensive multisystem damage from syphilitic infections of other organs usually accompanies early congenital syphilitic hearing loss, which is a bilateral profound symmetric SNHL. Relatively few vestibular symptoms and signs are noted.

Patients with late congenital syphilitic hearing loss are usually 8 to 20 years old when symptoms first appear, but occasionally the hearing loss takes longer to occur. These patients usually have a progressive but fluctuating hearing loss that is asymmetric. Audiograms show a flat sensorineural type of hearing loss. Frequently, there are low speech discrimination scores that are disproportionate to the loss in pure tone thresholds. Tinnitus may occur intermittently. These patients also may experience episodes of acute vertigo similar to episodes of Meniere's disease. Hennebert's sign (a positive fistula test with intact tympanic membranes) may be present. Frequently, decreased caloric responses are found.

Acquired syphilitic deafness usually occurs during secondary syphilis.[85] The hearing loss usually has an abrupt onset, tends to be bilateral, and is progressive. Usually minimal vestibular symptoms exist. Patients may have headaches, stiff necks, cranial nerve palsies, optic neuritis, secondary syphilitic rashes, and lymphadenopathy. The CSF shows lymphocytic pleocytosis, elevated protein, and normal glucose.

Acquired syphilitic hearing loss can also develop during the tertiary stage of syphilis.[199] Similar to the late congenital form, the hearing loss is progressive, fluctuating, asymmetric, and sensorineural. Tinnitus may occur. Episodes of vertigo similar to those in Meniere's disease may be experienced. Loss of speech discrimination may be disproportionate to the pure tone hearing loss. Decreased caloric responses and a positive fistula test with an intact tympanic membrane may exist. The CSF may show minimal pleocytosis and elevated or normal protein. Electrocochleographic features of endolymphatic syphilitic lesions generally resemble the features found in Meniere's disease.[200]

Diagnosis

The diagnosis of all types of syphilitic hearing loss requires recent SNHL in the presence of a positive serum rapid plasma reagin test and a positive fluorescent treponemal antibody absorption test or a positive CSF Venereal Disease Research Laboratory test. Spirochetes have been shown by dark-field examination of perilymph obtained from a diagnostic stapes footplate labyrinthotomy.

Management

The Centers for Disease Control and Prevention recommends aqueous crystalline penicillin G, 3 to 4 million U by intravenous injection every 4 hours for 10 days, to treat neurosyphilis.[201] In addition, administration of prednisone, 30 to 60 mg by mouth every day or every other day, is usually given for the first week unless contraindicated.[202] If hearing loss recurs after tapering, long-term maintenance of prednisone (10 to 20 mg every other day) may be necessary. This complication occurs most commonly in the late congenital and late acquired forms of the disease.

The prognosis is poor in the early congenital form; bilateral profound permanent hearing loss usually results. In the late congenital or acquired forms of syphilitic hearing loss, the prognosis is better. Overall, 50% of patients show minor to considerable improvement after management.

Temporal Bone Pathology

The pathology in cases of early congenital syphilitic hearing loss is primarily that of a labyrinthitis with lymphocytic infiltration and destruction of the labyrinth and CN VIII. Spirochetes have been shown in temporal bones obtained at autopsy and stained with a silver stain.[203] In late congenital syphilis, an osteitis of the otic capsule exists with secondary involvement of the membranous labyrinth[204]; this may give rise to endolymphatic hydrops. In early acquired syphilis, the predominant finding is a basilar meningitis affecting CN VIII, particularly its auditory branch. In late acquired syphilitic deafness, temporal bone osteitis is seen, resulting in secondary degeneration of the cochlear end organ.[199] Damage to the membranous labyrinth may occur, giving rise to endolymphatic hydrops.

Hearing Loss in Immunocompromised Patients

Immunocompromised patients are particularly susceptible to middle ear or inner ear infections. Most commonly, chronic fungal or bacterial middle ear infections spread to the inner ear by way of the oval or round window or from osteomyelitis of the petrous bone. Approximately 30% of patients with acquired immunodeficiency syndrome (AIDS) have otologic complaints that include dizziness, hearing loss, tinnitus, and

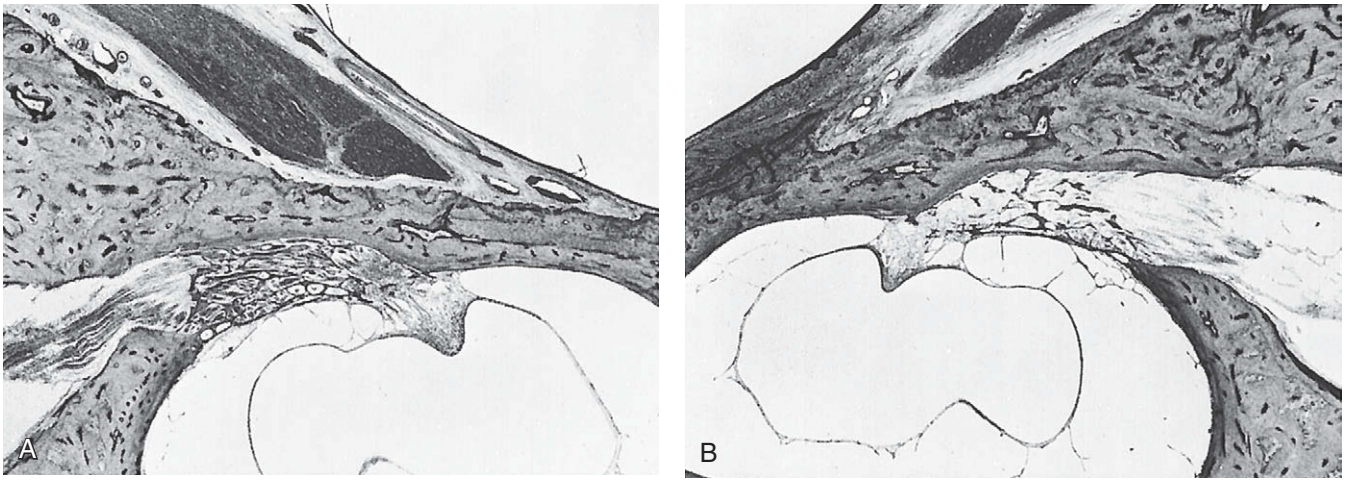

Figure 152-5. Vestibular neuritis developed in this man at ages 55 and 60 years, reducing caloric responses in the left ear. **A,** Right semicircular canal; nerve and crista are normal. **B,** Left semicircular canal; atrophy of nerve and partial atrophy of crista. *(From Schuknecht HF, Kitamura K. Vestibular neuritis.* Ann Otol Rhinol Laryngol. *1981;90[Suppl]:1.)*

otalgia.[205,206] CMV, adenovirus, and HSV have been recovered from perilymphatic fluid of patients with AIDS at death.[207] Histologic damage to the cochlea in viral infections was minimal, suggesting viral entry occurred immediately before death, or the inability of the patient to mount an immune inflammatory response resulted in little inner ear damage.[140,208] Other organisms implicated in SNHL include *Pneumocystis carinii, Candida albicans, S. aureus, Mycobacterium tuberculosis, Toxoplasma gondii, T. pallidum,* and *Cryptococcus neoformans.*[209] Some antiretrovirus medications, including azidothymidine, dideoxyinosine, and dideoxycytidine, have also been associated with SNHL.[209]

Vestibular Neuritis

Clinical Features

Vestibular neuritis has also been called epidemic vertigo, acute labyrinthitis, vestibular paralysis, vestibular neuropathy, and vestibular ganglionitis. The name *vestibular neuritis* is currently used because available pathology suggests that the vestibular nerve is the most common site of damage.[5,210]

The incidence of vestibular neuritis is unknown, but a Japanese questionnaire survey reported 35 cases per 100,000 population.[211] The peak onset of vestibular neuritis is between 30 and 60 years of age. Most patients experience an abrupt onset with a single, severe attack of prolonged vertigo.[212-215] Patients occasionally experience a flurry of attacks over several weeks.[213] Vestibular neuritis should not be accompanied by acute hearing loss or severe tinnitus, although some patients complain of "stuffiness" in the ear. Other neurologic signs or symptoms should not be present. Patients usually have a vigorous spontaneous nystagmus toward the uninvolved side, usually of a horizontal or horizontal-rotary type. Usually only one ear is involved. Caloric responses are diminished or absent in the involved ear in about 50% of patients, and the canal paresis may be permanent.[211,216] CSF examination and electroencephalograms are normal. The diagnosis is made on the basis of characteristic clinical signs. Unilateral diminished or absent caloric tests support the diagnosis.

Management

Early treatment of the patient with methylprednisolone has been shown in a randomized double-blind, placebo-controlled study to improve outcome.[217] Patients were given a 21-day tapering course of methylprednisolone beginning at 100 mg/day. The addition of acyclovir or valaciclovir in two studies did not improve outcome, however.[162,217] During the acute phase, nausea and vomiting may be severe enough to cause clinical dehydration and require hospitalization of the patient and the administration of intravenous fluids. The acute vertigo usually lasts many hours to 1 to 2 weeks.[218]

Spontaneous recovery occurs over weeks to months. There has been concern on the basis of animal studies that prolonged administration of antivertiginous medications may prolong the time to recovery.[219] Many physicians ask patients to stop medication as soon as they can tolerate it. By 6 months, most patients have fully recovered, but may still experience transient positional vertigo triggered by sudden head movements. With recovery, the caloric responses may return to normal or remain diminished or absent.

Temporal Bone Pathology

Studies of temporal bones have been reported from only a few patients with vestibular neuritis.[5,199,214] No patient who died during the acute illness has had his or her temporal bones studied. Most studies from patients dying in the subacute stage have shown primary damage to a branch of the vestibular nerve.[5] Partial to total loss of the superior division of the vestibular nerve supplying the horizontal and superior ampullae has been reported (Fig. 152-5). Associated degeneration of the hair cells occurs in the corresponding sensory organ.

Infectious Causes

Infectious illness, especially colds, sinusitis, and other respiratory tract infections, precede or occur with vestibular neuritis approximately 50% of the time.[211,212] Several viruses have been suggested to be a cause.[220] Patients with mumps may experience vertigo. In a study of proven mumps meningoencephalitis, 37% had impairment of balance, 13% experienced vertigo, and only 2% had an associated hearing loss.[147] In herpes zoster oticus caused by VZV, approximately 25% of patients have vertigo, and may have diminished or absent caloric responses on the ipsilateral side. Some patients have vertigo without an accompanying hearing loss. Patients with influenza often have transient dizziness and vertigo.[221,222] Enterovirus infections have been associated with vestibular neuritis, and the virus has been detected by PCR in CSF in one patient.[223,224] Patients with infectious mononucleosis from an infection with Epstein-Barr virus may have transient vertigo with vertical or horizontal nystagmus.[225] Human herpesvirus type 7 has been associated with one case of vestibular neuritis.[149]

HSV is also associated with vestibular neuritis. Evidence in favor of this association is severalfold. HSV-1 DNA has been identified in vestibular ganglia from tissue obtained at routine autopsies. In some vestibular ganglia, latency-associated transcripts to HSV-1 have been found by reverse transcriptase PCR.[14] Latency-associated transcripts are thought to be responsible for maintaining latency in neurons. Another study could not identify HSV latency-associated transcripts in vestibular ganglia, however.[12]

Studies using a nested PCR assay of 21 randomly selected temporal bones at autopsy reported finding HSV DNA in 62% of vestibular

ganglia and 48% of tissue taken from semicircular canals and macular organs.[226,227] The finding of HSV DNA within vestibular tissue suggests that a focal labyrinthine HSV recurrence could occur. Bacteria (*Borrelia burgdorferi* [Lyme disease] and *T. pallidum* [syphilis]) have also been associated with vertigo attacks similar to vestibular neuritis.[228,229]

Experimental Viral Infections of the Vestibular System

Several other viruses, including rubeola, HSV, mumps, and reoviruses, have been shown to infect the endolymphatic cells in the vestibular system and the vestibular ganglia after intracerebral, intravenous, or direct inoculation through the round window.[119] Generally, these viruses also infected the cochlea. When HSV-1 virus was inoculated into the auricle of 99 mice, 5% developed ataxia 6 to 8 days later.[230] Degeneration of Scarpa's ganglia was found in four of the five mice, and HSV viral antigen was identified in two ganglia. To date, there has been no experimental model that selectively damages branches of the vestibular nerve.

Meniere's Disease

Clinical, diagnostic, and management aspects of Meniere's disease are discussed in Chapters 149 and 164. The cause of Meniere's disease or endolymphatic hydrops remains elusive. Available temporal bone pathologic studies suggest an abnormality of endolymphatic overproduction or underabsorption.[231] Various pathophysiologic mechanisms have been proposed, with several suggesting an abnormal immune mechanism or persistence of a viral infection.[232,233]

In previous years, otitic syphilis was identified as a cause,[234] but more recently syphilis has rarely been found. Viruses have received considerable attention as a possible cause of Meniere's disease.[83,233,235] To date, viral associations have been mainly based on serologic studies.[236] No virus has been isolated from endolymphatic fluid or inner ear structures, and histologic studies have not identified characteristic viral inclusion bodies or viral antigens.

The herpesviruses have gained considerable interest because these viruses establish latency and could recur, causing repeated attacks of vertigo. CMV has been considered because approximately 1 in 100 to 200 infants are born with asymptomatic congenital CMV infection.[30] Some congenitally infected children subsequently have hearing loss that can occur more than 10 years after birth.[18] Evidence for persistence of CMV in the inner ear into adulthood is negligible, however. To date, CMV or its latent state has rarely been found in histologic material of inner ear tissue obtained at autopsy or endolymphatic shunt surgery from patients with Meniere's disease. Experimental inoculation of guinea pig CMV into adult seronegative or seropositive guinea pig endolymphatic sacs has produced the histologic picture of endolymphatic hydrops.[237]

HSV infections have also been considered to cause Meniere's disease.[236,238] Patients with Meniere's disease have been reported to have higher HSV serum antibody titers than controls.[233,236,239] HSV IgG antibody has been reported in perilymph of patients with Meniere's disease and in patients with otosclerosis.[238] One study reported HSV DNA in 100% of 25 vestibular ganglia from patients with Meniere's disease versus 81% of 37 vestibular ganglia from control patients.[240] Another study performed PCR assays for HSV, CMV, and VZV on 22 endolymphatic sacs obtained from patients with Meniere's disease.[241] On finding only two endolymphatic sacs positive for HSV DNA, the authors concluded that ongoing herpesvirus infection in the endolymphatic sac was an infrequent factor in the development of Meniere's disease. Another study using in situ hybridization on 10 endolymphatic sac specimens obtained at surgery for Meniere's disease reported VZV in 7, Epstein-Barr virus in 3, CMV in 1, and HSV in 0.[242]

The two aforementioned studies are difficult to interpret because, except for Epstein-Barr virus, DNA of the other herpesviruses is known to be latent only in neuronal cell bodies, which would not be expected to be present in endolymphatic sacs. Additional evidence against HSV as the etiology comes from several studies. HSV DNA has not been found in the vestibular ganglia of 11 individuals with Meniere's disease.[243] Palva and coworkers[244] were unable to culture HSV from Scarpa's ganglia of patients with Meniere's disease. Cowdry type A intranuclear inclusion bodies or HSV-like viral particles have not been identified in inner ear tissue of patients with Meniere's disease. Finally, Meniere's disease occurs usually in older adults, whereas recurrent herpetic infections occur typically in children and young adults. The current weight of evidence does not support a role for HSV, CMV, or VZV as an important cause of Meniere's disease.

CHAPTER ONE HUNDRED AND FIFTY-THREE

Autoimmune Inner Ear Disease

Steven D. Rauch

Marc A. Cohen

Michael J. Ruckenstein

Key Points

- Autoimmune inner ear disease (AIED) is a rare entity characterized by bilateral sensorineural hearing loss that progresses over weeks to months, and is responsive to steroids.
- Primary AIED refers to pathology restricted to the ear, and secondary AIED refers to inner ear involvement of multisystemic autoimmune diseases.
- Autoimmune diseases associated with the inner ear include Cogan's syndrome, Wegener's granulomatosis, systemic lupus erythematosus, rheumatoid arthritis, scleroderma, Sjögren's syndrome, and celiac disease.
- Approximately 50% of patients with AIED have vestibulopathy.
- Studies have shown that the inner ear does not represent an immune-privileged site, but can generate a local immune response after either local or systemic immunization of antigen.
- Studies suggest that there is likely B-cell and T-cell involvement in AIED, but the pathogenesis has not been elucidated.
- Diagnosis of AIED relies on clinical evaluation and a comprehensive assessment of immunologic markers; Western blot for an antibody to a 68-kD protein that binds heat shock protein 70 is not the standard of care in the evaluation of AIED.
- Treatment of AIED is not urgent because there is a 6- to 12-month period in which a significant recovery of hearing is possible with administration of high-dose corticosteroids.
- Initial therapy for AIED is 60 mg of prednisone per day for 4 weeks.
- Response to steroids varies, and treatment is tailored to the initial response.
- Neither etanercept nor methotrexate has been shown to be efficacious in improving hearing loss in patients with AIED.
- Research regarding AIED is important because this is a reversible cause of sensorineural hearing loss; protocols must be informed by expanding knowledge of the pathophysiology of the disorder, and multicenter studies are necessary to evaluate the best use of immunosuppressive drugs.

Otologists and otologic researchers have long believed that the immune system might be capable of damaging the inner ear or eighth cranial nerve, leading to symptoms of hearing loss or dizziness. Some well-documented examples in which systemic autoimmune disease can do this include systemic lupus erythematosus, ulcerative colitis, Cogan's syndrome, and multiple sclerosis. There are some inner ear diseases, such as Meniere's disease and idiopathic sudden sensorineural hearing loss (SNHL), in which an immune-mediated mechanism has been hypothesized but not shown.

One condition—characterized by the clinical presentation of idiopathic, rapidly progressive, bilateral SNHL—has come to be known as autoimmune inner ear disease (AIED), immune-mediated inner ear disease, or immune-mediated cochleovestibular disease. Whether all patients with this presentation have the same underlying pathophysiology, and whether the pathophysiology is autoimmune are unknown. Research regarding AIED is important because the disease represents one of the few medically reversible causes of SNHL.

Definition

Defense against microorganisms is the prevalent concept explaining the evolution and need for the immune system. The immune system must possess the capacity to respond to potential environmental pathogens, and must maintain mechanisms that allow it to distinguish between foreign constituents and the host's own tissue. An autoimmune reaction ensues when the immune system's ability to distinguish between self and nonself is disturbed.

The classic definition of AIED, as provided by McCabe,[1] is that of rapidly progressive (over weeks to months) bilateral SNHL that responds to the administration of immunosuppressive agents. Although McCabe is often credited as the first to describe AIED, the concept of autoimmune hearing loss was first described in the German literature by Lehnhardt in 1958,[2] who described an "antigen-antibody reaction" in the "hearing organs," which improved with steroids. Although this entity is likely an immune-mediated disorder, there is no direct evidence that it is autoimmune in etiology. Nonetheless, the nomenclature coined by McCabe has become established and accepted in the literature.

The disorder defined earlier as AIED refers to a pathology restricted to the ear (primary AIED). Multisystemic, organ-nonspecific autoimmune diseases may involve the inner ear (secondary AIED), however. Such disorders include Cogan's syndrome, Wegener's granulomatosis, systemic lupus erythematosus, and the various systemic vasculitides.

Epidemiology

Primary AIED is a rare disorder. Because of the lack of a definitive diagnostic test for AIED, the precise incidence cannot be determined. It is less common, however, than sudden SNHL, which occurs with an incidence of 1 case per 5000 to 10,000 population per year.[3]

With several exceptions, inner ear involvement is rare in multisystemic autoimmune disorders. Cogan's syndrome, the archetypal AIED, is defined by the presence of labyrinthine and ocular pathology (described in more detail later). Wegener's granulomatosis manifests a significant incidence of ear disease (30% to 50%), with most patients having middle ear pathology, such as chronic otitis media and conductive hearing loss.[4] The presence of concomitant SNHL in patients with middle ear involvement is approximately 30%.[4,5] AIED has been associated with other systemic diseases of the immune system, including rheumatoid arthritis, scleroderma, Sjögren's syndrome, and celiac disease.

Pathology and Pathogenesis

Animal Studies

Various experimental approaches have been used to gain insight into the pathogenesis of AIED. None of these studies has yielded an animal model that is definitively analogous to the human condition, however.

Harris and colleagues[6-8] have contributed significant information to the literature pertaining to the processes mediating inflammation in the inner ear. Using a sterile labyrinthitis, Harris and colleagues[6-8] showed in these studies that the inner ear does not represent an immune-privileged site, but can generate a local immune response after either local or systemic immunization of antigen. These immune responses depend on the presence of an intact endolymphatic sac.[9] Cells that mediate the labyrinthitis enter the scala tympani via the spiral modiolar vein.[10] The ensuing labyrinthitis results in physiologic dysfunction, loss of sensory cells, and, ultimately, fibrosis and osteoneogenesis within the cochlea.[11]

Although these studies shed light on the mechanisms by which an immune-mediated response can be elicited within the cochlea, they do not specifically address the issues of an autoimmune response. To that end, a model of AIED was proposed in which heterologous (bovine) temporal bone antigen and immune adjuvant were used to immunize guinea pigs systemically.[12] This model showed modest changes in physiologic measures of hearing and cochlear morphology. The model has proven to be difficult to replicate, however. The main contribution of this work pertains to the detection of a specific antibody that binds to a 68-kD bovine inner ear antigen on Western blot analysis. This antibody has been found in the guinea pig model, and in humans with AIED.[13] The same antibody also binds to the inducible form of bovine (but not human) heat shock protein 70 (HSP-70), although it does not seem that this antibody is primarily directed against HSP-70 in the in vivo setting. The primary antigenic epitope against which this antibody is directed is unknown, and its role in mediating AIED is unclear.

Another approach to understanding the etiology of this disorder was taken by Nair and coworkers.[14-18] They immunized mice with chick and guinea pig inner ear extracts and created monoclonal antibodies against inner ear cells. One particular antibody, KHRI-3, binds to supporting cells of the organ of Corti, creating a characteristic wine-glass staining pattern when observed through immunofluorescence.[15-18] Infusion of KHRI-3 into live guinea pigs produces hearing loss.[15,16] The KHRI-3 antibody also binds to a 68- to 72-kD antigen on a Western blot of inner ear extract.[18] Sera from some humans with AIED strongly stained a 68- to 72-kD inner ear antigen immunoprecipitated from guinea pig inner ear extract with KHRI-3, and these same patient sera stained organ of Corti–supporting cells in a wine-glass pattern.[19] This is strong evidence that KHRI-3 and human antibodies recognize the same inner ear–supporting cell antigen.

More recent data suggest that KHRI-3 targets multiple peptides similar to those present in the highly conserved protein CTL2, which is abundantly expressed in the guinea pig and human inner ear.[14] CTL2 coprecipitates with the protein cochlin, which is one of the most expressed proteins in the inner ear. Cochlin is critical to the structure and function of the inner ear, and mutations are known to cause cochleovestibular pathology. More recent work reveals that cochlin-specific serum antibody titers are significantly elevated in individuals with AIED compared with age-matched controls.[20] The same study also implicates T-cell response to this specific protein, supporting cochlin as a possible target antigen susceptible to B-cell and T-cell influence.

A third approach has incorporated the study of animal models of multisystemic, organ-nonspecific autoimmune disease. These mouse models of systemic lupus erythematosus spontaneously develop autoimmune disease; they do not require any experimental manipulation. Various strains have been examined, with the most detailed studies focusing on the MRL-Fas^{lpr} and C3H-Fas^{lpr} mice. These strains develop elevations in auditory thresholds, degeneration of the stria vascularis, and antibody deposition within the strial capillaries.[5,21-25] These changes occur in the absence of inflammatory response. The etiology of the observed strial degeneration is unknown. The administration of corticosteroids improves cochlear function in these animals without impeding the development of the morphologic changes.[24,25] Studies have shown that there is similar efficacy in resolution of hearing loss with glucocorticoid and mineralocorticoid administration. These results suggest that the mechanism of reversal of hearing loss occurs as a result of alterations in local ion transport in the cochlea.[25-27]

These studies illustrate that immune-mediated and autoimmune pathology can affect the inner ear. The various pathologies observed in these models do not correlate well, however, with the clinical entity known as AIED.

Human Temporal Bone Studies

A few studies have been performed on human temporal bones derived from patients with autoimmune disease, specifically Wegener's granulomatosis, polyarteritis nodosa, Cogan's syndrome, and systemic lupus erythematosus.[5,21-23] Morphologic changes show findings consistent with two different pathogenic mechanisms. Some bones show fibrosis and osteoneogenesis within the scalae, findings consistent with the end stages of inflammation, as described earlier. Other bones show changes more consistent with ischemia, including cellular atrophy in the absence of inflammation. In cases of ischemia, the vascular compromise is likely secondary to a nonspecific vasculopathy in which the labyrinthine artery becomes occluded in the absence of vascular inflammation and necrosis associated with vasculitis.

Clinical Presentation

The hallmark of AIED, as originally described by McCabe,[1] is the presence of bilateral SNHL that progresses over weeks to months. The hearing loss may initially be unilateral, and it may take months for the bilaterality to emerge. Fluctuations in hearing may occur, but the overall course is one of a relentless deterioration in auditory function. Approximately 50% of patients have symptoms of vestibular dysfunction, with 20% of patients experiencing episodes of vertigo consistent with those seen in Meniere's disease.[5]

Cogan's syndrome represents the classic autoimmune disorder leading to inner ear dysfunction.[21,22] The original definition included the presence of nonsyphilitic interstitial keratitis, SNHL, vertigo, and tinnitus. Labyrinthine pathology may be coincident with the ocular manifestations, or may occur 6 months before or after the onset of eye disease. Other forms of ocular inflammation, including uveitis, iritis, episcleritis, or conjunctivitis, may occur instead of the keratitis, in which case the disorder may be defined as atypical Cogan's syndrome.[21,22] Many patients with Cogan's syndrome note a prodrome with symptoms of an upper respiratory tract infection, symptoms often seen with autoimmune disorders.[28]

Vogt-Koyanagi-Harada syndrome manifests with symptoms similar to those seen in Cogan's syndrome. It also includes depigmentation of the hair and skin around the eyelashes, loss of eyelashes, and onset of aseptic meningitis. This syndrome may represent an autoimmune reaction to melanin-containing cells.[4]

Wegener's granulomatosis is another multisystemic autoimmune disease associated with inner ear dysfunction. The disease is characterized by the granuloma formation and vasculitis typically initially affect-

ing the upper and lower respiratory tracts. Ultimately, it may progress to a more diffuse granulomatous vasculitis with renal involvement. As noted earlier, the disorder is more commonly associated with middle ear disease resulting in a conductive hearing loss. Approximately 10% of patients may manifest an SNHL.[5]

Antiphospholipid antibody syndrome is a disorder of the immune system that causes coagulopathy and is defined by recurrent thrombosis, spontaneous abortions in women, and the presence of antiphospholipid antibodies (anticardiolipin or antilupus anticoagulant antibody). Investigators have noted the association of this autoimmune disorder with SNHL, likely related to microthrombus formation; 25% of all patients who fit the diagnostic criteria for Meniere's disease and idiopathic SNHL have at least one positive antiphospholipid antibody marker.[29]

Systemic vasculitides, such as polyarteritis nodosa, may rarely result in a rapidly progressive hearing loss.[30] In one prospective controlled study, the incidence of SNHL in patients with systemic lupus erythematosus was noted to be 58%.[31] Confounding variables in this study included the administration of potentially ototoxic medications and the presence of renal failure. One temporal bone derived from a patient with lupus did manifest evidence of intracochlear inflammation, including fibrosis and osteoneogenesis.[32]

Differential Diagnosis

AIED may initially manifest in a fashion similar to that seen in sudden SNHL. AIED and idiopathic sudden SNHL are two distinct disorders, however. AIED is considerably rarer than sudden SNHL. AIED is by definition bilateral, although at initial presentation AIED may not have affected both ears, whereas sudden hearing loss is virtually always unilateral. Sudden hearing loss develops in 72 hours or less. In contrast, AIED progresses over days to months; serial audiograms on a monthly basis show continued decline. Sudden hearing loss is an otologic emergency with a treatment window of perhaps 2 to 4 weeks, during which a short burst and taper of corticosteroids must be administered to achieve optimal recovery.

AIED is not urgent. Patients with hearing loss progression over 6 to 12 months can still achieve significant recovery with administration of a long course of high-dose corticosteroids or other immunosuppressive drugs. Throughout the otolaryngology community, there is general awareness that some cases of SNHL are potentially reversible with corticosteroids. There is little awareness, however, that these two entities are quite different in etiology, presentation, workup, and management. Hasty administration of a short tapering course of steroids can delay diagnosis of AIED, and can confuse interpretation of serologic testing.

The clinical presentation of AIED may closely mimic the presentation of Meniere's disease. During the first months of evaluation, the two entities may be difficult to differentiate. Both can manifest fluctuations in hearing and episodic vertigo. If corticosteroids are administered, a spontaneous recovery in hearing, as seen in Meniere's disease, may be mistaken for a positive response to immunosuppressive therapy. Ultimately, the more aggressive course of AIED allows for the differentiation of these two disorders. It has been suggested that a subgroup of patients with symptoms of Meniere's disease may share a common pathophysiology with patients who have AIED. This association is based on studies that have noted that approximately one third of patients with Meniere's disease may have a positive Western blot assay for anti-HSP-70 antibodies.[33,34] This finding was not supported by a later study, however, in which the commercially available assay was used.[35]

Otosyphilis is a disorder that can closely mimic AIED, and must be ruled out as part of the workup. An acoustic neuroma may manifest with sudden or progressive unilateral SNHL. Rarely, meningitis, multiple sclerosis, or malignancy (e.g., metastatic disease, lymphoma) involving the dura may manifest as rapidly progressive bilateral hearing loss.

Diagnosis

In patients suspected to have AIED, an appropriate review of systems would include questions pertaining to recurrent or chronic ocular disease, nephritis, arthritis, pneumonitis, sinusitis, and inflammatory bowel disease. Routine serologic tests in patients who may have AIED include a complete blood count with differential white blood cell count, erythrocyte sedimentation rate, rheumatoid factor, antinuclear antibody test, anti–double-stranded DNA antibodies, anti-SSA/B antibodies, antiphospholipid antibodies, C3 and C4 complement levels, antigliadin antibodies, and Raji cell assay for circulating immune complexes. A fluorescent treponemal antibody absorption test (or a *Treponema pallidum* hemagglutination test) must be obtained to rule out otosyphilis. A human immunodeficiency virus test may be considered to rule out hearing loss associated with acquired immunodeficiency syndrome. This workup is aimed at detecting evidence of systemic immunologic dysfunction. None of these tests has been shown to correlate with the diagnosis of primary AIED. Magnetic resonance imaging with paramagnetic enhancement must be obtained to rule out the retrocochlear lesions discussed earlier in this chapter.

Diagnosis of primary AIED can be difficult. No serologic or immunologic test has yet shown sufficient diagnostic accuracy to allow for the establishment of a definitive diagnosis. Tests of cellular immunity have been advocated by McCabe[23] (lymphocyte migration-inhibition assay), and Hughes and coworkers[36] (lymphocyte transformation test). These tests have never been adequately validated, and their diagnostic accuracy has not been determined. During the 1990s, most attention was focused on the role of Western blotting for detection of an antibody that binds to a 68-kD antigen derived from bovine temporal bone extract and to the inducible form of HSP-70.[5,13,37,38] As noted earlier, these antibodies were first determined to be significant when they were detected in guinea pigs immunized with bovine inner ear extract and in humans manifesting AIED.[13]

In a prospective controlled study, with well-defined entry criteria, Moscicki and colleagues[39] showed that 89% of patients with active, rapidly progressive hearing loss did have detectable levels of this antibody, whereas none of the control patients had positive Western blots. Subsequently, 66 additional cases of possible immune-mediated inner ear disease were studied using the same diagnostic criteria of Moscicki and colleagues.[39] Five patients were excluded from analysis because they had Cogan's syndrome, an autoimmune vasculitis characterized by SNHL, vertigo, and interstitial keratitis of the eyes, leaving 61 patients with AIED. Results are shown in Table 153-1. Demographic features and trends in the correlation of Western blot assay with steroid response in this group of patients are essentially the same as Moscicki's original cohort. The proportion of patients with positive Western blot assay and the proportion of Western blot–positive patients who responded to steroids are lower than in the retrospective study by Moscicki and colleagues.[39]

More recent studies have evaluated the use of positron emission tomography (PET) scan as a tool for the diagnosis of AIED. Although initial observations suggested an association between AIED and positive PET scans, the more recent work fails to show any diagnostic benefit to PET scan.[40,41] At this time, there is no role for PET in diagnosis of AIED.

The diagnosis of primary AIED is based on clinical evaluation, the demonstration of progressive SNHL on audiometric assessment done at monthly intervals, and, most importantly, a positive response to the administration of corticosteroids. The presence of a positive Western blot may support the diagnosis of AIED, but can neither confirm nor rule out the diagnosis.

Treatment

Corticosteroid therapy for AIED evolved during the mid-1980s through the 1990s as a result of clinical experience. Niparko and associates[42] reported a prospective, randomized trial that showed most patients with suspected AIED responded to corticosteroids, although the response was highly variable. These data seem to substantiate the current practice of most otologists. Initial therapy for adults consists of a therapeutic trial of prednisone (60 mg daily for 4 weeks). Pediatric patients receive 1 mg/kg/day of prednisone for 4 weeks. Although patients may occasionally respond early in the 4-week period, many do not begin to improve until late in the month; shorter courses of treatment usually result in relapse.

Table 153-1

Relationship of Western Blot Assay for Anti–Heat Shock Protein 70 Antibodies and Response to Corticosteroid Therapy in 61 Patients with Autoimmune Inner Ear Disease

		Steroid Response	
Western Blot	Positive	Negative	No Prescription
Positive	14	11	7
Negative	5	12	8
Undetermined	2	2	—

From Moscicki RA, San Martin JE, Quintero CH, et al. Serum antibody to increase ear proteins in patients with progressive hearing loss, correlation with disease activity and response to corticosteroid treatment. *JAMA*. 1994;272:611.

Patients' hearing is tested at the initiation of therapy and again at 4 weeks. If the threshold has improved by 15 dB or more at one frequency or 10 dB at two or more consecutive frequencies, or if the discrimination is significantly improved, patients are considered steroid responders. Nonresponders are tapered off their medication in 12 days. Responders continue full-dose therapy until monthly audiograms confirm that they have reached a plateau of recovery. Their medication is slowly tapered over 8 weeks to a maintenance dose of 10 to 20 mg every other day. This maintenance dose is continued for a variable time. Clinical observation suggests that patients with a treatment duration of less than 6 months are at increased risk of relapse compared with patients treated for 6 months or longer.

Patterns of response to corticosteroid therapy vary. Some patients have improvement in threshold, some have improvement in discrimination only, and some experience improvement in both areas. Some patients with hearing loss fluctuation and progression before therapy show stabilization in hearing without actual improvement. Historically, these cases have been considered nonresponders, but this issue is currently being reassessed. Most responders slowly taper off the steroid dose, wean from steroids, and do well. A subset of AIED patients relapses while tapering or after discontinuing the medication. In some instances, additional corticosteroid therapy is effective. Occasionally, the hearing loss becomes refractory to corticosteroids. In such cases, alternative immunosuppressive drugs are considered. Some patients, especially children, may occasionally show steroid-dependent hearing loss. In other words, they cannot be weaned below a certain level of steroid dosage without decline in hearing. Such patients often develop unacceptable side effects of long-term steroid administration. Methotrexate has been used as part of a prednisone-sparing regimen; however, a more recent randomized, prospective controlled, multicenter trial has shown methotrexate to be no better than placebo at maintaining a remission in these patients.[43]

Corticosteroid therapy has limitations. The risks of long-term administration include gastritis and ulcers, fluid retention and weight gain, blood pressure lability, altered blood glucose metabolism and diabetes, avascular necrosis of the hip, mood changes or psychiatric problems, sleep disturbance, accelerated cataract formation, osteoporosis, and cushingoid habitus. Overall steroid response rate is approximately 60% in AIED patients. Some initial responders become refractory at the time of relapse. Despite these limitations, corticosteroid therapy remains the mainstay of AIED treatment on the basis of the extensive clinical experience with its use.

Alternatives to systemic corticosteroids include methotrexate, etanercept, and cyclophosphamide. Low-dose methotrexate seemed to be useful as an adjunct in management of steroid-dependent hearing loss.[44] As noted earlier, a more recent large trial indicates that methotrexate may not serve an effective role as a prednisone-sparing drug.

Etanercept, an inhibitor of tumor necrosis factor-α, has been used to treat AIED. Anecdotally, it seems to work well in combination with methotrexate because of its steroid-sparing effect. As seen in rheumatoid arthritis, etanercept alone does not seem to be nearly as effective. In an open-label and blinded, prospective study, etanercept was shown not to be efficacious in improving hearing loss in patients with AIED.[40,45] A more recent study of nine patients showed, however, that the administration of transtympanic tumor necrosis factor-α inhibitor may aid in the tapering of high-dose steroids in AIED.[46] Although this is a pilot study, the results are promising and warrant further investigation.

Cyclophosphamide is a potent cytotoxic agent generally used for cancer chemotherapy and treatment of Wegener's granulomatosis. Although some authors advocate its use as a first-line drug,[23] the high risk of toxicity makes it a better choice as a salvage drug or treatment of last resort. An initial dose of 1 mg/kg/day orally for 4 to 6 weeks may be instituted. When no response is apparent, the dose is doubled to 2 mg/kg/day. Responders are treated for 6 to 12 months. Toxicity includes severe myelosuppression, opportunistic infection, hair loss, cystitis, infertility, and increased risk of malignancies. Weekly monitoring of hematologic status is mandatory. Many patients, when confronted with the risk of this medication, would rather consider cochlear implantation.

Intratympanic steroid therapy, intratympanic tumor necrosis factor-α inhibitor, systemic IgG injections, and plasmapheresis are possible treatments with sound theoretic justification. Intratympanic steroid therapy is particularly appealing because it is minimally invasive and enables direct application of the drug to the affected site with low risk of systemic effects. There are, however, no published series in which these treatments have been systematically applied. The best role for any of these treatment modalities remains to be determined.

The only drugs of proven utility in the management of AIED are the corticosteroids. All other immunosuppressants currently employed have not been systematically evaluated and carry with them serious toxicity risks. In a patient who cannot be maintained on corticosteroids because of complications, the possibility of withdrawing treatment, with the intention of inserting a cochlear implant when hearing becomes significantly impaired, must be considered.

Summary and Future Directions

The story of AIED from the initial description by McCabe to current therapy practices has been presented here as a simple and direct path. That has not been the actual case. It has been a broad and meandering path with significant contributions by many investigators and numerous important digressions. It is a story that still has far to go. The clinical description of this disorder is confined to its auditory manifestations. As noted earlier, 50% of AIED patients have vestibular symptoms. This aspect of the illness has not been well characterized clinically. Just as there are many AIED patients with auditory symptoms exclusively, there may be an equal number with vestibular symptoms exclusively. Such a presentation has not yet been reported.

Little is understood about the underlying pathophysiology of AIED. That SNHL can be reversible flies in the face of accepted dogma that, after SNHL, hearing cannot be restored. It is interesting to consider what pathophysiologic mechanism could disable neural signal transduction or transmission in the auditory system, yet be reversed months later by anti-inflammatory or immunosuppressive drugs. A solution to this puzzle is expected to come from systematic research into the nature of the humoral and cell-mediated immune response of affected patients. Although the Carey model using KHRI-3 is promising, as yet there is no widely accepted animal model of the AIED phenomenon in which to carry out such research, and human studies progress slowly because of the lack of the clinical material. This scarcity does not diminish the significance of the topic, however.

Understanding the mechanism of AIED would provide a new level of insight into the role of systemic and organ-specific immune reactions in disease of the inner ear. The fact that 20% of AIED patients

have a clinical presentation overlapping with Meniere's disease, and 33% of Meniere's disease patients have evidence of antibodies to the 68- to 72-kD antigen by Western blot assay is strong evidence of a shared pathophysiologic mechanism. Although AIED is rare, Meniere's disease is not. In the United States alone, there are an estimated 125,000 cases yearly. New ways of understanding Meniere's disease could have great public health benefit.

Diagnosis of AIED currently relies on clinical factors alone. As stated earlier, the observation that many AIED patients carry serum antibodies reactive with HSP-70 does not seem to implicate HSP-70 in the pathophysiology of AIED. HSP-70 may carry an epitope shared with the true target antigen, or may otherwise colocalize with it biochemically. Despite poor understanding of AIED pathophysiology, detection of this, CTL2, cochlin, or other marker antibodies may become clinically useful. The utility of an assay would be greatly enhanced by development of a quantitative measure that enables clinicians to follow antibody titers by serial testing. In addition, estimation of sensitivity and specificity of the assay must be made by its broad application to a wide variety of ear diseases and immunologic disorders.

Current AIED therapy is based on empiric experience gathered during the late 1980s and through the 1990s, and validated by more recent clinical studies; this is despite a clear understanding of the underlying pathophysiology. Future therapeutic protocols must be informed by expanding knowledge of the pathophysiology of the disorder. Large multicenter studies are necessary to evaluate carefully the best use of corticosteroids and other immunosuppressive drugs. Consensus must be achieved on the clinical diagnostic criteria and treatment regimens to enable comparison between studies. Even with strict adherence to rigorous methodology, it may take many years to address these questions. For the foreseeable future, AIED will remain one of the most interesting, important, and challenging problems confronting otologists and otologic researchers.

CHAPTER ONE HUNDRED AND FIFTY-FOUR

Vestibular and Auditory Ototoxicity

Leonard P. Rybak

Key Points

- Measurement of peak and trough serum levels of aminoglycosides provides rough guidelines for therapeutic efficacy, but is not an absolute guarantee for prevention of ototoxicity, particularly vestibular ototoxicity.
- Bacteremia, fever, hepatic dysfunction, the presence of another ototoxic, and renal dysfunction have been associated with increased incidence or severity of ototoxicity of aminoglycosides.
- Aminoglycosides seem to form an ototoxic complex with iron.
- Ototoxicity from aminoglycosides may be reduced by pretreatment with salicylates.
- Although some clinical improvement can be seen beginning 2 months after onset of symptoms, recovery from oscillopsia resulting from aminoglycoside ototoxicity is rarely complete.
- Cisplatin and aminoglycoside antibiotics damage outer hair cells in the base of the cochlea, resulting in high-frequency sensorineural hearing loss that may later involve lower frequencies.
- There is a genetic predisposition to aminoglycoside-induced hearing loss that involves a mutation of mitochondrial DNA.
- Ototoxicity caused by aminoglycosides and cisplatin seems to be related to the production of reactive oxygen species that damage the hair cells, resulting in cell death and hearing loss.
- Hearing loss caused by cisplatin seems to be highly variable, and seems to be related to dose; age of the patient; and other factors such as noise exposure, exposure to other ototoxic drugs, depleted nutritional state including low serum albumin and anemia, and cranial irradiation.
- Ototoxicity with difluoromethylornithine, salicylates, and erythromycin is nearly always reversible.
- Hearing loss caused by abuse of hydrocodone does not respond to corticosteroids.

Ototoxicity refers to the tendency of a drug or chemical agent to cause inner ear dysfunction, producing symptoms of hearing loss, dizziness, or both. Inner ear tissues may be damaged either temporarily or permanently. Many agents can cause ototoxicity. This chapter discusses some common drugs that can cause hearing loss or injury to the cochleovestibular apparatus.

Aminoglycoside Antibiotics

The aminoglycoside antibiotics are an important class of anti-infectious agents. They were developed to combat tuberculosis and other life-threatening infections. The first members of this class of drugs were streptomycin and dihydrostreptomycin. Initial clinical trials showed that these compounds could damage the kidneys and the inner ear. Since then, many new aminoglycosides have been developed. Dihydrostreptomycin proved to be too toxic and was taken off the market. Neomycin was found to be too toxic for systemic use and has been relegated to local application. Other members of this group of drugs include kanamycin, gentamicin, tobramycin, amikacin, netilmicin, and sisomicin. Some of these agents are more toxic to either the cochlea or the vestibular apparatus, although their ototoxicity is not completely selective. Toxicity generally occurs only after days or weeks of exposure. The overall incidence of aminoglycoside auditory toxicity is estimated to be approximately 20%, whereas vestibulotoxicity may occur in about 15%.[1]

Pharmacokinetics

Aminoglycosides are highly charged molecules and are poorly absorbed orally. Only approximately 3% of an orally administered dose is absorbed from the gastrointestinal tract. Aminoglycosides are normally used parenterally for severe systemic infections. The concentrations of aminoglycosides in tissues are usually approximately one third of the corresponding serum concentration. Penetration of the blood-brain barrier is generally poor, so aminoglycosides are injected intrathecally to treat meningitis. Previous studies have suggested that aminoglycosides are not metabolized. A toxic metabolite may be formed in the inner ear, however.[1] Aminoglycosides are excreted primarily by the kidney by glomerular filtration, and high concentrations of drug in the urine may be achieved. Impaired renal function reduces the rate of excretion. Renal failure is a risk factor for ototoxicity, and dosing of aminoglycosides must be modified to compensate for delayed renal excretion.

Measurement of peak and trough serum levels of aminoglycosides provides rough guidelines for therapeutic efficacy, but is not an absolute guarantee for prevention of ototoxicity, particularly vestibular ototoxic-

ity. An association between trough levels of aminoglycosides and ototoxicity has been pointed out.[2] Ototoxicity is likely related to the area under the curve of blood levels over time, rather than individual peak and trough measurements.[3] An animal study showed no relationship between ototoxicity and plasma level of aminoglycoside. The total dose or area under the curve was a much better predictor of amikacin ototoxicity in this animal model.[4]

Suggested guidelines for monitoring serum levels of aminoglycosides are as follows:

1. In patients with normal kidney function, the peak level is measured within the first 1 or 2 days of treatment, the trough level is measured within 1 week, and peak and trough levels are measured about every week after that.

2. In patients with impaired but stable renal function, the peak level is determined within the first 2 days of treatment, the trough and another peak level are determined within 1 week, and peak and trough levels are measured about twice weekly thereafter.

3. In the presence of impaired and unstable kidney function, peak and trough levels are obtained within the first 2 days of therapy. Serum levels may need to be measured every day as long as renal function is unstable.

4. After any changes in dosage, peak and trough levels are determined within the next 2 days.[5]

Aminoglycoside ototoxicity may be detected, but because of a life-threatening infection and a lack of suitable alternative antibiotic therapy, it may be necessary to continue treatment. Antibiotic ototoxicity may continue even after cessation of aminoglycoside therapy.[5]

More recent studies in animals and in humans have shown the presence of a metabolite of streptomycin in the serum of patients with tuberculosis treated with streptomycin. Five male patients treated with streptomycin for 35 to 90 days with 1 g/day presenting with mild to severe inner ear malfunction were found to have streptidine present. Streptidine may represent an ototoxic metabolite of streptomycin.[6]

Histopathology

Animal and human temporal bone histopathologic studies show that the cochlear and vestibular hair cells serve as primary targets for injury. In the organ of Corti, the outer hair cells of the basal turn are damaged first. As drug treatment is continued, the damage may spread to more apical regions. Inner hair cells seem to be more resistant to injury than outer hair cells. This difference could be a result of the higher concentration of the natural antioxidant, glutathione, in the inner hair cells and in the apical turn outer hair cells compared with in the outer hair cells of the basal turn.[7] Progressive destruction of spiral ganglion cells has been shown in animal studies and in human temporal bone reports.[8,9] In some patients, spiral ganglion cells may be damaged directly by aminoglycosides without injury to outer hair cells.[10] The stria vascularis may become thinner as a result of marginal cell death.[11] In the vestibular system, the hair cell damage may begin in the apex of the cristae and in the striola regions of the maculi.[12] Hair cell destruction may extend to the periphery of the vestibular sensory epithelium, where type I hair cells are primarily affected.[13]

A quantitative study of 17 temporal bones was carried out in patients with well-documented clinical evidence of aminoglycoside ototoxicity, and the results were compared with age-matched controls. Streptomycin caused a significant loss of type I and type II hair cells in all vestibular organs, with a greater loss of type I hair cells in the cristae, but not in the maculae. The vestibular toxic effects of kanamycin seemed to be similar to streptomycin, but neomycin did not cause the loss of any vestibular hair cells. There was no significant loss of Scarpa's ganglion cells for any of the aminoglycosides.[14]

Clinical Manifestations

High-frequency hearing loss tends to occur first and may be detectable before it becomes clinically noticeable.[15] Continued exposure to aminoglycosides may result in hearing loss that progresses to lower frequencies, including the important speech range, interfering with communication skills. A hearing loss of 20 dB or more at two or more adjacent frequencies should be documented to confirm the diagnosis of drug-related hearing loss after exclusion of other causes of hearing loss.

Delayed ototoxicity may occur after cessation of treatment with aminoglycoside antibiotics. Delayed onset of hearing loss usually manifests within 1 to 3 weeks after the end of therapy.[16]

Onset of vestibular ototoxicity is unpredictable, and may not correlate with cumulative dose of ototoxic medication.[17] Ambulatory patients are asymptomatic until they notice the presence of imbalance and ataxia, dramatically worsened by motion, with relative freedom from symptoms during periods of complete immobility. Patients change from being normal to being symptomatic during an easily identifiable 1- or 2-day period, after which symptoms are always present during motion or ambulation. The severity of symptoms varies, ranging from imbalance and staggering to complete inability to walk without assistance. Severely affected individuals also usually experience oscillopsia. Although some clinical improvement can be seen beginning 2 months after onset of symptoms, it is rarely complete.[18]

Rotational vestibular testing in a few patients indicated that results were normal in patients receiving aminoglycoside therapy who were asymptomatic. When abnormalities were observed, as they always were in symptomatic patients, the low-frequency rotational responses were affected first and most severely. When responses to all frequencies were absent, oscillopsia and severe imbalance were usually present. Improvement in function sometimes could be shown by rotational testing. This improvement was always greatest in the high frequencies, and clinical recovery was often not as great as the improvements in test results would have suggested.[18]

Various risk factors have been studied to determine whether they play a role in increasing the likelihood of ototoxicity in various patient populations. Bacteremia, fever, hepatic dysfunction, and renal dysfunction have been associated with ototoxicity in prospective, double-blind clinical trials of gentamicin, tobramycin, and amikacin.[19] Combinations of another ototoxic drug and an aminoglycoside may increase the risk and severity of ototoxicity. Ethacrynic acid was reported to exacerbate the ototoxicity of aminoglycosides in patients with uremia.[3] Furosemide was reported to result in severe sensorineural hearing loss (SNHL) in a patient who had received only five doses of gentamicin for pneumonia.[20] An extremely important risk factor is a mitochondrial RNA mutation, which dramatically increases the risk of ototoxicity. This mutation may sensitize a patient to even a single dose of aminoglycoside. This mutation follows a maternal inheritance pattern, and has been described in Chinese, Arab-Israeli, Japanese, and North American families.[21] Seventeen percent of patients with aminoglycoside-induced hearing loss may have this mutation.[1]

Mutations in mitochondrial 12S ribosomal RNA render patients highly susceptible to aminoglycoside ototoxicity. The first described mutation was an A1555G mutation in the 12S rRNA gene. Mutations in the mitochondrial 12S rRNA make this mammalian RNA more similar to the bacterial rRNA, the primary target of the bactericidal activity of aminoglycosides.[22] This mutation has been associated with spontaneous and aminoglycoside-induced hearing loss. In China, where this mutation seems to occur in 5% to 6% of sporadic patients, approximately one third of patients with aminoglycoside ototoxicity seem to have the A1555G mutation.[22] For an unknown reason, only the auditory system, but not the vestibular part of the inner ear, is sensitized to the toxic effects of aminoglycosides in patients with this mutation.[1]

The risks of intratympanic therapy for Meniere's disease and the use of potential otoprotective agents to prevent or reduce aminoglycoside ototoxicity are discussed in greater detail in Chapters 149, 155, and 165.

Mechanisms of Ototoxicity

Aminoglycosides, such as dihydrostreptomycin, enter the mouse outer hair cell through the mechanoelectrical transduction channel and act as a permeant blocker.[23,24] This channel can act as a one-way valve for aminoglycoside entry, promoting the accumulation of aminoglycoside

within the cell. There seems to be a competition between the aminoglycoside and calcium for entry into the outer hair cell. The normal low endolymph concentration of calcium promotes intracellular accumulation of aminoglycosides.[24]

The aminoglycoside reacts with inner ear tissues to form an active, ototoxic metabolite. The drug in its inactive form combines with iron to form an ototoxic complex. This complex reacts with oxygen to produce reactive oxygen species (ROS). These ROS can react with various cell components, primarily in the outer hair cell.

ROS formation by aminoglycosides in vitro requires iron and the presence of polyunsaturated lipids as electron donors. Electron spray ionization mass spectrometry showed that gentamicin strongly binds to L-R-phosphatidylinositol 4,5-bisphosphate (PIP_2), a membrane lipid rich in arachidonic acid. Studies using lipid-coated membranes confirmed that iron ions and gentamicin can form ternary complexes among gentamicin, iron, and phospholipids. Peroxidation of PIP_2 by ferrous ions significantly increased in the presence of gentamicin, and oxidative damage to PIP_2 was accompanied by the release of arachidonic acid. Arachidonic acid also forms a ternary complex with Fe^{2+}/Fe^{3+}-gentamicin. This complex reacts with lipid peroxides and molecular oxygen, leading to arachidonic acid peroxidation.[25] These ROS can react with various cell components, including the phospholipids in the cell membrane, proteins, and DNA to disrupt the function, primarily in the outer hair cell. This process can trigger programmed cell death, resulting in apoptosis.[1]

Data from experimental studies strongly suggest that aminoglycosides trigger apoptosis at clinically relevant doses,[26] whereas higher doses may trigger necrotic cell death.[27] The ototoxic effects of neomycin[28,29] seem to be mediated by c-Jun N-terminal kinase (JNK). JNK[30] and extracellular regulated kinase (ERK) 1/2 mitogen-activated protein kinases seem to be associated with gentamicin-induced apoptosis in the inner ear.[31] Gentamicin seems to trigger apoptosis by ROS and to be mediated by Ras/Rho GTPases.[30]

Inhibitors of apoptosis proteins play an important role in regulating apoptosis by preventing activation of effector caspases. The effects of specific inhibitors of the X-linked inhibitor of apoptosis (XIAP) on hair cell death caused by gentamicin were examined in basal turn organ of Corti explants from postnatal day 3 or 4 rats in tissue culture exposed to gentamicin. XIAP inhibitors increased gentamicin-induced hair cell loss, but an inactive analog had no effect. A caspase-3 inhibitor decreased caspase-3 activation and hair cell loss from gentamicin plus an XIAP, but caspase-8 and caspase-9 inhibitors did not. These findings indicate that XIAP acts normally to decrease caspase-3 activation and hair cell loss during gentamicin ototoxicity.[32]

Apoptosis may be related to the enzyme protein kinase C zeta. Amikacin treatment in animals induced the cleavage of this enzyme and nuclear translocation, leading to chromatin condensation and decreased nuclear factor kappa B (NFκB) levels in the nucleus. These deleterious effects were prevented by pretreatment with aspirin, resulting in protection of hair cells and spiral ganglion neurons.[33]

Concentration-dependent protection against the ototoxicity of kanamycin combined with ethacrynic acid was found in guinea pigs receiving dexamethasone by intracochlear administration with an osmotic minipump before and after the ototoxic treatment. A statistically significant preservation of outer hair cell counts and lower auditory brainstem evoked potential threshold shifts were found in the dexamethasone-infused ears. No significant rescue was observed.[34]

Antineoplastic Agents

Cisplatin

Cisplatin is a potent antineoplastic agent that is used to treat various malignant tumors, including ovarian, testicular, bladder, lung, and head and neck carcinomas. Side effects include nausea and vomiting, neurotoxicity, ototoxicity, and nephrotoxicity.

Pharmacokinetics

The pharmacokinetics of cisplatin follow a biphasic clearance pattern. After a 1-hour intravenous infusion of 70 mg/m^2, the plasma half-lives in patients were 23 minutes and 67 hours; 17% ± 2.7% of the dose administered was excreted in the urine within the first 24 hours, primarily by glomerular filtration. Cisplatin is extensively bound to serum proteins. This bound form is inactive against tumor cells. The half-lives of free cisplatin in serum are much shorter than the total platinum, with half-lives of 8 minutes (free cisplatin) and 40 to 45 hours (total platinum).[35] The liver rapidly converts cisplatin into nontoxic metabolites within 1 hour after administration. The cytosol of the liver cells seems to form adducts of cisplatin with glutathione and cysteine. Cisplatin is taken up into the cells of the cortex and outer medulla of the kidney during the time when nephrotoxicity begins.[36]

Clinical Ototoxicity

Hearing loss caused by cisplatin seems to be highly variable, and seems to be related to dose; age of the patient; and other factors such as noise exposure,[37] exposure to other ototoxic drugs, depleted nutritional state including low serum albumin and anemia,[38] and cranial irradiation.[39] Children seem to be more susceptible than adults.[40] Hearing loss tends to be permanent and bilaterally symmetric. Symptoms of ototoxicity include subjective hearing loss, ear pain, and tinnitus.[41] Tinnitus has been reported in 2% to 36% of patients treated with cisplatin, and may be transient or permanent.[41] Although higher frequencies are affected first, hearing impairment may extend into the middle frequency range when doses greater than 100 mg/m^2 are used. When ultra-high-frequency audiometric testing is used, 100% of patients receiving high-dose cisplatin (150 to 225 mg/m^2) may show some degree of hearing loss.[38] Dose-related ototoxicity is illustrated by a report that 20% of patients treated with cisplatin for testicular cancer experienced permanent ototoxicity, but more than 50% of patients who received cisplatin in doses of greater than 400 mg/m^2 cumulative dose had permanent hearing loss.[37]

Pediatric patients were studied for cisplatin ototoxicity by use of otoacoustic emissions. A good correlation between transient otoacoustic emissions and pure-tone audiometric threshold was shown in children with normal middle ear function. In this series, 90.5% of patients had a significant SNHL at 8 kHz. The magnitude of the hearing loss was associated with young age at first dose of cisplatin administration, large number of cycles of chemotherapy, and high cumulative dose of cisplatin.[42]

The incidence and severity of hearing loss are reportedly enhanced by cranial irradiation.[39] Patients with nasopharyngeal carcinoma seem to be particularly susceptible to the interaction of cochlear irradiation and cisplatin chemotherapy. The required dose of radiation that acts on the cochlea is greater than 48 Gy in such patients.[43] A more recent study reported that radiation therapy for brain tumors, such as medulloblastoma, can be modified to reduce the doses of radiation to the cochlea, while still delivering full doses to the desired target volume of tissue. Using the technique of intensity-modulated radiation therapy for these tumors, far fewer patients had hearing loss. Only 13% of patients receiving the intensity-modulated radiation therapy protocol with cisplatin had grade 3 or 4 hearing loss compared with 64% of the conventional radiation therapy group.[39]

Whether hearing loss progresses after cessation of cisplatin chemotherapy has been a matter of controversy. It has been reported that 8 years after cisplatin therapy for testicular cancer, elevated urinary and serum platinum levels can be measured; nevertheless, no long-term toxicity was detected in these patients.[44] Long-term audiometric studies of 26 women treated with moderate-dose cisplatin (50 mg/m^2 body surface area every 4 weeks) for gynecologic cancer showed progressive hearing loss equal to or greater than 15 dB at long-term (59 to 115 months after treatment) follow-up in 14 patients (54%). These changes were considered to be small and restricted to three frequencies or fewer in one ear. Only two patients (8%) showed more severe threshold changes. The authors concluded that adult patients who receive treatment with moderate-dose cisplatin have a negligible long-term risk of drug-induced social disability from hearing.[45]

Delayed ototoxicity from cisplatin seems to be much more significant in children. Pediatric patients treated with cisplatin at cumulative doses approaching 400 mg/m^2 showed worsening of hearing with time after treatment. Audiograms showed hearing loss in 5% of patients before the end of therapy. After more than 2 years of follow-up, 44%

had significant hearing loss.[46] A more recent study found that the median time for first significant decrease in hearing was 135 days in children. Additional follow-up for 6 to 44 months showed mild further progression of hearing loss of 10 to 15 dB after completion of therapy.[47]

Studies of vestibular function in patients receiving cisplatin chemotherapy have suggested vestibulotoxic effects, especially in patients with preexisting vestibular problems.[48] With the vestibular autorotation test to study the vestibulo-ocular reflex, patients receiving cisplatin were screened for vestibulotoxicity. Vestibulo-ocular reflex gains at 3.1 Hz, 3.9 Hz, and 5.1 Hz were decreased, and phase lags at 3.1 Hz and 3.9 Hz were increased.[49]

Because chemoradiation protocols with intra-arterial cisplatin include thiosulfate protection, one may think that there would be less ototoxicity with this regimen than with intravenous cisplatin. This does not seem to be the case, however. A prospective study[50] evaluated 146 patients receiving high-dose intra-arterial cisplatin chemotherapy (150 mg/m^2 for four courses) with sodium thiosulfate rescue and concurrent radiation therapy (70 Gy) for locally advanced head and neck cancer. After treatment, 23% of the ears were recommended to need hearing aids. With multivariate analysis, cumulative dose of cisplatin and radiation, and young age were found to have a causal relationship with increased SNHL during and after therapy. In the multivariate prediction analysis, the pretreatment hearing level of the involved ear was found to be an independent predictive factor for hearing capability after therapy.

Maximum threshold shifts occurred after the second cisplatin infusion, and occurred at 8 kHz. Hearing loss seemed to reach a plateau at higher levels (75 to 80 dB hearing loss) for frequencies greater than compared with frequencies less than 8 kHz (45 to 60 dB hearing loss). Recovery was detected after therapy in 27 ears that had extensive losses at 1 kHz, 2 kHz, and 4 kHz.[51]

Risk Factors

There seems to be considerable individual variation in susceptibility to cisplatin ototoxicity. The severity of hearing loss seems to be related to the cumulative dose.[43] Age seems to be an important risk factor for ototoxicity. Children younger than 5 years and elderly adults are more susceptible to cisplatin-induced hearing loss than younger adults.[52,53] Additional factors, such as renal insufficiency and preexisting hearing loss and noise exposure, may increase the probability of cisplatin ototoxicity.[37]

Genetic Predisposition

Genetic predisposition to cisplatin-induced hearing loss may be related to mitochondrial mutations. Five of 20 cancer survivors with cisplatin ototoxicity were clustered in a rare European J mitochondrial haplogroup that is also associated with Leber's hereditary optic atrophy.[54] Other genetic factors may render patients susceptible to cisplatin ototoxicity. Testicular cancer survivors who received cisplatin chemotherapy showed differences in functional polymorphisms for glutathione-S-transferase. Having both alleles of 105Val-GSTP1 seemed to offer protection against hearing loss from cisplatin. The risk of having a poor hearing result was more than fourfold greater in patients with 105Ile/105Ile-GSTP1 or 105Val/105Ile-GSTP1. Genotypes associated with poorer hearing after cisplatin could indicate patients with a limited amount of glutathione for detoxification of cisplatin.[55]

Another potential genetic variant that could influence cisplatin susceptibility is megalin. Megalin is a member of the low-density lipoprotein family that is highly expressed in kidney proximal tubular cells and in marginal cells of the inner ear. Marginal cells have been shown in experimental animal studies to accumulate high levels of platinum-DNA adducts.[56] Twenty-five patients who developed hearing loss after cisplatin therapy were compared with 25 patients who received cisplatin chemotherapy without hearing loss, and were tested for nonsynonymous single nucleotide polymorphisms of megalin. A higher frequency of the A-allele of rs2075252 was observed in patients with hearing impairment compared with patients with normal hearing after cisplatin treatment. These findings suggest that single nucleotide polymorphisms at the megalin gene may affect individual susceptibility to cisplatin ototoxicity.[57]

Histopathology

Human temporal bone histopathology studies have shown the effects of cisplatin on the inner ear. The cochlea of a 9-year-old child with a brain tumor who sustained hearing loss after cisplatin showed degeneration of outer hair cells in the lower turns of the cochlea, spiral ganglia, and cochlear nerve. The vestibular ganglion cells and vestibular nerve were reportedly normal.[58] Scanning electron microscopic studies of the inner ear tissues of five patients with cisplatin ototoxicity revealed fusion of stereocilia of the outer hair cells, with damage to the cuticular plate.[59] Another study of patients receiving cisplatin with or without irradiation revealed a decreased number of inner and outer hair cells and spiral ganglion cells. The stria vascularis was also found to be atrophic.[60]

Experimental Studies

Histopathologic studies of the inner ear in animals mirror the findings reported in humans. The outer hair cells of the basal turn of the cochlea are damaged first, which extends to the more apical cells when dosing is continued.[41,61] The first row of outer hair cells seems to be most vulnerable.[41] Damage progresses to the outer hair cells, with dilation of the parietal membrane, softening of the cuticular plate, vacuole formation, and increased number of lysosome-like bodies in the apical portion of the hair cells. Stereocilia abnormalities, including fusion, on inner and outer hair cells are visible.[62] Damage to the stria vascularis can also occur, especially after exposure to high-dose cisplatin.[63] Electrophysiologic studies have shown that cisplatin ototoxicity can be manifested by a decrease in the endocochlear potential,[64] by elevation in auditory brainstem response thresholds,[64-67] and by elevations of the distortion product otoacoustic emissions (DPOAE).[65,68,69] The DPOAE input/output protocol is most sensitive for early detection of hair cell damage.[65] Elevations of DPOAE thresholds 4 days after cisplatin infusion in dogs could not be attributed to differences in peak plasma platinum levels. The variability in susceptibility in individual animals could not be explained by variations in plasma concentration of filterable platinum between animals.[69]

Mechanisms of Ototoxicity

The ototoxicity of cisplatin seems to be mediated by the production of ROS. Reactive oxygen molecules such as superoxide anion, hydrogen peroxide, and reactive nitrogen species such as nitric oxide can cause cell damage by reacting with cellular lipids, proteins, and DNA. The inner ear has an antioxidant defense system, consisting of the tripeptide glutathione and its related antioxidant enzymes, such as glutathione peroxidase, glutathione reductase, and the other antioxidant enzymes catalase and superoxide dismutase. Glutathione and the antioxidant enzymes have been shown to be decreased in association with cisplatin-induced ototoxicity in the rat.[66,67] Cisplatin has been shown to increase the formation of ROS in the cochlea by use of electron paramagnetic resonance spectrometry[70] and fluorescent dyes.[71] The production of superoxide anions inside the cochlear hair cells has been shown in vitro by use of the nitroblue tetrazolium reduction assay.[72] Superoxide dismutates to hydrogen peroxide either spontaneously or by means of superoxide dismutase. Increased hydrogen peroxide formation has been detected in the inner ear after cisplatin exposure.[70]

One of the enzymes that can produce superoxide radicals is an isoform of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, NOX-3, which is unique to the cochlea. Cisplatin has been shown to activate this enzyme, leading to a dramatic increase in superoxide production[73] not only in cochlear cell lines, but also in the cochlea of rats exposed to cisplatin.[74] Superoxide can lead to the formation of hydrogen peroxide, as just shown. The latter can be catalyzed by iron to form the very reactive hydroxyl free radical, which can react with polyunsaturated fatty acids in membranes to form the extremely toxic aldehyde, 4-hydroxynonenal. Superoxide can also react with nitric oxide to form peroxynitrite, which reacts with proteins to form nitrotyrosine. Cochlear hair cells of cisplatin-treated guinea pigs show immunoreactivity for 4-hydroxynonenal, but auditory neurons were found to be immunopositive for 4-hydroxynonenal and nitrotyrosine.[75]

Because iron chelators have been shown to provide partial protection to hair cells exposed to cisplatin in vitro, it has been proposed that

part of the ototoxic mechanism of cisplatin includes an iron-dependent pathway.[72] The reaction of ROS with the plasma membrane leads to the formation of membrane lipid peroxidation products such as 4-hydroxynonenal, which are highly reactive and can lead to cellular damage and cell death.[76] The primary target of cisplatin ototoxicity seems to be the outer hair cells, with the hair cells in the basal turn being most susceptible. This increased susceptibility may result from the relatively low stores of glutathione in the outer hair cells of the basal turn compared with the inner hair cells and the outer hair cells in the more apical turns.[7] The ROS and reactive nitrogen species can attack cellular components as discussed previously, and superoxide anion can react with nitric oxide to form the highly toxic peroxynitrite, which can also attack cellular components.

A partial scheme for the mechanism for cisplatin ototoxicity has been shown in vitro. The reactive molecules, such as superoxide anion, nitric oxide, and others, can activate a cellular protein, p53. This activation can activate enzymes in the cell death pathway, the caspases. Caspase-8 has been shown to be activated, which converts a cellular protein BID from an inactive to an active form, truncated BID. Activated BID acts on a cytosolic protein, BAX, which translocates to the mitochondria. Activated BAX makes the mitochondrial membrane leaky, and the mitochondrial enzyme cytochrome-*c* leaks out into the cytoplasm. Cytosolic cytochrome-*c* interacts with another cell death enzyme, caspase-9, which activates caspase-3 and caspase-7, resulting in apoptosis or death of hair cells.[77] The application of caspase inhibitors to organ of Corti explants before and during exposure to cisplatin in vitro prevented apoptosis of hair cells.[78] This finding provides further evidence that cisplatin ototoxicity may be mediated by the cell death pathways, resulting in hair cell death and permanent hearing loss. These results need to be confirmed by the use of in vivo models of cisplatin ototoxicity. Additional research may provide clinically useful drugs that can block parts of these pathways and protect against ototoxicity of cisplatin.

A more recent study in rats treated with cisplatin confirmed that cisplatin induces an intrinsic apoptotic pathway in the cochlea. Cisplatin significantly increased the levels of caspase-3 and caspase-7 activity, active caspase-3 protein expression, and caspase-9 activity, and increased BAX protein expression accompanied by a decrease in the anti-apoptotic protein Bcl-2 expression in the cochlea. These changes were accompanied by elevation of auditory brainstem response threshold measurements.[79]

Cisplatin-induced cell death may be independent of p53 and caspases. A more recent study using the OC-k3 cell line exposed to cisplatin suggested that the mitogen-activated protein kinase cascade may be involved in induction of cell death by cisplatin. Cells exposed to cisplatin were found to express an increased phosphorylation of ERK 1/2 that was inhibited by PD98059 and suramin. Both of these inhibitors protected these cells from cisplatin-induced cytotoxicity. Activated ERK 1/2 may be a main effector of cell death, causing nuclear fragmentation, actin cytoskeleton rearrangement, and cell death. Cell death from cisplatin apparently occurred in a p53-independent and caspase-independent manner because these cell lines are functionally depleted of p53.[80]

Inflammatory cytokines may also play a role in cisplatin ototoxicity. These cytokines (tumor necrosis factor [TNF], interleukin-1β, and interleukin-6) may be up-regulated by activation of ERK and NFκB; this was shown in HEIOC1 cells in vitro. Neutralization of these cytokines by antibodies and pharmacologic inhibition of ERK significantly reduced the death of these cells exposed to cisplatin. These in vitro studies were confirmed in vivo using rats treated with cisplatin. TNF was immunolocalized to the spiral ligament, spiral limbus, and organ of Corti. NFκB protein expression was very strong in cells where TUNEL-positive staining was observed—the organ of Corti, spiral ligament, and stria vascularis. These findings suggest that proinflammatory cytokines, especially TNF-α, play a significant role in cochlear damage caused by cisplatin.[81]

A more recent review of potential protective agents tested against cisplatin ototoxicity pointed out that no successful clinical trials of protective agents against cisplatin had yet been published. Although numerous successful experiments showed protection in animal models, it is important to try to translate these results to the patients. One concern about the use of systemic protective agents, such as antioxidants, is the possible interference with the therapeutic effect of cisplatin. This problem could be circumvented with intratympanic administration of the protective agent, provided that it diffuses through the round window membrane and penetrates into the inner ear. Positive results with otoprotective regimens in clinical practice may increase the efficacy of cisplatin, and improve the quality of life in survivors of chemotherapy with cisplatin.[82]

Intratympanic dexamethasone has been reported to protect against cisplatin ototoxicity in guinea pigs and mice. In the study of guinea pigs, intratympanic saline also seemed to be protective.[83] In the mouse study, dexamethasone provided significant protection against auditory brainstem response threshold shifts with clicks, 8 kHz and 16 kHz compared with the contralateral, saline-injected ear.[84] A clinical study reported that, contrary to previous studies in the literature, amifostine (600 mg/m^2), given as an intravenous bolus immediately before and 3 hours after cisplatin and craniospinal irradiation in children with medulloblastoma, provided significant protection against hearing loss. One year after treatment initiation, 13 (37.1%) controls compared with 9 (14.5%) amifostine-treated patients had hearing loss sufficient to require a hearing aid in at least one ear ($P = .005$ chi-square one-sided test). There was no evidence that the amifostine interfered with the efficacy of the cisplatin, and the side effects of amifostine therapy were mild and well tolerated.[85]

Carboplatin

Carboplatin is a newer platinum compound that has been found to be less nephrotoxic than cisplatin. Preliminary data suggested that carboplatin was less ototoxic than cisplatin. The primary dose-limiting toxic side effect of carboplatin is bone marrow suppression. The latter effect can be overcome by autologous stem cell rescue and the use of hematopoietic growth factors; this has allowed the administration of higher doses of carboplatin to improve its antitumor efficacy and its therapeutic index. Carboplatin may be more ototoxic than initial studies indicated. High-dose carboplatin (2 g/m^2 total dose) was associated with hearing loss in 9 of 11 children (82%), with hearing losses in the speech frequencies that were sufficiently severe that hearing aids were recommended.[86] These children had each received prior treatment with cisplatin, and several of them had been treated with aminoglycoside antibiotics.

Carboplatin is highly effective in treating malignant brain tumors when given in conjunction with mannitol to open the blood-brain barrier. Fifteen of 19 patients (79%) had high-frequency hearing loss develop when this treatment regimen was used.[87] Patients with ovarian cancer were treated with combination therapy of carboplatin and cisplatin for six courses. A retrospective study of the first course area under the curve (AUC) concentration-time data for carboplatin was carried out. No patients with a low AUC had ototoxicity, but 12% of patients in the high AUC group were found to have hearing loss, and 45% had thrombocytopenia.[88]

Nearly half of a group of children undergoing hematopoietic stem cell transplantation were found to have deterioration in hearing. Children with neuroblastoma receiving carboplatin "conditioning" and children with renal dysfunction were found to be at higher risk for ototoxicity associated with hematopoietic stem cell transplantation[89]; all nine patients receiving high-dose carboplatin for cisplatin-resistant germ cell tumors were reported to develop a clinically manifested hearing loss.[90] A study of 30 children with unresectable neuroblastoma reported only one mild case of hearing loss at 6 years of follow-up.[91] The ototoxicity of carboplatin seems to vary according to the dose administered.

Carboplatin seems to be unique in that it has been shown to damage inner hair cells preferentially in the chinchilla.[92] The mechanisms of ototoxicity of carboplatin may be related to the production of ROS and reactive nitrogen species.[93] This idea is supported by the finding that pretreatment with butathione sulfoximine (BSO) enhances the ototoxicity of carboplatin in the chinchilla. BSO inhibits the synthesis of glutathione. Animals treated with BSO by continuous intracochlear infusion had significantly greater losses of inner and outer hair

cells than animals treated with carboplatin alone. DPOAE and evoked potentials recorded from the inferior colliculus were found to be significantly reduced in amplitude in animals receiving BSO in combination with carboplatin compared with animals receiving carboplatin alone.[94]

Difluoromethylornithine

Clinical Studies

D,L-α-difluoromethylornithine (DFMO) was developed as an irreversible inhibitor of the enzyme ornithine decarboxylase. It was hoped to be effective in chemotherapy for hyperproliferative diseases, including cancer and certain infectious processes. DFMO was found to cause treatment-limiting, but reversible ototoxicity at high doses.[95] DFMO is an antitumor agent and a chemoprotective compound that reduces the incidence and frequency of tumors, and is useful clinically in treating infections with *Trypanosoma brucei gambiense* (West African sleeping sickness).

In phase I studies, doses of 12 g/m^2/day for 28 days resulted in thrombocytopenia and gastrointestinal disturbances. Larger doses (64 g/m^2/day intravenously for 25 to 43 days by continuous infusion) caused diarrhea and metabolic acidosis. In phase II studies, hearing loss was observed. A clinical trial of DFMO administered orally daily for 6 months was carried out in 27 patients after surgery for cancer or who were at high risk for development of cancer. The dose-limiting toxicity was defined as high-tone hearing loss on audiogram. Hearing loss was determined in seven patients. It was not stated whether the hearing loss was reversible or irreversible. The total drug dose that resulted in ototoxicity was highly variable among patients studied.[96]

A clinical trial was carried out in 66 volunteer subjects with previously treated bladder, prostate, or colon cancer without evidence of recurrent or residual disease or healthy individuals at increased risk for developing colon cancer who were tested for potential ototoxicity of DFMO. Predictable shifts in auditory thresholds occurred that were related to the dose of DFMO. As the dose of drug increased, the magnitude and incidence of hearing threshold shift increased, and the time of its onset decreased. Threshold changes were greater in the lower frequencies than in the higher frequencies. No association could be made between the gender, age, or renal function of the subjects and hearing loss. Threshold shifts were reversible with discontinuation of DFMO.[97]

A prospective, placebo-controlled phase II clinical trial of DFMO in patients with a prior history of adenomatous colon polyp was carried out with long-term, low-dose administration of DFMO to assess the effects on hearing. Volunteers ($N = 123$) with normal hearing for frequencies between 250 Hz and 2000 Hz were tested for audiometric thresholds at baseline and 1, 3, 6, 9, and 12 months after starting treatment with either DFMO or placebo, and follow-up testing was done 3 months after cessation of treatment if there was a suggestion of audiometric changes at the 12-month measurement. Subjects receiving doses of 0.075 to 0.4 g/m^2/day for 12 months had little evidence for shifts in auditory pure-tone thresholds, and there were no statistically significant shifts in DPOAEs. There was only a subtle, approximately 2- to 3-dB hearing threshold elevation at the two lowest frequencies of 250 Hz and 500 Hz. The authors concluded that the administration of low-dose DFMO for 12 months did not produce hearing loss, in contrast to other studies that examined the ototoxicity of higher doses.[98]

Irreversible hearing loss has been reported in a patient treated with DFMO as a chemopreventive for Barrett's esophagus. After taking 0.5 g/m^2/day of DFMO for approximately 13 weeks, hearing loss of 15 dB was noted at 250 Hz, 2000 Hz, and 3000 Hz in the right ear, and hearing loss of greater than 20 dB was noted at 4000 to 6000 Hz in the left ear. These threshold shifts persisted for 7 months after DFMO was discontinued. This was the first reported case of irreversible ototoxicity related to DFMO administration.[99]

Animal Studies

Studies of DFMO ototoxicity in guinea pigs revealed that DFMO administered for 12 weeks resulted in loss of hair cells in the hook and first turn. Inner hair cell loss was greater than loss of outer hair cells. Hearing loss was confirmed by brainstem audiometry.[100]

Daily intragastric administration of D,L-DFMO did not produce any auditory dysfunction in rats given doses of 200 mg/kg/day to 1.2 g/kg/day for 8 weeks. In contrast, substantial ototoxicity was found in guinea pigs given intraperitoneal doses of D,L-DFMO of 500 mg/kg/day to 1 g/kg/day. Damage to inner and outer hair cells in the cochlea, with greater loss of inner hair cells, especially in the basal turn, occurred. These histologic findings corresponded to loss of compound action potential sensitivity. The ototoxicity of the enantiomers was also studied in the guinea pig. It was found that 1 g/day of the D-enantiomer of DFMO did not produce any evidence of hearing impairment; 1 g/kg/day of the L-enantiomer of DFMO produced a threshold shift greater than the same dose of the racemic mixture.[101]

Studies in neonatal gerbils at 21 days of age were designed to test DFMO ototoxicity. Click-evoked auditory brainstem response testing was carried out before and 3 weeks after completion of an 18-day regimen of daily subcutaneous injections of DFMO at 1 g/kg/day. DFMO administration resulted in click threshold elevations of 20 to 60 dB, which recovered by 3 weeks after cessation of the drug.[102] This study was repeated using tone pips at 2 kHz, 4 kHz, 8 kHz, 16 kHz, and 32 kHz in neonatal gerbils to see whether specific frequencies were affected, and to examine cochlear tissues after DFMO administration. Dosing regimens of 750 mg/kg/day or 1 g/kg/day subcutaneously administered were employed in two groups of gerbils. Hearing threshold shifts of 21 to 29 dB were found in the higher dose group, whereas threshold elevations of 11 to 17 dB were observed in gerbils receiving the lower dose. Higher thresholds were shown at the higher frequencies, although a broad frequency range was affected. No significant cochlear abnormalities were observed at the light microscopic level, consistent with the fact that the hearing threshold changes were reversible after 3 weeks of recovery.[102] The ototoxicity of DFMO may be mediated by alteration of the inward rectification of Kir4.1 channels, leading to a marked reduction in endocochlear potential and elevation of auditory brainstem response thresholds in mice.[103]

Conclusions

From the animal studies reported to date, it seems that DFMO has species-specific ototoxicity that apparently is dose related, but variable, depending on the rodent model used. The rat is resistant to DFMO ototoxicity, perhaps because DFMO may not inhibit polyamine synthesis in the rat cochlea to a critical level. The rat may not be used as a reliable animal model for the study of DFMO ototoxicity.[101] The guinea pig seems to be quite sensitive to DFMO ototoxicity. DFMO, particularly the L-enantiomer, caused hearing threshold changes and hair cell loss in the high-frequency region. Inner hair cells seem to be more sensitive to damage from DFMO than do outer hair cells. The neonatal gerbil apparently has an intermediate sensitivity to DFMO. Long-term administration of DFMO resulted in temporary threshold elevations, which recovered within 3 weeks after cessation of treatment, and no evidence of cochlear tissue damage was ascertained with light microscopy.[102] In mice, DFMO seemed to affect primarily the stria vascularis by altering the inward-rectification of potassium channels (Kir4.1). This alteration resulted in a concomitant elevation of auditory brainstem response thresholds. It was not specified whether this effect was temporary or permanent, and no histology was reported.[103]

Clinical studies have shown that DFMO administration is associated with reversible hearing loss. One article reported permanent hearing loss in one patient that persisted for 7 months.[99] It seems appropriate to warn patients about potential ototoxicity of this chemopreventive agent before its use. Future human temporal bone studies may shed additional light on the effects of DFMO on human cochlear tissues.

Loop Diuretics

The loop diuretics are potent synthetic drugs that exert therapeutic effects through their action on the loop of Henle of the kidney. They inhibit the reabsorption of sodium, potassium, and chloride ions by blocking an Na/K/2Cl carrier.[104] Through this action on the kidney, loop diuretics produce a rapid and dramatic increase in the volume of urine output. The most commonly used loop diuretics are furosemide and bumetanide. Ethacrynic acid is used less frequently. These drugs are used to treat congestive heart failure in infants and adults, to reduce

high blood pressure, to remove excess fluid from the lungs in newborns with immature lungs, and to assist in the control of edema from liver or kidney failure.

Ethacrynic acid can be administered either orally or by intravenous injection. It was soon discovered to cause hearing loss after it was introduced into clinical medicine in the 1960s. Numerous cases of transient and permanent deafness have been reported.[105] Permanent, profound midfrequency and high-frequency SNHL has been reported in a kidney transplant patient who was treated with ethacrynic acid. This patient was successfully rehabilitated with binaural hearing aids.[106]

Furosemide can be administered orally or by intravenous injection. Approximately 65% of an oral dose is absorbed after oral ingestion.[107] This diuretic follows a three-compartment pharmacokinetic model with an average half-life of 29.5 minutes for renal elimination. The half-life of furosemide increases dramatically in patients with severe renal failure, in whom the half-life may be 10 to 20 hours.[105] Furosemide has also been found to cause temporary and some permanent cases of hearing loss. Permanent hearing loss has been reported in certain adults[105] and in high-risk premature infants treated with furosemide.[108] Plasma levels of furosemide greater than 50 mg/L have been associated with hearing loss.[109,110] SNHL may be accompanied by tinnitus and vertigo. The incidence of ototoxicity with furosemide was reported to be approximately 6% in a small series of patients.[111]

Bumetanide, a more potent sulfonamide loop diuretic, has been reported to cause a much smaller incidence of hearing loss than furosemide.[111,112] A related loop diuretic, piretanide, was found to be equally effective as furosemide in treating patients with congestive heart failure in a study of a small group of patients, and no patients were found to have hearing loss.[113]

Studies of experimental animal and human temporal bones[114] show that the primary target of loop diuretics is the stria vascularis, where extensive edema develops in conjunction with loss of auditory function.[105] The primary target in the stria vascularis seems to be the Na/2Cl/K transporter (SLC12A2),[115] which may be similar to or identical to the transporter that furosemide and bumetanide inhibit in the kidney.[116] Mice lacking this transporter are deaf,[117] but it is unknown whether mutations of SLC12A2 contribute to human deafness.[118] The action of loop diuretics on the stria vascularis results in a reduction of the endocochlear potential, with an elevation of the threshold for the compound action potential.[119] Immature rats[120] and rats with low albumin[121] are more susceptible to the ototoxic effects of furosemide. This finding suggests that the ototoxic action of loop diuretics depends on the unbound fraction of drug in the serum.[121]

Clinical studies suggested that the ototoxicity of furosemide may be reduced by infusing the drug at rates of less than 15 mg/min.[110] Studies in the chinchilla have suggested that the ototoxicity of ethacrynic acid may be caused by impaired blood flow in the lateral wall of the cochlea. In these experiments, the blood vessels to the modiolus, spiral lamina, and vestibular end organs seemed normal. The vessels supplying the spiral ligament and stria vascularis had poor flow at 2 minutes after ethacrynic acid injection, however, and the vessels seemed to lack red blood cells 30 minutes after injection. The compound action potential, cochlear microphonics, and summating potential all declined without recovery after the microcirculatory changes in the lateral wall vessels, and reperfusion was delayed in the stria vascularis arterioles to other blood vessels in the lateral wall. Ischemia followed by reperfusion generates large quantities of oxygen free radicals that could cause structural and functional damage to the stria vascularis and organ of Corti.[122] Outer hair cell loss in the basal turn of the cochlea has been observed in temporal bone studies of patients experiencing ethacrynic acid ototoxicity.[114]

Torsemide, a new loop diuretic, was found to cause reversible hearing loss in cats at a dose that was similar to that of furosemide.[123] No evidence of ototoxicity has been shown in humans to date.[124]

Analgesics

Hydrocodone

Hydrocodone is a narcotic analgesic. It is often combined with acetaminophen, and is frequently prescribed for the relief of acute and chronic pain.[125] Common adverse reactions to this combination analgesic drug include dizziness, nausea, vomiting, drowsiness, and euphoria. More severe side effects include respiratory depression and mood disturbances. Because hydrocodone is a narcotic, abuse can lead to psychological and physical dependence. It is the most widely prescribed opioid narcotic analgesic in the United States, and is one of the most widely abused prescription drugs.[125]

Hearing loss from hydrocodone abuse has been reported in a few cases, but the incidence may be much greater than previously suspected. Two cases of rapidly progressive sensorineural deafness with relative sparing of the vestibular system and normal magnetic resonance imaging scans were reported in two patients taking huge doses of this combination. One patient took 15 tablets four times a day, and the second patient took up to 35 tablets per day. Neither patient responded to high-dose oral prednisone therapy. The first patient received a cochlear implant, with restoration of functional hearing, but no information was provided about auditory rehabilitation in the second patient, who progressed to profound bilateral SNHL.[126]

Hydrocodone abuse was associated with rapidly progressive SNHL in 12 patients reported from the House Ear Clinic. In four patients, the initial presentation was unilateral, and two patients also experienced vestibular symptoms. High-dose prednisone therapy was unsuccessful in improving hearing in any of the patients. Seven of eight patients who underwent cochlear implantation had early success with these devices. An additional series of five patients with a history of chronic ingestion of hydrocodone in doses ranging from 10 to 300 mg/day was reported. The duration of use varied from months to years. The initial audiogram showed typically a moderate SNHL. Subsequent audiograms showed rapid progression of hearing loss. Communication was severely affected. There was no spontaneous recovery of hearing in any patient reporting cessation of drug use. Hearing loss was asymmetric in three patients. Tinnitus was reported by three patients. The only significant comorbidity in this series was hepatitis C. All five patients underwent cochlear implantation and became successful users.[125]

The mechanisms of ototoxicity of hydrocodone/acetaminophen are unknown. Opioid receptors of the mu type have been shown in spiral and Scarpa's ganglia,[127,128] whereas delta and kappa receptors have been shown in hair cells.[127] Genetic abnormalities of drug-metabolizing enzymes and comorbidities such as hepatitis C infection may be factors in development of ototoxicity from this drug combination. More research is required to confirm or refute this theory, however.[125]

The following guidelines have been recommended:

1. The clinician should document rapidly progressive SNHL that is bilateral.
2. There should be no vestibular symptoms (although this is contradicted in a previous series).[129]
3. There should be no response to steroid therapy.
4. There should be no symptoms or laboratory evidence of intracranial infection or concurrent autoimmune disease with the exception of possible hepatitis C–induced autoimmune hepatitis.
5. The clinician should document prolonged daily use of hydrocodone or oxycodone, or high doses over a short interval preceding the onset of hearing loss.[125]

Salicylates

Salicylates are derivatives of benzoic acid that have been used to treat mild to moderate pain, such as headache, dental pain, and arthritis. These drugs have an anti-inflammatory and an analgesic effect. Salicylates are tightly bound to serum proteins after oral absorption, and only a small percentage of the concentration of salicylate in blood is unbound or free.

In animal experiments, it has been reported that after systemic administration, salicylates rapidly enter the perilymph. The percentage

of the corresponding blood level achieved in the perilymph can be 25% to 33%[130,131] in chinchillas,[130] and in rats,[132] the relationship between serum and perilymph concentrations is nearly linear. Serum levels of 25 to 50 mg/dL were reported in chinchillas receiving 450 mg/kg of salicylate intraperitoneally. The chinchillas were found to have threshold elevations for auditory brainstem response of 30 dB, on the average, primarily at the higher frequencies.[130] Guinea pigs receiving the same dose were found to have increased spontaneous activity of inferior colliculus neurons, which may be a neural correlate of tinnitus.[132] The effects of salicylates on the cochlea may be caused by changes in blood flow, and by changes in the stiffness of the lateral membrane of the outer hair cells.[133]

Hearing loss in humans may be related to the concentration of salicylates in blood. Patients with blood levels of 20 to 50 mg/dL can have hearing losses of 30 dB.[134] Lower concentrations of salicylate may correlate with hearing loss. At concentrations of 11 mg/dL, hearing loss was 12 dB. There seems to be a linear relationship between hearing loss and free salicylate concentrations.[135] Site of lesion testing in patients with salicylate-induced hearing loss shows a cochlear site of lesion.[136] Tinnitus seems to increase continuously with increasing plasma concentrations of salicylate over 40 to 320 mg/dL. Histopathologic studies of animal and human temporal bones from patients with documented hearing loss after receiving salicylates do not show significant hair cell damage or injury to the stria vascularis.[137] No damage to the spiral ganglion cells or myelin sheath of the eighth cranial nerve has been shown.[138]

Experiments in rats suggest that salicylate induces tinnitus throughout activation of *N*-methyl-D-aspartate (NMDA) receptors in the cochlea. The application of NMDA antagonists into the perilymph blocked the increase in pole-jumping behavior induced by salicylate, a behavioral procedure to measure tinnitus.[139] Salicylates probably cause a reversible SNHL by altering the function of the motor protein, prestin, in outer hair cells.[140]

Quinine and Related Drugs

Quinine is an alkaloid drug that is used to treat malaria and leg cramps. It is also present in tonic drinks. Quinine toxicity can manifest as a syndrome termed *cinchonism*. The symptoms include deafness, vertigo, tinnitus, headache, visual loss, and nausea. Twenty percent of patients may complain of high-frequency hearing loss with prolonged courses of treatment. There may be a 4-kHz notch, and speech discrimination score may be less than 30%, but the hearing loss may be reversible.[141] If hearing loss occurs within the speech frequencies, the loss may be permanent.[142] Guinea pigs were found to have increasing hearing loss with increasing blood concentrations of quinine.[143] Chinchillas receiving a single intramuscular injection of quinine, 150 mg/kg, were found to have a reversible 20-dB threshold elevation of auditory brainstem response, and similar shifts were observed after application of quinine to the round window.[144] Perceptual tinnitus may occur after quinine administration. A conditioned-suppression study of rats revealed a dose-dependent induction of behavioral tinnitus after quinine treatment. These effects were blocked by nimodipine, a calcium channel blocker.[145] Nimodipine did alter the threshold elevation of compound action potential observed after quinine, however.[146]

Chloroquine is an aminoquinoline drug initially used to treat malaria. In the 1950s, it began to be used to treat rheumatoid arthritis, then later other connective tissue diseases. It is chemically related to quinine. It seems to be ototoxic, but only a few cases have been reported. The ototoxicity may be reversible if detected early by auditory brainstem evoked response audiometry followed by cessation of therapy with chloroquine and administration of steroids and plasma expanders.[147,148]

Hydroxychloroquine is also a quinoline compound used to treat rheumatoid arthritis and lupus. It rarely causes ototoxicity. It has been reported to cause reversible SNHL in an adult with rheumatoid arthritis after 5 months of treatment.[149] Permanent SNHL was reported in two adults with lupus erythematosus[150] and in a 7-year-old girl after 2 years of treatment for idiopathic pulmonary hemosiderosis.[151]

Erythromycin and Related Macrolide Antibiotics

Erythromycin was introduced into clinical medicine in the 1950s. This antibiotic has been found to be useful in the treatment of various infections, including pneumonia caused by *Legionella pneumophila,* which has resulted in increased use of erythromycin by the intravenous route. It was screened for possible ototoxicity early on, but only vestibular testing was carried out. Nevertheless, it was concluded that erythromycin was not ototoxic. In 1973, the first case of ototoxicity in patients was reported.[152] Many cases of bilateral SNHL have been reported after intravenous or oral administration. Most of these patients were elderly and had liver or kidney disease, or had been treated with high-dose erythromycin for legionnaires' disease.

Ototoxic symptoms include "blowing" tinnitus, loss of hearing, and vertigo in some cases. Some patients complained of confusion, fear, psychiatric disturbances,[153] visual changes, slurred speech, a sensation of having been drugged, or lack of control.[154] Most cases of hearing loss and tinnitus have been transient. Recovery of normal hearing usually occurs within 1 to 2 weeks after stopping erythromycin.[155] Two cases of permanent ototoxicity have been reported, however: one with permanent tinnitus[156] and one with permanent hearing loss.[157] Hearing loss from erythromycin has been reported in liver or kidney transplant patients. The incidence of hearing loss in these patients seems to be dose related. Hearing loss was observed in 16% of patients receiving 2 g daily, but increased to 53% in patients treated with 4 g daily. Complete reversal of hearing loss occurred after modification of therapy.[158] In a separate series of three liver transplant recipients, it was believed that an interaction occurred between erythromycin and cyclosporine that may have caused the hearing loss.[159]

The audiometric pattern in patients with erythromycin ototoxicity can be a flat type of SNHL, although some patients manifest a high-frequency loss. Auditory brainstem response testing in two patients with erythromycin ototoxicity showed absence of waves I to III during erythromycin therapy, when pure-tone audiograms documented SNHL. The auditory brainstem response pattern and the audiograms normalized after cessation of erythromycin.[160]

Several guidelines have been recommended for the prevention of erythromycin ototoxicity: (1) Pretreatment audiograms should be obtained in elderly patients and in patients who have impaired liver or kidney function. (2) Caution should be used in combining erythromycin with other potentially ototoxic drugs. (3) If the serum creatinine is greater than 180 mol/L, the daily dose of erythromycin should not be greater than 1.5 g.[161]

Azithromycin is a newer antibiotic related to erythromycin. Similar to erythromycin, it is also ototoxic. This side effect was first reported in patients with acquired immunodeficiency syndrome undergoing long-term treatment for disseminated *Mycobacterium avium* infections. Three patients complained of hearing loss, and audiograms confirmed mild to moderate SNHL, which resolved within 2 to 4 weeks after cessation of treatment.[162] Another series of patients had reversible ototoxicity associated with high-dose oral azithromycin therapy (2400 mg/day). It took an average of 5 weeks for hearing to recover after cessation of treatment.[163] Two additional cases of reversible SNHL with azithromycin have been reported.[164] Two cases of apparently permanent hearing loss have been reported. A 47-year-old woman became completely deaf after 8 days of treatment with azithromycin.[165] A 39-year-old woman had tinnitus develop bilaterally within 24 hours of taking the drug and subjective hearing loss after the second day when she stopped taking the medication. An audiogram revealed moderate to severe high-frequency SNHL in the right ear and mild to moderate high-frequency loss on the left side. The tinnitus and hearing loss were still present 12 months later, although the tinnitus was less severe.[166] Guinea pigs treated with azithromycin or a related drug, clarithromycin, were found to have a reversible alteration of transiently evoked otoacoustic emissions.[167] The mechanisms of ototoxicity of these macrolide antibiotics are unknown.

Deferoxamine

Among a group of 153 children with β-thalassemia and treated with regular blood transfusions and iron overload chelation with deferoxam-

ine, 38% were found to have a significant SNHL at high frequencies with recruitment. Younger patients had a greater hearing loss. The hearing loss was apparently correlated with mean and peak doses of deferoxamine, and was more severe in patients with lower iron load.[168]

In a population of 75 adult transfusion-dependent patients with thalassemia major and other hematologic diseases treated with regular transfusions, 93% (70 of 75) had a history of long-term subcutaneous or intravenous deferoxamine therapy. Audiometric testing revealed hearing loss that was attributed to deferoxamine therapy in 22 of 75 patients (29%). Of patients with thalassemia, 35% (21 of 59) had hearing loss attributable to deferoxamine ototoxicity. These patients with deferoxamine ototoxicity had high-frequency SNHL. Seven of the 21 patients had a notch at 6 kHz, and 1 had a notch at 3 kHz. Few of the hearing losses were considered as disabling, however. Audiologic monitoring was recommended for patients undergoing deferoxamine therapy.[169]

Hearing loss was attributed to deferoxamine therapy in 6 of 30 patients 7 to 25 years old. Most of the patients with hearing loss had Cooley's anemia requiring regular blood transfusions and deferoxamine therapy in a dose of 40 to 50 mg/kg subcutaneously overnight for 8 to 10 hours by pump, 4 to 7 days per week. The hearing loss was sensorineural, mild to moderate, and involved the high frequencies (3 to 12.5 kHz). Only one patient had hearing loss at less than 6 kHz. Only one patient reported tinnitus. Transient evoked otoacoustic emissions and DPOAEs were abnormal in 27% and 33% of patients.[170]

Wide variations in the incidence of ototoxicity in transfusion-dependent patients receiving deferoxamine have been reported, ranging from 3.8% to 57%.[170] Although it has been reported that patients with deferoxamine ototoxicity were younger and had received higher doses of deferoxamine than patients who were not affected,[171] the doses of deferoxamine used in the 1980s were higher than the doses used in more recent years.[170] The latter study found no association between age and ototoxicity. Twenty-two patients had abnormal audiograms in the 4- to 8-kHz region, with thresholds of 30 to 100 dB. Of the 22 patients, 18 received deferoxamine doses greater than the recommended dose of 50 mg/kg subcutaneously. When deferoxamine was discontinued, audiograms in seven cases reverted to normal or near-normal in 2 to 3 weeks, and 9 of 13 patients who had symptomatic hearing losses became asymptomatic. When therapy was restarted with lower doses, no further ototoxicity was shown except in two cases. It was recommended that in patients with symptomatic hearing loss, the drug should be stopped for 4 weeks, and when the repeat audiograms were stable or improved, therapy could be restarted at 10 to 25 mg/kg per dose. The authors recommended serial audiograms every 6 months in asymptomatic patients receiving deferoxamine, and more frequent audiograms in young patients with normal serum ferritin values and in patients with hearing loss shown on audiograms.[172]

A therapeutic index has been recommended to avoid deferoxamine ototoxicity. This index is obtained by dividing the daily deferoxamine dose (mg/kg) by the serum ferritin level (ng/mL). A therapeutic index of 0.025 was considered safe.[173] For a patient with a ferritin level greater than 2000 ng/mL, deferoxamine doses of less than 50 mg/kg are considered as safe.[170] Audiometric screening for ototoxicity should include measurements of pure-tone thresholds at 6 kHz, which is the frequency most affected in patients with deferoxamine ototoxicity.[170] A more recent study showed that DPOAE testing was extremely sensitive and superior to pure-tone audiometry.[174]

Vancomycin

Vancomycin is a glycopeptide antibiotic that is used to treat methicillin-resistant infections caused by *Staphylococcus aureus* and *Staphylococcus epidermidis,* and other difficult-to-treat infections, such as enterococcal endocarditis in patients with penicillin allergies. It has been reported to be ototoxic. Vancomycin is used orally to treat pseudomembranous colitis caused by *Clostridium difficile*. Because of poor oral absorption, vancomycin is usually given intravenously. Multicompartment pharmacokinetic models have been described.[175,176] It is usually given every 12 hours in patients with normal renal function, but a once-daily regimen has been described more recently that has equivalent efficacy and a similar safety profile.[182]

As mentioned previously, vancomycin is given orally to treat pseudomembranous colitis. Usually, no significant absorption occurs after oral dosing.[9] It is sometimes administered intrathecally to treat bacterial meningitis, and severe SNHL has been reported in a patient receiving vancomycin by this route.[177] Elderly patients, even if they have normal renal function, have reduced renal clearance of vancomycin.[176] The half-life is significantly longer in premature infants; careful monitoring of blood levels in premature infants has been recommended.[178] Vancomycin administered to pregnant women did not cause hearing loss in their infants who were tested after birth.[179] In a large-scale newborn hearing screening, vancomycin was not associated with failure on automated auditory brainstem response.[180]

Vancomycin given in near-lethal doses in guinea pigs was found to be not ototoxic, but potentiation of gentamicin ototoxicity in guinea pigs was found.[181] A critical review of previously reported cases of permanent ototoxicity attributed to vancomycin suggested that most cases could be explained by concomitant aminoglycoside exposure.[181] Vancomycin seems to have a low probability of causing permanent ototoxicity if it is not given in combination with another ototoxic agent. Although the incidence of audiometrically proven hearing loss was 1 in 31 (3.2%) and 5 in 32 (15.6%) in patients receiving once-daily or twice-daily vancomycin therapy, these findings were based on a single post-treatment audiogram compared with the pretreatment baseline. It is unknown whether these hearing losses were temporary or permanent.[182]

Ototoxicity Monitoring for Hearing Loss

Audiometric monitoring for ototoxicity depends on the risk of the treatment regimen. For a low-dosage or short-duration treatment protocol for aminoglycosides with no clinical risk factors, the use of a pretreatment and post-treatment audiogram with a weekly self-assessment checklist monitoring may be adequate, but would not provide an early warning of potential hearing loss. For a high-risk, long-duration course of therapy with a high-risk agent such as amikacin, pretreatment and post-treatment testing with intervening weekly or biweekly monitoring of conventional audiometry and high-frequency audiometry may be advisable. For aminoglycosides, the final audiogram after treatment should not be performed until a few weeks after conclusion of therapy because additional delayed effects on hearing may occur.[183] For cisplatin treatment protocols, monitoring at baseline, just before beginning each cycle, when the patient is less ill and is able to cooperate better, and after the conclusion of therapy may be sufficient to document hearing loss and provide guidelines for rehabilitation because lifesaving therapy may impossible to modify.

As protective agents progress into clinical use, high-frequency audiometry may help to monitor the efficacy of the protective protocols.[183] DPOAEs seem to be more sensitive and superior to pure-tone audiometry in detecting early hearing loss caused by cisplatin[65,184] and deferoxamine.[174]

CHAPTER ONE HUNDRED AND FIFTY-FIVE

Pharmacologic and Molecular Therapies of the Cochlear and Vestibular Labyrinth

Anil K. Lalwani

John F. McGuire

Key Points

- The round window membrane (RWM) is a three-layered dynamic biologic structure capable of active and passive transport. Key features of RWM permeability have been described.
- The kinetics of RWM drug delivery are primarily affected by the method of delivery, the permeability of the substance applied, and the rate of clearance from the perilymph.
- Adhesions over the RWM may significantly alter delivery of therapeutics. Some clinicians advocate microscopic removal of adhesions before the administration of therapeutics.
- The concentration of steroids in perilymph is much higher after intratympanic application than after oral administration.
- The two principal indications of intratympanic steroids are Meniere's disease and sudden sensorineural hearing loss. Data are mixed on the use of intratympanic steroids for Meniere's disease. There are strong data for the use of intratympanic steroids as a salvage therapy after failure to respond to oral steroids. Results of salvage intratympanic steroid administration for sudden sensorineural hearing loss are best when steroids are applied as early as possible after the onset of symptoms.
- The use of intratympanic gentamicin has been studied extensively for its ability to relieve vertigo symptoms in Meniere's disease, but the incidence of hearing loss with this therapy is also high. There is currently no consensus on the intratympanic gentamicin protocol that best relieves vertigo, while preserving hearing.
- The pharmacodynamics of intratympanic gentamicin injections are much more variable than the pharmacodynamics of sustained-release intratympanic administration. Variability in pharmacodynamics may be responsible for the unpredictable incidence of hearing loss.
- Otoprotective therapies of the cochlea and labyrinth are in the experimental phase. Many of the new otoprotective strategies employ the use of neurotrophins.
- Gene therapy for the cochlea and labyrinth is also in the experimental phase. The primary mechanical issues with gene therapy for the cochlea and labyrinth are the choice of vector for gene transfer and the method of delivery of this vector to the cochlea. Optimizing safety of gene transfer continues to be a research priority.
- Most attempts at gene therapy to date involve up-regulating the production of neurotrophins. There have also been attempts to up-regulate apoptosis inhibitors, and to stimulate hair cell regeneration through gene therapy.

Protected by one of the hardest bones in body, the cochlea is nearly an impenetrable structure, frustrating bacteria and humans trying to gain access to it. Were it not for its windows, delivery of therapeutic agents to the inner ear would always necessitate traumatic disruption of the bony walls and fearful consequences to hearing. In the past 20 years, there has been a resurgence of interest in directed therapy to address inner ear disorders because indirect, systemic therapy has shown limited success and significant morbidity. Experimentally, as reviewed later, investigators have shown that intratympanic and intracochlear therapy is feasible and efficacious. The direct intracochlear application of therapeutic agents, previously feared, may become the standard therapy of the future. Inner ear "surgery" is expected to be developed to the fullest to prevent hearing loss and to restore hearing. This chapter reviews the knowledge regarding delivery of material into the inner ear and its therapeutic consequences. The dawning of a new era in ototherapy is here.

Round Window Membrane

Anatomy

The round and oval windows sit on the medial wall of the middle ear. The conduction apparatus of the middle ear converges on the oval window, an arrangement designed to transfer the mechanical energy of

sound waves into fluid waves that pass through the cochlea. Although situated at the tail end of this apparatus, the round window membrane (RWM) plays an essential role in acoustic dynamics because the compliance of the membrane allows for this mechanical energy to be released from the cochlea; without this outlet, no waves could travel through the perilymph. The actual RWM sits in the round window niche (fossula fenestrae cochleae) just posteroinferior to the promontory. When viewed from the intact tympanic membrane, the round window niche can be found an average of 3.44 mm (±0.68 mm) from the umbo, at an average angle of 113.2 degrees (±9.8 degrees) from the long process of the malleus.[1]

The RWM is a three-layered structure designed to protect the inner ear from middle ear pathology and to facilitate active transport. There is an outer epithelial layer that faces the middle ear, a central connective tissue layer, and an inner epithelial layer interfacing with the scala tympani. The outer epithelial layer is continuous with the promontory. Mucoperiosteal folds from the neighboring epithelium sometimes can obstruct the round window niche, forming a "false" RWM. The most prominent feature of the outer epithelial layer is the extensive interdigitations and tight junctions of its cells; in addition, there is a continuous basement membrane layer. This architecture, with tight junctions and a continuous basement membrane, functions as a defensive shield designed to protect the inner ear from middle ear infections. The cells also feature a well-developed rough endoplasmic reticulum and Golgi complex with occasional microvilli, suggesting that active transport of elements across the middle and inner ear compartments may occur.

The connective tissue core contains fibroblasts, collagen, and elastic fibers, and houses blood and lymph vessels. The connective tissue layer is divided roughly into thirds, differing by fiber type and cellular material. Closest to the middle ear epithelium are coarse, loosely arranged collagen fibers, devoid of elastic fibers. In the middle of this layer, these fibers are joined by fibroblasts and ground substance, with occasional blood vessels and elastic fibers. Bordering the inner ear epithelium, there is a gradual increase in fibroblasts, collagen, and elastic fibers. As a whole, the connective tissue layer is responsible for providing compliance to the RWM. A discontinuous inner epithelial layer bathes in the perilymph of the scala tympani. Cells in this layer house pinocytotic vesicles and amorphous intracellular components, and feature long lateral extensions that bathe in the perilymph, suggesting that the RWM participates in some form of active transport.[2] Figure 155-1 depicts the histologic complexity of the RWM.

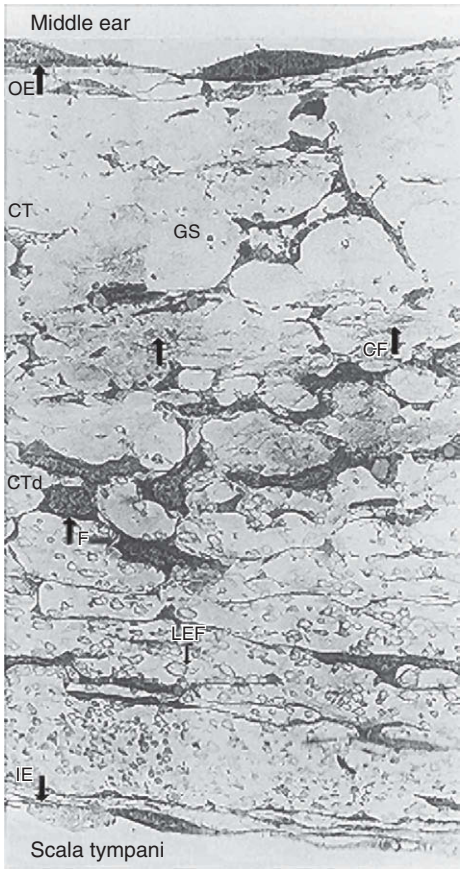

Figure 155-1. Normal human round window membrane in a 70-year-old individual. Clinical aspects of round window membrane permeability under normal and pathological conditions.* Acta Otolaryngol. *2001;121:437.)*

Physiology

The RWM is a dynamic biologic membrane. All three layers of the RWM participate in a defensive response to pathogen insult. In the context of otitis media, the outer epithelial cells become hyperplastic, whereas blood vessels within the connective tissue layer become edematous and dilated, permitting extravasation of neutrophils and macrophages. Fibroblasts also become hyperplastic, displaying an increased volume of basophilic cytoplasm.[2] Yoon and Hellstrom[3] found that although all layers of the RWM are involved in the defense response, the most dramatic changes are seen in the subepithelial space close to the basement membrane (Fig. 155-2). Certain toxins can also initiate these metaplastic changes, resulting in a thicker RWM. The thickness of the RWM doubles after exposure to *Pseudomonas* exotoxin.[4] Streptolysin O has been shown to cause breakdown of the RWM, increasing its permeability to substances in the middle ear space.[5]

Another dynamic aspect of the RWM is its ability to transport macromolecules. This process seems to be receptor mediated.[6] Transport starts at the outer layer, where molecules are taken up by pinocytosis and are brought into the connective tissue layer. From there, substances either are absorbed by blood or lymphatic vessels or are mobilized further to the inner epithelial layer, where they are released by pinocytosis into the perilymph. The RWM may also participate in the absorption of perilymph because experimental evidence has shown the passage of tracer substances from the perilymph compartment into the RWM.[2]

The RWM displays dynamic changes as it ages. Although there is no change in the thickness of the RWM with aging, changes in cellular density and elastic fiber patterns can be seen. These changes may decrease the compliance of the membrane and compromise the overall function of the auditory system.[7]

Permeability

A large range of materials are able to cross the RWM, including various antimicrobials, steroids, anesthetics, tracers, albumin, horseradish peroxidase, latex spheres, germicidal solutions, water, ions, and macromolecules (including bacterial toxins).[8] Several factors contribute to the permeability of the RWM, including size, charge, the morphology of the compound, and the thickness of the RWM. Size has proved to be a factor in permeability because 1-μm microspheres cross the RWM, but 3-μm microspheres do not.[9] Substances with a molecular weight of less than 1000 kD diffuse across the RWM rapidly, whereas substances greater than 1000 kD are transported by pinocytosis.[10] Charge of the molecule can also affect its ability to traverse the RWM: cationic ferritin crosses the RWM, but anionic ferritin does not.[9] The implication is that liposolubility is a factor in RWM permeability, a feature that is important in the design of liposome vectors for gene therapy.[8] The morphologic features of the compound can stimulate pinocytosis, presumably by a receptor-mediated mechanism.[8,10] Increased thickness of the RWM decreases permeability of substances.[8] Although the average thickness of the human RWM is 10 to 30 μm, this thickness can double in inflammatory conditions.[11,12]

RWM permeability can be altered with the use of exogenous adjuvants. Chandrasekhar and colleagues[6] compared the ability of three exogenous adjuvants to increase the perfusion of dexamethasone applied to the round window niche. These compounds included hista-

Ultrastructural characteristics of the round window membrane during pneumococcal otitis media in rat.* J Korean Med Sci. *2002;17:230.)*

mine (for its vasodilatory effects), hyaluronic acid (for its proposed osmotic effect), and dimethyl sulfoxide (for its ability to increase medication solubility in perilymph). Histamine adjuvant with dexamethasone resulted in significantly higher perilymph steroid levels than all other combinations, whereas hyaluronic acid and dimethyl sulfoxide had no significant effect. Although this study failed to show an increase in steroid perfusion with the use of hyaluronic acid, several practitioners advocate use of hyaluronic acid in their intratympanic steroid protocols.[1,13]

Kinetics

Delivery of therapeutic agents across the RWM displays a nonuniform distribution in the perilymph. Concentrations of the delivered agent are usually high in the basal turns in close proximity to the RWM, and are low at the apical turns. The permeability characteristics of the substance across the RWM and the rate of its clearance from the perilymph are the two major factors that determine the dispersal characteristics of substances in perilymph; this can include a combination of clearance to blood, clearance to any other scala, uptake or binding by cells, or metabolism by any of the cochlear tissues.[14] Knowing the RWM permeability and clearance rates of a given agent permits the simulation of its perilymphatic distribution with reasonable accuracy.

With these observations, Salt and Ma[14] described the development of a computer-simulated model of drug distribution in the perilymphatic space (Fig. 155-3). Their model, the Washington University Cochlear Fluids Simulator, is a public-domain program that is available on the Internet at http://otowustl.edu/cochlea/. An example of the power of this program is provided in the study by Plontke and coworkers,[15] in which a model of gentamicin kinetics in the perilymph was closely approximated to published in vivo kinetics data by adjusting input parameters defining RWM permeability, clearance, and interscala drug exchange. These investigators were able to establish that intratympanically administered gentamicin spreads from the RWM to the vestibule by communication through the scala, rather than by diffusion through the helicotrema. The study also suggested that drug concentrations and distribution in the perilymph were substantially influenced by the delivery method and the duration of exposure of the drug to the RWM. These computer-generated simulations are useful because they permit the optimization of different treatment protocols in humans, without resorting to simple trial and error or costly animal trials.

Another important finding from this simulated research is that the distribution of substances in perilymph is dramatically altered after perforation of the otic capsule. This finding is important because many previous pharmacokinetic studies have perforated the otic capsule to access perilymph for drug concentration sampling; their findings may be distorted by this phenomenon.[14]

Adhesions

As noted previously, the epithelium that neighbors the round window niche sometimes can create a veil that separates the RWM from the middle ear. Other reactive changes, such as scarring from repeated middle ear infections or from prior middle ear surgery, may also lead to adhesions that obstruct the RWM.[16] In a cadaveric study of 202 ears to determine the rate and nature of RWM obstruction, Alzamil and Linthicum[17] identified RWM obstruction in one third of ears. In their series, 21% had false RWMs, 10% had fibrous plugs, and 1.5% had fatty plugs. In cases in which temporal bones came from the same cadaver, 57% had no obstruction, 22% had bilateral obstruction, and 21% had unilateral obstruction. These investigators noted that the plugs filling the round window niche are 1 mm (in contrast to the RWM, which is approximately 20 µm thick).

Silverstein and coworkers[16] provided further evidence of RWM obstruction. In a series of 41 patients, they found that 17% of ears had partial obstruction and 12% had total obstruction of the round window niche. Because these adhesions may cause significant variability in the

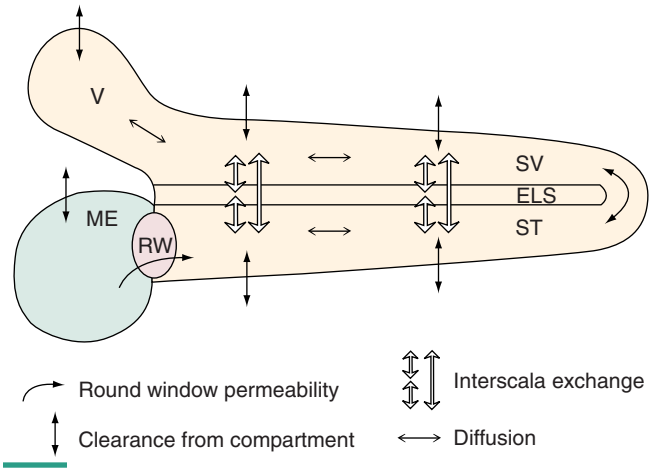

Figure 155-3. Schematic of the physical processes incorporated into the simulation program (the Washington University Cochlear Fluids Simulator, version 1.6, a public-domain computer program available at http://oto.wustl.edu/cochlea/). The compartments shown include the middle ear (ME), scala tympani (ST), cochlear endolymphatic space (ELS), scala vestibuli (SV), and vestibule (V). Drug enters through the round window (RW) in an amount depending on the permeability, and spreads longitudinally by diffusion. Local interscala exchange allows drug to spread to the endolymphatic space and the scala vestibuli, and from there to the vestibule. Drug clearance (losses to other compartments such as to blood) occurs from each compartment. Diffusion, clearance, and interscala exchange are calculated for each 0.1-mm segment of the fluid space. *(From Plontke SKR, Wood AW, Salt AN. Analysis of gentamicin kinetics in fluids of the inner ear with round window administration.* Otol Neurotol. *2002;23:967.)*

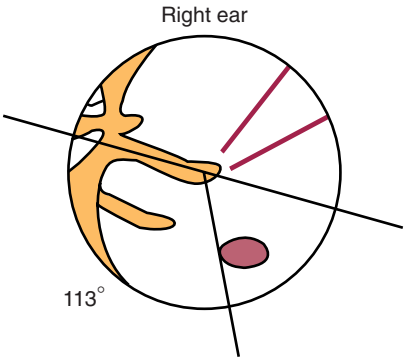

Figure 155-4. Illustration shows how the angle between the handle of the malleus and the round window (shown in the supine operative position) was calculated. *(From Silverstein H, Durand B, Jackson LE, et al. Use of the malleus handle as a landmark for localizing the round window membrane.* Ear Nose Throat J. *2001;80:444.)*

pharmacokinetics of intratympanically applied medications, these authors recommended that endoscopic removal of these adhesions should be performed before any intratympanic drug treatments. In their practice, they use a 1.7-mm endoscope with 0-degree and 30-degree viewing angles. Adhesions, if identified, are removed with a small right-angle pick. The clinical and therapeutic advantages of lysing adhesions before intratympanic drug therapy have yet to be shown in controlled clinical trials.

Delivery Method

Following is a description of how typical intratympanic injections are performed. The patient lies flat with the affected ear facing the ceiling. The external ear canal is cleaned of debris, and the tympanic membrane is visualized with an operating microscope. The round window niche can be found an average of 3.44 mm (±0.68 mm) from the umbo, at an average angle of 113.2 degrees (±9.8 degrees) from the long process of the malleus (Fig. 155-4).[18] Local anesthetic is applied to the tympanic membrane. Anesthetic preparations include topical tetracaine with alcohol, topical 15% phenol preparation, or ear canal injection of 1% lidocaine with 1:100,000 epinephrine.[19] If endoscopy is to be performed, a generous myringotomy incision is made from the umbo posteriorly to the anulus, large enough to pass the endoscope (with scope diameters of approximately 1.7 to 2.4 mm). If simple injection is performed, myringotomy may still be necessary because there needs to be a vent for air to escape the middle ear space as it is filled with fluid.

If endoscopic examination is performed, the round window niche is identified, and any mucosal adhesions are removed by use of an angled pick. The injection follows with a 1-mL tuberculin syringe and a spinal needle. Cutting 2 inches off of the tip shortens the needle and dulls the tip, decreasing the risk of a traumatic puncture of surrounding tissue. The injection should be administered slowly and directed so that the solution pools around the round window niche. Because the solution often drains into deeper air cells after the first injection, a second injection can be applied. The patient should remain with the injected ear toward the ceiling for approximately 15 to 30 minutes. It is important to instruct the patient to refrain from swallowing, talking, or yawning during this time.

Some protocols call for multiple injections over a short time. In these cases, it is useful to place a tympanostomy tube after the initial myringotomy. Montandon and colleagues[20] found that placement of tympanostomy tubes resulted in resolution of vertigo in 71% of patients with Meniere's disease in their study; if tubes are going to be used in a study, they should be acknowledged as a confounding variable.

Advances in microendoscopes may significantly increase the ease and accuracy of intratympanic drug delivery. Plontke and associates[21] described the development of a 1.2-mm endoscope that incorporates a thin fiberoptic, a working/laser channel (0.3 mm), and a suction/irrigation channel (0.27 mm). This new device would allow for several manipulations to occur at once, including direct observation of the RWM, lysis of adhesions (if present), and application of medications directly to the RWM.

Intratympanic injection is inherently inaccurate because the injected medication can leak down the eustachian tube, escape out of the external canal, or be sequestered in the middle ear. The amount of medication delivered potentially changes with each patient and each dose.[22] In an attempt to address this problem, several static sustained-release vehicles have been developed. A dry 2 mm × 3 mm Gelfoam (Upjohn, Kalamazoo, MI) pledget can be placed directly in the round window niche against the RWM. The treatment compound can be injected directly onto the Gelfoam pad. Because of the slow dissipation of Gelfoam, this injection can be repeated several times (as in titration protocols for gentamicin treatment of Meniere's disease).[19] Gelfoam slurry can also be used to suspend the medicine. This slurry can be directly injected into the middle ear space. This method has the advantage of the Gelfoam being easily removed from the middle ear in the case of an adverse reaction to the applied medicine.[23]

A two-component fibrin glue system also can be used (developed by Red Cross–Holland Lab, College Park, MD). The first component of the glue is deposited in the round window niche. The other component is mixed with the medicine and is added to the first (which is already in the round window niche). The two are mixed in situ and subsequently solidified, allowing the medicine to be slowly released from the glue onto the RWM.[23]

The ultimate degree of pharmacokinetic control is achieved with the use of mechanical sustained-release devices. These devices allow researchers to manipulate inner ear kinetic curves reliably by changing the rate and amount of dose delivered to the RWM.[22] Two devices are currently approved for use in humans and have been studied in clinical trials: the Silverstein MicroWick (Micromedics, Eaton, MN) and the IntraEar Microcatheter (Durect, Cupertino, CA). The Silverstein MicroWick (Fig. 155-5) is made from polyvinyl acetate and measures 1 mm × 9 mm long, small enough to fit through a tympanostomy tube. The wick absorbs medication (which can be administered by the patient at home) that has been applied to the external ear canal and delivers it to the RWM. The advantage of this system is that fitting the device is a simple, minimally invasive procedure (only nominally more invasive than tympanostomy tube placement), and the device can be removed without anesthesia. Long-term use is not advised because the wick material may become adherent to the mucosa of the round window niche. This device has been used to deliver steroids and gentamicin treatments in human clinical trials.[19]

The IntraEar Microcatheter (Fig. 155-6) consists of an electronic pump (Disetronics, Minneapolis, MN) connected to a catheter tip that is placed directly on the RWM. Implantation of the microcatheter is more invasive and requires the elevation of a tympanomeatal flap. Several sizes are available to secure a good fit of the catheter tip into the round window niche. The rate and dose of drug delivery are set by the practitioner at the time of implantation, but can be adjusted in the

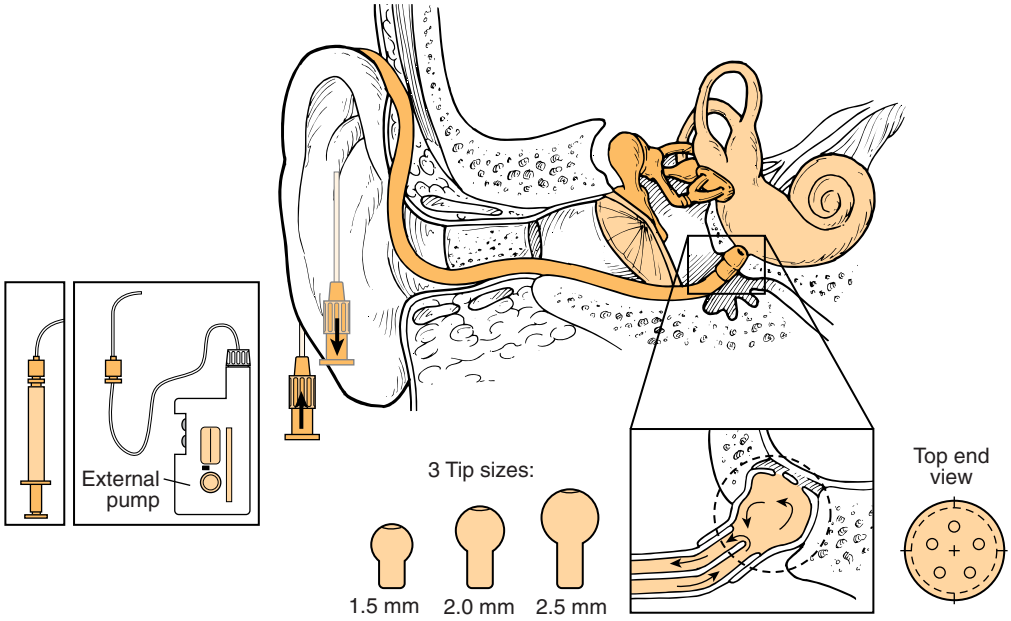

Figure 155-6. IntraEar Microcatheter. *(Reprinted with permission of the DURECT corporation.)*

middle of the treatment period. This device has also been extensively tested in human subjects for steroid and gentamicin therapy to the inner ear.[24]

Several new therapeutic agents (e.g., neurotrophins) require long-term or continuous application, which presents a serious challenge from a delivery point of view. In an attempt to address the need for a long-term delivery device, Praetorius and colleagues[25] developed a fully implantable micropump system. The device is made from pure titanium, polyethylene, and silicone, and is designed for lifelong implantation in humans. To place the device, a cavity is drilled out of the mastoid bone to house the pump and reservoir system, a procedure that is similar to the one used to place cochlear implants or implantable hearing devices. The catheter tip is placed into the round window niche. The design allows for variation in kinetics, enabling bolus and continuous infusions. The device is designed so that it can be refilled by a simple procedure without the need for reimplantation.

Steroids

The two principal indications for intratympanic steroids are sudden sensorineural hearing loss (SNHL) and Meniere's disease. The pathogenesis, pathophysiology, and diagnostic criteria for these indications are subject to controversy, making a comprehensive evaluation of the use of intratympanic steroids as a treatment for these conditions exceedingly difficult. The mechanism of action of steroids in the inner ear is incompletely understood. We review what is known about how steroids affect the inner ear, their systemic use for treatment of inner ear diseases, and the reported clinical outcomes of intratympanic steroid therapy.

Mechanism of Action

Steroids mitigate the destructive processes caused by the immune response by decreasing the number of circulating blood leukocytes and inhibiting the formation and liberation of inflammatory mediators.[26] They also inhibit the release of chemoattractive and vasoactive factors, decrease the secretion of lipolytic and proteolytic enzymes, and inhibit the release of proinflammatory cytokines, such as interferon-γ, granulocyte/monocyte colony-stimulating factor, interleukins, and tumor necrosis factor-α.[27] These actions decrease the damage from an inflammatory response, whether the insult is secondary to mechanic, hypoxic, ischemic, infectious, or autoimmunologic causes.[28]

Several studies have established how steroids attenuate pathogen-induced immune responses in the ear. On exposure to lipopolysaccharide, cultured endothelial modiolar cells and tissue exhibit a generic response and release proinflammatory cytokines.[29] These proinflammatory cytokines cause vasculitis, vascular leakage syndrome, entry of immunocompetent cells, and perivasculitis, ultimately leading to cochlear ischemia, intracochlear tissue damage, and hearing loss. Administration of dexamethasone can inhibit this cytokine immune response, and can potentially interrupt the beginnings of the inflammatory cascade at the level of cytokine expression.

Several other studies support the role of steroids in ion homeostasis in the inner ear. Serum glucocorticoid levels are directly correlated with activity and concentration of Na^+,K^+-ATPase in the inner ear.[30] Lee and Marcus[31] found that potassium secretion by marginal cells is immediately increased after the administration of steroids. Because the kinetics are too rapid for transcriptional activation to cause this change (it takes at least 30 minutes for RNA polymerase to be activated), a nongenomic mechanism is implicated. Modern theories of steroid pharmacology include not only nongenomic and genomic pathways of steroid hormone action, but also a nongenomic modulation of the genomic effects.[32] These relationships in the inner ear are just beginning to be understood.

Pharmacokinetics

Intratympanic administration yields much higher concentrations of steroids in the inner ear than either intravenous or oral administration.[6,33] Parnes and colleagues[33] compared intravenous and intratympanic administration of hydrocortisone, methylprednisolone, and dexamethasone (short-acting, intermediate-acting, and long-acting steroids). Although all three steroids successfully penetrated the blood-labyrinthine barrier, there was a much higher concentration of steroids in inner ear tissues with intratympanic administration. Other investigators have shown that the metabolism of steroids, including uptake and elimination, is different in cochlear tissues compared with other organs.[34] Methylprednisolone had the highest concentration and longest duration in perilymph and endolymph of the three compounds.[33] Similar concentrations of steroids were found in the scala tympani and scala vestibuli. The authors argue that the concentration of steroids in the endolymph implies some form of active transport through the membranous labyrinth.

The findings regarding the superior concentrations of methylprednisolone are controversial. First, other forms of steroids have been tolerated much better by middle ear tissues. Dexamethasone seems to be better tolerated and less irritative to middle ear tissues. Second, higher concentrations have not led to superior clinical results. It may be that higher perilymph and endolymph concentrations do not

translate into greater efficacy. In addition, although high methylprednisolone concentrations and high anti-inflammatory activity associated with attainable levels are observed with methylprednisolone, therapeutic efficacy may rely on other mechanisms of action. One possibility relates to Na^+-K^+ channel activity. The mineralocorticoid and glucocorticoid classes of steroids induce markedly different responses in Na^+-K^+ channel activity.[31] At this point, it is reasonable to use the less morbid middle ear therapeutic agents (i.e., dexamethasone) until more definitive studies can determine whether the higher concentrations in the study by Parnes and colleagues[33] translate into better clinical results, despite decreased tolerability.

Systemic Steroids

Currently, systemic steroids are the treatment of choice for sudden SNHL[35,36] and acute vestibular vertigo.[37] The most frequently used protocol of oral steroids for inner ear disease is 60 mg of prednisone (or 1 mg/kg/day for adults) taken for 10 to 14 days in idiopathic sudden SNHL or for 1 month in suspected autoimmune inner ear disease.[38] Both indications call for a gradual taper after the initial treatment period is finished. If hearing loss returns during the taper, a higher dose of prednisone is restarted. Relapse of hearing loss is often preceded by tinnitus.[39] Shea[40] recommended that in addition to oral steroids, 16 mg of intravenous dexamethasone should be perfused over 3 hours. The value of adjunctive intravenous delivery of steroids in addition to oral therapy remains to be established.

Meniere's Disease

Meniere's disease may be due in some cases to immune dysfunction. Steroids are often used in Meniere's disease treatment protocols.[1] Itoh and Sakata[41] reported the first intratympanic steroid protocol in 1987, in which four to five weekly injections of 2 mg of dexamethasone were administered to 61 patients with unilateral Meniere's disease. This protocol resulted in relief of vertigo in 80% of patients and reduction in tinnitus in 74% of patients. Subsequently, additional studies have used intratympanic steroids to treat Meniere's disease, some with more promising results than others.

Sennaroglu and colleagues[42] placed tympanostomy tubes in 24 patients with Meniere's disease with intractable vertigo and applied 5 drops of 1 mg/mL dexamethasone solution into the middle ear space every other day for 3 months (administered at home by the patient). This protocol resulted in a vertigo control rate of 72%, improved hearing in 17%, decreased tinnitus in 75%, and reduced aural fullness in 75%. This protocol is attractive because the drug is self-administered, the entire procedure can be accomplished under local anesthesia, and the delivery method provides flexibility to titrate the dose. The authors acknowledge that their results may be confounded by a placebo effect secondary to the tympanostomy tubes. They cite a study by Montandon and associates[20] that reported that tympanostomy tube placement prevented vertigo attacks in 71% of patients.

Barrs and coworkers[43] also used tympanostomy tubes to administer intratympanic dexamethasone. They used a dose of 0.3 to 0.5 mL of 4 mg/mL dexamethasone. Injections were given daily for the first 2 days and weekly thereafter for a total of 1 month and five treatments. The vertigo control responses were reported in time intervals, with an 86% response at less than 3 months, a 52% response at 3 months, and a 43% response at 6 months. There was an average of 2.7-dB hearing loss, but one patient had a 35-dB hearing loss. The authors propose that intratympanic steroid treatment is effective for short-term management of vertigo, but is less successful for long-term vertigo control.

Shea[40] reported on a protocol that uses a combination of intravenous, intratympanic, and oral dexamethasone to treat patients with Meniere's disease. A mixture of 0.5 mL hyaluronan containing 16 mg/mL of dexamethasone is injected into the middle ear after argon laser myringotomy and removal of RWM adhesions. The patient sits with the injected ear up for 3 hours while receiving 16 mg of intravenous dexamethasone. This treatment is performed for 3 consecutive days. Then 0.25 mg of oral dexamethasone is taken for 30 to 90 days, depending on the response to treatment. This protocol resulted in a vertigo control rate of 77%, hearing improvement in 35.4%, and hearing loss in 6.3%. With the 6-point functional level score recommended by the American Academy of Otolaryngology–Head and Neck Surgeons (AAO-HNS) guidelines,[44] 61.3% of patients were improved, 32.3% were unchanged, and 6.4% were worse after treatment.

In a rare controlled trial, Silverstein and colleagues[1] conducted a prospective, randomized, double-blind, crossover trial of intratympanic dexamethasone and placebo in 17 patients with Meniere's disease. All patients had stage IV Meniere's disease by the Shea classification (they no longer had vertigo, had poor hearing, and had significant fullness and tinnitus). Patients received intratympanic injection of either placebo (0.2 to 0.3 mL of 1:1 normal saline and sodium hyaluronate) or 0.2 to 0.3 mL of a 1:1 mixture of 16 mg/mL dexamethasone and sodium hyaluronate. This treatment was performed for 3 consecutive days. Three weeks after the initial treatment, the groups received the crossover treatment (the placebo group received intratympanic steroids and vice versa). The parameters recorded were audiometric data, electronystagmography recordings, and tinnitus evaluations; several questionnaires and telephone interviews were included. Intratympanic steroids provided no significant benefit over placebo in any of the parameters recorded, and patients could not guess which arm of the study they were in. This study would seem to confirm the lack of benefit of intratympanic steroid use for Meniere's disease. The severely diseased patient population (all stage IV) may be a selection bias not present in other studies, however, leaving open the possibility that intratympanic steroids may be useful in less severe cases. Also, most successful intratympanic steroid protocols involve steroid treatments that last longer than 3 days.

In another well-designed study, Garduño-Anaya and associates[45] conducted a prospective, placebo-controlled, double-blind, randomized study with 2-year follow-up, and found dramatically different results than Silverstein and colleagues.[1] A regimen of 5 consecutive days of intratympanic dexamethasone (4 mg/mL) versus saline for placebo control was administered to 11 study patients and 11 controls, all having unilateral disease as outlined by the 1995 AAO-HNS Committee on Hearing and Equilibrium. In the dexamethasone group at 2-year follow-up, complete control of vertigo (class A) was achieved in 9 of 11 patients (82%), and substantial control of vertigo (class B) was achieved in the remaining 2 patients. In the control group, only 7 of 11 patients finished the trial, and of these, 4 patients (57%) achieved class A vertigo control, 2 patients (29%) achieved class C, and 1 patient (14%) achieved class F. These results were statistically significant. There were several other outcome measures with variable results, with significant improvement in AAO-HNS 6-point functional level; Dizziness Handicap Inventory; and subjective vertigo, tinnitus, and aural fullness scores in the treatment group, but no significant changes in the Tinnitus Handicap Score, pure-tone average, speech discrimination score, electronystagmography, or electrocochleography tests between the two groups. The final verdict on intratympanic steroid use for Meniere's disease is still pending, and more data on optimal dosing and protocols are needed.

Sudden Sensorineural Hearing Loss

Systemic and intratympanic steroid therapy has also been used for treatment of sudden SNHL. The major prognostic factors predicting response to treatment for sudden SNHL are initial severity of hearing loss and time between onset and treatment.[6,46] There is a high spontaneous recovery rate of 30% to 60%; treatment efficacy of any intervention has to be greater than the spontaneous recovery rate. Oral steroid therapy within the first 2 weeks has shown recovery rates approaching 80% and decreasing thereafter.[46,47] Because of the high initial response to oral steroids, few practitioners have attempted to use intratympanic steroids, and most intratympanic steroid trials enroll patients who had oral treatment fail. That being said, numerous studies, mostly retrospective, have shown that intratympanic steroids do provide an excellent method for salvage of hearing in the case of systemic steroid treatment failure.

Gianoli and Li[35] reported results of a trial of intratympanic steroids for patients with sudden SNHL who had failed to improve after high-dose systemic steroids (1 mg/kg/day of prednisone for a minimum of 1 week). The protocol consisted of tympanostomy tube placement followed by instillation of 0.5 mL of steroid solution consisting of either

25 mg/mL of dexamethasone or 62.5 mg/mL of methylprednisolone. Four treatments were administered over 10 to 14 days, and audiometric data were recorded 1 to 2 weeks after treatment. The results showed a pure-tone average improvement of 10 dB or greater in 44% of patients. The authors argued that although this improvement seems modest, this is in a cohort of patients who would otherwise be considered refractory to steroid treatment. Although there was a trend toward better outcomes for methylprednisolone, there was no significant difference between the two steroid solutions.

Kopke and colleagues[46] reported results of the use of methylprednisolone perfusion by means of an RWM microcatheter in patients with sudden SNHL who failed oral prednisone therapy. The catheter delivered 62.5 mg/mL of methylprednisolone at a continuous rate of 10 µL/hour for 14 days with an electronic pump. Audiometric changes were the main outcome measures recorded. Of the six patients who had catheter placement 6 weeks or less after the onset of hearing loss, five had improvements of 10 dB or more in pure-tone averages, and four of these had a return to baseline pure-tone averages. Results were less promising for patients receiving treatment more than 6 weeks after onset of symptoms; in one patient, there was additional hearing loss associated with vertigo.

Several other, smaller reports have been published. Chandrasekhar[47] reported results from a series of 10 patients treated with intratympanic dexamethasone. The dexamethasone concentration and number of intratympanic injections varied among patients, and several patients were taking oral medications in addition to intratympanically administered steroids, making outcomes difficult to assess. Of the 10 patients treated, 6 experienced hearing improvements greater than 10 dB, however. Parnes and colleagues[33] reported results from a similar series of 13 patients with sudden SNHL treated with intratympanic steroids. Because there was considerable variation in the number of treatments applied and the drug administered (dexamethasone vs. methylprednisolone), the results are difficult to assess. Of the 13 patients treated, 6 showed hearing improvements of 10 dB or more.

One point of consensus about these studies is that they show that the longer between the insult and the administration of intratympanic steroid treatment after oral steroid failure, the lower are the chances of salvaging hearing. If intratympanic steroids are to be used, they should be used as soon as possible after it becomes clear that oral steroids are not improving hearing, preferably within the first 2 weeks of the original insult.[48]

Dosing

The most widely used steroid for intratympanic protocols is dexamethasone, followed by methylprednisolone. Intratympanic dexamethasone preparations vary from 1 to 25 mg/mL.[49,50] Some studies use a hyaluronic acid preparation consisting of a 1:1 mixture of 16 mg/mL of dexamethasone and 0.5 mg/mL of hyaluronate sodium.[1,40] Most intratympanic methylprednisolone studies use a solution of 62.5 mg/mL.[22,46] The amount of solution injected in each protocol is designed to fill the middle ear space (which is 0.3 to 0.5 mL). The interval of dosing depends mostly on the instillation method. Protocols that include self-administration through tympanostomy tubes have every-other-day dosing.[49] Intratympanic injection protocols are much less frequent, and often include "shotgun" dosing with multiple injections over the first 2 weeks of treatment.[1,51]

Side Effects

The side effects of long-term systemic steroid use are well known and include compromise of the immune system leading to infections, osteoporosis, peptic ulcers, hypertension, myopathy, ocular effects, impaired healing, psychologic effects, and avascular necrosis.[52] In contrast, intratympanic steroids are characterized by minor local morbidities. Several preclinical studies have documented that intratympanic steroids cause no morphologic or functional compromise in animal models.[27,53] Human clinical trials have reported benign side-effect profiles, even after multiple and long-term treatments.[33] There are several reports of decreased hearing in human clinical trials of patients with Meniere's disease,[40,43] but it is unclear whether this is a side effect of treatment or part of the natural course of the disease.[51,54] There are some reports of tympanic membrane perforations and otitis media secondary to the perfusion process.[35] Some patients experience a mild burning sensation in the ear after injection of methylprednisolone. This side effect has been avoided by combining 0.1 mL of 1% lidocaine with 0.9 mL of standard intravenous methylprednisolone solution (40 mg/mL).[33]

Summary

There is currently no consensus on the mechanism of action of steroids in the inner ear. Experience with intratympanic steroids is insufficient to recommend their routine use in autoimmune hearing loss, sudden SNHL, or Meniere's disease. Intratympanic steroid use is proving to have a role as a salvage therapy, however, for sudden SNHL unresponsive to oral steroids.

Gentamicin

Fowler[55] first described the use of aminoglycosides for chemical ablation of the labyrinth in 1948, using systemic streptomycin to treat patients with Meniere's disease with intractable vertigo. Bilateral cochlear damage led to the abandonment of this effort, but in 1957, Schuknecht[56] revived interest in chemical ablation with the introduction of intratympanic administration of aminoglycosides. Although loss of hearing was almost as common as the resolution of vertigo, his work set the stage for the development of modern intratympanic chemical ablation protocols. In the mid-1970s, Beck and Schmidt[57] described a low-dose strategy that departed from the goal of total vestibular ablation. They compared a high-dose ablative protocol with a low-dose, low-injection-frequency protocol, and found that although vertigo control was essentially the same, the hearing loss rate decreased from 58% to 15%. This improvement rekindled interest in intratympanic gentamicin therapy, and led to the development of strategies that maximize vertigo control, while minimizing hearing loss.

Mechanism of Action

Despite the widespread belief that gentamicin is selectively toxic to vestibular hair cells, this assertion is not fully supported by the literature. Several researchers have shown that gentamicin and streptomycin cause parallel and dose-dependent damage to vestibular and cochlear hair cells.[58,59] Wanamaker and colleagues[59] stated, "When the vestibular system was severely damaged, the cochlea was severely damaged; when loss in the vestibular system was mild, loss in the cochlea was mild. We did not observe any dose-related selectivity for the vestibular system over the cochlea." The clinical finding of significant correlation between loss of caloric response and hearing loss after gentamicin exposure further betrays the notion of selective vestibular toxicity.[60,61]

If there is no selective vestibular toxicity, how is it that clinicians have achieved good vertigo control with minimal hearing loss? In part, the answer may lie in pharmacokinetics.[22,62,63] Hoffer and colleagues[22] compared the kinetic profiles of intratympanic injection versus microcatheter delivery of gentamicin, and correlated these data with the functional and morphologic changes observed in the inner ear. Despite the fact that the total dose in both methods was roughly equal, the resulting morphologic changes were quite different. Intratympanic injection led to erratic changes, sometimes causing obliteration of auditory functioning within 4 hours, and in other cases showing significantly delayed ototoxic effects. In contrast, controlled perfusion by microcatheter caused predictable and uniform damage.

Hoffer and colleagues[22] explained that these different morphologic changes may be due to two different patterns of hair cell loss, patterns that correlate with the timing and concentration of aminoglycoside delivery. These patterns include a necrotic pattern that is associated with rapid and high-dose perfusion, and an apoptotic pattern that is associated with slower or chronic perfusion.[53,64] This complicated relationship may be secondary to saturation of anionic binding sites on the cell membrane or to modifiable active uptake patterns that depend on gentamicin kinetics.[65] In addition to the amount of gentamicin that accumulates in the perilymph over time, the nature of the distribution curve, timing of the peak, and total dose determine morphologic and functional consequences of aminoglycoside exposure.

There is overwhelming clinical evidence that vestibular ablation is not required for vertigo control. These observations have caused a shift

in strategy from vestibular ablation to *chemical alteration* or *subablation*. These terms describe the clinical goal of balancing vertigo control and hearing loss. This quest has spawned numerous clinical trials with various dosing protocols and delivery methods, all designed to achieve this goal.

What is the histologic and physiologic correlate of partial ablation? It is known that gentamicin damages type I hair cells more rapidly and severely than type II hair cells.[66] In the chinchilla, investigators showed that type II hair cells regenerated to approximately 55% of the baseline population, whereas type I hair cells showed no regeneration at all. It may be that these patterns of hair cell destruction and regeneration describe the partial vestibular ablation seen in intratympanic gentamicin clinical trials. Carey and associates[67] examined the changes in the angular vestibulo-ocular reflex after a single dose of intratympanic gentamicin, and found that in all cases there was a decreased, but not abolished, angular vestibulo-ocular reflex gain. These authors concluded that this finding provides evidence of incomplete hair cell destruction, which may account for the phenomenon of "partial ablation." Minor[68] speculated that there may be a critical level of vestibular activity required to initiate an episode of vertigo, and that the regions of vestibular epithelium or groups of afferent nerve fibers responsible for vertigo may be more susceptible to gentamicin toxicity than others. Minor[68] also speculated that hair cell regeneration may explain the phenomenon of recurrent vertigo after initial control with intratympanic gentamicin.

Although selective hair cell destruction and regeneration have yet to be established in humans, this may explain some of the more puzzling findings documented in clinical trials. Numerous trials have reported that there is an increase in hearing after gentamicin treatment.[61,69,70] In addition, in the microdose infusion trials by Hoffer and colleagues,[71] vestibular function improved in 78% of patients. These findings are hard to reconcile with traditional models of aminoglycoside toxicity.

The alternative explanation for how gentamicin achieves a selective vestibular effect is the proposal that gentamicin primarily affects secretory, rather than sensory, cells; this is known as the dark cell theory. Although cited in almost every article related to intratympanic gentamicin treatment, there is no firm documented scientific evidence showing how the effect actually occurs. Vestibular dark cells are important (but not essential) in creating and maintaining ion homeostasis in the inner ear.[72-74] Several studies have documented that aminoglycosides induce structural and functional alteration of these dark cells.[19,75] This damage is thought to alter the ionic homeostasis of the inner ear in such a way that it brings the ionic dysregulation in endolymphatic hydrops back into balance.[76,77] This theory helps explain how the hearing restoration and vestibular improvement referenced earlier might occur; re-establishment of ionic homeostasis would restore baseline function in the cochlea and labyrinth. There is uncertainty, however, whether this dark cell damage occurs before damage to sensory cells. Chen and colleagues[58] looked at secretory and sensory cells in response to aminoglycoside challenge, and found no significant changes in dark cells, despite extensive damage in cochlear and vestibular hair cells in the same animal. If dark cells are responsible for the selective effect of gentamicin, this has yet to be established in any preclinical models. Explanation of this mechanism, if it exists, would be a great advance in otology.

Pharmacokinetics

Intratympanic gentamicin kinetics in the perilymph follow a one-compartment model.[22,78] Gentamicin rapidly diffuses across the RWM; the kinetics of gentamicin in perilymph are largely determined by the method of delivery.[22,78,79] Intratympanic injection has a faster absorption phase, shows higher peak concentrations, and exhibits significantly more variability in all measurements than sustained-release delivery methods.[22,80] In pharmacokinetic studies, large value ranges and standard deviations are characteristic of intratympanic injection delivery (Fig. 155-7).[22]

Elimination of gentamicin from the perilymph compartment is rapid and dose-dependent.[78] Because of this rapid elimination, a sustained-release vehicle for drug delivery, such as a fibrin-based glue[80] or delivery by microcatheter, is the only way to maintain high concentrations of gentamicin in perilymph.[22] Although elimination in perilymph is rapid, there seems to be significant uptake of gentamicin in inner ear tissues, essentially constituting a second, "deeper" compartment. Access of aminoglycosides to the organ of Corti is probably directly from the perilymph, rather than from the endolymph.[81] That gentamicin appears in the endolymph at all seems to be a function of it being slowly released from inner ear tissues. This delayed release may explain why aminoglycosides are not immediately toxic when applied into the perilymph, whereas toxicity in vitro (without compartments) is seen immediately.[82] Hiel and coworkers[83] showed that gentamicin is rapidly and specifically captured by hair cells, such that there is significant uptake of gentamicin before morphologic ototoxic changes occur. Hair cells store aminoglycosides in lysosomes, essentially constituting the "deep" intracellular compartment referred to previously. This compartment provides prolonged exposure of these cells to aminoglycosides, and may be the basis for the delayed morphologic and functional effects seen clinically.

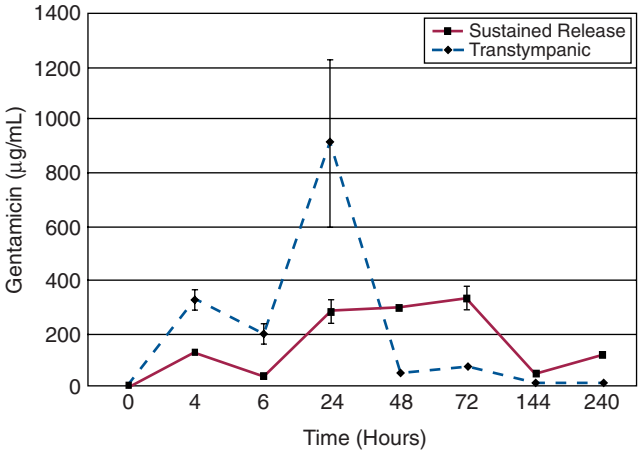

Figure 155-7. Perilymph gentamicin kinetics after sustained-release and transtympanic local delivery. Kinetic curves of perilymphatic gentamicin concentrations after sustained-release and transtympanic delivery are depicted. *Solid line* shows the sustained-release curve. The transient 4-hour peak followed by sustained delivery from 24 to 72 hours with the presence of gentamicin at 6 and 10 days is also depicted. *Dashed line* is the transtympanic curve with rapid uptake and almost total elimination within 48 hours. The SEM bars are much larger for transtympanic delivery than for sustained-release delivery. *Note*: The *x*-axis (time) is not to scale. *(From Hoffer ME, Allen K, Kopke RD, et al. Transtympanic versus sustained-release administration of gentamicin: kinetics, morphology, and function.* Laryngoscope. *2001;111:1343.)*

The pharmacokinetic data generated in animal models seem to fit what occurs in humans. Becvarovski and colleagues[79] devised an in vivo human pharmacokinetic study by recruiting patients who were undergoing either translabyrinthine surgery or labyrinthectomy and exposing them to gentamicin intraoperatively through the facial recess. In these patients, there was rapid diffusion of gentamicin into the perilymph that peaked after 30 minutes. After this peak, concentrations were in a stable range until the limit of the experiment at 110 minutes. Although there was no evidence of gentamicin in the cerebrospinal fluid, gentamicin was detected in serum shortly after administration (1 to 2 hours). This study confirms that rapid diffusion of gentamicin across the RWM occurs in humans. This study indicates that the elimination of gentamicin involves crossing the blood-labyrinthine barrier because gentamicin was detected in the serum shortly after administration.

As mentioned previously, progress in understanding gentamicin pharmacokinetics has been made with computer simulations. Plontke and colleagues[15] approximated published in vivo kinetics data by adjusting input parameters defining RWM permeability, clearance, and interscala drug exchange. The results are shown in Figure 155-8. They were able to establish that intratympanically administered gentamicin spreads from the RWM to the vestibule by communication through the scala,

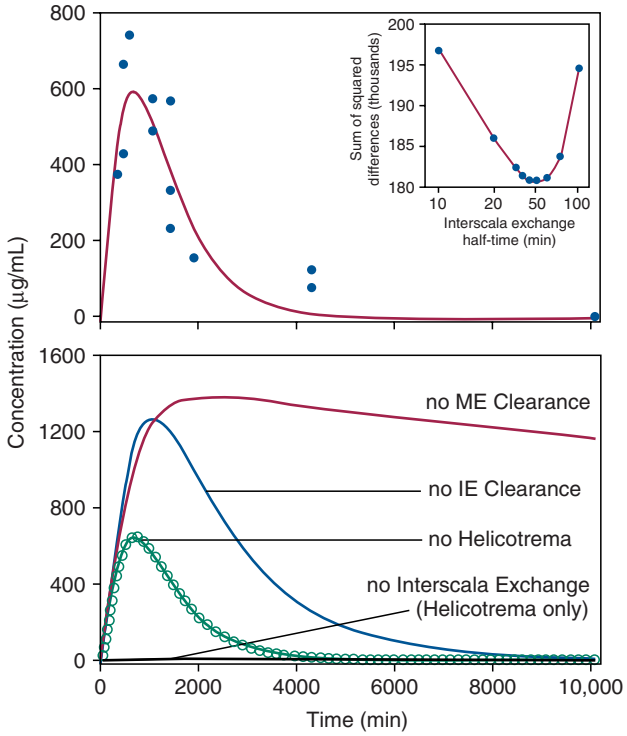

Figure 155-8. *Top,* Experimental measurements of gentamicin levels in perilymph samples taken from the vestibule after application to the round window *(solid circles)*. Data are replotted from Hoffer and colleagues and Balough.[23,80,169] *Solid line* shows best fit of the concentration time course established by the simulator (the Washington University Cochlear Fluids Simulator, version 1.6) based on physical processes of solute movement. The curve represents the calculated concentration of a simulated 15-µL sample taken from the vestibule (as described in the text). *Inset graph,* A unique best fit (using methods described in the text) was found to occur with an interscala exchange half-time of 45 minutes. *Bottom,* Calculated gentamicin time course in the vestibule with best-fit parameters *(open circles)* and with specific processes in the simulator disabled *(solid lines)*. *(From Plontke SKR, Wood AW, Salt AN. Analysis of gentamicin kinetics in fluids of the inner ear with round window administration.* Otol Neurotol. *2002;23:967.)*

rather than by diffusion through the helicotrema. The study also suggested that drug concentrations and distribution in the perilymph were substantially influenced by the delivery method and the duration of exposure of the drug to the RWM.

Clinical Protocols

Although many studies that used intratympanic gentamicin have been published, because of extreme differences in the quality of data, comparison of the different intratympanic gentamicin protocols is exceedingly difficult. Instead, several studies representing various strategies are discussed, and their results are summarized. There are three basic strategies used in intratympanic gentamicin therapy: fixed protocols, titrated protocols, and sustained-release protocols. Fixed protocols use a specific dose and number of injections in all patients. Titration protocols adjust the total dose delivered to a predetermined end point, such as paralytic nystagmus, decreased tandem gait, subjective dysequilibrium, or, more simply (and more commonly), relief from vertigo.[76] Sustained-release protocols work on various principles, depending on the delivery mechanism.

There is little difference between fixed and titration protocols because most fixed protocols can be repeated if no clinical response is seen, and most titration protocols deliver a fixed number of injections in the beginning of the protocol, and then repeat them as necessary. The supposed advantage of fixed protocols is that each patient receives the same treatment, making outcomes easier to interpret across individuals. Fixed protocols can be more cost-effective because excessive testing and clinical visits are avoided.[61] The flexible structure of titrated protocols supposedly allows for more control of the ototoxic effects of gentamicin, decreasing the risk of hearing loss.[84] Close monitoring for ototoxic symptoms does not confer the ability to reverse these symptoms, however.[85]

Much of the controversy in intratympanic gentamicin therapy in the 1990s concerned a form of fixed protocol known as a "shotgun" protocol. The classic "shotgun" protocol was popularized by Nedzelski and colleagues in 1992.[86] There have been periodic reports on this original "shotgun" protocol, and it is now one of the largest series in the literature, spanning a decade and including more than 90 patients. The protocol calls for three daily injections for 4 consecutive days of 26.7 mg/mL of gentamicin, and results in a vertigo control rate of 94% and hearing loss rate of 26%.[60,61,86] The main argument against "shotgun" protocols is that they lead to higher rates of hearing loss,[87] and that the hearing loss realized is profound.[69] Toth and Parnes[87] followed the classic "shotgun" protocol outlined previously, but encountered an unacceptable rate of hearing loss (57%) following 18 patients. After they changed to a titration protocol that involved weekly injections, the hearing loss rate decreased to 19%. Altlas and Parnes[69] pointed out that in "shotgun" protocols, the proportion of patients who experience hearing loss greater than 30 dB (10% to 24%) is much higher than the proportion seen in titration protocols (0% to 4%).

More recently, "hybrid" protocols have been introduced. Quaranta and associates[88] used a fixed schedule of two 0.5-mL intratympanic injections of 20 mg/mL of gentamicin solution spaced 1 week apart. Patients who did not achieve vertigo control after the first two doses were offered additional doses to a total of four doses. This was a prospective study that included a control group of patients with Meniere's disease who refused treatment. At the 2-year follow-up point, the vertigo control rate was 93% versus 47% for the untreated group. Hearing loss was 7% for the treated group versus 47% for the untreated group. Tinnitus rate and aural pressure relief were 20% and 40% for the treated group versus 27% and 27% for the untreated group. In the protocol, 47% of patients had residual vertigo after two doses and went on to receive a third dose, and 27% went on to receive a fourth dose. This study illustrates the paradoxic effect that intratympanic gentamicin actually improves hearing outcomes of patients with Meniere's disease. Improvement in hearing from the baseline decline encountered in untreated Meniere's disease is not a logical outcome if the mechanism of action of intratympanic gentamicin is merely the selective ablation of vestibular hair cells.

The microcatheter delivery method has been recommended to provide sustained gentamicin levels in the perilymph. Schoendorf and associates[89] used a high-precision insulin pump and a microcatheter to deliver 40 mg/day of gentamicin to the RWM. The treatment was continued at this fixed rate until vestibular symptoms appeared (in essence, a titration protocol). Although vertigo control was achieved in most patients, 8 of 11 patients treated became deaf. The authors claim that the occurrence of deafness was not correlated with dose because one deafened patient received 720 mg and another received only 60 mg, and hearing was unchanged in a patient who received 240 mg. The authors noted that continuous perfusion protocols should not use titration strategies because the adequate dose for vertigo control may be quickly exceeded. This study highlights the notion that kinetics can have a larger impact on morphologic and functional outcomes than dose-related effects.

In contrast to the preceding study, most continuous-delivery protocols use microdose, slow-infusion strategies. Seidman and colleagues[90] reported retrospective data from a multi-institutional trial that compared results of different microcatheter infusion rates. The vertigo control rate was 90% in the group receiving infusions of 1 µL/hr versus 79% in the group receiving infusions of greater than 10 µL/hr, a nonsignificant difference. The hearing loss rate was 23% in the group receiving 1 µL/hr versus 50% in the group receiving greater than 10 µL/hr, however, and this difference was statistically significant. The authors recommended the slow infusion rate and suggested that infusion rates less than 1 µL/hr might have even lower hearing loss rates, while maintaining equal clinical efficacy.

In a study that epitomizes the microdose, slow perfusion rate strategy, Hoffer and colleagues[91] reported the 2-year results of 27 patients who underwent microcatheter gentamicin therapy. The study used a pediatric solution of 10 mg/mL, with the pump set at 1 µL/hr for 10 days, resulting in total dose of 2.4 mg. This strategy achieved vertigo control in 93% of patients, hearing loss in only 4%, tinnitus relief in 63%, and elimination of aural pressure in 74%. The protocol included a wide variety of vestibular tests, including vestibulo-ocular gain, phase, and symmetry; posturography score; and step velocity testing. Ninety-six percent of patients had no decrease in vestibular function; however, caloric testing was not performed. The investigators found that vestibular function was improved in 79% of patients.[71] These results represent some of the most impressive results of intratympanic gentamicin therapy.

Chia and coworkers[92] conducted a meta-analysis of intratympanic gentamicin trials. The study included seven studies ($N = 218$) that used multiple daily dosing technique (delivery three times per day for ≥4 days), two studies ($N = 84$) that used weekly dosing technique (weekly injections for four total doses), eight studies ($N = 253$) that used the low-dose technique (one to two injections with re-treatment for recurrent vertigo), four studies ($N = 156$) that used continuous microcatheter delivery, and six studies ($N = 269$) that used the titration technique (daily or weekly doses until onset of vestibular symptoms, change in vertigo, or hearing loss). The titration method of gentamicin delivery showed significantly better complete (81.7%; $P = .001$) and effective (96.3%; $P < .05$) vertigo control compared with other methods. The low-dose method of delivery showed significantly worse complete vertigo control (66.7%; $P < .001$) and trended toward worse effective vertigo control (86.8%; $P = .05$) compared with other methods. The weekly method of delivery trended toward less overall hearing loss (13.1%; $P = .08$), and the multiple daily method showed significantly more overall hearing loss (34.7%; $P < .01$) compared with other groups. No significant difference in profound hearing loss was found between groups, and the degree of vestibular ablation after gentamicin therapy was not significantly correlated with the resulting vertigo control or hearing loss status.

As with all meta-analyses, caution needs to be used when interpreting these results. Differences in patient profiles, dose and concentration of gentamicin delivered, quality of follow-up analysis, and multiple other factors are necessarily bracketed for the sake of getting a reasonable idea of what treatments are best for patients. Perhaps the best outcome of this effort is that it can guide a rational design for a well-run, controlled trial that would provide a new level of evidence regarding superior treatment for patients with vertigo.

Practical Considerations

The argument for the use of intratympanic injection is that it is the simplest, most cost-effective, and least invasive method of delivery, and from published studies, it provides comparative vertigo control and hearing preservation rates to sustained-release protocols. Blakely[93,94] argued that even though there are no head-to-head comparisons of these methods, the published results suggest that there is no reason to use anything but the simplest administration protocols. The argument for using sustained-release mechanisms, particularly continuous infusion devices, is that they seem to produce lower rates of hearing loss, allow for standardization across individuals, lead to more predictable and uniform results, and improve vestibular and auditory functioning.[71]

Dose

Eklund and coworkers[95] found that frequency of deafness was dose-dependent in their intratympanic injection study. There is no minimum safe dose, however, because the lowest documented intratympanic gentamicin dose to produce hearing loss is 0.24 mg.[96] The method of delivery is as important as dose in terms of ototoxicity; this was illustrated earlier in the trial by Schoendorf and colleagues,[89] in which a microcatheter delivered a severely ototoxic dose of gentamicin, a dose that would be considered to be a "low dose" in intratympanic injection protocols. Per the pharmacokinetic studies of Hoffer and colleagues[22] mentioned previously, functional and morphologic end organ damage depends less on the total dose delivered to the inner ear than on the kinetics of how the drug reaches inner ear tissues.

Concentration

The concentration of gentamicin used varies among different studies. Low-dose protocols use the pediatric formulation of gentamicin, which comes in a preparation of 10 mg/mL.[96] The adult preparation of 40 mg/mL is often diluted to 30 mg/mL. Abou-Halawa and Poe[76] compared outcomes between intratympanic gentamicin preparations of 30 mg/mL and 40 mg/mL, and found that although both cohorts had similar vertigo control and hearing loss rates, the cohort receiving 40 mg/mL required fewer injections to achieve these results. Several other studies have confirmed that with low-dose protocols, more periodic treatments are needed, and there is an increase in the recurrence rate.[71]

Interval

The injection interval depends on the end point chosen for the study. There is increasing support for spacing the injections over at least a week, primarily because of the delayed onset of gentamicin toxicity. The typical deafferentation syndrome occurs only 3 to 5 days after injection.[88,97] Other advocates say that if a patient has Meniere's disease with episodes that are only every other week, it is unreasonable to check for results on a weekly basis.[98] In Blakely's review of intratympanic gentamicin protocols,[93,94] he argued that differences in injection intervals have little impact, if any, on outcomes.

Number of Injections

The general belief in the literature is that the fewer intratympanic gentamicin injections, the better. Youssef and Poe[70] found that the chances of gentamicin being effective after three injections are significantly reduced. Other reasons to limit the number of injections include an increased risk of permanent perforation of the tympanic membrane with each injection (unless tympanostomy tubes are placed), the increased cost and inconvenience to the patient and the physician, and an increase in the risk of hearing loss (although this is not supported by all studies).[87]

Complications

The most notorious complication of intratympanic gentamicin treatment is hearing loss. Risk factors for hearing loss have been inconsistently identified across studies; this is partially due to the substantial differences in protocols between studies. Kaplan and associates[60] found that the only factor related to hearing loss was poor hearing before treatment. Although some series have reported that the rate of hearing loss increases after multiple daily injections,[87] others have found no correlation between the number of injections and hearing loss.[70,72,95] There may be a genetic disposition to hearing loss after aminoglycoside treatment because of a maternally inherited 1555 A-to-G nucleotide substitution in the 12s mitochondrial ribosomal RNA.[99] Several patients who experienced hearing loss secondary to intratympanic gentamicin have been tested for this substitution, and, to date, not one has been positive for this substitution.[60,93,94,100]

One issue that has been raised in assessing hearing loss across studies is the extent of the hearing loss. Most studies document hearing loss as being greater than 10-dB pure-tone average loss or greater than 15% decrease in speech discrimination scores (1995 AAO-HNS guidelines[44]). This may be a poor reporting format, however, because it does not indicate whether hearing loss is serviceable or profound. As noted previously, Altlas and Parnes[69] argued that "shotgun" protocols result in substantial rates of hearing loss greater than 30 dB (range 10% to 24%[84,86,97,101]), whereas titration methods report low rates of substantial hearing loss (range 0% to 3.5%[69,96,98,102]). Although scientifically valid comparisons of these studies are impossible because of substantial difference in protocols, this trend is a troubling feature of "shotgun" protocols.

Reporting of hearing loss n gentamicin trials does not distinguish whether the deficit is due to drug-induced toxicity or the natural consequence of Meniere's disease. The long-term hearing outcome for untreated Meniere's disease has been reported to be approximately 30% with medical therapy.[68] This figure is close to the hearing loss rates

reported by most intratympanic gentamicin trials. The implication is that any intratympanic gentamicin trial that reports rates significantly better than 30% hearing loss rate of untreated patients may represent an actual prevention of hearing loss.

Determination of when hearing loss occurs in the course of therapy may be just as important as if hearing loss occurs. Several studies reported that if severe hearing loss occurs, it is noticed within 24 hours of gentamicin administration.[96] Kaplan and associates[60] reported updated data from patients who underwent the classic "shotgun" protocol, including statistics on the hearing loss rates at 1 month and 2 years. Of the 22 patients with worse hearing at 2 years, 80% realized this loss in the first month after treatment. Similarly, 91% of patients whose hearing was unchanged at the 1-month checkup had unchanged hearing at the 2-year checkup. Of the patients who experienced early hearing loss, 14 of 17 had profound hearing loss (defined as >50 dB or <50% word discrimination score), whereas of the patients who experienced late hearing loss, 4 of 5 had nonprofound hearing loss. These findings imply that the 1995 AAO-HNS guidelines[44] might be improved if they asked clinicians to report hearing results immediately after treatment and at the 2-year interval. This information also supports efforts to use otoprotective agents to salvage hearing after toxic gentamicin treatment. Finally, although no formal data have been published to date, Jackson and Silverstein[19] described initial efforts to use steroids as a salvage treatment for hearing loss secondary to ototoxic side effects of gentamicin treatment in patients with Meniere's disease.

Acute vestibular deafferentation syndrome should be an anticipated outcome of treatment, and in this sense it is not strictly a complication. Acute vestibular deafferentation syndrome, also known as acute chemical labyrinthine upset, is the consequence of unilaterally insulting the vestibular apparatus.[103] This phenomenon usually occurs 3 to 5 days after the injection. Symptoms include vertigo, nausea, oscillopsia, and dysequilibrium. Patients can readily distinguish these symptoms from symptoms typically related to Meniere's disease. These symptoms become progressively worse until they peak 1 week after onset. During this peak, patients usually require 2 to 3 days of bed rest. Gradual resolution is achieved in 2 to 4 weeks in most patients.[88,97] Because acute vestibular deafferentation syndrome is an expected outcome of therapy, some authors recommend that a vestibular rehabilitation team be available to work with severely affected patients.[104]

Other vestibular-related side effects include constant unsteadiness and dizziness, insecure gait in dark rooms, instability of the field of vision when turning the head, and very short episodes of losing control over balance or gait (or so-called Tumarkin attacks, which characterize the symptoms of some patients with Meniere's disease). Tumarkin attacks may not depend on the vestibular function because these attacks have been reported in patients with no caloric response after treatment.[89] Visual vestibular mismatch is currently being investigated as a possible side effect of gentamicin therapy. Visual vestibular mismatch is a syndrome in which visual and vestibular information is poorly coordinated in the brain, resulting in complaints of malaise and "dizziness." Classic complaints include feeling uneasy, nauseous, or unsteady in supermarket aisles or in shopping malls, new-onset motion sickness, a dislike of fluorescent lights, or an aversion to elevator and escalator rides. This syndrome is believed to result from an overreliance on visual signals. Longridge and colleagues[105] found that 17 of 28 patients with Meniere's disease who had previous gentamicin therapy had visual vestibular mismatch. Currently, visual vestibular mismatch is a clinical diagnosis, does not correlate with posturography or caloric tests, and is a relatively new diagnostic category; conclusions about visual vestibular mismatch and gentamicin therapy should be interpreted with caution.

Indications and Contraindications

Intratympanic gentamicin treatment is indicated in patients with Meniere's disease who have had conservative therapy fail and have recurrent vertigo. Conservative therapy consists of a diuretic and diet restrictions (salt, caffeine), and is effective in 70% of cases. Some patients try additional medical treatments, including vasodilators, vestibular suppressants, tranquilizers, calcium antagonists, betahistine, antidepressants, histamine, and steroids.[72] Most practitioners consider intratympanic gentamicin therapy only after conservative therapy has failed after being tried for at least 1 year. At this junction, intratympanic steroids, endolymphatic sac surgery, and intratympanic gentamicin therapy are considered.

Sennaroglu and coworkers[42] argued that it is reasonable to try to use intratympanic steroids before using intratympanic gentamicin. In a prospective study that compared intratympanic dexamethasone (n = 24) and gentamicin (n = 16), they found that vertigo control rates were 72% and 75%. Intratympanic gentamicin was considerably more cochleotoxic than intratympanic steroids, however. Vestibular nerve section and labyrinthectomy are reserved for only the most severe and refractory cases with and without residual hearing.

Some practitioners recommend that elderly patients should be treated with caution because central compensation for peripheral vestibular loss is less effective in elderly patients.[104] Bilateral Meniere's disease (incidence of 15% to 30%) is considered by some practitioners to be a contraindication for unilateral intratympanic gentamicin treatment because if hearing loss results from treatment the remaining ear may be vulnerable to hearing loss as a natural course of the disease.[106] If bilateral disease is treated, some authors advocate that an intramuscular streptomycin protocol, rather than an intratympanic protocol, be used.[107] Patients with no serviceable hearing in the problematic ear are generally considered candidates for labyrinthectomy, but some authors recommend that the low-morbidity, low-cost intratympanic gentamicin protocol should be attempted in these patients before surgery is considered.[108]

There is some debate as to whether otologic surgery is a contraindication to intratympanic gentamicin treatment. Minor[68] reported that of patients with prior otologic surgery, only one of six achieved vertigo control. Eklund and colleagues[95] also noted that patients with prior endolymphatic sac surgery had poorer hearing outcomes. Other authors have found that prior otologic surgery does not affect either vertigo or hearing outcomes.[24] The importance of this debate is that several practitioners advocate endolymphatic shunt procedures before resorting to intratympanic gentamicin when treating intractable vertigo in patients with Meniere's disease.[68]

Summary

Gentamicin has complex pharmacokinetics, depending on the dose and route of delivery. Its toxicity is related to peak dosage, dosage interval, and route of delivery. For some practitioners, intratympanic gentamicin therapy, using low doses with long intertherapy intervals, has become the treatment of choice for medically recalcitrant Meniere's disease. The primary complication of intratympanic gentamicin is permanent hearing loss.

Otoprotective Agents

Several otologic conditions may benefit from protective or preventive treatment, including noise-induced hearing loss, exposure to ototoxic medications, and salvage of spiral ganglion neurons (SGNs) for the purposes of maximizing the effectiveness of cochlear prostheses. Otoprotective agents can be categorized as either primary or secondary interventions to the overall pathophysiologic process. Primary interventions act directly at the site of insult, whereas secondary interventions act on the intracellular sequelae of primary insults (i.e., apoptosis). Examples of primary interventions include MK801, an *N*-methyl-D-aspartate receptor antagonist, which has shown protection against acoustic trauma and aminoglycoside toxicity,[109,110] and methionine for gentamicin and cisplatin toxicity.[111,112] Secondary interventions include steroids,[28] apoptosis inhibitors,[95] and neurotrophins.[113]

There is a sort of "intermediate intervention" that is possible with noise-induced hearing loss and the use of antioxidants. The contribution of free radical damage in noise-induced hearing loss results from metabolic and oxidative stress, ionic flux and dysregulation of calcium homeostasis, and mitochondrial injury. A more recent example of antioxidant treatment for noise-induced hearing loss is the use of *N*-acetyl cysteine.[114] We focus here mainly on neurotrophins as otoprotective agents because these are most cogent to the emerging pharmacology of the cochlea and labyrinth.

Apoptosis has been shown to be the major pathway of cell death in various conditions, including aminoglycoside toxicity,[53] cisplatin

toxicity,[115] hypoxia,[116] acoustic trauma,[77] neurotrophin withdrawal,[113,115] and presbycusis.[117] Neurotrophic support may be crucial in preventing apoptosis. Malgrange and associates[113] prevented apoptosis in explanted outer hair cells by administering various neurotrophins. In the same experiment, these investigators prevented apoptosis by administering protein synthesis inhibitors. These observations imply that neurotrophic support (among other things) provides tonic suppression of proteins in the apoptotic cascade. Rong and colleagues[118] provided proof of this notion by showing that nerve growth factor (NGF) promotes cell survival by regulating proteins that are essential to the apoptotic cascade.

Free radicals also play an important role in hearing loss. They are primary inducers of apoptosis (as in free radical–generating aminoglycoside-iron compounds) and secondary consequences of cochlear insult (as in the oxidative stress of excitotoxicity). The generation of free radicals may be a required step in apoptosis. There is a strong connection between free radicals and neurotrophins. Dugan and coworkers[119] showed that removal of NGF from cultured auditory neurons caused a rapid increase in intracellular free radical generation and subsequent apoptosis. Reapplying NGF rapidly diminished the concentration of these free radicals and decreased apoptotic cell death. Shulz and coworkers[4] showed that inhibition of caspases (proteases associated with apoptosis) not only blocked apoptosis, but also blocked the formation of free radicals, implying that the formation of free radicals is downstream from caspases in the apoptotic cascade. Likewise, exogenous brain-derived neurotrophic factor (BDNF) not only protects cisplatin-exposed neuronal cultures from apoptosis, but also reduces the free radical species in the culture.[120] These results have led researchers to believe that free radicals are effector molecules in the apoptotic cascade, and that they can be regulated not only by antioxidants, but also by neurotrophins.

Neurotrophins modulate calcium homeostasis,[94] regulate apoptotic proteins,[118] and alter expression of endogenous free radical scavengers,[4,119,120] and any of these functions may account for their otoprotective effects. Several specific neurotrophins have been used for in vivo models of noise-induced hearing loss with variable success. Glial cell line–derived neurotrophic factor (GDNF) greatly enhances the survival of guinea pig cochlear neurons (but not hair cells) if administered 4 days after noise-induced trauma.[121] Keithley and associates[122] showed that hair cells are preserved if GDNF is administered before or immediately after toxic noise exposure. Damage was attenuated if GDNF was applied after 2 hours, but not after 4 hours. The method of delivery in this experiment was topically to the RWM.

Shoji and coworkers[123] found that GDNF provides bilateral protection even when administered in only one ear. Because their experiment used long-term application of GDNF, it may have diffused through the cerebrospinal fluid. Another possibility is that GDNF influences higher cortical centers in the auditory pathway, which has a rich efferent projection and is highly bilateral. Yamasoba and colleagues[124] combined GDNF with antioxidants to determine whether synergistic protection could be achieved. They found that additional functional, but not morphologic, protection was achieved, implying that the interventions in antioxidant and neurotrophin therapy are additive, not synergistic. Neurotrophin-3 (NT-3) showed equal or greater physiologic and histologic protection from acoustic trauma relative to GDNF (with the same animal model).[125] BDNF and fibroblastic growth factor show no protective effect against toxic noise.[125]

Many experimental otoprotective treatments have been shown to be effective only if administered prophylactically or immediately after injury. Many of these injuries clinically manifest long after the initial insult, precluding any hope of salvaging hair cells. There is a much larger window of opportunity to salvage the auditory neurons after injury, however. Although there is rapid degeneration of the peripheral processes of the auditory nerve after inner hair cell loss (within hours or days), the degeneration of SGN soma and central auditory projections takes much longer (weeks to years).[126] There is intense interest in the use of neurotrophic agents to enhance SGN survival, mostly in anticipation of future cochlear implantation. This is because the hearing benefits of cochlear implants are directly related to the number of surviving auditory neurons[127] and their proximity to stimulating electrodes.[126,128]

Neurotrophins are essential not only for the normal development of the central and peripheral nervous systems, but also for their maintenance and normal function.[126] The destruction of cochlear hair cells and supporting cells because of exogenous insults (e.g., ototoxicity, acoustic trauma) results in the de facto withdrawal of trophic support. The ensuing degeneration of SGNs after cochlear insult is most likely a result of the loss of cochlear trophic support, rather than from direct toxic insult.[126] Withdrawal of neurotrophins in vitro causes apoptosis in SGNs.[116] The application of antisense oligonucleotides to inhibit expression of BDNF and NT-3 induces programmed cell death in explanted auditory neurons.[115] Apoptosis inhibitors have been shown to block neurotrophin withdrawal–induced cell death.[116]

Numerous neurotrophins have been shown to be effective in preventing SGN demise after experimental destruction by various insults. Exogenously applied NT-3,[129,130] BDNF,[130-132] BDNF in combination with a ciliary neurotrophic factor analogue,[133] NGF,[134] and 4-methylcatechol (an inducer of NGF synthesis)[135] enhance SGN survival after aminoglycoside insult. BDNF and GDNF enhance SGN survival after acoustic trauma[121]; BDNF[136] and GDNF[137] enhance SGN survival after cisplatin exposure. The enhancement of SGN survival with electric stimulation may also involve neurotrophins because depolarization induces an autocrine neurotrophin loop.[138] A strategy to use neurotrophins to enhance SGN survival before implantation and electric stimulation to promote autocrine neurotrophin release after implantation may be effective in enhancing hearing outcomes in patients receiving cochlear implants.

Aside from neuronal salvage, numerous studies have documented the ability of neurotrophins to stimulate innate regenerative and repair capabilities in auditory cells. Enfors and colleagues[129] showed that NT-3 induced neurofilament growth after aminoglycoside ototoxicity, as evidenced by the appearance of Gap 43, a growth cone marker. Lefebvre and colleagues[139] showed that NGF is a potent stimulator of repair and reinnervation in auditory neurons. Ylikoski and coworkers[121] showed that GDNF has potent trophic effects on the cochlear-neuron perikarya. Fibroblastic growth factor alone[140] or in combination with BDNF[141] produces a dose-dependent increase in the number and length of SGNs. These and other similar findings are significant because closer contact between stimulating electrodes on cochlear implants and auditory neurons leads to reduced stimulation thresholds, increased dynamic range of responsiveness, and potentially enhanced specificity of excitation.[126,128] It is possible that these growth-stimulating properties of neurotrophins could be exploited to engineer intimate contact with implanted electrodes, such that increasingly focused tonotopic stimulation could be matched to advanced signal-processing strategies.[126]

Preliminary studies on the interactions between auditory neurons and alloplastic cochlear implant materials have been performed, paving the way for the development of implant-tissue interfaces for the next generation of cochlear prostheses.[142] Neurotrophins are expected to play a role in this effort to unite biologic and synthetic materials, an effort that may lead to the development of a fully functional artificial cochlea. Neurotrophins have also been tested as a secondary intervention after aminoglycoside toxicity. Ruan and colleagues[143] used long-term infusion of NT-3 and BDNF in the setting of aminoglycoside challenge, and found that NT-3, and to a much lesser extent BDNF, protected hair cells from aminoglycoside toxicity. Although the mechanism of action is unclear, the authors speculate that just as SGNs rely on trophic support from hair cells, these hair cells may have trophic dependence on SGNs. This notion is supported by an increasing body of evidence showing that there is anterograde transport, transcytosis, and recycling of neurotrophic factors in neural networks.[144] Hair cell survival is partly determined by neurotrophin support. Malgrange and colleagues[113] tested a panel of 13 different growth factors and found that acidic fibroblastic growth factor, insulin-like growth factor-1, epidermal growth factor, transforming growth factor-β1, and GDNF were able to sustain adult explanted outer hair cells (which otherwise experience rapid demise in in vitro culture media).

Table 155-1

Features of Various Gene Therapy Vectors

Vector	Genome	Insert Size	Site	Efficiency	Cell Division	Expression	Advantages	Disadvantages
AAV	ssDNA	4.5 kB	Genome	Variable	Not required	Permanent	No human disease	Difficult to produce
Retrovirus	RNA	6-7 kB	Genome	Low	Required	Permanent	Suited for neoplastic cells	Insertional mutagenesis
Adenovirus	dsDNA	7.5 kB	Episome	Moderate	Not required	Transient	Ease of production	Inflammatory response
Herpesvirus	dsDNA	10-100 kB	Episome	Moderate	Not required	Transient	Neural tropism	Human disease
Plasmid	RNA/DNA	Unlimited	Episome	Very low	Not required	Transient	Safe, easy production	Low transfection
Liposome	RNA/DNA	Unlimited	Episome	Very low	Not required	Transient	Safe, easy production	Low transfection

Summary

One of the goals of rational drug discovery is to dissect the specific molecular mechanisms in a given pathophysiologic process, and determine where they are redundant and where they are independent. If nonredundant mechanisms can be identified, synergistic strategies to treat the pathologic process can be devised. In the context of hearing loss, multiple interventions can be constructed that are nonredundant and synergistic, as in the combination of an antioxidant, a neurotrophin, and an apoptosis inhibitor. The new understanding of the molecular mechanisms of hearing loss is creating quantum advances in otopharmacology by supplying researchers with a multitude of potential targets for therapeutic intervention and prosthetic augmentation.

Gene Therapy

Although gene therapy of the inner ear is a technology still in its infancy, advances in pharmacologic and gene therapy offer prospects to manage degenerative disorders of the labyrinth. Much of the experimental data so far concern the development of suitable vectors for gene transfer and methods of delivering these vectors to their target. Some teams have reported successful gene transfer of therapeutic genes, however. These advances may be able to stimulate hair cell regeneration and, ultimately, restoration of the transduction potential within the organ of Corti.

Otologic science was revolutionized by the observation that avian hair cells regenerate after insult.[145,146] Since then, barriers to inducing regeneration within the mammalian cochlea have been elucidated, including strategies that can address mature and damaged inner ear.[147] Beyond hair cell regeneration, there is the related problem of inducing synaptogenesis and nerve regrowth to these newly created hair cells.[148] These and a host of other concerns are currently being investigated. The ultimate vision is to orchestrate through pharmacology and gene therapy a recapitulation of the embryonic events that lead to a functioning auditory system. Although this section deals mainly with gene therapy, there are exciting new stem cell therapies that address similar topics on the horizon as well.[149]

Vectors

There is no single ideal vector for gene transfer because each vector has characteristics that make it more or less suitable to each application (Table 155-1). The length of the gene to be transferred, the specific inner ear tissue that is targeted, the desired method of delivery, and the duration of transgene expression are all factors that determine the most suitable vectors. Various viral and nonviral vectors are available to the gene therapist. The variability in the transgene expression pattern with different gene transfer vectors is likely a consequence of numerous factors, including the size of the viral particle, presence or absence of viral receptors, and mode of delivery. Inspection of Table 155-1 allows for some generalization about the ability of various viral vectors in transfecting cochlear tissues. The spiral ganglion cells, spiral ligament, and Reissner's membrane were transfected by every virus tested. Only adenovirus showed transgene expression within the stria vascularis. Immune response was present in the cochlea after transfection with adenovirus, herpes simplex virus, and vaccinia virus.

Delivery

Local gene therapy to the inner ear is feasible because of its relatively closed anatomy. Developing a delivery method for genetic vectors to the inner ear without causing local destruction is a significant obstacle. Several delivery methods have been used, including mini–osmotic pump infusion (either through cochleostomy or through the RWM), microinjection into the RWM, injection into the endolymphatic sac, and diffusion across the RWM after local Gelfoam placement. Cochleostomy has been shown to cause histopathologic alterations (including localized surgical trauma and inflammation), and may lead to hearing loss.[150]

Introduction of viral vector by means of infusion with a mini–osmotic pump was characterized by evidence of trauma at the basal turn adjacent to the cochleostomy associated with an inflammatory response and connective tissue deposition. Carvalho and Lalwani[150] showed preservation of preoperative auditory brainstem response thresholds in the lower frequencies (1 to 2 kHz), mild postoperative elevation of thresholds (<10 dB) in the midfrequencies (4 to 8 kHz), and marked increase (>30 dB) in auditory brainstem response thresholds at higher frequencies (>16 kHz) after mini–osmotic pump infusion by way of a cochleostomy.

Several studies have documented that direct microinjection through the RWM can be accomplished without causing permanent hearing loss or tissue destruction seen with cochleostomy.[56,124] Histologically, cochleae microinjected through the RWM showed intact cochlear cytoarchitecture and an absence of inflammatory response 2 weeks after microinjection through the RWM. Microinjection through the RWM did not cause permanent hearing dysfunction.[151]

The potential for surgical trauma, inflammation, and hearing loss associated with these infusion or microinjection techniques led to the investigation of a less invasive delivery method. Diffusion across the RWM has been shown to be an effective, atraumatic, but vector-dependent method of delivery for gene transfer vectors. Jero and coworkers[152] investigated the potential to deliver various vectors across an intact RWM by loading vectors onto a Gelfoam patch that was placed in the round window niche. Adenovirus and liposome vectors, but not the AAV vector, effectively infected inner ear tissues, as evidenced by detection of reporter genes. Lipocomplexed plasmid vectors have also been shown to cross the RWM effectively.[153]

Preclinical Applications

Most of the preclinical applications for gene therapy in the inner ear have concerned neurotrophin therapy. This is because for some applications of exogenous neurotrophins (e.g., to maintain SGN survival or to induce neurite outgrowth), the neurotrophins must be applied long-term. In this sense, gene therapy is being used as a long-term drug delivery strategy, rather than to replace defective or missing genes.

Staecker and colleagues[130] used a herpes simplex virus-1 vector to deliver BDNF to the inner ear. After neomycin injection, the gene therapy group showed a 94.7% salvage rate for SGNs, in contrast to a 64.3% loss of SGNs in control animals. Although BDNF staining was ubiquitous in inner ear tissues, this was not the case for the reporter gene, β-galactosidase. Although only 50% of cells were transfected (as determined by the number of β-galactosidase cells), this was enough to cause cochlea-wide BDNF distribution and to ensure 95% SGN survival. The authors speculate that SGNs must require only a few BDNF-producing cells to ensure the survival of the entire ganglion.

Lalwani and colleagues[154] used in vitro and in vivo models to test effectiveness of an AAV vector for BDNF transfer. They found a significant survival effect from controls after aminoglycoside challenge in cochlear explants. Although direct measurements of BDNF could not be recorded, the vector's ability to salvage SGNs was tested against a gradient of known BDNF concentrations. They found that the vector system was able to achieve the same protective effects as 0.1 ng/mL of BDNF. This dose is subtherapeutic because the most efficient dose was determined to be 50 ng/mL, a concentration of BDNF that results in almost total SGN protection. In the in vivo experiment, animals infused with AAV-BDNF with a mini-osmotic pump displayed enhanced SGN survival. The protection from AAV-BDNF therapy was region specific; there was protection at the basal turn of the cochlea, but not the middle or apical turn. The authors propose that this regional selectivity is a pharmacokinetic phenomenon.

NT-3 gene transfer for protection against cisplatin-induced ototoxicity has been achieved by the use of a herpes simplex virus-1 amplicon–mediated delivery system.[155,156] Chen and associates[156] established efficacy of the vector in an in vitro study, in which amplicon-mediated transfer of NT-3 (shown by production of NT-3 mRNA proteins and by reporter gene expression) conferred increased survival to cochlear explants after cisplatin exposure. Bowers and colleagues[155] confirmed these effects in an in vivo model, in which amplicon-mediated transfer of NT-3 to SGNs suppressed cisplatin-induced apoptosis and necrosis. The authors suggest that these findings not only may be useful to prevent cisplatin-related injury, but also may provide preventive treatment for hearing degeneration because of normal aging.

Several studies have established the efficacy of an Ad vector carrying the GDNF gene (Ad.GDNF) to protect against various ototoxic insults. When administered before aminoglycoside challenge, Ad.GDNF significantly protects cochlear[157] and vestibular[158] hair cells from cell death. Pretreatment with Ad.GDNF also provides significant protection against noise-induced trauma.[50] Finally, Ad.GDNF enhances SGN survival when administered 4 to 7 days after ototoxic deafening with aminoglycosides.[159]

Some studies have used gene therapy to induce the expression of target proteins other than neurotrophins. Several studies have transduced genes that express proteins that inhibit the apoptosis cascade, and protect against ototoxic insult. Liu and associates[160] used an AAV vector to induce Bcl-x(L), an apoptosis inhibitor to mitigate aminoglycoside toxicity. Chan and colleagues[161] successfully induced the expression of the X-linked apoptosis inhibitor using an AAV virus, and this proved to be protective against cisplatin toxicity. In another line of research, attempts are being made to overexpress *Math1* through gene transfer. The significance of *Math1* gene is that it is intimately associated with cochlear and vestibular stem cells, and the overexpression of the *Math1* protein stimulates hair cell regeneration. Izumikawa and colleagues[162] used an adenovirus vector to induce overexpression of *Math1* after aminoglycoside deafening, and showed cellular and functional repair in the organ of Corti. Similarly, Staecker and coworkers[163] used an adenovirus vector to induce expression of *Math1* after vestibulotoxic aminoglycoside exposure, and successfully induced the regeneration of vestibular hair cells. These and other studies are adding to the list of potential targets for gene therapy for the inner ear.

Safety Concerns

Early investigations in the development of gene transfer in the cochlea identified potential safety concerns. Through use of AAV as the gene therapy vector, Lalwani and associates[164] observed transgene expression within the contralateral cochlea of the AAV-perfused animal, albeit much weaker than within the directly perfused cochlea. Subsequently, Stover and colleagues[165] showed transgene expression in the contralateral cochlea using adenovirus. This finding of transgene expression in the contralateral cochlea raises concern about dissemination of the virus from the target tissue. The appearance of the virus, distant from the site of infection, may be due to its hematogenous dissemination to near and distant tissues; however, this is unlikely.[165,166] Other possible explanations include migration of AAV by way of the bone marrow space of the temporal bone[166] or the cerebrospinal fluid space to the contralateral ear.[165,166] The perilymphatic space into which the virus is perfused is directly connected to the cerebrospinal fluid by way of the cochlear aqueduct; transgene expression within the contralateral cochlear aqueduct has been shown after introduction of the viral vector in the ipsilateral cochlea. Collectively, these results suggest potential routes for AAV dissemination from the infused cochlea through the cochlear aqueduct, or by extension through the temporal bone marrow spaces. Subsequent investigations have shown that dissemination outside the target cochlea can largely be eliminated by the use of microinjection or RWM application of vector, and avoidance of the infusion technique.[152,167,168]

Summary

A crucial step forward toward the eventual application of gene therapy for hearing disorders has been accomplished: viral and nonviral vectors have been shown to introduce and express exogenous genes capably into the peripheral auditory system. Future refinements will include the development of newer hybrid vectors that assimilate the infectivity and stability of the viral vectors and the safety of liposomes. The hybrid vectors will largely replace the current generation of vectors. The preferred mode of introduction of gene therapy vectors will be one that minimizes tissue damage and hearing loss, such as microinjection or application of the vector at the RWM. Safety concerns, especially regional and distant dissemination of the therapeutic agent, will need to be monitored and minimized.

CHAPTER ONE HUNDRED AND FIFTY-SIX

Otologic Symptoms and Syndromes

Carol A. Bauer

Herman A. Jenkins

Key Points

- Otalgia in the absence of detectable ear pathology can arise from a wide range of sources and requires a complete head and neck examination for accurate diagnosis.
- Chronic painful bloody otorrhea should prompt an evaluation for malignant otitis externa or neoplasia of the external auditory canal.
- The most informative features in evaluating hearing loss are the time course of the loss, associated symptoms, and age of the patient.
- The most common bacterial pathogens causing otitis externa are *Pseudomonas aeruginosa* and *Staphylococcus aureus*.
- Radiographic imaging of the temporal bone with high-resolution CT is essential in the evaluation of clear watery otorrhea.
- A complete history with a careful description of the symptoms is needed to discriminate between central and peripheral causes of vertigo.

Various symptoms can be either suggestive or diagnostic of ear disease. Accurate clinical assessment is facilitated by understanding the significance of symptom combinations and the relative frequency of specific otologic diseases in different patient populations. This chapter reviews the common symptoms associated with otologic diseases and the diagnoses to be considered when evaluating these symptoms. Common symptoms that indicate an otologic problem are otorrhea, otalgia, aural fullness, hearing loss, vertigo, and tinnitus. The symptoms of hearing loss, vertigo, and tinnitus are discussed in other chapters, and are addressed only briefly here.

Otorrhea

In adults and children, otorrhea can arise from numerous sources (external ear canal, middle ear, mastoid) and may have a variety of etiologies (Box 156-1). Diagnostic considerations and subsequent treatment plans are directed by the source of the otorrhea; the age of the patient; the type of otorrhea (clear, mucoid, purulent, or bloody); the nature of the drainage (acute, chronic, or pulsatile); and the presence of other symptoms, such as otalgia, neurologic deficits, or associated systemic disease or symptoms. Evaluation requires meticulous suctioning of secretions under a microscope to identify the source of the drainage, and to differentiate between a primary infection or purulent drainage occurring secondary to an underlying inflammatory process.

Common causes of otorrhea differ between adults and children. In children, otorrhea is caused most commonly by either acute otitis media with tympanic membrane rupture or chronic otitis media in the presence of a tympanic membrane perforation. In adults, otorrhea results most commonly from either external otitis or chronic otitis media with a perforation. The initial history and physical examination should be directed toward establishing the time course of the symptom and the source of the otorrhea (ear canal, middle ear, mastoid).

The diagnosis of external otitis as the source of purulent otorrhea is suggested by a history of ear trauma or swimming-related water contamination of the canal. Trauma resulting in external otitis may occur from the use of cotton-tip swabs, irrigators for cerumen removal, in-the-canal hearing aids, or digital ear thermometers. A history of otalgia and drainage after swimming easily leads to a diagnosis of external otitis. Although typically painful, there are usually no additional systemic symptoms associated with this localized infection. The typical findings on physical examination include an exquisitely tender ear canal that is partially to completely obstructed by edematous skin, and associated with preauricular tenderness.

Purulent otorrhea may develop secondarily in patients with chronic dermatitis or eczema of the ear canal, without any prior history of trauma or water contamination. Bacterial or fungal infections may complicate this chronic skin condition. Symptoms of chronic dermatitis of the ear canal include complaints of dry, itchy ears. Secondary infection of chronic dermatitis of the ear canal is usually painless. Important points include a history of recent use of topical antibiotic ointments or solutions that may cause an localized allergic skin reaction with canal pruritus, edema, and purulent drainage. Physical examination should document the presence of fungal hyphae in the canal, keratin debris from chronic dermatitis, or, uncommonly, a canal cholesteatoma or keratoma. After suctioning all purulent material from the canal, the tympanic membrane must be examined for evidence of a retained foreign body, such as a pressure equalizing tube with localized granulation tissue, as the source of the otorrhea.

The most common bacterial pathogens causing external otitis are *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Less commonly, other aerobic, facultative, and anaerobic organisms have been cultured from infected ears. Rarely, external otitis results from a local or regional infection that involves the ear secondarily. *Actinomyces israelii* is an

Box 156-1

Sources of Otorrhea

External Canal
Otitis externa (fungal, bacterial, viral)
Necrotizing otitis externa
Acute dermatitis
Keratosis obturans
Canal cholesteatoma
Neoplasm
Regional infection (parotid)

Tympanic Membrane
Granulation tissue
Granular myringitis
Bullous myringitis
Retraction pocket with cholesteatoma

Middle Ear
Acute otitis media with perforation
Chronic otitis media with perforation
Neoplasm

Mastoid
Mastoiditis, acute or chronic, with perforation
Granulomatous disease
Cholesteatoma
Neoplasm

Cerebrospinal Fluid
Temporal bone fracture
Tegmen defect
Cochlea deformity
Hyrtl's fissure

anaerobic gram-positive bacterium that can cause external otitis from a primary dental or parotid infection. This infection may manifest as refractory otitis externa with granulation tissue in the ear canal and thick yellow otorrhea. Recognition of this entity is important because treatment involves surgical débridement and prolonged antibiotic therapy.[1]

Malignant or necrotizing external otitis is a locally aggressive, potentially progressive form of otitis externa. Inflammation and necrosis can extend beyond the ear canal skin to involve underlying cartilage and bone. Extensive disease involves local and regional osteomyelitis of the temporal bone, resulting in severe, deep ear pain. Malignant otitis externa occurs most commonly in adults. The diagnosis should be considered, however, in children with poor general health or concurrent systemic disease with acute onset of painful otorrhea. Fifteen cases of malignant external otitis occurring in infants and children 2 months to 15 years old have been reported in the literature.[2,3] Risk factors in these patients included poor general health, immunosuppression, and diabetes mellitus. Common presenting findings on physical examination include granulation tissue within the external auditory canal, preauricular and auricular edema and erythema, tympanic membrane necrosis, and facial nerve paralysis. *P. aeruginosa* is the most common causative organism in children and adults with malignant external otitis.

Fungal infections of the ear (otomycoses) are typically limited to the external ear canal as a superficial infection. Rarely, these infections are invasive and involve the temporal bone. Common fungal species infecting the external ear canal are *Aspergillus niger* and *Candida albicans*. The former is easily recognized as pigmented fungal tufts atop a tangle of hyphal threads resembling a ball of cotton. *Candida* spp. also may colonize the ear canal, especially in patients previously treated with prolonged courses of antibiotic eardrops. A canal infected with *Candida* appears wet and macerated, filled with soft, curdlike debris. If the fungal infection has an associated bacterial component, the fungal elements may not be immediately evident. Rarely, the external ear canal and mastoid are primarily involved with coccidioidomycosis, which may resemble eczema or an allergic dermatitis.[4]

Secondary mycosis of the temporal bone is quite rare and may arise from a primary focus of infection involving the meninges or the paranasal sinuses. Causative agents include *Cryptococcus, Candida, Blastomyces,* and *Mucor*. Primary otogenic invasive fungal infections can occur in immunocompromised hosts who are human immunodeficiency virus positive, elderly individuals, and patients with diabetes mellitus. These cases may develop invasive fungal disease within the mastoid and temporal bones, resulting in rapidly progressive hearing loss and facial paralysis. *Aspergillus fumigatus* and *Aspergillus flavus* are sources of invasive fungal mastoiditis with serious morbidity and mortality.

An uncommon cause of purulent otorrhea arising from the external canal in children is infection of a first branchial cleft cyst. In some forms of this congenital anomaly, there is a sinus tract adjacent to the external canal causing localized edema, whereas in others a fistula may be present with an external opening into the external ear canal. The anomaly may not be recognized until drainage and swelling of the ear canal occur. An even rarer source of secondary external canal otorrhea in children and adults is a primary infection of the parotid gland that extends into the external ear canal through the fissures of Santorini. These fibrous channels within the cartilaginous ear canal can serve as a direct route of disease extension.

Severe otalgia associated with bloody or serous otorrhea should prompt examination of the canal and tympanic membrane for evidence of vesicles. Bullous external otitis and myringitis result in hemorrhagic vesicles on the bony external canal and tympanic membrane. This uncommon infection causes exquisite ear pain out of proportion to the physical examination. The infection may be viral, but *Mycoplasma pneumoniae* and *Haemophilus influenzae* have also been cultured from the vesicles. Conductive hearing loss secondary to an associated middle ear effusion often accompanies the localized infection. A mixed loss with a significant sensorineural component has been shown in 30% to 65% of cases of bullous myringitis in which audiometric assessment was performed. The hearing loss completely resolved in 60% of cases.[5,6]

Herpes zoster oticus (Ramsay Hunt syndrome) should be considered if vesicles with an erythematous base are evident on the external canal, pinna, or soft palate. Significant otalgia described as a burning sensation is present with this infection, along with hearing loss, vertigo, and facial paralysis.

Tympanic Membrane, Middle Ear, and Mastoid Sources of Otorrhea

If the physical examination shows a normal-appearing external ear canal, the source of the otorrhea is the tympanic membrane, the middle ear, or the mastoid. Acute otitis media, chronic otitis media, and cholesteatoma are the most common sources of purulent or mucoid drainage from the middle ear and mastoid. Less common causes of chronic otorrhea from the middle ear and mastoid are neoplasms that become secondarily infected and systemic diseases with otologic manifestations.

If a patient with chronic otorrhea has undergone prior mastoid surgery, the physical examination should be directed toward establishing whether the drainage is from a superficial infection of the mastoid cavity or is caused by recurrent or residual mastoid disease. When the mastoid cavity is inspected, any anatomic factors should be noted that predispose toward poor aeration and bowl hygiene, such as a small meatus, high facial ridge, or large dependent mastoid tip. In these cases, the tympanic membrane may appear normal, and the middle ear may be aerated, but because of poor hygiene the mastoid bowl collects debris, and a superficial infection develops. The infection may be fungal or bacterial in nature; examination with meticulous cleaning under a microscope establishes the diagnosis.

In most cases, débridement and treatment with topical antifungal or antimicrobial eardrops or acidifying and drying agents, such as boric acid and alcohol solution, or dilute vinegar solution, suffice as manage-

ment. In chronic infection, granulation tissue and mucosalized epithelium in the bowl can develop, however, requiring more aggressive treatment with chemical cauterization. Meticulous inspection of the mastoid bowl also reveals evidence of retained mastoid air cells or recurrent cholesteatoma debris as the cause of recurrent otorrhea. Revision mastoid surgery is usually required to eliminate these sources of infection.

In the case of otorrhea from acute otitis media, the drainage may be bloody, mixed with mucus, or mucopurulent, and is typically short-lived. Bloody or purulent otorrhea associated with pain also may occur either immediately or in a delayed fashion after placement of pressure equalization tubes. This otorrhea may occur because of granulation tissue obstructing the tube lumen, middle ear contamination after bathing or swimming, acute otitis media, or reflux of nasopharyngeal secretions through the eustachian tube into the middle ear.

Neglected or inadequately treated acute or chronic otitis media may progress to acute coalescent mastoiditis or chronic bacterial otomastoiditis. Typically, acute otomastoiditis manifests with otalgia, mastoid tenderness, and purulent drainage from the middle ear. Uncommonly, mastoiditis may result from obstruction of the aditus ad antrum; the tympanic membrane and middle ear appear normal in this situation. In acute mastoiditis, the ear canal typically is edematous and tender, resembling external otitis with retroauricular extension. In addition to external canal edema, patients with acute mastoiditis may have auricle protrusion, mastoid tenderness, and swelling, and possibly systemic symptoms of fever. Additional symptoms may be present if there are aural or intracranial complications of the acute or chronic infection. Aural complications include subperiosteal abscess, petrositis, facial paralysis, and labyrinthitis. Intracranial complications include extradural abscess; thrombosis or thrombophlebitis of the sigmoid sinus, transverse sinus, or sagittal sinus; subdural abscess; brain abscess; meningitis; and otitic hydrocephalus. A high index of suspicion and a thorough neurologic examination are required to detect possible aural and intracranial complications of a mastoid infection.

Acquired cholesteatoma is a common cause of painless, recurrent purulent otorrhea in adults and children. The otorrhea may be scant or profuse depending on the extent of the disease, and whether the keratin debris is infected. There is usually an associated long-standing hearing loss. Vestibular symptoms are typically not present, unless there is extensive bone destruction by the cholesteatoma. Erosion of the lateral semicircular canal with formation of a labyrinthine fistula may occur, and the patient may note dysequilibrium that is either spontaneous or induced by loud sounds (Tullio's phenomenon) or positive pressure applied to the external ear canal. Diagnosis of cholesteatoma as the source of otorrhea is evident after meticulous cleaning of the ear canal and examination with binocular microscopy. Typically, a retraction pocket is seen in the posterosuperior quadrant of the tympanic membrane or in the pars flaccida region. The otorrhea and keratin debris emanating from the abnormal retraction are indicative of the acquired cholesteatoma.

Granular myringitis is an uncommon, idiopathic, inflammatory process involving the tympanic membrane. Granulation tissue and mucosalized epithelium extend over patchy areas of the tympanic membrane. In extensive cases, the entire tympanic membrane is thickened, and the granulation tissue exudes a thin transudate that may become secondarily infected.[7]

Systemic Disease Associated with Otorrhea

Noninfectious Causes

Granulomatous diseases of the temporal bone are uncommon. Presenting symptoms can mimic acute or chronic mastoiditis. Children with histiocytosis of the temporal bone can present with symptoms of painful purulent or bloody otorrhea. The three forms of histiocytosis (eosinophilic granuloma, Letterer-Siwe disease, and Hand-Schüller-Christian disease) all may involve the temporal bone.[8] In addition to complaints of localized ear pain, there is evidence of suppurative drainage from the middle ear and mastoid, granulation tissue within the external auditory canal, local swelling of the postauricular or preauricular region, and bone destruction on radiographic imaging. Auditory and vestibular deficits, facial palsy, and lower cranial nerve deficits also may be present.[9]

Wegener's granulomatosis is a granulomatous disorder consisting of inflammatory vasculitis of the upper and lower respiratory tracts and kidney. Almost one fourth of patients have otologic disease at some point during their illness. Otologic involvement may manifest as a serous otitis media or a suppurative otitis media with either thickening or perforation of the tympanic membrane. Granulation tissue may be present within the middle ear and mastoid, causing a painless chronic otorrhea that is associated with conductive, sensorineural, or mixed hearing loss.[10] A high index of suspicion and confirmation with an elevated cytoplasmic antineutrophil cytoplasmic autoantibody titer facilitate the diagnosis.

Churg-Strauss syndrome is an autoimmune disease that may have otologic manifestations in the late stages of the disease. Asthma, recurrent sinusitis, peripheral neuropathy, eosinophilic infiltrates, systemic vasculitis, and peripheral eosinophilia are hallmarks of the disease. In advanced disease, otologic involvement may include a dense aural discharge, granulomatous eosinophilic infiltrates of the middle ear and mastoid, and severe to profound mixed hearing loss. Recognition of this entity is important because the disease is highly responsive to systemic steroids.[11]

Infectious Causes

Aural tuberculosis and nontuberculous mycobacterial mastoiditis are granulomatous infections with presentations that may mimic either otitis externa or chronic otomastoiditis in adults or children. The typical history is that of an indolent infection of the external canal or middle ear with chronic painless otorrhea that is thin, watery, or serous in nature. In documented cases of aural tuberculosis, patients have had acute otalgia with purulent drainage when a bacterial superinfection is present. Typically, patients with aural tuberculosis do not have a history of pulmonary infection or exposure to a known source of tuberculosis. The diagnosis of tuberculous or atypical mycobacterial otomastoiditis is suspected when the infection fails to clear after multiple treatments with antibiotics. The ear canal and middle ear have granulation tissue, polyps, and inflammatory tissue, all of which may be diffusely destructive. In addition, there may be associated cervical, postauricular, or occasionally preauricular adenopathy and systemic symptoms of fever and malaise. The physical examination findings of a postauricular fistula associated with preauricular adenopathy, a denuded malleus, and multiple tympanic membrane perforations are reported to be pathognomonic of aural tuberculosis. Facial palsy associated with aural tuberculosis has been reported in 45% of patients.[12-14]

Neoplastic Disease Causing Otorrhea

The presenting signs and symptoms of neoplastic involvement of the temporal bone include conductive and sensorineural hearing loss, otalgia, mastoiditis, facial nerve paralysis, and purulent or bloody otorrhea. The chronic purulent or bloody otorrhea can arise from neoplasms in the ear canal, middle ear, or mastoid. In adults, the most common neoplasms of the external canal causing otorrhea are squamous cell carcinoma, basal cell carcinoma, and ceruminous gland tumors. In the early stages of disease, these neoplasms may remain asymptomatic and unnoticed until a secondary bacterial infection develops. Advanced disease with temporal bone destruction is associated with chronic deep otalgia. Examination of the ear canal with binocular microscopy after removal of purulent debris may reveal the tumor as an erosive or fungating lesion. These lesions also may manifest as persistent granulation tissue that is refractory to routine management. Biopsy of the granulation tissue is indicated to rule out an underlying neoplastic process. Glomus tumors may be isolated to the middle ear or jugular foramen region and usually do not result in otorrhea. Large tumors may fill the mesotympanum and extend into the ear canal, however, resulting in bloody or purulent otorrhea. Performing a biopsy of glomus tumors extending into the ear canal can result in profuse bleeding and should be avoided.

Metastatic lesions to the temporal bone rarely manifest with otorrhea as an initial symptom. Primary tumors from the breast, lung,

kidney, prostate, and stomach are the common sources of temporal bone metastatic lesions.[15] These tumors metastasize predominantly to the petrous apex marrow through hematogenous dissemination. Metastatic involvement of the mastoid air cells and the tympanic cavity may occur. Lymphoma and leukemia also may infiltrate the petrous apex and subsequently involve mastoid air cells. Infiltration into the middle ear cleft along mucosal folds and into the fallopian canal and internal auditory canal is common.[16]

Acute myelogenous leukemia may involve the temporal bone by chloroma formations, which are masses of leukemic cells seen as discrete green collections within the mastoid or internal auditory canal. In children, uncommon neoplasms that result in otorrhea include histiocytosis, rhabdomyosarcoma, leukemia, and lymphoma. Because the presenting symptoms can resemble chronic otitis media with purulent or bloody otorrhea, granulation tissue, and aural polyps, diagnosis of the underlying neoplasm is often delayed.

Intracranial Sources of Otorrhea

The unique presentation of continuous or intermittent clear otorrhea may represent cerebrospinal fluid (CSF). Clear otorrhea may manifest spontaneously through a perforated tympanic membrane or through a pressure equalizing tube. It may be caused by an underlying congenital anomaly or an idiopathic dural dehiscence within the temporal bone. CSF otorrhea may occur as a direct result of trauma or as a complication of neoplasia, infection, or previous surgery. Regardless of the etiology, all cases of clear otorrhea must be investigated because of the risk of meningitis associated with a persistent CSF leak. If possible, the clear fluid should be collected and the sample analyzed for the presence of β_2-transferrin. This is a protein found in CSF and perilymph, but not in blood, nasal secretions, or inflammatory effusions.[17] If the fluid is identified as CSF, immunization for *Streptococcus pneumoniae* should be considered to prevent meningitis, in addition to pursuing appropriate measures directed to stop the CSF leakage. Occasionally, serous discharge from chronic mastoiditis (or through a ventilating tube) can be profuse and mimic CSF leakage.

Radiographic imaging using high-resolution computed tomography (CT) is essential in the diagnostic evaluation of patients with clear otorrhea. Axial and coronal views should be obtained and evaluated for evidence of congenital labyrinthine abnormalities, erosive changes within the mastoid air cells, dehiscence of the middle or posterior cranial fossa dural plates, or temporal bone fractures.

Congenital labyrinthine abnormalities are an uncommon cause of CSF otorrhea. The most common labyrinthine anomaly associated with spontaneous CSF leak is a Mondini malformation. The leak may manifest as recurrent meningitis in childhood or as intermittent leakage of clear fluid from a tympanic membrane perforation or myringotomy tube. CSF leakage occurs through a defect in the lamina cribrosa of the internal auditory canal in association with a defect in the stapes footplate. A high index of suspicion should be maintained when evaluating a child with a history of recurrent clear otorrhea and sensorineural hearing loss. A much rarer source of CSF in the middle ear is through a persistently patent perilabyrinthine pathway, such as a persistent Hyrtl's fissure. This bony cleft extends medially from below the round window niche to the posterior fossa and normally ossifies during development.[18] In the absence of normal ossification, this tympanomeningeal fissure may persist as an abnormal connection between the middle ear and the subarachnoid space, resulting in a CSF fistula.

Spontaneous CSF leaks also may occur from the middle or posterior cranial fossae secondary to progressive erosion and weakening of the dura by aberrant arachnoid granulations. These leaks typically occur after the fifth decade, and manifest as a persistent unilateral effusion or profuse clear otorrhea after myringotomy.[19,20] The leakage site often is evident on CT scan as a dehiscent area of either the superior or the posterior surface of the temporal bone.

Temporal bone CSF leaks can also occur after mastoidectomy, skull base surgery, or any surgical approach to the internal auditory canal or cerebellopontine angle (e.g., translabyrinthine, middle cranial fossa, posterior cranial fossa). Inadequate dural closure at the time of surgery results in CSF leakage. Occasionally, the CSF leak occurs weeks, months, or years after temporal bone surgery in which dura was exposed but not damaged. In open mastoid cavities with exposed dura, subsequent infections may incite the formation of granulation tissue with subsequent weakening of the underlying dura. The weakened dura allows prolapse of either the temporal lobe or the cerebellum into the mastoid cavity. Over time, intracranial pressure results in erosion and exposure of the subarachnoid space with leakage of CSF. When this occurs, surgical exploration and direct dural repair with tissue grafts and supporting packing is necessary.

In an ear previously known to be normal, watery otorrhea after severe head trauma almost certainly represents meningeal laceration and CSF leakage. Egress of fluid from the ear canal occurs most commonly in cases of longitudinal temporal bone fractures because the tympanic membrane often is disrupted in these situations. Leakage of CSF from the external auditory canal occurs in 21% to 44% of temporal bone fractures.[21,22] Because the drainage typically is mixed with blood, the presence of CSF should always be suspected. If profuse clear otorrhea follows trauma that is confined to the external auditory canal and tympanic membrane, stapes dislocation and a congenital abnormality of the labyrinth are suggested. Prompt surgical exploration and, if appropriate, oval window sealing are necessary.

A rare source of clear, painless otorrhea that is not CSF in origin is gustatory otorrhea or Frey's syndrome of the external ear canal.[23] Excisional biopsy of the canal skin showing thickened skin with sudomotor gland hyperplasia is diagnostic. A parotid fistula to the external canal is another diagnostic consideration for symptoms of gustatory otorrhea.

Otalgia

Otalgia most commonly reflects either localized otologic pathology or a problem within a contiguous, periauricular structure. The physical examination usually reveals the source of the pain. It is common, however, for a patient to complain of ear pain and have no identifiable pathology within the ear. Evaluation of patients with otalgia is facilitated by a thorough understanding of the innervation of the ear. Appreciation of the anatomy underlying shared neural pathways and the potential causes of referred otalgia arising from a distant site enables an astute physician to reach a diagnosis when evaluating a patient with the complaint of ear pain.

The auricle, periauricular region, external canal, and middle ear are supplied with sensory afferents from the trigeminal, facial, glossopharyngeal, and vagal nerves, and the cervical plexus. The auriculotemporal branch of the mandibular division of the trigeminal nerve provides sensation to the tragus, anterior pinna, anterior lateral surface of the tympanic membrane, and anterosuperior external auditory canal wall. The vagus nerve provides sensation to the larynx, hypopharynx, trachea, esophagus, and thyroid gland. The auricular branch of the vagus nerve (Arnold's nerve) provides sensation to the concha, inferoposterior external auditory canal, tympanic membrane, and postauricular skin. The glossopharyngeal nerve provides sensory innervation to the oropharynx, tonsils, and tongue base. Jacobson's nerve is the tympanic branch of the glossopharyngeal nerve that provides sensation to the medial surface of the tympanic membrane, mucosa of the middle ear, eustachian tube, and mastoid air cells. The cervical roots C2 and C3 provide sensation to the postauricular region. The facial nerve innervates the skin of the lateral concha and antihelix, lobule, mastoid, posterior external auditory canal, and posterior portion of the tympanic membrane.

Primary Otalgia

Primary otalgia arises from local or regional pathology. Sources of primary otalgia include acute otitis media, otitis externa, mastoiditis, eustachian tube dysfunction, cerumen impaction, inflammation or infection of the auricle, or ear trauma. Regional causes include temporomandibular joint dysfunction and periauricular lymphadenopathy from scalp or neck infections.

Referred Otalgia

Pain may be referred to the ear from distant sources, such as periodontal or dental disease, parotitis, sinusitis, thyroiditis, tonsillitis, laryngitis, or hiatal hernia with gastroesophageal reflux. Referred pain to the ear

can arise from any structure within the head and neck that shares a common neural pathway with the temporal bone and periauricular region. In the initial assessment, examination of the ear indicates whether the otalgia is local or regional in origin. If the ear examination is normal, it is helpful to ask the patient to point with one finger to the area of maximal pain.

The trigeminal nerve has a wide sensory distribution throughout the head and neck. Infection and neoplasms within the nasal cavity or paranasal sinuses, particularly the sphenoid or maxillary sinuses, can cause irritation of the vidian nerve, resulting in referred otalgia. Contact points between the turbinates and septal spurs can cause a similar type of pain. Nasopharyngeal surgery and neoplasms and infections in this region are common sources of referred otalgia. In children, erupting dentition is the most common cause of referred ear pain, which is recognized as ear pulling in preverbal children. Similarly, an impacted molar in an adult may cause symptoms of ear pain. Dental malocclusion resulting from temporomandibular joint dysfunction (Costen's syndrome) can cause referred ear pain from masticator muscle spasms. A history of excessive gum chewing, malocclusion, and bruxism may suggest this diagnosis. Sluder's neuralgia consists of lancinating pain in the lower face that radiates to the orbit, temple, forehead, and upper neck. The sphenopalatine branch of the trigeminal nerve is the source of this pain.

The facial nerve can be involved in referred ear pain in cases of geniculate neuralgia, Bell's palsy, and herpes zoster oticus. The ear pain of herpes zoster oticus can occur even in the absence of a significant vesicular eruption. The otalgia associated with Bell's palsy frequently occurs before the onset of facial paralysis.

The glossopharyngeal and vagus nerves can transmit referred ear pain as a result of pathology originating from anywhere within the upper aerodigestive tract. The ninth cranial nerve can be stimulated from pathology in the pharynx, such as tonsillitis, postoperative tonsillectomy, peritonsillar abscess, and neoplasms. Lingual tonsillitis and impacted foreign bodies within the tongue can also cause otalgia. Eagle's syndrome consists of ear pain secondary to stretching and irritation of the glossopharyngeal nerve from elongation of the styloid process. Glossopharyngeal neuralgia is similar to tic douloureux or trigeminal neuralgia. The pain is sharp and lancinating in quality, and originates in the tongue base, soft palate, or tonsillar fossa and radiates to the ear. Rosenmüller's fossa may be the trigger zone with this form of neuralgia.

Neoplasms within the larynx and esophagus have long been recognized as causes of referred otalgia. Ulcerations, foreign bodies, and reflux also can be seen in this manner. Chronic or subacute inflammation of the thyroid gland may cause referred ear pain through stimulation of the vagus nerve.

Aural Fullness

Patients often describe aural fullness as a stuffy feeling in the ear, ear pressure, or a clogged sensation. This subjective symptom may be associated with various ear disorders.

Aural fullness may occur because of obstruction of the external ear canal by cerumen, debris, or a foreign body. A sensation of fullness also may result from a soft tissue mass either in the middle ear or arising from the tympanic membrane. Cholesteatoma and neoplastic disease can manifest in this manner. If the patient's history reveals associated ear pain, drainage, or hearing loss, the physical examination easily establishes the diagnosis.

An abnormally patent or an obstructed eustachian tube also may elicit the sensation of aural fullness. Patients complain of autophony and of hearing breath sounds in the ear. A history of weight loss, steroid use, or hormonal therapy may precede the onset of symptoms. Evidence for an abnormally patent eustachian tube includes relief of symptoms (1) when the patient is supine or bending over, (2) during periods of nasal congestion, and (3) with sniffing. Evidence for a chronically obstructed eustachian tube orifice includes the inability to insufflate the ear with Valsalva's maneuver, chronic retraction of the tympanic membrane, and a history of nasal congestion and allergic disorder.

Aural fullness is part of the symptom complex of Meniere's disease. When the fullness is associated with fluctuating hearing and discrete spells of vertigo, its significance is apparent. Aural fullness also may occur as the result of a perilymphatic fistula. Seltzer and McCabe[24] noted that 25% of patients with fistulas confirmed at exploratory tympanotomy had aural fullness.

Box 156-2

Hearing Loss in Adults

Acute
Sudden idiopathic sensorineural hearing loss
Infection (acute otitis media, external otitis, syphilis, Lyme disease, viral)
Perilymphatic fistula
Ischemia of retrocochlear structures
Multiple sclerosis
Autoimmune disease
Traumatic
Metabolic (chronic renal failure)
Hematologic (sickle cell anemia)

Gradual
Presbycusis
Noise-induced
Familial
Retrocochlear neoplasm
Chronic otitis media, cholesteatoma
Otosclerosis
Endocrine (hypothyroidism, diabetes mellitus)
Paget's disease
Metabolic (chronic renal failure, hyperlipoproteinemia)
Mucopolysaccharidosis

Fluctuating
Perilymphatic fistula
Meniere's disease
Multiple sclerosis
Migraine-associated hearing loss
Infection (syphilis)
Autoimmune (Cogan's syndrome, systemic lupus, polyarteritis nodosa, Wegener's syndrome, temporal arteritis, scleroderma)
Sarcoidosis

Rapidly Progressive
Autoimmune inner ear disease
Meningeal carcinomatosis
Vasculitis secondary to infection (Rocky Mountain spotted fever)
Lyme disease
Ototoxic exposure (aminoglycosides, diuretics, chemotherapy)

Hearing Loss

A complaint of hearing loss can reflect a wide variety of abnormalities (Box 156-2), and diagnostic considerations are different in pediatric and adult patients. Evaluation should determine whether the loss is unilateral or bilateral or fluctuating in nature. The time course of the hearing loss should be established, and associated symptoms should be documented. The medical history should investigate current and past treatments with oral and intravenous medications, and nonprescription drug use. The patient should be screened for systemic diseases, including cardiovascular, metabolic, endocrine, neurologic, hematologic, infectious, and autoimmune diseases. Prior ear surgery, cardiac bypass surgery, and lumbar puncture also may be relevant to the current complaint of hearing loss.[25] A family history of hearing loss, neoplasms, renal disease, and balance disorders should be obtained. Finally, previ-

ous sharp or blunt head trauma, noise trauma, or barotrauma should be noted.

The most informative features that facilitate determining the etiology of hearing loss are the time course of the loss, associated symptoms, and age of the patient. It should be determined whether the loss is acute or gradual in onset, long-standing, fluctuating, rapidly progressive, or of unknown duration. Associated symptoms of aural fullness, pain, otorrhea, vertigo, tinnitus, or cranial neuropathies can assist diagnosis. The clinical feature of unilateral or bilateral hearing loss is less revealing in determining the etiology of hearing loss.

Acute Hearing Loss

Acute unilateral hearing loss may result from a range of disease states. Sudden or acute sensorineural hearing loss may be idiopathic; iatrogenic; a complication of a viral or bacterial infection, labyrinthine fluid abnormality, vascular event, trauma, neoplasm, autoimmune abnormality, or neurologic disease; or a side effect of medication.

Viral infections such as mumps, rubella, rubeola, and Epstein-Barr virus may involve the ear directly by causing varying degrees of transient or permanent hearing loss with or without associated vertigo. These infections may also cause a serous labyrinthitis, causing sensorineural hearing loss from toxins affecting the inner ear. Ramsay Hunt syndrome is an example of a viral polyneuropathy that typically involves facial and cochleovestibular dysfunction. Bacterial and fungal meningitis may also extend to the labyrinth, causing sudden hearing loss. Other infectious causes of sudden hearing loss are acute otitis media, suppurative labyrinthitis from acute or chronic otitis media, and syphilis. In most of these cases, the history, physical examination, and appropriate serology establish the etiology of the hearing loss.

Abnormalities of labyrinthine fluid include hydrops and perilymphatic fistula. Both of these conditions typically cause fluctuating hearing loss, but sudden, permanent loss also is possible. A history of recent heavy lifting or straining, head trauma, or barotrauma suggests a possible perilymphatic fistula. Hydrops typically causes low-frequency hearing loss. The presence of diplacusis and recruitment on examination and associated spells of recurrent vertigo support the diagnosis.

Sudden hearing loss may occur as the result of a vascular event involving the cochlea. Thrombosis or embolic occlusion of the labyrinthine and cochlear arteries is an uncommon but well-recognized cause of hearing loss. Hyperviscosity states such as polycythemia vera may result in cochlear ischemia. Obstruction of small vessels as a result of diabetes mellitus, atherosclerosis, and sickle cell anemia should also be considered when no other causes of hearing loss can be identified.

Head trauma, barotrauma, and noise trauma all can result in acute hearing loss that may be transient or permanent. Direct head trauma resulting in temporal bone fracture may cause either a conductive or a sensorineural hearing loss. Hearing loss also may occur because of a concussive injury to labyrinthine membranes without an associated temporal bone fracture. The history is usually sufficient in these cases to establish the cause of the hearing loss.

Sudden transient or permanent hearing loss is an atypical presentation of a retrocochlear neoplasm in the cerebellopontine angle. This diagnosis can be difficult to make because associated symptoms from a tumor manifesting in this manner are uncommon, particularly in the case of small tumors. Radiographic imaging should always be performed in cases of sudden hearing loss without any identifiable etiology.

When evaluating a patient with sudden or rapidly progressive hearing loss, the presence or absence of other neurologic symptoms should be investigated. Hearing loss that is unilateral, bilateral, sudden, subacute, or insidious may be the presenting symptom for multiple sclerosis.[26,27] Presentation of hearing loss associated with ophthalmologic disease should prompt investigation of Susac's syndrome. First described in 1979, Susac's syndrome is characterized by the triad of retinal arterial occlusions, encephalopathy, and cochlear microangiopathy. The neurotologic features are frequently misdiagnosed as multiple sclerosis, delaying the effective treatment and control of symptoms with systemic immunosuppression.[28]

In adults, a gradual or long-standing hearing loss may reflect various disorders (see Box 156-2). Bilateral gradual hearing loss may reflect presbycusis, noise-induced hearing loss, or familial sensorineural hearing loss. A history of exposure to ototoxic medication should also be investigated. If the sensorineural hearing loss is unilateral, a retrocochlear lesion should be investigated as the cause of the loss. If the loss has a conductive component, diagnoses such as otosclerosis, chronic otitis media with effusion, malleus head fixation, tympanosclerosis, myringosclerosis, tympanic membrane perforation, cholesteatoma, or ossicular chain disruption should be considered.

Table 156-1

Lower Cranial Nerve Deficits Associated with Jugular Foramen Syndromes

	Cranial Nerve			
Syndrome	**IX**	**X**	**XI**	**XII**
Avellis		X		
Tapia		X		X
Vernet	X	X	X	
Jackson		X	X	X
Collet-Sicard	X	X	X	X

Patients with tumors of the jugular foramen commonly present with unilateral hearing loss. This loss may be conductive because of a mass effect of the tumor impinging on the tympanic membrane and ossicles, or sensorineural secondary to erosion of the cochlea or compression of the eighth cranial nerve within the internal auditory canal and cerebellopontine angle. Although symptoms related to these tumors may be subtle, diagnostic suspicion should be high when evaluating a patient with a middle ear or external auditory canal mass associated with pulsatile tinnitus. Dysfunction of the lower cranial nerves may occur in many combinations (Table 156-1), depending on the size and location of the tumor.

Fluctuating Hearing Loss

Fluctuating hearing loss can reflect various diseases. The most common causes are Meniere's disease, perilymphatic fistula, and luetic labyrinthitis. Less commonly, systemic diseases such as multiple sclerosis, tuberculosis, and sarcoidosis cause fluctuating hearing loss. Meniere's disease is usually easily recognized because of the associated vestibular symptoms. Diagnosis of a perilymphatic fistula can be challenging because the symptoms can be quite variable. A history of prior ear surgery, head trauma, barotrauma, or straining may increase suspicion for perilymphatic fistula. Syphilitic inner ear disease also can be an elusive diagnosis because of the various possible presenting symptoms. When hearing loss is associated with either autoimmune disorders or sarcoid, the patient typically has other systemic symptoms relating to the primary disorder that facilitate recognition of the nature of the hearing loss.[29] Autoimmune diseases with cochlear involvement can mimic Meniere's disease early in the course of the disease, before permanent nonfluctuating sensorineural hearing loss occurs.

An uncommon cause of fluctuating hearing loss is an endolymphatic sac tumor. These tumors originate from the epithelium of the vestibular aqueduct and endolymphatic sac. A high index of suspicion is needed to diagnose these tumors, which manifest with symptoms similar to Meniere's disease.[30]

Rapidly Progressive Hearing Loss

Rapidly progressive hearing loss may occur as a result of isolated autoimmune inner ear disease or systemic autoimmune disease with otologic involvement. The hearing loss may be unilateral initially, but progresses to bilateral involvement. Less commonly, the loss may fluctuate or manifest as a sudden sensorineural hearing loss. Autoimmune diseases associated with hearing loss are Cogan's syndrome (nonsyphi-

litic interstitial keratitis with audiovestibular involvement),[31,32] polyarteritis nodosa, relapsing polychondritis, sarcoid, ulcerative colitis, systemic lupus erythematosus, Wegener's disease, Churg-Strauss syndrome, and Behçet's disease.

An unusual cause of rapidly progressive or sudden hearing loss is neoplastic disease metastatic to the brain or temporal bone from a distant primary site. Hearing loss is usually associated with additional symptoms, such as tinnitus, vertigo, dysequilibrium, and facial nerve paralysis. Metastatic disease may involve the brain and skull base by several mechanisms. Metastatic disease may involve the temporal bone directly through hematogenous spread to petrous bone marrow. Metastases may be single or multiple intraparenchymal or epidural lesions. Diffuse multifocal seeding of the leptomeninges (meningeal carcinomatosis) also may occur. The most common sources of metastatic disease directly affecting the temporal bone are breast, lung, kidney, stomach, bronchus, and prostate neoplasms. The most common tumor type that causes intraparenchymal lesions is carcinoma of the lung. Generally, 20% of intraparenchymal brain metastases occur in the cerebellum and brainstem. Prostate carcinoma and breast cancer have a propensity to metastasize to the dura. Non-Hodgkin's lymphoma, breast carcinoma, and melanoma are the most common tumor types associated with leptomeningeal metastasis. A high index of suspicion for metastatic disease should always be maintained when evaluating a patient with a known history of cancer who presents with new cranial nerve deficits.[15,33,34]

Pediatric Sensorineural Hearing Loss

Pediatric hearing loss can be categorized as congenital (present at birth) or acquired (auditory function was present initially with subsequent loss of hearing). Congenital and acquired hearing loss may result from an abnormality in the genetic code (syndromic or nonsyndromic, single gene or chromosomal abnormality), or may result from perinatal insults that are infectious, toxic, or systemic in nature. The Joint Committee on Infant Hearing[35] has outlined the identifiable risk factors associated with neonatal hearing loss. These risk factors include a family history of hereditary childhood sensorineural hearing loss; perinatal infection with cytomegalovirus, rubella, syphilis, herpes, or toxoplasmosis; evidence of craniofacial abnormalities; birth weight less than 1500 g; significant hyperbilirubinemia requiring exchange transfusion; treatment with ototoxic medications; history of bacterial meningitis; history of Apgar scores between 0 and 4 at 1 minute, or 0 and 6 at 5 minutes; history of prolonged mechanical ventilation in the postnatal period; or any other findings on physical examination suggestive of a syndrome associated with hearing loss.

Diagnostic considerations for nongenetic causes of hearing loss include kernicterus, prematurity with low birth weight, birth trauma, postnatal anoxia requiring mechanical ventilation, use of extracorporeal membrane oxygenation therapy, and treatment with ototoxic medications in the postnatal period. Perinatal infections can result in congenital and delayed hearing loss. Young children are particularly vulnerable to bacterial meningitis, and the incidence of hearing loss after such an infection is 3.5% to 37%.[36] Prenatal exposure to toxoplasmosis, rubella, cytomegalovirus, herpes simplex virus, and syphilis can result in mild to profound sensorineural hearing loss. Box 156-3 lists the 10 most common syndromes associated with hearing loss and some rare disorders in which hearing loss is a major feature.[37]

Approximately 20% of patients with congenital sensorineural hearing loss have radiographic evidence of an inner ear malformation.[38] Malformations of the inner ear may occur in isolation or associated with other physical abnormalities as part of a syndrome. The malformation may result from exposure to teratogens (chemical or viral) during embryogenesis, or may be idiopathic in nature. Congenital inner ear abnormalities constitute a spectrum of recognized malformations that are associated with various hearing loss patterns. Complete aplasia of the labyrinthine capsule (Michel's aplasia) is associated with profound deafness. The most common malformation is cochleosaccular dysgenesis (Scheibe's aplasia), which is a malformation limited to the membranous portion of the pars inferior. The Mondini deformity derives from arrested development of the labyrinthine capsule during the 7th week of gestation, resulting in a small cochlea with an incomplete partition and an abnormally dilated vestibular aqueduct and vestibule.

Box 156-3

Hearing Loss in Congenital and Genetic Conditions

Syndromes Most Commonly Associated with Hearing Loss

1. Oculoauriculovertebral spectrum (hemifacial microsomia, Goldenhar's syndrome)
2. Stickler's syndrome (hereditary arthro-ophthalmopathy)
3. Congenital cytomegalovirus
4. Usher's syndrome
5. Branchio-oto-renal syndrome
6. Pendred's syndrome
7. CHARGE association (coloboma [of eyes], *h*earing deficit, choanal *a*tresia, *r*etardation of growth, genital defects [males only], endocardial cushion defect)
8. Neurofibromatosis type 2
9. Mitochondrial disorders
10. Waardenburg's syndrome

Rare Disorders with Hearing Loss as a Major Feature

1. Otopalatal-digital syndromes
2. Skeletal dysplasias (osteogenesis imperfecta)
3. Metabolic storage diseases (mucopolysaccharidoses, Refsum's disease)
4. Townes-Brock syndrome
5. Wildervanck's syndrome
6. Biotinidase deficiency

Variable degrees of hearing loss and vestibular dysfunction are associated within the spectrum of labyrinthine developmental abnormalities. Generally, the more severe the malformation, the greater the associated hearing loss.

More than half of all cases of prelingual sensorineural hearing loss are the result of a genetic abnormality. Autosomal recessive patterns of inheritance are responsible for almost three quarters of these cases, and most are nonsyndromic. Most of these inherited forms of hearing loss are permanent and irreversible. An exception is the sensorineural hearing loss associated with biotinidase deficiency. This is an autosomal recessive disorder of failure to recycle the vitamin biotin, resulting in mental retardation, hypotonia, seizure disorder, alopecia, and skin rash. Sensorineural hearing loss is now recognized to occur in 75% of children with a symptomatic biotinidase deficiency. Early recognition in the neonatal period is crucial for initiating appropriate therapy.[39]

One third of the inherited forms of congenital hearing loss occur as part of a syndrome.[40] Recognition of these forms of hereditary hearing loss is assisted by the identification of associated physical and metabolic abnormalities. The presence of renal abnormalities suggests the possibility of Alport's syndrome, which can be inherited in an autosomal dominant, autosomal recessive, and X-linked pattern. Branchio-oto-renal syndrome should be considered if there are structural abnormalities, such as auricular pits, malformed pinnae, or branchial cleft fistulas or cysts, in association with conductive, mixed, or sensorineural hearing loss. A complete eye examination, including electroretinography, is crucial to early identification of retinitis pigmentosa associated with Usher's syndrome.[41] Associated metabolic dysfunction may be obvious, as in inherited mucopolysaccharidoses, or more subtle, as in Pendred's syndrome. A family history of fatal cardiac arrhythmias should suggest the possibility of Jervell-Lange-Nielsen syndrome. Pigmentary abnormalities such as a bicolored iris, white eyelashes, or piebald skin are associated with Waardenburg's syndrome.

Pediatric Conductive Hearing Loss

Most pediatric conductive hearing loss is the result of acute or chronic otitis media and the sequelae of these diseases. Noninfectious causes of congenital conductive hearing loss include congenital cholesteatoma,

external auditory canal atresia,[42] and labyrinthine structural abnormalities such as ossicular chain fixation and congenital absence of the oval window.[43-45] A rare developmental abnormality that results in a prominent conductive hearing loss in children is a salivary gland choristoma of the middle ear. Twenty-six cases of heterotopic salivary gland tissue in the middle ear have been documented in the literature. Patients are seen at a young age with a persistent conductive hearing loss and a middle ear mass. Often the mass is adherent to the tympanic or descending portions of the facial nerve. Associated malformations of the ossicular chain and external ear also have been found.[46-48]

Vertigo

The sensations of vertigo and dysequilibrium in children and adults may reflect disease within the labyrinth, a retrocochlear abnormality involving either the eighth cranial nerve or more central structures, or the effects of a systemic abnormality. A thorough and well-directed history discriminates otologic from nonotologic causes of vertigo in most cases. Identification of associated symptoms, the time course of the vertigo or dysequilibrium, precipitating and alleviating factors, and the general medical history should be assessed in patients with vertigo.

The patient's description of symptoms helps in discriminating between central and peripheral causes of vertigo. A sensation of spinning or motion commonly results from acute vestibular dysfunction, such as viral neuronitis, labyrinthitis, and Meniere's disease. Nonvestibular causes of imbalance, such as cardiogenic, metabolic, neurogenic, or psychogenic dysfunction, are often described as a more nonspecific sensation of light-headedness. Encouraging the patient to describe the symptoms or spells in detail without using the word *dizzy* can be helpful.

The time course of the patient's symptoms is crucial to distinguish between otologic and nonotologic causes of vertigo (Box 156-4). Vertigo that is continuously present for weeks without fluctuation is generally not the result of a peripheral vestibular abnormality. Acute injury to the inner ear or eighth cranial nerve initially results in severe and prolonged vertigo. As central compensation progresses, the vertigo subsides over days to weeks. Persistent vertigo indicates an uncompensated labyrinthine or eighth cranial nerve lesion, or a central abnormality.

Vertigo in discrete isolated spells should be characterized by the frequency and duration of symptoms. Vertigo that lasts for less than 1 minute can represent benign paroxysmal positional vertigo. Spells lasting several minutes may represent migraine-associated vertigo or transient ischemia of the vertebrobasilar circulation. Vertigo that is prolonged for hours is typical of Meniere's disease or endolymphatic hydrops. Vertigo that persists for days but gradually subsides is seen with vestibular neuritis.

Labyrinthine Vertigo

Diseases affecting the labyrinth that result in vertigo may be categorized as infectious, post-traumatic, metabolic, autoimmune, ischemic, drug-induced, hydropic, or multifactorial in character. The most common infectious cause of acute vertigo is viral labyrinthitis. Most patients with viral labyrinthitis have isolated vestibular dysfunction of sudden onset, without associated hearing loss. In some cases, identification of the inciting agent is evident because of systemic manifestation of the disease, such as with measles, mumps, infectious mononucleosis, herpes zoster, and cytomegalovirus. Bacterial infection from acute or chronic otitis media also may result in a toxic or serous labyrinthitis with vestibular symptoms. A more severe infection can result in suppurative labyrinthitis either from direct bacterial invasion into the inner ear from chronic otomastoiditis (through a labyrinthine fistula from a cholesteatoma) or from bacterial meningitis contaminating the perilymphatic space of the labyrinth through the cochlear aqueduct or internal auditory canal. Chronic infections such as syphilis and Lyme disease may cause persistent or recurring symptoms of vertigo and dysequilibrium through direct invasion of the otic capsule or by leptomeningeal involvement.

Traumatic causes of vertigo include temporal bone fractures, labyrinthine concussion, and perilymphatic fistula. Transverse fractures of the temporal bone extend from the posterior fossa across the petrous portion of the temporal bone into the vestibule. Rupture of the membranous labyrinth and laceration of the cochleovestibular nerve in these cases result in profound deafness and severe vertigo. Longitudinal temporal bone fracture without violation of the labyrinth and blunt head trauma without associated temporal bone fracture also may cause hearing loss and vertigo because of a concussive injury to the membranous labyrinth.

Metabolic causes of vertigo should always be considered when a labyrinthine or central etiology is absent. Systemic metabolic abnormalities that can affect vestibular function include hyperviscosity syndromes (hyperlipidemia, polycythemia, macroglobulinemia, and sickle cell anemia), diabetes mellitus, hyperlipoproteinemia, and hypothyroidism. Hormonal fluctuations occurring in the premenstrual and perimenopausal periods and oral contraceptives and estrogen replacement therapy also may cause neurotologic symptoms, including vertigo. Metabolic dysfunction isolated to the labyrinth may occur because of cochlear otosclerosis. In addition to sensorineural hearing loss, cochlear otosclerosis may cause vestibular symptoms of dysequilibrium or vertigo. Altered cochlear microvascularization, direct otosclerotic degeneration of vestibular nerve fibers, and humoral toxicity secondary to proteolytic enzymes within the perilymph all have been proposed as mechanisms for vertigo associated with otosclerosis.

Numerous collagen vascular disorders have been associated with vestibular dysfunction as a form of autoimmune inner ear disease. Common disorders of this type include rheumatoid arthritis, polyarteritis nodosa, temporal arteritis, nonsyphilitic interstitial keratitis, lupus, sarcoid, relapsing polychondritis, dermatomyositis, and scleroderma.

Ischemia of small labyrinthine vessels causes isolated infarction of the vestibular labyrinth and vertigo. Occlusion of larger vessels, such as the anterior inferior cerebellar artery or its branches, causes sudden and profound loss of auditory and vestibular function and regional infarction of the brainstem.[49]

Aminoglycoside ototoxicity is a well-recognized cause of drug-induced vertigo. The degree of cochlear and vestibular toxicity of these drugs varies with each drug, the duration of treatment, concomitant exposure to noise, and genetic susceptibility of the individual.[50]

Endolymphatic hydrops or Meniere's disease is defined by the well-recognized symptoms of vertigo, hearing loss, tinnitus, and aural fullness. The underlying mechanism that causes abnormal homeostasis of endolymph resulting in distention and rupture of the membranous labyrinth is unknown. Histopathologic findings suggest that fibrosis of the endolymphatic sac, altered glycoprotein metabolism, and viral infections may be pathogenic mechanisms, but further study in this area is needed.[51]

Retrocochlear Vertigo

Retrocochlear causes of vertigo can be categorized as neoplastic, paraneoplastic, vascular (infarction or ischemia), and demyelinating in origin. Diagnosis relies on a thorough history and physical examination documenting other associated cranial nerve or neurologic deficits, evidence of malignancy, and identification of risk factors for vascular disturbances.

Cerebellopontine angle tumors such as acoustic neuroma and meningioma more commonly cause a sense of dysequilibrium or unsteadiness rather than true vertigo. Because these tumors are slow-growing, central compensation occurs over time for the unilateral loss of vestibular function. In addition, these space-occupying lesions of the posterior fossa may cause dysequilibrium and positional vertigo because of cerebellar compression. Brainstem tumors such as gliomas and medulloblastomas commonly manifest with vestibular and cochlear symptoms in addition to long tract signs, cranial nerve deficits, ataxia, and headache.

Although paraneoplastic syndromes associated with carcinoma are uncommon causes of vertigo, they are worthy of mention because the vestibular symptoms may precede the diagnosis of underlying malignancy.[52] Paraneoplastic encephalomyelitis is an autoimmune process most commonly associated with small cell carcinoma of the lung. Inflammatory changes may occur throughout the neuraxis, with subsequent neuronal destruction and glial activation. When the brainstem is involved, degeneration of the vestibular nuclei and the lower cranial nerves is common. Paraneoplastic cerebellar degeneration has been associated with lymphoma and with carcinoma of the ovary, breast, and lung. Paraneoplastic cerebellar degeneration may manifest as sudden-onset vertigo or progressive truncal and extremity ataxia with nystagmus, dysarthria, and diplopia.

Cerebellar atrophy and diffuse small vessel ischemia associated with aging may cause mild unsteadiness, but rarely true vertigo. The coexistence of multisensory deficits with decreased peripheral sensitivity and proprioception and poor visual acuity exacerbates any central or vestibular hypofunction resulting in dysequilibrium.

Acute vascular events affecting the cerebellum and brainstem usually produce more pronounced and severe symptoms. Transient ischemia of the vertebrobasilar system may cause acute onset of vertigo that lasts only minutes and resolves without sequelae. Occlusion of the vertebral artery or the posterior inferior cerebellar artery results in infarction of the dorsolateral medulla (Wallenberg's syndrome). Cerebellar ataxia, vertigo with nausea and vomiting, Horner's syndrome, conjugate gaze paresis, and contralateral loss of pain and temperature sensation are the associated signs and symptoms.

Episodic vertigo may be a component of a migraine aura. The vertigo may occur in conjunction with or precede the migraine headache. Vertigo also may occur without headache; this is known as migraine equivalent.

Demyelinating disorders of the central nervous system are uncommon causes of vertigo and dysequilibrium. Unusual causes of demyelination include exposure to toxins (carbon monoxide, lead, and methotrexate), nutritional disorders (vitamin B_{12} deficiency), postviral syndromes (measles and papovavirus), and hereditary degeneration. Multiple sclerosis is the most common demyelinating disorder encountered by otolaryngologists assessing cochleovestibular dysfunction. Although vertigo is the presenting symptom in only 5% of patients with multiple sclerosis, dysequilibrium and unsteadiness are common in most of these patients at some point in their disease.

CHAPTER ONE HUNDRED AND FIFTY-SEVEN

Implantable Hearing Aids

Lawrence R. Lustig

Charles C. Della Santina

Key Points

- Limitations of conventional hearing aids compared with newer implantable hearing aids include insufficient amplification, acoustic feedback, distortion of spectral shape and phase shifts, nonlinear sound distortion, occlusion effects, poor auditory transduction, and cosmetic appearance. Abnormalities in the ear canal also prevent the use of a conventional hearing aid.
- All middle ear implantable hearing aids include a transducer (either piezoelectric or electromagnetic) and couple to one of the three middle ear bones in one of many ways to drive the ossicular chain directly. Some newer designs also couple directly to the round window.
- Economic factors have limited the availability of middle ear implantable hearing aids in the United States; there is more widespread application in Europe.
- Bone-anchored hearing aids are useful for patients with conductive hearing loss who cannot use a conventional hearing aid for a variety of reasons, including patients with chronically draining ears despite multiple corrective attempts, patients with discomfort from the sound levels required from a traditional hearing aid, and patients with a large mastoid bowl or meatoplasty.
- Bone-anchored hearing aids are beneficial in patients with otosclerosis, tympanosclerosis, or canal atresia, and in patients who have undergone external auditory canal closure after extensive skull base surgery.
- Patients with unilateral deafness benefit from a bone-anchored hearing aid through improved hearing in noise, although objective evidence of improved sound localization is unavailable.

Hearing aids are the principal means of auditory rehabilitation for patients with sensorineural hearing loss (SNHL). Hearing aids may also play a role in the management of patients with conductive hearing losses (CHL), particularly losses that result from pathologies that are not amenable to medical and surgical treatment. Improvements in signal processing capabilities and increasing miniaturization of hearing aids have increased their acceptance among patients. Hearing aids remain a "tough sell" to many patients who could potentially benefit from them, however, owing to lack of sufficient perceived benefit, expense, complications of external auditory canal occlusion, and cosmetic concerns. In a restaurant, multiple competing sound sources, such as conversations, the ventilation system, and music, can undermine the ability to detect and resolve speech cues. Many other patients simply cannot wear a hearing aid because of problems with the external auditory canal, chronic infections, or extreme discomfort. Although newer hearing aid technologies have tried to address many of these difficulties, many patients still find that hearing aids fall short in meeting expectations in a variety of situations (Box 157-1). Partly for these reasons, less than one in eight eligible adults actually use a hearing aid.[1]

These inherent limitations in hearing aids, combined with the social stigma of their use, have led to the development of implantable hearing aids (Figs. 157-1 and 157-2). Implantable hearing aids offer patients with hearing loss several potential advantages over conventional hearing aids, including increased gain and dynamic range, reduced feedback, reduced maintenance, improved appearance, and freedom from ear canal occlusion. These potential benefits must be weighed against the possible downsides of their use, including the risk of surgical implantation, difficulty of maintenance, and increased initial device cost (Table 157-1). Complicating this risk-benefit calculation is the uncertain future of corporations marketing and supporting various implantable hearing aids. Before discussing each of the implantable hearing aids currently available or in development, it is important to review in more detail *why* there is a desire for their implementation in the first place.

Limitations of Auditory Rehabilitation Using Traditional Hearing Aids

Physical Factors

Traditional hearing aids are limited in their ability to amplify sound without imparting distortion or generating feedback, in part because these three aspects of performance are physically interrelated.

Insufficient Gain

For patients with severe to profound hearing loss, sound amplification (or *gain*) is a primary concern. For a patient with air-conduction thresholds of 80 dB hearing level (HL) to perceive quiet sounds at a normal threshold of 0 dB HL, a hearing aid must amplify sound intensity by 80 dB, generating a 10,000-fold increase in sound pressure wave amplitude and a 100,000,000-fold increase in sound power intensity.[2] This represents the limit of existing traditional hearing aids. The maximum amplification at 1 kHz for a behind-the-ear (BTE) Phonak SuperFront PPCL4 power digital hearing aid is about 75 to 82 dB.[3] Gain generally scales with hearing aid size, so that cosmetically less

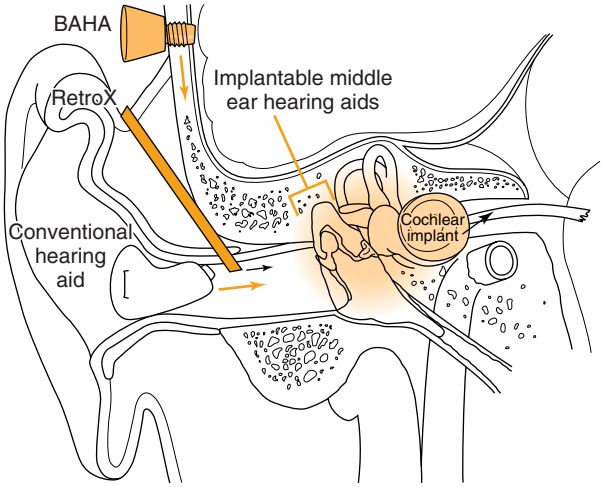

Figure 157-1. Overview of how various implantable hearing aids interface with the auditory system. Conventional hearing aids amplify from within the canal, whereas bone-anchored conductive devices are applied to the retroauricular skull to provide hearing via bone conduction. The RetroX sits behind the ear, but delivers sound through a channel that emerges in the external auditory canal. Implantable middle ear hearing aids interface at the level of the ossicles, bypassing the eardrum. In contrast, cochlear implants directly stimulate the remaining neural elements within the cochlea. Lack of directionality

obtrusive hearing aids offer less gain. The maximum gains for digital in-the-ear (ITE), in-the-canal (ITC), and completely-in-canal (CIC) hearing aids currently are about 55 to 65 dB, 45 to 55 dB, and 35 to 50 dB.[3]

Acoustic Feedback

In practice, feedback often limits the useful gain of traditional hearing aids to less than the above-listed maximum gains. Acoustic waves from the hearing aid speaker leak through the air space between the hearing aid body and the external auditory canal wall back to the microphone, where (for a subset of frequencies) they add to existing microphone input and are amplified further. The resulting positive feedback loop causes the familiar squealing and hum that signify a poorly fitting or overamplified aid. Potential for feedback is worst for CIC aids, in which the microphone is closest to the speaker, and for ears with mastoid bowls, in which an air seal is difficult to obtain. At very high amplification, it is a problem even for BTE aids. Fitting aids tightly into the external auditory canal can decrease feedback, but at the cost of increased discomfort, and the risk of otitis externa, autophony, and blockage of natural sound input.

Distortion of Spectral Shape and Phase Shifts

Traditional hearing aids are limited in the frequency range over which they amplify sound. Most are optimized for performance in the speech band (500 to 2000 Hz) and cannot provide much amplification at less than 100 to 200 Hz or greater than 5000 to 6000 Hz. Although the most important spectral components for speech recognition are amplified, the loss of "bass" and "treble" can give the resultant sound percept an artificial character. Isolated severe hearing loss at low frequencies (e.g., in Meniere's disease) or high frequencies (e.g., in presbycusis or ototoxic exposure) can be difficult to remediate with traditional hearing aids without overamplifying the midrange frequencies at which a patient may have normal hearing. Even in the 500- to 2000-Hz band, steep changes in audiometric threshold at neighboring frequencies (e.g., noise-induced hearing loss) cannot be perfectly fit because of inherent limitations in the rate of change of gain across frequencies. Too steep a change in amplifier gain across frequencies typically imparts phase shifts that distort sound percepts such as pitch and timbre. Digital signal processing technology has greatly improved spectral shaping options compared with analog aids, but these fundamental limitations persist.

Nonlinear Distortion

Similar to most other amplifiers, hearing aids are designed under assumption of linearity—that is, if a given sound input at the microphone leads to some output at the speaker (amplified and spectrally shaped by the aid), doubling the sound input's magnitude should exactly double the output, without changes in spectral content or phase shifts. For high-intensity speaker output, this assumption breaks down as the speaker is driven into the range of movements for which it begins to saturate or clip. An input sinusoid can appear at the output as a waveform with blunted peaks. This nonlinear distortion imparts aberrant spectral components into the sound percept, giving it an artificial or robotic character. Although digital signal processing can mitigate distortion effects within an aid's amplification circuitry, distortion produced by a speaker generating loud sounds in air remains a fundamental limitation of traditional hearing aids.

Occlusion Effects

To minimize feedback, most traditional hearing aids are fit to create an airtight seal with the external auditory canal wall, with the hearing aid's speaker being isolated in the occluded ear canal. Canal occlusion has several undesirable effects. First, it can be uncomfortable because of pressure on canal skin. Second, it increases the likelihood of otitis externa because of disturbance of wax egress and air circulation. Some patients with chronic suppurative otitis media cannot tolerate hearing aids because of exacerbation of otorrhea. Third, it causes autophony and a sense of aural fullness that can worsen with changes in ambient barometric pressure. Fourth, it blocks the normal pathway for sound entry to the ear. Finally, canal occlusion disrupts the spectral shaping that normally occurs as a result of external auditory canal resonances.

Poor Appearance

Many patients reject hearing aids because of the social stigma of being seen as old or infirm. Eight percent of hearing aid candidates wearing the less noticeable ITC hearing aids listed poor cosmetic appearance as a major contributing factor in their decision not to use a hearing aid.[4] Hearing aids are difficult to conceal in patients who are balding or who wear their hair short. Miniaturization of electronics continues to improve hearing aids in this regard, and CIC hearing aids are essentially invisible to the casual observer. Miniaturization comes at the cost of lower gain, more feedback, and higher cost, however. Ultimately, battery size becomes the limiting factor, with smaller batteries costing more and requiring more frequent replacement.

Poor Transduction Efficiency

Loss of energy because of impedance mismatching and transduction losses is another inherent drawback of conventional hearing aids. The mechanical impedance (change in pressure for a given displacement flow) of the air-filled external auditory canal differs from that of the fluid-filled cochlea. Without a middle ear mechanism, most of the acoustic energy striking the stapes footplate reflects back into the air. When the tympanic membrane and ossicular chain are functioning normally, they act as an impedance-matching transformer by virtue of

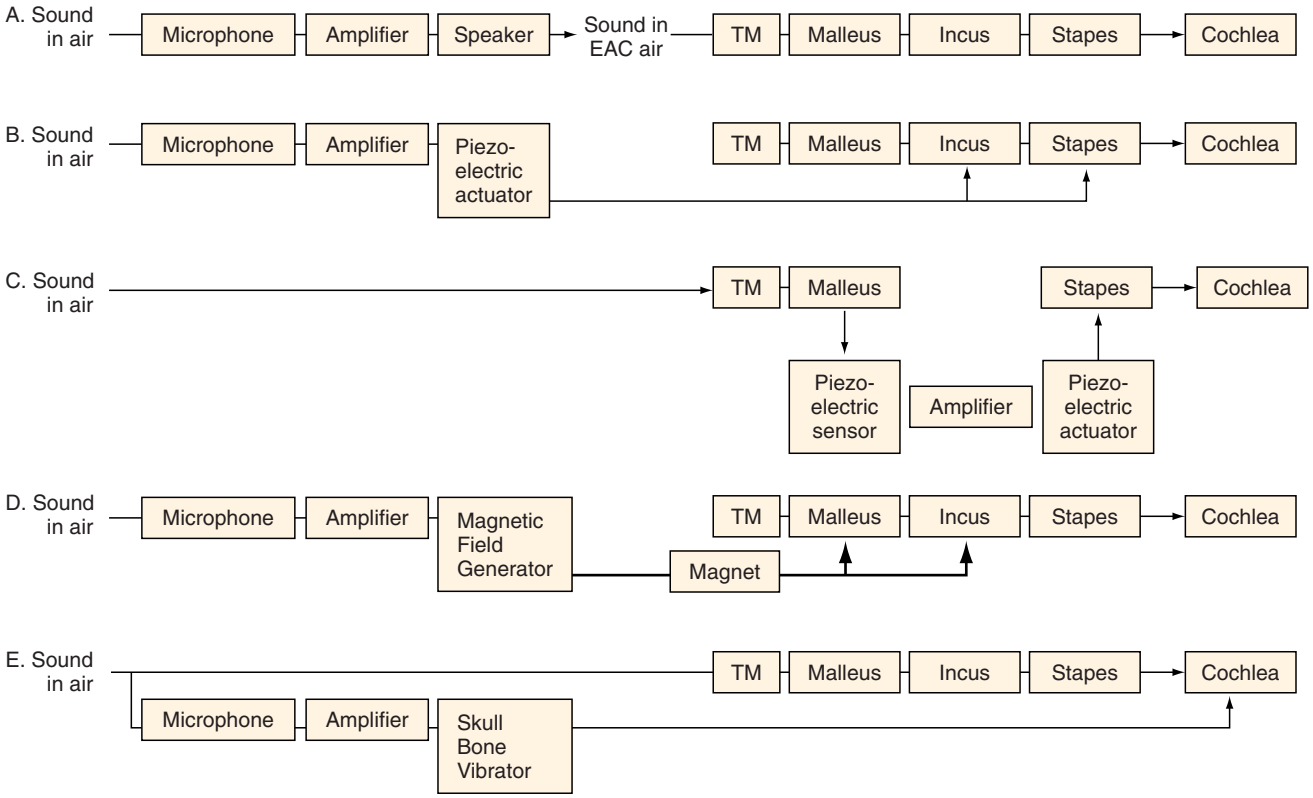

Figure 157-2. Sound transduction and coupling to the auditory system for different classes of hearing aids. **A,** Conventional air-conducting hearing aid. **B,** Implantable aids with piezoelectric actuator (e.g., Rion-E, Otologics MET, and Implex TICA). **C,** Implantable aids with piezoelectric sensor and actuator (e.g., St. Croix Envoy). **D,** Implantable aids with magnetic actuator (e.g., Vibrant Med-El Soundbridge, Soundtec DDHS). **E,** Bone-anchored hearing aid (e.g., Cochlear/Entific BAHA). EAC, external auditory canal; TM, tympanic membrane.

the relative areas of the tympanic membrane and stapes footplate, and by the lever action of the ossicular chain.[5] The relatively large-displacement, low-pressure movements of air against the tympanic membrane are transduced to the relatively small-displacement, high-pressure movements of the footplate. Except for bone-conducting hearing aids, all traditional hearing aids use a speaker to output an (amplified) acoustic wave into the air of the external auditory canal. When this middle ear apparatus is malfunctioning, as occurs in otosclerosis, tympanic membrane perforation, or a canal wall down mastoidectomy, traditional hearing aids must overcome the impedance mismatch. The result is reduced effective gain, increased distortion, or both.

Even when the ossicular chain is functioning normally, the transduction of acoustic energy from air at the input of a traditional hearing aid to stapes footplate motion is imperfect. Whenever a signal flows from one physical realm (e.g., electric current in a speaker) to another (e.g., acoustic waves in air), some energy is lost (e.g., to heat) and noise or distortion can add to the desired signal. There are several transduction steps for a traditional hearing aid—from acoustic waves in ambient air, to electric current in a microphone, to a larger electrical current in a speaker wire or piezoelectric driver, to acoustic waves in air within the external auditory canal, to movement of the tympanic membrane and ossicular chain, to acoustic waves in perilymph, to hair cell stereociliary deflection and depolarization. Most steps are unavoidable (although cochlear implants bypass these steps through direct cochlear nerve stimulation). Directly coupling a hearing aid actuator movement of the ossicular chain can delete some of these transduction steps, however, boosting gain and reducing distortion. Nearly all implantable hearing aids make use of this approach.

Human Factors

Although not specific to traditional hearing aids, SNHL imposes additional constraints on the degree to which sound amplification can overcome hearing deficits. These factors must be considered when evaluating whether technical improvements such as increased amplification gain are worth pursuing for a given patient.

Recruitment and Compression of Dynamic Range

A primary source of frustration of patients with SNHL is reduced speech intelligibility. The common complaint, "I can hear, but I cannot understand," underscores this point. This problem relates to abnormal frequency resolution and aberrant patterns of growth in loudness, each of which reduces speech intelligibility in challenging listening conditions such as noisy surroundings.[6,7]

SNHL also imposes severe constraints on the dynamic range of perceived sound. For normal listeners, the dynamic range from sensing soft sounds to the loudest tolerable noise is more than 100 dB. Within this wide dynamic range of hearing lies an approximately 35-dB dynamic range of conversational speech. In contrast, the dynamic range of patients with SNHL is often narrowed by an increase in the threshold of audibility and a lowering of the ceiling of tolerance to high-intensity sounds. This compaction of dynamic range leads to "recruitment," an abnormal growth in loudness as sound intensity increases.[8,9] What sounds normal for someone with normal hearing may be too soft for someone with recruitment, whereas what is too loud for someone with normal hearing is *also* too loud for a patient with recruitment. In effect, there is a much narrower range of sound intensity that a patient with recruitment can tolerate. Further adding to the difficulty, recruitment is observed in frequencies that are most impaired, in the high frequencies, which also carry crucial information for speech understanding.

Recruitment remains one of the principal challenges of hearing aid rehabilitation, and is responsible for a common phenomenon most clinicians dealing with hearing loss have witnessed or experienced: At average speaking levels, an individual with recruitment may ask a speaker to talk more loudly, yet with even a slight increase in intensity the speech becomes intolerably loud, and the speaker is told not to

Table 157-1

Comparison of Implantable and Nonimplantable Hearing Aids

Device (Manufacturer)	Sensor	Actuator	Regulatory Approval	Totally/Partially Implanted	Surgical Placement	Audiologic Indications	MRI	Special Advantages/ Disadvantages	EAC Occlusion
Envoy (St. Croix Medical, Intl., St. Paul, MN)	Piezoelectric, coupled to malleus/ TM	Piezoelectric, to stapes	In clinical trials	Total	Transmastoid, mandatory incus removal	Figure 157-9		Very high power; requires incus removal	No
MET Middle Ear Transducer (Otologics, LLC, Boulder, CO)	Piezoelectric, coupled to malleus	Piezoelectric, to incus	FDA clinical trials Phase 2	Partial	Transmastoid	Moderate to severe		High-powered output; fully implantable; ossicles remain intact; adjustable for ossicular abnormalities	No
Vibrant Soundbridge (Vibrant-Med-El, Innsbruck, Austria*)	External BTE microphone	Magnetic, clipped to incus	Approved, U.S. FDA and CE Mark	Partial	Transmastoid and endaural	Figure 157-4		First FDA approved, largest install base	No
Bone-anchored device (BAHA) (Cochlear Corp., Lane Cove, Australia)	External microphone	Electromagnetic vibrator, coupled to titanium screw in skull	Approved, U.S. FDA and CE Mark	Partial	Cortical skull bone screw	CHL unable to tolerate conventional HA	+	Simple placement, nothing in ear or mastoid	No
RetroX (Auric Hearing Systems, Rheine, Germany)	External BTE microphone	Acoustic, to TM	Approved U.S. FDA and CE Mark	Partial	Transconcha	Mild to severe CHL or SNHL	+	Noninvasive placement; acoustic coupling	Yes
Conventional Digital BTE (many manufacturers)	External BTE microphone	Acoustic, to TM	Yes	NA	NA	Mild to severe CHL or SNHL	NA	No surgery required; visible, EAC occlusion	Yes
Conventional Digital CIC (many manufacturers)	External microphone at lateral end of CIC device	Acoustic, to TM	Yes	NA	NA	Mild to moderate CHL or SNHL	NA

shout. Although many hearing aids can be programmed to prevent sound from amplifying into a range that is uncomfortable, even the most advanced aids cannot fully replicate the complex, nonlinear response patterns of a healthy cochlea.[9]

Disordered Perception of Pitch and Sound Localization

Another challenge faced by conventional hearing aids relates to impaired pitch resolution and sound localization. Although simple amplification strategies can compensate for this loss of sensitivity, they do little to restore the exquisite selectivity of the cochlea in organizing pitch information. Much of the benefit provided by the normal auditory system is based on the presence of two ears that independently sample the acoustic environment and send this information to the brain for comparison and analysis. Sound detection is an important first step in hearing, and can be performed reasonably well by one sensitive ear. There is significant additional auditory benefit, however, when sound input occurs through both ears. When only one ear functions, or when there is a drastic difference in hearing levels between ears, the ability to locate the source of sound decreases, as does suppression of background echoes and the ability to "block out" background noise.

All of the aforementioned factors play a role to various degrees in patients, and combine to increase the noncompliance rate in hearing aid users. For most patients, these are the principal reasons why hearing aids are unacceptable.[10] With all these challenges concerning conventional hearing aids, it is not surprising that many hearing aid users feel frustrated when hearing aids fail to perform to expectations.

Promise of Implantable Hearing Aids

The limitations of traditional air-conduction hearing aids have constituted the driving force behind the new generation of implantable hearing aids. Can implantable hearing aids solve these difficult challenges? Implantable hearing aids face most of these same challenges, but also have the added obstacle of requiring surgery for their placement, and being potentially much more costly. Their appeal includes the possibility of improved signal-to-noise ratios, greater amplification/gain potential, invisibility, loss of distortion and feedback, getting the aid out of the canal with the associated occlusion effect, greater dynamic range, and improved cosmetics. For some patients who simply cannot wear a hearing aid because of underlying medical problems or extreme discomfort, implantable hearing aids may be the only option.

It is widely accepted that implantable hearing aids should provide distinct advantages over conventional hearing aids, including better cosmetics, improved fidelity, broader frequency response, less distortion, reduction or elimination of feedback, and better speech understanding, without reducing residual hearing, limiting patient activities, or predisposing patients to infection.[11,12] In other words, implantable hearing aids should be at least as good as, and preferably better than, the best available noninvasive method of hearing rehabilitation: binaural amplification with the best available aid.[13]

Although significant strides have been made in many of these areas, implantable hearing aids have yet to deliver on all these features. There also remain questions regarding candidacy for implantation and willingness of patients to accept the costs and surgical risks. As noted by Junker and colleagues,[14] the number of patients in a fairly typical population of hearing-impaired individuals who would be considered realistic candidates is limited, on the order of 0.09%. The market for implantable hearing aids may not be sufficiently large to support the current array of device manufacturers. The 2002 financial failing of Symphonix Corp., the first company to gain U.S. Food and Drug Administration (FDA) approval and market their implantable middle ear hearing aid in the United States, strongly underscores this point, as do the subsequent withdrawal of the Soundtec and TICA devices described subsequently in the review of technologies.

The focus of the remainder of this chapter is on critical reviews of the advantages and disadvantages of each of the implantable hearing aids that are either in development or already in clinical use. A different type of implantable hearing aid, the bone-anchored hearing aid (BAHA), is widely used in hearing rehabilitation for some very specific indications, and this also is discussed.

Middle Ear Implants

Basic Design Features

Transducer Design

Conventional hearing aids function by receiving acoustic energy through a microphone, processing and amplifying the signal (in either an analog or a digital fashion), and transmitting the signal through a speaker adjacent to the eardrum. This amplified sound travels through the normal auditory pathway of the tympanic membrane and ossicles to the inner ear. Implantable middle ear hearing aids also employ a microphone that senses sounds and a signal processor that amplifies and alters the sound signal, just as in a conventional hearing aid. From here, they differ from conventional hearing aids. In one of several mechanisms unique to each device, the implantable middle ear hearing aids convert the electric signal into a mechanical energy that is coupled directly to the ossicular chain (see Fig. 157-1).The critical components of these systems are the transducer, which enables the device to output a signal that can be received by the ossicles, and the mechanism by which the transducer is coupled to the ossicles, which can either be a direct or indirect contact.[15] Variations in these critical components distinguish the various implant designs (see Fig. 157-2). Goode and colleagues[11] previously outlined the history of the development of implantable middle ear hearing aids.

Two basic types of transducers have been incorporated into middle ear implantable hearing aids: *piezoelectric* and *electromagnetic*. Piezoelectric implantable hearing aids function by connecting the ossicles to an amplifier using a piezoelectric crystal vibrator. Piezoelectric materials are dielectric materials with coupled electrical and mechanical properties. Applying a voltage across an appropriately designed piezoelectric rod causes it to bend or lengthen, with a predictable change in deflection based on the voltage applied. Within the implant, sounds picked up by a microphone are converted by the signal processor to an electrical signal, and sent to the piezoelectric rod. As this rod vibrates in response to the converted auditory signal, it lies in direct contact with the ossicles. In this manner, sound waves are transferred directly to the ossicles, which travel along the normal auditory pathway. A critical feature of implants that use a piezoelectric transducer is direct contact between the piezoelectric unit and the ossicles.

Implantable middle ear hearing aids may also incorporate an electromagnetic transducer. These transducers generate a magnetic field using a coil carrying a current that encodes the microphone output. This magnetic field from the coil can cause motion in a ferromagnetic substance that is nearby, causing it to vibrate.[15] As applied to middle ear implants, sound received from a microphone is converted by the signal processor, amplified, and sent to the electromagnetic transducer. The electromagnetic field that is set up vibrates a ferromagnetic unit coupled directly to the ossicles. In contrast to the piezoelectric unit that must be in direct contact with the ossicles, electromagnetic transducers need only to be near the ossicles, which have attached to them the ferromagnetic device that transmits the auditory signal to the ossicles.

These two types of amplification have different advantages for use in an implantable hearing aid. Electromagnetic transducers do not directly contact the ossicular chain, but rely on electromagnetic transmission to a ferromagnetic unit that is attached to the ossicles. Electromagnetic transducers can be packaged in a smaller housing, an important factor in the ear. In contrast, piezoelectric devices are larger and couple directly to the ossicular chain. The advantage of this type of transducer is its ability to deliver more distortion-free amplification directly to the ossicular chain.[15] In either event, to accommodate patients with moderate to severe SNHL in the 55- to 90-dB hearing level range, any implant, whether electromechanical or piezoelectric, should be able to deliver a maximum mechanical stimulation output equivalent to 120 to 130 dB sound pressure level (SPL).[16,17] How each implant achieves this output level is described subsequently.

Ossicular Coupling

As noted by Huttenbrink,[18] to obtain optimal efficiency in implantable hearing aids, they must adapt to the mechanics of the middle ear and ossicular chain. As the third ossicle in the chain, and the one in conti-

nuity with the inner ear, the motion of the stapes is crucial in sound transmission. The stapes moves in a piston-like fashion.[19] The ideal motion of the stapes by a prosthesis would be in this piston-like fashion. Any implant that directly attached to the stapes would function best by mimicking this motion.[20,21]

Various implants employ numerous ways to couple vibration stimuli to the inner ear. Some employ a piezoelectric transducer to contact either the stapes head directly (e.g., St. Croix Envoy/Esteem-Hearing Implant) or the incus body (e.g., Implex TICA). Others use an electromagnetic transducer typically attached to the incus (e.g., Med-El Vibrant Soundbridge, Otologics Carina/MET), but sometimes adapted to contact the stapes capitulum, stapes footplate, or round window membrane. Others clip to the incudostapedial joint (e.g., Soundtec Direct Drive System). Each of these systems is described in greater detail individually.

Total versus Partially Implantable Hearing Aids

Implantable middle ear hearing devices may be either totally or partially implantable. Partially implantable devices consist of an external microphone and speech processor that are connected to a transmitter with an external coil that transmits electrical energy transcutaneously to the internal device, in much the same way cochlear implants are now powered. The battery-powered system is contained within the external device, decreasing the size of the implanted component. The internal device consists of an internal receiving coil, which provides electric energy to the mechanical driver connected to the ossicular chain.

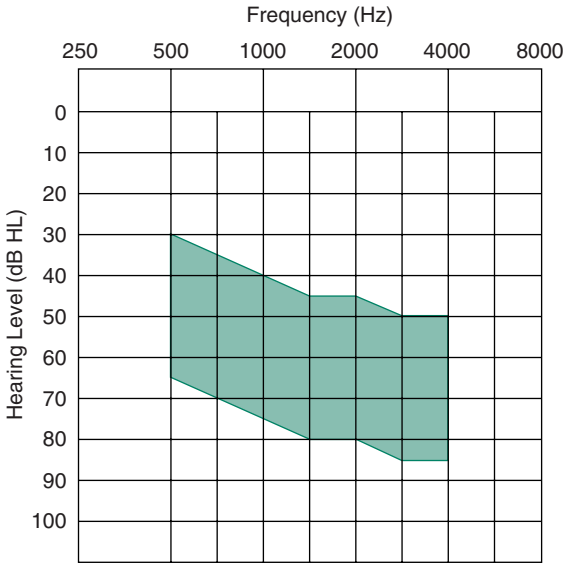
In contrast, the fully implantable systems house all of the above-mentioned components within the implanted portion of the device, including the battery pack. Although the size and complexity of the implanted components are increased, the visibility of the device is reduced, a feature that is desirable among hearing aid users. Because of the finite life of the rechargeable batteries, the totally implantable designs employed in clinical settings so far require reoperation at approximately 5-year intervals to exchange the spent device with one containing a new battery.

Electromagnetic Middle Ear Implantable Hearing Aids

Vibrant Soundbridge

To date, the implantable middle ear hearing aid with the most clinical data is the Vibrant Soundbridge, manufactured by Symphonix Corporation until 2002, when Symphonix was dissolved and the Vibrant technology was bought and later re-released by a subsidiary of the Med-El Corporation (Innsbruck, Austria), which resumed Vibrant Soundbridge sales in 2004. Because it was the first commercially available, FDA-approved middle ear hearing aid, a thorough review of this device is instructive.

The Vibrant Soundbridge is a semi-implantable hearing aid that was first introduced in 1997 (Fig. 157-3). Since its introduction in 1997, more than 2300 patients have been implanted worldwide.[14] The device was approved for commercial availability in Europe in 1998, and in the United States in 2000. The electromagnetic transducer uses a proprietary vibrating ossicular prosthesis (VORP), which typically is attached to the long process of the incus. The VORP contains a rare earth magnet surrounded by a receiving coil, a demodulator package, a conductor link, and a proprietary floating mass transducer (FMT).[22,23] The transducer was developed by Ball, and incorporated prior conceptual work performed by Goode and colleagues.[11,22,24] The VORP is electrically connected to the internal receiver.[25] These internal components are coupled to the audio processor via a telemetry link, similar to a cochlear implant. The processor, which is worn behind the ear, contains the microphone, audio processing electronics, magnet, telemetry transmission equipment, and room for a standard 675 zinc battery to power the implant.



Soundbridge Clinical Indications:
Pure-tone air-conduction thresholds within selection criteria
Normal middle ear anatomy
Word recognition score of ≥50% using recorded material
Absence of retrocochlear or central involvement
≥18 years old

Figure 157-4. Audiologic selection criteria for the Soundbridge. The Soundbridge is indicated in patients with moderate to severe sensorineural hearing loss of 70 dB pure-tone average hearing thresholds. The shaded area of the figure corresponds to the pure-tone audiometric implant criteria.

The function of the externally worn processor is similar to a conventional hearing aid. Sound is picked up by the microphone and processed by the external receiver by the electronics. The signal is sent via telemetry to the internal receiver. From here it is sent to the demodulator, which provides a safety feature to limit maximum power output and prevent overstimulation. The demodulator generates a current encoding the sound, and this current travels to the FMT, causing the FMT to vibrate through inductive interaction with the magnet. Because the FMT is firmly attached to the incus using a titanium clip, amplified sound is transmitted directly to the ossicular chain. Because the FMT includes a magnetic component, implantation of this device prevents a patient from undergoing magnetic resonance imaging (MRI) without device removal.

The Vibrant Soundbridge is indicated in patients with moderate to severe SNHL and desire for an alternative to an acoustic hearing aid (Fig. 157-4).[23] Studies have indicated that it may be suitable for patients with hearing loss of 70 dB pure-tone average (PTA) hearing thresholds.[26] When first introduced, the externally worn audio processor was an analog device that incorporated a wide dynamic range compression. Because of inadequate gain of the device, particularly at lower frequencies and with low sound levels,[27] a newer, more powerful digital audio processor was introduced in 1999. Studies done shortly after its introduction failed to show superior hearing results compared with conventional aids, although patients preferred the device, in part because of ability to wear it for a much longer time without discomfort.[26]

The device typically is implanted using a standard transmastoid, facial recess approach to the middle ear. The VORP is crimped into the long process of the incus. The internal receiver is placed in a bony trough in the retrosigmoid bone several centimeters behind the ear, in a location similar to the receiver placed during cochlear implantation. One potential drawback of this design concerns the size of the VORP. Because of the confined space between the eardrum and the incus, the dimensions and mass of the FMT are limited, restricting its output.[28] A second potential drawback is erosion of the incus long process, owing to ischemia at the clip attachment site. Modifications of the typical surgical approach allow treatment of mixed hearing losses resulting from otosclerosis or ossicular erosion or agenesis through direct placement of the VORP on the stapes superstructure, round window, or oval window.[29-32]

Owing to its primacy in regulatory approval processes and patient availability, to date more clinical data are available for the Vibrant Soundbridge than for all other middle ear implants. Results from the phase III clinical trial of 53 patients were sufficiently favorable to merit FDA approval of the device (phase I trials typically test feasibility and safety in a small group of subjects, phase II trials typically test effectiveness in a slightly larger group, and phase III trials assess safety and effectiveness in a large group).[23] Patients in the study were analyzed with conventional analog hearing aids, digital hearing aids, and the Vibrant Soundbridge. Standard audiologic tests included pure-tone air-conduction and bone-conduction thresholds (250 to 8000 Hz), functional gain, speech recognition tests, the Profile of Hearing Aid Performance, and the Hearing Device Satisfaction Scale.

Although one patient had a shift of 18 dB after device placement, the effect of implantation on residual, native hearing was believed not to be significant (<10 dB PTA at 500 to 2000 Hz). This finding corroborated earlier studies that showed little to no effect of the presence of the FMT on hearing sensitivity.[33] When compared with presurgical conventional hearing aid test scores, the implant showed a statistically significant improvement in functional gain at all frequencies and greater than 10 dB improvement at 2 kHz, 4 kHz, and 6 kHz. No significant difference was noted in speech recognition (NU-6 word list) between the preoperative hearing aid and the implant. On the revised speech reception in noise score, 7 patients (13%) showed significantly better scores, 70% showed no change, and 17% had worsening of their scores. As an entire group, there were no significant differences between the conventional hearing aid and implant group test scores on speech reception scores. Significant improvements were noted in the implanted group on the two self-assessment questionnaires (Profile of Hearing Aid Performance and Hearing Device Satisfaction Scale).

It seemed from the results of this phase III study that there were some objective gains in auditory scores with the implants compared with conventional hearing aids, and patient perceptions of the implant were better than conventional aids. Most of the subjective benefits of the implant centered around the ability to wear the device all day without the discomfort afforded by conventional aids.

The European experience with the Vibrant Soundbridge seems similar to the experience in the United States.[24,25,34] A multicenter study from Europe, which included 63 patients, focused on the gain provided by the implant and attempted to assess the quality of the amplified speech.[25] In contrast to the U.S. FDA phase III study, the European study did not compare results with a conventional hearing aid, but used the unaided condition as a comparison. The study noted a large variability in gain for each patient. For most patients, the greatest gain was in the 1- to 2-kHz region, where the transducer has its resonance.[22] The authors reasoned that an inefficient coupling in some patients (e.g., the FMT may be loose) may be responsible for the wide variability seen, and highlighted the importance of effective placement of the VORP on the incus.

When the authors compared gain at threshold and gain at normal speech, there was only a small difference noted (6 dB), indicating that the gain is effective at normal speech levels. The authors also concluded that the amplified sound from the Vibrant Soundbridge had adequate quality for speech intelligibility. Overall, the authors believed that there was clear benefit from the Vibrant Soundbridge, but there was a subgroup of patients with low gain, secondary to the limited bandwidth of the amplified signal. Other work from this same multicenter European group has shown a significant improvement in communication in various listening conditions with the Vibrant Soundbridge compared with conventional aids.[24,34]

A more recent report relates the Belgian experience with the Vibrant Soundbridge.[35] In a study of 13 patients, the average functional gain between 500 Hz and 4000 Hz was 30 dB, similar to prior European and American studies published. The authors noted, however, that not all of their patients studied were able to afford the best possible digital hearing aid preoperatively, and they could not adequately compare

satisfaction levels. The cost of the implant is severalfold higher than for the top-of-the-line digital aids, and it is likely that these patients could not afford the implant on their own. The authors reported high satisfaction of all the users of the device, and the "impressive" functional gains, particularly at higher frequencies.

One study that has specifically addressed the functional gain of the Vibrant Soundbridge with conventional hearing aids is from Todt and associates.[36] Examining five patients first fit with an analog and then digital conventional processor, the authors compared results with a digital processor of the Vibrant Soundbridge. As with previous studies, no significant differences were noted in underlying, residual hearing as a result of implant placement. Their data showed a significant improvement of hearing compared with conventional aids in quiet (approximately 10 dB PTA), and a better functional gain in noise for the Soundbridge compared with conventional aids. Subjective outcomes of a hearing aid questionnaire (Abbreviated Profile of Hearing Aid Benefit) also showed significant improvement of the Symphonix implant compared with conventional aids. As with other studies, the greatest gains were noted in the higher frequencies.

Placement of the Vibrant Soundbridge on the round window for treatment of conductive and mixed hearing loss has become commonplace in Europe. FDA approval in the United States for this approach and indication is still under investigation in a clinical trial that started in 2008.

The Vibrant Soundbridge story provides a cautionary insight into potentially the future of all implantable hearing aids. In late 2002, before the ultimate purchase of Symphonix by Med-El Corp., the Symphonix corporate website abruptly announced dissolution of the company. The Symphonix announcement raised poignant medical and ethical questions not just for the more than 600 patients already implanted with Symphonix devices, but also for the middle ear implantable hearing aid field as a whole. When novel implantable technologies are championed by small companies dependent on venture capital for continued support of operations, the longevity of corporate support of a device must be in question. Should there arise a serious liability issue with the device in the future, would implanted patients have any recourse? In this instance, an established company (Med-El Corporation, a manufacturer of cochlear implants) bought the technology and offered to provide patient support. Would a similar bailout occur if another of the middle ear implantable hearing aid companies fails? Surgeons and patients must consider these issues before implanting a middle ear hearing aid from a company without a proven track record of product reliability and financial stability.

MET (Middle Ear Transducer) and Carina

The Otologics MET (Middle Ear Transducer) is an electromechanical middle ear hearing aid using a mechanism initially developed by a group headed by Fredrickson in collaboration with Storz Instrument Co. It is now manufactured by Otologics LLC.[16] Although the original MET (on which most data reviewed here are based) was semi-implantable, that design has been replaced by a fully implantable version marketed as the Carina (Fig. 157-5).

The MET implantable unit consists of the transducer coupled to an electronic receiver.[16,37] The transducer vibrates a probe that is in direct contact with the incus. For the semi-implantable version, two external devices were developed. The device initially used in clinical trials was a modified version of Oticon's JUMP-1 hearing aid (Oticon Inc., Copenhagen, Denmark), and comprised a BTE signal processor, microphone, amplifier, and battery. This device was attached to a transmitter coil via a short cable. A newer unit housed the transmitter coil together with the BTE components. These semi-implantable designs enabled the MET to deliver the equivalent of greater than 135 dB SPL over a frequency range of 250 to 6250 Hz.[16] This output should theoretically provide adequate gain for patients with moderate to severe SNHL.

Placement of the MET Ossicular Stimulator requires a general anesthetic and approximately a 2-hour operation (Fig. 157-6). Using a standard, postauricular approach to the mastoid cortex, the root of the zygoma, posterior canal, and linea temporalis are clearly delineated (see Fig. 157-6).[16] A limited mastoidectomy (antrostomy) is performed

Figure 157-5. Otologics Carina fully implantable system. *(Courtesy of Otologics, LLC, Boulder, CO.)*

directly superior to the external canal and inferior to the tegmen tympani using a 6-mm bur, and extended until the incus body (approximately a 10-mm width) and head of malleus are exposed. When complete, a mounting system is attached over the opening using bone screws. The MET Ossicular Stimulator is maneuvered into the mounting system with the transducer probe tip fully retracted. A laser is used to make a small hole in the incus body to accept the probe tip. The tip is advanced into position using a micrometer screw, and ultimately becomes firmly attached to the incus from fibrous tissue. The receiver capsule and transducer electronics are placed in a recess drilled in the mastoid, similar to cochlear implant electronics.

Ultimately, 282 patients were implanted with the semi-implantable MET in Europe and the United States during phase I and II trials.[16] Pure-tone audiometry, speech recognition, and subjective assessment of benefit were tested before the surgery and 12 months after. Group mean postoperative bone-conduction and air-conduction thresholds were not significantly changed from preoperative levels compared with a well-fit digital hearing aid used preoperatively. A slight (approximately 5 dB) increase in CHL was attributed to mass loading by the transducer on the ossicles. Sufficient gain was available to make the device useful for subjects with moderate to severe SNHL. Speech and subjective assessment of patient preference indicated that patients did as well or better with the MET compared to their "walk-in" aid or the standardized digital hearing aid (Fig. 157-7).[37]

The Otologics Carina fully implantable hearing system is similar to the original MET except that it requires no external components apart from a charger and remote.[38] It uses a subcutaneous microphone rather than an external microphone, and it is designed to work for waking hours of 1 day between charging sessions that require 1 hour. Phase I trial results in the United States showed 10 to 20 dB of functional gain across audiometric frequencies at 3 months postoperatively.[39,40] Pure-tone bone averages were minimally changed from preoperative values. Pure-tone air averages and monaural word recognition scores were initially slightly worse with the device than measured preoperatively with the walk-in aid, but patients reported greater subjective benefit with the implanted device.

Within 12 months postoperatively, a high rate of device failure was observed, leading to explantation in 5 of the 20 adult study subjects as of early 2008. Failure modes included partial device extrusion, inability to communicate to external components, and failure of the recharging mechanism. Even among devices that did not require explantation, degradation in hearing performance commonly occurred at approximately 6 months after implantation and was attributed to movement of the subcutaneous microphone. These observations led to a redesign

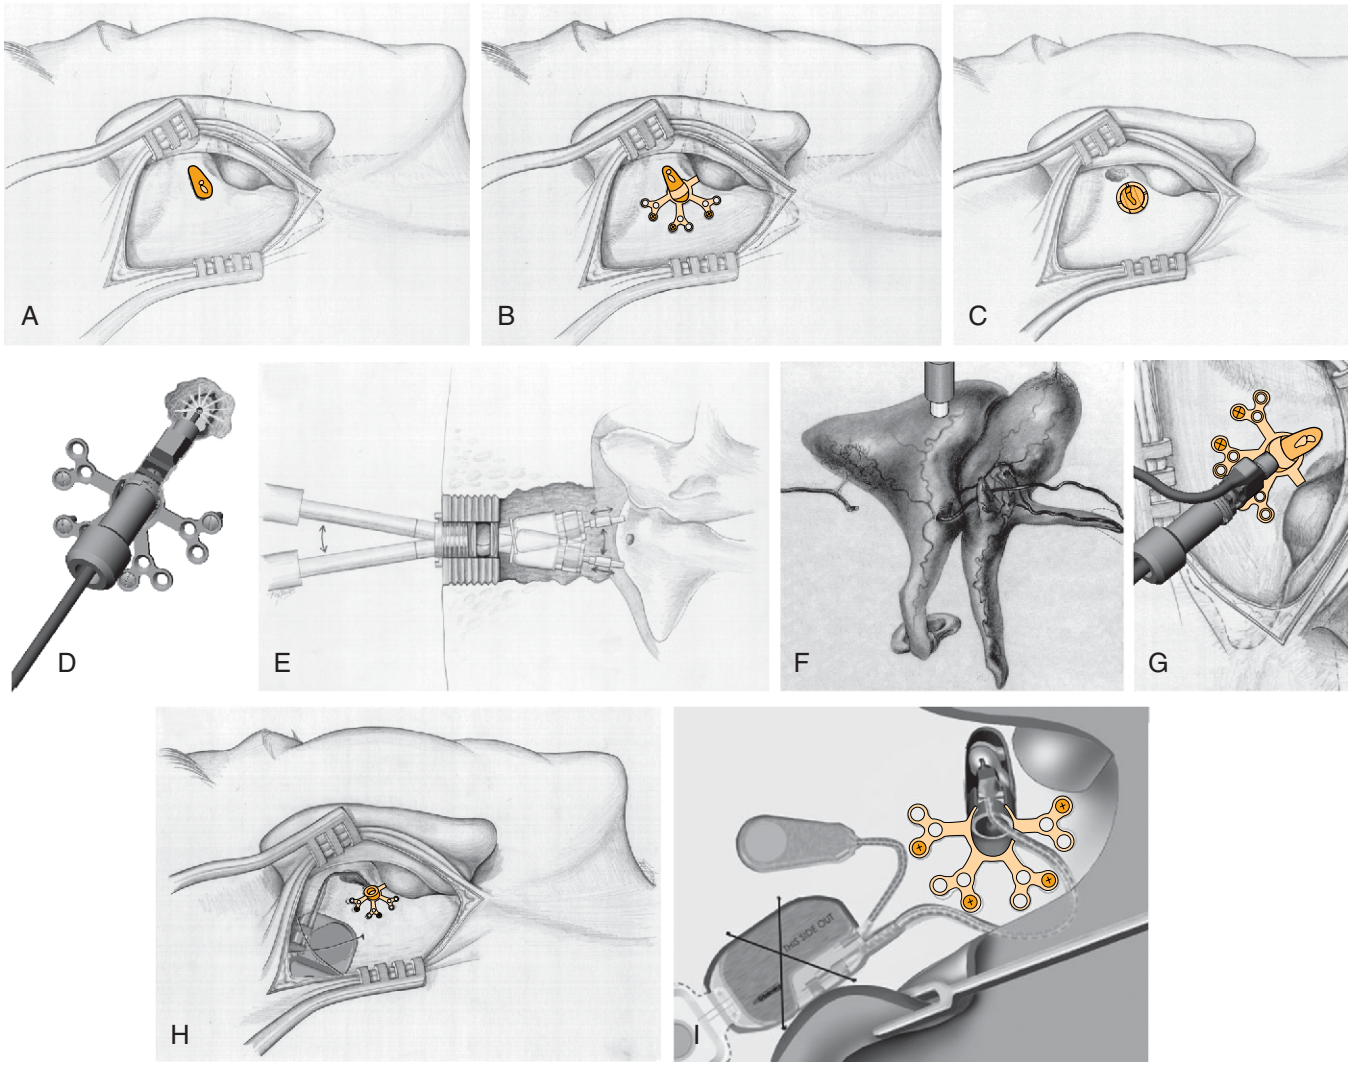


Figure 157-6. **A-I,** Surgical implantation of the Otologics MET or Carina begins with a limited antrostomy **(A)** sparing cortical bone ledges for attachment of a metallic stage **(B, C)**, which is used to steady a laser **(D)** for creation of a small hole in the posterosuperior incus **(E)**. The laser is removed and replaced with the MET actuator, the tip of which inserts into the incudotomy **(F)**. The actuator is secured to the stage **(G)**, and the remainder of the implanted device is secured to retromastoid cortical bone **(H)**. In the Carina totally implantable version of this device **(I)**, a subcutaneous microphone beneath the skin covering the mastoid replaces the external microphone and inductive link used in the MET, but the implantation procedure is otherwise similar.

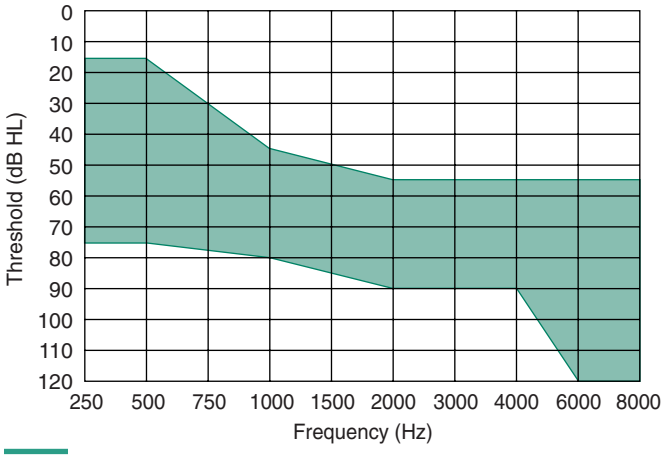

Figure 157-7. Audiologic selection criteria for Otologics MET. The shaded area of the figure corresponds to the pure-tone audiometric implant criteria.

and revision in surgical technique emphasizing creation of a well adequately deep to prevent device extrusion and a tie-down mechanism to prevent microphone migration. Intraoperative measurement and optimization of ossicular coupling compression resulted in more consistent and better coupling efficiency of the transducer to the ossicles.[41,42]

The Carina has received the CE Mark for clinical use in Europe, and phase II trials are under way in the United States. As of early 2008, more than 50 patients had been implanted with the redesigned device, and the failure modes identified during the phase I trial had not recurred.[39] Variations on the size and length of the ossicular coupling have expanded the application of the Carina to patients with aural atresia and ossicular discontinuity, via direct attachment of the device on the stapes capitulum, stapes footplate, and round window.[41,43]

Piezoelectric Middle Ear Implantable Hearing Aids

Esteem-Hearing Implant

A piezoelectric bimorph placed on the malleus head can effectively use the tympanic membrane as a microphone, offering a viable alternative to a subcutaneously implanted microphone. Studies in cadaveric temporal bones have shown that such a device had a dynamic range of

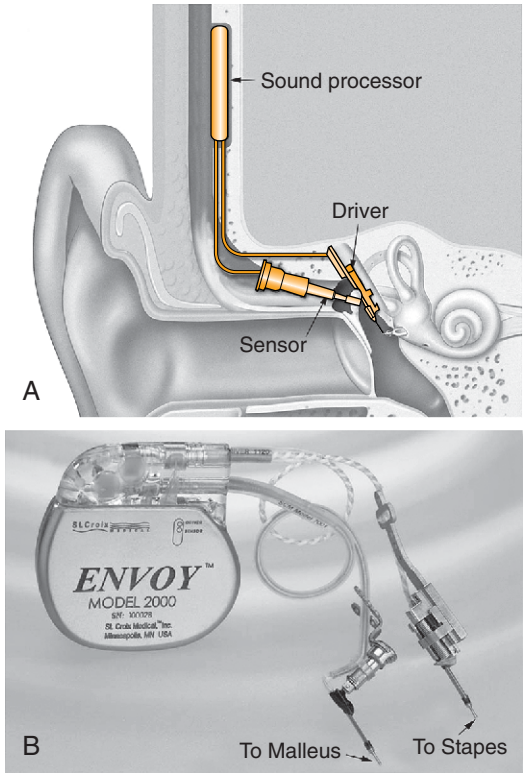

Figure 157-8. The Envoy/Esteem piezoelectric totally implantable hearing aid. **A,** Implantation schematic. Instead of a microphone, sound enters the device via a piezoelectric transducer coupled to the malleus and tympanic membrane. A piezoelectric actuator produces amplified stapes motion. The incus has been removed to prevent feedback. **B,** Complete device.

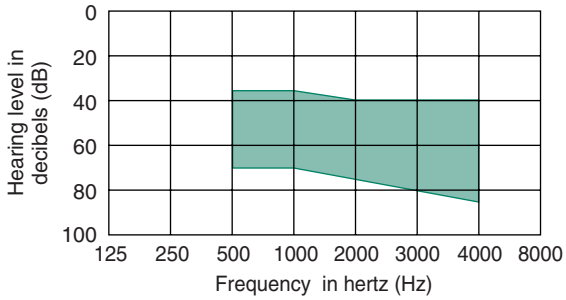

Figure 157-9. Audiologic selection criteria for the Envoy. The Envoy is designed for patients with moderate to severe hearing loss (35 to 85 dB) between 500 Hz and 4000 Hz in the implanted ear that is equal to or worse than the hearing loss in the nonimplanted ear, normal tympanometry, and speech discrimination 60% or greater. The shaded area of the figure corresponds to the pure-tone audiometric implant criteria.

80 dB at 1000 Hz, with precise ossicular tracking out to 4000 Hz.[44] The Esteem-Hearing Implant developed by Envoy Medical (formerly called the Envoy device and developed by St. Croix Medical, Inc., Minneapolis, MN) is a fully implantable piezoelectric device that uses this approach (Fig. 157-8). It received the CE Mark in Europe in 2006 and as of 2008 was in a phase II clinical trial in the United States.

Similar to all passive transducers, piezoelectric devices are bidirectional. The Esteem/Envoy uses a piezoelectric crystal to convert malleus vibrations (owing to sound waves impinging on the tympanic membrane) into a voltage encoding sound. After amplification, this electric signal is applied to a piezoelectric output transducer, which converts from the applied voltage to mechanical vibration coupled to the stapes. Power is provided by a nonrechargeable lithium-iodine battery designed to last 5 years between replacements, according to the manufacturer.[45] Programming and control of the device are accomplished through a radiofrequency transcutaneous link to a hand-held device or laptop computer.

By using acoustic input measured at the malleus, the Esteem/Envoy should maintain the spectral shaping and sound-localizing characteristics of the pinna, external auditory canal, and tympanic membrane. Implantation of the Esteem/Envoy requires partial removal of the incus, however, to prevent feedback from actuator to sensor; this ensures a maximal CHL in the event of device failure or removal, unless an ossiculoplasty is performed. This drawback has presented a significant hurdle to acceptance of the Envoy, which has not yet obtained FDA approval for routine clinical use in the United States despite earning a CE Mark in 2006. The internal battery must be replaced approximately every 5 years, and this requires repeated surgeries.

The Esteem/Envoy is designed for patients with moderate to severe hearing loss. Indications include age 18 years or old, mild to severe (35 to 85 dB) SNHL between 500 Hz and 4000 Hz in the implanted ear that is equal to or worse than the hearing loss in the nonimplanted ear, a healthy ear with normal pneumatization and adequate space for device implantation on computed tomography (CT), normal tympanometry, and speech discrimination 60% or greater (Fig. 157-9). A phase I trial in the United States and Germany was completed in 2003. By 1 year after implantation, three of seven subjects continued to use the implant, three had been revised and then explanted, and one was awaiting revision surgery. For the three subjects with functioning implants, there was no significant change in bone thresholds, and the 4-frequency (500 Hz, 1000 Hz, 2000 Hz, and 3000 Hz) average functional gain was 17 dB ± 6 dB, which was comparable to conventional hearing aids except at 3000 Hz, where the Envoy performed less well than conventional hearing aids. The decline in performance was attributed to a gradual ingress of moisture in the transducers.[46]

Implantable Bone-Conduction Hearing Aids

Conductive and mixed hearing losses are highly prevalent disorders that often may be effectively treated using standard surgical techniques or rehabilitated with traditional hearing aids. For a variety of reasons, a large subset of these patients are not suitable surgical candidates for correction of their deficit, however, or are unable to tolerate a conventional hearing aid. This group includes patients with chronically draining ears despite multiple corrective attempts, patients with discomfort from the sound levels required from a traditional hearing aid, and patients unable to tolerate a hearing aid because of a large mastoid bowl or meatoplasty after chronic ear surgery. Additionally, patients with otosclerosis, tympanosclerosis, or canal atresia, and who have a contraindication to surgical repair may also fall into this category of patients who defy traditional attempts at hearing restoration. Patients who have undergone external auditory canal closure after extensive skull base surgery also are not amenable to traditional hearing aid rehabilitation. The osseointegrated BAHA device was originally intended for this group of patients.[47-49] The BAHA device now has also been used extensively for patients with unilateral deafness with good results.[49]

Conventional bone-conducting hearing aids have been advocated as an alternative for patients with conductive or mixed hearing loss who cannot benefit from a traditional hearing aid. The utility of these devices is constrained, however, by several physical factors. Because the bone conductor must be applied with steady pressure to the mastoid cortex (usually via a headband or eyeglasses), patients often experience pain, headache, and skin irritation at the contact site. Sound fidelity is limited by soft tissue attenuation, variable placement of the vibrator, and flaccidity of the securing device (usually eyeglass frames).[50,51] Coupling the bone vibrator to an osseointegrated implant, as originally performed by Tjellstrom and colleagues[51] at the Institute of Applied Biotechnology in Sweden in 1977, circumvents many of these drawbacks. This new generation of osseointegrated conductive hearing aids

now offers an effective alternative to hearing rehabilitation for this difficult subset of hearing-impaired patients.

Osseointegration

Background

In the 1960s, Branemark and associates[52] from Gothenburg, Sweden, discovered that titanium had a unique ability to become firmly anchored in bone without interposed soft tissue, while at the same time achieving a reaction-free epithelial penetration of the implant. In these permanent fixtures, Branemark presciently foresaw the ability of implanted titanium to support functional prostheses, and termed this state *osseointegration*. Osseointegration is considered to be successful if the implant became rigidly anchored into adjacent bone with no reaction at the implant-bone interface.[53] This concept was initially applied to dental implants, but in 1975, Branemark's group began studying the possibility of creating a *skin*-penetrating implant. By the 1980s, Branemark and colleagues, including Albrektsson, Jacobsson, and Tjellstrom,[54] had developed a clinical program with percutaneous titanium implants to provide an anchor for facial prosthetics (pinna, eye, or nose), and an attachment for a BAHA device.

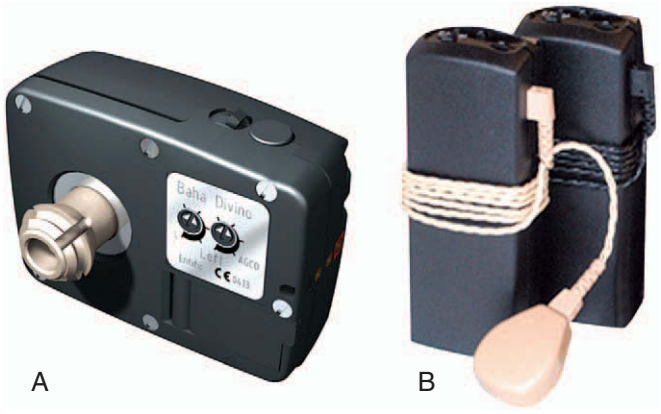

Figure 157-10. Osseointegrated bone-anchored hearing aid (BAHA). **A,** BAHA Divino is shown with its schematic attachment to the abutment and titanium implant. **B,** For patients with a more severe sensorineural component, the Cordelle offers increased amplification. *(Courtesy of Cochlear Corp, Lane Cove, Australia.)*

Biophysical Principles

Implant Material

One initial determinant of successful osseointegration is the chemical composition of the implant. Titanium has survived osseointegration's "test of time," and now represents the standard by which all other biomaterials are measured. Titanium is available commercially as "pure" titanium, which is 99.75% pure titanium, and titanium alloy, containing 90% titanium, 6% aluminum, and 4% vanadium. Titanium, similar to all other metals, forms several types of oxides on exposure to oxygen. In contrast to many of its metallic counterparts, however, titanium has the ability to create a tightly bonded and corrosion-resistant oxide layer on the surface of the implant. This oxide coating of the implant is in contact with the host tissue, which seems most important in determining the biocompatibility of titanium.[55,56] Because the implant may be worn for several decades or longer, the toxicity and carcinogenicity of the oxide coating take on particular importance.[53] Reports have shown that titanium is superior to stainless steel, lacking steel's high potential for corrosion or the toxicity of its components.[56] To date, pure titanium has shown none of these adverse sequelae, and continues to represent an ideal implant material.[55]

Implant Design

Implant microstructure and macrostructure also impact the likelihood of osseointegration. Although a rough-surfaced implant would theoretically better distribute a weight-bearing load, a rough, porous surface less than 100 µm would greatly increase the surface area and increase the risk of implant corrosion, even with a relatively corrosion-free material such as titanium. According to Eriksson and Branemark,[53] it is important that the microarchitecture of the implant surface features a topography with micropits that fit the dimensions of the cell membrane and large biomolecules; this facilitates direct bonding of the implant's oxide surface with the bone matrix. Parametric studies also show that *threaded,* screw-shaped implants have a greater likelihood of osseointegrating, and seem to distribute stress more efficiently than T-shaped or cylindric types of implants.[53,57] The threaded design success is probably most critical in conferring stability in the initial healing phase. If an implant is not absolutely stable after placement, connective tissue may form between the implant and the bone, preventing sufficient osseointegration.

Biology and Histology

Various studies have addressed the biologic correlates of osseointegration. First, there must be *direct* contact between the bone matrix and the implant, without interposed fibrous or soft tissue.[52] Pure (99.75%) titanium has shown this capability histologically, whereas titanium alloys, despite some clinical success, have not. Additionally, for successful osseointegration to occur, there should be no evidence of inflammation at the implantation site, including an infiltrate surrounding the implant or evidence of osteolysis with bone loss.[58] Pure titanium, as opposed to alloyed titanium, has also been shown to be superior in this regard.[51,55] Lastly, there should ideally be no evidence of a connective tissue capsule on the implant surface, although studies have shown that an implant with a capsule less than 30 µm in thickness may achieve osseointegration.[59] By all the above-mentioned criteria, pure titanium seems superior in every category for successful osseointegration compared with alloyed titanium. This superiority is borne out by several clinical studies as well.[50,60,61] Most authors continue to recommend pure titanium for implant material.

Radiologic Implications

A chief disadvantage of any metallic implant is interference with subsequent radiologic studies. Many osseointegration implant candidates are considered for implantation because of surgical defects caused by tumor extirpation, or other medical problems that require long-term surveillance with repeated postoperative CT or MRI scans. The presence of an implant that diminishes the quality of these scans, by introducing echo artifact, takes on increased importance. Pure titanium produces little degradation of images on either CT or MRI. Because of backscatter emissions, a radiation dose delivers 11% of the radiation dose in front of the implant, and 89% behind it.[62] This scatter effect produces little effect on the quality of CT images produced. Similarly, MRI is not contraindicated with the presence of a titanium implant. Any attached components must be removed before the MRI scan, however.

Operative Technique

Complete insertion of osseointegrated implants for the BAHA generally is done in a single stage (Figs. 157-10 and 157-11).[63] Although most surgeons perform the BAHA application in the operating room, there are reports of performing the procedure in an outpatient clinic setting.[64] Because of the importance of the implant's surface-bone interface, the surgeon must use a meticulous and precise method of implant insertion. This method sets the stage for osseointegration with minimal surrounding tissue damage. Only a single implant is needed for a BAHA. According to Branemark's original studies, insertion of the implant *must* be performed meticulously and as gently as possible to minimize thermal damage to surrounding bone.[65] This insertion is optimally performed with a high-torque drill at slow speeds (1500 to 3000 rpm) with sharp drill bits. The use of disposable drill bits avoids the possibility of worn cutting surfaces that damage the implant bed. Maximal irrigation is employed to prevent temperature elevations greater than 33° C. Previous studies have shown that heating tissue to 47° C for 1 minute obviates osseointegration because osteocytes are lost.

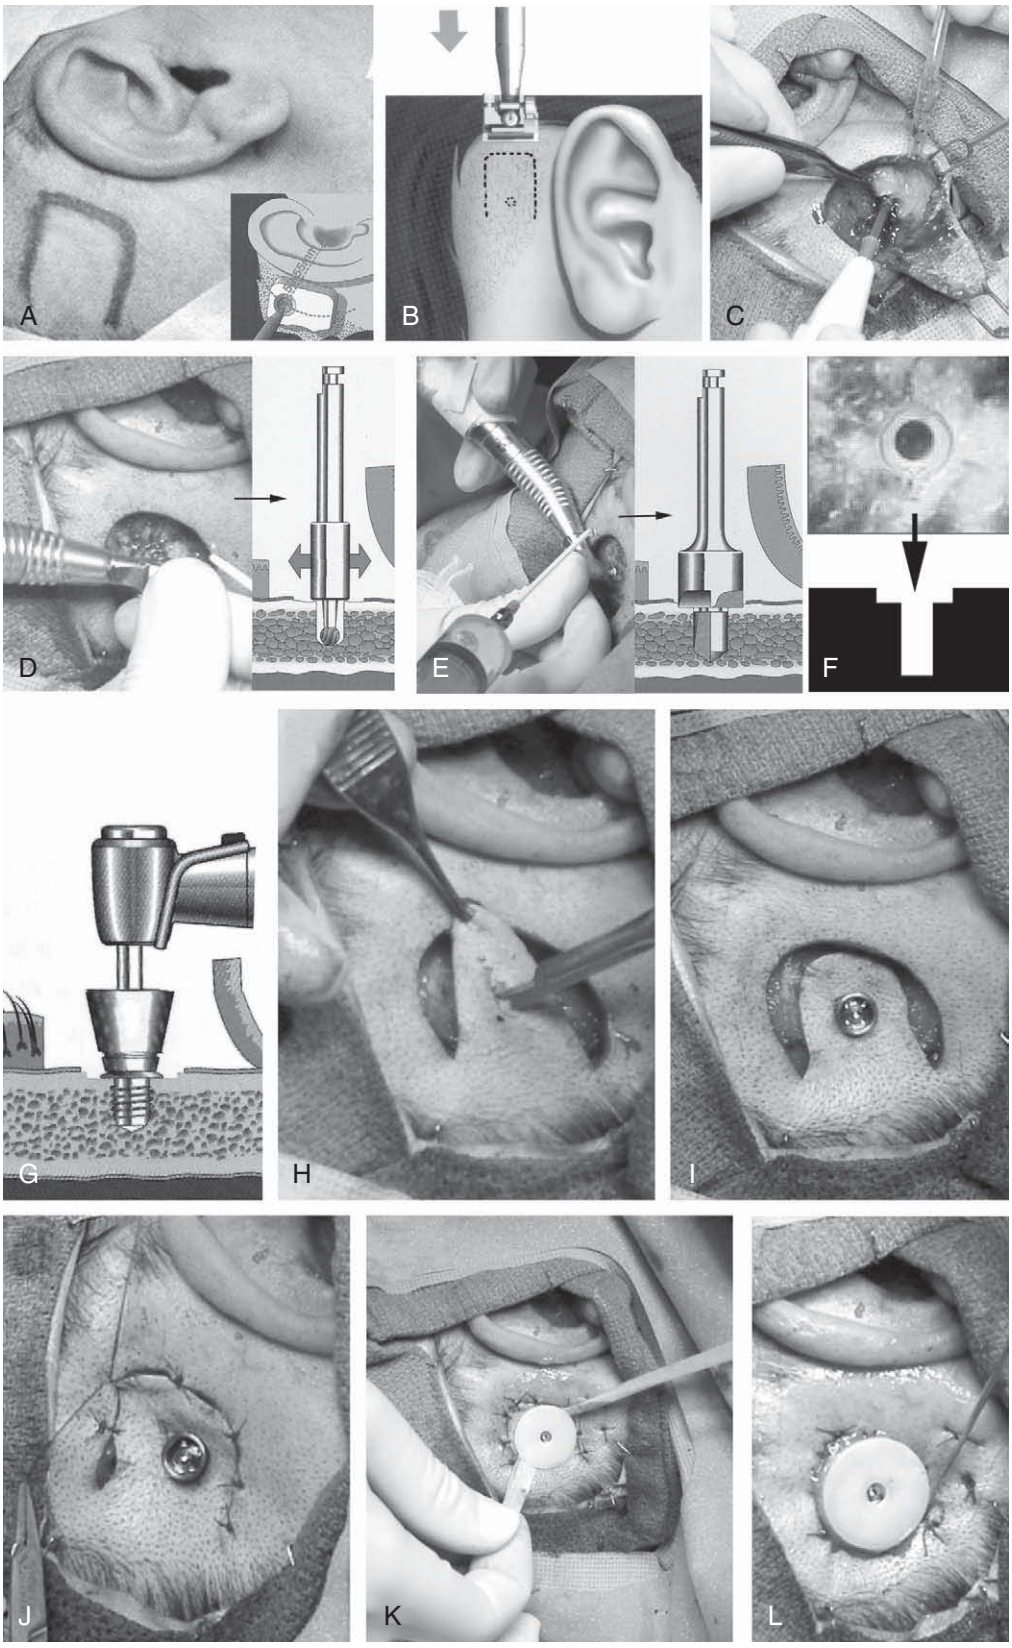

Figure 157-11. **A-L,** Operative technique for placement of Entific BAHA. **A,** Posterior-based skin flap is outlined. **B,** BAHA dermatome is used to elevate a thin flap (in this schematic the flap is inferiorly based). **C,** Soft tissues beneath and adjacent to flap are excised to create a smooth transition from surrounding tissue to thin central skin flap. **D,** A 3- to 4-mm hole is drilled in mastoid or retromastoid cortex. **E** and **F,** Countersink creates a recessed surface for implant placement. **G,** In the single-stage procedure used most commonly, the titanium implant with attached abutment is drilled into the skull at low torque. For a staged procedure, the abutment is removed, and the implant is closed laterally with a sealing screw (not shown). **H** and **I,** Skin flap is replaced, and a hole punch is used to create an opening to transmit the abutment. **J,** Flap is sutured closed. **K** and **L,** Healing cap is placed with gauze wrapped medially to apply pressure to the skin flap. *(Courtesy of Cochlear Corp, Lane Cove, Australia.)*

High-speed drilling typically used in surgery causes temperature elevations to 89° C.[66]

During the surgery, the postauricular skin surrounding the implant must be prepared for percutaneous attachment. The cutaneous-implant interface, as originally conceived by Branemark, is based on biologic principles found elsewhere in the body and throughout nature. Teeth and nails in humans, and talons, tusks, or claws as found in other species, all interface with a thin, firmly attached cutaneous or mucosal border, with little to no hair. This arrangement limits tissue mobility and increases stability of the area, while inhibiting the penetration of microbes with subsequent inflammation or infection.[67,68]

To recreate surgically a reaction-free implant-cutaneous junction, two preconditions *must* be met: The skin penetrated by the implant must be hairless, to facilitate keeping the implant site clean, and subcutaneous tissue should be aggressively thinned to minimize skin mobility in relation to the implant. The dermal layer is allowed to heal directly on the mastoid periosteum, creating a solid, immobile foundation for the implant.[63] To achieve these prerequisites in the temporal bone, hair-bearing skin overlying the implant is aggressively thinned, and hair follicles are removed from the level of the dermis. Some authors originally advocated removal of skin and replacement with a full-thickness skin graft, but this was associated with an increased incidence of skin breakdown surrounding the implant.[69] More recently, a dermatome has been developed specifically for use with the BAHA that has decreased the incidence of skin necrosis.[70] The final skin flap or graft should be less than 1 mm thick at the implant site and adjacent area. The edges of the surrounding skin flaps are sutured down to the periosteum to minimize tension on the flap.

After cutaneous work, disposable 3- and 4-mm drill bits are used to drill a hole in the skull corresponding to the central region of the flap, located at a distance approximately 5.5 cm posterior to the external auditory canal. This hole may be moved for specific anatomic irregularities or the presence of a plate from a prior skull base operation, ensuring that the placement of the abutment would not allow the hearing aid to contact the auricle. After the pilot drill hole, the countersink of the appropriate depth is used, again using maximal irrigation. Subsequently, the titanium implant with attached abutment is drilled into the skull under low torque until secured.

A hole is punched in the skin directly over each implant, and the abutment is screwed into the implant. A healing cap is placed over the abutment with antibiotic ointment–soaked gauze wrapped underneath, which helps prevent hematoma formation during the healing phase by anchoring the flap or graft to the mastoid cortex. After allowing for 12 weeks (adults) or 16 weeks (children) for osseointegration, the BAHA is simply snapped onto the abutment.

Bone-Anchored Hearing Aid in Young Children

The manufacturer of the BAHA recommends the osseointegration procedure in children older than 5 years. For children younger than 5 years in need of bone-conduction hearing rehabilitation, the BAHA-Softband is available.[71] Similar to a conventional bone-conduction hearing aid, the Softband allows bone-conduction hearing by coupling a standard BAHA device to a soft headband, providing hearing that is nearly equivalent to the osseointegrated hearing aid.

Some groups have advocated a traditional osseointegrated implant in this younger age group.[72,73] One complication that must be overcome, however, is the higher incidence of nonintegration in this younger age group, reported to be 15%.[74] Several recommendations have been proposed to avoid this complication. One is to use a two-stage procedure, whereby the implant is placed into the bone without the abutment, and the skin closed directly over this.[72,73] At a later second stage (6 months later if the skull is particularly thin), the skin flap is re-elevated, the abutment is placed, and the remainder of the procedure is finished as with the single stage. One can also leave the abutment in place during the first stage.[72] During the second stage when elevating the skin flap, a scalpel is used rather than the dermatome when the skin is tented by the healing screw, or the flap is infiltrated with local anesthetic to balloon it before using the dermatome. A final recommendation is to create an extremely thin flap to prevent cellulitis during the healing period.[72] Studies have shown that equal hearing results can be obtained when applying this staged approach in children younger than 5 years.[73]

Complications Associated with Osseointegration

The most frequently encountered complication associated with osseointegration is a soft tissue reaction at the percutaneous implant site. Soft tissue and skin reactions associated with percutaneous attachments were studied during the initial development phases of osseointegration technology. In one of the first large studies to address this issue specifically, Holgers and coworkers[75] monitored the soft tissue reactions of 67 patients who underwent osseointegrated implantation. With an average follow-up of 3 to 96 months, 14 of the 67 patients eventually developed adverse tissue reactions. One patient required removal of the abutment because of an infection, 5 patients developed redness and moisture at the abutment site requiring surgical revision (usually subcutaneous tissue thinning), 2 patients had redness with moisture requiring only local treatment, and 13 patients had developed minor erythema requiring temporary local treatment.

Jacobsson and colleagues[76] also published a case report of a patient who developed a soft tissue infection at an abutment site, eventually necessitating implant removal. Despite the presence of an ongoing infection, the implant showed histologic evidence of osseointegration. Niparko and associates[61] reported the first U.S. results with extraoral osseointegrated implants in 14 patients, noting a 3.5% incidence of symptomatic soft tissue reactions, with no implant extrusion. In the largest series to date, Tjellstrom and Hakansson[63] reported implant results on 456 patients, noting a 3.4% incidence of adverse tissue reactions; 3 patients required implant removal for infection, 3 required revision surgery for continued erythema and moisture, and 23 had tissue reactions requiring local treatment only. In the first large U.S. survey of BAHA devices, soft tissue complications were minimal and consisted of local inflammation at the percutaneous-implant junction (three patients).[47] A study of 149 consecutive cases showed that skin overgrowing the abutment was the most common complication (7%), which occurred on average 1 year after the initial surgery.[77]

Observations from these studies indicate that soft tissue reactions with percutaneous implants are largely prevented by soft tissue reduction and attachment of dermis to subjacent bone, to achieve immobility, and patient compliance with routine cleaning of the abutment site and close monitoring of skin attachment of the implant to the abutment. Complications other than adverse skin reactions are rare. Osseointegration failure is the second most common complication of the technique. In the study by Tjellstrom and Hakansson,[63] of 149 patients, 5 were considered failures; 4 failed to osseointegrate, whereas the fifth implant was lost through direct trauma. The first large U.S. series had only one patient with osseointegration failure,[47] whereas a more recent study by House and Kutz[77] had a 3.4% rate of implant extrusion. A rarely described complication is an intracerebral abscess.[78] Overall, studies consistently show that when Branemark's original surgical guidelines are followed, osseointegrated implantation is associated with high surgical success, and a low rate of morbidity and subsequent complications.

Results

In the largest series to date, Hakansson and colleagues[79] reported on their 10-year experience in 147 patients who received the BAHA. Patients were divided into three groups based on their PTA bone thresholds: 0 to 45 dB, 46 to 60 dB, and greater than 60 dB. The authors noted a strong relationship between PTA thresholds and successful rehabilitation. In the group with the best cochlear reserve (PTA <45 dB), 89% of patients' hearing was subjectively improved by the implant, whereas 8% believed their hearing was worse. Conversely, in the groups with progressively less cochlear function, 46 to 60 dB and greater than 60 dB, 61% and 22% of patients reported subjective hearing improvement. On average, speech discrimination scores improved from 14% unaided and 67% with a traditional hearing aid to 81% with the BAHA. This number increased to 85% if subjects with SNHL less than 60 dB HL were excluded, and to 89% if subjects with PTA less than 45 dB were excluded. Based on these results, the authors recommended that to be in consideration for a "high success

Table 157-2

Indications and Contraindications for Bone-Anchored Hearing Aid

Indications	Contraindications
Any patient using a conventional BC hearing aid	PTA BC thresholds (0.5-3.0 kHz) worse than 45 dB HL, SDS >60%
Any AC hearing aid user with chronic otorrhea	Emotional instability, development delay, or drug abuse
Any AC hearing aid user experiencing too much discomfort because of chronic otitis media or otitis externa	Age <5 yr
Any AC hearing aid user experiencing uncontrollable feedback because of a radical mastoidectomy or large meatoplasty	
Otosclerosis, tympanosclerosis, canal atresia with a contraindication to repair, such as in an only-hearing ear. Also, otosclerosis in combination with second, third, and fourth indications	

AC, air conduction; BC, bone conduction; HL, hearing loss; PTA, pure-tone average; SDS, speech discrimination score.

rate" with the BAHA, patients should have a PTA less than 45 dB, although improvements in hearing should still be expected for a PTA of 60 dB (Table 157-2).

In describing the Birmingham experience, Stevenson and colleagues[80] reported on the BAHA in seven children. Four children obtained improvements in PTA by 5 dB or more compared with their previous hearing aid, whereas four had changes in their thresholds of less than 5 dB. Only one of the six children tested for speech discrimination postoperatively had a significant improvement over his prior hearing aid, although the average speech discrimination score in this group was about 90% compared with 0% unaided. Liepert and DiToppa,[81] citing the Edmonton experience in 15 patients, reported an average gain of 30 dB SRT with the NAS compared with unaided speech. In the 10 patients queried, all reported that the BAHA was "better" to "much better" than their previous hearing, with or without their prior hearing aid, in all situations. Overall, the BAHA seems to offer patients with a PTA less than 45 dB a high degree of hearing rehabilitation, and excellent patient satisfaction with the device.

In the initial review of the U.S. experience with the BAHA,[47] the most common indications for implantation included chronic otitis media or draining ears and external auditory canal stenosis or aural atresia. Patients who had undergone skull base surgery and had complete closure of the external auditory canal were also included. Overall, each patient had an average improvement of 32 dB ± 19 dB with the use of the BAHA. Closure of the air-bone gap to within 10 dB of the preoperative bone-conduction thresholds occurred in 80% of patients, and closure to within 5 dB occurred in 60%. Nearly one third of patients showed "overclosure" of the preoperative bone-conduction threshold of the better hearing ear.

The BAHA Compact and the older BAHA Classic 300, on which these earlier studies are based, use an analog technology. A newer device, termed the Divino, featuring more contemporary signal processing has been developed. A more recent review comparing the Compact and Divino showed roughly equivalent results, with an average improvement over all frequencies of 27 to 28 dB for each device.[82] For speech understanding in noise, an advantage of 2.3 dB for the BAHA Divino versus the BAHA Compact was found, if noise was emitted from a loudspeaker to the rear of the listener, and the directional microphone noise reduction system was activated. Subjectively, the Divino was rated better in terms of overall sound quality by the patients.[82]

The BAHA Cordelle is the device with the most powerful gain. Although the recommended levels of hearing loss for the traditional BAHA (Classic, Compact, and Divino) encompass a PTA bone-conduction loss at 500 Hz, 1000 Hz, 2000 Hz, and 3000 Hz at less than 40 dB HL, the body-worn BAHA Cordelle is recommended for patients with a more compromised cochlear reserve. Studies have shown that bone-conduction PTAs of less than 65 dB are acceptable for fitting.[83] There is also the BAHA Intenso, and similar to the Divino, but with additional power for an intermediate sensorineural component.

Bone-Anchored Hearing Aid for Unilateral Sensorineural Hearing Loss

BAHA is gaining increasing popularity for the rehabilitation of unilateral SNHL.[49,84,85] It is hypothesized that using the BAHA device on the deafened ear can expand the sound field for the patient and improve the patient's speech understanding in noise, similar to a contralateral routing of signal (CROS) hearing aid or transcranial CROS system. A prospective trial of subjects with unilateral deafness using benefit surveys, source identification testing, and hearing in noise testing was undertaken by Niparko and colleagues.[84] This study consisted of 10 adults with unilateral deafness (PTA >90 dB, SD <20%) for a variety of etiologies, including acoustic neuroma, meningitis, sudden SNHL, and sudden SNHL with chronic suppurative otitis media. Patients were fitted with contralateral routing of offside signal amplification devices (CROS) for 1 month and tested with contralateral routing of offside signal before mastoid implantation of the deaf ear, fitting, and testing for BAHA.

The results of this study showed that there was consistent satisfaction with BAHA implantation and amplification, and poor acceptance of CROS amplification. Sound localization was poor at baseline and with BAHA and contralateral routing of offside signal. Relative to baseline, CROS and the BAHA produced significantly better speech recognition in noise under most conditions. The BAHA enabled significantly better speech recognition than CROS in quiet and in a composite of noise conditions, a result that may have been related to averting the interference of speech signals delivered to the better ear, as occurs with conventional CROS amplification. The study showed that the BAHA, when placed on the side of a deaf ear, yielded greater benefit in subjects with normal monaural hearing than did CROS amplification.

Another study by Wazen and colleagues[85] has also evaluated the BAHA for unilateral SNHL. This prospective study of nine patients included hearing loss from congenital aural atresia or mastoidectomies secondary to chronic ear infections with or without cholesteatoma, or temporal bone tumor excision. Comparing BAHA-aided with the unaided condition, the authors showed that all patients had tonal and spondee threshold improvement with BAHA compared with thresholds before treatment. Speech recognition performance in BAHA-aided conditions was comparable to the patient's best score in unaided condition, and patients reported a significant improvement in their hearing handicap scores with the BAHA.

A more recent study by Lin and coworkers[86] for patients with unilateral SNHL showed consistent satisfaction with BAHA amplification and poor acceptance of CROS amplification. Sound localization was worse when using the CROS aid, but showed no benefit with the BAHA. In keeping with prior studies, the BAHA produced significantly better speech recognition in noise. Similar findings have been borne out by other studies.[87] These studies show that the BAHA is an excellent tool for rehabilitation of unilateral SNHL, and seems to outperform the only other rehabilitative option available for this difficult problem, the CROS hearing aid. The primary benefit seems to be improved hearing in noise, whereas the BAHA provides no objective benefit of sound localization.

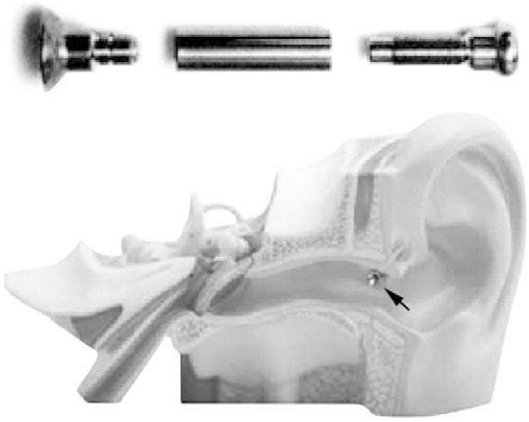

Figure 157-12. Auric metallic tube and transcutaneous placement from retroauricular sulcus to external auditory canal.

Implantable Adjuncts to Conventional Hearing Aids

RetroX

The RetroX (Auric Hearing Systems, Rheine, Germany) consists of an inert titanium metal tube that passes from the postauricular sulcus to the posterior aspect of the external auditory canal, passing just lateral to the mastoid cortical bone and external auditory canal bone (Fig. 157-12). Its major purported advantages are that it does not block the external auditory canal, and it does decrease feedback by separating the device microphone (which lies in a BTE unit) and the output of the speaker in the external auditory canal. Secondarily, there is a cosmetic advantage over traditional BTE aids in that the device is largely hidden behind the pinna, with no speaker tube visibly entering the external auditory canal. According to the manufacturer, the device is appropriate for patients with SNHL or CHL to 30 dB HL at 1 kHz and less and 30 to 80 dB HL loss at 3 to 8 kHz, and is especially suitable for cases of high-frequency SNHL with a steep slope (ski-slope audiogram).

To date, few peer-reviewed reports of device results have appeared in the literature. In one study of 10 patients, all were satisfied with the hearing improvement provided by the RetroX.[88] There was an improvement of pure-tone thresholds at 1 kHz, 2 kHz, and 4 kHz, whereas in quiet, the speech reception threshold improved by 9 dB. Speech audiometry in noise showed that intelligibility improved by 26% for a signal-to-noise ratio of −5 dB, by 18% for a signal-to-noise ratio of 0 dB, and by 13% for a signal-to-noise ratio of +5 dB. Complications included one patient with acoustic feedback and one patient with a granulomatous reaction to the foreign body that necessitated removing the implant. Refinements to the surgical process of placing the titanium tube seem to have diminished the rate of this complication.[89]

A subsequent study of 25 patients by this same group was reported after 2.5 to 15 months of use.[90] Of 25 patients, 23 were satisfied with the device, whereas 4 patients developed a persistent granulomatous reaction that disappeared after explantation, and 2 patients complained of acoustic feedback and needed supplementary fitting. The authors of this study observed a statistically significant improvement of the pure-tone thresholds, with similar speech in quiet and noise scores as their initial study. A study in 2005 by Barbara and colleagues[91] showed that the RetroX provided better hearing in noise with higher rates of satisfaction compared with a CIC hearing aid.[91]

Conclusion

Technology has brought about new and revolutionary means of rehabilitating patients with SNHL and CHL. Totally implanted and semi-implanted hearing aids have the potential to deliver improved sound quality, greater amplification, less distortion, better directional hearing, and better cosmetic appearance than conventional hearing aids. Whether this potential will be fully realized depends on further refinements of their design, acceptance by patients and third-party payers, and the financial viability of the corporations promoting them. Although current economic and financial obstacles may make the short-term outlook for these devices unclear, they will undoubtedly continue to be improved, and ultimately may prove to be a critical part of the armamentarium of devices used for rehabilitation of hearing loss.

CHAPTER ONE HUNDRED AND FIFTY-EIGHT

Cochlear Implantation: Patient Evaluation and Device Selection

P. Ashley Wackym

Christina L. Runge-Samuelson

Key Points

- Cochlear implants are auditory prostheses designed to link an internal device interfaced with the auditory nerve to an external device that uses a specific speech coding strategy to translate acoustic information into electric stimulation.
- Prelingually deafened children acquire speech and language through central plasticity resulting from stimulation by auditory prostheses.
- Postlingually deafened children and adults, as well as those with severe to profound hearing loss, who derive marginal benefit from hearing aids, are appropriate cochlear implant candidates.
- The medical evaluation begins with a detailed collection of the patient's history including age of onset, progression, and bilaterality of the hearing loss; risk factors for hearing loss (e.g., noise exposure, ototoxicity, trauma); and ear infection and surgery.
- Congenital deafness occurs in approximately 1 in every 1000 children, and at least 60% of these children have hereditary causes of the deafness.
- The diagnosis of auditory neuropathy/auditory dys-synchrony has been specified as a hearing disorder where preserved outer hair cell function exists with abnormal auditory neural responses; some of these patients may be cochlear implant candidates.
- Preoperative imaging using CT and/or MRI is essential.
- Current adult selection criteria in the most recent clinical trials include (1) severe or profound hearing loss with a pure-tone average of 70 dB HL, (2) use of appropriately fit hearing aids or a trial with amplification, (3) aided scores on open-set sentence tests of less than 50%, (4) no evidence of central auditory lesions or lack of an auditory nerve, and (5) no evidence of contraindications for surgery in general or cochlear implant surgery in particular.
- With the benefits of binaural cochlear implantation being realized, current candidacy decisions now include whether to receive two implants rather than one.
- We suggest the following referral criteria for cochlear implant evaluation for adults: (1) unaided thresholds of 70 dB HL or poorer at 1000 Hz and above in the better ear, even if hearing levels at 250 and 500 Hz are better; (2) unaided word discrimination less than 70%; and (3) frustration on the part of the patient because of communication difficulties, even with appropriate hearing aid use.
- Cochlear implant evaluation for children can be considered with (1) unaided thresholds of greater than 90 dB HL at 2000 Hz and above in the better ear, even if hearing levels at 250 and 500 Hz are better; (2) aided thresholds in the better ear are greater than 35 dB HL, especially at 4000 Hz; (3) no response for ABR testing in both ears or no response for one ear and responses at elevated levels in the other ear; (4) parents are frustrated with their child's development of auditory and/or communication skills; (5) progressive hearing loss with detection levels at or near the profound range at 2000 Hz and above; or (6) evidence of severely impairing auditory neuropathy/dys-synchrony. There is no lower age limit for evaluation.
- Signal-processing strategies may affect device selection for a given patient (e.g., patients who are music enthusiasts may be interested in comparing aspects of fine structure strategies, whereas other patients with neurologic processing issues may benefit from having strategies that offer slower stimulation rates).

The development and improvement of cochlear auditory prostheses have radically improved the management of children and adults with profound hearing loss. Rapid evolution in the candidacy criteria and the technology itself has resulted in large numbers of individuals who have benefited from implantation. Likewise, the introduction of three device manufacturers into the U.S. marketplace has accelerated the research and development of these auditory prostheses. In this chapter, the evaluation and expectations for both children and adults are presented, as are the similarities and differences among all three available devices in the United States.

General Background

Cochlear implants are auditory prostheses designed to link an internal device interfaced with the auditory nerve to an external device that uses

a specific speech coding strategy to translate acoustic information into electrical stimulation. For the majority of causes of deafness, the auditory hair cells are lost or dysfunctional. The bipolar spiral ganglion neurons and their primary afferent dendrites remain intact, to varying degrees on the basis of etiology, and are available for direct electrical stimulation by the cochlear implant. The tonotopic organization of the cochlea is emulated by orienting the electrode contacts toward the modiolus within the scala tympani and assigning frequencies to specific electrodes along the length of the electrode array such that electrical stimulation corresponding to the highest pitches are delivered within the basal region of the cochlea while electrical stimulation corresponding to the lowest pitches are delivered within the apical region of the cochlea. The electrical impulses directly depolarize the primary afferent neurons, effectively bypassing the dysfunctional hair cells. All three device manufacturers use an external processor that encodes speech on the basis of features that are critical for word understanding in normal listeners, and these features are discussed later in this chapter. More than 70,000 individuals have received cochlear implants, and these devices are now reliably enabling speech comprehension in the vast majority of appropriate cochlear implant recipients.

Prelingually deafened children acquire speech and language through central plasticity resulting from stimulation by auditory prostheses. Some prelingually deafened adults are appropriate cochlear implant recipients but have limited central plasticity that is required for auditory pathway development and processing. Postlingually deafened children and adults, as well as those with severe to profound hearing loss, who derive marginal benefit from hearing aids, are appropriate cochlear implant candidates.

Patient Evaluation

Otologic/Medical Evaluation and Imaging

The medical evaluation begins with a detailed collection of the patient's history, followed by physical examination. The otologic history includes age of onset, progression, bilaterality of the hearing loss; risk factors for hearing loss (e.g., noise exposure, ototoxicity, trauma), and ear infection and surgery. History of possible vestibular dysfunction includes delayed walking, difficulty in riding a bicycle, or difficulty maintaining balance while walking with eyes closed or in the dark. A thorough family history is important including the age of onset, severity, and rate of progression of any hearing loss.

GENETIC HEARING LOSS. The etiology of the hearing loss is an important consideration. Profound hearing loss and deafness, although clear symptoms, have a heterogeneous group of causes. Of the genetic causes, more than 400 forms of syndromic hearing loss have been described, and the list of nonsyndromic loci now exceeds 80,[1] many of which are discussed elsewhere in this book.

Congenital deafness occurs in approximately 1 in every 1000 children, and at least 60% of these children have hereditary causes of the deafness.[2] It is estimated that 70% of all hereditary hearing losses are nonsyndromic, nearly 80% of which are inherited in an autosomal recessive fashion.[3] To date, 54 autosomal recessive, 24 autosomal dominant, and 8 X-linked loci have been characterized for nonsyndromic sensorineural hearing loss (NSHL).[1] Several mitochondrial DNA variants have also been implicated.[1] Studies indicate that up to 50% of all NSHL cases are due to a mutation in a single gene encoding connexin 26 (Cx26).[4] The gene coding for Cx26 (gap junction protein beta 2 or *GJB2*) is located at locus DFNB1 on human chromosome 13q12. The coding sequence of the protein is contained in a single exon that can be easily analyzed using sequencing methods.[5] Children with nonsyndromic genetic hearing loss, if implanted early, are typically excellent performers with their devices.

Genetic syndromal deafness represents a small proportion of all profound hearing impairment; however, there are typically other considerations to be made when these individuals are being considered for cochlear implantation. Although there are more than 400 genetic syndromes that include hearing loss, most syndromic deafness is confined to a limited number of syndromes.[6] Only two common autosomal recessive forms of syndromic deafness exist: Pendred's syndrome (deafness, wide vestibular aqueduct, and thyroid dysfunction) and Usher's syndrome (deafness, blindness due to retinitis pigmentosa, with or without vestibular dysfunction). Jervell and Lange-Nielsen syndrome (deafness and sudden death syndrome due to prolonged QT interval) occurs in families with strong histories or in population isolates. It is, however, important to consider when preparing to bring a child to the operating room when there is a family history of deafness and cardiac death. Unfortunately, the electrocardiogram (ECG) is not entirely sensitive or specific for this syndrome[7]; however, referral to a cardiologist for evaluation and treatment is essential for any deaf child with prolongation of the QT interval on an ECG, history of syncopal episodes, or a family history of prolonged QT interval. Neurofibromatosis type 2 (NF2) is usually diagnosed between the ages of 10 and 30 years, and these individuals can express the phenotype of bilateral acoustic neuromas, which is an important issue to consider when developing a management algorithm. If one of the tumors is removed while small and if the cochlear nerve is preserved, despite losing functional hearing, cochlear implantation is appropriate if a several-year interval has been observed indicating that a recidivistic tumor will not compromise the cochlear nerve. Otherwise, auditory brainstem implantation is an appropriate alternative.

The previous four syndromic disorders are not readily diagnosed at birth by history and physical examination. The most common dominant syndromes resulting in deafness are Stickler syndrome, branchio-oto-renal syndrome, and Waardenburg syndrome. When physical examination or history suggests a syndromic hearing loss, online resources have been developed to help the physician during the evaluation process.[8]

AUDITORY NEUROPATHY/AUDITORY DYS-SYNCHRONY. Over several years evidence has emerged regarding the existence of a hearing disorder that does not fit into the standard conductive, mixed, or sensorineural hearing loss categories. Relatively recently, the diagnosis of auditory neuropathy/auditory dys-synchrony (AN/D) has been specified as a hearing disorder in which present cochlear outer hair cell function is found in conjunction with absent or abnormal auditory neural responses, which is indicative of poor neural synchrony.[9] Reports on the incidence of AN/D symptoms range from 0.5[10] to 1.3%[11] of the population suspect for hearing loss, and 15% of those with absent auditory brainstem response,[11] which is otherwise consistent with severe to profound sensorineural hearing loss. Behavioral audiometric thresholds may or may not be within normal limits and can fluctuate over time, and speech perception in AN/D patients is often much poorer than the behavioral thresholds would predict. There are many possible reasons for poor auditory neural synchrony including, but not limited to, dysfunction of cochlear inner hair cells, of the inner hair cell/spiral ganglion nerve synapse, or of the auditory nerve itself.

The variety of etiologies in AN/D results in a heterogeneous population. Starr[12] reported the diagnoses from 70 patients with AN/D as fitting into the following categories: 40% hereditary, often associated with Charcot-Marie-Tooth disease; 20% with a mix of etiologies including toxic-metabolic (i.e., anoxia, hyperbilirubinemia), immunologic, and infectious; and 40% idiopathic. Transient AN/D has also been documented with temperature fluctuation in cases of severe illness.[13,14] In addition, AN/D may coexist with peripheral neuropathy, which has been observed as a loss of myelin and neural fibers in the cross section of sural nerves from some AN/D patients.[12]

Fitting AN/D patients with hearing aids may not provide sufficient benefit for communication because amplification provides increased sound intensity but does not have the capability to contribute to improved neural synchrony. After careful evaluation and when recommended, electrical stimulation with cochlear implants holds promise as a treatment option for individuals who are severely hearing impaired from AN/D,[15,16] and has been successful in our clinical experience. However, cochlear implantation may be contraindicated in cases in which neural function is significantly compromised or the auditory nerve is deficient or absent.[17]

ACQUIRED DEAFNESS. In young children, many acquired forms of deafness cannot be easily differentiated from genetic deafness. Prenatal infection with TORCH microorganisms (toxoplasmosis, syphilis,

rubella, cytomegalovirus [CMV], and herpes) is commonly associated with deafness. This spectrum of infections can result in reduced ganglion cell counts, cognitive dysfunction, and abnormal position of the facial nerve, all issues limiting the effectiveness of cochlear implants or increasing the risk of cochlear implant surgery. Prematurity and low birth weight, low Apgar scores, and hyperbilirubinemia can all be associated with deafness and, because of the central auditory processing abnormalities associated with these conditions, expectations for performance outcome following cochlear implantation should be tempered. Similarly, there can be rehabilitation needs and problems with these multiply disabled children.

Autoimmune inner ear disease (see Chapter 153) is typically rapidly progressive and often associated with highly favorable outcomes in postlingual patients receiving cochlear implants, likely due to the well-preserved primary afferent neuron population and the short duration of deafness. Although it is unusual for patients with bilateral Meniere disease to lose enough hearing to require cochlear implantation, such patients typically perform at excellent levels with an implant, likely due to significant residual hearing and auditory memory.

Many inherited or acquired diseases affect the temporal bone, which can produce severe to profound hearing loss requiring cochlear implantation. Otosclerosis, Paget disease, Camurati-Engelmann disease,[18] and meningitis with secondary labyrinthitis ossificans are a few examples of diseases that can present management challenges with cochlear implantation. Aside from the potential difficulty in electrode insertion, the reduction in bone density often leads to unwanted sequelae such as facial nerve stimulation due to current spread outside of the cochlea, affecting the postoperative programming of the device.

Although rare, bilateral temporal bone fractures resulting in deafness can be rehabilitated with cochlear implants. Early implantation should be performed to avoid cochlear fibrosis. If imaging studies suggest trauma to the auditory nerve, it is important to determine if the auditory nerve is functional using promontory electrical stimulation while recording electrically evoked auditory brainstem potentials (ABR). The use of auditory brainstem implantation in this clinical setting has been reported in Europe[19]; however, the first such application of this technology in the United States occurred only recently.

PHYSICAL EXAMINATION. All adults or children with profound hearing loss should have a complete physical examination. Clinical correlates of specific etiologies of sensorineural hearing loss are addressed in Chapters 147, 148, and 149 of this text.

CHRONIC SUPPURATIVE OTITIS MEDIA. Cochlear implantation was initially viewed as contraindicated in young children with chronic suppurative otitis media (CSOM) because of the potential risk of infection.[20] However, selective retrospective studies have shown that the prevalence and severity of OM does not increase following implantation,[21,22] leading surgeons to advocate cochlear implantation if the ear is dry at the time of implantation.

Some surgeons advocate a two-stage operative approach; the first operation involves a radical mastoidectomy (if not already performed), eustachian tube obliteration, and mastoid cavity obliteration with oversewing of the ear canal. Cochlear implantation is performed at a later time, usually 2 to 6 months postobliteration.[23] The major risk of mastoid obliteration is the formation of cholesteatoma, which must be carefully monitored on a long-term basis. Other authors advocate an individualized management strategy: (1) patients with a dry tympanic membrane perforation receive a first-stage myringoplasty followed by implantation in 3 months; (2) patients with cholesteatoma or an unstable mastoid cavity receive a radical mastoidectomy and obliteration followed months later by a second stage cochlear implantation; (3) patients with a stable cavity receive one-stage cavity obliteration and electrode implantation.[24] Finally, some practitioners advocate treating radical mastoid cavities with a one-stage operative approach that includes oversewing the external auditory canal and cochlear implantation without obliteration or reduction of the cavity.[25,26] Luntz and colleagues[27] have described a treatment algorithm with multiple steps aimed at resolving the draining ear. Using this strategy, cochlear implantation is performed at the completion of any step if the ear is dry. The existence of multiple protocols for managing cochlear implant candidates with CSOM reflects the problematic nature of this disease process. Regardless of the management protocol, all patients currently receive selected antimicrobial prophylaxis immediately before implantation.

Microbial biofilms are a common if not normal phenomena in nature; however, in the clinical arena biofilm formation is associated with increased morbidity and mortality.[28,29] Biofilms are characterized by a complex three-dimensional architecture with a network of adherent cells connected by water channels and encapsulated within an extracellular matrix.[30] Biofilms are recalcitrant to antibiotics, antiseptics, and industrial biocides. Possible mechanisms include (1) restricted penetration of drugs through the matrix; (2) phenotypic changes resulting from a decreased growth rate or nutrient limitation; and (3) surface-induced expression of resistance genes. Although there is an extensive literature on bacterial biofilms, little attention has been paid to medically relevant fungal biofilms, despite the fact that yeasts are the third leading cause of catheter-related infections, with the second highest colonization to infection rate and the highest crude mortality. Transplantation procedures, immunosuppression, use of chronic indwelling catheters, and prolonged intensive care unit stays are salient risk factors for fungal disease.[31] Biomedical devices including stents, shunts, and prostheses (voice, heart valve, knee, etc.); implants (breast, lens, dentures, etc.); endotracheal tubes; pacemakers; and various types of catheters have been shown to support colonization and biofilm formation by *Candida*.[32] Antifungal therapy alone has been shown to be insufficient for cure, requiring removal of the biomedical device.[33]

Since the advent of antibiotics in the 1940s, many authors have reported fungal overgrowth following antibacterial therapy.[34] Although bacteria usually cause CSOM, fungal infection or overgrowth is surprisingly common. One prospective study in CSOM patients reported growth of *Candida* species in 10% of ears with purulent otorrhea and in 35% of ears treated for purulence with topical ciprofloxacin for 3 weeks.[35] Furthermore, another study in which cultures were obtained from ears with ventilation tubes and otorrhea before and after a 10-day course of topical ofloxacin ear drops (Floxin) or oral amoxicillin/clavulanate demonstrated a 5% incidence of *Candida* superinfections in the amoxicillin/clavulanate group but negligible incidence in the ofloxacin group.[36] These results confirm the findings of an earlier study in which the incidence of *Candida* was significantly greater for patients treated with amoxicillin/clavulanate compared with a group treated with topical ofloxacin. We have had one case of fungal colonization of a cochlear implant with *Candida albicans*.[37] No guidelines have been proposed for dealing with episodes of otitis media in the early postoperative period. During this time interval, the physical barrier created by the fibrous sealing of the cochleostomy is in the process of being laid down, and thus the electrode array provides direct access to the inner ear. An infection of the middle ear during this period may easily extend along the electrode array, induce damage to the auditory nerve, and possibly lead to biofilm formation, requiring immediate removal of the implant. In addition, this puts the patient at higher risk for further spread of infection into the intracranial space and subsequent meningitis.[38] The high prevalence of bacterial biofilms in chronic otitis media have been recently demonstrated,[39] and bacterial biofilms have also been demonstrated in cases of infected cochlear implants that required explantation.[40]

IMAGING. Preoperative high-resolution temporal bone computed tomography (CT) scans, without contrast, should be performed on all cochlear implant candidates. Determination of intact internal auditory canals, normalcy of the cochlea, primary or secondary bone diseases affecting the cochlea, and presence of a wide vestibular aqueduct represent an important data set to complete. Many children with congenital deafness will be found to have an associated cochlear malformation, typically dilated vestibule, wide vestibular aqueduct, cochlear hypoplasia, or a common cavity.[41] When congenital or acquired narrow internal auditory canals are identified on preoperative CT scanning, primary afferent innervation may be lacking and cochlear implantation is therefore contraindicated.[18,42] Another important finding to identify is a wide vestibular aqueduct, which, when present, is an indication to perform preoperative magnetic resonance imaging

(MRI). This is an important preoperative consideration because this abnormality is associated with an abnormal communication between the cerebrospinal fluid (CSF) space and the cochlea. Clinically, this is often associated with a "perilymph gusher," and sealing of the cochleostomy with pericranium or fascia is particularly important to avoid meningitis following acute suppurative otitis media. Hypoplastic cochleas are associated with shorter length and range in character from a common cavity to an incomplete partition at the apical region of the cochlea. In children with auditory neuropathy/auditory dys-synchrony, MRI should be performed because up to 18% of these children can have small or absent cochlear nerves despite normal internal auditory canal size as demonstrated with CT.[17] Other anomalies such as the abnormal course or position of the facial nerve and round window niche occur. With the exception of an absent auditory nerve or internal auditory canal, most malformed cochleas can be implanted with a sufficient number of electrodes to provide open-set (unlimited word or sentence possibilities) speech perception.

Labyrinthitis ossificans can occur after meningitis, particularly when *Streptococcus pneumoniae* is the infecting mocroorganism.[38] Whereas temporal bone CT can show complete ossification well, MRI can provide complementary information when partial ossification has occurred. T2-weighted MRI sequences are particularly useful in determining whether a scala tympani with partial ossification or fibrosis contains perilymph.

High-resolution temporal bone CT scanning can also be helpful in sorting out issues related to device dysfunction or when unexpectedly poor outcome occurs. Figure 158-1 shows the temporal bone containing a Med-El C40+ device in a patient who has otosclerosis and the new onset of facial nerve stimulation. The reduced bone density and lucency seen around the otic capsule resulting from her advanced cochlear otosclerosis allowed current to spread from the cochlea to the facial nerve. Figure 158-2 shows the temporal bone of a young child whose performance was unexpectedly low and who was also noted to have facial nerve stimulation with cochlear implant use. After his referral to our center for evaluation, a high-resolution temporal bone CT was obtained. The CT scan showed a malformed cochlea with an incomplete partition at the apex and the electrode tip leaving the cochlea and extending into the internal auditory canal. This type of cochlear malformation is typically associated with a thin partition between the modiolus and the internal auditory canal.

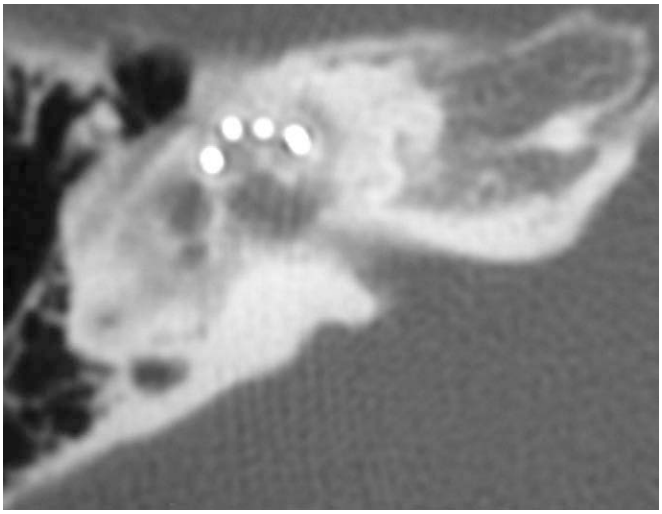

Figure 158-1. High-resolution temporal bone axial computed tomography scan using a bone window algorithm shows a right ear with a well-positioned electrode array (Med-El C40+) within a cochlea affected by otosclerosis. Note the reduced density of the otic capsule bone and the lucency surrounding the otic capsule *(center, top right).* This patient was experiencing facial nerve stimulation with cochlear implant use due to current spread through the otic capsule to the facial nerve *(Published with permission, copyright © 2009 P.A. Wackym, MD.)*

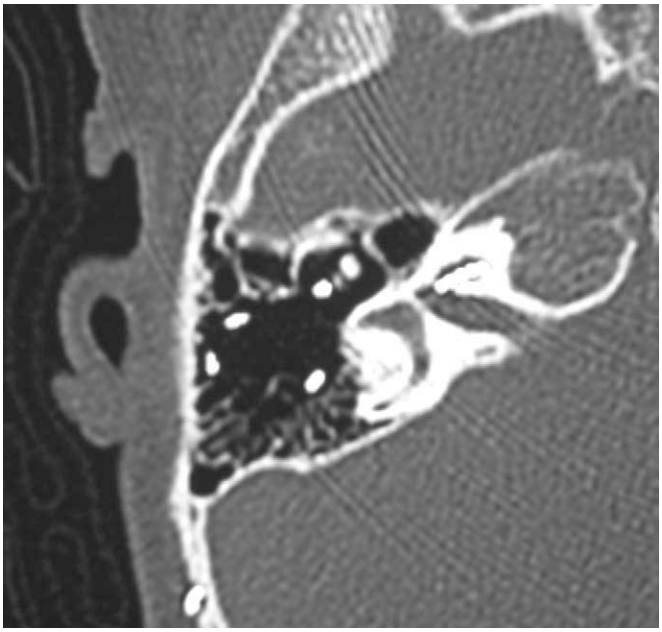

Figure 158-2. High-resolution temporal bone axial computed tomography (CT) using a bone window algorithm shows a right ear with a cochlear implant electrode array that has broken through the cochlea/modiolar wall to enter the internal auditory canal (CII Bionic Ear with HiFocus 1j electrode). The implanting surgeon, at another institution, did not recognize that the child had an incomplete partition at the apex of the cochlea. This malformation can be associated with a thin bony wall between the cochlea and the modiolus. This child was performing at a level lower than expected with his cochlear implant and had facial nerve activation with implant use, which led to the CT scan to evaluate the electrode position. The child's second side was implanted with a HiRes 90K device, and the initial device was removed and replaced with a HiRes 90K device, resolving his facial nerve stimulation problem. *(Published with permission, copyright © 2009 P.A. Wackym, MD.)*

Evaluation of Adult Cochlear Implant Candidates

The benefits of cochlear implantation have increased substantially over the past quarter century due to changes in technology and expanded candidate criteria. Consideration for cochlear implantation in adults still requires careful assessment to (1) determine preimplant hearing aid fitting and performance, (2) compare a candidate's preimplant performance with that of current implant recipients, (3) provide a recommendation for or against cochlear implantation, (4) select an ear for implantation, and (5) determine appropriate expectations that will guide the counseling of prospective patients, which is critical for user satisfaction.

Current Adult Selection Criteria

Food and Drug Administration (FDA) approved guidelines for cochlear implantation vary slightly with different clinical trials depending on the manufacturer's submission and labeling aims. Guidelines also change over time, in part, because cochlear implant recipients' average scores have been found to be higher than individuals with better hearing or word recognition. Current adult selection criteria in the most recent clinical trials include (1) severe or profound hearing loss with a pure-tone average (PTA) of 70 dB HL, (2) use of appropriately fit hearing aids or a trial with amplification, (3) aided scores on open-set sentence tests of less than 50%, (4) no evidence of central auditory lesions or lack of an auditory nerve, and (5) no evidence of contraindications for surgery in general or cochlear implant surgery in particular. Additionally, cochlear implant centers generally recommend at least 1 to 3 months of hearing aid use, realistic expectations by the patient and

family members, and willingness to comply with follow-up procedures as defined by the center.

The goal of the evaluation process is to determine whether an individual would perform as well with appropriately fit hearing aids as with a cochlear implant. In addition to comparing the candidate's performance with average cochlear implant users, it is important to compare the candidate with cochlear implant users who are matched for such factors as length of profound hearing loss or useable residual hearing, which are known factors that contribute to the variance in patient performance. In other words, if a candidate has had recent onset of profound hearing loss, it is more appropriate to compare him or her to the top 25% of cochlear implant users. Likewise, if a candidate has had no hearing aid use for 20 years and long-term deafness, it is more appropriate to compare that individual with the lower 25% of implant recipients' performance. However, even with the most educated guess of cochlear implant outcome for a given individual and the knowledge that detection levels can be improved, specific postimplant results cannot be guaranteed, and this principle must be effectively communicated to candidates.

ADULT AUDIOLOGIC PROTOCOL. For adults, sound detection and speech perception abilities are assessed to determine candidacy. Preoperatively, patients are evaluated with a battery of measures while using hearing aids, and the results are compared with the most recent average and range of cochlear implant performance. Preoperative measures are also repeated postimplant for longitudinal monitoring of patient performance. Single-subject research designs are often implemented in clinical trials in which each patient serves as his or her control, primarily due to the large variability within the population of cochlear implant candidates and users. The selection of preoperative test measures, therefore, should also take into consideration comparative postimplant measures.

Preimplant audiologic tests include unaided and aided detection thresholds for pure-tone and warble-tone stimuli, respectively. Unaided thresholds are obtained in each ear individually, and aided detection thresholds may be obtained monaurally and binaurally. Although there are no aided detection level criteria, it is helpful to determine aided levels as one aspect of appropriate hearing aid fitting and for comparison with expected postimplant sound field detection thresholds. For some patients, aided testing can also reveal recruitment (i.e., unusual sensitivity to loud sounds), which may limit benefit from amplification due to the inability to incorporate needed hearing aid gain.

Aided speech perception abilities are often assessed in both monaural and binaural conditions, depending on the use of amplification in each ear. Speech perception measures are conducted in the sound field, typically at a presentation level of 60 dB SPL and include open-set recorded presentations of words and sentences in quiet, and if appropriate, in noise. In the best-aided condition, the assessment of individual ears provides critical information for determining which ear to implant for unilateral implantation. In addition, the best-aided condition, whether it be either ear alone or both ears together, provides information about the candidate's maximum performance for comparison with cochlear implant performance.

Word and sentence recognition tests included in the Minimum Speech Test Battery for Adult Cochlear Implant Users (MSTB) are used at many cochlear implant centers to assess performance. The MSTB is a set of compact disc recordings designed to provide word and sentence tests for the preimplant and postimplant evaluation of speech recognition, regardless of implant device. The Consonant-Nucleus-Consonant (CNC) Monosyllable Word Test[43] assesses single-syllable word recognition. One CNC list contains 50 monosyllabic words presented in an open-set format. The CNC Words were among the original set of words from which the Northwestern University Auditory Test 6 (NU6) Monosyllabic Word Test[44] were taken.

The presentation of auditory-only sentence lists from the Hearing in Noise Test (HINT)[45] evaluates each patient's ability to understand sentence material in quiet or in the presence of background noise. Each HINT list is phonemically balanced and contains 10 sentences recorded by a male speaker that are equivalent in the features of length, intelligibility, and naturalness. When the sentences are presented in noise, the signal-to-noise ratio typically used is +10 dB, although this ratio can be adjusted to make the test condition more or less difficult. For patients with some open-set speech recognition for words and/or sentences preoperatively, the BKB (Bamford-Koval-Bench) Sentences[46] may be administered in an adaptive procedure (i.e., BKB SIN; sentences-in-noise). In this condition the sentences are presented at a fixed presentation level (e.g., 65 dB SPL), and the noise is varied for signal-to-noise (S/N) ratios between +20 and −5. Clinical observations suggest that, when testing adults, scores on open-set word and sentence measures, particularly in the presence of noise, are more reflective of patient satisfaction with hearing aids and more useful for determining cochlear implant candidacy than unaided and/or aided detection thresholds.

As performance with cochlear implants continues to improve because of advances in technology and broadening candidacy criteria, it is recommended that speech perception performance be assessed with measures that approximate everyday listening. Study findings by Skinner and colleagues[47] and our cochlear implant team[48] suggest that speech recognition tests be presented at 60 rather than 70 dB SPL to determine implant candidacy. These findings have resulted in the use of 60 dB SPL in U.S. clinical trials and general clinical practice across centers. Additional steps toward the use of measures that approximate everyday listening include the presence of background noise, variation in speaker gender and rate, and variation in the location of the speaker.

Following the evaluation of sound detection and speech perception, other areas of assessment may include vestibular testing, tinnitus assessment, and patient satisfaction or quality-of-life questionnaires.

OUTCOME EXPECTATIONS FOR ADULTS. Almost all patients demonstrate improved sound detection with their cochlear implants compared with their preoperative performance with hearing aids, and this is especially evident in the high-frequency range. Average postoperative sound-field detection thresholds for warble-tone stimuli are approximately 25 to 30 dB HL for frequencies 250 through 4000 Hz.[48]

When determining patient's expectations for cochlear implant performance and when counseling patients preimplant, it is important to stay abreast of both the average speech perception performance of cochlear implant recipients and the range of performance. In a recent study of 78 of adult cochlear implant users, 26 each with the Clarion, Nucleus, and Med-El device, the average CNC word scores at 70, 60, and 50 dB SPL were 42%, 39%, and 24%, respectively.[48] In this same group of subjects the mean HINT scores at 70, 60, and 50 dB SPL were 72%, 73%, and 57%, respectively. When the HINT was presented at 60 dB SPL in the presence of speech spectrum noise at an S/N ratio of +10, the average score for this subject sample was 48%. These results represent average performance; however, there was a great deal of variation in scores for individuals, ranging from 0% to 100% for most measures. In general, patients perform less well on single syllable word tests compared with sentence tests, and less well in the presence of noise than in quiet. Many cochlear implant users can understand sentences without lipreading cues and can therefore converse on the telephone. Although the primary objective of speech coding strategies is the perception of speech, some patients also enjoy music.

The majority of postlingually deafened adults demonstrate significant preoperative to postoperative improvements on open-set speech perception measures, often as early as 1 month postimplant. Compared with postlingual affected adults, some prelingually affected adults, defined as having onset of profound or severe-to-profound hearing loss at younger than 3 to 6 years of age (depending on the respective study), demonstrate open-set speech recognition, although the percentage is smaller and often the length of device use needed to achieve this is longer. Although the average postoperative scores for individuals with prelingual hearing loss are generally lower compared with those with postlingual hearing loss, there have been significant preoperative to postoperative improvements in speech perception reported for this group.[49] Therefore adults with prelingual onset of severe-to-profound hearing loss may be appropriate candidates for cochlear implantation.

Providing that older patients are enjoying relatively good health, there is presently no upper age limit for cochlear implantation. Audiologic results for cochlear implant users ages 65 to 80 years indicate significant improvements for both preoperative to postoperative comparisons[50,51] and for varied speech stimulus presentation levels.[48]

Note the receiver/stimulator, removable magnet, loop antenna, separate ground electrode, and 10-mm electrode array. Inset shows the side and top view of the array that is designed to minimize electrode insertion trauma and preserve residual hearing. *(Published with permission, copyright © 2007 Cochlear Americas.)*

Current Trends That Affect Adult Cochlear Implant Candidacy

COMBINED ELECTRIC AND ACOUSTIC STIMULATION. For patients with more residual hearing preimplant than the average cochlear implant candidate, performance is expected to be better. In addition, some patients have considerable residual hearing in the lower frequencies (i.e., 250 and 500 Hz) but little measurable hearing for frequencies at 1000 Hz and above. In these patients it is difficult to obtain good aided benefit in the high frequencies with a hearing aid while maintaining appropriate gain in the lower frequencies where little, if any, amplification is necessary. The ability to understand speech is consequently compromised by the inability to detect and/or discriminate important high frequency sounds. Also, low-frequency sounds may be masked or distorted by the power needed in the high frequencies. These findings have led to the investigation of combined electrical and acoustic stimulation (EAS), such that the basal end of the cochlea receives electrical signals that are complemented by acoustic signals received at the apical portion of the cochlea. To use EAS, the low-frequency residual hearing must be preserved when the electrode array is inserted in the cochlea (Fig. 158-3). This is obtained by using shortened electrode arrays (20 mm for the Med-El device, and 10 mm for the Nucleus Hybrid device) inserted into the scala tympani and specific surgical techniques designed to make the electrode insertion as atraumatic as possible. These modifications include controlled opening and no direct suctioning of perilymph from the scala tympani; avoidance of perilymph contamination by blood and debris; use of nonototoxic topical antibiotics, corticosteroids, and lubricant (hyaluronic acid) during insertion; and immediate sealing of the cochleostomy after insertion using fascia. Speech perception findings reported thus far suggest improved performance in the combined EAS condition compared with either stimulation condition alone and compared with preimplant performance.[52] Additionally, recent data suggest that speech perception performance while listening in the presence of noise including multitalker babble is superior in the combined EAS condition compared with that of traditional cochlear implant users under the same adverse listening conditions.[53] It is likely that future candidacy may include patients with more low-frequency hearing, which is therefore a consideration during patient evaluation.

REHABILITATION OF ASYMMETRIC HEARING LOSS. A large number of patients who have lost hearing in one ear are not traditional cochlear implant candidates. These patients vary in the amount of hearing in their functional ear, ranging from normal hearing to severe hearing loss associated with marginal hearing aid benefit. As more experience has been gained with implantation of patients with more residual hearing and patients who benefit from hearing aid use in the nonimplanted ear,[52] the concept of cochlear implantation to rehabilitate asymmetric hearing loss is being considered.

BINAURAL COCHLEAR IMPLANTS. Historically, individuals received cochlear implants in one ear only. With the completion of clinical trials with bilateral implantation and the benefits of binaural implantation being realized, current candidacy decisions now include whether to receive two implants rather than one. Outcomes data regarding the benefits of binaural implantation continue to be published, and clear benefits in sound localization and listening in noise have been demonstrated.[54] Specifically, studies have shown that binaural implants provide a "head shadow" effect for listening to speech in the presence of other noise or competing speakers. This occurs because one ear is "shadowed" from the noise source when speech and noise come from different directions, allowing the ear with the better signal-to-noise ratio to do the listening. Other binaural advantages occur when information from both ears is combined to improve listening. Binaural summation effects have been reported whereby performance is improved in the binaural condition compared with monaural condition when speech and noise are in the front.[55] Binaural squelch effects have been reported less frequently to date, but in some cases, improvement in performance has been shown by adding the ear nearer the noise source.[56] Both binaural summation and binaural squelch effects rely on successful bilateral interaction of the brainstem and central auditory system nuclei, whereas the head shadow effect is simply a physical phenomenon created by the listener's head. We have found that presentation of more difficult auditory stimuli helps to demonstrate the improved benefit obtained by patients tested in the binaural condition compared with the benefit from their better-performing cochlear implant.[57]

Binaural implantation in adults recently completed clinical trials at a number of centers and with each of the cochlear implant manufacturers in the United States. Because results have been generally positive and the majority of bilateral recipients indicate a strong preference for bilateral over unilateral implant use, it is now the case that binaural implantation has become a part of the candidacy decision.

Recommendations for Referral for Adult Cochlear Implant Evaluation

At our center, we suggest the following referral criteria for cochlear implant evaluation for adults. Referral to a cochlear implant center does not mean that the individual is necessarily going to receive a cochlear implant, but that an evaluation is recommended to determine whether a cochlear implant would be beneficial. If the individual meets the following criteria, an evaluation is suggested. The criteria are (1) unaided thresholds of 70 dB HL or poorer at 1000 Hz and above in the better ear, even if hearing levels at 250 and 500 Hz are better; (2) unaided word discrimination less than 70%; and (3) frustration on the part of the patient due to communication difficulties, even with appropriate hearing aid use.

Evaluation of Pediatric Cochlear Implant Candidates

Cochlear implants have been available for children ages 2 to 17 years since 1990. Originally, children who were candidates for cochlear implantation typically had profound bilateral sensorineural hearing loss with pure-tone average thresholds of 100 dB HL or greater, often with corner audiograms. These children also displayed aided sound-field thresholds well below the range of average conversational speech and typical speech detection thresholds at and above 60 dB HL. During early clinical trials, pediatric candidates were not able to understand words when using their hearing alone, even with high-gain hearing aids and well-fitted earmolds. Since then, candidacy criteria have changed and technology has improved, both of which have influenced benefit. As with adults, consideration for cochlear implantation still requires careful assessment to (1) determine preimplant fitting of hearing aids and baseline performance, (2) compare a candidate's preimplant performance with that of current implant users, (3) provide a recommen-

dation for or against cochlear implantation, (4) select an ear for implantation, and (5) determine appropriate expectations that will guide the counseling of prospective families.

Current Pediatric Selection Criteria

The selection criteria for children vary slightly depending on the respective FDA-approved clinical trial and/or criteria recommended by the cochlear implant center. Generally speaking, the subject selection criteria include the following: (1) 12 months through 17 years of age; (2) profound sensorineural hearing loss (unaided PTA thresholds of ≥ 90 dB HL); (3) minimal benefit from hearing aids, defined as less than 20% to 30% on single-syllable word tests, or for younger children, lack of developmentally appropriate auditory milestones measured using parent report scales; (4) no evidence of central auditory lesions or lack of an auditory nerve; and (5) no evidence of contraindications for surgery in general or cochlear implant surgery in particular. Additionally, cochlear implant centers generally recommend at least 3 to 6 months of hearing aid use, unless cochlear ossification is noted or anticipated; realistic expectations by family members; enrollment in a postoperative rehabilitation program that supports the use of cochlear implants and the development of auditory skills; and willingness on the part of the family to comply with follow-up procedures as defined by the center.

PEDIATRIC AUDIOLOGIC PROTOCOL. As with adults, children are assessed preoperatively with a battery of sound detection and speech perception measures while using hearing aids, and this baseline is compared with the most recent average and range of cochlear implant performance. For children, speech perception measures assess a wide range of auditory skills from sound detection to recognition of words and sentences. Measures are selected that are developmentally appropriate for the child's age, language level, and auditory ability. Although the audiologic assessment will play a key role in candidacy, with children other factors may influence the candidacy decision and/or postimplant outcome, and therefore a multidisciplinary team approach is advised.

Before cochlear implant evaluation, most children will have an ABR test as an objective measure of the status of the peripheral and brainstem auditory system. With an ABR, acoustic click stimuli are presented to assess auditory sensitivity to each ear. Children who are implant candidates typically have no response to acoustic stimuli at the limits of the testing equipment, suggesting with reasonable accuracy hearing loss in the profound range. Another group of children that can display absent or abnormal ABR findings are those with auditory neuropathy.[9] In these cases of absent or abnormal ABR, comparison of positive (condensation) and negative (rarefaction) polarity stimuli will show an inversion of the peaks of the cochlear microphonic. The cochlear microphonic appears as an early latency response on the ABR waveform and is indicative of outer hair cell function. Otoacoustic emission testing can also be used as a measure of outer hair cell function. Due to the prevalence of children diagnosed with AN/AD[15] and the number of these children who have received cochlear implants,[58] our current protocols for electrophysiologic assessment include otoacoustic emission and ABR testing because these measures are sensitive to cochlear and auditory nerve function, respectively. The diagnosis of auditory neuropathy does not necessarily preclude a child from cochlear implant candidacy.

Unaided detection thresholds for pure-tone stimuli are obtained in individual ears using standard clinical procedures. Aided thresholds are obtained in the binaural condition, and if possible, the monaural conditions. For young children who are unable to participate in speech perception tasks, both unaided threshold testing and electrophysiologic measures become important criteria for cochlear implantation. Because we know the limitations of hearing aids, if we are confident in the reliability of the unaided threshold levels, we can predict with some certainty the eventual aided benefit. Using hearing aids, the measurement of sound detection levels, and when possible, speech perception abilities, can provide confirmation of the unaided thresholds. Although one criterion for pediatric candidacy is profound hearing loss, published reports and clinical experience both indicate that adults with severe hearing losses perform well with cochlear implants. Therefore we might expect the same outcome for children with similar severe hearing losses. With respect to children with AN/AD, unaided detection levels vary considerably and may not be predictive of aided levels or speech perception abilities.

Tests of speech perception assess a range of skills depending on the child's auditory abilities and language level. Closed-set measures include a small number of choices that are provided to the child either as objects or pictures (e.g., Early Speech Perception Test or ESP).[59] Monosyllable, spondee, and/or trochee words are spoken with audition alone (no visual cues), and the child is asked to select the object or picture that represents the stimulus. With open-set measures of word and sentence recognition, no choices are provided. The child repeats the words or sentences presented in quiet or in the presence of background noise. For example, using the Lexical Neighborhood Test (LNT),[60] 50 monosyllabic words are presented that are either "easy," occurring with high frequency in the English language and having few lexical neighbors, or "hard," occurring less frequently and with many lexical neighbors. For children with vocabulary levels that approximate those of a 5-year old, the Phonetically Balanced Kindergarten (PBK) Test[61] can be administered. It includes 50 words and has been in clinical use for many years. Recordings of the BKB Sentences[46] and the HINT-C Sentences[45] are typically used in the evaluation process for children who have some language and auditory experience. For children who are too young to participate in speech perception measures, parent interview scales are administered. The Meaningful Auditory Integration Scale (MAIS)[62] asks questions of parents or family members related to the child's spontaneous awareness of sound and use of audition in a meaningful way at home, school, or other natural environments.

OTHER EVALUATIONS FOR PEDIATRIC COCHLEAR IMPLANT CANDIDATES. For children, the results of speech production assessments are good indicators of hearing history and whether the child has learned to use his or her residual hearing. Language evaluations are also important because the ultimate goal of cochlear implantation is effective communication. Neither of these areas of assessment dictates candidacy, but they contribute to the confirmation of hearing levels and expected preimplant communication coincident with auditory experience. Results are also used to monitor either preimplant or postimplant performance over time and to develop rehabilitation goals for educators, clinicians, and parents.

A psychologic evaluation is obtained to assess the child's verbal and nonverbal intelligence, attention and memory skills, and visual-motor integration. When considering a child for a cochlear implant, counseling the family preimplant, and planning for possible rehabilitative needs postimplant, it is important to know the cognitive abilities of the child. If the child is gifted, for example, then expecting average cochlear implant performance may be an underestimation. Likewise, if the child has a developmental delay, this will affect rate and eventual level of performance with the implant and counseling may be directed toward more conservative expectations. Differentiating the influence of deafness and cochlear implantation from other disabilities or diagnoses such as developmental delay, autism, attention deficit disorder, or learning disabilities can be difficult. These issues are addressed in the psychologic evaluation preimplant and influence the recommendation for or against cochlear implantation, provide guidance for counseling families, and assist in rehabilitative planning.

Success with a cochlear implant can be influenced by the collaboration of individuals working with the child (parents, educators, and therapists). A team effort is best initiated during the preimplant process and sets the stage for later communication between the individuals on the implant team and the child's educators and family. Early cultivation of communication is important for a variety of reasons including confirmation of the child's test results and use of residual hearing, discussion of areas of concern, sharing effective test-taking and rehabilitative strategies, setting expectations, and identification of postimplant rehabilitation resources and goals.

OUTCOME EXPECTATIONS FOR CHILDREN. Auditory detection levels with a cochlear implant are expected to be similar to those for adults, which are approximately 25 dB HL for frequencies 250 through 4000 Hz. These detection levels allow access to information that is important for the development of auditory skills and communication.

As with adults, when determining expectations, it is important to stay informed of the average and range of pediatric cochlear implant performance.

In a publication by Geers and colleagues,[63] the results of 181 prelingual deaf children, implanted before 5 years of age who had used their cochlear implants for an average of 5 years, were reported for the outcome areas of speech perception, speech production, spoken language, total language, and reading. The average scores reported for several measures are as follows: ESP-spondee 85%, ESP-monosyllable 79%, LNT-easy 48%, LNT-hard 44%, and BKB sentences 57%. Children who were good speech perceivers were also the children who exhibited superior performance for measures of speech intelligibility, language, and reading. Half of the children were enrolled in oral communication programs, and the other half were enrolled in programs using total communication. Those children enrolled in educational environments that emphasized auditory and spoken language development had the highest scores on speech perception, speech production, and language measures. In this study, subjects were implanted between 1992 and 1994, mostly using the Nucleus 22 and SPEAK coding strategy; therefore the most recent cochlear implant technology and candidacy criteria were not represented.

Studies conducted with children indicate that earlier implantation is associated with higher performance for a given time period postimplant,[64] that preimplant unaided residual hearing influences performance and the development of speech perception skills postimplant,[65] and that there is a steady increase in performance over time that does not plateau during the first 3 to 5 years of implant use.[66]

On the basis of research studies and clinical experience, we describe in this section general expectations for children with onset of deafness of less than 1 year on the basis of their age at implantation. Expectations for children implanted at age 2 years and before include the potential for communication skill development at rates similar to normal-hearing peers, potential for speech to be easily understood by strangers, reduced or possible elimination of language delay, attendance at a neighborhood school with minimal support services by kindergarten or first grade, and increased likelihood of becoming an auditory/oral communicator. Expectations for children implanted before the age of 4 years include substantial improvement in speech perception, increased vocalizations/verbalizations at early stages postimplant, auditory behaviors evident before they can be formally measured, speech production skills reflective of auditory abilities, and language delays that are reduced. For children implanted between 4 and 5 years, expectations include improvement in speech perception with excellent closed-set performance and varied open-set abilities, improvements in speech production, use of hearing to support improvements in language, and reduced dependence on visual cues for communication. For children implanted at or after age 6 years, we expect improved auditory detection abilities, improvements in speech perception that entail good closed-set abilities but limited open-set skills, possible improvements in speech production, and continued dependence on visual cues for communication. Generally, children implanted at an older age require more time to reach their potential with the device than those implanted at younger ages.

In addition, for children with progressive or sudden onset of hearing loss, we expect excellent progress with cochlear implantation and achievement of these skills with a shorter duration of cochlear implant use. Likewise, for children with some residual hearing preimplant, we also expect higher levels of performance in relatively shorter periods of time. As discussed regarding adults, it is important to match expectations with reasonable appropriate outcomes for children on the basis of their hearing history, age at implantation, and nonaudiologic factors.

Current Trends That Affect Pediatric Cochlear Implant Candidacy

BINAURAL COCHLEAR IMPLANTS. Far beyond what has been experienced with adult patients, the majority of major cochlear implant centers are now performing bilateral cochlear implantation in the majority of children. Reports in children have followed similar trends as those for adults, with improvements in the ability to recognize speech in noise and to localize a sound source. The ability to follow large spatial changes in speaker location is a critical skill for academic learning in the classroom setting, as is the ability to follow rapid changes between speakers in a smaller space such as in a small group setting at school or during a conversation with multiple speakers at home. Bilateral implantation is desirable for young children during the critical period for the development of spoken communication. To study the observed clinical benefits reported by parents and teachers and observed by clinicians caring for these children, there are several multicenter investigations of bilateral cochlear implantation in children currently under way in North America and Europe. Due to the longer periods required for speech language development in young children, these trials are designed to extend a minimum of 5 years. On the basis of the findings in these trials, the circumstances for which we would recommend bilateral implants for children will be evident.

Factors That Affect Pediatric Cochlear Implant Performance

The most common preimplant factors that affect performance for children include age at implantation, hearing experience (age at onset of profound hearing loss, amount of residual hearing, progressive nature of the hearing loss, aided levels, consistency of hearing aid use), training with amplification (in the case of some residual hearing), presence of other disabilities, and parent and family support. Postimplant factors that contribute to performance levels include length of cochlear implant use, rehabilitative training, and family support. Communication mode is also a documented variable that affects postimplant outcome because children in programs and homes that focus on the development of spoken language perform higher than children in programs without this emphasis.[63] Children using total communication at school and home can achieve substantial levels of performance; however, this achievement will be less likely if an emphasis on auditory skill development and spoken communication is not included with the use of sign language.

Ear Selection in Pediatric Cochlear Implant Candidates

For children whose parents elect for their child to receive a single cochlear implant, the selection of the ear for unilateral implantation follows the same logic as discussed earlier for adults. At our center, the pediatric population differs from the adults in that fewer children have an etiology of progressive hearing loss (22%), compared with those with congenital bilateral hearing loss (65%) or sudden onset of bilateral hearing loss (13%). In general, this results in fewer children having ear asymmetries or patterns of change in hearing over time. Therefore fewer children have ear differences. Because we encourage the use of a contralateral hearing aid postimplant if at all possible, we select the ear for implantation that is least likely to benefit from amplification. All things being equal, we select the right ear to capture the possible advantage of contralateral, left hemisphere specialization for speech recognition.[67]

Recommendations for Referral for Pediatric Cochlear Implant Evaluation

At our center, we suggest the following referral criteria for cochlear implant evaluation for children. As mentioned previously with adults, referral to a cochlear implant center does not mean that a child is necessarily going to receive a cochlear implant, but that an evaluation is recommended to determine whether a cochlear implant would be beneficial. If the child meets one or more of the following criteria, an evaluation is suggested. The criteria are (1) unaided thresholds of 90 dB HL or poorer at 2000 Hz and above in the better ear, even if hearing levels at 250 and 500 Hz are better; (2) aided levels in the better ear poorer than 35 dB HL, especially at 4000 Hz; (3) no response for ABR testing in both ears or no response for one ear and responses at elevated levels in the other ear; (4) parents are frustrated with their child's development of auditory and/or communication skills; (5) progressive hearing loss with detection levels at or near the profound range at 2000 Hz and above; or (6) evidence of severely impairing auditory neuropathy/dys-synchrony. Evaluation has no lower age limit; age at implantation is a critical factor that influences postimplant performance, and children who may be too young for the operation are not too young for evaluation.

Device Selection

All cochlear implant systems include external and internal hardware. The external equipment includes a microphone, speech processor, and transmission system. The internal device includes a receiver/stimulator and an electrode array.

In general, an external microphone picks up sound and speech in the environment and sends the information to a speech processor, either the body-worn (BW) or ear-level type. The speech processor converts the sounds into electric signals, which are sent across the skin via radio frequency transmission to the internal receiver/stimulator. The transmission of the signal occurs when there is successful alignment of the external magnet housed in the transmitter with the internal magnet housed in the receiver/stimulator. The receiver/stimulator decodes the signals and delivers them to the electrodes positioned within the cochlea. The electrodes stimulate the auditory nerve, and the signal is sent along the auditory pathway to the auditory cortex. A description of the most recent available equipment for each cochlear implant manufacturer used by patients in the United States is provided as follows.

Internal Receiver Stimulators and Electrode Designs

NUCLEUS FREEDOM WITH CONTOUR ADVANCE ELECTRODE. The Nucleus Freedom device with Contour Advance electrode (CI24RE[CA]) consists of an internal receiver/stimulator that uses a flexible silicone housing surrounding a titanium case. The Nucleus Freedom device with the Contour Advance electrode is shown in Figures 158-4 and 158-5. The magnet is removable/replaceable and allows for MRI studies with magnets up to 1.5 tesla (T), after removal of the magnet. The electrode design is a perimodiolar electrode and is preformed to conform to the modiolus. A stylet is positioned within this electrode array and maintains the electrode in a straight configuration until its removal during the operation. The electrode array is curved, consisting of 22 half-banded platinum electrodes, variably spaced over 15 mm. The diameter of the intracochlear portion ranges from 0.5 mm to 0.8 mm. Overall, the length of the electrode array distal to the first of three silicon marker rings is 24 mm; however, the electrode is designed to be inserted 22 mm, and a platinum band is present at this position to use as a guide for depth of insertion. The half-banded electrodes face the modiolus with a width of 0.3 mm and a geometric area ranging from 0.28 mm^2 to 0.31 mm^2. Of all available electrodes on the market, this is the stiffest electrode and consequently is relatively easy to insert. The greatest disadvantage of this current electrode design is that once the stylet has been removed, it cannot be replaced. This is problematic should the electrode insertion be difficult because of anatomic variations, in which case the back-up device would be required. Manual positioning of the electrode tip within the opening of the cochleostomy is performed, and guiding the tip into this position is assisted by the use of a claw-shaped instrument held in the dominant hand. Once the electrode tip is retained within the opening of the cochleostomy, bimanual advancement of the electrode array using two claw-shaped instruments held opposing each other, as close to the cochleostomy as possible, assists advancement of the electrode array within the scala tympani. There is a white marker incorporated along the electrode that is used to determine when the electrode array should be advanced off of the stylet until complete insertion has been achieved. The Nucleus Contour electrode array has three Silastic bands outside of the electrode array that represent the proximal limit, and these should remain outside of the cochleostomy. Once this level is reached, the remainder of the stylet is withdrawn and discarded. The electrode is then maintained in a perimodiolar position.[68]

The Nucleus device also has a second electrode design, a double electrode array to be used for implantation of severely ossified cochleas (Fig. 158-6). The configuration for this includes two electrode arrays, each with 11 contacts within a length of 8.5 mm.

HiRes 90K. The Advanced Bionics Corporation system includes the HiRes 90K receiver/stimulator (Fig. 158-7) and a choice of two electrodes; the HiFocus 1j array or the Helix array. The HiRes 90K system has a removable magnet that has been approved by the FDA to allow for an MRI with a field strength of up to 1.5 T, providing that the magnet has been removed. The HiFocus 1j electrode system is shown in Figure 32-14. This electrode is "banana shaped" and curved toward the modiolus, consisting of 16 contacts, spaced every 1.1 mm over 17 mm. The length of the electrode array inserted into the cochlea is 23 mm. The electrodes face the modiolus with a width of 0.4 mm and length of 0.5 mm. The HiFocus 1j electrode system uses an insertion tube through which the insertion tool allows advancement of the electrode array. Both a metal (outer diameter of 1.5 mm) insertion tube and a Teflon (outer diameter of 2 mm) insertion tube are included, and selection is based on surgeon preference; however, the metal tube provides greater stability. Gentle pressure along a thumb-driven advancement mechanism is required to insert the electrode. Should errors occur during electrode insertion, the electrode is easily reloaded into the insertion tube, and additional electrode insertion attempts can be completed until the electrode insertion has been achieved.

The HiFocus Helix electrode system is shown in Figure 158-8. This electrode is designed to be perimodiolar in location after insertion. The array consists of 16 contacts, spaced every 0.85 mm over 13 mm.

Figure 158-4. General appearance of the Nucleus Freedom device with the Contour Advance electrode. Note the receiver/stimulator, removable magnet, loop antenna, separate ground electrode, and electrode array. *(Published with permission, copyright © 2008 Cochlear Americas.)*

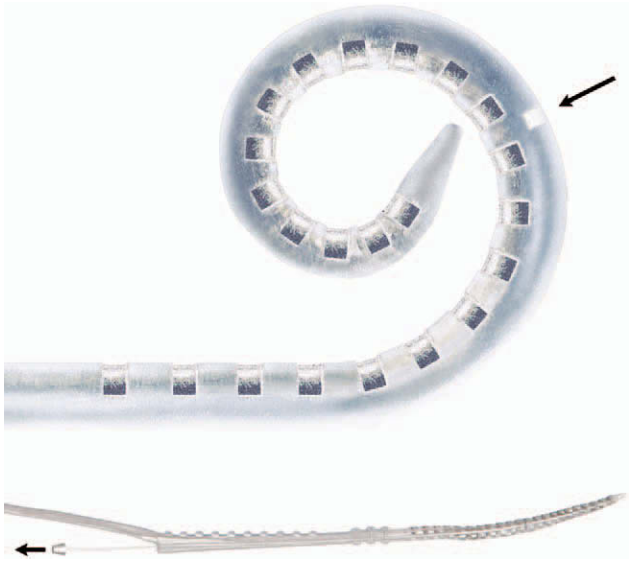

Figure 158-5. Nucleus Contour Advance electrode after *(top)* and before *(bottom)* stylet removal. The electrode array has a more linear configuration before stylet removal. The electrode is advanced until the white marker *(long arrow)* is located at the level of the cochleostomy. The electrode is then advanced off of the stylet by holding the stylet with a forceps and inserting the electrode. Removal of the stylet *(short arrow)* allows the electrode to return to the precurved configuration of the array, which places the electrode contacts in a perimodiolar position. *(Published with permission, copyright © 2008 Cochlear Americas.)*

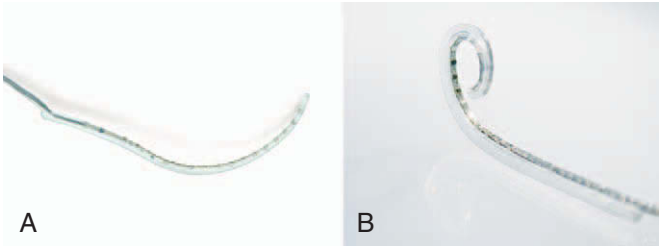

Figure 158-8. Photographs of the HiFocus 1j and Helix electrodes. **A,** The 1j electrode is banana shaped and has flat contacts oriented toward the modiolus. The raised partitions shown in the inset, between electrode contacts, are designed to reduce electrode interactions. **B,** The Helix electrode uses the same flat contact configuration with the raised partitions but is precurved to place the electrode array in a perimodiolar position after insertion. *(Published with permission, copyright © 2008 Advanced Bionics Corporation.)*

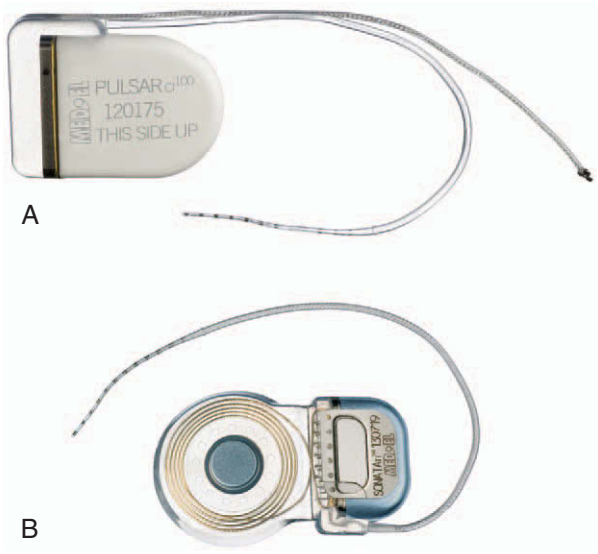

Figure 158-9. **A,** General appearance of the Med-El PulsarCI100 device. The internal device is housed in a ceramic case containing the receiver/stimulator, internal magnet, and loop antenna. **B,** General appearance of the Med-El SonataTI100 device. The internal device is housed in Silastic and has a similar configuration for the receiver/stimulator, internal magnet, and loop antenna as does the Nucleus Freedom and HiRes 90K devices. *(Published with permission, copyright © 2008 Med-El Corporation.)*

The diameter of the intracochlear portion ranges from 0.6 mm to 1.1 mm. The length of the electrode array inserted into the cochlea is 24.5 mm. The electrodes face the modiolus with a width of 0.4 mm and length of 0.5 mm. The HiFocus Helix electrode system uses a preloaded stylet assembly by which the electrode array is advanced. Should errors occur during electrode insertion, the electrode is easily reloaded into the insertion stylet assembly, and additional electrode insertion attempts can be completed until the electrode insertion has been achieved. This is in contrast to the Nucleus Contour Advance perimodiolar electrode, which cannot be reloaded after removal of the stylet.

MED-EL PULSARCI100 AND SONATATI100. The Med-El PulsarCI100 system uses a receiver/stimulator that is housed in a ceramic case (Fig. 158-9). The PulsarCI100 system has FDA approval for use with MRI at 0.2 T causing no additional risk to the patient or significant impact on the device or image quality, except for the magnet-induced artifact surrounding the internal magnet. In Europe many patients with Med-El implants have safely undergone MRI studies with 1.0 and 1.5 T scanners.[69] The Med-El system has six separate electrode designs (see Figs. 158-12 and 158-13). The standard electrode is the longest electrode available in the marketplace and is tapered in design. Twelve pairs of electrode bands are distributed over the 31.5 mm electrode array length. A FLEXeas array (20.9 mm) is also available for applications such as EAS; for cochleas that are partially ossified, a compressed electrode is available; and for severely ossified cochleas, a split electrode array is available. In July 2007 FDA approval was granted for the Med-El SonataCI100 internal device (see Fig. 158-9). The SonataCI100 Cochlear Implant contains the same electronics as the PulsarCI100 device, but the electronics are encased in a titanium housing that is smaller and thinner than the PulsarCI100 ceramic casing. All Med-El electrode arrays are compatible with the SonataTI100. The receiver coil and internal magnet are positioned outside

of the electronics package in flexible silicone, although the magnet is not removable for MRI. The SonataTI100 is also MRI compatible in the United States at 0.2 T without magnet removal.

If ossification of the cochlea is encountered during the opening of the cochleostomy, the use of the Med-El Insertion Test Device (ITD) can be helpful to determine which of their various electrode options should be used. If the ITD can be inserted to the small flanges present 17.8 mm from the tip, the standard array should be used; if less than that, the medium or compressed array should be used. The medium electrode array (PulsarCI100M) has all 12 pairs of electrodes distributed over 21 mm spaced 1.9 mm apart. The PulsarCI100 compressed electrode (PulsarCI100S) is designed with the same number of electrode contacts ($n = 12$ pairs), but arranged closer together on the apical end of the array and spaced over 12.1 mm. With ossification present, the ITD is advanced through the cochleostomy and the depth of insertion is determined. If it is apparent that insertion of the standard electrode array would result in electrodes being extracochlear in location, the compressed or medium electrode array should be used and fully inserted.

For more severely ossified cochleas, the Med-El split electrode design (PulsarCI100GB) has two compressed electrode arrays with five and seven pairs of electrode contacts, respectively (Fig. 158-10). These electrode arrays are inserted via two cochleostomies. When the two arrays are in place, the electrode contacts provide more sites of potential stimulation than a single standard array incompletely inserted into the cochlea. The sixth electrode design is for applications in patients who have a common cochlear cavity (see Figs. 158-10 and 158-11). This electrode uses the basic PulsarCI100S array with 3 to 5 mm of Silastic and a distal nonfunctional platinum ball.

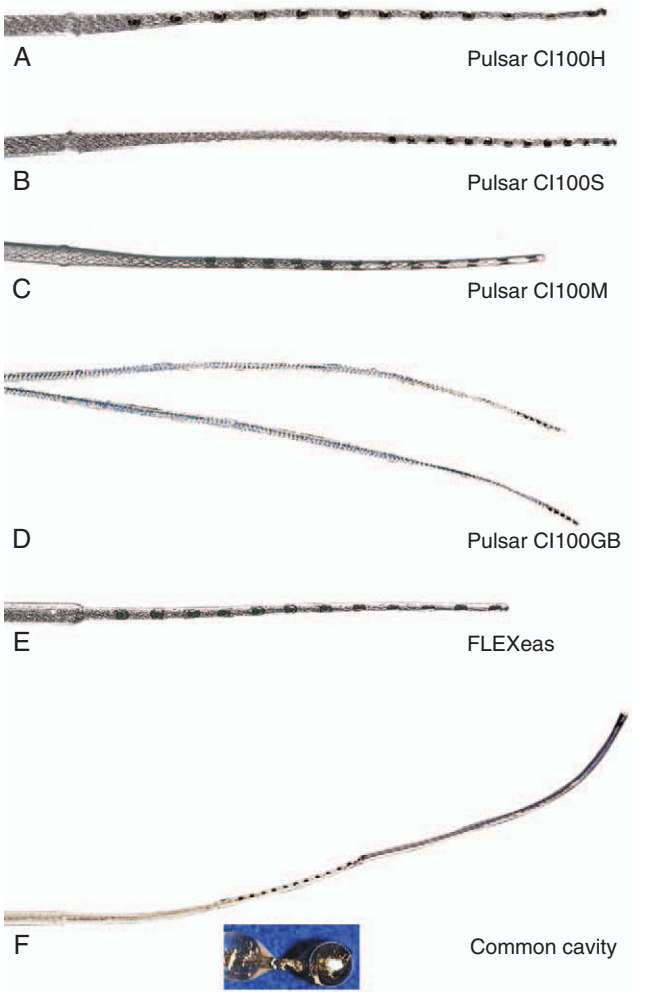

Figure 158-10. Six electrode designs available for the Med-El PulsarCI100 and SonataTI100 cochlear implants. **A,** Standard 31.5 mm electrode with the electrode contacts distributed over 26.4 mm. When ossification is encountered during creation of the cochleostomy, use of the insertion test device allows determination of whether to open the standard electrode array or one of the two shorter arrays or the split electrode array. **B,** The compressed array distributes the electrode contacts over 13 mm. **C,** The medium array distributes the electrode contacts over 21 mm. **D,** The split array has one with five pairs of electrode contacts, while the other has seven pairs of electrode contacts. **E,** For hearing preservation and application of electroacoustic stimulation, the FLEXeas electrode is designed to be thin and 20.9 mm in length. **F,** For severe cochlear malformations such as a common cavity, the custom-manufactured common cavity electrode can be used. This electrode array uses the basic compressed electrode with a nonfunctional Silastic extension terminating in a platinum ball *(inset),* which is used to place the electrode array via a double labyrinthotomy technique as shown in Figure 158-11. *(Published with permission, copyright © 2009 P.A. Wackym, MD.)*

External Speech Processors

Each manufacturer offers a body-worn (BW) and behind-the-ear (BTE) processor. The BW processors were the first wearable devices for each implant type, followed by the introduction of BTE processors, which are generally preferred by adults and some children/parents. Both BW and BTE processors have program switches, volume and/or sensitivity controls, batteries (rechargeable or alkaline), and accessories. External processor wear options vary from one device to another but may include, for example, a remote battery pack worn off the ear or a rechargeable battery pack worn on the processor at the ear. A variety of mechanisms (e.g., earhooks, indicator lights) perform functions such as alerting parents to a low battery or a disconnected headpiece. External auditory input sources can be connected to the processors such as auxiliary microphones, telephone adaptors, tape recorders, television audio amplifiers, or FM systems. Other cosmetic considerations include a variety of processor and transmission coil colors, decorative caps, processor belt clips, and harnesses or hip packs for daily wear. Because the external equipment changes regularly, the specifics for each manufacturer are reviewed at the time of device discussion and selection, which occurs once cochlear implantation has been recommended.

Current Signal Processing Strategies

Each device manufacturer provides a selection of signal processing strategies that may affect device selection for a given patient. For example, patients who are music enthusiasts may be interested in comparing aspects of fine structure strategies, whereas other patients with neurologic processing issues may benefit from having strategies that offer slower stimulation rates. Below are summaries of currently available signal processing strategies.

Temporal Strategies

CONTINUOUS INTERLEAVED SAMPLING. Continuous interleaved sampling (CIS) is a speech processing strategy that has been implemented in cochlear implant devices in recent years. One problem encountered with early speech processing strategies was interaction between electrical fields when electrodes were stimulated simultaneously, particularly with broad, monopolar stimulation. This is referred to as channel interaction, and it is thought to result in a degradation of the intended signal. CIS was introduced by Wilson and colleagues[70] as a way to minimize overlap between monopolar electric fields across stimulated electrodes, thereby preserving the integrity of the electrical signal. In CIS, biphasic pulses are delivered to electrodes with timing offsets so that none of the electrodes are stimulated simultaneously. This sequential stimulation pattern results in increased electrical channel independence, which, in addition to decreasing channel interaction, allows for the possible advantage of using more channels.

Although several versions of CIS are implemented across devices, the pulse amplitudes in CIS are generally determined by several steps. First, at a given point in time, the acoustic input signal is bandpass filtered, with the lower frequency information allocated to apical channels and higher-frequency information allocated to basal channels.

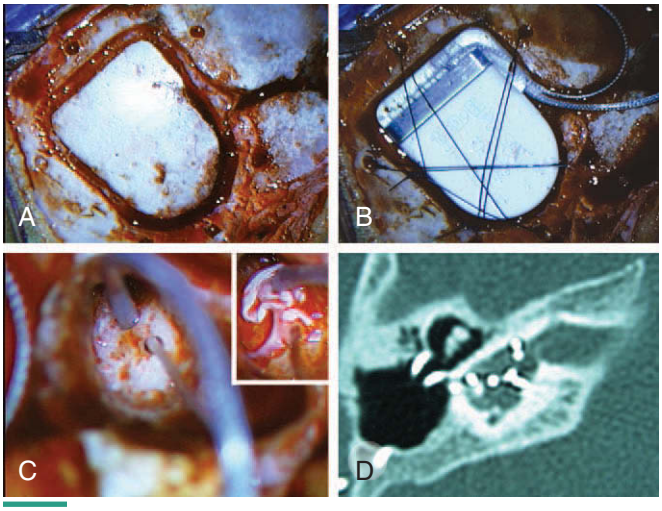

Figure 158-11. Cochlear implantation in a common cavity malformation. **A,** Craniotomy with the bone island technique. **B,** The Med-El internal receiver/stimulator secured with three 3-0 nylon sutures. **C,** the common cavity electrode was inserted via a double labyrinthotomy technique. Inset shows fascia sealing both labyrinthotomies. **D,** Postoperative computed tomography scan shows the position of the electrode array within the common cavity. *(Published with permission, copyright © 2009 P.A. Wackym, MD.)*

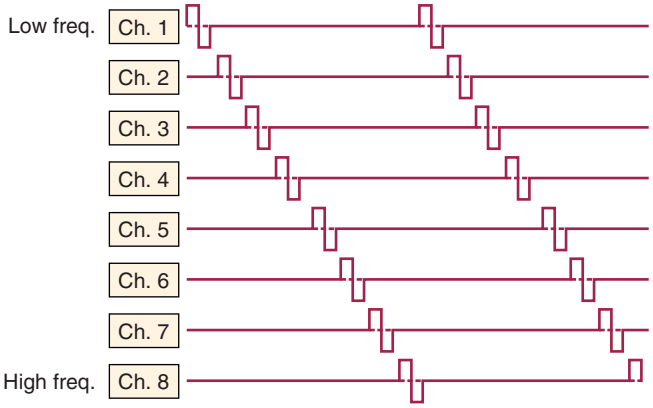

Figure 158-12. Analog stimulation. Each electrode is stimulated continuously and simultaneously. In this example, electrode 1 carries the lowest frequency information and electrode 7 carries the highest frequency information. The Simultaneous Analog Stimulation (SAS) implemented by Advanced Bionics Corporation uses a bipolar electrode configuration to reduce electrode interaction. *(Published with permission, copyright © 2008 Advanced Bionics Corporation.)*

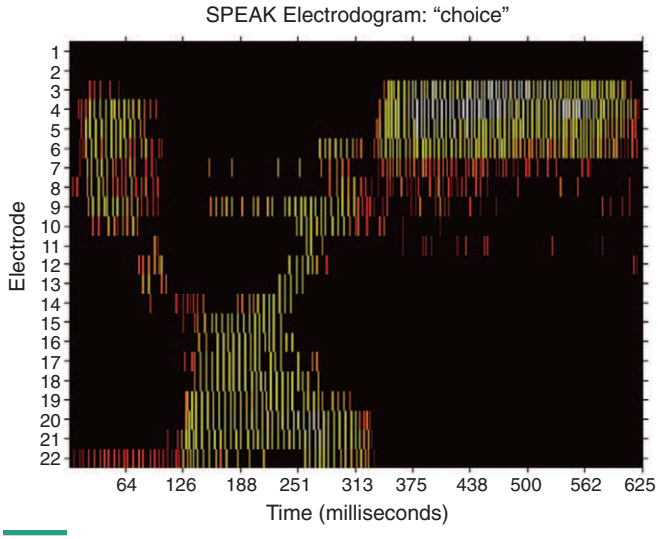

Figure 158-13. Spectral Peak Extraction (SPEAK). An electrodogram is shown for the word "choice" encoded by the SPEAK strategy. Time is plotted on the abscissa and electrode number on the ordinate, and the more intense stimuli are indicated by brighter bars. The relatively low stimulation rate of 250 Hz is apparent. *(Published with permission, copyright © 2008 Cochlear Americas.)*

Next, within each frequency band, the amplitude of the input signal is determined, and this envelope amplitude is compressed to fit into the appropriate dynamic range of electrical hearing for each channel. The compressed amplitude calculated from the input signal is used to determine the amplitude of the stimulus pulses that are sent to the designated electrodes. In this way, CIS primarily conveys temporal information from the input signal. All three devices available in the United States have a CIS strategy option.

ANALOG STIMULATION. Electric analog stimulation is a digitized representation of the original acoustic signal that is presented continuously over time and simultaneously to the different electrodes in a tonotopic manner. Preservation of the original acoustic signal would presumably be beneficial for electrical hearing, but limitations to this stimulation paradigm warrant consideration. An early analog speech processing strategy, compressed analog (CA),[71] was presented using a monopolar electrode configuration. The combination of broad current spread and continuous, simultaneous stimulation resulted in extensive channel interaction. Current spread can be reduced by changing the electrode configuration from monopolar to bipolar mode, which localizes the electric field by stimulating between a pair of electrodes on the array.[72] Using a bipolar coupling mode, the analog strategy available in the Clarion 1.2, CI Bionic Ear, CII Bionic Ear, and HiRes 90K devices is referred to as Simultaneous Analog Stimulation (SAS). An example of SAS is shown in Figure 158-12, with the low-frequency analog stimulation sent to the apical channel (channel 1 in the Advanced Bionics Corporation devices) and the highest frequency stimulation to the basal channel (channel 7).

Spectral Emphasis Strategies

SPECTRAL PEAK EXTRACTION. Spectral peak extraction, or SPEAK, is implemented in the Nucleus device.[73] SPEAK includes a bandpass filter analysis of the input signal, and the outputs selected for stimulation are those with the highest amplitude components, or the largest spectral peaks. The corresponding electrodes are activated sequentially in a basal-to-apical direction at a relatively low rate (≈250 Hz). Typically, the number of electrodes stimulated, or maxima, is 6 to 8, although it may range from 1 to 10, with the more electrodes stimulated, the slower the rate. Figure 158-13 shows an example of the stimulus output pattern for the SPEAK strategy in the Nucleus device. The plot, referred to as an *electrodogram,* shows the electrodes stimulated over time for the word "choice," with intensity indicated by the relative brightness of the lines.

ADVANCED COMBINATION ENCODER. The Advanced Combination Encoder (ACE) strategy was designed for the Nucleus device to incorporate the spectral representation benefits of SPEAK with a high rate CIS.[74] ACE provides a range of stimulation rates per channel, from 500 to 3500 pulses per second, and allows for a maxima range from 1 to 20. An electrodogram for the word "choice" processed with ACE is shown in Figure 158-14. The rapid stimulation rate and increased number of stimulated electrodes is apparent when compared with the SPEAK strategy.

Fine Structure Signal Processing

Fine structure signal processing combines both temporal and spectral cues, is typically presented using high pulse rates, and may incorporate a recently implemented "virtual channel" paradigm. The higher rate

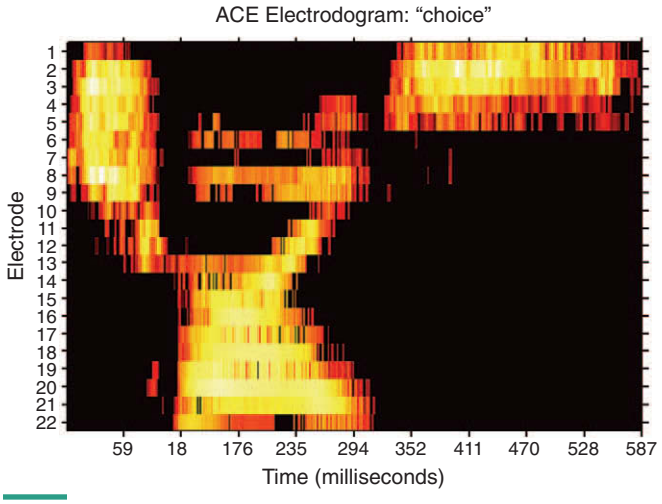

Figure 158-14. Advanced Combination Encoder (ACE). An electrodogram for the word "choice" (as plotted in Fig. 158-17) is shown for coding with the ACE strategy. Compared with SPEAK, the stimulation rate is faster and the number of electrodes stimulated is greater. *(Published with permission, copyright © 2008 Cochlear Americas.)*

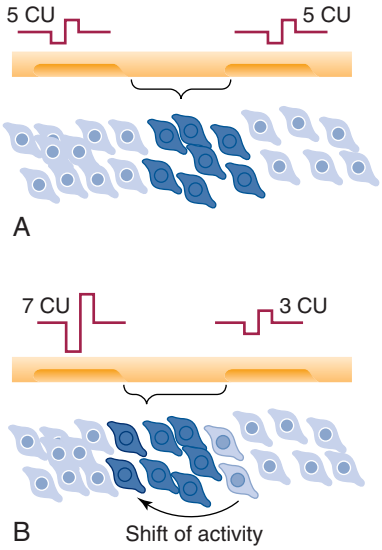

Figure 158-15. Schematic illustration of current steering between adjacent electrodes and stimulation of neural elements. **A** shows equal proportions of current presented to the electrodes, which effectively focuses stimulation halfway between the contacts. **B** shows a shift in the current proportions between electrodes and the resulting shift of activity toward the more heavily weighted contact. *(Published with permission, copyright © 2008 Advanced Bionics Corporation.)*

strategies generally use short duration pulses and increased filter update rates. It is theorized that this results in electrical stimulation that more accurately represents the input signal.

Improving delivery of spectral cue information with coding strategies has become of particular interest with advances in device design and evolving patient expectations such as music appreciation and listening in noise. Stimulation of different electrodes along the array typically elicits different pitch percepts in cochlear implant users. The number of different pitch percepts a person has reflects that individual's spectral resolution abilities. Until recently, spectral resolution with cochlear implants was limited by the number of stimulating electrodes. A method of stimulus current delivery has been developed to increase the number of pitch percepts given a finite number of electrodes. This stimulation paradigm is referred to as "current steering," and the resulting additional pitch percepts are called "virtual channels."

Current steering is accomplished when two adjacent electrodes are stimulated simultaneously, subsequently eliciting a pitch percept that falls between the pitches from each electrode when stimulated alone.[75,76] This effect has also been shown with sequential stimulation of adjacent electrodes.[77] Figure 158-15 shows a schematic example of equal proportions of current presented simultaneously to two electrodes *(top),* thus stimulating the neural population halfway between the contacts. By changing the proportion of current delivered to each electrode, the responding neural population likewise shifts (Fig. 158-15, *bottom*) and thus creates an additional pitch percept without changing the loudness.[78] Algorithms for current steering between electrodes and across the array have been developed by all three manufacturers, for use with their recent-generation devices.

Factors That Affect Device Choice

NEED FOR SPECIAL ELECTRODE ARRAYS. When individuals have hearing loss that is appropriate for cochlear implantation, it is possible that the cochlea may be malformed, depending on the etiology of the hearing loss. This includes varying degrees of Mondini malformation, in which there may be fewer cochlear turns or dehiscent cochleae. The cochlea may be ossified, to varying degrees, which may occur with meningitis, Paget disease, or otosclerosis. In addition, there are types of hearing loss that may necessitate preservation of hearing with implantation. In any of these cases, it may be necessary to have special electrode arrays available such as short, compressed, split, or custom arrays, all of which have been described earlier.

TECHNOLOGY DIFFERENCES IN SPEECH CODING STRATEGY AND ELECTRODE CONFIGURATION. Device selection is also influenced by changes in technology that may make one device more appealing than another for a given individual. For example, a speech coding strategy that emphasizes both temporal and spectral cues may be desirable for a patient who has a great love of music. Depending on an individual's work or other daily life environment, certain noise reduction features may become relevant. As discussed previously, in some cases a patient may be limited to selecting a given device on the basis of his or her cochlear anatomy or hearing status that requires the use of a particular electrode array design.

MAGNETIC RESONANCE IMAGING COMPATIBILITY. MRI is a powerful noninvasive diagnostic tool that uses magnetic fields and pulses of radio waves to generate images. The components of an MRI unit include a static magnetic field (0.5 to 4 T); magnetic fields caused by switched gradients (0 to 20 T/s at ≈ 15 Hz); and radiofrequency energy (0 to 6 kW peak at 64 MHz [for 1.5 T]).[79,80] It is an imaging modality with an already wide range of clinical applications that continues to expand. Ideally, this diagnostic tool should be available for the benefit of cochlear implant (CI) recipients. The Cochlear Corporation's CI24M, CI24R(CA), and CI24ABI devices, as well as the Advanced Bionics Corporation's HiRes 90K device, were all designed so that the internal magnet could be removed and replaced to complete an MRI study.

Studies with the Med-El Combi 40/40+ and Clarion 1.2 (Advanced Bionics) cochlear implants have delineated many of the factors in CI/MRI interactions.[81,82] The factors that have been studied include demagnetization, artifacts, induced voltages, temperature increases, torque, and force. These investigations have used both the 0.3 T and 1.5 T MRI units. The force and torque exerted by the MRI unit on the internal magnet of the cochlear implant receiver are of particular concern. The potential for a catastrophic force on the implant to fracture the inner table of skull and exert pressure on the brain demands full investigation of cochlear implant/MRI compatibility. Previous studies concluded that a 0.2 T MRI evaluation force and torque remained within "acceptable limits."[81,82] There have been several in vivo studies performed in Europe using 1.0 T MRI.[69] In this largest series of 30 patients with Med-El cochlear implants who underwent 1.0 T MRI evaluations with a variety of MRI sequences, none suffered pain, burning, auditory sensation, deterioration of their auditory abilities, or other adverse sequelae. Presently, patients with the

Med-El C40+, PulsarCI100, or SonataTI100 devices in place greater than 6 months are approved by the FDA to undergo MRI studies with a 0.2 T scanner, provided the company approves the protocol for the radiologist.

We have completed studies to determine the magnitude of force required to fracture the floor of a cochlear implant receiver bed.[83] The testing protocol was designed to create a physical worst-case scenario yet approximate the in vivo condition. Several considerations went into attaining this dual goal. Each recessed cochlear implant bed was drilled to a maximum uniform thinness rather than drilling just deep enough to accommodate the cochlear implant. A stainless steel template was chosen for impacting the specimens because the arc of its edge would closely approximate that of the cochlear implant affecting the skull in vivo. In addition, a line load system more realistically approximated the in vivo condition than a point load system. The center of the specimen was chosen for contact with the template. This placement minimized the risk of the template touching any surface other than the floor of the recessed cochlear implant bed. It also assisted identical placement of the template for each specimen. Finally, this placement allowed the template to affect the specimen at its least reinforced site, thereby providing a worst-case scenario. Since the in vivo system had the thinned bone in continuity with the native skull and it is this region that receives the force vector during the cochlear implant magnet/MRI magnet interaction, it is anticipated that the biomechanical forces required to produce failure at this interface would be much greater than those measured in the study referenced earlier.[83] In an earlier investigation of cochlear implant/MRI compatibility, 0.3 to 1.0 newtons (N) was used as an acceptable level of force exerted on a cochlear implant during MRI evaluation.[81] The researchers recommended this range because it represents the magnitude of force that a cochlear implant may experience during a regular day in the life of a cochlear implant recipient. More specifically, this is the magnitude of the force exerted on the internal magnet of a cochlear implant when the external transmitter and magnet are removed. In these prior studies, the measured force vectors ranged from 0.17 to 0.42 N. Calculations using these measured force vectors and appropriate geometry resulted in maximum forces of approximately 8 N exerted on the cochlear implant during 1.5 T MRI evaluation in a worst-case scenario. The results of our biophysics studies showed that the load-carrying capacity of a recessed cochlear implant bed drilled into fresh frozen human calvaria specimens, with bone thickness of 0.3 to 0.6 mm (S.D. 0.11 mm), is more than an order of magnitude greater than this force (mean = 134.13 *N*).[83] When a bone island with exposed dura is necessary to inset the internal device, titanium or resorbable mesh has been shown in vitro to provide even greater mechanical support beneath a cochlear implant and this approach also has the advantage of providing immediate support.[84] Moreover, we have demonstrated that no demagnetization of the internal device magnet occurs after 15 successive MRI scans in a 1.5 T unit.[85] Further studies in patients will be necessary to demonstrate the safety of this practice using cochlear implants with the internal magnet remaining in place. However, for all candidates, and particularly those who are in need of frequent MRI scans, the options and limitations of each device should be discussed so that the patient can make an informed decision.

EXTERNAL SPEECH PROCESSOR SIZE, WEIGHT AND AESTHETICS. Often, the design and aesthetics of the external components, specifically the speech processor, have a great deal of influence on device selection (Figs. 158-16 to 158-18). Individuals tend to prefer a BTE processor because it is lighter, smaller, and does not have a cord that runs down the back of the neck. For young children, it may be desirable to use a BW processor that can be worn on the child's back and out of reach. In addition, some BTE processors may be too large or heavy to stay on a child's ear. However, some manufacturers have introduced smaller, lighter BTE wear options designed specifically for children. Patients with dexterity or vision problems often select a processor with larger, more accessible controls. Color choice of the external components is also relevant. Some prefer to match hair and/or skin tone, and others like interesting designs or colors that they can change to match their clothing.

BATTERIES. The type, cost, and lifespan of batteries are important to some patients when choosing a device. Body-worn speech processors can use either disposable alkaline or rechargeable batteries. BTE processors use either disposable high power 675 hearing aid batteries or proprietary rechargeable batteries, depending on the manufacturer of the device. The specific processor, battery type, speech coding strategy, and patient programming needs each affect battery life. However, the generally expected battery life and ease of changing the batteries may cause a patient or family to choose one implant design over another.

CHAPTER ONE HUNDRED AND FIFTY-NINE

Cochlear Implantation: Medical and Surgical Considerations

Thomas J. Balkany

Kevin D. Brown

Bruce J. Gantz

Key Points

- Diagnostic therapy, including auditory verbal therapy with appropriate hearing aids, is critical before implanting devices in children with severe to profound hearing loss.
- MRI offers numerous advantages over CT, including direct visualization of the cochlear nerve, assessment of the patency of the cochlea, and visualization of the cerebellar pontine angle and brainstem for other abnormalities.
- Children and adults should be immunized against *Streptococcus pneumoniae* according to the high-risk schedule before cochlear implantation.
- Auditory neuropathy is not a contraindication to cochlear implantation.
- Cochlear implantation in children is ideally performed before 12 months of age.
- Michel's aplasia or absence of the cochlear nerve are absolute contraindications to cochlear implantation.
- Patients who require revision implant surgery (reimplantation) generally perform as well with their second implant as with their first.
- A second cochlear implant (implanted sequentially or simultaneously) improves sound localization and speech recognition in noise over a single implant.

Cochlear implantation has become a standard medical procedure for the rehabilitation of hearing-impaired adults and children. The medical and surgical decision to undertake cochlear implantation is based on the doctor-patient relationship. Candidacy issues, device selection, and planning for postoperative habitation are more complex than for other otologic surgeries, and they require a dedicated cochlear implant team. Decisions about whether to operate and which ear and device to select are made on the basis of input from the cochlear implant team, a detailed medical history and physical examination, and laboratory and imaging studies.

The physical characteristics of receiver stimulators and electrode arrays vary among manufacturers, thus necessitating surgical techniques that are specific to the device to minimize complications.[1-4] The facial nerve monitor is recommended in all cases as an adjunct for preventing overheating or other damage to the facial nerve while working within the facial recess and the middle ear.

Cochlear implant surgery—like technology and candidate evaluation—has evolved since the mid 1980s. During that time, techniques have been developed to reduce complications, to safely place implants in children who are younger than 12 months old, to insert electrodes in ossified and dysplastic cochlea, and to replace failed devices. The implantation procedure includes elements of mastoid and middle ear surgery, as well as cochleostomy, electrode insertion, and securing of the receiver stimulator.

Medical and Surgical Evaluation

This evaluation includes all aspects of cochlear implant candidacy, including critical analysis of hearing tests, motivation of the patient and family, and status of language development (Box 159-1). It should also focus on the patient's general health, especially with regard to his or her ability to undergo general anesthesia. A complete history and physical examination is followed by appropriate laboratory tests. Imaging studies play a particularly important role in this evaluation. When necessary, consultation with appropriate specialists is indicated.

During the physical examination, special attention is paid to the ear and central nervous system. Extensive laboratory evaluations such as thyroid function studies, lipid profiles, and viral screens are expensive and have not been found to be helpful unless specifically indicated by the history and physical examination.

Hearing tests with ear-specific auditory information in both aided and unaided conditions must be obtained. It is critically important to be certain that the patient's hearing aids are appropriate for the hearing loss. In young, prelinguistically deafened children, it may not be possible to accurately assess hearing during a single session or even a series of sessions within a sound booth. In very young children, a combination of diagnostic audiometric strategies may be necessary, including auditory brainstem response (ABR), auditory steady-state response (ASSR), and behavioral observation. The ABR is limited in its ability to obtain tone-specific information (limited frequency specificity).

Box 159-1

Candidacy Criteria for Children

- Severe to profound bilateral sensorineural hearing loss
- Benefits from hearing aids less than that expected from cochlear implants
- Medical clearance to undergo general anesthesia
- Family support, motivation, and appropriate expectations
- Rehabilitation/educational support for the development of aural language, speech, and hearing in children

ASSR uses a continuous tone with a carrier frequency that is amplitude and frequency modulated. Similar to an ABR, the ASSR is recorded from scalp electrodes, but the recordings show primary energy at the carrier frequency and two sidebands separated from the carrier by the modulation frequency. Recent studies have demonstrated correlation between the degree of hearing loss measured by standard PTA and ASSR at 500, 1000, 2000, and 4000 Hz.[5]

In diagnostic therapy, the patient is fit with the appropriate hearing aids, placed in a program of auditory-verbal or auditory-oral therapy, and followed up for a period of months. During that time, it is typical to see hearing-impaired children make some gains with regard to receptive language function, and these may be compared with the expected gains that typically occur with cochlear implants.

Genetic testing continues to evolve as an important adjunct in the diagnosis of hearing loss. Approximately half of the estimated 1 in 1000 infants born with bilateral severe to profound deafness are thought to have genetic factors. There are more than 46 genes currently identified that contribute to hearing loss, but one gene, *GJB2*, which encodes the protein connexin 26 and maps to the autosomal recessive deafness gene (*DFNB1*) locus, is responsible for a significant proportion of these cases. When mutations in *GJB2* and *GJB6* (connexin 30) are screened together, the cause of 50% of bilateral severe to profound hearing loss is identified in certain populations. Four main benefits of genetic testing have been identified.[6] First, the identification of a specific genetic cause precludes further costly testing. It also defines the chance of transmission by understanding the specific genetic cause of the hearing loss and its method of inheritance. Testing also provides parental reassurance that it was nothing done during the pregnancy that contributed to the hearing loss, thus helping to prevent unnecessary guilt. It also provides prognostic information with respect to the possible development of other medical problems and can help in predicting outcomes with hearing rehabilitation such as cochlear implantation.[7]

Both high-resolution computed tomography (HRCT) and magnetic resonance imaging (MRI) may be used in the preoperative evaluation of patients with profound deafness who are candidates for cochlear implantation. HRCT may assist in the evaluation of inner ear morphology (Fig. 159-1), patency of the cochlea (Fig. 159-2), position of the facial nerve, location of large mastoid emissary veins, size of the facial recess, thickness of the parietal bone, and height of the jugular bulb (Box 159-2). MRI has been used more frequently for preimplantation evaluation in recent years. Although MRI is not as effective in visualizing the fallopian canal or the bony structure of the otic capsule, it is more effective in identifying fibrosis of the cochlea by assessing its patency, in identifying the presence and caliber of the cochlear nerve (especially on sagittal T2 imaging of the internal auditory canal), and in providing information about brainstem and cortical lesions. A study compared the ability of HRCT and MRI for identifying abnormalities of the cochlea and modiolus, and MRI was found to be superior.[8] For these reasons, it has subsequently become the preferred means for preoperative evaluation of children undergoing cochlear implantation at many institutions. It is recommended, however, that HRCT still be performed in cases in which there are malformations of the external canal, semicircular canals, or vestibule due to the higher incidence of an anomalous facial nerve.[8] Both tests may be indicated in the presence of labyrinthine anomaly.

Figure 159-1. Cochlear dysplasia, absence of modiolus and bony partition. This coronal high-resolution computed tomography scan of a child with congenital deafness demonstrates a cystic cochlea without bony partition, the absence of a partition from the vestibule, and a wide, stubby, horizontal, semicircular canal. A large oval window niche can also be seen in this view.

Figure 159-2. Coronal high-resolution computed tomography scan demonstrating nearly complete cochlear ossification. This scan demonstrates nearly complete ossification of the labyrinth. A small portion of the upper turns may remain patent. Note that ossification generally begins in the basal turn and proceeds apically.

Ear Selection

Selection of the ear to be operated on is somewhat complex and prescriptive for the individual patient. The factors to be considered include the following.

Physical Characteristics

Physical characteristics of the temporal bone that are used for ear selection include the presence of the cochlea and the auditory nerve, the degree of dysplasia, the degree of ossification, prior surgical procedures

(e.g., canal-wall-down mastoidectomy), facial nerve anomalies, and chronic otitis media.

Residual Hearing Level

At this time, the risk of losing residual hearing during electrode insertion is estimated at 50% to 70%, although recent techniques may reduce the risk to 20%.[9] Thus, if there is significant aided benefit from the better ear, the worse ear is often favored. Conversely, it is widely held that patients with more residual hearing have better outcomes from cochlear implantation. For this reason, if a patient is anacusic, the ear that has more residual hearing may be favored. Fig. 159-3 presents an algorithm that may be helpful when considering these issues.

If one ear has had profound deafness for more than 10 to 15 years, the ear with better hearing is usually selected, because duration of deafness is one of the few measures that correlate with performance outcome. If the individual can use a hearing aid for sound awareness, preserving the ear with better hearing may assist with binaural localization and may assist with competing noise.

Box 159-2

Computed Tomography and Magnetic Resonance Imaging Information

- Inner ear morphology
- Cochlear patency
- Position of fallopian canal
- Presence of cochlear nerve
- Size of facial recess
- Location of large mastoid emissary veins
- Height of jugular bulb
- Thickness of parietal bone

Vaccination for Meningitis

In 2003, a *New England Journal of Medicine* article highlighted an increased incidence of pneumococcal meningitis in cochlear implant recipients in comparison to an age-matched general population.[10] A total of 4264 children were evaluated and 26 children were identified with streptococcal meningitis, representing an incidence of 0.6% in cochlear implant recipients. This was a 30-fold increase over their age-matched convenience sample cohort. Two major limitations of the study were that, first, 11.5% of children receiving an implant have a previous history of meningitis, and these children have an increased risk of recurrence. Second, 8.5% of children receiving implants have labyrinthine dysplasia, which also places them at an increased risk for meningitis. The degree to which an increase in meningitis is due to a cochlear implant, versus high risk factors such as prior meningitis or dysplasia, requires an adequate control group of deaf children rather than normal children as used in this study.

In order to test whether this risk was theoretical or actual in nature, animal experiments were performed in rats to determine whether placement of a cochlear implant increases the risk of meningitis.[11] In this study, rats receiving a cochlear implant were at a significantly increased risk of developing bacterial meningitis when inoculated with *S. pneumoniae* by any route (intraperitoneal, middle ear, inner ear) in comparison to surgical controls. In a later companion study, vaccination with 23-valent pneumococcal capsular polysaccharide vaccine (PPV23, Pneumovax) prevented the development of meningitis in rats inoculated by an intraperitoneal route and significantly reduced the frequency of meningitis in rats inoculated by a middle ear route. There was a nonsignificant reduction in frequency of meningitis

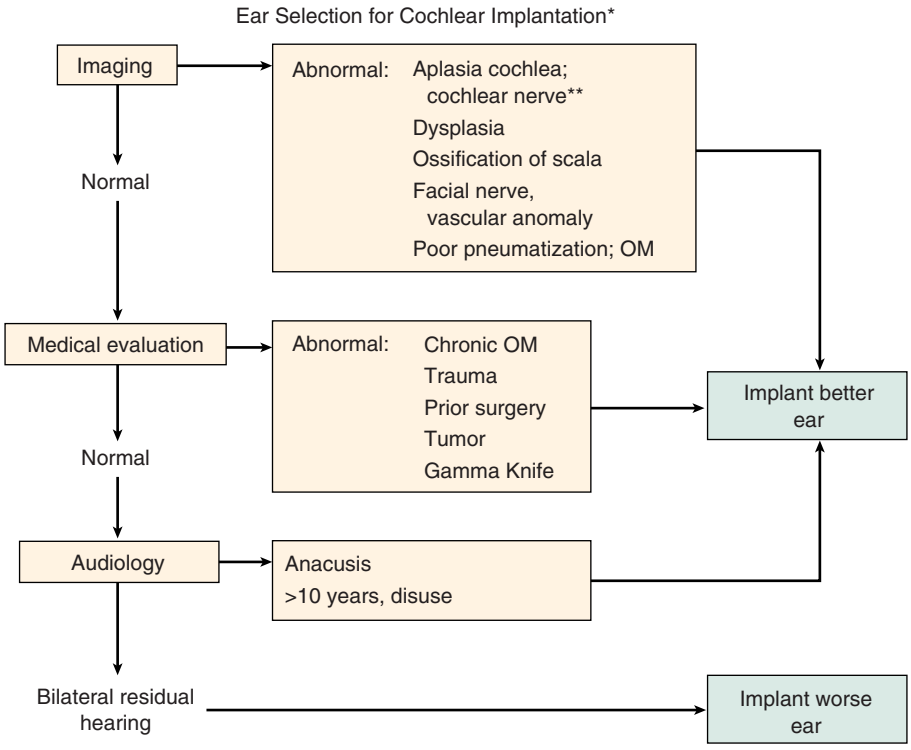

Figure 159-3. Ear selection algorithm. Selection of the ear to receive a cochlear implant is not a simple matter and must be prescribed specifically for each patient. The three general considerations are imaging, otologic history, and residual hearing level. Individual considerations such as lifestyle (driver vs. passenger), handedness (regarding ability to place the external device), and the patient's preferences must also be taken into consideration. OM, otitis media.

in rats inoculated via the inner ear. This suggested PPV23 can protect healthy rats from meningitis caused by a vaccine-covered *S. pneumoniae* serotype.[12]

There are currently two vaccines available that both generate antibodies to the polysaccharide capsule of *S. pneumoniae*. These include the PPV23 vaccine, which is a 23-valent vaccine composed of pure capsular antigen, and the heptavalent pneumococcal conjugated vaccine (PCV7, Prevnar), which contains seven pneumococcal serotypes conjugated to a nontoxic variant of diphtheria toxin. Both of these generate an antibody response, although PPV23 is not recommended for children younger than 2 years of age because of immaturity of their immune systems that may lead to a potentially poor response to pure capsular antigen.[13] It is the current recommendation of the Centers for Disease Control and Prevention (CDC) to ensure that children receiving a cochlear implant are immunized according to age-appropriate pneumococcal vaccination with PCV7, PPV23, or both according to the Advisory Committee on Immunization Practices (ACIP) schedules for persons at high risk (Box 159-3).[14]

Surgical Technique

Preparation and Draping

Under general anesthesia, the patient is placed supine with the head turned 45 to 60 degrees away from the surgeon. With very young children, care should be taken to avoid excessive rotation of the head so as to avoid subluxation of the cervical spine when the child is relaxed under general anesthesia. Long-lasting neuromuscular blockade is avoided to allow the use of the facial nerve monitor. Minimal shaving is used to reduce the psychologic impact of the procedure. The ear is prepped in a sterile manner, and a povidone-iodine–impregnated occlusive drape is used to retract the pinna anteriorly and to seal off the external auditory meatus. Using the appropriate implant guides provided by the manufacturer, the location of the implantable receiver stimulator may be marked on underlying parietal bone transcutaneously using methylene blue. A single intravenous injection of prophylactic antibiotics within 30 minutes of surgery is recommended, although this has not been subject to a prospective trial.

Incisions and Flap Design

Cochlear implant incisions have evolved over time (Fig. 159-4), but the principles of incision design remain constant. The resulting flap should cover the implant with margins of at least 1 cm in all directions, and a good blood supply should be maintained. Access to the linea temporalis, mastoid tip, and spine of Henle, without undue retraction, is necessary.

The original postauricular C-shaped incision used with single-channel implants was effective and had a low rate of complications. However, as multichannel devices came into use, the larger receiver stimulators required a larger flap. These larger postauricular C-shaped incisions were associated with a higher rate of complications—mainly device extrusion—and were subsequently replaced by an inferiorly based "inverted U" flap. This has undergone further modification (see Fig. 159-4), to an extended postauricular incision that has gradually become shortened and remains the most commonly used incision at this time. An extended endaural incision has also been used, but early experience with this incision demonstrated an unacceptably high incidence of skin breakdown at the external auditory meatus.

Box 159-3

ACIP Recommendations for Persons Receiving a Cochlear Implant

- Children younger than 24 months with cochlear implants should receive PCV7, as is universally recommended; children with a lapse in vaccination should be vaccinated according to the catch-up scheduled after the PCV7 shortage resolved.
- Children 24 to 59 months old with cochlear implants who have not received PCV7 should be vaccinated according to the high-risk schedule; children with a lapse in vaccination should be vaccinated according to the catch-up scheduled after the PCV7 shortage resolved; children who have completed the PCV7 series should receive PPV23 2 months or more after vaccination with PCV7.
- Persons 5 to 64 years with cochlear implants should receive PPV23 according to the schedule used for persons with chronic illnesses; a single dose is indicated.
- Persons planning to receive a cochlear implant should be up-to-date on age-appropriate pneumococcal vaccination at least 2 weeks before surgery, if possible.

ACIP, Advisory Committee on Immunization Practices.

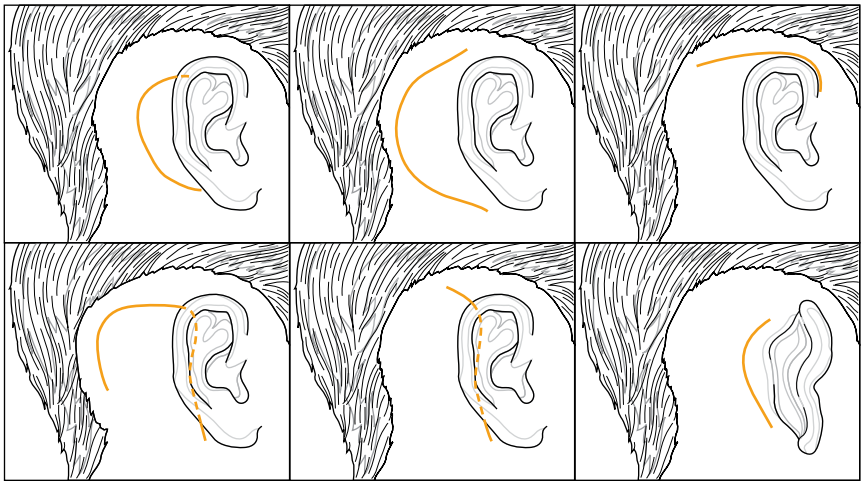

Figure 159-4. Cochlear implant incisions. Since the 1970s, a number of incisions have been used for cochlear implantation. The original small C-shaped incision was used for the relatively small, single-channel cochlear implant. When multichannel cochlear implants came into wide use in the 1980s, the C-shaped incision was simply enlarged. At that time, most complications had to do with flap breakdown. The large C-shaped incision had to be extended superiorly and inferiorly to allow for adequate arterial and venous blood supply. In response to the wound problems, an extended endaural incision was widely used in Europe, and an inferiorly based or U-shaped incision was developed in Australia. This gradually evolved into a simple extension of the standard postauricular incision. At the present time, a minimal incision is used in many centers for children and, in some centers, for adults as well.

A "minimal incision" has also been used for cochlear implantation. This incision is approximately 3 to 4 cm long and situated 1 cm posterior to the retroauricular crease. The advantages of this incision are that it requires minimal hair shaving, it heals faster and with less swelling than larger incisions, and it allows for initial stimulation at 2 weeks in most cases. Disadvantages include the need for additional skin retraction, reduced visibility, and somewhat limited access when drilling a bone seat and tie-down holes for securing the device.

Before incision, the intracutaneous infiltration of 1 to 3 mL of 1:100,000 epinephrine may be used to obtain better hemostasis. Similarly, a monopolar cautery knife may be used for both incision and flap elevation. It should be noted, however, that in cases of simultaneous or sequential cochlear implantation, monopolar cautery is contraindicated due to potential current interaction with the circuitry of the receiver-stimulator. In these cases, it is advisable to perform the approach for both sides before placing the implant (simultaneous implants)[15] to use a nonconducting means of dissection to provide hemostasis, including the bipolar, Shaw scalpel, and most recently the Plasma Knife in cases of sequential implantation.[16]

Skin Flap

The skin flap is elevated, along with subcutaneous tissue, in the plane of the temporalis fascia. By splitting the fascia, the flap may be raised in an avascular plane; this plane is most easily identified in the superior area of the flap and carried inferiorly.

Because the receiver stimulator will be situated at an angle of 30 to 45 degrees from vertical (it is more vertical in younger children), the skin and subcutaneous tissue flap are usually not elevated inferiorly to the lamdoidal suture. If dissection is carried below this point, large branches of the occipital artery and vein may be encountered, thereby causing unnecessary blood loss and delaying the procedure.

Because the external processor must transmit across the skin, the efficiency of both power and information transmission is governed by the thickness of the skin flap. The stability of the external transmitting coil, which is held in place magnetically, is similarly affected by skin thickness. Current devices require that the flap be less than 10 to 12 mm thick. Significant risk is inherent whenever a skin flap must be thinned. It is recommended to avoid thinning the skin flap to less than 0.8 cm and to prevent thinning to the level of hair follicles in all cases. When hair follicles are exposed, the risks of infection around the receiver/stimulator and of eventual extrusion are heightened.

After the skin/subcutaneous tissue flap has been elevated, a separate anteriorly based pericranial flap is then elevated. This flap extends along the linea temporalis posteriorly from a point just above the exterior auditory canal to a point that will cover at least the anterior portion of the receiver stimulator. The subcutaneous pericranial flap should be 2 to 3 cm in the cephalocaudal dimension and at least 2 cm in length. The pericranial incision is then carried inferiorly to a point just above the occipital crest and then anteroinferiorly, staying above the attachment of strap muscles, to the mastoid tip. In young children, the usual precautions to avoid the facial nerve in the absence of a mastoid tip are exercised. This flap is elevated anteriorly and retained in fishhooks or with a self-retaining retractor to expose the mastoid cortex and the area of the receiver/stimulator seat and tie-down sutures.

It is important to carry the soft tissue dissection anteriorly to expose and thin the bony wall of the posterior external auditory canal. In young children, care must be taken when placing the retractor, because it can tear the skin of the external auditory canal, thereby contaminating the surgical area.

A subperiosteal pocket for the receiver-stimulator is elevated beneath the pericranium posterosuperior to the mastoid using a periosteal elevator. The dimensions of the pocket depend on the design of the receiver-stimulator.

Bony Seat

A custom-fit bony seat and tie-down holes may be drilled into the parietal bone to recess and immobilize the receiver/stimulator; this reduces its profile and protects it from trauma as well as making it less noticeable to the patient and family. Drilling the seat and bone holes in young children often exposes dura, and care must be taken to avoid complications. Cerebrospinal fluid (CSF) leak, subdural hematoma, epidural hematoma, lateral sinus thrombosis, and cerebral infarct have all been reported.[17-19] At this time, techniques are being developed that do not require bone seats or bone tie-down holes.

The anterior edge of the receiver/stimulator should be at least 1 cm behind the skin incision. In addition, the location of the internal magnet should be far enough posterior so that the patient will not have a problem wearing an ear-level processor. Each manufacturer provides a mock implant and guide to help determine the site of the receiver-stimulator seat. Bony tie-down holes are drilled superior and inferior to the seat (Fig. 159-6). In young children, the bony fixation holes are often epidural and require that the dura be slightly elevated to avoid damage. Later, the receiver-stimulator will be secured with a single nonreabsorbable suture. The knot should be rotated into an inferior tie-down hole using two mosquito clamps.

Mastoidectomy

A complete mastoidectomy is performed, but, unlike in chronic ear surgery, the mastoid cortex is not marsupialized but rather is left slightly overhanging superiorly, posteriorly, and inferiorly to help retain and control the electrode cable. Likewise, it is not necessary to exenterate all retrosigmoid or tip cells.

The facial recess is widely opened. Care is taken to preserve a layer of bone overlying the facial nerve. It may be necessary to remove bone on the anterior medial surface of the fallopian canal just below the pyramidal process to provide adequate access to the round window. The bony external auditory canal wall should be thinned maximally, but it should never be penetrated. The chorda tympani can usually be preserved. Thinning the posterior canal wall allows the microscopic view to vector from anterolateral to posteromedial, because the round window niche is a posterior structure of the mesotympanum.

The incus bridge that separates the fossa incudis from the facial recess may be divided between the short process of the incus and the horizontal semicircular canal (Fig. 159-5). Although this requires only a few seconds with a 0.5-mm diamond burr, it allows the electrode cable to be passed under the short process into the epitympanum and firmly lodges it in position. Another benefit of this procedure is to direct

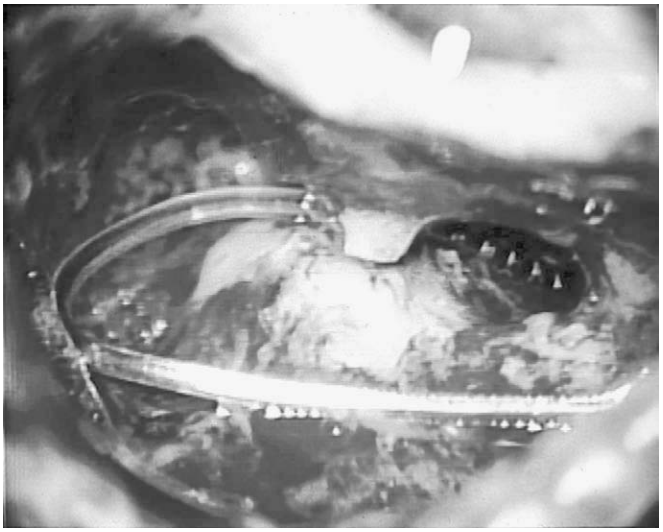

Figure 159-5. Split bridge. The incus bridge is divided using a 0.5-mm diamond burr between the short process of the incus anteriorly and the horizontal, semicircular canal. In doing this, the posterior incudal ligament is sacrificed. A cochlear implant electrode is seen after it has been placed inside the split bridge; this fixes the electrode in place, prevents extrusion, and directs the electrode away from the drill-exposed segment of the fallopian canal and the tympanic membrane (in the event that it should retract).

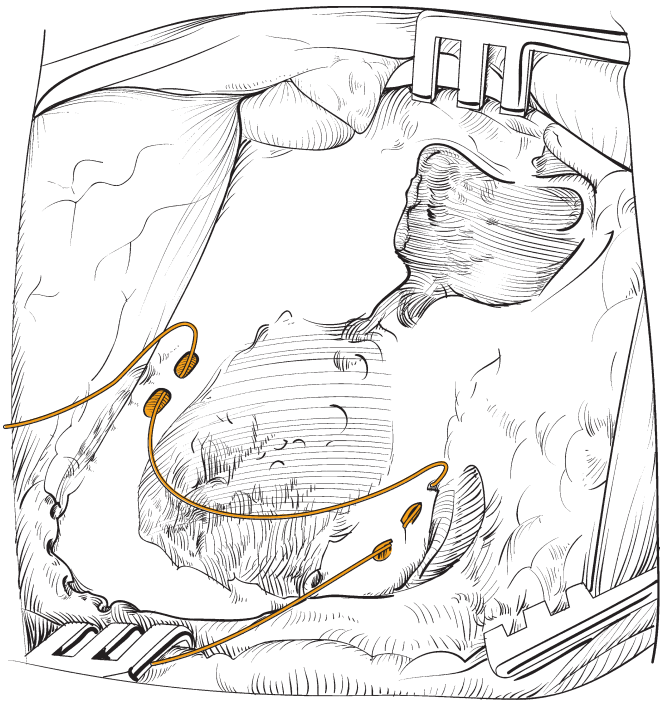

Figure 159-6. Bony seat and tie-down sutures with mastoid cavity. A custom-designed bony seat is made to recess the implantable receiver stimulator, thereby reducing its profile, providing a degree of protection from trauma, and minimizing mobility, which could result in work hardening of the electrode lead. A 2-mm diamond drill bit is used to create connecting suture holes superiorly and inferiorly, and a 2-0 nonabsorbable monofilament suture is used to secure the device into its seat. A trough is drilled to connect the seat to the mastoid cavity.

the cable away from the tympanic membrane in cases in which retraction or the need for myringotomy may arise.[20]

Cochleostomy

In the past, there have been instances in which the electrode was inadvertently placed into a hypotympanic air cell. It is important to identify the round window membrane to be certain that the cochleostomy and electrode insertion will proceed properly. The round window membrane is rarely more than 1- to 1.5-mm inferior to the stapedius tendon.

As with other aspects of the surgery, the placement and size of the cochleostomy varies somewhat depending on the implant to be used. In general terms, the cochleostomy is drilled through the promontory just anterior and inferior to the round window membrane. Care is taken to prevent bleeding into the cochleostomy by elevating the mucoperiosteum away from the selected site and using topical epinephrine on Gelfoam pledgets (Pharmacia & Upjohn Co., Kalamazoo, MI), if necessary. Good hemostasis should be obtained before opening the cochlea. If necessary, large Gelfoam pledgets may be placed in the epitympanum or mastoid cavity to prevent the drip down of blood. Bone dust should also be kept out of the cochlea.

A 1.5-mm diamond burr is used to thin the bone anteroinferior to the round window membrane. The overhanging niche is removed, if necessary, to positively identify the round window membrane. A 1-mm burr is used to remove remaining bone down to the endosteum itself. As the endosteum is approached, meticulous drilling is necessary to avoid inadvertent penetration. As a correlate, exposure of the endosteum of the scala tympani should be treated like a stapedotomy because penetration into the scala exposes the inner ear to significant acoustic trauma of up to 130 dB.[21] Endosteum is continuous with and found at the level of the round window membrane, which is used as a guide to the depth of the drilling. After this, the middle ear is carefully irrigated to remove all bone dust. It is imperative to prevent the rotating drill shaft from contacting the facial recess bone that overlies the facial nerve while drilling the cochleostomy. Overheating may result in delayed or immediate postoperative facial weakness.

The size of the cochleostomy is determined by the manufacturer and varies from 1.0 to 1.4 mm. The endosteum may be opened with a 25-gauge spinal needle, straight pick, or Beaver 59-10 cataract knife (Becton Dickinson Co., Franklin Lakes, NJ) just before insertion of the electrode.

Recent research has focused on the benefit of preserving low-frequency hearing in patients with predominantly high-frequency (speech frequencies) hearing loss by atraumatic insertion of the cochlear implant electrode. Low-frequency hearing may be preserved because the typical electrode does not extend into the distal apex of the cochlea, the frequency place of low tones. Use of a short/hybrid electrode has resulted in improved patient word understanding, particularly in noise, as well as improved music perception.[22,23] This has also been investigated using standard electrode insertion through the round window as opposed to performing the previous standard cochleostomy. In a noncontrolled case series, five of nine children were shown to have preserved low-frequency hearing after surgery, and eight of nine demonstrated a benefit of combined electric and acoustic stimulation.[24] Patients undergoing implantation by a round window approach may also have reduced postoperative vertigo.[25]

The round window approach to cochlear implant insertion has support in anatomic studies as well. Reduced damage to intracochlear structures has been directly demonstrated and/or suggested by multiple cadaveric temporal bone studies.[26-28] In addition, temporal bone studies have revealed the potential for significant acoustic trauma while drilling the cochleostomy, with up to 130 dB levels experienced by the inner ear.[21] The round window approach also is technically less difficult than cochleostomy and uses easily visible landmarks in many cases.[28]

Receiver Stimulator

The pocket for the receiver stimulator is copiously irrigated with dilute bacitracin solution, and any final hemostasis necessary is undertaken. Monopolar electrocoagulation systems are turned off and unplugged. The receiver stimulator is then placed into its bony seat/pocket and tied down with suture.

Electrode Insertion

The electrode tip is placed in the cochleostomy using specially adapted instruments or jeweler's forceps. It is important to direct the natural curvature of the electrode away from the basilar membrane and to insert it into the principal axis of the scala. Hyaluronic acid or 50% glycerine may be used to keep blood out of the scala during electrode insertion and to lubricate the electrode. Specialized instruments provided by the manufacturer may then be used to slowly and gently insert the electrode.

The electrode cable may be stabilized by placing it into the split bridge, if desired. Then, 1- to 2-mm pieces of temporalis fascia, pericranium, or muscle are used to pack 360 degrees around the electrode at the cochleostomy. Alternatively, a 3-mm piece of tissue may be buttonholed and slipped up the electrode array past all of the contacts. After near total insertion, it is then slipped back into the cochleostomy, and the electrode is advanced 1 mm farther.

The entire area is then copiously irrigated, and the incision is closed in layers. A light mastoid pressure dressing is applied overnight and removed after a wound check in the morning. Typically, drains are not used.

Special Considerations for Children

Hearing loss during the first few years of life is known to delay the development of language and to lead to serious developmental consequences. During the language-sensitive first years of life, loss of peripheral hearing has been shown to cause central auditory system abnormalities in experimental animals and to cause auditory perceptual disorders in children.[29-32] Cochlear implants, on the other hand, have shown a protective effect when electrical stimulation is delivered to the developing auditory system of deafened animals.[33-35] These issues have

led to the initial perception that the restriction of cochlear implantation to children older than the age of 2 years may limit potential development and linguistic outcomes. Children who have received implants by the age of 2 years acquire language at approximately the same rate as children without implants.[36] When implanted at this age, however, the child may not be able to overcome the original language gap caused by a lack of auditory input during the preimplant years. This has led to an increased interest in earlier implantation. A number of studies have demonstrated the safety and benefit of cochlear implantation in children younger than 12 months of age as well as the benefit to the children with respect to preverbal communication.[37-40] One study that evaluated children who had received their implants before 12 months of age revealed language comprehension and expressive development comparable to hearing peers. Their levels of language comprehension and expressive development was significantly better than those of children receiving implants between 12 and 24 months of age, thus supporting the practice of earlier implantation.[41] This has led to recommendations for implantation in appropriate candidates as young as 6 months of age. It is difficult to perform surgery much earlier, because approximately 6 months is needed for diagnostic testing, medical evaluations, and trials with hearing aids.

As the age of implantation has decreased, the acceptable levels of residual hearing of cochlear implant candidates has increased. Thus, although cochlear implants were originally restricted to children who were nearly anacusic, experience has shown that children with more residual hearing often perform better with implants. Hearing results in children with some measurable open-set speech recognition ability before implantation are better than those in children with none at all.[42-46]

Because the cochlea is full size at birth, there is no anatomic difficulty with electrode insertion in infants. However, deliberate surgical techniques for stimulator fixation and mastoidectomy and accommodation for head growth have been necessary for successful implantation. In very young children, it is often necessary to expose small areas of dura for the placement of tie-down sutures or seating of the implant. The skin incision must avoid the exposed facial nerve at the stylomastoid foramen. Redundancy of the electrode cable has been sufficient to prevent the extrusion of implants placed in very young children.

No specific complications associated with putting implants into very young children have been reported.

Otitis Media

The increased incidence of otitis media in very young children was once considered a relative contraindication to implantation. However, a number of studies have demonstrated that, after the ear infections are controlled medically or with ventilation tubes, implantation may proceed. Cochlear implantation is associated with neither increased incidence of otitis media nor complications such as labyrinthitis.[47-53] Some evidence has in fact suggested that mastoidectomy when combined with the improved ventilation of the middle ear afforded by performing a facial recess may decrease the incidence of otitis media.[54]

Otitis media should be managed aggressively to avoid delay in cochlear implantation. Treatment may require acute and prophylactic antibiotics, insertion of ventilation tubes, and in some cases, mastoidectomy with obliteration. The latter is usually performed as a staged preliminary step toward implantation in patients with chronic otitis media. It has been suggested that ventilation tubes be placed before implantation in children with unremitting otitis media with effusion and left in place for spontaneous extrusion.[55]

The recent association of meningitis and cochlear implantation has altered the thinking of some physicians regarding the management of recurrent otitis media, active otitis media with effusion, and an ear with a perforation. If severe chronic eustachian tube dysfunction is evident, a subtotal petrosectomy and closure of the eustachian tube and ear canal is advocated by some. This procedure should be performed 2 to 3 months before implantation of the internal stimulator receiver.

Auditory Neuropathy

Auditory neuropathy (AN) or dyssynchrony is associated with hearing loss in which outer hair cells function but inner hair cells or the cochlear nerve are dysfunctional. The diagnosis is made when otoacoustic emissions or cochlear microphonics are recordable (thus indicating outer hair cell function to be present) and the auditory brainstem response is absent. AN is suspected when the audiogram shows disproportionately low word recognition scores and the MRI is normal. It is critical in this population to provide an adequate trial of hearing aids and auditory verbal therapy because, despite an absent ABR, some children will have adequate benefit from hearing aids alone. Our experiences (as well as that of others) with AN implantees have been excellent in both adults and children.[56-58] The diagnosis of AN should not preclude consideration of a child for implantation. However, receipt of cochlear implants in many children has been delayed after a diagnosis of AN is made.

Meningitis and the Ossified Cochlea

Deafness caused by meningitis is associated with a reduction in spiral ganglion cells and often with ossification of the fluid spaces of the cochlea.[32] Because children who are deafened by meningitis may regain some of the hearing that was initially lost, immediate implantation is not recommended. However, fibrosis and ossification of the cochlea may occur within a few months after meningitis, and follow-up with serial MRIs performed at 2- to 3-month intervals may be done. If the perilymph/endolymph signature is lost, it indicates that fibrosis and eventual ossification may be occurring. In such cases, hearing does not return, and early implantation may be indicated. In some cases, the horizontal semicircular canal may show ossification earlier than the cochlea.

Meningitic patients generally require higher stimulation levels and more adaptive changes in their programming modes over time as compared with other patients.[59] This population has also been found to be at an increased risk of stimulation of the facial nerve (as have otosclerotic patients); however, this may be due to the higher stimulation amplitudes that are necessary, and it is usually controlled by inactivation of the offending electrodes or decreasing maximum stimulation levels. This may result in reduced performance of the implant. Nonetheless, patients with postmeningitic deafness and cochlear ossification can receive their implants via a variety of techniques,[60,61] and they can be electrically stimulated with generally good outcomes.[62] In the decade of the 1990s, approximately 3% to 9% of pediatric cochlear implant candidates had some degree of cochlear ossification, but in nearly 90% of these patients, the ossification is limited to the area that is adjacent to the round window membrane.[61] This may be drilled through to reach the open lumen of the basilar turn. When there is more extensive ossification of the scala tympani, the scala vestibuli may be patent and used for insertion. In both of these instances, a standard, full-length electrode is used, and results are similar to those of patients with no ossification.[61,63]

When both scala are ossified beyond the ascending turn of the cochlea, a complete drill out procedure or the use of a special electrode may be implemented.[64,65] Med-El Corporation (Innsbruck, Austria) manufactures a compressed electrode that has all of its contacts within a 10-mm distance for insertion into the inferior segment tunnel of the basal turn. Both Med-El and Cochlear Corporation (Melbourne, Australia) produce a split electrode array in which some contacts are placed in the inferior segment tunnel and others in the superior segment of the basal turn or in the second turn of the cochlea (see Fig. 159-7).

Labyrinthine Dysplasia

Deformities of the cochlea were once considered an absolute contraindication to cochlear implantation. However, at this time, deafness as a result of cochlear dysplasia is routinely managed with cochlear implants. Results vary directly with the degree of abnormal development. The majority of cases—including Mondini's dysplasia (incomplete partition), large vestibular aqueduct, and other, less severe forms of dysplasia—are associated with excellent results.[66,67]

The common cavity deformity, however, has highly variable results that are generally not as good as those seen in children with normal cochlea. Aplasia of the cochlea (Michel's deformity) or absence of the auditory nerve are absolute contraindications to implantation of the affected ear.

Absence of the cochlear nerve is suspected in anacusic patients with internal auditory canal (IAC) diameters of 1.5 mm or less. When a stenotic bony IAC is found, sagittal high-resolution MRI with heavily T2-weighted images is indicated to identify the presence of nerve bundles. The normal cochlear nerve may be seen coursing anteriorly toward the base of the modiolus. When facial nerve function is normal, one of the visible nerve bundles is considered to be the seventh cranial nerve. If the child has vestibular responses to calorics, another bundle may be considered the vestibular nerve; however, this nerve may be combined with the cochlear nerve. Electrical auditory brainstem responses may be performed to document the presence of the auditory nerve when there is doubt. In adults and children who are 6 years old and older, simple promontory testing may be performed in the office with topical anesthesia to obtain the same information.

CSF gushers should be expected in all cases of labyrinthine dysplasia. When a gusher occurs, implantation may proceed through the clear fluid, or the surgeon may elect to elevate the head of the table by 15 degrees and wait until no further fluid emerges. After the electrode is inserted, muscle and fascia are tightly packed into the cochleostomy to prevent further CSF leakage. A lumbar drain should not be used before sealing the cochleostomy, because it reduces the CSF pressure head, thereby making it impossible to determine whether the tissue seal is adequate.

Patients with Compromised Healing

Patients with reduced wound-healing capabilities because of underlying medical conditions or who are immunosuppressed by medications are considered to be at increased risk for postoperative infection and device extrusion. Nonetheless, in a review of patients with systemic autoimmune disorders as well as after liver and kidney transplantation, after high-dose radiation to the surgical field, or who were taking relatively high-dose immunosuppressive medications, implantation has been accomplished without significant complications.[68]

Older Patients

Some unique changes associated with aging must be considered in patients older than age 70 years. These include degeneration of all elements of the auditory system, the likelihood of prolonged duration of deafness, diminished central auditory function and communication ability, and coexisting medical and psychosocial problems.

Nonetheless, cochlear implantation in older adults has been successful, with results comparable to those in younger adults overall.[69] In our experience, patients up to the age of 87 years have obtained excellent results as evaluated by audiometric and quality-of-life measures. Nonetheless, in patients who are older than 80 years, these outcomes are not as good overall as they are in younger patients. Perioperative attention to medical and surgical details has allowed for safe insertion and a minimum of postoperative problems. Patients at this age are generally observed overnight in the hospital after surgery and are discharged the following morning.

Older patients may have difficulty understanding and recalling the information necessary for proper operation of their external device. Difficulties associated with arthritis and fine motor abilities may lead to problems changing batteries or adjusting the controls of the device. Older adults may also progress less rapidly with the use of their device if they live alone and are not exposed to verbal communication on a consistent basis.[69] Extensive counseling is required to address all of these issues and limitations. The ability to retain and use the relatively large amount of technical information by older patients must be kept in mind during counseling.

Bilateral Cochlear Implantation

The psychoacoustic literature has demonstrated improved auditory function when normal-hearing people listen with both ears and when hearing-impaired subjects use bilateral hearing aids.[70] This finding extends to bilateral implant recipients who have been clearly demonstrated to have improved speech recognition in noise compared with unilateral conditions.[15,71-74] This binaural advantage is predominantly from the head shadow effect in which speech and noise are spatially separated such that one ear is protected from the noise due to an acoustic shadow, and therefore has a better signal-to-noise ratio. Binaural summation and squelch have variable effects.[75] Because much social discourse occurs within a background of noise (classroom, party, busy restaurant), this advantage is of paramount importance to patients.

Sound localization is better in patients with bilateral implants than in patients with unilateral listening conditions. Unilateral localization accuracy has been identified between 50 and 67 degrees, whereas bilateral accuracy was determined to be between 24 and 29 degrees.[76-78] Sound localization is of critical importance in avoiding a potentially dangerous situation (e.g., locating an ambulance speeding down the street); it also permits the listener to focus on source and position of sound to improve the signal-to-noise ratio in daily situations.

In 2008, a position statement from the William House Cochlear Implant Study Group formally advocated bilateral cochlear implantation in children and adults because their review of literature supported the conclusion that both children and adults performed better with two implants than with one.[79]

Complications

Drilling the internal cochlear stimulator (ICS) seat and tie-down holes engenders the possibility of damage to the dura or the underlying dural blood vessels. Performing the mastoidectomy and opening the facial recess have the same risks as are present in other transmastoid procedures. However, because of the absence of chronic disease in most cases, the risks are somewhat reduced. Nonetheless, when operating on children with congenital deformities, there is a greater risk that the facial nerve may follow an aberrant course within the temporal bone.

Cochlear implantation also includes the insertion of a very delicate electrode, and the incidence of damaged or misplaced electrodes has declined from 1.74% to 1.18% since the late 1990s. The risk of postoperative facial paresis has also decreased from 1.74% in 1995 to 0.41%.[80,81]

Revision cochlear implantation surgery is not an uncommon occurrence after initial surgery. Reported rates of revision surgery vary, but recently revision surgery in adults has been reported at 5.4% to 7%.[81,82] The rate of revision implantation in children has typically been higher, with reports placing the rate between 8% and 12.5%.[81-83] The most common indications for revision surgery in a 2008 report was "hard failure" or device malfunction that occurred in 46% of the cases of revision surgery.[83] Medical-surgical reasons (e.g., wound healing, electrode malposition, cholesteatoma) were the second most common cause, occurring in 37% of cases. A "soft failure" (decrease in auditory performance or aversive symptoms in a device that performs within manufacturer specifications) occurred in 15% of cases. In general, patients performed as well after reimplantation as their best performance before surgery.[83,84]

Reimplantation may also be necessary when technology advances to the point that the device in use is outmoded (e.g., the transition from single-channel to multichannel implants). Studies of repeat electrode insertion depth show results that are generally equal to the original, although cases of both improved and diminished function have been reported.[84,85]

CHAPTER ONE HUNDRED AND SIXTY

Cochlear Implants: Results, Outcomes, Rehabilitation, and Education

Charles J. Limb

Gerard O'Donoghue

John K. Niparko

Key Points

- Performance of cochlear implants is affected by baseline factors that should be assessed as implant candidacy is considered. A multidisciplinary team enables simultaneous input from multiple perspectives, and is the most effective approach to assessing a candidate's needs and desires and the potential for an implant to meet them.
- In the 1980s, candidacy requirements for a cochlear implant required total or near-total sensorineural hearing loss as characterized by a pure-tone average of 100 dB or greater; amplified thresholds that failed to reach 60 dB; and an absence of open-set speech recognition despite the use of powerful, best-fit hearing aids. Because clinical experience has indicated that the mean speech reception scores of implant recipients generally exceed the aided results of individuals with lesser impairments, the audiologic criteria have been progressively relaxed since the early stages of multichannel implants to include a range of pure-tone averages, focusing instead on functional benefits provided by amplification.
- Although a cochlear implant facilitates sensitive hearing reliably, actual "listening" capabilities are less easily characterized.
- Speech recognition remains the standard metric of cochlear implant candidacy and performance. Speech recognition results show high variability, however, and awareness is increasing that epiphenomena surrounding implantation and the postimplant experience affect performance.
- For children, the extent to which the implant experience assists oral language development is a key reflection of the effectiveness with which developmental learning is normalized. Children with early-onset deafness lack the base of auditory memory needed to pair implant-mediated precepts with meaning. They may harbor other disabilities that may prevent instinctive language learning. Such conditions can produce a wide range of individual variability, particularly when intervention with a cochlear implant is delayed.
- In children, initial reports suggested that implantation before age 3 years provides distinct advantages over later implantation in cases of early-onset deafness. More recent data suggest that speech recognition and language skills are facilitated with implantation in earlier toddler and even infancy stages. Whether earlier implantation may yield greater benefits requires longitudinal follow-up of the development of ever younger infants undergoing implantation.
- Adults with cochlear implants exhibit a similarly wide range of results, often owing to factors outside of the device per se.
- To improve the accuracy of predicting an implant's outcome and to counsel patients effectively, comprehensive preimplant assessment is necessary.
- Screening for other handicapping conditions, particularly conditions that would impair the acquisition of receptive and productive communication skills, helps determine candidacy and direct rehabilitative strategies.
- Postimplantation rehabilitation can be important for some adult implant recipients, but is crucial for children to optimize the usefulness of an implant. It is often assumed that effective interactive skills and language comprehension directly result from the sensitivity with which sound is perceived through a cochlear implant. Hearing is not a sufficient condition for these higher skills, however, and a high priority should be placed on auditory rehabilitation to enhance fundamental skills in verbal communication.

Three decades of clinical experience with cochlear implantation suggest that notions of "success" or "failure" are highly nonspecific. There is a wide spectrum of the effects of cochlear implantation, which span a range of communication, psychosocial, and cognitive outcomes. Assessment of "success" with a cochlear implant is complex. The sense of hearing is pivotal to the phonologic awareness and processing that supports speech and language, including the development of visual language reception (reading) and production (writing), and a range of communicative behaviors and cognitive functions. This chapter examines the broad effects of cochlear implants in children and adults. We have drawn information from reports of clinic-based results and patient-based surveys. Basic assessment of physiologic response to auditory nerve stimulation, measures of receptive and productive benefit, and surveys of life effects as reflected in measures of quality of life and economic outcomes are described.

Although we characterize the effects of the implant per se, clinicians caring for hearing-impaired patients are increasingly aware that *clinical practices* related to cochlear implantation—especially practices related to candidate selection and rehabilitation—modify expectations and observed results. The most obvious effect of severe to profound sensorineural hearing loss is that there is insufficient phonologic access to encode complex information contained in speech streams. Cochlear implants seem to enable a level of phonologic access that can reliably overcome barriers to speech recognition. It has been tempting to assume that restored audition through a cochlear implant would provide sufficient input for a child to achieve a normal trajectory of developmental learning or an adult to reacquire the skills of verbal communication fully. The tasks of developmental learning and spoken communication require more than basic perceptive capacity, however.

A child or adult with an implant must attempt to process information conveyed by a prosthetic device using afferent tracts that may be altered consequent to early deafferentation. The ability to assimilate auditory information in facilitating communication tasks cannot be assumed because of well-recognized deprivation effects inherent in advanced sensorineural hearing loss. Environment and developmental experience are likely important, if not determinative, of implant benefit in some domains. Through a fuller understanding of the elements of success and failure with cochlear implants, clinicians can gain insight into criteria for candidate selection, and for the services and environments that would optimize use of an implant as a communication tool.

Results of Implantation

Factors Related to the Measurement of Auditory Performance

Auditory performance is measured at preimplant and postimplant intervals. Preimplant assessments form the basis of evaluating patient candidacy. Postimplant measures document the progress of the patient, while allowing the clinician to monitor for device-related and environmental factors that can influence long-term outcomes. Measurement variables associated with auditory testing should be standardized as much as possible. Clinicians can choose between closed-set tests (e.g., forced choice of one answer from a list of four) and open-set tests (auditory alone without context) of words or sentences. Closed-set tests are easier for patients than open-set tests, and are susceptible to "ceiling effects," reflecting high contextual information available when word and sentence material are presented.[188] The method of presentation can also affect speech perception scores.[1a] Live presentation typically produces higher rates of correct responses than taped presentations.

Trends toward higher rates of open-set speech recognition with newer implant technology and longer implant experience have prompted more stringent assessments. Increasing the difficulty of a speech perception test has the effect of limiting the "ceiling effect" that results from testing with simple, everyday phrases. To generate meaningful comparative data, increasing test difficulty normalizes distributions of scores, enabling more powerful statistical tests of differences between groups.

Tests of Implant Performance

The Minimum Speech Test Battery (MSTB) was developed for adult cochlear implant users. The MSTB is a set of high-fidelity disc recordings that provide a standardized set of comprehensive tests of preoperative and postoperative speech recognition.[2] To minimize the effects of learning and memorization, MSTB word and sentence tests have different lists for at least six testing trials. The average and range of performance of cochlear implant users are crucial to defining audiologic performance boundaries for implant candidacy.

The major components of the MSTB are the Hearing in Noise Test (HINT) and the Consonant/Nucleus/Consonant Test (CNC). The HINT[2] provides a measure of speech recognition ability for sentences in quiet and in noise. The background noise is filtered to match the long-term average spectrum of the sentences. In the MSTB, the HINT sentence lists are presented at 70 +dB in quiet and at 10 +dB signal-to-noise ratio (i.e., noise at 60 +dB). Smaller signal-to-noise ratios (e.g., 5 +dB or 0 +dB) may also be used to avoid ceiling effects. Although normal-hearing listeners can comprehend sentences effectively with signal-to-noise ratios of 3 +dB, implant recipients typically show degraded speech recognition when signal-to-noise ratios are reduced beyond 10 +dB.

The CNC consists of lists of monosyllabic words with equal phonemic distribution, with each list having approximately the same phonemic distribution as the English language.[3] Such lists provide material for performance testing that is more likely to represent daily experience with speech stimuli. These tests measure percentage of words correctly recognized. Open-set conditions for monosyllabic word recognition are considered the most difficult challenge to a listener with a cochlear implant, and such tests are useful to compare outcomes in adults.[4] Revised CNC lists[5] were developed to eliminate uncommon words and proper nouns. Ten lists of 50 words contain monosyllabic words that are employed with a frequency of greater than 4 per 1 million, as calculated in word-frequency tables. As part of the MSTB protocol, during each preoperative and postoperative evaluation, one CNC and one HINT list should be presented in quiet at 70 dB(A). In addition, if the patient performs greater than 30% under quiet conditions, HINT sentences can be presented in noise at 10 +dB signal-to-noise ratio.

Implant Performance in Adults

Improved speech perception is the primary goal of cochlear implantation. Although initial clinical series judged implant efficacy mostly on environmental sound perception and performance on closed-set tests, greater emphasis is now placed on measures of open-set speech comprehension. Speech-perception results from early clinical trials have served to guide the evolution of cochlear implantation. Gantz and colleagues[6] provided early comparative data in their assessment of environmental sound and speech perception in a large cohort of nonrandomized single-channel and multichannel implant users. Multichannel implants provided significantly higher levels of performance on all measures. Cohen and associates[7] performed the first prospective, randomized trial of cochlear implants through the U.S. Veterans' Administration hospital system. The trial provided high-quality clinical data and convincing evidence of open-set speech recognition, and established the clear superiority of multichannel over single-channel designs. The study was the first to report a low complication rate and high device reliability in individuals deafened after language acquisition from multiple centers with varying levels of prior programmatic implant experience.

Cohen and Waltzman,[8] Skinner and colleagues,[9,10] and Wilson and associates[11] assessed effects of changing external processing capabilities. They compared the performance of subjects fitted with processors designed to increase the rate of information transfer through higher rates of pulsed stimulation. Each study assessed a different processor, and study design and processing strategy also differed among studies. In each study, the use of a more sophisticated speech processor led to significantly better performance in open-set speech recognition.

Clinical observations in patients with current processors indicate that for patients with implant experience longer than 6 months, the mean score on open-set word testing approximates 25% to 40% (range 0% to 100%).[7,12-14] Results achieved with the most recently developed speech processing strategies reveal mean scores greater than 75% on words-in-sentence testing (range 0% to 100%). Although subjects perform substantially poorer on single-word testing, these mean scores

continue to improve as speech-processing strategy evolves.[10] After implantation, speech recognition by telephone[15] and music appreciation are often observed.

Benefits are enhanced through the use of more recently developed processing strategies. Spahr and colleagues[16] observed that differences in implant design affect performance, especially in difficult listening situations. Input dynamic range and the method by which compression is implemented seem to be the major factors that account for results in difficult listening situations, with greater performance associated with the expanded dynamic range offered by current processing strategies employed by the Advanced Bionics and MedEl devices.

Predictors of Benefit in Adults

Assessments of speech recognition in adults with cochlear implants offer the opportunity to develop models of benefit prediction. As investigators identify the salient predictive factors, candidacy, device and processing strategy, and the degree of postoperative auditory rehabilitation necessary, they can be better informed. The contributions of modifiers to differences in performance (multivariate analysis) have been addressed in several large studies.[6,7,12-14,17-19] The following factors have been evaluated:

- *Subject variables*: age of onset, age of implantation, deafness duration, etiology, preoperative hearing, survival and location of spiral ganglion cells, patency of the scala tympani, cognitive skills, personality, visual attention, motivation, engagement, communication mode, and auditory memory

- *Device variables*: processor, implant, electrode geometry, electrode number, duration and pattern of implant use, and strategy employed by the speech processing unit

Although the significance of the above-listed factors varies across different populations, multiple regression analysis has identified variables with high predictive value for speech comprehension. Length of implant use accounts for a high degree of variance in speech perception measured postoperatively. When length of use is controlled, preoperative hearing (particularly with respect to speech recognition) also accounts for a high degree of variance. Duration of deafness, age of implantation, cochlear patency, subject engagement with the therapeutic regimen, and processor type also carry high predictive values for speech understanding.

In addition to the factors in the list, the choice of ear to implant is a highly compelling issue. Other studies have emphasized the utility of implanting the better hearing ear.[13] At Johns Hopkins Hospital, we have long advocated the implantation of the poorer hearing ear. Although more data are needed, our studies so far reveal no significant difference in implant performance based on whether the better or worse hearing ear is implanted. Figure 160-1 shows a regression plot of the predicted postoperative word scores for each patient as modeled by the Johns Hopkins (implant poorer ear) and Iowa formulas (better ear).[17] Virtually identical scores are predicted on the basis of each patient's duration of deafness and preoperative sentence recognition scores. These data suggest that results obtained through cochlear implantation of the poorer hearing ear are statistically equivalent to results obtained through implantation of the better hearing ear. The similarity of results obtained through both methods suggests that implantation may have a beneficial effect on central auditory pathway development regardless of sidedness.

Another variable that influences speech perception is technologic sophistication of the implanted device. Improvements in speech perception have been associated with generational improvements in signal processing strategies, speech processors, and electrode arrays,[20] but may reflect clinical trends and technologic advances.[13] Criteria for cochlear implant candidacy are constantly expanding. Research has shown that patients with greater residual hearing show even more promising results. Identification of monosyllabic words for individuals using early generations of the Nucleus (Cochlear Corp., Sydney, Australia) multichannel cochlear implant averaged 16%,[6] whereas performance exceeds 50% on similar measures with current technology.[10,16] Earlier studies have contrasted performance across different manufacturers of devices. Differences in performance seem more closely related, however, to general demographic differences across patient populations, tests used, and length of experience with the devices than to differences in characteristics of like-generation devices per se.[21,22]

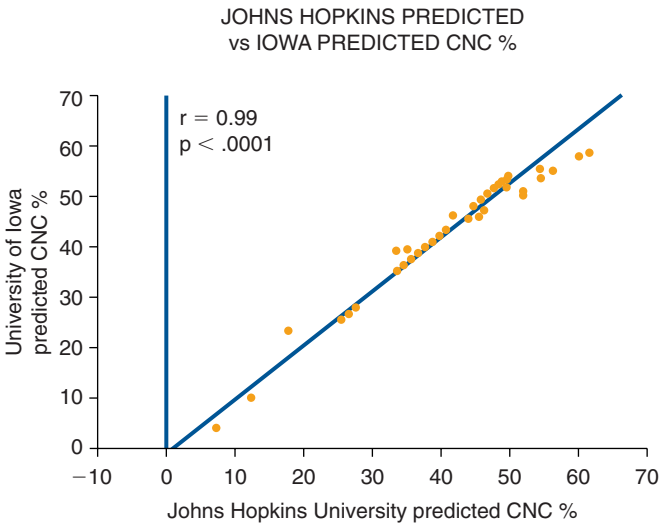

Figure 160-1. Regression plot of the predicted postoperative word scores for each patient as modeled by the Johns Hopkins (implant poorer ear) and Iowa formulas (better ear). There are virtually identical scores predicted on the basis of each patient's duration of deafness and preoperative sentence recognition scores. These data suggest that results obtained through cochlear implantation of the poorer hearing ear are statistically equivalent to results obtained through implantation of the better hearing ear. The similarity of results obtained through both methods suggests that implantation may have a beneficial effect on central auditory pathway development regardless of sidedness. CNC, Consonant/Nucleus/Consonant Test.

Cochlear Implantation with Hearing Preservation in Adults

There has been considerable interest in clinical strategies that combine residual acoustic hearing with electric hearing provided by a cochlear implant. Two strategies have been developed, depending on baseline hearing status. A *combined* mode uses a cochlear implant in one ear and a hearing aid in the other ear.[23] A *hybrid* strategy uses a hearing aid and a cochlear implant in the same ear.[24,25]

The goal of combining amplification with a cochlear implant in the opposite ear is to preserve perceptual advantages inherent in (predominantly low frequency) acoustic hearing in an attempt to capture at least some binaural cues. In fact, binaural advantages are observed in some patients.[23] Tests of speech perception in noise reveal trends toward a binaural advantage for word recognition depending on the direction of origin of noise (with advantages obviated when noise is on the hearing aid side). Localization ability improved with both devices. These data support the use of a hearing aid opposite a cochlear implant for appropriate patients.

Success with hearing preservation[26,27] in ears implanted with scala tympani electrodes has encouraged the development of hybrid modes of stimulation—electroacoustic hearing. Various surgical strategies have been adopted in attempts to limit cochlear trauma with scala tympani electrode insertion, enhancing opportunities for preserving residual (typically, <1 kHz) hearing. Hearing preservation procedures are designed to avert basilar membrane rupture and attendant spiral ganglion cell loss. Optimal preservation seems to be achieved with placement of the cochleostomy in a strategic location (away from the basilar membrane) along with cautious insertion of adapted, smaller arrays in a manner that limits impact on the endosteal and basilar membrane surfaces.[28]

Electroacoustic hearing seems to confer distinct advantages in speech perception and in music listening.[25,29] Improvements in speech-

in-noise understanding and melody recognition are linked to the ability to distinguish fine pitch differences through preserved, low-frequency acoustic hearing. There may be expanded spectral representation that more faithfully supports higher frequency hearing over time.[30] These observations suggest that the preservation of residual low-frequency hearing should be considered in selected patients. Observations of advantages in electroacoustic hearing may expand candidate selection criteria for cochlear implantation.

Although electroacoustic stimulation is a promising treatment for patients with residual low-frequency hearing, a small subset lose residual hearing despite best attempts with preservation. Such patients may obtain expected levels of benefit using the electric mode of the hybrid implant alone. For patients unable to achieve this benefit from an electroacoustic strategy after losing residual hearing, reimplantation with a standard array seems to provide higher levels of speech recognition.[31]

Implant Performance in Children

Pediatric cochlear implantation began with House-3M, single-channel implants in 1980. Investigational trials with multichannel cochlear implants began with adolescents (10 to 17 years old) in 1985 and with children (2 to 9 years old) in November 1986. Implantation of infants and toddlers younger than 2 years began in 1995.[32] Although clinical experience with cochlear implantation is shorter in children than in adults, a large body of clinical reports is now available.[33,34] Investigators have evaluated the hearing and speech receptive benefit of cochlear implants in children since 1985.

Auditory Performance Assessments for Children

Auditory performance in children is assessed with a battery of audiologic tests that can address the wide range of perceptual skills exhibited by children with severe-to-profound sensorineural hearing loss. Although substantial auditory gains are apparent in implanted children, the range of quantifiable improvement varies widely among children, and depends heavily on the duration of use of the device, preoperative conditions, and longitudinal experience and training effects. For this reason, testing should survey a range of levels of speech recognition, including simple awareness of sound, pattern perception (discrimination of time and stress differences of utterance), closed-set (multiple choice) speech recognition, and open-set (auditory only) recognition.

Methodologic variables must be considered when attempting to rate objectively the effect of cochlear implants on the development of speech perception in deaf children. Difficulties are inherent in objectively rating communication competence in very young children. Older children may exhibit advantages by virtue of greater familiarity with a test's context, independent of perceptual skills. Objective assessment mandates a structured setting that is not always conducive to eliciting a child's best cooperative effort. Investigators must also account for discontinuity in the age-appropriate measures necessary for longitudinal assessment.[34] Methodologic challenges and developmental considerations inherent in pediatric implant assessment have been examined in detail by Kirk and Diefendorf,[35] who categorized variables as relating to the following:

- *Internal variables*: the child's age and level of language and cognitive development
- *External variables*: the child's ability and willingness to respond as influenced by reinforcement and required memory task
- *Methodologic variables*: the procedure of voice presentation, the test administered, and the available options from which to choose a response

Tests of speech perceptions typically used for childhood assessment have been described in detail,[1a,35-37] and usually consist of closed-set tests that assess word identification among a limited set of options with auditory cues only, open-set tests (scored by percentage of individual words correctly repeated), and structured interviews of parents using criteria-based surveys[38] to assess response to sound in everyday situations and behaviors related to spoken communication.

Early Studies of Speech Reception in Children with Cochlear Implants

House and colleagues[39] found that children with cochlear implants obtain substantial improvement in auditory thresholds, closed-set speech recognition, and limited open-set speech recognition with the House-3M single-channel implant. Miyamoto and coworkers[40] provided systematic, well-controlled assessments of childhood cohorts and consistently showed performance advantages of multichannel over single-channel implants. Other early studies by Fryauf-Bertschy,[41] Gantz,[42] Miyamoto,[18] and Waltzman[43] and their colleagues observed that implanted children gain substantial speech perceptive capabilities for 5 years after implantation. Because many of the implanted children tracked in these studies were congenitally or prelingually deaf, there are compelling data to indicate that implantation can provide auditory access during critical developmental stages to form the early correlates of spoken language.

The studies we have cited have shown implant benefit in children with total or near-total hearing loss. An important issue for candidacy of children with lesser degrees of hearing impairment is the study of implant benefit relative to controls who have not received implants. Classification of children according to preoperative hearing levels can provide a common ground for comparison. Miyamoto and associates[44] described the following candidacy scale for stratifying children according to aided pure-tone detection thresholds: "Gold" class hearing aid users have unaided thresholds of 90 to 100 dB at two of three frequencies (0.5 kHz, 1 kHz, 2 kHz), with a mean of 94 dB. "Silver" class hearing aid users have unaided thresholds of 101 to 110 dB at two of three frequencies, with a mean of 104 dB. "Bronze" class users have unaided thresholds of greater than 110 dB at two of three frequencies, with a mean greater than 110 dB.

Hearing aid users in the "gold" category generally fall into Boothroyd's[45] category of "considerable residual hearing." In many such cases, hearing aid users that function at this level show substantial capabilities for near-normal trajectories of speech and oral language acquisition. This particular group of profoundly hearing-impaired children sets a comparative standard for speech perception performance. "Silver" category hearing aid users receive few spectral cues and rely heavily on temporal cues for speech perception. "Bronze" category users are considered "totally deaf," and receive only low-frequency percepts and restricted or no temporal cues.

Most hearing-impaired children who have received cochlear implants fell into or were eventually moved into the "bronze" category. Compared with children using amplification, children with implants have shown the following:

- After 2 years of implant experience, mean speech intelligibility scores of implanted children surpass those of "silver" category hearing aid users and approach within 10% scores of "gold" category users, particularly on more stringent tests of speech comprehension.[44,46] Longitudinal tracking of implanted children shows no evidence of a plateau effect in mean scores of speech comprehension. In conjunction with evidence based on multivariate analysis, this observation suggests that length of implant use is the primary determinant of receptive benefit.
- Trends toward continued improvement in speech reception are also associated with improved intelligibility of speech.[47] Although the measured proficiency of speech produced remains low through the first 2 years after implantation, intelligibility scores thereafter show dramatic gains and surpass those of hearing aid users in the "silver" category.[48] These observations are consistent with observations of gains in speech intelligibility in other childhood cohorts.[49,50]

More Recent Studies of Speech Reception in Children with Cochlear Implants

Between 1994 and 2004, numerous reports documented various levels of gains in speech recognition in young deaf children using multichan-

nel cochlear implants. Miyamoto and coworkers[18] noted that in 29 children with 1 to 4 years of experience with a cochlear implant, approximately one half achieved open-set speech recognition. Waltzman and Cohen[51] found that 14 children implanted before age 3 years attained high levels of speech perception performance with only 2 years of experience. Fryauf-Bertschy and coworkers[52] examined speech perception in cochlear-implanted children over 4 years, and noted significant increases in pattern perception and results of closed-set speech perception tests.

Variability in speech-perception performance across subjects is widely recognized, and is related to several variables, including age of implantation,[33,42,52-54] mode of communication,[43,55] family support,[52] and length of deafness.[56,57] Miyamoto and colleagues[40] found that duration of deafness, communication mode, age at onset of deafness, and type of processor accounted for approximately 35% of variance in closed-set testing. The length of implant use alone accounted for a larger percentage of variance on all speech perception measures. In a 5-year follow-up study, O'Donoghue and associates[53] found that age at implantation was the most significant covariant, and that mode of communication was the most significant between-individuals factor. The latter study showed that young age at implantation and oral communication mode are the most important known determinants of later speech perception in young children after cochlear implantation.

Waltzman and colleagues[43] and Brackett and Zara[58] reported improved speech reception in children implanted at age 2 to 3 years compared with children implanted at an older age. Multicenter data reported by Osberger and associates[59] indicated that implant performance of children implanted before age 2 years is significantly better than implant performance of children implanted between age 2 and 3 years. The authors also identified an important confounding variable, however, that exists in the children who receive a cochlear implant at a younger age: they are more likely to use an oral mode of communication. This, by itself, may be a predictor of higher implant performance—an observation borne out in early studies of a national childhood cohort assembled by Geers and colleagues.[55]

Osberger and coworkers[59] also found that children with more residual hearing relative to earlier cohorts were undergoing implantation. Gantz and colleagues[60] compiled data from across centers that indicate children with some degree of preoperative open-set speech recognition obtain substantially higher levels of speech comprehension. Taken together, these studies suggest the strongest potential for benefit exists with implantation at a young age, when intervention is provided early and, in the case of a progressive loss, before auditory input is lost completely.

Cheng and associates[33] performed a meta-analysis of relevant literature on speech recognition in children with cochlear implants. Of 1916 reports on cochlear implants published since 1966, 44 contained sufficient patient data to compare speech recognition results between published (n = 1904 children) and unpublished (n = 261) trials.[33] Meta-analysis was complicated by the diversity of tests required to address the full spectrum of speech reception in children with cochlear implants. An expanded format of the Speech Perception Categories[61] was designed to integrate results across studies. The main conclusions of this meta-analysis were that earlier implantation is associated with a greater trajectory of gain in speech recognition (Fig. 160-2), performance comparing deafness of congenital and acquired etiologies levels out over time, and there is an absence of reaching a plateau of speech recognition benefits over time. More than 75% of the children with cochlear implants reported in peer-reviewed publications have achieved substantial open-set speech recognition after 3 years of implant use.

Implantation of Infants

New diagnostic approaches and improved treatment options have enhanced real-life outcomes and transformed clinical approaches to the treatment of early-onset hearing loss. Universal newborn hearing screening now routinely identifies hearing loss that might have gone unnoticed in years past until a child had failed to develop language skills. Such early identification affords the opportunity to provide clinical intervention during a brief and critical growth period when neural connections develop physiologic support needed for children to achieve verbal communication.

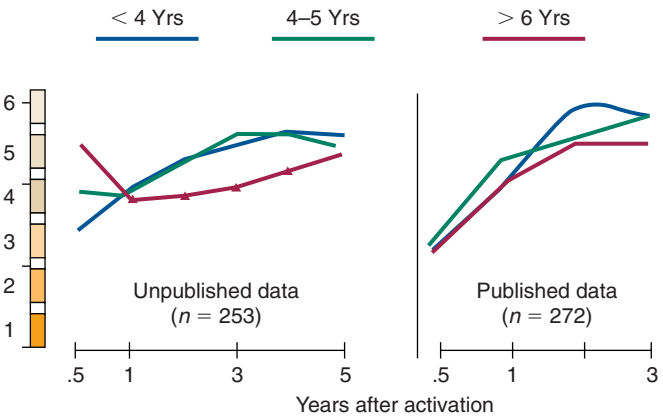

Figure 160-2. Meta-analysis of speech perception results with cochlear implantation in children, showing effects of age at implantation on speech perception. Published and unpublished data are shown. Three different ages at implantation groups are compared (<4 years, 4 to 5 years, and >6 years). The ordinal scale represents levels of speech perception: 1, detection; 2, pattern; 3, limited closed-set; 4, substantial closed-set; 5, limited open-set; and 6, substantial open-set.

A growing body of evidence supports the early application of cochlear implantation in congenitally deaf children. Meta-analyses of the effects of age at implantation have shown that children undergoing implantation at younger ages achieve greater progress in speech perception skills than children implanted at older ages.[33,62,63] Because the development of language follows the same trajectory as that reflecting speech perception, language growth is more favorable in children who receive cochlear implants early in life.[64] To the extent that higher language ability results in greater independence in school settings,[65] earlier intervention would enhance the cost-effectiveness of the cochlear implant.

Cochlear implantation has been shown to be a safe procedure in children younger than 12 months old.[66,67] The motivation to pursue implantation when a child has been deemed an appropriate candidate is supported by compelling data showing the benefits of earlier intervention. Tait and colleagues[68] showed that preverbal skills develop much more rapidly in children who receive cochlear implants before 2 years of age compared with children implanted between 2 and 3 years old, or between 3 and 4 years old. Connor and colleagues[69] examined latent growth curves and showed the value of very early implantation as it translated into more favorable outcomes. Dettman and colleagues[70] in Australia and Lesinski-Schiedat and associates[71] in Germany have convincingly shown with longitudinal assessment that the language trajectories of children implanted before age 12 months are greater than those achieved with implantation after 12 months of age.

Nicholas and Geers[72] showed that language outcomes for deaf children for whom appropriate intervention occurs within the first months of life are far superior to outcomes associated with later intervention. They noted that the first 3 years in a child's life are crucial for acquiring information about the world, communicating with family, and developing a cognitive and linguistic foundation from which all further development unfolds.

Because of the demonstrated safety of early implantation and the effectiveness of early linguistic intervention, cochlear implantation in younger children (12 months old) has been approved by the Food and Drug Administration in the United States. The current approval for implantation at age 12 months should be interpreted with caution. The intent of that approval is based on open market applications from manufacturers; delaying intervention results and the risk of prolonged auditory deprivation and adverse consequences for development should be weighed in each individual case.

Bilateral Cochlear Implantation

In an effort to expand the benefits obtained with unilateral cochlear implantation, bilateral implantation has been pursued in increasing

numbers of patients, either simultaneous or sequential. As of this writing, approximately 20% of all implant users have bilateral devices based on generally positive subjective experiences with low rates of complication. An important development within the field of cochlear implantation is to assess fully the impact of bilateral intervention.

Normal listeners possess a range of auditory capabilities owing to binaural processing, as follows:

Localization: Normal listeners are able to tell where sound is coming from in the horizontal plane (at ear level) with an accuracy of ±14 degrees.[73] The brain uses differences in intensity and time between the two ears to determine the location of a sound source. To localize sound in the vertical plane (up and down), or when time and intensity cues between the two ears are ambiguous, spectral (pitch) information is important.[74] The shapes of the outer ear and ear canal change the intensities of all of the pitches arriving at the ear (by reflecting them differently) to determine the location of sounds in the vertical plane.[75]

Head shadow: When listening to speech in noise, the head acts as a sound barrier that makes noise quieter on the side away from the speech. When one ear is close to the noise source, adding the other ear (away from the noise) provides a second ear where the speech is louder than the competing noise.

Squelch: When signals and noise come from different directions, the brain is able to separate them by comparing time, intensity, and pitch differences between the two ears. The practical effect is that the brain is able to suppress signals that the listener does not wish to hear.

Summation: When identical signals are presented to the two ears, there is an advantage when hearing with both ears instead of just one alone. The brain has a special ability to use the signals from both ears to produce this binaural advantage.

Studies of subjects with unilateral hearing loss illustrate some of the problems that a listener with only one "good" ear may encounter. Background noise often interferes with word recognition in quiet and noisy conditions even when the speech is directed to the good ear. People have reported difficulty hearing and understanding speech even in relatively quiet situations that include low-level noise (e.g., car radios, air conditioners).[76] Children with unilateral hearing loss not only have difficulty in noise,[77] but also show delays in language development and academic performance relative to their peers with normal hearing.[78]

In addition to the general advantages of binaural hearing, there may be other compelling reasons for considering bilateral implantation in very young children. Congenitally deaf children depend on their cochlear implants for learning spoken language. Children with normal hearing acquire language through incidental learning—that is, through participation in everyday communication and social experiences, which are often unintended and incidental. Although studies have shown improved language acquisition in children with unilateral implants relative to their preimplant performance with hearing aids,[64,79] children still lag behind their peers with normal hearing in mastery of more complex language structures that are requisites for academic success.[80] If a young deaf child has two implants, the rate of incidental language learning is likely to be accelerated because they would be better able to understand speech in everyday situations (most of which are noisy), and to localize to the most relevant (speech) events in their environment. The improved benefits with bilateral implants in young deaf children have important implications for language acquisition, academic success, and educational and occupational opportunities.

Providing sound input to both ears in a young deaf child ensures that sound is processed on both sides of the brain. The right and left auditory cortices can develop in a more normal sequence. If a child is implanted on only one side, the parts of the brain that would have been stimulated by the nonimplanted ear do not develop, and eventually plasticity is greatly diminished. Ryugo and colleagues[81] reported that electric stimulation of the auditory system largely prevents or reverses the synaptic abnormalities seen in congenitally deaf white cats.

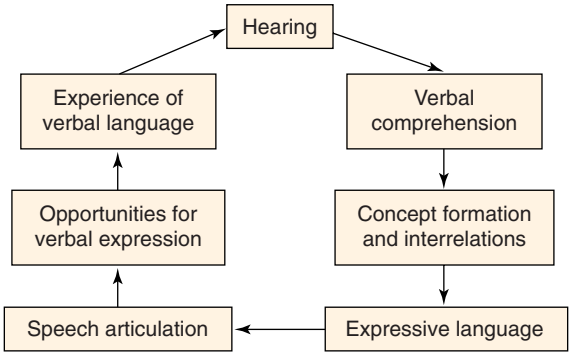

Figure 160-3. The cycle of verbal communication. Hearing is crucial to the process of verbal communication and allows for verbal comprehension. Concept formation gives rise to expressive language and speech articulation capabilities, which are applied as verbal language in appropriate situations. Successful verbal communication ultimately depends on hearing. *(Modified from the Reynell Developmental Scales Manual. Los Angeles: Western Psychological Services.)*

Reports of the bilateral benefits experienced by adult and pediatric patients with two implants continue to increase.[82-91] There are few prospective studies of children who receive two implants during early childhood, however.

Although the "era of bilateral implantation" has been introduced, there are few controlled trials to date.[92] Preliminary results reveal evidence of an expanded sound field and loudness summation, and some level of sound localization ability to most bilateral recipients. In a few patients, benefits attributable to effective squelch are noted. Such findings show central integration of electric stimulation from the two ears despite an absence of precise tonotopic matching of binaural inputs. Systems that enable integrated speech processing of inputs from the bilateral sound fields have yet to be introduced clinically. It is uncertain whether potential benefits of bilateral implantation could be expanded through such processing.

Language Development in Children

A primary goal of implantation in children is to assist comprehension and expression through the use of spoken language. Language is defined as a vehicle for shaping and relating abstractions for communication.[93] The meaning of language-mediated abstraction is independent of the immediate situation. Practical use of language is based on the assignment of a single name to various appearances and situations under varying conditions. Information exchange via spoken language involves a conversion of thought into speech. This conversion relies on mental representations of phonologic (sound) structure and syntactic (phrase) structure.

All fundamental models of language development propose that the acquisition of language is the result of progressive organization from an initially undifferentiated state. As incremental differentiation occurs, language skills become more sophisticated and hierarchically integrated. The child first must learn to form internal representations of acoustic speech patterns (Fig. 160-3). These experiences enable a child to identify consistent patterns in phonologic inputs and to develop associations between context and semantic and syntactic patterns. Through increased familiarity, these associations between spoken language and their actual counterparts build a child's semantic awareness.[94] Social cognition and emotional needs are likely to encourage such development, as supported by observations that infants become "tuned" to their language environment in the form of "perceptual maps" (Fig. 160-4),[95] and show protolinguistic behaviors with caretakers that are bidirectional.[96-98]

Early communication between infants and caregivers forms a critical foundation for development. This foundation provides a base on which cognition, affect, and social interaction may evolve.[99] If communication is hindered, development fails to proceed normally, with

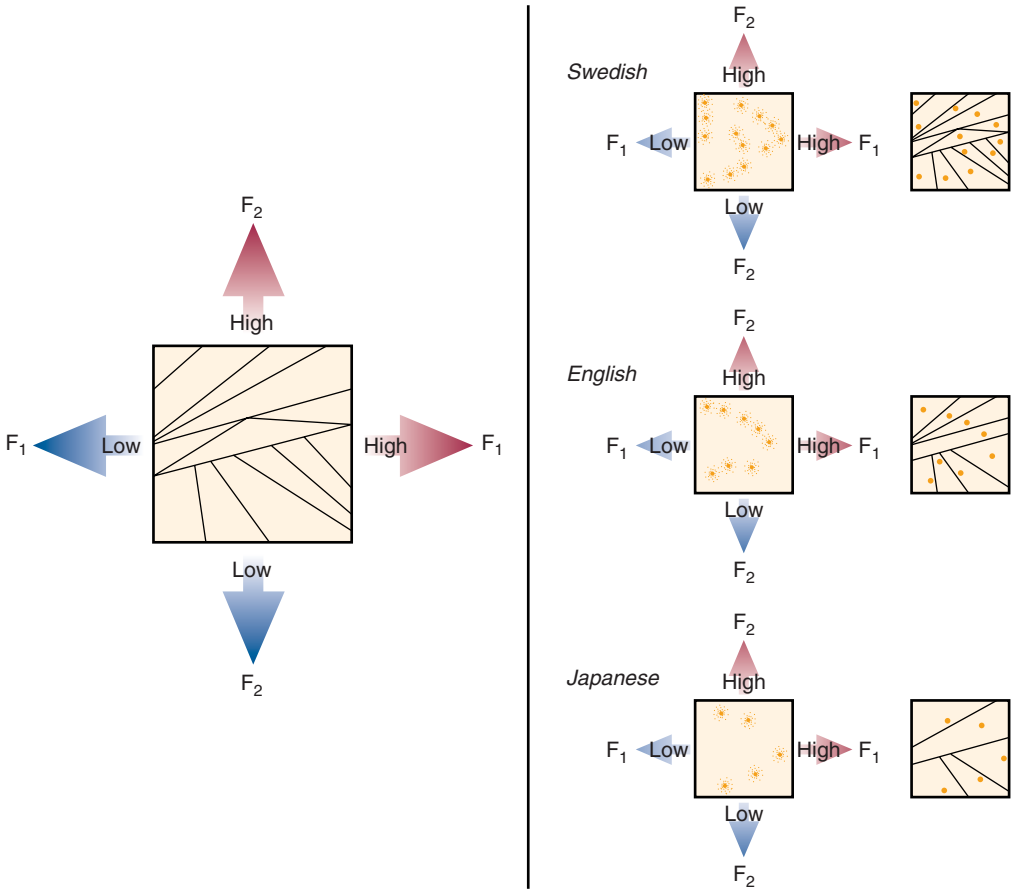

Figure 160-4. *Left,* Schematic figure shows natural auditory boundaries according to F_1 and F_2 formant frequencies. These boundaries are thought to provide a framework by which infants process incoming sound streams into gross categories. Intrinsic phonetic differences separate boundary regions from one another. *Right,* The ability to partition auditory input according to these boundaries is independent of linguistic experience, and is present throughout various languages. Examples of vowel processing in three different languages (Swedish, English, and Japanese) are shown. *(Adapted from Kuhl PK, Meitzoff A. Speech as an intermodal object of perception. In: Yonas A, ed. Perceptual Development in Infancy. Hillsdale, NJ: Lawrence Erlbaum Associates; 1988:235-266; and Kirk KI. Challenges in the clinical investigation of cochlear implant outcomes. In: Niparko JK, ed.* Cochlear Implants: Principles and Practices. *Philadelphia: Lippincott Williams & Wilkins; 2000:225-259.)*

detrimental sequelae in terms of cognitive, behavioral, and social development. Hearing loss and subsequent obstacles to communication threaten optimal development.[100-102] Because most children who have sensorineural hearing loss are born to hearing parents, a "mismatch" may exist between child and parent[103] that prevents effective communication.[104,105] Because sign language skills in hearing parents tend to be absent or basic, such children are at further risk for developmental delay.[106,107] Additional evidence confirms that children with sensorineural hearing loss who engage in linguistic interactions with their parents show age-appropriate cognitive, social, and behavioral development.[100] More recent theories suggest the processes linking language to cognition, affect, and behavior are dynamic and bidirectional, rather than discrete or independent.[108,109]

For successful bidirectional communication to occur within the family unit, language must be linked to cognition, affect, and behavior. Visual attention, which may be reliably assessed at 4 months of age, is crucial for guiding development.[99,110] Data suggest that visual attention is highly relevant to the development of emotional bonds to caregivers, language learning, and the processing of perceptual information.[111-114] In normal development, much of this early visual attention is actually directed by sound. Infants look longer in the direction of sound and longer at visual events whose temporal rhythms match what they hear.[115,116] When sound perception is impaired, visual and auditory integration is similarly disrupted, forcing a child with sensorineural hearing loss to rely on vision for communication and cues about when and where to direct attention.[117,118] This notion has been confirmed in studies of hearing-impaired children using computerized task performance measures.[117,119,120] These impairments have been found to contribute to behavioral problems.[120] By comparison, two studies found that children with cochlear implants perform better on this computerized task than children without cochlear implants.[117,119]

In addition to visual attention, other types of preverbal communication underlie the acquisition of verbal language. Substantial gains in prelinguistic behaviors, including eye contact and turn-taking,[121] and in verbal spontaneity[122] are observed as early correlates of implant benefit, developing within 6 months of implantation in young children.[123] Tait and associates[124] found that preverbal measures obtained 12 months after implantation are predictive of late performance on speech perception tasks. They observed a significant association between the preverbal measure of "autonomy" obtained before implantation and later speech perception performance. This latter finding has important theoretic implications for understanding of language development, and suggests that intervention that promotes autonomy in adult-child interaction may lead to improved outcomes. Such intervention can be introduced as soon as deafness is discovered.

Language Acquisition in Children with Cochlear Implants

By improving auditory access, cochlear implants augment sound and phrase structure. Although difficult to characterize, benefits in receptive language skills and language production after implantation are the crucial measure by which effectiveness of implants in young children should be assessed. One approach is to compare language performance on standardized tests. The Reynell Developmental Language Scale evaluates receptive and expressive skills independently.[125] These scales

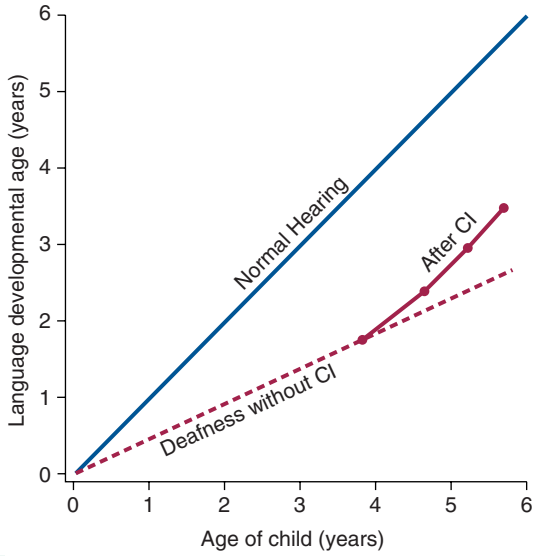

Figure 160-5. The effect of cochlear implantation (CI) in children on language development. *Solid line* depicts normal language development as it correlates to chronologic age. *Dashed line* shows the developmental delay that occurs in deafness before CI. After CI, language development progresses at the same rate as children with normal hearing. This suggests that language delay is a product of cumulative deficits acquired before CI, rather than from impaired progress after CI. *(Modified from Svirsky MA, Teoh SW, Neuburger H. Development of language and speech perception in congenitally, profoundly deaf children as a function of age at cochlear implantation.* Audiol Neurootol. *2004;9:224-233.)*

have been normalized on the basis of performance levels of hearing children in an age range of 1 to 8 years, and have been used extensively in populations of deaf children. Although deaf children without cochlear implants achieved language competence at half the rate of normal-hearing peers, implanted subjects exhibited language-learning rates that matched, on average, those of their normal-hearing peers.[125,126] In a study of 23 children who became deaf before 3 years of age, Svirsky and colleagues[126] studied language development after cochlear implantation. The average age of implantation in this cohort was approximately 4 years. These investigators found that speech development progressed at a decreased rate before implantation, but that after implantation, language development in implanted children was parallel to that of normal-hearing children (Fig. 160-5). The implication of this study is that differences in language delay between implanted and normal-hearing children could be explained by the initial period of deafness before implantation, rather than performance or progress after implantation. These findings also emphasize the importance of early implantation. Data are rapidly being gathered to confirm that earlier implantation might limit early language delays to enable more age-appropriate language acquisition.

Robbins and associates[125] noted that implantation improved language-learning rates for children in oral communication and total communication settings based on the Reynall Developmental Language Scale. Geers and coworkers,[55] also assessing language skills in implanted children enrolled in oral communication and total communication settings, found that the groups did not differ in language level, although the oral group showed significantly better intelligibility in their speech production.

Delays in receptive and expressive language among hearing-impaired children have consistently been documented in the literature, although such delays are not strongly related to degree of hearing loss.[127,128] Performance on language measures can be influenced by the child's mode of communication such that results may not directly reflect the influences of auditory perception or prosthetic intervention. Clinical findings support the hypothesis, however, that some deaf children are able to use the acoustic-phonetic cues provided by the implant in ways that may reduce the language gap between normal-hearing and deaf children.

Central nervous system processing is a primary determinant of the level of verbal language ultimately attained after cochlear implantation.[129] Pisoni[129] assessed performance in two groups of pediatric cochlear implant users: "Stars" were children whose phonetically balanced kindergarten scores placed them in the top 20%. The second group, children with scores in the bottom 20%, comprised the control group. Speech perception, spoken word recognition, speech intelligibility, and language level were compared between the two groups at preimplantation and at yearly postimplant intervals. Children in the "Stars" group did not score consistently better on all behavioral measures than children in the control group. Differences between the groups were manifest only on specific tests and task demands. Children with superior implant performance were consistently better on measures of speech perception (i.e., vowel and consonant recognition), spoken word recognition, comprehension, language development, and speech intelligibility than were the control children. The two groups did not differ, however, in their vocabulary knowledge, nonverbal intelligence, visuomotor integration, or visual attention. It was concluded that "Star performance" on measures of spoken language processing and speech intelligibility was not attributed to global differences in overall performance, but to differences specifically in the task of processing auditory information provided by the cochlear implant.

The authors also examined the differential performance on various behavioral tests of communicative ability administered after 1 year of cochlear implant use. Strength of correlation revealed a significant association between spoken word recognition, language development, and speech intelligibility for the "Stars" group, but not for the control group. "Star performance" seemed to result from an enhanced language processing ability and the development of phonologic and lexical representations.

The strong relationship between spoken word recognition and speech intelligibility for superior implant performers suggests that (1) a transfer of knowledge exists between speech perception and production, and (2) that speech perception and production share a common system of internal representation. According to Pisoni and Geers,[130] the exceptional performance of the "Stars" seems to be a result of their superior abilities to perceive, encode, and retrieve information about spoken words from lexical memory. They described the capacity for processing tasks that require the manipulation and transformation of the phonologic representations of spoken words as "working memory." Pisoni and Geers[130] then investigated the impact of working memory on measures of speech perception, speech intelligibility, language processing, and reading in implanted children with prelingual deafness. The investigators evaluated correlations between children's ability to recall lists of orally presented digits and their performance on these measures. The authors observed correlations between auditory memory and performance in each outcome area, suggesting that working memory plays an important role in mediating performance across these higher communication tasks.[130]

Promising clinical studies have generally supported wider application of cochlear implants in children. Childhood implant research has often relied, however, on case-series design, based in a single center that evaluated children who used different generations of implant technology. Few studies have examined the impact of cochlear implants on the "whole" child, particularly when one considers the importance of understanding longitudinal measures of cognitive, social, and behavioral development. There is also little information available on the perceived benefit of childhood implantation from a perspective of cost-effectiveness.

The need and significance of this information is underscored by the fact that clinical decisions to pursue early cochlear implantation are often prompted by parental choice. Parents of deaf children choose among options which have vastly different implications for the use of medical, (re)habilitative, educational, and other societal resources. A pressing issue concerns the validity of generalizing from early observations of benefit from cochlear implantation to the decision to implant younger children. Should very young infants identified with severe to profound sensorineural hearing loss undergo cochlear implantation within weeks of diagnosis?

An ongoing multicenter study is examining the clinical modifiers of postimplant developmental outcomes, including oral language acquisition, speech recognition skills, selective attention and problem-solving skills, behavioral and social development, parent-child interactions, and quality-of-life measures in children undergoing implantation in six U.S. implant centers.[131] It is hoped that a detailed assessment of communicative and psychosocial results will contribute to an understanding of the factors predicting implant-associated language use, communication competence in early childhood, and the perceived value of early cochlear implantation in light of associated costs. It is hoped that conclusions will enable an informed approach to implant candidacy when considering (re)habilitative strategies designed to enhance developmental learning in children with severe to profound sensorineural hearing loss.

Outcomes after Cochlear Implantation

Educational Placement and Support of Implanted Children

A hearing-impaired child is at substantial risk for educational underachievement.[132,133] Educational achievement by a hearing-impaired child can be enhanced by verbal communication. Traditional methods of speech instruction are more successful with children who have enough residual hearing to benefit from early devices of hearing rehabilitation.[134] Improved speech perception and production provided by cochlear implants offer the possibility of increased access to oral-based education and enhanced educational independence.

Francis[135] and Koch[136] and their colleagues tracked the educational progress of implanted children by using an educational resource matrix to map educational and rehabilitative resource use. The matrix was developed on the basis of observations that changes in classroom settings (e.g., into a mainstream classroom) are often compensated by an initial increase in interpreter and speech-language therapy. Follow-up of 35 school-aged children with implants indicated that, relative to age-matched hearing aid users with equivalent baseline hearing, implanted students are mainstreamed at a substantially higher rate, although this effect is not immediate, and requires rehabilitative support to be achieved. Within 5 years after implantation, the rate of full-time assignment to a mainstream classroom increases from 12% to 75% (Fig. 160-6).

Quality of Life and Cost-Effectiveness

Prior studies of the cost-utility of cochlear implants have assessed quality of life and health status to determine the utility gained from cochlear implants.[19,137,138] *Utility* is a concept that reflects the true value of a good or service. Cost-utility methods determine the ratio of monetary expenditure to change in utility as defined by a change in quality of life over a given period. The assessment of cost-utility is based on the following:

$$\text{Cost-utility} = \text{costs (in \$)}/(\text{quality-adjusted life-years})$$
$$= \text{costs (in \$)}/(\text{life-years} \times \text{health utility})$$

Life-years is the mean anticipated number of years of implant experience based on a life-expectancy analysis of the participating cohort. The change in health utility reflects the difference between preimplant and postimplant scores on survey instruments that have been designed and validated to reflect quality of life. In the United States, England, and Canada, health interventions with a cost-utility ratio less than $20,000 (U.S.) are generally considered to represent acceptable value for money expended (i.e., they are "cost-effective").[139-141]

Quality-of-Life Studies in Adults and the Elderly

Costs per quality-adjusted life-year (QALY) for cochlear implants in adult users were determined using cost data that account for the preoperative, postoperative, and operative phases of cochlear implantation.[19,138] Benefits were determined on the basis of functional status and quality of life. The precise cost-utility results varied among studies, mostly because of methodologic differences in the determination of benefit, level of benefit obtained, and differences in costs associated with the intervention. Nonetheless, these appraisals consistently indicated that the multichannel cochlear implant in adult populations is associated with cost-utility ratios in the range of $14,000 to $18,000/QALY, indicating a highly favorable position in terms of cost-effectiveness (Table 160-1).

†Patient rating of health utility before implantation.

HUI, Health Utilities Index; QWB, Quality of Well-Being Scale; VAS, Visual Analog Scale.

Hearing impairment is one of the most common clinical conditions affecting elderly individuals in the United States.[142] Hearing loss is so profound in 10% of elderly hearing-impaired individuals that little or no benefit is gained with conventional amplification.[143] Assessing the effectiveness of cochlear implants in elderly patients requires consideration of audiologic and psychosocial factors. The social isolation associated with acquired hearing loss in elderly individuals[144] is accompanied by a significant decline in quality of life and an increase in emotional handicap.[145] The rehabilitation of hearing loss is an important goal in this vulnerable population, providing functional and psychologic contributions to quality of life.

Age-related degeneration of the spiral ganglion[146,147] and progressive central auditory dysfunction[148,149] raise potential concerns about the efficacy of cochlear prostheses in the elderly. Comparable gains in speech understanding have been reported for elderly and younger groups of implant recipients,[150] but the implications of these functional gains on the quality of life of older adults have not been well characterized. The determination of auditory efficacy and quality of life is crucial to any cost-benefit analysis in elderly patients, and may help guide clinical resource allocation, particularly in light of the high costs associated with cochlear implantation as a nonlifesaving intervention.

Reports of quality of life gains in elderly patients with cochlear implants have been favorable,[151-153] but are based on questionnaires that are difficult to correlate with function and cost-utility. Francis and colleagues[151] evaluated 47 patients with multichannel cochlear implants, 50 to 80 years old, who completed the Ontario Health Utilities Index Mark 3 (HUI3) survey and a quality-of-life survey. This study assessed preimplantation and postimplantation (6 months and 1 year after implantation) responses to questions related to device use and quality of life. A significant mean gain occurred in health utility of 0.24 (SD 0.33) associated with cochlear implantation ($P < .0001$) (Fig. 160-7). Improvements in hearing and emotional health attributes were primarily responsible for this increase in health-related quality-of-life measure. A significant increase occurred in speech perception scores at 6 months after surgery ($P < .0001$ for Central Institute for the Deaf sentence and monosyllabic word tests), and there was a strong correlation between the magnitude of health utility gains and postoperative enhancement of speech perception ($r = 0.45$, $P < .05$). Speech perception gain was also correlated with improvements in emotional status and the hours of daily implant use. The authors concluded that cochlear implantation has a statistically significant and cost-effective impact on the quality of life of older deaf patients.

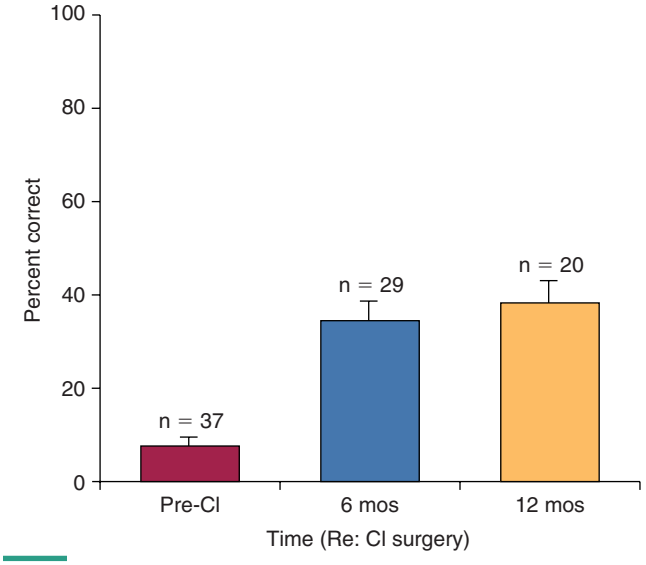

Figure 160-7. Mean monosyllabic word scores obtained in older adult subjects with postlingual hearing impairment just before cochlear implantation (CI) and at 6 and 12 months afterward (error bar = 1 SE). Monosyllabic word scores, which are generally considered one of the most difficult tests of speech perception, clearly increase during the first year after CI.

Quality-of-Life Studies in Children

Published cost-utility analyses of the cochlear implant in children have been limited by using either health utilities obtained from adult patients[19,139,154] or hypothetically estimated utilities of a deaf child.[155-158] These studies yielded cost-utility ratios that spread over a wide range ($3141 to $25,450/QALY). Utility assessments derived from adult patient surveys may not capture the impact of issues unique to childhood deafness.[33] To address this issue more rigorously, Cheng and coworkers[137] surveyed parents of a cohort of 78 children (average age 7.4 years, with 1.9 years of cochlear implant use) who received multichannel implants at the Johns Hopkins Hospital to determine direct and total cost to society per QALY. Parents of profoundly deaf children

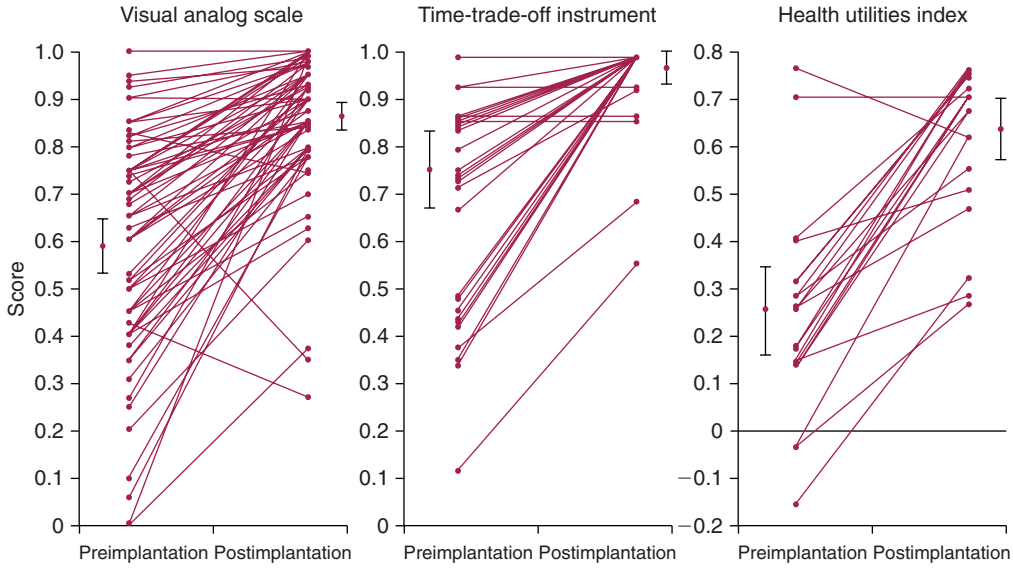

Figure 160-8. Retrospective health utility scores from parents of children with cochlear implants. Three different methods of assessing health utility scores are shown. The mean change in utility (postintervention—preintervention scores) was 0.27 for the visual analog scale, 0.22 for the time-trade-off instrument, and 0.39 for the health utilities index. The error bars on the side of each graph show mean scores with 95% confidence intervals.

($n = 48$) awaiting cochlear implantation served as a comparison group to assess the validity of recall. Using the Time-Trade-Off (TTO), Visual Analog Scale (VAS), and HUI3, parents rated their child's health state "now," "immediately before," and "1 year before" the cochlear implant. Mean VAS scores increased 0.27 on a scale of 0 to 1 (from 0.59 to 0.86), TTO scores increased 0.22 (from 0.75 to 0.97), and HUI scores increased 0.39 (from 0.25 to 0.64) (Fig. 160-8). Discounted direct medical costs were $60,228, yielding cost-utility ratios of $9029/QALY using the TTO, $7500/QALY using the VAS, and $5197/QALY using the HUI3. Including indirect costs, such as reduced educational expenses, the cochlear implant yielded a calculated net savings of $53,198 per child. Based on assessments of this cohort from a single center, childhood cochlear implantation produces a positive impact on quality of life at reasonable direct costs and results in societal savings.

The educational resource matrix used by Francis[135] and Koch[136] and their colleagues offers a basis for assessing overall cost-benefit ratios of the cochlear implant in children. Although educational costs for all implanted students remain static or initially increased, ultimate achievement of educational independence for most implanted children produces net savings that range from $30,000 to $100,000 per child, including the costs associated with initial cochlear implantation and postoperative rehabilitation. Language-related and education-related outcomes in children with cochlear implants have been supplemented with parental perspectives of quality-of-life effects to yield cost-utility ratings.[137,154] Despite conservative assumptions, results show that cochlear implantation is, relative to other medical and surgical interventions, highly cost-effective in profoundly hearing-impaired young children.

Auditory Rehabilitation after Cochlear Implantation

The uniqueness of the listening experience enabled by a cochlear implant is underscored by qualitative differences in how sound perception is elicited compared with other strategies of auditory rehabilitation. A hearing aid filters, amplifies, and compresses the acoustic signal, delivering a processed signal to the cochlea for transduction. In contrast, a cochlear implant receives, processes, and transmits acoustic information by generating electric fields. Electric hearing bypasses nonfunctional cochlear transducers by directly depolarizing auditory nerve fibers. Implant systems convey an electric code based in selected features of speech that are crucial to phoneme and word understanding in normal listeners, without the advantages of signal preparation provided by cochlear mechanisms of sound processing that render complex sounds listenable and discriminable. The listening experience with the cochlear implant also differs from normal audition in the timing of when that experience begins.

Either through a process of learning in the early, formative years in children, or by virtue of "auditory memory" in adults, capabilities for meaningful listening develop for most implant recipients. A central clinical question relates to the potential benefit to be derived from dedicated sensory training, commonly referred to as "auditory training." Can such training enable a cochlear implant user to apply latent skills and adaptive strategies to listening tasks that offset deprivation effects and the limitations of cochlear implant listening to capitalize on the device capabilities?

Exposure to conversational speech likely provides insight otherwise unavailable. Language learning may be too complex to be acquired using didactic methods alone. Consistent, frequent exposure may offer the greatest prospects of refining oral language skills. Through tracking the temporal, spectral, and intensity parameters of sound, the cochlear implant provides cues of voicing and articulation patterns that are not visually detectable. For deaf children who experience difficulty in developing their language skills, the possibilities afforded by early implantation, before the onset of changes consequent to deafferentation, seem to be substantial. The best method of achieving such outcomes are yet to be determined, however.

Efficacy of Auditory Training in Cochlear Implant Rehabilitation

Auditory training that provides real-world utility to restored audition in implant recipients is necessarily highly individualized. That is, the goals for a patient's auditory, speech, language, and cognitive development rely on a host of influences unique to the individual. Because of the need for such an individualized approach, studies of treatment efficacy of auditory training with high internal validity are difficult to construct. Carney and Moeller[159] noted that earlier efficacy studies target specific treatment areas of perceptual skill development, language development, speech production, academic performance, and social-emotional growth. Treatment goals within various treatment areas often vary, limiting the ability to assess the impact within any single category.

Prior studies have systematically assessed the development of speech perception with training in implant listeners. Watson[160] noted

that studies of the perception of complex nonspeech sounds have shown that individual parts of spectral-temporal waveforms can become more salient through selective training. One consequence of training is that the same sound can be perceived quite differently, depending on earlier experience as it affects a listener's expectancy and the psychologic mindset brought to the task. The time course of learning to identify initially unfamiliar speech sounds by normal-hearing listeners extends through months, possibly even years, before reaching a stable level of performance. If implant users are required to learn to interpret sounds as unfamiliar to them as the nonspeech sounds used in research are to normal-hearing listeners, a similar lengthy experience may be required to reach a plateau of maximum performance. Why this has not been the case in some clinical studies is a puzzle.

Watson[160] offered an explanation in that speech perception may depend heavily on abilities other than sensory acuity or tonal resolution. Studies of individual differences in auditory temporal and spectral acuity have not shown strong correlations between individual differences in those abilities and individual differences in speech perception. It is argued that one way to interpret this observation is that differences in the ability to hear speech (as by two hearing-impaired listeners with the same audiogram) may be the result of differences in the way in which central pathways generate the ability to infer an original stimulus from its fragments.

Dawson and Clark[161] tested whether the ability to use place-coded vowel formant information would be subject to training effects in a group of congenitally deafened patients with limited speech perception ability. They investigated the relationship between electrode position difference limens and vowel recognition. Young subjects were assessed with synthesized versions of the words "hid," "head," "had," "hud," "hod," and "hood." Performance during a nontraining period was compared with the change in performance after 10 training sessions. Two of four subjects showed significant gains, and improvements were consistent with their electrode discrimination ability. Difference limens ranged from one to three electrodes for these patients, and for two other patients who showed minimal to no improvements. Minimal gains shown by one subject could be partly explained by poorer apical electrode position difference limen. The authors concluded that significant gains in vowel perception occurred after training, and suggested the need for children to continue prolonged aural rehabilitation for a period after implantation. Despite intensive efforts, minimal improvements can sometimes occur, however, and such limited success is not always accounted for by limitations at the level of the auditory periphery.

Svirsky and coworkers[162] examined two possible reasons underlying longitudinal improvements in vowel identification by cochlear implant users: improved labeling of vowel sounds and improved electrode discrimination. Improvements in vowel identification were attributed to improved labeling, suggesting cortical learning effects were responsible for the observed changes, as opposed to enhanced electrode discrimination.

Rehabilitation in Adults with Cochlear Implants

After implant activation, adult users must adjust to the novel signals transmitted by the speech processor. Recipients must learn to associate electrically elicited sound patterns with perceptions that were previously meaningful sound sensations. Rehabilitative needs differ in implant recipients depending on their auditory experience before the onset of deafness. For a prelinguistically deafened implant recipient, auditory and speech (articulation) training are crucial in facilitating communication change. For a postlinguistically deafened patient, auditory training often focuses on more complex listening skills—understanding speech in noise, telephone use, and music appreciation.[163]

Auditory Training in Children with Cochlear Implants

Programs of auditory training in children with implants are often organized with a hierarchic approach by which the child learns to associate meaning with unfamiliar and possibly unnatural sounds.[122,164] After showing awareness of sounds (detection), the child is taught to determine whether sounds are the same or different (discrimination), to recognize sounds and to associate meaning with them (identification), and to respond appropriately in verbal discourse (comprehension). Expressively, the child learns to imitate phonemes and syllables and to coarticulate these sounds to produce progressively more difficult words and phrases. Imitation or approximation of speech sounds and words is a strategy used for developing an "auditory feedback loop"—the interrelated function of perception of sound and production of speech. Functional use of spoken language depends on the child's ability to produce meaningful linguistic utterances spontaneously. This process begins with a single word and progresses through sequential stages to complex phrases and entire stories.[165] Boothroyd[166] stressed the need for flexibility in guidelines for therapy sessions, noting that "the structure needs to exist in the mind of the teacher, and not be so obvious in the activities done with the child."

Boothroyd and colleagues[167] provided a model of auditory development that highlights the time course of development and identifies component skills that are crucial to effective auditory perception in children. They defined auditory perception as the interpretation of sensory evidence that is derived from sound and is reflective of objects and events that caused the sound. Similar to other perceptual events, auditory perception involves not only sensory evidence, but also contextual evidence, prior knowledge, memory, attention, and processing skills. Auditory speech perception is special because the events to be perceived are those of language. Similarly, the listener's knowledge base and processing skills must include those related to language in general and to spoken language in particular.

The normal auditory system is complete and functional at birth, but myelination continues for several years in the higher auditory pathways. Correspondingly, infants display increasingly sophisticated discrimination and recognition ability. Psychoacoustic performance does not reach adult levels for several years, however. Infants at 6 months of age show the beginnings of phonemic classification. Their capacity of performance improves during childhood, including phonetic contrast perception, phoneme recognition, perception of speech in noise, selective attention, and the use of linguistic context. Because experience plays a key role in the development of the knowledge and skills required for auditory perception in general, and for auditory speech perception in particular, intensifying that experience in hearing loss and with prosthetic devices is theoretically attractive.

Boothroyd and colleagues[167] noted that it is tempting to assume that the sensory evidence available to a developing child is determined only by the functional integrity of the peripheral auditory system, independent of auditory experience. Basic science investigations document the influence of auditory experience on the organization of auditory pathways,[168] however, and observe that better organization through experience could increase the sensory evidence made available from patterns of neural excitation produced in the cochlea.

Cochlear implants provide profoundly deaf children with a level of hearing sensitivity that enables them to perceive most of the sounds of spoken language, even when presented at low levels of intensity. Rehabilitative practices are designed to build on this level of sound awareness. In the case of a child who developed an audition-based language system before the onset of deafness, the cochlear implant restores access to spoken language—in many cases with expanded phonemic access. In the case of children who have never heard or who lost their hearing before the establishment of spoken language, access to sound provided by the cochlear implant initially lacks meaningful associations.

Current cochlear implant technology also provides the potential for deaf children to make use of generalization and incidental learning. Benefits of "hearing" extend well beyond contexts of one-on-one repartees with predictable discourse. Age of onset, degree of hearing loss, and amplification history[47] determine the quantity and quality of auditory stimulation received before implantation and readiness to interpret acoustic information. A child experienced in using residual hearing from an early age through amplification is likely to adapt to the sounds provided by the implant more quickly than a child with limited experience in listening.[167] The close scrutiny afforded by regular interaction with an auditory training therapist allows for the early detection of either the need for device reprogramming or failure of components of the implant system.

Components of auditory training in children with cochlear implants are designed to foster the development of auditory and speech skills in a manner that simulates a hearing child's acquisition of spoken language, while addressing remedial needs that arise as a consequence of auditory deprivation during early development.[169] Rehabilitative strategies related to auditory, speech, and language skills should seek to achieve overall communicative competence.[50] Ideally, rehabilitative strategies do not teach specific, isolated auditory, speech, or language subskills. Because subskills are only a means to an end that is multimodal communicative competence, training in any one individual subskill should not be given too much weight. Programs are most effective when they take an integrated approach to rehabilitation and avoid rote, drill-oriented approaches.

Maintenance of the Device

An important role in developing auditory skills and using a cochlear implant successfully is maintenance of the device itself.[155,156] This maintenance includes keeping all external parts in good functioning order, and working with an audiologist who specializes in cochlear implants on a regularly scheduled basis for device programming. In most cochlear implant centers, the audiologist serves as the case manager for the patient during the cochlear implant candidacy process and postimplantation.

Programming the device requires software and hardware from the cochlear implant manufacturer. For an adult patient, programming the cochlear implant involves numerous perception judgments, such as threshold of hearing, loudness level, loudness balancing, and in some cases pitch ranking. The patient's hearing history can determine the ease or difficulty of these tasks. Other factors, such as tinnitus, can come into consideration when establishing threshold levels of hearing with an electric stimulus. These measurements are necessary to program a patient's dynamic range of hearing with the cochlear implant. These settings are individual and can vary from patient to patient. The program that is saved to the external components is referred to as the cochlear implant map. Changes in the stimulus levels are most frequently seen in the initial stages of activation of the device. Many appointments are involved in the activation process to keep up with the physiologic changes involved with an individual learning to hear with the electric input. Through time, the stimulus levels become more stable, and primarily fine-tuning adjustments are made. Little research is available to explain the physiologic changes that induce needed map changes. Anecdotal reports are available that also suggest various program changes are needed when the patient is undergoing hormonal changes, such as pregnancy, puberty, or menopause.

If the patient is unable to participate in the judgments needed to create a cochlear implant map, some objective measures may be used. Cochlear implant manufacturers have created software that can measure an electrically evoked compound action potential through the cochlear implant: Neural Response Telemetry (NRT), by the Cochlear Corporation of Englewood, Colorado (manufacturer of the N24 device), and Neural Response Imaging (NRI), by the Advanced Bionics Corporation of Sylmar, California (manufacturer of the Clarion/Hi-Res devices). NRT measures are found at levels between threshold and maximal comfort in an individual's map. Limitations exist when using these measurements.[170,171] Although direct nerve responses seem to have value in some populations, behavioral testing is the tried and true method of programming.

Another objective measurement that has been previously used in device programming is electric acoustic reflex thresholds. Studies have found that the electric acoustic reflex threshold highly correlates with comfort levels on a cochlear implant map.[172,173] These measurements are not present in all patients, however, so this option may not always be available. If the reflex is measurable, this can provide valuable information for the audiologist when programming a child. Some children have high tolerance levels for the electric stimulus and do not react negatively if the map is created using inappropriately high levels. If the cochlear implant program is too loud, it can prevent the child from developing auditory skills or responding appropriately.

Audiograms may also be used to check the validity of a cochlear implant map. Using the audiogram has limitations, however, when determining the integrity of a cochlear implant program. The audiogram is going to show the patient's responses to the perception of soft stimuli. It does not tell you, however, whether the program is at an appropriate comfort level, or whether the sound quality of the map is good. Most cochlear implant audiograms are in the 20- to 30-dB range. It is possible to have a good audiogram with inappropriate map settings in the external device. A strength of the audiogram is that it can flag equipment malfunction or gross changes needed in the cochlear implant settings.

Intensive follow-up is required for successful outcomes after cochlear implantation. The adult cochlear implant patient should have his or her external devices reprogrammed at least annually. Pediatric patients should, at a minimum, come on a biannual basis. Many children are seen more frequently than a twice a year if any questions arise on how their listening skills are developing, and to ensure that their devices are programmed appropriately. Regularly scheduled program checks also offer an opportunity for the audiologist to track the development of the patient's speech understanding scores using the MSTB protocol explained previously. Conducting speech perception measures at regular intervals can provide the cochlear implant audiologist or therapist with valuable information on what the patient is hearing and understanding. This information can be used to change the patient's map or as an indication of where to focus therapy goals. Also, if the patient reports a sudden change in performance, this change can be documented by showing a decrease in speech perception abilities. This documentation validates the patient's concerns and assists the audiologist and therapist to help return the patient to baseline functioning.

The cochlear implant should not be considered a "fix" for severe to profound hearing loss. This device requires intensive rehabilitation to use it effectively and requires regular follow-up and maintenance. Although the learning process with the cochlear implant seems complex and unpredictable, the cochlear implant can provide an opportunity for deaf individuals to hear sounds that would never be possible with conventional amplification. This is especially true for deaf children, who can use the cochlear implant as a tool for receptive and expressive oral speech abilities and, most importantly, language learning.

Educating Children with Cochlear Implants

Deaf education has long been concerned with the necessity of overcoming the devastating effect profound deafness has on language acquisition and on educational attainments. Normally hearing children come to education and the development of literacy and numeracy skills with language already acquired through the channel of hearing in interaction with their care providers. For children deaf from birth, this normal process is disrupted with consequent effects on language acquisition. Deaf education is concerned not only with the processes of educational attainments of literacy and numeracy, but also with the processes of linguistic development and how to overcome the problem of lack of hearing in the normal communicative development.

The two major questions that have challenged educators for years have been which communication method to use (oral or sign language), and where to educate children (in special or mainstream schools). Visual means of communication were promoted, with sign language being seen as the solution by some, and oral language using visual support of lip-reading and other clues as the way forward. In 1880, the Milan conference on deaf education promulgated the opinion that oral language was "superior" to that of sign language. This statement, at a time when there was little amplification available, began the predominance of oralism throughout the world, and a polarization of views between individuals who believed that all deaf children should communicate by spoken language alone, and individuals who believed that all deaf children should communicate by sign language.

Although the oral view was held strongly in the 19th century and first half of the 20th century, reports of poor linguistic and educational attainments and speech intelligibility of deaf children began to challenge it. The increasing voice of the deaf community, wanting recognition of its own language and culture, also began to be heard. Signed methods of communication were increasingly introduced to educational systems in many countries, often taking the form of total, or simultaneous, communication, where spoken language is used with

signed support. This method does not use the grammar of sign language, however, and in the 1980s interest grew in the use of sign bilingualism, where the languages of the deaf community and the hearing community are used to varying degrees and emphases. In the United States, the term "bi-bi" is often used to describe bilingual and bicultural approaches. Although terminology may vary, communication approaches may be grouped into three broad categories:

- Oral/aural—spoken language alone
- Use of speech and sign simultaneously (total communication)
- Bilingualism

There are subcategories within each category; oral communication methods include natural oralism, the use of cued speech, and auditory verbal approaches. These subcategories make comparison of the effectiveness of differing communication choices complex, and make the appropriate communication choices challenging for parents.

Another major choice for parents pertains to the setting in which their deaf child should be educated. Historically, deaf children were educated in special schools for the deaf. These schools were often residential and in remote areas, requiring children to leave home and obtain their education away from their families. Large schools for the deaf were established in many countries in the 19th century, and deaf culture and language thrived in these institutions. During the second half of the 20th century, there was an increasing trend for children with any disability to be educated in mainstream schools with appropriate support. For deaf children, the development of more effective hearing aids and the provision of FM systems facilitated the greater possibility of participation in mainstream education.

The closure of many schools for the deaf has been a worldwide phenomenon, which may be seen by the deaf community as a threat to their culture and language. With more children in mainstream schools, a reduction in special schools may also mean greater difficulty in providing specialist educational support to deaf children, and greater difficulty in accessing individuals working with deaf children in mainstream schools for continuing professional development and attaining the knowledge and expertise they need.

The options for educational placement today are the following:

- A school for the deaf (residential or day)
- A unit or resource base in a mainstream school (with varying degrees of integration into the mainstream school)
- A mainstream school (with varying degrees of support in quality and quantity)

These situations are not mutually exclusive, but overlap to a large degree, with wide variations in practice, particularly in degree of support. This overlap makes comparisons about educational independence in varying educational settings complex, and comparing the effectiveness of differing educational settings complex. Francis and colleagues[135] produced a useful matrix of educational resource use, illustrating the continuum of support; a child in a mainstream school with full-time support in class may have less educational independence than a child in a class of 10 in a special school.

Historically, the education of deaf children has been the subject of great controversy, often fed by rhetoric rather than fact, and with few data about the comparative efficacy of various alternatives, or information about making such important choices for parents. Into this already controversial area, the advent of cochlear implantation has added another dimension.

Advent of Cochlear Implantation

The advent of cochlear implantation was hoped to ameliorate the educational challenges produced by profound deafness.[80] In providing useful hearing across the speech frequencies, cochlear implantation facilitates the development of early communication skills and spoken language through interaction with care providers. Early reports of encouraging levels of spoken language perception and production led many authors to predict that mainstream education would be the likelihood for most profoundly deaf children. The success of cochlear implantation has often been measured in terms of access to mainstream education, not least because it has been seen as a means of measuring cost-benefit from cochlear implantation.[135,154] Children with implants are attending mainstream schools in greater numbers after implantation,[174] and this has been thought to be associated with potential savings in educational costs.[154]

What are the needs of children with implants, and are they different from the needs of users of traditional hearing aids? Children with implants need the implant system working well and worn consistently, good listening conditions, and good communication opportunities. These needs are not so different from the needs of hearing aid wearers. What cochlear implants have done is enable profoundly deaf children to function as moderately deaf—and many with a unilateral loss, despite the trend to bilateral implantation. Cochlear implants provide useful hearing to enable profoundly deaf children to acquire language through hearing,[169] to hear all the grammatical features of speech, and to develop wholly intelligible speech. Cochlear implants require complex technology, which requires a surgical procedure and long-term maintenance. How to ensure that children with implants obtain the maximum benefit from this technology remains a challenge.

It has long been recognized that the long-term management of deaf children with implants is in the hands of educators, and there is a major need for educators responsible for the children on a daily basis to have training and regular updates on this complex technology and the expectations they can have. In a survey of parents, community-based implant professionals, and implant professionals in Europe,[175] the most common thread in the responses was the need for long-term support in education for the implant system and for educational services to become more flexible in meeting the needs of this growing group of children. Parents expressed great frustration that their children did not receive the support they needed particularly as they went to secondary or high school, and frustration that there were not greater links between the implant centers and the local educational services. A survey of European teachers of the deaf showed that they were highly interested in receiving information and training about cochlear implants.[176]

To be successful in mainstream education, it must be ensured that the classroom situation is appropriate, with good acoustics, and that the technology is successfully managed, with high expectations of its use. We know the educational implications of a unilateral or moderate hearing loss in the busy mainstream classroom environment[177,178]; children would mishear or misunderstand in noise and not follow the fast-moving discourse around the classroom. For some children, implants may work too well: their speech intelligibility may be such that they appear as normally hearing children, and their needs may be overlooked, and for the children themselves it is difficult to articulate their needs. In such situations, misunderstandings would continue, and children would be unlikely to realize their academic potential. For other children, the implant may not have provided the outcomes expected; the range of outcomes from implantation is large. For these children, an auditory processing disorder or a language learning difficulty may be present, which affects the development of spoken language. The educational needs of these children may not be met in mainstream provision, as had been predicted.

Educational Outcomes

With regard to these educational decisions that parents make for their children, there is evidence that cochlear implantation has had an influence. More children with cochlear implants are going to mainstream schools than to schools for the deaf compared with a group of profoundly deaf children with hearing aids of the same age.[174] These were children 5 to 7 years old; Thoutenhoofd[179] did not find such a trend long-term toward mainstream placement, and there is anecdotal evidence that children with implants are findin g challenges in managing in the secondary or high school environment. Geers and colleagues[180] also found a trend toward mainstream education, but again this was in children at the primary stage.

With regard to communication mode and choices of communication after implantation, there is varying evidence of the influence of oral and signing environments. On the whole, the trend is to support the use of oral input,[180] but the context in which this is best provided in the long-term is still debated, and the situation is complex. Archbold and colleagues[181] showed that the outcomes in terms of speech perception and production 3 years after implantation were not different in children who had begun with some form of signed input and changed to oral, and children who had used oral communication only. Further study showed that children implanted before age 3 change from using signed communication to oral communication,[182] and children implanted at a younger age change communication mode faster.[68] There is evidence that although young people with implants develop intelligible spoken language, they also value the use of sign language, or signed support.[183] If children are to develop spoken language, however, they need to be in an educational environment that values it and promotes its use.

With regard to educational attainments, Stacey and coworkers[184] and Thoutenhoofd[179] showed that children with cochlear implants had improved educational attainments compared with children with hearing aids. Increasing evidence is showing that children with implants have better reading skills than comparative groups with hearing aids,[185] and that children implanted younger are continuing to read at improved rates.[186] In providing access to the grammatical features of spoken language through hearing, cochlear implants have enabled profoundly deaf children to have a greater awareness than previously of the phonology of language before coming to the written word. Spencer and Marschark[187] stated, "Spoken language development of deaf children may be more possible today than ever before. We are poised on a threshold of what often seem like unlimited possibilities." This statement reflects the ways in which new hearing technologies, and cochlear implantation in particular, have transformed educational opportunities for deaf children.

CHAPTER ONE HUNDRED AND SIXTY-ONE

Central Neural Auditory Prosthesis

Robert J. S. Briggs

Key Points

- The concept of auditory brainstem implantation was introduced in 1979 by House and Hitselberger at the House Ear Institute.
- The biocompatibility of direct electric stimulation of the auditory brainstem has been shown in experimental preparations and clinical experience. The electric threshold for tissue damage, relating most specifically to charge density, is typically orders of magnitude greater than the threshold for activating the auditory pathway.
- The auditory brainstem implant (ABI) is now established as an effective method of partial hearing restoration in patients with neurofibromatosis type 2 (NF2). The ABI can provide environmental sound awareness and an aid to lip reading; however, open set speech perception is achieved only rarely.
- The most common indication for ABI is in patients with NF2. The current criteria for use in the United States are NF2 patients 12 years old or older, undergoing first or second side vestibular schwannoma removal. There are no specific audiologic criteria.
- The ABI consists of a multielectrode surface array that is placed over the cochlear nucleus within the lateral recess of the fourth ventricle. Intraoperative electrically evoked auditory brainstem responses are measured to confirm and refine correct position.
- Although some pitch differentiation is achieved between electrodes on the surface array, the tonotopic orientation of cochlear nucleus neurons is unfavorable for surface stimulation. Electric stimulation from individual electrodes may activate a broad area of neurons; in addition, adjacent electrodes may activate overlapping regions of neurons, so provision of independent spectral information by electric stimulation is very limited. The cochlear nucleus comprises a variety of specialized neurons with extrinsic and intrinsic projections that are either excitatory or inhibitory in function. In addition to losing the degree of peripheral tonotopic stimulation achieved with a cochlear implant, direct stimulation of the cochlear nucleus with an ABI may mean loss of specialized neural function within the cochlear nucleus.
- Because the tonotopicity of the cochlear nucleus is not adequately accessed with a surface electrode, it is proposed that a penetrating array might allow more selective tonotopic stimulation of the cochlear nucleus. A clinical trial has been undertaken at House Ear Institute, with 10 NF2 patients implanted with a prototype penetrating ABI in combination with a surface array. The outcomes are not proving any better than the surface electrode ABI, in terms of the reliability of achieving auditory sensations or of the speech perception levels achieved. In the cases where the penetrating ABI provided little benefit, the surface electrode array was successful in providing auditory benefit.
- The inferior colliculus is an obligatory synaptic terminus in the ascending auditory system. The central nucleus of the inferior colliculus also has a clearly defined tonotopic map, and so has been proposed as an alternative site for stimulation with a penetrating electrode. Clinical trials with a prototype auditory midbrain implant electrode are currently under way.
- Improved speech perception outcomes have been shown in ABI recipients without NF2—patients with cochlear nerve avulsion or injury or cochlear ossification who cannot benefit from a cochlear implant. These improved outcomes have led to the hope that children with cochlear nerve aplasia, who are unsuitable for cochlear implants, might benefit from ABI.

Multichannel cochlear implantation is now well established as an extremely effective method of hearing restoration for congenital and acquired sensorineural hearing loss. When conditions involving the cochlear nerve make peripheral intracochlear stimulation ineffective, some patients cannot benefit from cochlear implantation. Most commonly, this situation occurs in patients with neurofibromatosis type 2 (NF2), where bilateral vestibular schwannoma growth or surgical removal results in loss of cochlear nerve function. In this situation, direct electric stimulation of the cochlear nucleus at the brainstem using an auditory brainstem implant (ABI) is possible. Although the hearing outcomes with ABIs are limited compared with cochlear implants, the ABI is currently the most sophisticated and successful central neural prosthesis.

There is now a large experience with the use of ABIs in NF2 patients. Although some auditory benefit is usually achieved, it is generally limited to perception of environmental sound and an aid to lip reading. Rarely, open set speech understanding is achieved.

More recently, there has been increased interest in the use of ABIs for conditions where cochlear implants are ineffective, in particular, postmeningitic cochlear ossification or bilateral eighth cranial nerve

injury from temporal bone fractures or avulsion. Better hearing outcomes have been observed in these patients without NF2, suggesting that NF2 is associated with intrinsic dysfunction of the cochlear nucleus. This suggestion has led investigators to attempt stimulation higher up the auditory pathway at the inferior colliculus with auditory midbrain implants (AMIs). The improved performance with ABIs in patients without NF2 has also provided hope that children with cochlear aplasia, who are unsuitable for cochlear implants, might benefit from ABIs.

Biocompatibility

Direct stimulation of the central nervous system entails unique safety concerns. The mechanisms of tissue damage resulting from the direct injection of current into brain parenchyma have been extensively studied.[1-3] Charge transfer from an electrode to biologic tissue depends on two independent electrochemical mechanisms, as follows:

1. The first mechanism is a simple capacitive mechanism of current that flows when a relatively high dielectric boundary exists between electrode and tissue. When an alternate voltage is created across the interface, charges accumulate differentially on each side of the dielectric boundary, alternating in polarity as dictated by the stimulus. Charging and discharging on either side of the dielectric boundary induces current flow in the biologic medium *without* the direct transfer of the carriers of the charge between electrode and tissue.

2. A second mechanism is one without a dielectric boundary. Charge carriers transfer between electrode and tissue as a result of reduction-oxidation reactions. Reversible reactions are confined to the electrode-tissue interface. Irreversible reactions generate new chemical species, however, which migrate into the tissue and may cause damage.

Safety thresholds of neuroprosthetic stimulation depend on several factors. Yuen and colleagues[4] have shown that the extent of neural injury with contemporary electroprosthetic materials producing direct stimulation closely correlates with the *charge density per phase*. Charge density directly relates to stimulation intensity, stimulation duration, and the effective area of the electrode terminus. The effective area of an electroprosthesis can differ from its geometric area. Brummer and Turner[5] measured the real surface area and suggested that surface roughness factors would range from 1.4 to 30.

The threshold for damage to the cerebral cortex found by Agnew and associates[6] was 320 μA, with a corresponding charge density of 3200 μcoul/cm^2/phase. Niparko and colleagues[7] found that the threshold for tissue damage within the cochlear nucleus (with a penetrating electrode) was 150 μA, a current that corresponded with a charge density of 600 μcoul/cm^2/phase. Stimulation at intensities of 150 μA and 200 μA (approximately 600 μcoul/cm^2/phase and 800 μcoul/cm^2/phase) produced significant tissue response at the site of the electrode terminus with neuronal loss, fiber necrosis, and reactive cells present. The injury threshold was found to exceed the threshold for functional activation, however, by a factor of at least five across all animals studied.

Differences between the damage thresholds determined across studies of central nervous system stimulators may relate to differences in implantation sites and variance in calculations that relate to effective versus geometric surface area. Differences also may be attributable to differences in microelectrode design (e.g., percentage of iridium) and fabrication that affect real charge densities at the electrode terminus for the same stimulation intensities.

History of Clinical Approaches

The concept of auditory brainstem implantation was introduced by House and Hitselberger at the House Ear Institute (HEI, Los Angeles, CA). In 1979, they implanted a two-ball electrode in a woman with NF2 undergoing acoustic neuroma removal. This first ABI was stimulated with a modified hearing aid, and the patient received useful auditory sensations.[8] Nonauditory stimulus occurred, which limited use of the electrode. Subsequently, this original electrode was replaced with a specially designed two-electrode surface array, which used a Dacron mesh carrier. This electrode was attached to a percutaneous pedestal connector and was stimulated by a modified 3M-House cochlear implant speech processor. This patient has continued to achieve acoustic percepts with electric stimulation, and has continued to use the device successfully 10 to 12 hours a day.[9] Between 1984 and 1992, 24 NF2 patients were implanted at HEI, with the single-channel, initially two-electrode, and subsequently three-electrode, ABI under an investigational device exemption from the U.S. Food and Drug Administration (FDA).

The first fully implantable ABI was manufactured by Cochlear Pty Ltd, based on the CI 22 mini–cochlear implant. The electrode array was modified to an eight-electrode pad, developed by HEI in collaboration with Cochlear Ltd and Huntington Medical Research Institute (Pasadena, CA). After initial trials at HEI, a multicenter clinical trial, based in North America, was undertaken. In Europe, a 21-electrode array was also developed by Cochlear Ltd and used with the same receiver stimulator.[10-13] Clinical experience from these trials led to the best features of both electrode arrays being combined to create the current Nucleus ABI electrode, a 21-electrode array connected to the CI 24M receiver stimulator (Fig. 161-1). The system functions similar to a cochlear implant with a fully implantable receiver stimulator package and an externally worn speech processor and transmitting coil. The receiver stimulator package has a removable magnet because

many recipients require repeated postoperative cranial magnetic resonance imaging examinations.

ABIs have also been produced by Med El in Europe and Advanced Bionics in the United States. The function of all these devices is the same as a cochlear implant with variation only in the size of the electrode pad and number of electrode contacts.

The Nucleus 24 ABI is the multichannel 21-electrode surface array, which remains commercially available with FDA and CME approval. Studies have been undertaken at HEI with a penetrating electrode array with limited success. The most recent development is the use of an AMI, in an attempt at inferior colliculus stimulation, either with a surface array or with a penetrating electrode.

With respect to biocompatibility, there is no clinical evidence for neuronal injury occurring as a result of chronic electric stimulation, as evidenced by the demonstrated gradual improved performance over time.

Indications

The most common indication for an ABI is in patients with NF2. In the United States, the ABI is approved only for use in NF2 patients. The current criteria for use in the United States are postlingual NF2 patients 12 years old or older, undergoing first or second side vestibular schwannoma removal. There are no specific audiologic criteria.

Auditory brainstem implantation should be considered in all NF2 patients undergoing vestibular schwannoma removal, in whom there is no expectation of ipsilateral residual hearing. ABIs are indicated particularly if contralateral hearing is absent or poor, or if there is a contralateral tumor that is likely to result in hearing loss in the foreseeable future.

Usually, the ABI is placed at the time of second side vestibular schwannoma removal, when the patient either has a preoperative profound-to-total hearing loss or will have one postoperatively. Some patients choose to have an ABI placed at the time of first side tumor removal (if hearing preservation is not attempted), as a so-called sleeper, in the expectation that the patients will not use the device while they have useful residual hearing in the contralateral ear.

An ABI can be successfully placed as a second-stage procedure after previous vestibular schwannoma surgery. There may be an advantage in delayed implantation if, at the first surgery, there is a large tumor deforming the brainstem and distorting the lateral recess anatomy and position. There is potential, however, for fibrosis and loss of brainstem landmarks occurring after initial tumor surgery that would make placement of the ABI difficult at a second procedure. Prior stereotactic radiotherapy, particularly by gamma knife, is a relative contraindication to ABI placement because of the potential for radiation necrosis of the cochlear nucleus region or fibrous tissue preventing proper device placement. There have been reports where this has been a problem, and where successful ABI use after radiotherapy was achieved.[14,15] The use of ABIs in patients without NF2 is discussed later in this chapter.

Anatomy and Surgical Approaches

Much of the early ABI research focused on gaining a better understanding of the three-dimensional anatomy of the cochlear nerve root, foramen of Luschka, and cochlear nucleus, and potential surgical approaches.[16-23] The cochlear nucleus comprises ventral and dorsal components, situated in the pons where the eighth cranial nerve enters the brainstem at the pontomedullary junction, medial to the cerebellar peduncle. The surfaces of the ventral and dorsal cochlear nuclei are exposed in the anterosuperior aspect of the lateral recess of the fourth ventricle. The ABI electrode is placed into this recess. The foramen of Luschka is the lateral opening of the recess and contains choroid plexus.

The surface landmarks for the lateral recess are the adjacent lower cranial nerves. The foramen of Luschka is situated immediately posterior to the origin of the ninth glossopharyngeal and tenth vagal nerve rootlets, inferior to the eighth nerve root entry zone and posteroinferior to the seventh nerve origin. The flocculus of the cerebellum overlies the foramen. The recess runs in a posteromedial direction from the foramen of Luschka to enter the fourth ventricle.

The translabyrinthine approach has been favored by most surgeons for ABI placement in NF2 patients undergoing tumor removal.[10] Some centers have used a retrosigmoid approach for recipients with NF2 and without NF2.[24] The translabyrinthine approach provides a more lateral view of the brainstem and better view into the foramen of Luschka. Possibly this better view assists in atraumatic electrode array placement; however, translabyrinthine and retrosigmoid approaches can be used effectively. Cerebellar retraction is reduced or avoided by the translabyrinthine approach. If a retrosigmoid or lateral suboccipital approach is used, it is important that the exposure is made as far forward and inferiorly as possible, skeletonizing and retracting the sigmoid sinus anteriorly, to allow a low anterior approach to give the most direct access to the region of the foramen, with the least cerebellar retraction.

The cochlear nucleus is identified within the lateral recess of the fourth ventricle. The cochlear nucleus is identified by following the eighth and ninth cranial nerves medially. The flocculus is retracted posteriorly, and the foramen of Luschka is identified, immediately posterior to the origin of the ninth cranial nerve. The cochlear nerve is followed medially, as it enters the lateral recess of the fourth ventricle. Dissection is carried between the eighth cranial nerve and the choroid plexus, which may need to be removed or shrunk with bipolar cautery. Within the lateral recess, as the cochlear nerve is followed medially, two prominent structures can be visualized anterosuperiorly curving around the brainstem caudally to the pontobulbar sulcus. The cranial structure is the bulging of the cochlear nucleus, and the caudal structure is the pontobulbar body. Between them, a small straight vein is a constant finding and important landmark. The taenia of the choroid plexus is a fibrous band at the entrance of the fourth ventricle. This band usually needs to be divided to allow visualization within the lateral recess and create room for the electrode array insertion. The location of the lateral recess usually can be confirmed by observing flow of cerebrospinal fluid as the anesthesiologist induces a Valsalva maneuver in the patient.

Positioning the electrode array within the lateral recess is crucial to successful auditory stimulation. If the array is too lateral, stimulation of the glossopharyngeal and facial nerves or other lower cranial nerves and cerebellar flocculus can occur. If the array is too deep, the medial electrode contacts would lie within the fourth ventricle and be ineffective. Similarly, caudal or cranial rotation of the electrode array can significantly affect position over the cochlear nucleus. Figure 161-2 shows a schematic representation of the electrode array position.

Intraoperative Monitoring

Successful positioning of the electrode array and final adjustment of position is confirmed by the use of intraoperative electric evoked auditory brainstem response (ABR) testing. The technique of intraoperative recording of short latency auditory potentials induced by electric stimulation of the cochlear nucleus was developed by Waring[25] at HEI. When the electrode array is initially positioned within the lateral recess using anatomic landmarks, electrodes within the array are stimulated, and the evoked ABR response is recorded. Initially, stimulation is performed across the entire length of the electrode array. If a response is achieved, a selection of distal, proximal, and lateral electrode combinations is used in forward and reserve polarity to differentiate stimulus artifact from real response. Presence or absence of response at different electrode combinations allows careful manipulation of the electrode array, such as deeper insertion or caudal or cranial rotation, to identify optimal position and improve the ABR responses.

Typically, either two or three wave responses are seen, as shown in Figure 161-3. The electric evoked ABR response waves are of short latency (0.7 to 3.6 ms). If large late potentials greater than 4 ms are observed, this is usually an indication of motor cranial nerve stimulation. While electric evoked ABR testing is undertaken, monitoring of cranial nerves V, VII, and IX should be continued. This monitoring helps identify inadvertent nonauditory stimulation, and may assist electrode positioning further.

Outcomes

Complications

Because the ABI is usually placed at the time of vestibular schwannoma removal, the occurrence of postoperative problems, including bleeding

and cranial nerve deficit, particularly facial nerve and cerebellar dysfunction, is generally attributed to the tumor removal and not specifically to the ABI placement. Similarly, postoperative cerebrospinal fluid fistula is well recognized after vestibular schwannoma surgery, and it is not thought that the presence of the electrode cable or subcutaneous receiver stimulator increases this risk. Cerebrospinal fluid fistula through the wound and the attendant risk of infection in the presence of the ABI is a potentially disastrous problem, however. As with cochlear implants, meticulous care must be taken with planning of incisions and placement of the receiver stimulator package to avoid problems with wound breakdown and infection. There have been anecdotal reports of hydrocephalus after surgery and ABI placement, possibly resulting from obstruction of cerebrospinal fluid flow through the lateral recess of the fourth ventricle by the electrode array position.

For patients without NF2, in whom there is no indication for surgery to remove a tumor, the potential risks of a craniotomy, cerebellar retraction, brainstem and lower cranial nerve manipulation, and electrode placement all need to be weighed against the potential hearing benefit with the ABI.

Long-term follow-up of ABI recipients, particularly the initial multicenter clinical trial subjects, has involved extensive neurologic examination, and no changes in neurologic status have been identified that seem to be related to the ABI electrode and electric stimulation. Probably the most specific ABI complication is the failure to achieve auditory stimulation and sensation. The normal anatomy of the fourth ventricle lateral recess allows the electrode array with its Dacron mesh backing to be held securely. Displacement of the electrode array can occur, however. This displacement is more likely when there has been distortion of the brainstem by a large tumor. The foramen of Luschka and lateral recess is often widely effaced, and so secure positioning of the array is difficult. Despite packing with fat or oxidized cellulose (Surgicel), migration of the array may occur in the early postoperative period. If there is absence of auditory perception on electrode stimulation, nonauditory stimulation, particularly of the facial, trigeminal, or lower cranial nerves, is more likely.

Even with accurate stable electrode positioning within the lateral recess, there is a high incidence of nonauditory or somatic sensations occurring with stimulation of at least some electrodes across the array. Otto and coworkers[26] reported results from a multicenter study in which 42% of all electrodes resulted in noticeable nonauditory sensations. The most commonly reported nonauditory sensations are ipsilateral facial tingling or throat discomfort or sensation of jittering of the visual field. Less commonly, discomfort or tingling occurs in the limbs or trunk, either ipsilateral or contralateral. Only rarely are motor responses (muscle twitch) in the arm or leg reported; and cardiorespiratory changes have been reported very rarely with electrode stimulation.

It is presumed that nonauditory sensation occurs from stimulation of adjacent anatomic structures, in particular (1) cerebellar flocculus (visual jitter), (2) facial nerve, (3) glossopharyngeal nerve (throat discomfort), and (4) retrograde activation of cerebellar peduncle (ipsilateral tingling and motor activation). Usually, the nonauditory sensation occurs together with an auditory percept, on a particular electrode or pair of electrodes. The nonauditory effect can usually be reduced or eliminated by increasing the pulse width of stimulus, referencing the electrode to a different stimulation ground, or turning off that electrode.[12] It has been observed that there is a decrease in nonauditory sensations over time. Possibly this decrease is due to fibrous encapsulation of the electrode array or, perhaps, alteration of brainstem shape after removal of a compressive tumor.

Auditory Performance

The auditory performance achieved with the ABI in NF2 patients has been very encouraging with similar outcomes reported from different centers and patient groups. Although useful auditory perception is usually achieved, the hearing level does not compare with that of current cochlear implant recipients. When auditory sensations are achieved with the ABI, the hearing has generally been limited to perception of environmental sound and an aid to lip reading. Ebinger and colleagues[27] reported the results of the U.S. multicenter ABI clinical trial. Of 92 subjects, 85% showed auditory sensation, of whom 93% showed improvement in speech understanding using audition with ABI and lip reading compared with the ABI alone or lip reading alone. Significant open set speech understanding in the audition alone condition (e.g., telephone use) is rare.[28] Remarkably similar outcomes have been reported from various centers in Europe and Australia.[11,29-31]

The ABI provides subjects with auditory percepts sufficient to give environmental sound awareness (as shown by the Sound Effects Recognition Test).[32] Information is also provided on the stress and rhythm in speech, which assists subjects with lip reading. Why ABI performance is limited compared with cochlear implant speech perception outcomes is unclear. On psychophysical testing, there is limited pitch variation between separate electrodes or channels on the ABI array.[33] This means limited tonotopic stimulation and limited independent channels of spectral information can be provided. The first step in mapping the ABI is the pitch ranking of the electrodes with auditory percepts. Most ABI patients exhibit a rising pitch percept from lateral to medial across the array, a few have a falling pitch pattern, and some have a variable or flattened pitch pattern.

The tonotopic orientation of neurons within the cochlear nucleus is suboptimal for surface electrode stimulation. The frequency change is from superficial to deep, rather than across the cochlear nucleus surface. Electric stimulation from individual electrodes or channels may activate a broad area of neurons; in addition, adjacent electrodes may activate overlapping regions of neurons, so provision of independent spectral information by electric stimulation is very limited.

The cochlear nucleus is composed of various specialized neurons with extrinsic and intrinsic projections that are either excitatory or inhibitory in function. In addition to losing the degree of peripheral tonotopic stimulation achieved with a cochlear implant, direct stimulation of the cochlear nucleus with an ABI may mean loss of specialized neural function within the cochlear nucleus.

Penetrating Auditory Brainstem Implant

Because the tonotopicity of the cochlear nucleus is not adequately accessed with a surface electrode, it is proposed that a penetrating array might allow more selective tonotopic stimulation of the cochlear nucleus.[34] Animal studies have shown that selective neural stimulation is possible with proximal recording in the inferior colliculus.[35]

A prototype human penetrating ABI (PABI) has been developed at HEI. There have been two generations of PABI with each being a combination of penetrating and surface arrays (Fig. 161-4). In the first, there were 8 penetrating electrodes and 14 surface electrodes. The second contained 10 penetrating electrodes and 12 surface electrodes. Placement of the PABI presents a greater surgical challenge than a surface array. The electrode needs to be accurately inserted into the cochlear nucleus for auditory stimulation to be successful. A stimulating probe has been used to generate an evoked ABR in an attempt to confirm the site of the cochlear nucleus before PABI insertion. This probe has not proven specific enough in site of stimulation to identify the cochlear nucleus definitely. The penetrating array must also be inserted rapidly to avoid any shearing effect on neural tissue because of brainstem movement during the insertion. To facilitate accurate rapid placement, a pneumatic insertion tool has also been developed.

A clinical trial has been undertaken at HEI, with 10 NF2 patients implanted with the two generations of PABI. The outcomes are not proving any better than the surface electrode ABI in terms of the reliability of achieving auditory sensations or of the speech perception levels achieved. In the cases where the PABI provided little benefit, the surface electrode array was successful in providing auditory benefit (Brackmann D, Otto S, personal communication).

Outcome of Auditory Brainstem Implants in Patients without Neurofibromatosis Type 2

Although the ABI has been predominantly implanted in NF2 patients, there is increasing international experience with ABI use in patients without NF2 who are unsuitable for, or have failed, cochlear implantation. Typically, these subjects have loss of eighth cranial nerve integrity because of skull base fracture or traumatic avulsion, or have severe postmeningitis cochlear ossification.

The hearing outcomes achieved in these patients are significantly better than the outcomes in NF2 patients. Some non-NF2 ABI recipients achieve speech perception at levels comparable to successful cochlear implant recipients. Colletti and colleagues[36] reported 63% open set sentence recognition in the audition alone mode in nontumor patients compared with 12% in NF2 patients. Similar outcomes have been reported Grayeli and associates.[37]

This difference in performance between the tumor and nontumor groups implies that the NF2 condition and presence of bilateral vestibular schwannomas has an intrinsic effect on cochlear nucleus function that adversely effects the speech perception achieved with electric stimulation. Colletti and Shannon[38] examined two groups of ABI recipients, 10 NF2 and 10 non-NF2 patients. Parameters studied included electric stimulation thresholds, electrode selectivity, and amplitude modulation and speech perception. These investigators showed that the NF2 patients have significantly worse modulation detection and speech discrimination than non-NF2 recipients. Both groups had similar range of pitch perception and loudness percepts, and so the investigators postulated that the poorer amplitude detection may be due to damage to a specific cell type or region within the cochlear nucleus. Possibly the chopper cells are more susceptible to damage because of their large size and large metabolic requirements. Alternatively, the small cell cap of the cochlear nucleus may be specifically damaged. These cells receive projections from the vestibular nerve root, and so may be affected by vestibular schwannoma growth or surgical removal.

It is unclear why the presence of the vestibular schwannoma has an adverse effect. It may be neural damage associated with progressive sensorineural hearing loss, brainstem distortion owing to the mass effect of a large tumor, or direct brainstem trauma or alteration in vascularity associated with surgical tumor removal. It does not seem to be simply a tumor mass effect or brainstem manipulation that limits ABI outcomes. Some NF2 patients lose hearing with only small tumors that do not contact the brainstem. In the author's experience, these patients do not perform better with an ABI than patients who had large tumors and significant brainstem compression.

Penetrating Auditory Midbrain Implant

The fact that the ABI can produce high levels of speech perception in non-NF2 patients, presumably owing to intrinsic cochlear nucleus

dysfunction, raises the possibility that stimulating the auditory midbrain proximal to the damaged cochlear nucleus may be a better alternative in NF2 patients. Lenarz and coworkers[39] suggested the central nucleus of the inferior colliculus as the potential site.

Colletti and colleagues[40] reported placement of an electrode array (Med El ABI) on the dorsal surface of the inferior colliculus in an NF2 patient. The patient was considered unsuitable for an ABI because of prior surgery and radiation therapy for vestibular schwannomas. The electrode array was placed via a median infratentorial, supracerebellar approach. All 12 electrodes on the array produced auditory sensations without nonauditory responses. Postoperatively, some electrodes apparently developed higher thresholds, presumably because of movement of the array. Seven electrodes were activated with discernible pitch differentiation, measured on only three of the seven electrodes. Apparently, the patient could discriminate multisyllabic words in a five-choice test, and achieved an aid to lip reading with audition via the AMI.

To achieve useful speech perception with multielectrode AMI stimulation, pitch differentiation between electrodes is necessary. The inferior colliculus is an obligatory synaptic terminus in the ascending auditory system.[41] It consists of the central nucleus, the external nucleus, and the dorsal nucleus. The central nucleus contains a clearly defined tonotopic map with preserved tonotopic projections to the ipsilateral auditory thalamus and cortex and to the contralateral inferior colliculus.[42] Most of the tonotopic structures of the inferior colliculus are internally oriented along a dorsolateral to ventromedial axis. A penetrating electrode array has been developed by MHH and Cochlear Limited to access the tonotopic orientation of the inferior colliculus. The penetrating AMI array is 6.2 mm long and 0.4 mm in diameter with 20 platinum ring electrodes. The array is constructed of soft silicon with a central removable stainless steel stylet to facilitate insertion into the inferior colliculus (Fig. 161-5).

Samii and associates[43] reported use of the lateral suboccipital approach for combined vestibular schwannoma removal and supracerebellar access to the inferior colliculus for insertion of the penetrating AMI. Three NF2 patients were implanted in Hannover, Germany, using this approach with intraoperative stereotactic navigation to identify the appropriate trajectory for electrode insertion. All three subjects got auditory percepts; however, postoperative imaging and the presence of nonauditory sensations showed that proper electrode placement was achieved in only one case with the other two electrodes being in the dorsal cortex of the inferior colliculus and the surface of the lateral lemniscus. Each subject showed various pitch, temporal, loudness, and directional percepts. They achieved environmental sound perception and obtained an aid to lip reading, but at 6 months did not get open set speech perception.[44] The hearing obtained apparently improves over time, as is observed in cochlear implant and ABI patients over several years.

The hearing result in the patient with accurate central nucleus inferior colliculus placement was superior to the other two. The electrophysiologic properties of the inferior colliculus neurons are different from the peripheral auditory nerve or cochlear nucleus. Modified stimulation and speech processing strategies may be necessary to activate neurons more effectively across the frequency and isofrequency dimensions of the central nucleus of the inferior colliculus and to optimize speech perception outcomes.

Alternative Strategies in Patients with Neurofibromatosis Type 2

Because the speech perception outcomes achieved with ABIs and AMIs remain limited, tumor management strategies that preserve an intact cochlear nerve should be considered. Successful cochlear implantation has been reported in patients after vestibular schwannoma removal.[45-47] Cochlear implantation after long-term vestibular schwannoma growth control by stereotactic radiation therapy can also provide open set speech perception (Briggs RJS, personal experience). Planned partial tumor removal preserving the cochlear nerve, possibly with radiation therapy if necessary, in association with cochlear implantation rather than ABI may give better hearing outcomes in selected NF2 patients.

Auditory Brainstem Implants in Children with Cochlear Nerve Aplasia

Because of the improved outcomes in non-NF2 ABI recipients, there is hope that the same improved level of hearing may be possible in children with cochlear dysplasia or cochlear nerve aplasia who are unsuitable for cochlear implantation. There is limited experience in numerous centers with ABI placement in children with various cochlear dysplasias and cochlear nerve aplasia or hypoplasia. Colletti and colleagues[48] showed that ABI placement is technically feasible, and that some auditory rehabilitation is possible with children showing environmental sound awareness and limited speech detection.

Although the ABI electrode array can be placed in children younger than 2 years, the subsequent programming of the ABI to achieve potentially useful sound detection is an enormous challenge. As discussed earlier, the successful use of an ABI depends on programming the device to use electrodes that produce auditory sensation without significant nonauditory stimulation, and to use pitch ranking of electrodes across the array. Although electric evoked ABR recording can give some indication of which electrodes produce an auditory response, it is extremely difficult to differentiate auditory from nonauditory responses, and virtually impossible to pitch rank electrodes in prelingual children who cannot give meaningful feedback. Device programming is undertaken on an empiric basis, using cautious and lengthy stepwise programming sessions.

Although initial reports of sound detection and device use in these children have been encouraging, it will be some time before it is shown

whether the hearing achieved is sufficient for useful speech and language development. Of three young children implanted in Manchester, one had a potentially life-threatening postoperative posterior fossa bleed, but made a good recovery and shows benefit with the ABI (Ramsden R, personal communication). Presumably, as with cochlear implantation, the younger the age of intervention, the better the hearing outcome will be; however, the potential hearing benefits need to be well shown and carefully weighed against the potential risks of such major surgery in young children.

Summary

The ABI is now established as an effective method of partial hearing restoration in patients with NF2. The ABI can provide environmental sound awareness and an aid to lip reading; however, open set speech perception is achieved only rarely. Trials of a penetrating ABI and penetrating inferior colliculus AMI have not provided improved hearing outcomes yet. Better speech perception outcomes have been shown in ABI recipients without NF2. These improved outcomes have led to hope that children with cochlear nerve aplasia, who are unsuitable for cochlear implants, might benefit from ABI.

CHAPTER ONE HUNDRED AND SIXTY-TWO

Hearing Aids: Strategies of Amplification

Brad A. Stach

Virginia Ramachandran

Key Points

- Hearing aid technology is advancing at a rapid pace, resulting in an expansion of candidacy and enhancement in benefit from hearing aid use.
- Resulting in large part from the adaptability of modern technology, indications for successful hearing aid use relate more to a patient's communication needs and challenges than to the specifics of degree or configuration of hearing loss.
- Most modern hearing aids use digital signal processing, with high-fidelity signal reproduction and considerable flexibility for matching hearing loss and communication needs.
- Input to the hearing aid is ordinarily received by microphones with variable directionality that may change as a function of the listening environment. Signals may also be received by various wireless transmitter/receiver technologies.
- Directional microphones enhance signal-to-noise ratios, allowing for improved speech perception in noise.
- The digital amplifier allows for variable control in the frequency, amplitude, and time domains to permit programming to fit an individual's hearing loss and ability.
- Hearing aid selection involves matching hearing loss and communication needs with style, technology, and features.
- Type, degree, and configuration of hearing loss are the most important determinants of the style and type of signal processing and features that are indicated.
- Hearing aid validation is carried out by in situ measurement of speech and other signals being delivered to the tympanic membrane.
- Outcome measures provide valuable information regarding satisfaction with and benefit from hearing aid use.

The most common treatment for sensorineural hearing loss is the use of conventional hearing aid amplification. Despite substantial strides in the implementation of implantable technology, hearing aids remain the most widely used and appropriate treatment solution for most patients with hearing loss. Although hearing devices implanted worldwide during a year now number in the thousands, more than 2.4 million hearing aids were dispensed last year in the United States alone.[1]

Previously, hearing aid amplifiers used analog circuits with limited flexibility to fit a patient's hearing loss. Modern hearing aids incorporate digital signal processing (DSP), sophisticated noise and feedback reduction, adaptable directionality, and wireless connectivity. These advances permit accurate fitting over a broader range of hearing loss degree and configurations, and lead to noticeable enhancement in quality of amplified sound and listening performance. This chapter provides a general overview of hearing aids, including indications for their use; amplification technologies; and the selection, fitting, and verification process.

Indications for Hearing Aid Use

Whether a patient is a candidate for a hearing aid is determined by three primary factors and several secondary considerations. Assuming that surgical or other medical management of the hearing loss has been exhausted, candidacy is based on the interaction of degree and configuration of hearing loss, the extent of the communication disorder resulting from the loss, motivation of the patient to address the communication disorder, and attitude toward hearing aid use.[2] Generally, most patients who seek hearing aids can benefit from their use. Even in cases in which the prognosis for successful hearing aid use is guarded, an amplification solution is usually available if the patient is sufficiently motivated.

Hearing Loss Considerations

A primary consideration in successful hearing aid use is the nature, degree, and configuration of hearing sensitivity loss. Although no firm criteria exist about how much hearing loss is too little or too much to preclude successful hearing aid use, some general rules guide prognosis.

In an effort to provide a realistic view of the characteristics of hearing aid users, we evaluated data from 1860 ears of 1049 consecutive patients who were fitted with hearing aids at the Henry Ford Hospital during 2007. Patients ranged in age from 1 to 101 years old. The distribution of ages is shown in Figure 162-1. Of all patients, 81% were at least 60 years old, and 61% were 70 years or older. These percentages are typical of the hearing aid population in general. The prevalence of hearing loss is progressively greater with age, as is the use of hearing aids. Hearing aids are predominantly fitted on ears with sensorineural (88%) or mixed (11%) hearing loss. In this sample, less than 1% of

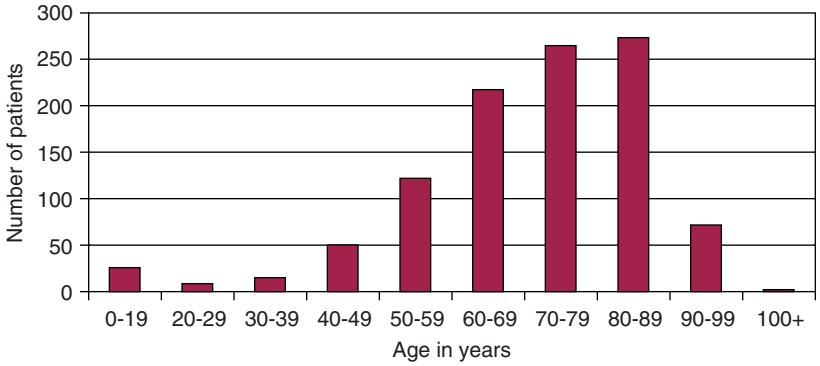

Figure 162-1. Distribution of hearing aid patients by age.

hearing aid devices were fitted on ears with pure conductive hearing loss.

Among people with hearing loss, there are significantly more individuals with mild hearing loss than severe or profound loss. Among this group of hearing aid users, most patients who choose to use hearing aids have hearing loss that is at least moderate in degree. The proportion of patients who have hearing loss and use hearing aids increases substantially with increasing severity of hearing loss. Stated the other way, the penetration of hearing aids into the potential market is low for mild hearing loss and considerably greater as hearing loss increases.

Slope of the audiometric configuration is another factor that influences hearing aid usage. Most patients have flat or sloping hearing loss—that is, hearing sensitivity that is similar across frequencies, or that is better in the low frequencies than the high frequencies. For some audiometric configurations, it is very challenging to provide appropriate amplification. One difficult configuration is a high-frequency precipitous loss, where hearing sensitivity is normal through 500 Hz and decreases dramatically at higher frequencies. There may even be dead regions in the cochlea, where hair cell loss is so complete that no transduction occurs. Depending on the frequency at which the loss begins and the slope of the loss, this type of hearing loss can be very difficult to fit effectively. The other extreme is the rising audiogram, a relatively unusual audiometric configuration in which a hearing loss occurs at the low frequencies, but not the high frequencies. Although this type of loss seldom causes enough of a communication problem to warrant hearing aid use, when it does, certain aspects of the fitting can be troublesome, and the prognosis for successful fitting is limited. In the present sample, less than 2% of ears had rising audiograms.

Although degree of loss is associated with hearing aid use, the audiogram offers only one piece of information needed to determine candidacy. Most patients with minimal to mild hearing loss do not pursue hearing aids, although some do. This fact indicates that the presence of hearing loss alone may be insufficient to compel a patient to hearing aid use, but that a mild degree of hearing loss does not contraindicate hearing aid use. Even patients with minimal hearing losses can wear mild gain hearing aids with benefit. Generally, if the hearing impairment is enough to cause a problem in communication, the patient is a candidate for hearing aids.

Some patients have too much hearing loss for hearing aid use. Severe or profound loss can limit the usefulness of even the most powerful hearing aids. In many cases of profound hearing loss, a hearing aid can provide only environmental awareness or some rudimentary perception of speech. Many patients do not consider this benefit to be valuable enough to warrant the use of hearing aids. In these cases, cochlear implantation is often the most beneficial treatment strategy.

Another audiometric consideration in hearing aid use is suprathreshold speech recognition ability. In most patients, speech recognition is commensurate with degree of hearing loss and is simply a reflection of audibility of spoken speech. In these patients, amplification of the sound that is missing can provide significant enhancement of speech recognition. In other patients, speech recognition is poorer than expected for a given hearing loss. For example, cochlear hearing loss secondary to endolymphatic hydrops can cause substantial distortion of sound, resulting in very poor speech recognition ability. If it is sufficiently poor, hearing aid amplification may contribute to audibility but will be unsatisfactory overall.

Auditory processing disorders in young children and in aging adults can also reduce the benefit from conventional hearing aid amplification. It is not unusual for geriatric patients who were previously successful hearing aid users to experience increasingly less success as their central auditory nervous systems change with age.[3] The problem is seldom extreme enough to preclude hearing aid use, but these patients may benefit more from assistive technology to complement hearing aid use.[4] Prognosis for hearing aid benefit in these patients is guarded.

Communication Disorder and Motivation

The impact of a hearing loss can vary considerably among patients and is an important factor in hearing aid candidacy. Some patients with slow onset presbycusis, of even moderate degree, perceive no difficulty with communication. Such patients effectively use communication strategies such as speech reading and manipulation of the environment to minimize the impact of hearing loss. The prognosis for successful hearing aid use is limited by the patient's lack of recognition of the hearing loss. Other patients, who have considerably less hearing loss but greater communication demands or less success with coping strategies, might perceive communication difficulties and be anxious to quantify the hearing loss for the purpose of obtaining hearing instruments.

Patient motivation is another key factor in predicting success with hearing aids. A patient who is internally motivated to hear better is an excellent candidate for successful hearing aid use. The breadth of amplification options for such a patient is substantial. In contrast, an unwilling patient who gives in to the requests of a spouse or other family members to seek hearing aid amplification often finds numerous reasons why hearing aid amplification is unsatisfactory.

Candidacy for hearing aid amplification is fairly straightforward. If a patient has a sensorineural or other nontreatable hearing loss that is causing a communication disorder, the patient is a candidate for amplification. Even when a hearing impairment is mild, if it is causing difficulty with communication, and the patient is motivated to do something about it, the patient is a candidate for hearing aid amplification and is likely to benefit from its use.

Otologic and Other Factors

Other factors can influence hearing aid candidacy, although they are more likely to influence the selection of type and style of device than to preclude its use. Although a progressive or fluctuating hearing loss does not rule out conventional hearing aid use, the selected hearing instrument must be sufficiently flexible to allow for alterations in programming to accommodate the patient's changing hearing. Patients with microtia or other anomalies may have ear canals or pinnae that prevent fitting with a conventional custom hearing instrument or the ear mold used with a behind-the-ear (BTE) hearing aid. More commonly, the size of the ear canal of a patient sometimes limits the use

of certain in-the-ear (ITE) hearing aids. Other physical and medical limitations can make conventional hearing aid use difficult. Occasionally, a patient with hearing loss has external otitis or ear drainage that cannot be controlled medically. Placing a hearing aid in such an ear can be a constant source of problems. Certain rare pain disorders may also limit access to the ear canal.

Physical and cognitive limitations may influence hearing aid candidacy. Physical limitations are primarily limitations pertaining to dexterity issues from arthritis and other conditions that affect a patient's ability to manipulate certain styles of hearing aids.[5,6] Limited cognitive ability can be a barrier to successful hearing aid use when a patient has difficulty remembering how to operate a hearing aid and its components.

Hearing Aid Technology

Evolution of Hearing Aid Technology

Hearing aid technology has advanced rapidly. Modern hearing aids use DSP for high-fidelity sound reproduction. They have adaptive directionality, feedback control, noise reduction, and low battery drain. They are readily programmable, providing substantial flexibility for precise fitting. Modern hearing aids also have advanced amplification strategies that reduce distortion and enhance listening comfort.[7]

One early step in the progress of technology was component miniaturization. Microphones, amplifier circuits, loudspeakers, and batteries all have been reduced in size. This miniaturization has allowed sophisticated signal processing circuits to be fitted into a completely-in-the-canal (CIC) style of hearing aid. It has also allowed for more technology components, such as wireless receivers, to be incorporated into smaller sized devices worn over or in the ear.

Programmability of hearing aids was a major step in the advancement of hearing aid technology. This programmability provided flexible control of hearing aid characteristics. In the recent past, a hearing aid circuit had to be matched carefully to a patient's audiogram at the time of hearing aid selection. Now hearing aids are available that can be programmed over a wide fitting range so that the matching is done at the time of hearing aid fitting, rather than at the time of selection. Programmability also provides multiple memories for a single hearing aid, allowing the potential for use of different response parameters for different listening situations.

Hearing aids have progressed since the late 1990s from analog to DSP. In analog hearing aids, acoustic signals followed an analog path that was under analog control, wherein an acoustic signal was converted by a microphone into electric energy in a continuously variable manner. In DSP hearing aids, acoustic signals are converted from analog to digital and back again, with digital control over various amplification parameters. DSP eliminated many of the barriers faced in trying to design analog circuits to fit in a small hearing aid and run on low-powered batteries. Along with flexibility inherent in enhanced programmability, modern devices provide more precise and flexible frequency shaping, more sophisticated compression algorithms, better acoustic feedback reduction, and enhanced noise reduction algorithms.[8,9] The degree of sophistication of signal processing that is used in modern hearing aids seems limited only by the conceptual framework of how hearing aid amplification should work.

The most recent technologic advance in hearing aids is the growing opportunity of wireless connectivity, permitting communication from one hearing aid to another and from hearing aids to other electronic devices and signal sources.[10]

Hearing Instrument Components

A hearing aid is an amplification device that consists of three basic components: a microphone, an amplifier, and a receiver. The power source for the amplifier is a battery. Most hearing aids also have some external controls, such as a program button or volume control on the hearing aid, or a remote control. A schematic of the basic components is shown in Figure 162-2.

The most common input transducer in a hearing aid is a microphone, which converts acoustic energy into electric energy. As a sound source vibrates, it creates pressure waves of expanding and compressing air molecules. The membrane of the microphone vibrates in response to these pressure changes, creating an electric energy flow that corresponds to the amplitude, frequency, and phase of the acoustic signal.

Sound can also be delivered to the amplifier of a hearing aid via direct audio input, wherein a sound source reaches the hearing aid directly via a wire connector or "boot" that connects to a BTE hearing aid. One of the most common alternative input transducers is the telecoil, or t-coil. A telecoil allows the hearing aid to receive electromagnetic signals directly, bypassing the hearing aid microphone. The telecoil is often used with the telephone to reduce background noise, and to minimize the potential for feedback that occurs when placing a device near the microphone. A telecoil can be activated by a manual control on the hearing aid, by remote control, or automatically when the hearing aid senses an electromagnetic field.[11]

The telecoil can also be used to provide input for remote-microphone sources. The signal from the remote microphone is transmitted in some form to a loop of wire, which transmits the signal electromagnetically to the telecoil of the hearing aid.[11] This type of technology is often used in a classroom situation, to allow the signal delivered from the remote-microphone worn by a teacher to be directly input to the hearing aid worn by the student.[12] This technology minimizes the degradation of the auditory signal caused by background noise and distance.

A hearing aid may have some other form of wireless transducer, such as a frequency-modulated (FM) receiver or Bluetooth or other modern wireless connectivity. An FM receiver can be built into a hearing aid or attached as a boot on a BTE hearing aid. The FM receiver acts like an FM radio, receiving signals from a transmitter and directing them to the amplifier of the hearing aid.[13] Increasingly, modern hearing aids are equipped with other wireless connectivity solutions, so that the hearing aid amplifier can receive signals directly from mobile phones, computers, or personal music players.[10]

The function of a hearing aid is to amplify sound. This amplification is accomplished through the power amplifier of the hearing aid. The amplifier adds gain to the level of the electric signal that is delivered to the hearing aid's transducer. The amplifier can differentially enhance higher or lower frequency and higher or lower intensity sounds. It also has a limiting function so that it does not deliver excessive energy to the ear.

The output transducer of a hearing aid is its receiver, or loudspeaker. The loudspeaker receives an amplified electric signal from the hearing aid amplifier and converts it back into acoustic energy. Hearing aid receivers have a broad, flat frequency response to reproduce accurately the signals being processed by the hearing aid amplifier.

Electroacoustic Characteristics

The acoustic response characteristics of hearing aids are described in terms of frequency gain, input-output, and output limiting. Gain is the amount of energy that is added to the input signal. The amount of gain

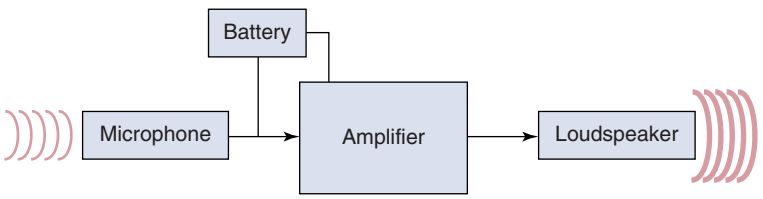

Figure 162-2. The components of a hearing aid.

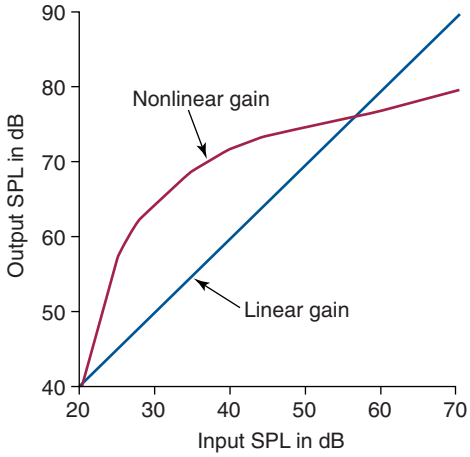

Figure 162-3. Relationship of sound input to output in linear and nonlinear hearing aid circuits. For the linear circuit, gain remains at a constant 20 dB, regardless of input level. For the nonlinear circuit, amount of gain changes as a function of input level. SPL, sound pressure level.

varies as a function of frequency to accommodate varying hearing loss configurations. The relationship of gain as a function of frequency is the frequency gain response of a hearing aid. The frequency gain response represents the gain produced by a hearing aid to a specified intensity level of a signal presented across the frequency range. It reflects the difference between the intensity level of the output of the hearing aid and the intensity level of the input. Most methods used for prescribing a hearing aid are based on providing a specified amount of gain at a given frequency, based on a patient's pure-tone audiogram.

The amount of gain also varies as a function of intensity level. The input-output characteristic of a hearing aid describes this relationship. The input-output function can be linear or nonlinear.

With linear amplification, the same amount of amplification, or gain, is applied to an input signal regardless of the intensity level of the signal so that low-intensity sounds are amplified to the same extent as high-intensity sounds. Figure 162-3 shows an example of a linear input-output function. In this example, for every dB increase in the input, there is a corresponding dB increase in the output. Fitting of linear hearing aids was a standard approach in the early years of hearing aids and remains applicable for conductive hearing loss and some mild sensorineural hearing losses. A problem with this type of amplification is that it does not address the nonlinearity of loudness growth that occurs with sensorineural hearing impairment. Many patients with sensorineural hearing loss do not hear low-intensity sounds, but can hear high-intensity sounds normally or even excessively loud owing to recruitment phenomena. Because a linear device amplifies soft and loud sounds identically, if a low-intensity sound is made loud enough to be audible, a high-intensity sound is likely to be too loud for the listener.[14]

In nonlinear amplification, the relationship between input and output is not constant, so that low-intensity sounds are amplified to a greater extent than high-intensity sounds; this is shown schematically in Figure 162-3. The overall effect is to make low-intensity sounds audible; moderate sounds comfortable; and high-intensity sounds loud, but not too loud.

Nonlinear amplification is designed to address two problems with sensorineural hearing loss: reduced dynamic range, and loudness growth that is different from that of a normal ear. *Dynamic range* in this case is a term used to describe the decibel difference between the level of a person's threshold of hearing sensitivity and the level that causes discomfort. In an individual with normal hearing, this range is 0 to about 100 dB hearing level (HL). In a patient with sensorineural hearing loss, the range is reduced. A patient with a 50-dB hearing loss and a discomfort level of 100 dB has a dynamic range of only 50 dB. Compression circuitry is used to boost the gain of low-intensity sounds so that they are audible, but to limit the gain of high-intensity sounds so that

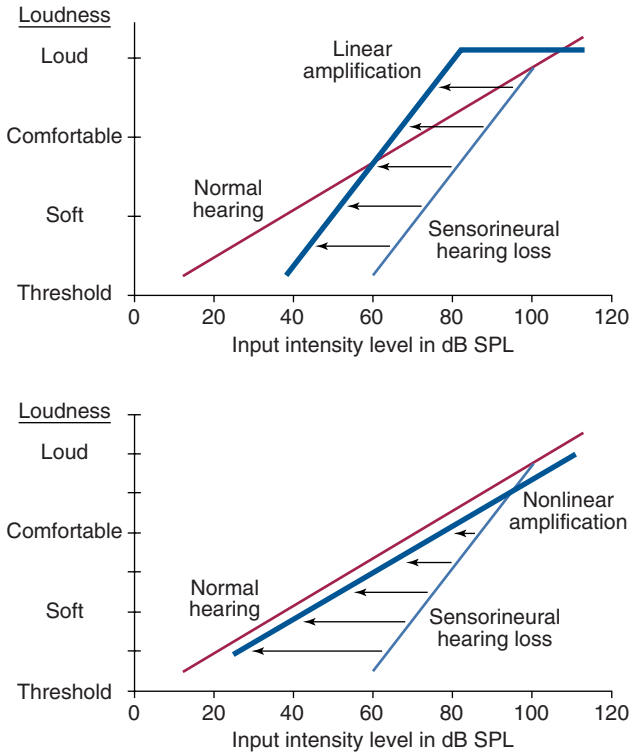

Figure 162-4. The difference between linear and nonlinear amplification in an ear with sensorineural hearing loss and nonlinear loudness growth. SPL, sound pressure level. *(From Stach B. Clinical Audiology: An Introduction. 2nd ed. Clifton Park, NY: Delmar Cengage Learning: 2010, 583.)*

they are not uncomfortable. Figure 162-4 illustrates the difference between linear output and dynamic-range compression as it relates to an ear with sensorineural hearing loss and nonlinear loudness growth.

Nonlinear amplification is achieved with compression circuitry. *Compression* is a term that is used to describe how the amplification of a signal is changed as a function of its intensity. Compression techniques are used to limit the maximum output of a hearing aid and to provide nonlinear amplification across a wide range of inputs.[14,15]

Numerous nonlinear compression strategies have been developed to address the dynamic-range issue, and they vary in approach and complexity. Some strategies are designed to provide compression over a portion of the dynamic range. Partial dynamic-range compression typically provides linear amplification for low input signals and some level of compression when the input reaches a certain level. Other strategies are designed to provide compression over a wider portion of the dynamic range. Wide dynamic-range compression has as its basis the enhanced amplification of quiet sounds and reduced amplification of loud sounds, and is designed to package speech into a listener's residual dynamic range. For most systems, dynamic-range compression can be altered in multiple frequency bands. In this way, if a patient's dynamic range is reduced in one frequency range and nearly normal in another, the compression can be tailored to the frequency band where it is needed, and the other band can act as more of a linear amplifier.[14-16]

An amplifier also contains circuitry that limits its output. It is important that the output level of a hearing aid be limited to some maximum because high-intensity sounds can be damaging to the ear and uncomfortable to the listener. The classic method of limiting output, known as *peak clipping*, does not allow the peaks of signals to exceed a certain level. This method commonly causes distortion for high-intensity inputs. Compression limiting, the current standard method of output limiting, allows the amplifier to become nonlinear as input signals reach a predetermined level, so that the amount of gain is diminished significantly near the maximum output level.[14,15]

Other Hearing Aid Features

Today's hearing aids include many features that make an important contribution to successful hearing aid fitting: directionality, noise reduction, feedback reduction, program management, automatic adaptivity, and data logging. During normal hearing, sound pressure waves reach the tympanic membrane after the acoustic signal has been modified by the resonance characteristics of the pinna, concha, and ear canal. These changes to the acoustic signal greatly aid the localization of a sound source in space, and contribute to the ability to hear in the presence of background noise.[17] With hearing aid use, sound is received by the microphone, which is removed from the location of the tympanic membrane. The signal from the microphone does not include the spatial cues provided by the ear, reducing the ability to hear in background noise.

One important strategy for restoring some of these spatial cues is the use of directional microphones. A directional microphone is one that is designed to be more sensitive to sounds emanating from one direction than another. In most listening situations, the signal of interest is in front of the listener, and background noise is separated spatially, often from behind the listener. A directional microphone is designed to enhance the signal from the front and reduce the signal from behind or from wherever else it might be detected.

In its simplest form, a microphone is equally sensitive to sounds coming from all directions, or is omnidirectional in nature. A microphone can be made to be more directional by using two ports, one on the front and one on the back of the hearing aid. Each port leads to the opposite side of the diaphragm of the microphone. The rear port of the microphone is filtered in a way that causes a phase shift, or time delay, between sounds reaching each side of the microphone. In this way, sounds emanating from behind the listener are delayed so that they arrive at the back of the diaphragm simultaneously with their arrival at the front of the diaphragm. Equal sound pressure levels at both sides of the diaphragm essentially cancel those from behind because the diaphragm cannot move. The directional response pattern can be manipulated by changing the spacing of the ports or the time delay or both.

The modern version of the directionality feature uses two or more directional microphones in an array within the hearing aid. The directionality is created by subtracting the sound at the rear microphone from that at the front. The time delay is manipulated acoustically and electronically based on the number of microphones, the physical nature of the array, and the filters used to optimize the directionality pattern.

Most hearing aids can be changed from an omnidirectional to a directional setting. Typically, omnidirectional microphones are used in quiet environments.[18] Directional microphones are beneficial in background noise so that the microphone sensitivity is focused in a desired direction. In some instruments, the directionality feature is activated manually by the patient. In other instruments, it can be activated automatically and adaptively when the hearing aid senses background noise, changing the amount of directionality based on the extent of the noise.[19]

Noise reduction circuitry is available in most modern hearing aids to reduce unwanted background noise in an effort to improve patient comfort and speech recognition. The sophistication of noise reduction strategies has advanced dramatically,[20] and a thorough description is beyond the scope of this chapter. A simple example might serve to illustrate how the problem can be approached. The frequency and intensity of ongoing speech is highly variable and of short duration, whereas some background noise is relatively constant in nature. A DSP hearing aid can easily detect the difference in time constant and reduce the gain of the hearing aid in the frequency band of constant noise. Modern strategies use increasingly sophisticated algorithms to improve comfort and audibility in noise.

Acoustic feedback occurs when the amplified sound emanating from a receiver is directed back into the microphone of the same amplifying system. Physical separation of the microphone and receiver is the most effective way to reduce feedback. Another feedback reduction mechanism is feedback suppression circuitry. With feedback suppression, the hearing aid recognizes the occurrence of feedback based on frequency, intensity, and temporal characteristics. It reduces amplification in the offending frequency range to reduce feedback or uses phase cancellation of the feedback signal to eliminate audible feedback.[21,22]

All listening situations are not equal. As a result of modern programming capabilities of hearing aids, different responses can be programmed for different situations. One hearing aid response may be appropriate for a certain acoustic environment, such as telephone use, whereas a different type of response may be more appropriate for listening in a noisy environment. Most modern hearing aids have multiple memories that contain different acoustic responses or programs. Multiple memories have the potential to make many programmed responses available in the same hearing device. These programs can be manually accessed through push-button or other types of switches to change settings, or can be changed automatically by the hearing aid as it responds adaptively to the acoustic environment.

The more recent trend in hearing aids is to reduce user control of the response in favor of adaptive control by the hearing aid itself. In such cases, the device continuously samples the acoustic environment and makes changes based on what it measures. This type of automatic control of the hearing aid is beneficial because changes can be made without users needing to monitor the environment themselves. The willingness and ability to use the various programs and features of the hearing aid effectively varies among hearing aid users. These differences can be addressed with adaptivity, as the hearing aid algorithms dictate when the acoustic environment calls for changes to the hearing aid function. In some cases, patients may choose to retain control over the hearing aid, even when adaptive features are available, owing to very specific listening requirements.

Data logging is a feature available in most modern digital hearing aids. The programming software of the hearing aid is designed to track and record user settings and changes to provide statistics that characterize hearing aid use. Commonly accrued information includes time of hearing aid use by the patient, use of automatic or manually controlled hearing aid programs and features, and classification of the listening environments of the user. Data logging is typically used for counseling of patients regarding hearing aid use. If data logging indicates that a patient has used a hearing aid only for a limited time each day, the patient can be effectively counseled regarding the benefit of consistent hearing aid use. Data logging can also be used for troubleshooting of patient complaints. In addition, based on the changes that are typically made by the user and the examination of the typical listening environments of the user, changes can be made to hearing aid programming by the provider.[23] Many data logging systems suggest changes based on listener preferences and experiences. Some data logging systems allow for changes to be automatically made to programming based on these factors and with input by the user when hearing aid characteristics are optimal for a particular listening environment.[24]

Hearing Aid Styles

Hearing aids are available in several styles and with a range of functionality. Each style type has characteristic advantages and disadvantages that must be weighed against user needs and preferences. The most common styles of hearing aids are BTE and ITE hearing aids.

Behind-the-Ear Hearing Aids

A BTE hearing aid consists of the microphone and amplifier in a case that is worn behind the ear. The receiver may be located behind the ear or in the ear canal. Amplified sound is delivered to the ear canal through a tube that leads to a custom-fitted ear mold, a standard open-canal coupler, or a receiver in the canal. External controls for patient manipulation, usually volume control or program button or both, are located on the back side. Figure 162-5 shows BTE hearing aids.

One method for delivery of sound to the ear canal is to channel sound from the ear hook through tubing that terminates in a custom ear mold that fits in the auricle. Ear molds are custom-made in a variety of styles. The resonance characteristics of the ear mold and tubing significantly alter the acoustic properties of amplified sound. The frequency gain characteristics of the hearing aid output can be modified by ear mold and tubing selection and modifications.[25]

Another method of coupling the BTE to the external canal is known as *open-fit technology* or *open-canal fittings*. With these fittings, the ear canal coupler is typically nonoccluding so that it does not completely fill the ear canal. It typically uses thinner tubing than that found with traditional custom-made ear molds, and it is usually a standard, rather than custom-made, coupler. Open-canal fittings are especially useful for high-frequency hearing loss. Low-frequency sound is free to pass through the ear canal in an unobstructed manner, permitting natural hearing in the lower frequencies.[25]

Another BTE variation is the receiver-in-the-canal (RIC) fitting. The RIC fitting can be an open-canal fit, or a conventional, occluded BTE fit. The use of the RIC fitting reduces potential for acoustic feedback by increasing the separation of the receiver from the microphone, creating opportunity for more hearing aid gain when using an occluded fit. When using an open-canal fit, the opportunity for acoustic feedback is similar to that of an open-canal fit with the receiver in the BTE.[26] With an RIC device, the tubing that is used with other BTE devices is replaced by a thin wire that directs the amplifier output to the receiver.

In-the-Ear Hearing Aids

An ITE hearing aid has all of the components contained in a custom-fitted case that fits into the outer ear or ear canal. A device that fills the outer ear concha is referred to as an ITE hearing aid. A device that is smaller and fits into the ear canal is known as an in-the-canal (ITC) hearing aid. Another device, a CIC hearing aid, is even smaller and fits deeply in the canal. Figure 162-6 shows ITE hearing aids.

Style Considerations

The choice of hearing aid style is based on several important factors. The first consideration is acoustic feedback. The higher the intensity of output, the more likely it is that sound will escape from the ear canal, and feedback will occur. Potential for acoustic feedback is lowest in BTE hearing aids, where the distance between the microphone and loudspeaker is greatest. Feedback potential is also reduced by sealing off the ear canal with a tightly fitting aid or ear mold.[27] Although electronic feedback control has reduced these problems,[22] smaller ITE hearing aids are generally restricted to milder hearing losses.

Occlusion of the ear canal creates problems in some patients, and may influence style consideration. Occlusion of the ear canal results in reduced aeration of the external auditory meatus, which may lead to problems associated with external otitis. In addition, a certain amount of hearing loss, known as *insertion loss,* occurs with occlusion of the ear canal while the hearing aid is in place. This occlusion creates hearing loss for patients who have normal low-frequency hearing. Occlusion of the ear canal also causes a phenomenon referred to as the *occlusion effect,* wherein a patient's own voice is perceived as loud and "echoing."[28]

One solution to occlusion problems is the placement of a vent. A vent is simply a passageway for exchange of air and sound around or through a hearing aid or ear mold. The acoustic characteristics of the hearing aid response can be manipulated by the size and type of vent used.[29] Low-frequency amplification can be eliminated, and natural sound can be allowed to pass through the hearing aid for patients with normal low-frequency hearing. Generally, the larger the vent, the more pronounced is the effect. A vent also creates opportunity for acoustic feedback to occur, however, because sound is more likely to escape from the ear canal and be directed into the microphone.[25] The use of an open-canal fit also reduces problems associated with occlusion,[30] with the same feedback-related challenges encountered with venting.

The choice of hearing aid style has an impact on microphone placement. Our ability to localize sound benefits from the natural influences of the auricle and concha. In addition, the auricle and concha increase high-frequency hearing by collecting and resonating sound greater than 2000 Hz. The closer the microphone is to the tympanic membrane, the more the hearing aid can benefit from these natural influences. Conversely, the farther removed the microphone, the more the hearing aid would have to make up for the elimination of these influences. CIC hearing aids can have an advantage over other styles in terms of microphone location.[17] Placing the microphone deeply in the ear canal has other practical advantages, including reduction of wind noise, ease of telephone use, and enhanced listening with headsets and stethoscopes.

Hearing aid style also affects effectiveness of directional microphones. Directional effectiveness is greatest when there is sufficient distance between the microphones located on the hearing aid. Because larger devices such as BTEs and ITEs have microphones that are farther removed from the tympanic membrane, directionality is more of a necessity. Larger devices also have more space available to accommodate optimal microphone placement, so greater directionality is more easily achieved.

An important style consideration relates to durability of the instruments. In ITE instruments, all of the electronic components are placed within the ear canal and are subjected to the detrimental effects of perspiration and cerumen. As a result, repair rates and downtime can be considerably greater for these devices. In contrast, BTE hearing aids have these components housed away from the ear canal, minimizing these effects.

Hearing Assistive Technologies

Assistive technologies other than hearing aids are available for situation-specific hearing, including assistive listening devices (ALDs), alerting

Figure 162-6. In-the-ear hearing aids. **A,** Completely-in-the-canal aids. **B,** In-the-canal aids. **C,** In-the-ear aids. *(Courtesy of Oticon, Inc., Somerset, NJ.)*

and signaling devices, and telephone amplifiers. ALDs include personal amplifiers, FM systems, and television listeners. These devices are designed to enhance an acoustic signal over background noise by the use of a remote microphone. The use of a remote microphone allows the signal to be received by the listener without the degrading effects of distance and reverberation.[13]

Several groups of patients benefit from use of ALDs. Some patients with severe hearing loss do not receive sufficient benefit from hearing aids and find that supplementing hearing aid use with ALDs is necessary. Other individuals with high communication demands in their workplace or social life also benefit from ALDs. Some patients may have communication limitations only in very specific situations, so that general use of a hearing aid is not indicated. An example is a patient who notes difficulty only with watching television or attending a meeting. ALDs tailored to particular needs are often a more appropriate solution in such cases. Some patients have auditory processing disorder that is not accompanied by a loss in hearing sensitivity. Communication difficulties for such patients are characterized by difficulty understanding speech in background noise. For these patients, use of a remote microphone for enhancement of signal-to-noise ratio is more appropriate than amplification from a hearing aid.

A personal FM system is an ALD designed to minimize the effects of noise and distance with a remote microphone. The system consists of two parts, a microphone-transmitter and an amplifier-receiver. The microphone and transmitter are worn by or are close to the speaker. Some transmitters have array microphones that are designed for directionality. The signal is transmitted to the receiver via FM radio waves. The amplifier and receiver are worn by the listener, usually integrated into the hearing aid or coupled to the listener's ear via earphones.[13] Newer forms of wireless coupling of transmitter and receiver are also emerging as a solution for enhancing spatial hearing.[10]

Other assistive technologies are available to provide solutions for specific listening situations. Telephone amplifiers, which are available in several forms, increase the ability to hear on the telephone for many patients. Another commonly used assistive technology is closed captioning of television shows, which allow the viewer to see the spoken dialogue in printed form. Alerting devices, such as alarm clocks, fire alarms, and doorbells, are designed to flash a light or vibrate a bed when activated.

Selection and Fitting Process

The process of hearing aid selection and fitting usually follows this course: selection, quality control, programming, verification, and adjustment. Hearing aids are selected based on the degree and configuration an individual's hearing loss, the individual's communication needs, and other factors relating to style choice. After hearing aid selection, impressions are made of the ear canal for custom ear molds or hearing aids. When the hearing aids are received from the manufacturer, the aids are subjected to quality control of form and electroacoustic function. The hearing aids are programmed based on the patient's audiometric outcomes and needs. Verification of the frequency response is usually made by probe-microphone measurement. A small microphone is placed near the tympanic membrane, and the responses of the hearing aids to speech or speechlike sounds are determined for different levels of input. The hearing aids are adjusted so that the responses approximate the desired targets. The electroacoustic performance is verified further with formal or informal assessment of quality, loudness, or speech perception. The hearing aids may be adjusted again if perceptual expectations are not met.

Target Gain

The fundamental way to specify a starting point for determining the response of a hearing aid is to prescribe frequency-gain characteristics based on audiometric measures.[31] Numerous prescriptive rules have been developed. Some are based on hearing thresholds alone and attempt to specify gain that would amplify average conversational speech to a comfortable or preferred listening level. The half-gain rule prescribes gain equal to one half the amount of hearing loss; the third-gain rule prescribes gain equal to one third of the loss. Most prescriptive rules have this simple approach as a basis, then adjust individual frequencies based on empirically determined correction factors. One popular early threshold-based procedure, which still serves as the basis for some current approaches, is that of the National Acoustic Laboratory.[32]

Another approach is to prescribe frequency-gain characteristics based on threshold and discomfort levels.[31] One notable effort is the desired sensation level (DSL) method.[33] The DSL was originally designed for fitting hearing aids in children, and it prescribed gain based on thresholds and predicted discomfort levels. A newer alternative, the DSL[i/o], is designed to ensure audibility of soft sounds[34] and is used in many modern fitting systems.

Prescriptive procedures were also developed in response to wide-dynamic range compression amplifiers. In these approaches, targets were determined for soft, moderate, and loud sound.[35] More recent procedures combine the linear approach of the early threshold-based prescription methods with different prescription requirements for soft and loud sounds.[31,36]

Other considerations for determining targets include the type of hearing loss and whether one or both ears are being fitted. When there is a conductive component to the hearing loss, target gain is usually increased by approximately 25% of the air-bone gap at a given frequency. When the hearing aid fitting is binaural, the target gain for each ear should be reduced by 3 to 6 dB for binaural summation.[31,37]

Hearing Aid Selection

The process of hearing aid selection first involves assessment of the patient's communication needs and other patient factors that may have an impact on hearing aid use. Appropriateness of the patient for hearing aid candidacy is assessed, and the determination is made whether to pursue hearing aid amplification. This decision is followed by determination of the style and features that would be most appropriate for the patient's hearing loss and communication needs.[38]

The fitting range of a hearing aid is used to determine appropriateness of a hearing aid circuit for a patient's degree and configuration of hearing loss. The fitting range shows the general response curve of the amplifier and is used to determine the ability of a particular hearing aid amplifier to provide necessary gain. This response curve can be manipulated with software controls to reduce or enhance specific frequency ranges to provide the necessary gain for a specific hearing sensitivity. An example is shown in Figure 162-7. Newer hearing aid circuits have a more generic frequency response that can be extensively manipulated, creating a "one-size-fits-many" concept of hearing aid circuitry.

Because of the inherent flexibility of the DSP platform of modern hearing aids, a given hearing aid can be programmed to fit a wide range of degree and configuration of hearing loss. Generally, the factors that separate one hearing aid from another are related to features and processor algorithms, rather than to the frequency gain response of the hearing aid.

Ear Considerations

For most patients, it is best to fit both ears with hearing aids because of the binaural advantage. The brain relies on differences in time and intensity of signals between the ears to localize the source of a sound in the environment.[39] Binaural processing of sound enhances the audibility of speech coming from different directions,[40] and the ability to focus on a desired sound source[41] while suppressing background noise. The use of two ears also improves the perception of sound quality[42] and enhances hearing sensitivity.[37] If a patient has relatively symmetric hearing loss, he or she would benefit more from two hearing aids than from one hearing aid.[41] Evidence suggests that unilateral hearing aid fitting places the unaided ear at a relative disadvantage, which may have a long-term negative effect on the speech perception ability of the unaided ear.[43,44]

Sometimes it is impossible to fit binaural hearing aids effectively. In cases where both ears have hearing loss, but there is significant asymmetry between ears, it is generally more appropriate to fit a hearing aid on the better hearing ear than on the poorer hearing ear.[45,46] This is because fitting the better ear would provide the best aided ability of either monaural fitting. Rarely, in cases of poor speech recognition in

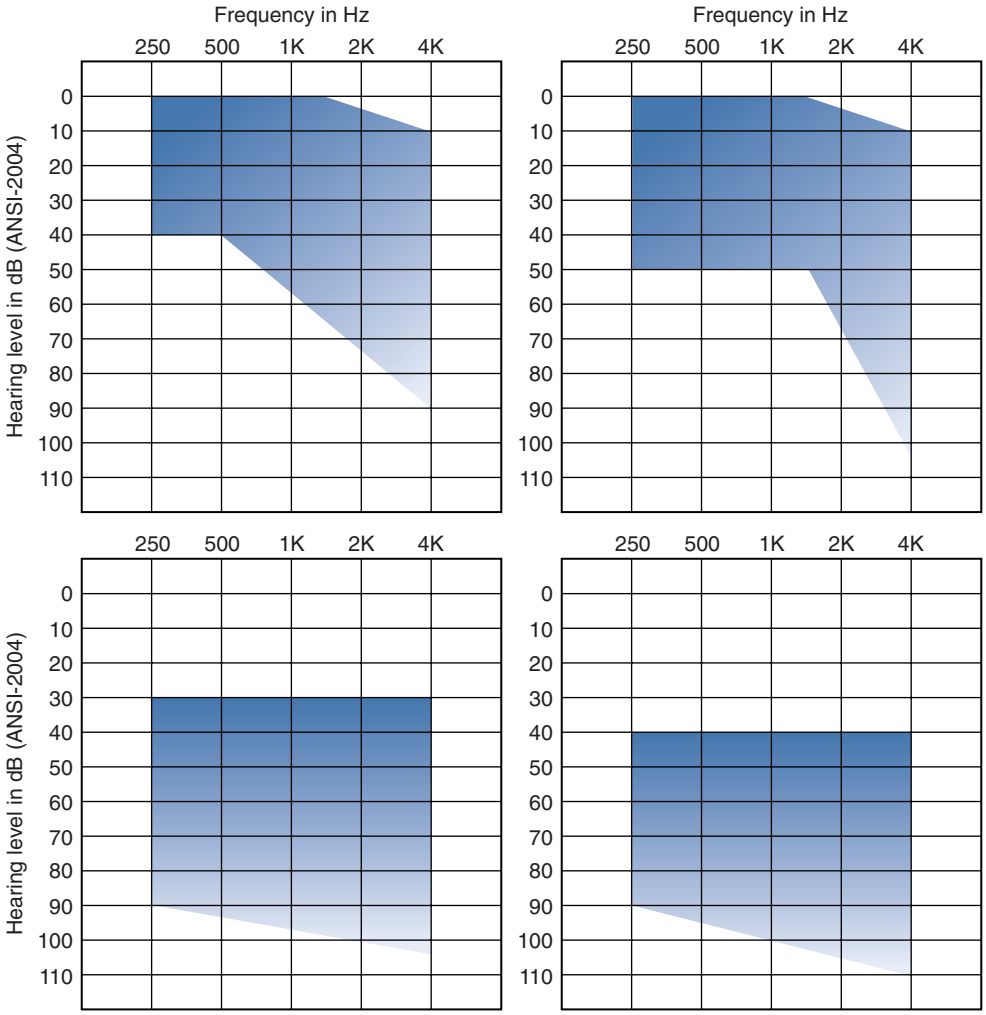

Figure 162-7. Fitting ranges for four different hearing aids, ranging from a mild gain to a power hearing device. ANSI, American National Standards Institute.

one ear, stimulation of the poorer ear can lead to a binaural interference effect, wherein speech understanding is decreased overall.[45,47]

If only one ear has hearing loss, and it can be effectively fitted with a hearing aid, a monaural fitting is indicated. If the poorer ear cannot be effectively fitted, the approach of contralateral routing of signals may be used. A microphone and hearing aid are placed on the poorer or nonhearing ear to deliver signals to the other ear either through bone conduction or via a receiving device worn on the normal-hearing ear.[48]

Other Considerations

Other factors that must be considered in the hearing aid selection process include hearing aid style, directional microphones, occlusion issues, feedback suppression, noise reduction, number and size of user controls, telecoil and other wireless options, and device costs.[38,49] Many of these factors interact with each other because hearing aid manufacturers tend to group availability of features into particular technology levels.

The selection process usually begins with a discussion of hearing aid style. In many cases, the hearing loss may dictate or at least influence this decision. The decision is also influenced by patient preference, which is often based on appearance, convenience issues, or past experience.

The feature/technology level of the hearing aid must also be determined. Grouping of hearing aid features varies among and within manufacturers. Higher levels of technology increase the financial cost of the device.

Some hearing aid selection decisions are made by the provider, and others are made by the patient. The selection of the appropriate feature/technology level involves negotiation with the patient about communication needs and the cost-effectiveness of the various solutions. The communication needs assessment plays a vital role in determination of the hearing aid characteristics that are most important for a given patient. When all of the decisions have been made, the selection is narrowed down to a set of device options. A decision is made regarding specific hearing aids for the patient by comparing these options against the knowledge of devices available from the hearing aid manufacturers.

Fitting and Verification

The general process of fitting and verification includes crafting ear impressions, quality control measures, device programming, verification of fit, and verification of function.

Fitting

The fitting process begins with making impressions of the outer ear and external auditory meatus. The impressions are used by the manufacturer to create custom-fitted ear molds or ITE hearing aids. The quality of the impression dictates the quality of the physical fit of the hearing instruments.

Impression making begins with otoscopic inspection of the ears and ear canals to ensure that they are healthy and suitable for the introduction of impression material. The ear canal is assessed for signs of external otitis and of the tympanic membranes for perforations or

inflammation. The inspection process also includes an evaluation of the amount of cerumen in the canals to ensure that they are not impacted or would not become impacted as a result of the impression-making process.

Care must be taken to protect the tympanic membrane and middle ear from impression material. Significant complications have been reported from impression material entering the middle ear space or mastoid cavity.[50,51] For protection, a foam or cotton block is placed deep into the ear canal as a barrier between the tympanic membrane and the impression material. When ear impressions are being made for CIC hearing aids or ear molds for profound hearing loss, very deep impressions of the ear canal are taken, and extra precautions may be necessary. When the blocks are in place, impression material is mixed, and the ear canals are filled. Several types of materials are available for making impressions. Impressions that are silicone-based tend to be more viscous than the powder and liquid forms. It seems likely that additional viscosity should reduce the risk of complications. After the material has set, and the impressions are removed, the ear canals are inspected again to determine that all impression material has been removed, and no trauma has occurred during the impression-making process.

If the ear molds are to be used with BTE hearing aids, decisions are made about the style of ear mold, the material to be used, and the style and size of tubing and venting. Ear mold materials vary in softness and flexibility. Some materials are nonallergenic. The decisions regarding which material and style to use are based on issues relating to comfort and feedback.[27] Decisions regarding bore size, tubing, and venting affect the frequency gain of the hearing aid.

Electroacoustic analyses of the hearing aids are made before programming to ensure that their output meets specified design parameters. This is done with the hearing aid placed in a test chamber of a hearing aid analyzer, in a 2-cc coupler, attached to a microphone. The chamber has a loudspeaker to deliver test signals to the hearing aid. The amplified signal is sent to the analyzer, which is a sophisticated sound-level meter.[52]

Hearing aid analyzers measure the acoustic output of a hearing aid according to specifications of the American National Standards Institute's Standard for Characterizing Hearing Aid Performance (ANSI S3.2-2003).[53] Standard electroacoustic analysis of a hearing aid provides information about the hearing aid's gain, maximum output, and frequency response. It also provides a measure of circuit noise, distortion, and battery drain. Results of this analysis are compared with the hearing aid specifications provided by the manufacturer to ensure that the hearing aid is operating as expected.[52]

Programming of hearing aids is accomplished via computer software that is proprietary for each manufacturer. The basic response of the hearing aid is derived from the patient's audiogram based on a prescriptive target. Manufacturers usually use proprietary targets that match the assumptions underlying their signal processing strategy. Most parameters of the response can be adjusted as indicated. Some decisions are based on patient characteristics, such as age or experience using a hearing aid. New users typically initially prefer less gain than what might be prescribed for their hearing losses after they adjust to the amplification. For experienced users, response settings may vary depending on the type of processing used in the past.

During this initial stage, preliminary decisions are made about management of programming controls. A decision is made as to whether multiple memories are to be used for a given patient, and how the programs are organized among the memories. Decisions are also made regarding the activation of manual controls, telecoil preferences, noise and feedback reduction responses, and level of sensitivity or responsiveness for adaptive technology in hearing aids. The gain response, maximum output, and prescriptive formula are evaluated to determine appropriateness for the patient. These decisions are made based on the particular characteristics of the device and patient factors, including age and cognitive abilities, degree and configuration of hearing loss, patient experience with hearing aids, and communication needs.

After programming, the physical fit of the device is assessed. Appropriateness, comfort, and security of the fit are determined, as are the absence of feedback and appropriateness of the microphone location. If the fit is inadequate, the hearing aids or ear molds can be modified. Assessment of occlusion effect is typically made by patient perception of his or her own voice, and alterations are made if necessary. The patient's ability to insert and remove the devices and manipulate controls independently is also determined.

Verification

The overall process of verifying suitability of hearing aids includes objective measurements of gain and frequency response from the hearing aids in the ear canal, adjustment of parameters to meet targets for gain and frequency response, and subjective judgments from patients regarding sound quality.

As sound leaves the hearing aid, it is modified by the resonance characteristics of the physical features of the ear canal. The methods for prescriptive gain for the hearing aid take into account the physical characteristics of average ears and must be adjusted for individual variations. The characteristics of transducers can also vary slightly across hearing aids. The output of the hearing aid in the ear canal itself must be verified with real-ear testing. This testing assesses whether the targeted gains are achieved across the frequency range for a given input to the hearing aid. The most commonly used real-ear tests are probe-microphone measurements.

Probe-microphone measurements are made using a spectrum analyzer that delivers various types of signals to a loudspeaker located near the ears of a patient. A small thin tube is inserted into the ear canal down close to the tympanic membrane. The other end of the tube is attached to a sensitive microphone that records sound from deep in the ear canal. This tube allows for measurement of the acoustic changes that occur owing to the resonance of the patient's pinna and ear canal.[54-56]

With the probe tube in place, speech or speechlike sounds are presented through the loudspeaker at a given intensity level, and measurements are made of sound in the ear canal without a hearing aid in place. This measurement is called the real-ear unaided response or gain (REUR/G). Next, the same sounds are presented with the patient's hearing aid in place and functioning. This measurement is called the real-ear aided response or gain (REAR/G). The difference between the aided response and the unaided response (REAG − REUG) is the real-ear insertion gain (REIG). The REIG provides information about the amount of sound that the hearing aid adds when it is in place in the ear. This process is typically performed for low-intensity, average-intensity, and high-intensity signals. If the response does not match the expected target, programming changes are made to the hearing aid until the target is approximated.[54-57]

Another approach to probe-microphone measurements is known as *speech mapping*. In this case, the signal presented through the loudspeaker is low-intensity, average-intensity, and high-intensity speech. The response of the hearing aid is measured near the patient's tympanic membrane, and adjustments are made to approximate targets for speech input. Live speech, such as from a spouse, can also be used to examine the audibility of a particular voice with the hearing aid programming. This process results in verification that the amplified signal being delivered to a patient's tympanic membrane meets prescriptive targets for different input levels. If the targets are correct, when the patient is wearing the hearing aids, low-intensity sounds should be audible, average sounds should be comfortable, and high-intensity sounds should be loud but tolerable.[58]

After objective verification measures, the quality of the amplified sound is assessed with some form of subjective quality judgments or functional intelligibility procedures. Perceptual verification is done in many ways, informally and formally. Strategies include speech perception judgments, loudness judgment ratings, functional gain measurement, and speech recognition measures.

Orientation, Counseling, and Follow-up

After the completion of hearing aid fitting and verification, the patient is oriented to the hearing aid and its use. Areas addressed typically include components and functioning of the hearing aids, battery use, and care and maintenance of the hearing aids. One of the most crucial aspects of the hearing aid orientation is discussion of reasonable expec-

tations of hearing aid use and strategies for adapting to different listening environments.[59] The goal of the hearing aid orientation is for the patient to learn how to use their hearing aid effectively.[60,61]

At the end of the orientation and counseling session, patients are typically scheduled for a follow-up visit. At the follow-up appointment, benefit and satisfaction with the hearing aid are assessed, and any necessary adjustments are made. It is often at this follow-up that outcome measures are made to ensure that the patient's communication needs are being met and to help in planning of any additional rehabilitative services.

Outcome Measurement

The goal of the hearing treatment process is to reduce the communication disorder imposed by a hearing loss. We generally define success at reaching this goal in terms of whether the patient understands speech better with the hearing aid, and whether the hearing aid helps to reduce the handicapping influence of hearing impairment. Outcome measures are designed to assess the impact of hearing aid use on communication. Self-assessment scales can be administered before and after amplification use to determine whether the hearing aids have had a positive impact in reducing communication disorder resulting from hearing loss.[62] Assessments may also be completed by spouses or other individuals who are affected by the hearing loss.

Patient perceptions of hearing ability and challenges are measured with self-assessment tools such as the Hearing Handicap Inventory for the Elderly (HHIE),[63] the Abbreviated Profile of Hearing Aid Benefit (APHAB),[64] and the Client Oriented Scale of Improvement (COSI).[65] Quality-of-life measures are used to determine how hearing aid amplification affects overall well-being. Measures such as the Glasgow Hearing Aid Benefit Profile (GHABP)[66] and the International Outcome Inventory—Hearing Aids (IOI-HA)[67] can help to measure the impact of audiologic treatment on quality of life.

Special Considerations Based on Patient Age

Infants and Children

Hearing aid selection and fitting for infants and children are more challenging than for adults for many reasons.[68-70] There is a smaller volume of space between the end of the ear mold and the tympanic membrane in children, owing to the smaller size of the ear canal, resulting in higher sound pressure levels delivered to the ear than in adults. Children also have different resonance characteristics than adults, which means that certain frequencies are emphasized more than others. In addition, because children are growing over time, these physical factors change, and must be regularly accounted for in hearing aid adjustments.[71]

Another major difference between hearing aid selection and fitting with children is that there is often considerably less information known about the hearing loss in a child compared with an adult.[70] This situation complicates the ability to prescribe gain in a hearing aid when fitting a child. Children are also less able to participate in the selection and fitting process and to provide useful information regarding perception of hearing aid sound quality and function.

There are important factors to consider regarding hearing aid use in children.[70] First, because children are still in the process of learning speech and language, it is crucial to provide consistent and undistorted auditory input.[72] Although adult knowledge of speech and language can fill in for missing or distorted input, children learning language through the auditory system have no linguistic basis for doing so. Second, children have less ability to control their listening environment than adults to maximize audibility. They also have less control over their hearing aids because most controls are disabled to protect against the child accidentally reducing the gain of the aid inappropriately.[71] Third, because of fluctuating hearing loss, such as that from otitis media with effusion, hearing may be more variable in young children.

Some general guidelines exist for fitting hearing aids on children. Children are always fitted with binaural hearing aids to maximize audibility, unless contraindicated by medical factors or extreme hearing asymmetry. BTE hearing aids are used in most cases because the auricle and ear canal grow in size, requiring that the custom portion of the hearing aid be changed frequently while the child is young; this is most appropriately accomplished by remaking the ear mold of a BTE, rather than an entire custom hearing aid. Soft material is used for ear molds, and the ear molds are connected to pediatric ear hooks for proper fitting.[71] BTE hearing aids are also indicated because flexibility in the fitting range of the hearing aid is necessary. Detailed information regarding the hearing loss may be incomplete at the time of the hearing aid fitting because of patient age. If the hearing loss fluctuates because of progressive hearing loss or otitis media with effusion, the BTE hearing aid allows for greater programming flexibility. Another advantage of BTE hearing aids for children is the nearly universal capacity for access to devices from remote microphones. The use of direct audio input, telecoils, and other wireless techniques are important for classroom and other listening environments to maximize the ability of the child to understand the teacher in a noisy classroom situation.[12]

The making of ear impressions can be challenging in a young child. If a child is sedated for the purpose of auditory brainstem response testing or surgical procedures, such as placement of pressure equalization tubes, this procedure can be readily accomplished at that time.

Prescriptive targets for hearing aid gain have been developed for children. An example is the DSL[i/o] approach.[34] These targets can be verified by probe-microphone measurements, which is even more important in pediatric ears because of the variability in ear canal size and its impact on the acoustic response of the hearing aid. Because of the difficulty of making real-ear measurements in children, a different measure, known as the real-ear coupler difference, is often useful. In this case, resonance characteristics of the child's ear are determined by making a single probe-tube measurement with a hearing aid in place. This measurement is compared with the resonance characteristics of a 2-cc coupler. Use of the coupler for measurement minimizes the impact of the patient's cooperation on verification procedures.[71,73,74]

Functional measures are more frequently made for pediatric patients than for adult patients to verify the appropriateness of hearing aid output.[75] Functional gain is the difference between the threshold with the hearing aid and without the hearing aid. Another useful functional measure is speech recognition with the hearing aids. Speech targets can be presented in the presence of background competition. The task of the child is to identify the correct speech stimulus, usually through a picture-pointing task. Aided results can be compared with unaided results and to expectations for normal hearing ability under similar circumstances.

Aging Patients

In some older patients, hearing loss sensitivity is compounded by changes in central auditory nervous system function. The consequence of such changes is typically reduction in speech recognition even in quiet, reduced temporal processing of auditory information, and reduced ability to hear speech in background noise because of diminished ability to use two ears to localize sound. Patients with significant changes in auditory nervous system function do not seem to benefit as much from hearing aid devices as their younger counterparts.[76] In fitting hearing aids for older patients, strategies designed to improve listening in background noise, such as the use of directional microphones,[19,77] noise-reduction processing, and use of remote microphones, are likely to improve patient benefit.

Another important consideration for fitting hearing aids in older patients is that there may be greater difficulty with physical manipulation of the hearing aid, owing to arthritis and other conditions.[6,78] Diminished vision may also be a problem.[79] Additionally, patients with cognitive decline may have difficulty remembering how to use or maintain their hearing aids effectively,[80] and in general may have greater difficulty understanding speech, even when speech is made audible with hearing aids.

Hearing Aids: Some Rules of Thumb

Most otolaryngologists encounter patients with medically intractable hearing loss on a daily basis in their clinics. Many clinicians do not have the opportunity to stay abreast of changes in hearing aid technology or fitting approaches. Patients seek their counsel about the

appropriateness of devices. Although the details may change quickly, there are some rules of thumb that have withstood the test of time, as follows:

"Two ears are better than one." Most patients hear better with binaural amplification, are more satisfied with sound quality and with hearing in noise, and find better overall benefit.

"Bigger is better." BTE hearing aids are considerably more durable than ITEs, are often less conspicuous, are easier to get a comfortable fit, have fewer feedback issues, can have more features, have a longer battery life, and are easier to manipulate.

"It's about communication not the audiogram." If a patient is having difficulty communicating because of sensorineural hearing loss and is motivated for an amplification solution, one can be found.

"If you haven't tried a hearing aid in 2 years, you haven't tried a hearing aid." There is a technology arms race out there, and the result is higher quality devices, more flexible fitting opportunities, and better quality-of-life outcomes.

CHAPTER ONE HUNDRED AND SIXTY-THREE

Principles of Applied Vestibular Physiology

John P. Carey

Charles C. Della Santina

Key Points

- The vestibular system primarily drives reflexes to maintain stable vision and posture.
- By modulating the non-zero baseline firing of vestibular afferent nerve fibers, semicircular canals encode rotation of the head, and otolith organs encode linear acceleration and tilt.
- Stimulation of a semicircular canal produces eye movements in the plane of that canal.
- A semicircular canal normally is excited by rotation in the plane of the canal bringing the head toward the ipsilateral side.
- Any stimulus that excites a semicircular canal's afferents will be interpreted as excitatory rotation in the plane of that canal.
- High-acceleration head rotation in the excitatory direction of a canal elicits a greater response than does the same rotation in the inhibitory direction.
- The response to simultaneous canal stimuli is approximately the sum of the responses to each stimulus alone.
- Nystagmus due to dysfunction of semicircular canals has a fixed axis and direction with respect to the head.
- Brainstem circuitry boosts low-frequency vestibulo-ocular reflex (VOR) performance through velocity storage and neural integration. Failure of these mechanisms suggests a central pathologic process.
- The utricle senses both head tilt and translation, but loss of unilateral utricular function is interpreted by the brain as a head tilt toward the opposite side.
- Sudden changes in saccular activity evoke changes in postural tone.
- The normal vestibular system can rapidly adjust the vestibular reflexes according to the context, but adaptation to unilateral loss of vestibular function may be slow and susceptible to decompensation.

This chapter presents an approach to the vestibular system that provides a basis for understanding the evaluation and management of vestibular disorders described in subsequent chapters. The chapter is organized around 12 basic principles of vestibular system function, reviewing the physiologic underpinnings of each and illustrating their importance in clinical findings when appropriate. This core set of organizing principles can help clinicians quickly recognize the significance of findings on the vestibular exam and precisely localize peripheral vestibular problems to the affected end organs.

Several reviews can be consulted for further explanations of vestibular physiology.[1-4]

Principles

Principle 1: The Vestibular System Primarily Drives Reflexes to Maintain Stable Vision and Posture

Anatomic and Physiologic Basis

The vestibular system's main function is to sense head movements, especially involuntary ones, and counter them with reflexive eye movements and postural adjustments that keep the visual world stable and keep us from falling. The labyrinth of the inner ear senses head rotation and linear acceleration and sends that information to secondary vestibular neurons in the brainstem vestibular nuclei. Secondary vestibular neuron signals diverge to other areas of the central nervous system to drive vestibular reflexes. Specifically, neurons encoding head movement form synapses within the ocular motor nuclei to elicit the patterns of extraocular muscle contraction and relaxation needed for the vestibulo-ocular reflex (VOR), which stabilizes gaze (eye position in space). Other secondary vestibular neurons synapse on cervical spinal motor neurons to generate the vestibulocolic reflex (VCR), or to lower spinal motor neurons to generate the vestibulospinal reflexes (VSRs). These reflexes stabilize posture and facilitate gait. Vestibular sensory input to autonomic centers, particularly information about posture with respect to gravity, is used to adjust hemodynamic reflexes to maintain cerebral perfusion. Finally, vestibular input to the cerebellum is essential for coordination and adaptation of vestibular reflexes when changes occur such as injury to a vestibular end organ or alteration in vision (e.g., a new pair of glasses).

Vestibular signals also reach cortical areas to mediate the perception of movement and orientation. Nevertheless, the common head movements of everyday life usually go unnoticed, which is why ves-

tibular sensation is not included among the vernacular "five senses"—sight, smell, taste, touch, and hearing. Yet the loss of vestibular sensation causes distinct and often severe symptoms. This distress has perhaps been best captured in the first-hand account of J.C., a physician who lost his vestibular sense to an ototoxic aminoglycoside antibiotic: "By bracing my head between two of the metal bars at the head of the bed I found I could minimize the effect of the pulse beat that made the letters on the page jump and blur… In these corridors I had the peculiar sensation that I was inside a flexible tube, fixed at the end nearest me but swaying free at the far end."[5]

Like many other patients who have lost vestibular function, J.C. soon recovered and resumed most of his usual activities without the distressing sense of *oscillopsia*, the perception that the world is moving whenever the head is moved. This recovery is due to a combination of central adaptation to abnormal vestibular signals and the use of information from other sensory systems that provide information about movement and posture. For example, somatosensory information from proprioceptive sensors in the limbs contributes to the sense of vertical body orientation.[6] Proprioceptors in the neck mediate a cervico-ocular reflex that can augment the deficient VOR.[7,8] Likewise, postural information may be supplied by gravity receptors in the major blood vessels and abdominal viscera.[9] Because head movements may be also sensed by their impact on the retinal image, vision-based oculomotor systems can partly supplant a deficient VOR. For example, smooth pursuit is a type of reflexive eye movement that helps to stabilize images on the retina. During smooth pursuit, movement of a target image on the retina causes a conjugate following movement of the eyes to keep the target fixed on the fovea. The stimulus for this reflex is the difference between the velocity of the visual target and the velocity of the eye, which is called *retinal slip velocity*. This visual error is computed by the primary visual cortex; transmitted to the middle temporal, parietal, and frontal cortices; and forwarded to the brainstem and cerebellum to generate the oculomotor command signals. The multiple synapses involved in this reflex impose a long latency (approximately 100 msec), and the reflex breaks down at relatively modest velocities (more than approximately 50 degrees/second)[10] and frequencies (more than approximately 1 Hz).[11] Optokinetic nystagmus, which elicits eye rotation in response to optic flow of the visual scene, operates over a range of velocities and frequencies similar to smooth pursuit.[12] These limitations make these visually driven reflexes inadequate to stabilize vision during many common head movements. For example, the head pitches up and down at a frequency of approximately 2 Hz and velocity of approximately 90 degrees/second during walking, while during running head pitch harmonics may extend to 15 to 20 Hz. Voluntary head-on-body horizontal rotations can reach 800 degrees/second and can also have significant harmonics to 15 to 20 Hz.[13]

The limitations of smooth pursuit and optokinetic nystagmus illustrate the important concept that reflexive sensorimotor systems have optimal operating ranges. Smooth visual pursuit functions best for low-frequency and slow head movements. Autonomic gravity receptors function best for static and very-low-frequency conditions. These and other reflexes overlap with the vestibular system for part of its operating range, but nonvestibular systems largely break down during quick head movements. Therefore, the vestibular system is essential for gaze stabilization during *high-frequency*, *high-velocity*, and *high-acceleration* head movements.

Clinical Importance

The reflexive nature of the vestibular system is central to understanding vestibular pathophysiology. The brainstem interprets imbalances in vestibular input due to pathologic processes in the same way that it interprets imbalances due to physiologic stimuli. Therefore, the cardinal signs of vestibular disorders are reflexive eye movements and postural changes. These reflexive signs can largely be understood as the brainstem's responses to *perceived* rotation around a specific axis or *perceived* tilting or translation of the head, even though the head is still and upright. Knowing the effective stimulus for each vestibular end-organ allows determination of which end organ or combination of end organs must be stimulated to produce the observed motor output. Working backwards in this fashion, the end organs affected by pathology can usually be inferred.

In interpreting reflexive eye movements and postural changes in the search for vestibular dysfunction, an important consideration is that vestibular reflexes may be observed only in isolation under certain conditions. For many conditions, in fact, other reflexive systems can compensate for the loss of vestibular reflexes, thereby masking any deficit. For example, a patient with well-compensated, longstanding bilateral loss of vestibular function may surprisingly appear to have no problem keeping vision fixed on the examiner as the examiner rotates the patient's head slowly from side to side. In such persons, smooth pursuit, optokinetic nystagmus, and (to a lesser extent) the cervico-ocular reflex make up for the vestibular deficit. This is an example of a head movement that *can* be sensed by the vestibular system, but which is not in the range of frequencies and accelerations sensed *exclusively* by the vestibular system. However, when the examiner suddenly and rapidly rotates the head to either side, the eyes do not stay on target. The vestibular deficit can thus be unmasked by very dynamic head movements.

Principle 2: By Modulating the Non-Zero Baseline Firing of Vestibular Afferent Nerve Fibers, Semicircular Canals Encode Rotation of the Head, and Otolith Organs Encode Linear Acceleration and Tilt

Anatomic and Physiologic Basis

Sensory Transduction

The labyrinth of the inner ear houses a set of inertial sensors that detect rotary and linear acceleration. Each bony labyrinth encloses a membranous labyrinth consisting of three semicircular canals arrayed roughly at right angles to each other and two roughly orthogonal otolith organs, the utricle and saccule (Fig. 163-1). Semicircular canals primarily sense rotational acceleration of the head. The utricle and saccule primarily sense linear acceleration in horizontal and vertical (superoinferior) directions, respectively.

Sensation by semicircular canals works as follows. When the head accelerates in the plane of a semicircular canal, inertia causes the endolymph in the canal to lag behind the motion of the membranous canal, much as coffee in a mug initially remains in place as the mug is rotated about it. Relative to the canal walls, the endolymph effectively moves in the opposite direction as the head. Inside the ampulla, a swelling at the end of the canal where it meets the utricle, pressure exerted by endolymph deflects the cupula, an elastic membrane that spans a cross-section of the ampulla[14] (Fig. 163-2). Vestibular hair cells are arrayed beneath the cupula on the surface of the crista ampullaris, a saddle-shaped neuroepithelium. Hair cells are so named for tufts of stereocilia that project from their apical surfaces. These stereociliary bundles are coupled to the cupula so that its deflection creates a shearing stress between the stereocilia and the cuticular plates at the tops of the hair cells.

Stereocilia deflection is the common mechanism by which all hair cells transduce mechanical forces (Fig. 163-3). Stereocilia within a bundle are linked to one another by protein strands called "tip links" that span from the side of a taller stereocilium to the tip of its shorter neighbor in the array. The tip links are believed to act as gating springs for mechanically sensitive ion channels, meaning that the tip links literally tug at molecular gates in the stereocilia.[15,16] These gates, which are cation channels, open or close (or, more precisely, spend more or less time in the open state), depending on the direction in which the stereocilia are deflected. When deflected in the open or "on" direction, which is toward the tallest stereocilium, cations, including potassium ions from the potassium-rich endolymph, rush in through the gates, and the membrane potential of the hair cell becomes more positive (see Fig. 163-3B, C). This in turn activates voltage-sensitive calcium channels at the basolateral aspect of the hair cell, and an influx of calcium leads to an increase in the release of excitatory neurotransmitters, principally glutamate, from hair cell synapses onto the vestibular primary afferents (see Fig. 163-3D). All of the hair cells on a semicircular canal crista are oriented or "polarized" in the same direc-

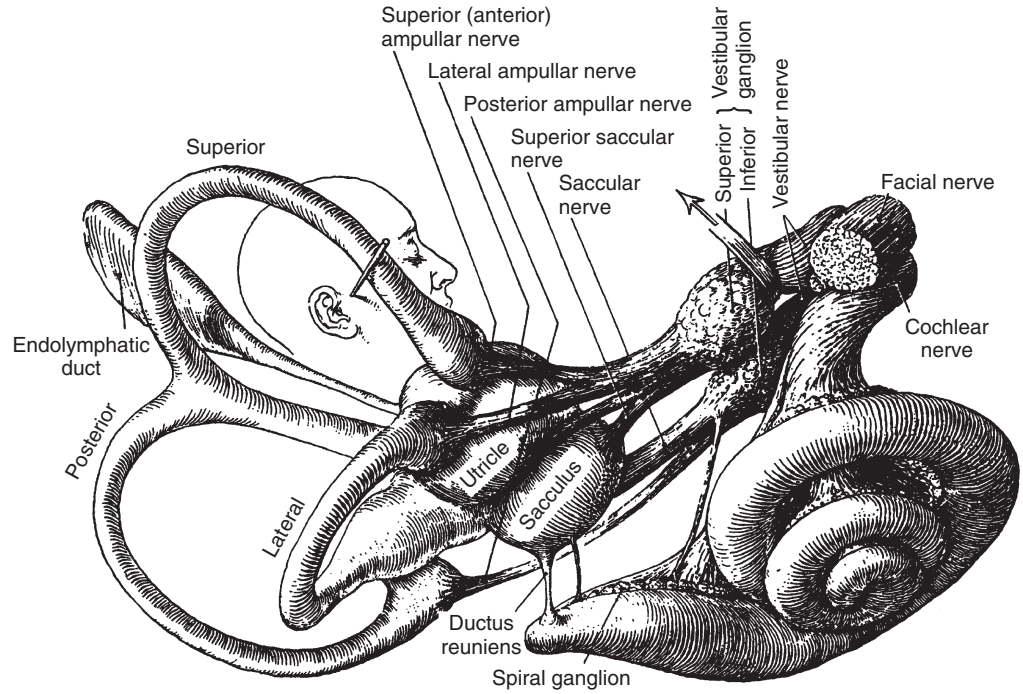

Figure 163-1. The vestibular end organs. *(From Brodel M.* Three Unpublished Drawings of the Anatomy of the Human Ear. *Philadelphia: WB Saunders; 1946.)*

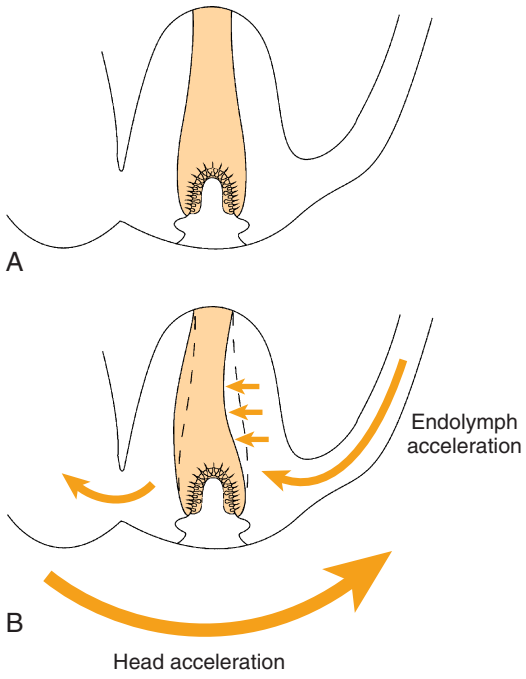

Figure 163-2. **A,** The cupula spans the lumen of the ampulla from the crista to the membranous labyrinth. **B,** Head acceleration exceeds endolymph acceleration. The relative flow of endolymph in the canal is therefore opposite to the direction of head acceleration. This flow produces a pressure across the elastic cupula, which deflects in response.

tion. That is to say that their stereociliary bundles all have the tall ends pointing the same way, so that the endolymph motion that is excitatory for one hair cell will be excitatory for all of the hair cells on that crista (Fig. 163-4).

The otolith organs sense linear accelerations. These organs contain sheets of hair cells on a sensory epithelium called a *macula* (Fig. 163-5). A gelatinous membrane sits atop the macula, and microscopic stones made of calcium carbonate, the *otoliths* (or *otoconia*), are embedded on the surface of this otolithic membrane. The *sacculus* (or *saccule*), located on the medial wall of the vestibule of the labyrinth in the spherical recess, has its macula oriented vertically. Gravity therefore tonically pulls the saccular otolithic mass inferiorly when the head is upright. The *utriculus* (or *utricle*) is located above the saccule in the elliptical recess of the vestibule. Its macula is oriented in roughly the same plane as the horizontal semicircular canal, although its anterior end curves upward. When the head tilts out of the upright position, the component of the gravitational vector that is tangential to the macula creates a shearing force on stereocilia of utricular hair cells. The cellular transduction process is identical to that described above for the crista. However, the hair cells of the maculae, unlike those of the cristae, are not all polarized in the same direction (Fig. 163-6). Instead, they are oriented relative to a curving central zone known as the *striola*. The utricular striola forms a C shape, with the open side pointing medially. The striola divides the utricular macula into a medial two thirds (polarized to be excited by downward tilt of the ipsilateral ear) and a lateral one third polarized in the opposite direction. Hair cells of the sacculus point away from its striola, which curves and hooks superiorly in its anterior portion. Each macula is essentially a linear accelerometer, with the saccular macula encoding acceleration roughly within a parasagittal plane (along the naso-occipital and superoinferior axes), and the utricular macula encoding linear acceleration roughly in an axial plane (along the naso-occipital and interaural axes). A given linear acceleration may produce a complex pattern of excitation and inhibition across the two maculas (Fig. 163-7), a pattern that encodes the direction and magnitude of the linear acceleration.[17] By contrast, each of the three semicircular canals senses just a one-dimensional component of rotational acceleration.

Modulation of neurotransmitter release from hair cells within each vestibular endorgan modulates the action potential frequency, or *firing rate*, of vestibular nerve afferent fibers (Fig. 163-8). The afferents have a baseline rate of firing, probably due to a baseline rate of release of neurotransmitter from the vestibular hair cells. Changes in vestibular nerve afferent firing are conveyed to secondary neurons in the brainstem. Baseline firing gives the system the important property of *bidirectional sensitivity*: Firing can increase for excitatory head movements and decrease for inhibitory head movements.[18] Thus, loss of one

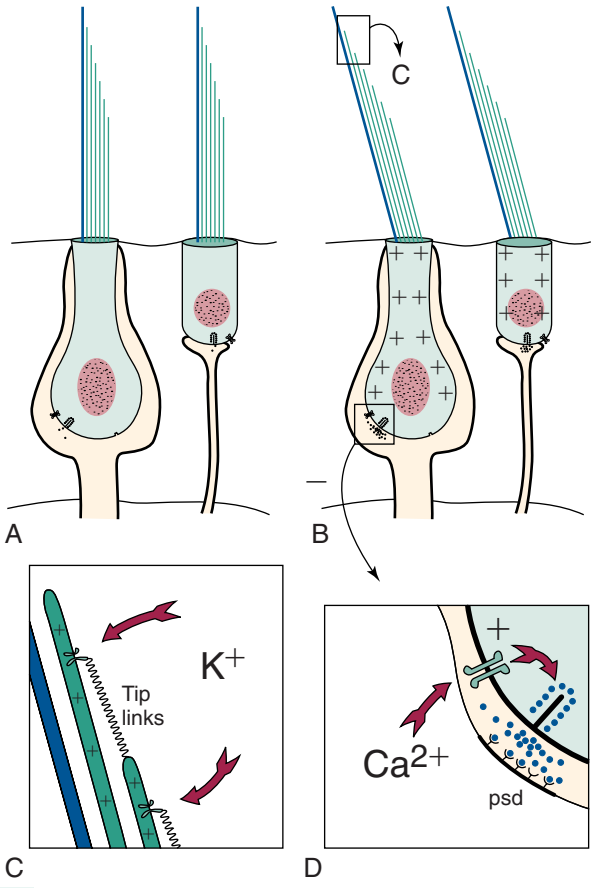

Figure 163-3. Sensory transduction by vestibular hair cells. **A,** At rest there is some baseline release of excitatory glutamate from the hair cell synapses onto the vestibular afferents. **B,** Hair cells are depolarized when the stereocilia are deflected in the "on" direction (toward the kinocilium, in dark blue). **C,** This occurs because the stretched tip links mechanically open cationic channels in the stereocilia membranes. The influx of potassium ions raises the hair cell's membrane potential. **D,** The increased membrane potential activates voltage-sensitive calcium channels in the basolateral membrane of the cell. Synaptic release of glutamate increases, and receptors in the postsynaptic (*psd*) density on the afferent increase its membrane potential, which in turn increases afferent firing rate.

labyrinth does not mean loss of the ability to sense one half of the head's movements.

Response of the Cupula

How a semicircular canal encodes head rotation can be understood using a mathematical model of a fluid-filled *torsional pendulum*.[4] Figure 163-9 depicts the mechanical forces acting on the left horizontal semicircular canal seen from above during counterclockwise head rotation through angle $H(t)$ in the plane of the canal. Head rotation carries the membranous semicircular canal along with it, whereas the inertia of the endolymph and cupula tend to keep these elements stationary in space (like the coffee in a mug as the mug is quickly turned). Nevertheless, two things act to accelerate the endolymph in the same direction that the head is turning but through the smaller angle $X(t)$. The first is the elastic or spring-like push from the distended cupula as it pushes against the endolymph (deep blue in Fig. 163-9). The second is the viscous drag exerted on the endolymph at its interface with the walls of the membranous canal.

Recall that for linear motion, Newton's Second Law states that $\sum F = ma$, where $\sum F$ is the sum of all applied forces, m is mass, and a is the resultant acceleration. For rotational motion, the analogous equation is $\sum T = I\alpha$, where T is torque, I is the moment of inertia, and α is rotational acceleration. For the rotating semicircular canal, the equation can be written

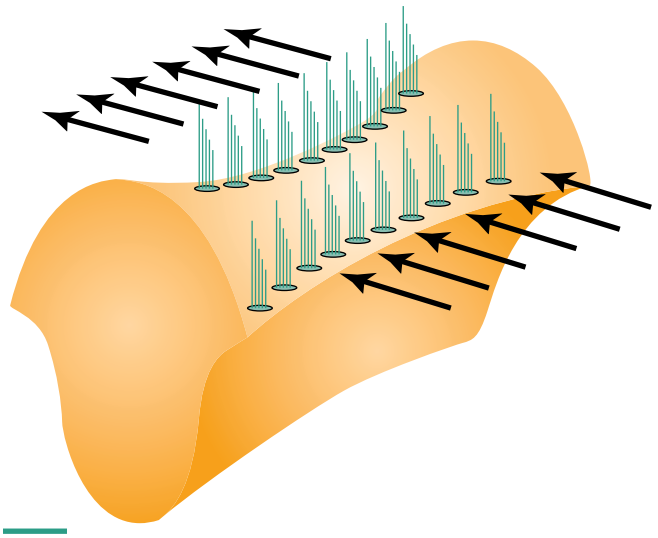

Figure 163-4. Morphologic polarization of the stereociliary bundles in the crista ampullaris. The "on" direction of deflection is always toward the kinocilium, which is next to the tallest stereocilium. Hair cells on the crista ampullaris of a given semicircular canal have all their stereocilia polarized in the same direction.

$$\sum T = T_{elastic} + T_{viscous} = I\ddot{X}(t). \qquad \text{Eq. 163-1}$$

Equation 163-1 says that the sum of the elastic and viscous torques acts on the moment of inertia I of the endolymph and cupula to accelerate the endolymph through space by $\ddot{X}(t)$. (Overdots are used to denote time derivatives, so $X(t)$, $\dot{X}(t)$, and $\ddot{X}(t)$ are endolymph rotational position, velocity, and acceleration, respectively.)

The elastic torque exerted by the cupula is proportional to the deflection of the cupula from its resting position (light blue in Fig. 163-9). That deflection is given by the difference between how far the head moves in space and how far the endolymph moves in space:

$$\Theta(t) = H(t) - X(t). \qquad \text{Eq. 163-2}$$

Thus, the elastic torque is

$$T_{elastic} = K\Theta(t). \qquad \text{Eq. 163-3}$$

The viscous torque is proportional to the velocity of the endolymph relative to the walls of the canal. Differentiation of Equation 163-2 gives this relative endolymph velocity:

$$\dot{\Theta}(t) = \dot{H}(t) - \dot{X}(t). \qquad \text{Eq. 163-4}$$

Therefore,

$$T_{viscous} = B\dot{\Theta}(t). \qquad \text{Eq. 163-5}$$

Finally, to get endolymph acceleration, $\dot{X}(t)$, we differentiate Equation 163-2 and rewrite it as

$$\ddot{X}(t) = \ddot{H}(t) - \ddot{\Theta}(t) \qquad \text{Eq. 163-6}$$

Now Equation 163-1 can be written as

$$K\Theta(t) + B\dot{\Theta}(t) = I\ddot{H}(t) - I\ddot{\Theta}(t). \qquad \text{Eq. 163-7}$$

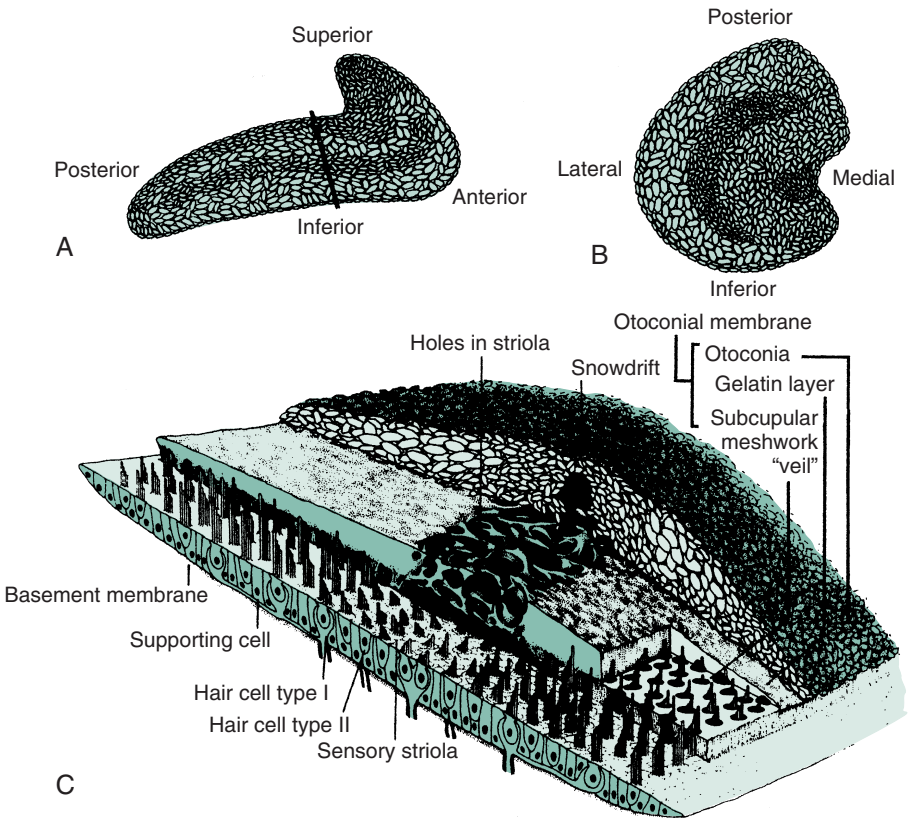

Figure 163-5. Arrangement of otoliths in the two maculae. **A,** Saccule. **B,** Utricle. **C,** Composition of the saccular otoconial membrane in a section taken at the level shown in **A.** *(From Paparella MM, Shumrick DA, eds.* Textbook of Otolaryngology. *Vol 1. Philadelphia: WB Saunders; 1980.)*

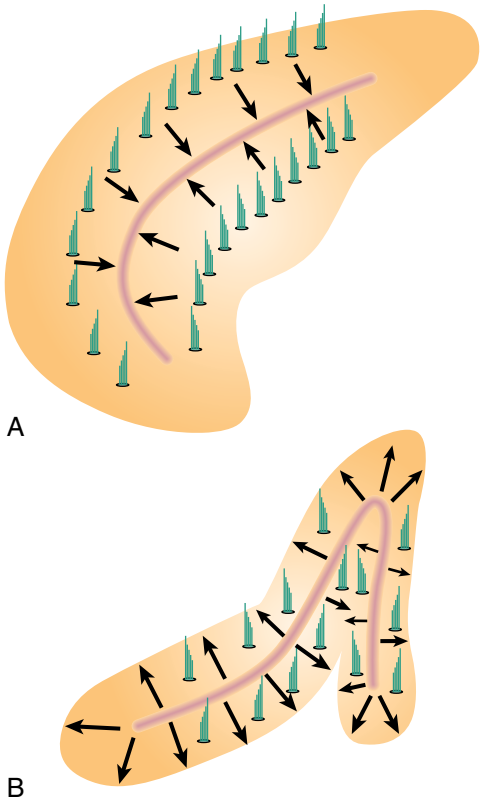

Figure 163-6. Morphologic polarizations of the stereociliary bundles in the maculae of the utricle (**A**) and saccule (**B**). The "on" direction of stereociliary deflection is indicated by the *arrows*. In the utricle (**A**), hair cells are excited by stereociliary deflection toward the striola *(curving central zone)*. In the saccule (**B**), hair cells are excited by stereociliary deflection away from the striola.

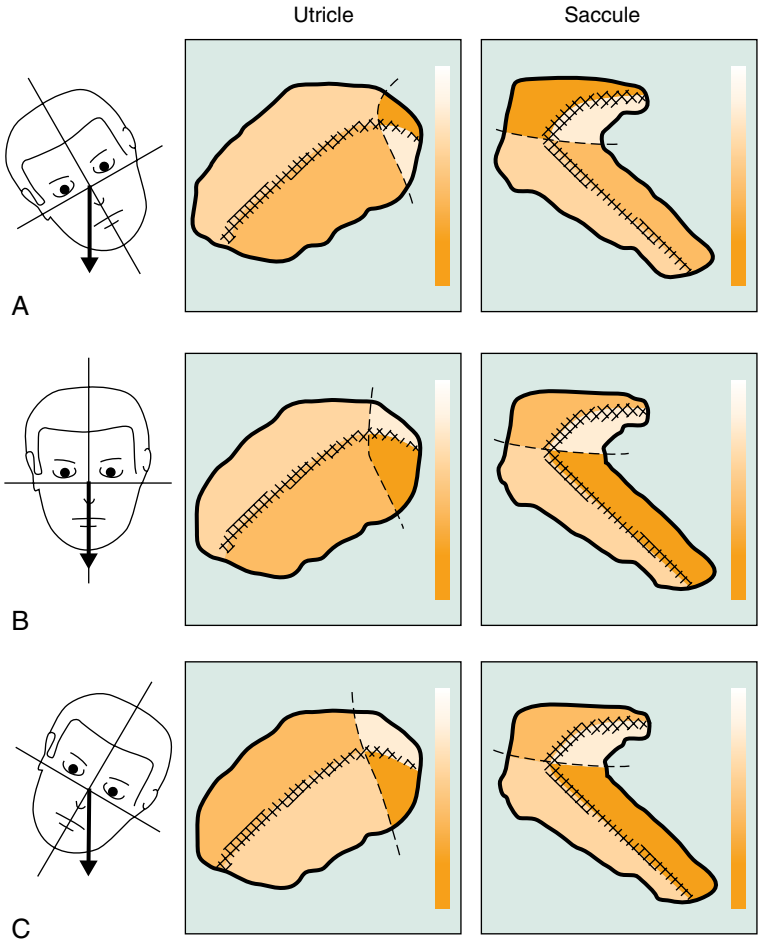

Figure 163-7. Estimated patterns of excitation and inhibition for the left utricle and saccule when the head is (**A**) tilted with the right ear 30 degrees down, (**B**) upright, and (**C**) tilted with the left ear 30 degrees down. The utricle is seen from above, and the saccule from the left side. The nidpoint of the color scale represents baseline activity, whereas dark orange and white represent depolarization and hyperpolarization, respectively. *(Modified from Jaeger R, Takagi A, Haslwanter T. Modeling the relation between head orientations and otolith responses in humans.* Hear Res. *2002;173:29.)*

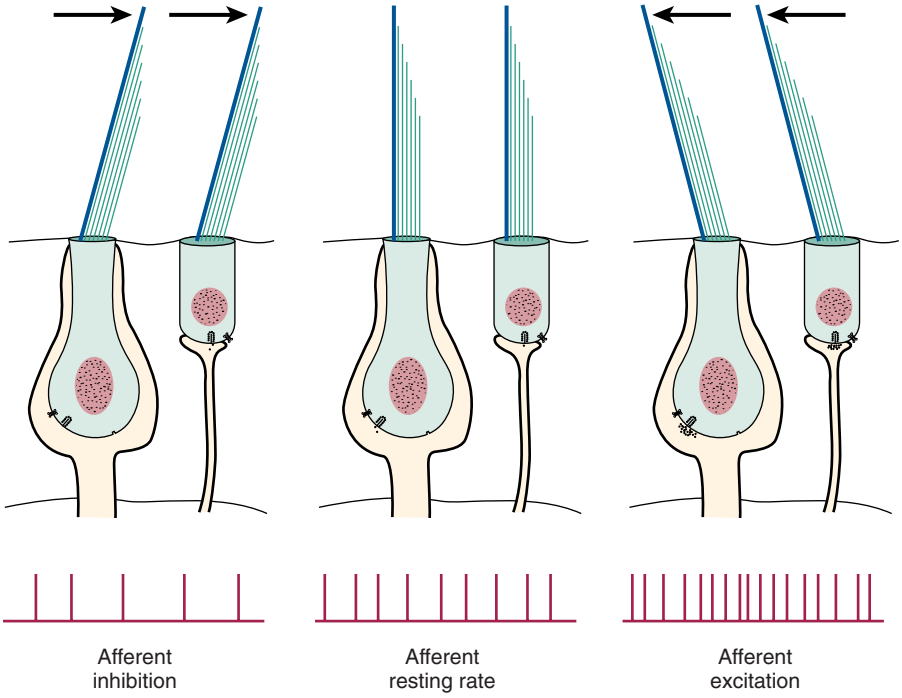

Figure 163-8. A vestibular afferent nerve fires actively at rest (*center*). Its firing rate is modulated by sensory transduction. The afferent is inhibited when its hair cells' stereocilia are deflected in the "off" direction (away from the kinocilium, in dark blue *left panel*) and excited when the stereocilia are deflected in the "on" direction (toward the kinocilium, *right panel*).

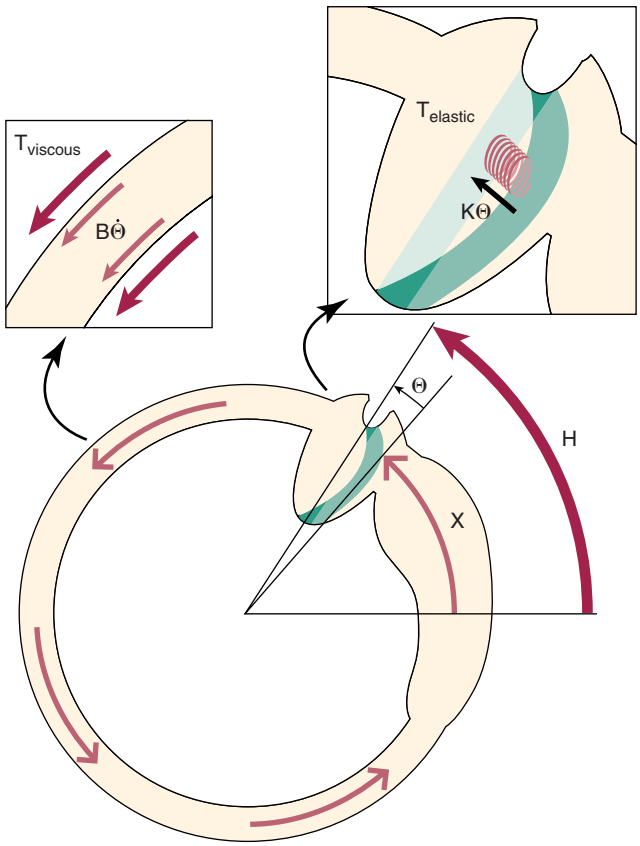

Figure 163-9. The torsional pendulum model of the mechanical forces acting on the cupula and endolymph of the left horizontal canal during leftward angular head acceleration as seen from above. As the head rotates through space over an angle *H*, endolymph inside the canal also rotates through space, but over a slightly smaller angle *X*. The difference between the angles through which the head and endolymph rotate in space is Θ, which approximates the angular deflection of the cupula. This creates an elastic torque proportional to the deflection: $T_{elastic} = K\Theta$. A viscous or drag torque is produced by the relative flow of endolymph along the walls of the canal and is proportional to the endolymph velocity relative to the canal: $T_{viscous} = B\dot{\Theta}$. The sum of these torques will equal the moment of inertia of the cupula and endolymph times their acceleration: $K\Theta + B\dot{\Theta} = I\ddot{X} = I\ddot{H} - I\ddot{\Theta}$.

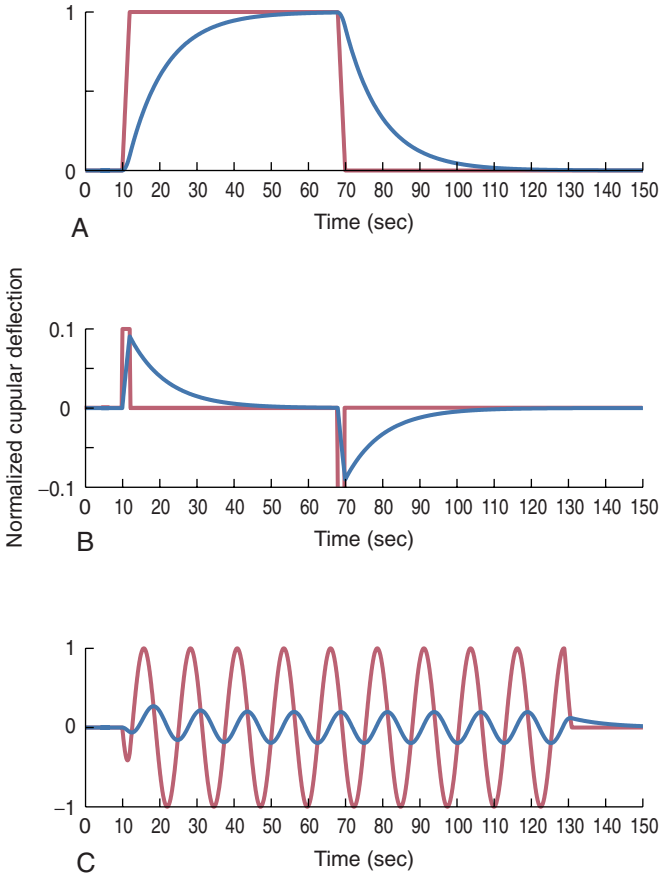

Figure 163-10. Patterns of cupular displacement in response to rotational head movements as predicted by the torsional pendulum model. **A,** A step of constant head acceleration *(red tracing)* results in a constant cupular deflection *(blue)* after an exponential increase in deflection with a time constant of about 10 sec. **B,** A step of constant velocity is produced by an impulse of acceleration in one direction followed by an impulse of deceleration in the opposite direction (acceleration impulses are shown in *red*). The cupula is transiently displaced, returning to its resting position with a decay time constant of about 10 sec. **C,** Sinusoidal *acceleration* of the head (*red*) yields a response in phase with head *velocity*.

The movement of the cupula can now be described as a function of head acceleration:

$$K\Theta(t) + B\dot{\Theta}(t) + I\ddot{\Theta}(t) = I\ddot{H}(t) \qquad \text{Eq. 163-8}$$

The full solution to Equation 163-8 is derived in the Appendix, but considerable insights can be gained without the full solution simply by inserting measured values for the physical constants in Equation 163-8 and considering the behavior under special circumstances.

For example, during a constant, low-acceleration head rotation (Fig.163-10A), cupular deflection eventually reaches a steady-state constant value. Because cupular velocity and acceleration eventually decay to zero under these circumstances, Equation 163-8 reduces to

$$K\Theta(t) \approx I\ddot{H}(t) \qquad \text{Eq. 163-9}$$

and cupular deflection (and afferent firing rate) is approximately proportional to head acceleration. The time course of cupular displacement in response to a constant acceleration approximates a single exponential growth, and the time constant with which cupular displacement reaches its maximum deflection is approximately 10 seconds, the time constant of the cupula (see Appendix). When the constant acceleration stops, the cupula returns to its zero position exponentially with the same time constant.

The same time constant governs the cupular response to very brief pulses of head acceleration. Figure 163-10B shows the predicted cupular deflection to an impulse of acceleration, which brings the head to a constant velocity plateau until an impulse of deceleration stops the rotation. Such "velocity steps" are often done as part of clinical rotary chair tests. However, the measured value of the time constant of the VOR in such testing is generally much longer than what would be anticipated by this calculated cupular response because of further processing by the brain (This is addressed later in the discussion of Principle 9.)

During sinusoidal head rotations in the range encompassing most natural head movements (approximately 0.1 to 15 Hz), viscous friction dominates the cupular response, and Equation 163-8 reduces to

$$B\dot{\Theta}(t) \approx I\ddot{H}(t) \qquad \text{Eq. 163-10}$$

This implies that

$$\Theta(t) \approx \frac{I}{B}\dot{H}(t), \qquad \text{Eq. 163-11}$$

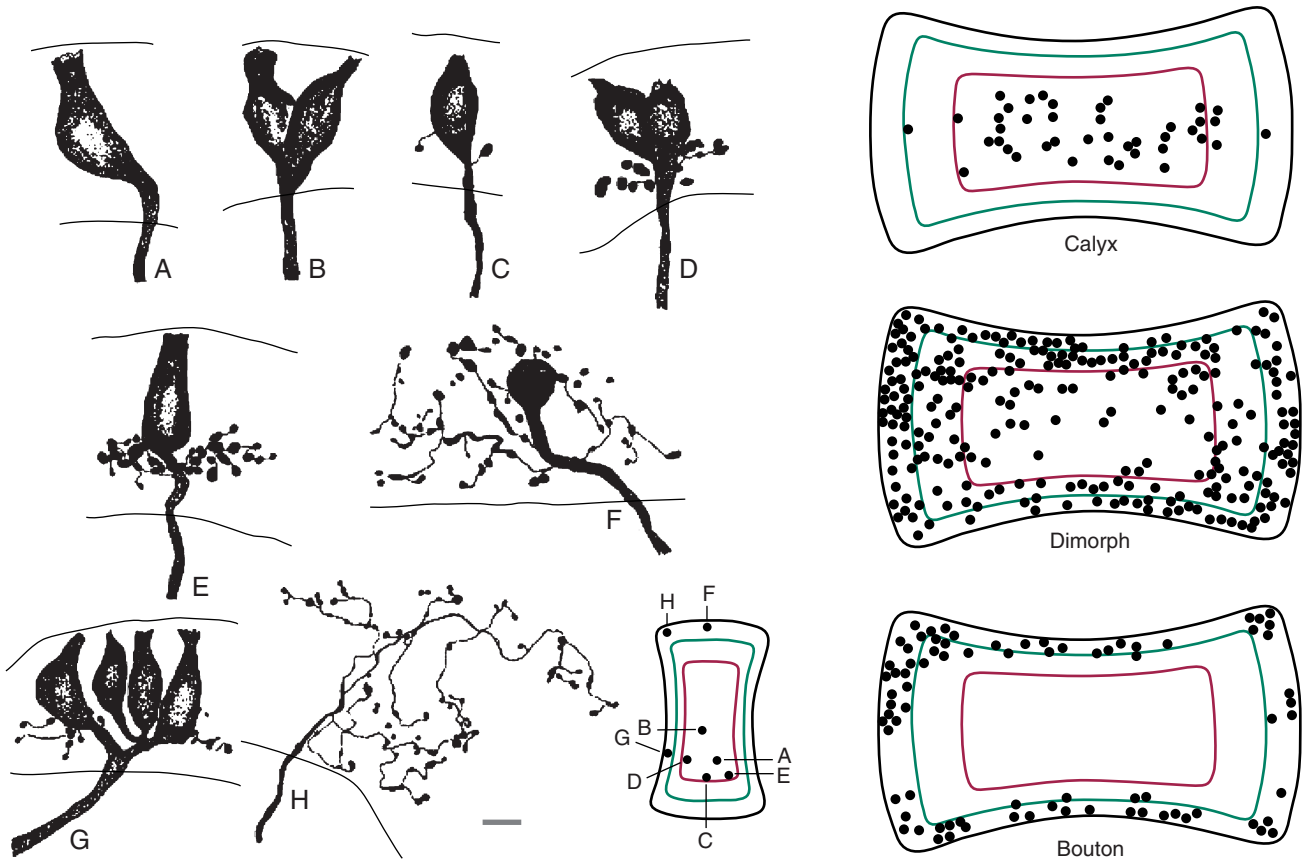

Figure 163-11. Morphology of mammalian vestibular afferents as revealed by horseradish peroxidase labeling of individual units in the chinchilla. **A,** Calyx fiber innervating a single type I hair cell. **B,** Calyx fiber innervating two type 1 hair cells. **C** to **G,** Dimorphic fibers innervate both type 1 and 2 hair cells. **H,** Bouton fiber. *Inset*: Locations of these afferents are placed on a standard map of the crista. *Right*: Three standard maps of the cristae divided into concentrically arranged central (*inside red border*), intermediate, and peripheral (*outside green*) zones of equal areas. Shown are the locations of calyx, dimorphic, and bouton fibers, with each colored dot representing a single dye-filled fiber. Dimorphic units make up 70% of the population, bouton units 20%, and calyx units 10%. *(From Fernandez C, Baird RA, Goldberg JM. The vestibular nerve of the chinchilla. I. Peripheral innervation patterns in the horizontal and superior semicircular canals.* J Neurophysiol. *1988;60:167.)*

so that cupular deflection is proportional to head *velocity*. This is demonstrated in Figure 163-10C: Note that the cupula's predicted response is not in phase with the sine wave that describes head acceleration (red). Rather, the cupula's motion appears to peak one-fourth cycle in advance of the head's motion. This 90-degree phase advance in the cupula's motion can be represented by a cosine wave, which is the integral of the sine wave. The endolymph and cupula thus act as a mechanical integrator of the input head acceleration. The integral of acceleration is velocity, so the important point here is that the cupula encodes head velocity over its physiologically relevant frequency range, even though the stimulus acting on the endolymph is head acceleration. Because of this, and because retinal image slip velocity is an important determinant of visual acuity, clinical and experimental tests conventionally report findings with respect to head velocity.

Response of the Otoconial Membrane

An approach similar to the analysis of cupular motion yields an equation relating the predicted movement of the otoconial membrane to head acceleration.[4] Unfortunately, the otoconial membrane is an inhomogeneous structure whose complexities make it difficult to estimate the physical parameters in the model that would predict its responses under different conditions. The membrane consists of the dense otoconial layer on top, a stiff mesh layer in the middle, and an elastic gel layer on the bottom.[19] At the macular surface it is presumably fixed. It is unclear how tightly otoconial displacement is coupled to the motion of the stereocilia. These uncertainties lead to models that variously predict that the otoconial membrane responds to linear acceleration or velocity, but the actual behavior remains unresolved.[17,20]

Encoding by the Afferents

Morphologically, mammalian vestibular afferents can be grouped into calyceal, bouton, and dimorphic fibers[21-23] (Fig. 163-11). Calyceal fibers (see Fig. 163-11A and B) form chalice-shaped calyx synapses on one or several neighboring type 1 hair cells. Each calyx engulfs the basolateral membrane of the enclosed type 1 hair cell(s). At the other end of the morphological spectrum, a bouton fiber (see Fig. 163-11H) forms 15 to 100 button-like synapses on multiple type 2 hair cells distributed over 25 to 75 µm. Dimorphic fibers (see Fig. 163-11C to G) include 1 to 4 calyceal synapses with type 1 hair cells and 1 to 50 bouton-type synapses with type 2 hair cells. The spatial distribution of afferent endings within the sensory neuroepithelium differs for these three different morphologic groups (shown to the right in Fig. 163-11). Calyceal afferents in the crista are found exclusively in the central zone (on the top of the crest) and in the macula exclusively in the striola. Bouton fibers mostly arborize in the peripheral zone of the crista and in the extrastriolar zones of the maculae. Dimorphic afferents innervate all regions of the vestibular sensory epithelia, and are the dominant fiber type.[22-24]

In mammals, physiologic response characteristics segregate vestibular nerve afferent fibers into two classes based on the regularity in the spacing of spontaneous action potentials[25] (as reviewed by Goldberg and Fernández[26]). *Regular afferents* (Fig. 163-12A) fire at 50 to 100 spikes/second at rest, with very little variation in resting rate for a given

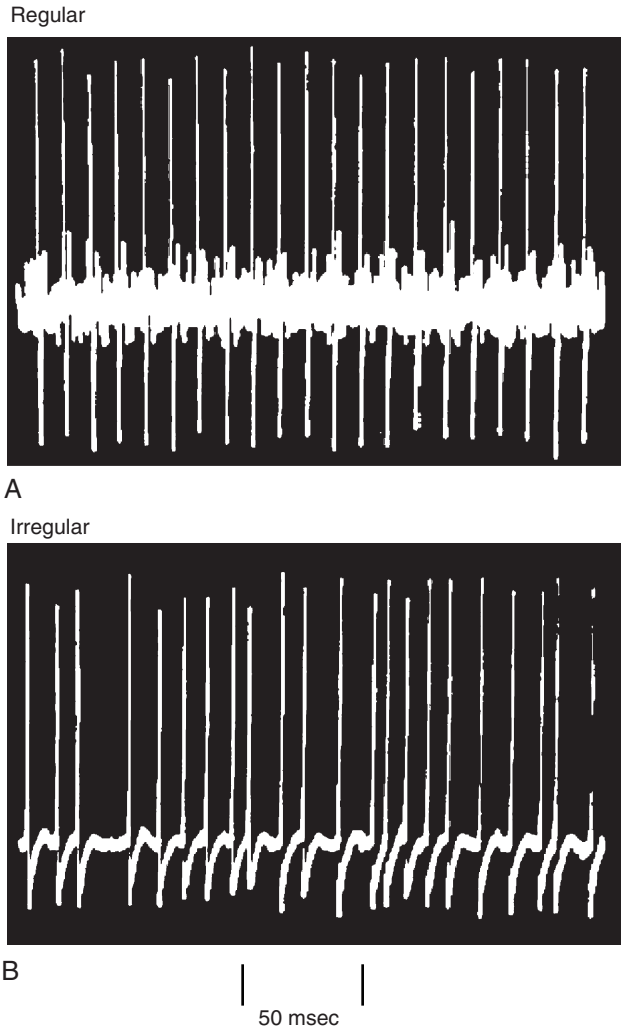

Figure 163-12. Regular (**A**) and irregular (**B**) discharge patterns in the spike trains recorded from two afferents from the superior canal crista in the squirrel monkey. *(From Goldberg JM, Fernandez C. Physiology of peripheral neurons innervating semicircular canals of the squirrel monkey. I. Resting discharge and response to constant angular accelerations.* J Neurophysiol. *1971;34:635.)*

fiber.[27,28] In general, they respond to vestibular stimulation with *tonic* responses. That is, their firing modulates about the baseline, going up and down in close approximation to the stimulus acting on the hair cells. For the otolith organs, the presumed stimulus acting on the hair cells is linear acceleration. The regular afferents in the macula fire in close approximation to linear acceleration.[29,30] For the semicircular canals, the effective stimulus acting on the hair cells turns out to be rotational *velocity*, not acceleration, as explained earlier and in the Appendix. Regular afferents innervating the crista respond with firing rate variations that closely approximate that head velocity signal. Regular units typically have a relatively low sensitivity (change in spike rate for a change in stimulus) to head rotation, to activation of efferent pathways, and to galvanic stimulation.[27,29,31,32] Regular afferents typically have medium or thin axons with bouton-only or dimorphic arborizations in the peripheral zones of cristae or otolithic maculae.[27,33-35]

In contrast with regular vestibular afferents, *irregular afferents* typically are thick to medium-sized axons that end in calyceal or dimorphic terminals in the central (or *striolar*) zones of vestibular endorgans.[27,32-35] Their interspike intervals are much more variable (see Fig. 163-12B). As a population, irregular afferents have a wider range of spontaneous rates than do regular fibers. Irregular units show *phasic* responses to the stimulus acting on the endorgan. That is, the response is more transient, and it approximates the rate of change of the stimulus acting on the endorgan rather than simply the stimulus itself. Thus, irregular units in the crista approximate the head's rotational *acceleration*, which is the rate of change of velocity.[27,29,31] Irregulars in the macula approximate the linear *jerk*, the derivative of linear acceleration.[29,30] Irregular units may have very high sensitivity to vestibular stimuli, except for a unique group of low-sensitivity calyx units in the crista, whose function is still unclear.[25] Sensitivities to activation by efferent pathways and to galvanic stimulation also are generally greater for irregular afferents.[26,36]

Smith and Goldberg[37] have described a model of vestibular nerve afferent spike-initiation dynamics that accounts for many of these observed differences between classes of afferent discharge (Fig. 163-13). After the peak of an action potential (caused by inward sodium currents), outward potassium currents briefly hyperpolarize the vestibular afferent membrane. The potassium conductance decays in a time-dependent manner, and the membrane potential rises again toward the threshold voltage for spike generation. Excitatory postsynaptic potentials (EPSPs) due to synaptic neurotransmitter release superimpose on this repolarization. The model assumes that variations in this potassium conductance between different afferents accounts for their regularity of discharge. In regularly discharging afferents, the model proposes that a

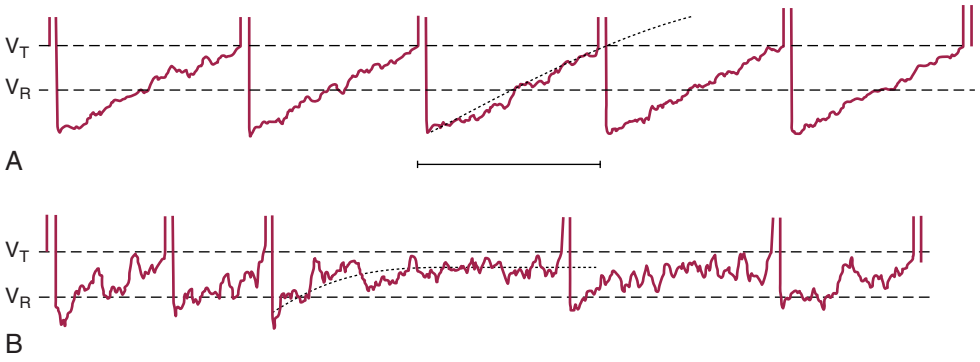

Figure 163-13. The stochastic afterhyperpolarization (AHP) model of repetitive discharge in vestibular afferents. V_R, resting potential; V_T, threshold for spike generation. Two model units are shown with their mean interspike trajectories *(dotted lines)*. **A,** The unit at the top has a regular discharge because of its deep and slow AHP and relatively small miniature excitatory postsynaptic potentials (EPSPs). **B,** The bottom unit is irregular because its AHP is shallow and fast, and its miniature EPSPs are somewhat larger than those in **A.** Note that regular discharge is associated with the mean trajectory eventually crossing V_T at regular intervals. For the irregular discharge, the mean trajectory does not cross V_T, and the actual unit potential crosses V_T only when sufficient EPSPs are added to the mean trajectory. As a result, the timing of spikes in the regular unit is largely determined by the mean trajectory, whereas timing for the irregular unit's spikes is largely determined by synaptic noise. *(Data from Smith CE, Goldberg JM. A stochastic afterhyperpolarization model of repetitive activity in vestibular afferents.* Biol Cybern. *1986;54:41.)*

large potassium conductance decays slowly but inexorably, so that the repolarization continues in a deterministic fashion until the membrane potential again reaches firing threshold (see Fig. 163-13A). The model assumes that quanta of neurotransmitter released from hair cells cause relatively little variation in the trajectory of the repolarization. This deterministic nature of the repolarization means that the membrane reaches the threshold for another spike at almost the same time for each spike. Thus, the interspike intervals are all similar, and the unit's discharge is regular. By contrast, in irregularly discharging afferents, the model assumes a potassium conductance that is high initially but decays rapidly so that it does not carry the membrane potential back up to the threshold for firing by itself (see Fig. 163-13B). These fibers sit just below threshold voltage until driven above it by the added potential due to EPSPs. Neurotransmitter release and EPSPs are quantal and random, so that the time at which the membrane reaches firing potential is highly variable from spike to spike. Thus, the unit's discharge is irregular.

These firing characteristics of the different classes of afferents may be dictated by morphologic and biochemical specializations of their membranes. The variation in discharge regularity is best correlated with the position of the afferent's endings in the neuroepithelium. Irregular units arise from the central zone of the crista or striola of the macula, and regular units arise from the peripheral zone of the crista or extrastriola of the macula. These variations may be due to regional variations in the ion channels that govern interspike intervals.[25] Alternatively, the correspondence between afferent discharge regularity and the number of hair cells with which an afferent forms synapses suggests that discharge regularity may be due in part to combining inputs from many stochastically independent synapses.[38]

Because regular and irregular vestibular nerve afferent fibers have distinct characteristics in so many respects, it seems likely that they mediate different functions.[25] One hypothesis holds that regular and irregular afferents may help compensate for different dynamic loads of the different vestibular reflexes. Regular afferents carry signals roughly in phase with head velocity, the expected output of the mechanics of the semicircular canals (as described; see also the Appendix). Irregular units with high gains have responses more in phase with head acceleration than velocity. The VOR for low-frequency head rotations requires a signal that approximates head velocity, and the regular afferents seem to provide an ideal input for this reflex.[39] By contrast, the VSRs involve very different mechanical loads and may require inputs from the labyrinth that better reflect the head's acceleration, a task to which the irregulars seem better suited.[40] Anatomically, regular and irregular afferents overlap extensively in their distributions to the central vestibular nuclei.[41-43] However, physiologic evidence suggests that there is some segregation of regular and irregular inputs between central projections to the ocular motor centers and the spinal motor centers.[44,45] Another role for the irregular afferents may be to initiate the vestibular reflexes with a very short latency for rapid head movements.[46] Finally, some evidence suggests that the dynamics of irregular afferents are better suited to provide the modifiable component of the VOR when gain must be changed rapidly. Examples are the higher gain needed when the eyes are verged on a near target,[47,48] the change needed to adapt to magnifying or "minifying" spectacles,[49,50] and the adaptation that must occur on one side when function is lost on the other side.[51,52]

In addition to more than 10,000 afferents, each labyrinth also receives efferent innervation from approximately 400 to 600 neurons that lie on either side of the brainstem adjacent to the vestibular nuclei.[53,54] Highly vesiculated efferent endings synapse onto type 2 hair cells and onto the axons of vestibular afferents.[55-57] In mammals, excitation of efferents causes an increase in the background discharge of vestibular afferents, particularly irregular ones.[26] Mammalian efferents can be activated by high head velocities.[58] In fish, vestibular efferents can be activated during behavioral arousal in which head movement would be anticipated.[36] These observations have led to the hypothesis that the efferents may serve to raise baseline afferent firing rates, particularly of irregular afferents, in anticipation of rapid head movements so as to prevent inhibitory silencing.[26,36] Yet Cullen and Minor[59] found that in alert monkeys, afferents responded identically to actively and passively generated rapid head-on-body rotations, making an efferent role in such brief movements unlikely. These investigators hypothesized that vestibular efferents may act to balance firing between the two labyrinths, a role that may be particularly important after some degree of loss of unilateral function.

Principle 3: Stimulation of a Semicircular Canal Produces Eye Movements in the Plane of that Canal

This important principle often is referred to as *Ewald's First Law*. Ewald cannulated the individual membranous canals in pigeons and observed the effects of endolymph motion on body, head, and eye movements. Although Ewald may have codified this principle on the basis of his work,[60] it is clear that earlier workers like Flourens and Mach recognized that manipulations of an isolated semicircular canal in experimental animals produced eye or head movements in the plane of that canal.[61]

Anatomic and Physiologic Basis

The anatomic basis of this principle begins with the anatomy of the semicircular canals. The arrangement of the canals places fluid motion sensors at the ends of relatively long, slender, fluid-filled, donut-shaped tubes. Each tube lies more or less in one plane. The most effective stimulus to move the fluid in such a planar semicircular tube is angular acceleration in that plane, about an axis perpendicular to the plane and through the center of the "donut hole."

The three semicircular canals of the labyrinth are roughly orthogonal to each other, so that one labyrinth can sense any rotation in three-dimensional space. Canals in the two labyrinths are arranged in complementary, coplanar pairs.[62] The two horizontal canals are roughly in one plane, which is nearly horizontal when the head is in an upright position. The left anterior canal is roughly coplanar with the right posterior canal in the *LARP* (left anterior–right posterior) plane, which lies approximately 45 degrees off the midsagittal plane with the anterior end toward the left and the posterior end toward the right. And the right anterior canal is roughly coplanar with the left posterior canal in the *RALP* (right anterior–left posterior) plane, again roughly 45 degrees off the sagittal plane and orthogonal to the LARP and horizontal planes (Fig. 163-14). These canal planes define the cardinal coordinate system for vestibular sensation.

The power of this principle goes beyond the notion that the canal planes simply provide a coordinate system for vestibular *sensation*. Canal planes also provide the coordinate system for the final *motor output* of the VOR (and for the vestibulo-colic neck reflex). The beauty of this canal-fixed (and thus head-fixed) coordinate system for eye movements is that it reduces the neural computation required for ocular motor output to exactly compensate for the head movement.

How is this coordinate system preserved in the central connections of the VOR? Figure 163-15 shows the connections from the left horizontal canal that mediate the VOR when that canal is excited. We have already seen how this movement excites the afferents from this canal; the inset demonstrates this increase in firing from the baseline rate. Secondary vestibular neurons in the ipsilateral vestibular (medial and superior) nuclei receive these afferent signals and connect to the ocular motor nuclei controlling the medial and lateral rectus muscles, which also lie roughly in a horizontal plane. Secondary vestibular neurons carry excitatory signals to the ipsilateral third nucleus and contralateral sixth nucleus to excite the ipsilateral medial rectus and contralateral lateral rectus, respectively. These muscles pull the eyes toward the right as the head turns toward the left, accomplishing the goal of keeping the eyes stable in space. Other secondary vestibular neurons carry inhibitory signals to the contralateral third and ipsilateral sixth nuclei to simultaneously relax the antagonist muscles, the contralateral medial rectus and the ipsilateral lateral rectus, respectively. This reciprocal activity is typical of the extraocular muscles, which work in contraction-relaxation pairs.[63]

Just as the extraocular muscles work in reciprocal pairs, so too do the coplanar semicircular canals. Like the left horizontal canal, the right horizontal canal is also stimulated by the horizontal head turn (Fig. 163-16). However, because the polarity of stereociliary bundles in the

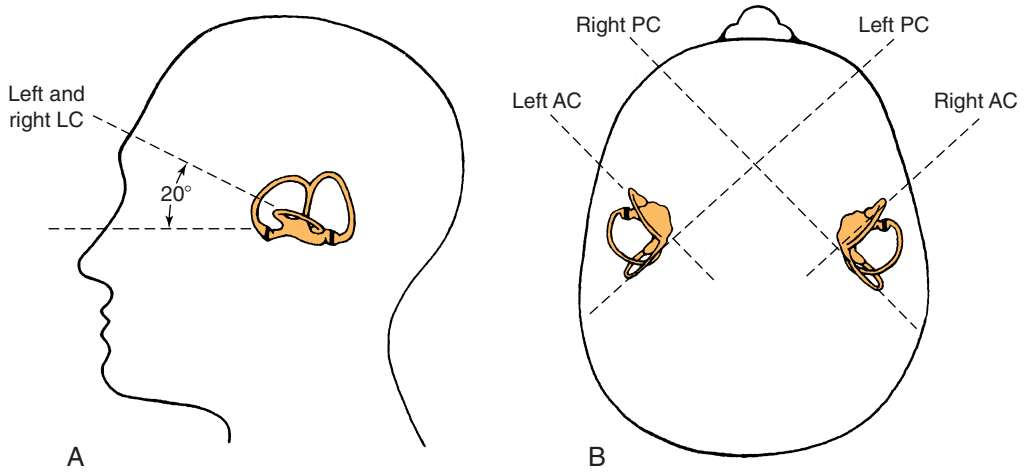

Figure 163-14. Orientation of the semicircular canals. **A,** When the head is upright, the horizontal canal (or lateral canal [LC]) is tilted approximately 20 degrees upward from the horizontal plane at its anterior end. **B,** The vertical canals are oriented in planes roughly 45 degrees from the midsagittal plane. The right anterior canal (AC) and left posterior canal (PC) lie in the same plane, the right anterior–left posterior (RALP) plane. The left anterior and right posterior canals lie in the left anterior–right posterior (LARP) plane. *(Adapted From Barber HO, Stockwell CW.* Manual of Electronystagmography. *St Louis: Mosby; 1976.)*

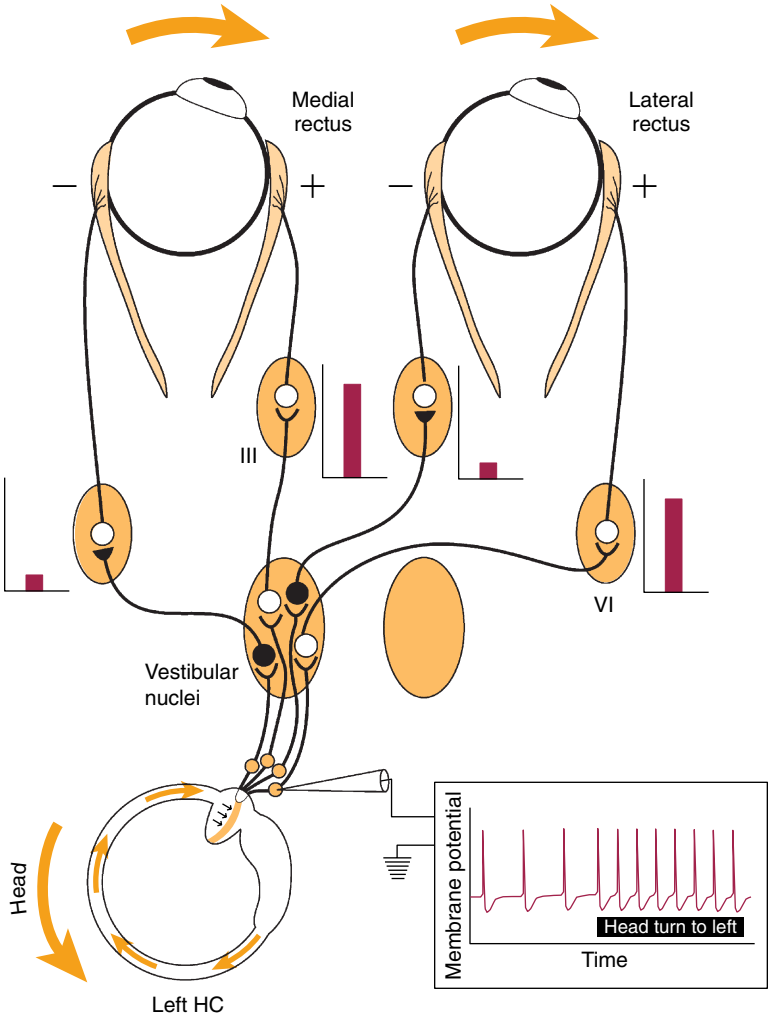

Figure 163-15. Neural connections in the direct pathway for the vestibulo-ocular reflex (VOR) from excitation of the left horizontal canal (HC). As seen from above, a leftward head rotation produces relative endolymph flow in the left HC that is clockwise and toward the utricle. The cupular deflection excites the hair cells in the left HC ampulla, and the firing rate in the afferents increases *(inset)*. Excitatory interneurons in the vestibular nuclei connect to motor neurons for the medial rectus muscle in the ipsilateral third nucleus (III) and lateral rectus muscle in the contralateral sixth nucleus (VI). Firing rates for these motor neurons increase *(mini bar graphs)*. The respective muscles contract and pull the eyes clockwise, opposite the head, during the slow phases of nystagmus. Inhibitory interneurons in the vestibular nuclei connect to motoneurons for the left lateral rectus and right medial rectus. Their firing rates decrease, and these antagonist muscles relax to facilitate the eye movement.

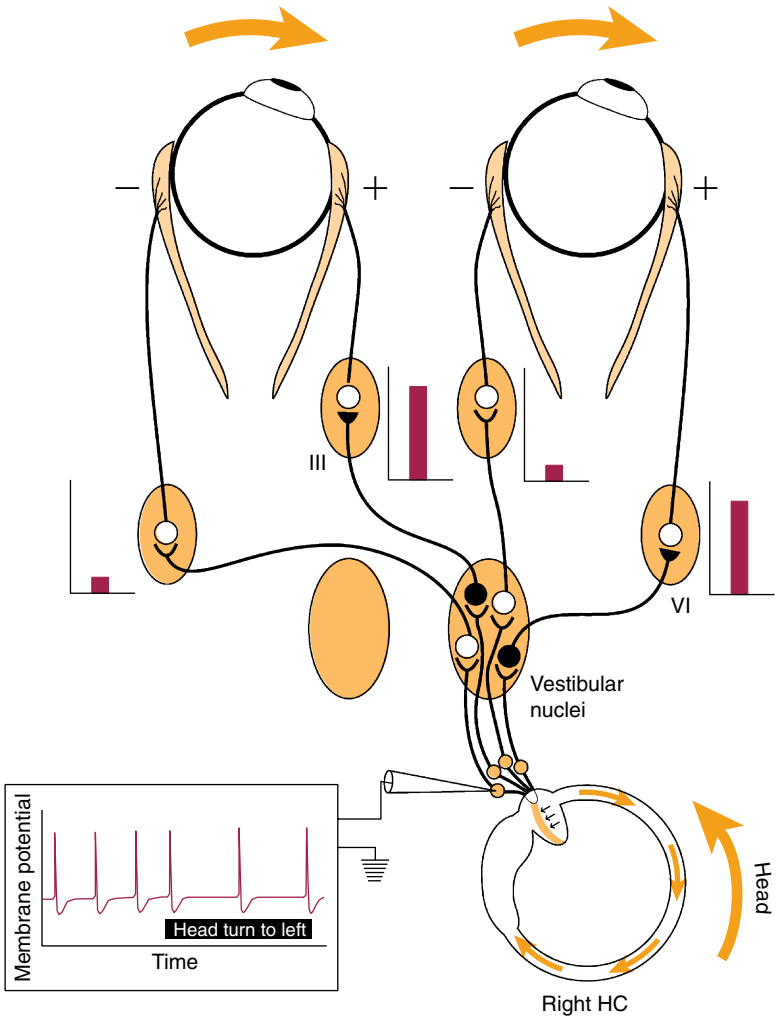

Figure 163-16. Complementary neural connections in the direct pathway for the vestibulo-ocular reflex (VOR) from inhibition of the right horizontal canal (HC). As seen from above, a leftward head rotation again produces relative endolymph flow that is clockwise in the canal. However, for the right HC, this flow is away from the utricle. The cupular deflection inhibits the hair cells in the right HC ampulla, and the firing rate in the afferents decreases *(inset)*. Inhibitory interneurons in the vestibular nuclei reverse this inhibition, sending further excitatory signals *(mini bar graphs)* to the motorneurons for the medial rectus muscle in the ipsilateral third nucleus (III) and lateral rectus muscle in the contralateral sixth nucleus (VI). The contraction of these muscles is augmented. Simultaneously, excitatory interneurons *(open circles)* in the vestibular nuclei preserve and convey inhibition *(mini bar graphs)* to motoneurons for the lateral rectus muscle in the left sixth nucleus (VI) and medial rectus muscle in the right third nucleus (III). The inhibitory signals further relax these antagonist muscles.

right horizontal canal is a mirror image of the arrangement on the left, the flow of endolymph with respect to the head, still clockwise as seen from above, has an *inhibitory* effect on the right horizontal canal afferents. Connections from the right vestibular nuclei to the ocular motor nuclei also mirror those on the left. With the inverse signals coming through this mirror-image circuit from the right side, the ocular motor nuclei receive greater excitatory stimuli for the right lateral and left medial rectus muscles, and more inhibition for their antagonists. Thus, head rotation produces an excitatory contribution to the VOR from one canal and an inhibitory contribution from its coplanar mate. This often is referred to as the "push-pull" arrangement of the canals. Thanks to the nonzero baseline firing rate of vestibular afferent neurons, both of the canals in a coplanar pair can encode rotational acceleration in that plane.

Like the horizontal canals and the lateral and medial recti, the vertical semicircular canals are linked to the vertical pairs of eye muscles, a fact that helps explain the pulling directions and insertions of the superior and inferior oblique muscles. Figure 163-17 demonstrates that the LARP plane aligns with the pulling directions of the left superior and inferior rectus muscles as well as the right superior and inferior oblique muscles. The connections from the secondary vestibular nuclei can be traced, just as shown in Figures 163-15 and 163-16. The important result is indicated by the contrast coding in Figure 163-17. Excitation of the left anterior canal (shading) and inhibition of the right posterior canal (shading) result in contraction of the muscles that pull the eyes upward in the LARP plane and relaxation of the muscles that pull them downward in that plane. Similarly, the RALP plane aligns with the pulling directions of those vertical eye muscles that move the eyes in the RALP plane.

The alignment of canal planes and extraocular muscle planes is not exact, and the excitation of a single canal pair does not solely produce activity in a dedicated pair of extraocular muscles. Other muscles must be activated to compensate for a head rotation even when it is purely in the plane of one semicircular canal. However, this arrangement between semicircular canals and extraocular muscles is remarkably constant across vertebrate species, even allowing for the shift between lateral-eyed species (e.g., rabbits) and frontal-eyed ones (e.g., humans). Because the vestibular labyrinth evolved before movable eyes,[64] extraocular muscles may have evolved to pull in the preexisting canal planes. Robinson[65] has argued that there is an evolutionary advantage to keeping the extraocular muscles aligned with the semicircular canals. Such an arrangement minimizes the brainstem processing

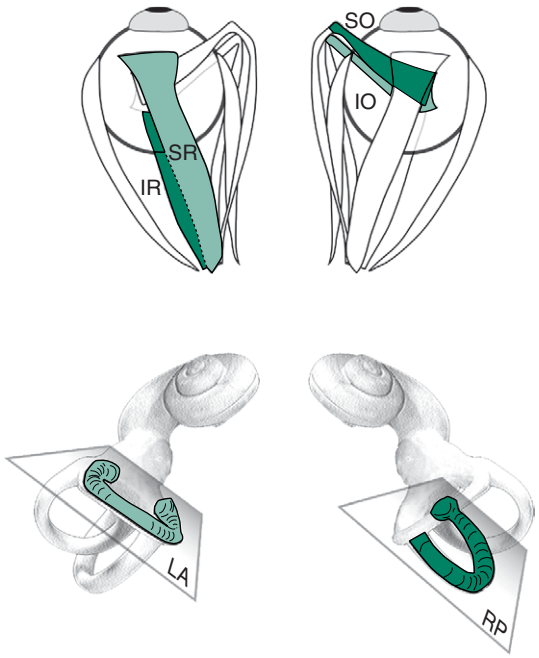

Figure 163-17. The left anterior–right posterior canal (LARP) plane aligns with the pulling directions of the left superior rectus (SR) and inferior rectus (IR) muscles, as well as the right superior oblique (SO) and inferior oblique (IO) muscles. As indicated by the shading, excitation of the left anterior canal (and inhibition of the right posterior canal) causes contraction of the left superior rectus and right inferior oblique muscles and relaxation of the darker-shaded antagonists. The result will be an upward movement of the eyes in the LARP plane. Excitation of the right posterior canal will produce the opposite effect.

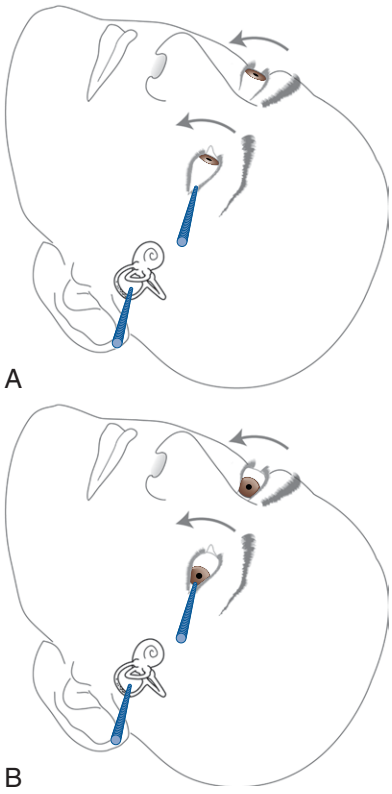

Figure 163-18. Excitation of the left posterior canal (PC) by moving canaliths in benign paroxysmal positional vertigo (PC-BPPV) causes slow phase eye movements downward in the plane of the affected PC. The eyes rotate around an axis parallel to the one going through the center of the affected PC. **A,** When gaze is directed perpendicular to the axis of eye rotation, the pupil appears to move up and down in an eye-fixed reference frame. **B,** When gaze is directed parallel to the axis of eye rotation, the pupil appears to move torsionally in an eye-fixed reference frame. In either case, the eyes rotate around the same axis when considered in a canal-fixed frame of reference.

needed to activate the appropriate ensemble of eye muscles to compensate for head movement. Minimizing the number of synapses involved in the reflex preserves its remarkably short latency of approximately 7 msec,[66] which in turn minimizes retinal image slip during very rapid head movements.

Clinical Importance

Because of the primacy of the canals in determining how the eyes move under vestibular stimulation, it is helpful to think about vestibular eye movements in a *canal-fixed frame of reference*. A good example of the power of this approach is in investigation of benign paroxysmal positional vertigo (BPPV). In the most widely accepted current model of BPPV, otolith crystals displaced from the utricular otoconial mass come to rest in one of the semicircular canals (typically the posterior semicircular canal).[67] When the patient lies down and turns the head toward the affected side, aligning the posterior canal (PC) with the pull of gravity (the left Dix-Hallpike maneuver), the otolith crystals fall toward what is now the "bottom" of the canal. As the otoliths fall, they push endolymph ahead of them, causing cupular deflection and exciting hair cells on the posterior canal crista. Nystagmus develops during the time that endolymph moves. Ewald's First Law predicts the direction of that nystagmus: It will be in the plane of the affected posterior canal, independent of pupil position or head position.

Trying to apply this principle to PC-BPPV confuses many novice examiners. They observe instead that the nystagmus seems to change direction depending on where the patient directs the gaze. When the patient looks out to the side (toward the affected ear), the examiner sees a primarily torsional movement of the eyes. When the patient looks up toward the ceiling (away from the affected ear), the eyes appear to move vertically (Fig. 163-18). With the eyes in a neutral position (straight-ahead gaze), the nystagmus is a mixture of vertical and torsional movements. How can the principle be valid if the nystagmus changes directions?

In reality, no change occurs in the direction of the nystagmus with respect to the canal planes; it is a figment of the wrong frame of reference. In examining eye movements, we are accustomed to thinking in an eye-fixed reference frame in which the line of sight (the line extending forward from the pupil) determines what is up, down, left, right, clockwise, and counterclockwise relative to that axis. But Ewald's First Law demands that we abandon this oculocentric view of eye movements and instead see them in a canal-centric view. In this view, the location of the pupil does not matter. The globe continues to rotate around the axis parallel to the one passing perpendicularly through the posterior canal that is being stimulated (shown in blue in Fig. 163-18). The pupil is simply a surface feature going along for the ride, wherever it happens to be directed. Ewald's First Law states that *the eyes will move in the plane of the stimulated canal no matter where gaze is directed*. In fact, the apparent variation in pupil movement with gaze direction during nystagmus can be used to an examiner's advantage in trying to discern which canal is affected in BPPV (or any other cause of single-canal dysfunction). By asking a patient to look parallel and perpendicular to the plane of the canal in question during periods of nystagmus, one should observe that when the pupil is in the plane of the affected canal, the nystagmus moves the pupil most obviously. This is because the pupil is at the equator of the rotating globe, where rotation will carry it the farthest. When the patient's gaze is directed perpendicular to the plane of the affected canal, the pupil is at the pole of the rotating globe, and eye movement is limited to cyclotorsion about the axis of rotation, which

can be subtle to detect. Finding these two gaze directions can identify and confirm the canal (or at least the coplanar canal pair) causing the nystagmus.

Principle 4: A Semicircular Canal Normally Is Excited by Rotation in the Plane of the Canal Bringing the Head toward the Ipsilateral Side

Anatomic and Physiologic Basis

A semicircular canal crista is excited by rotation in its plane in one direction and is inhibited by rotation in its plane in the opposite direction. Another look at Figure 163-9 shows that turning the head toward the left in the horizontal canal plane produces endolymph rotation to the left *relative to space.* But that endolymph rotation is less than the head rotation by the angle Θ. Thus, *relative to the canal*, there is endolymph rotation of Θ to the right, and the cupula is deflected toward the utricle. The pattern of afferent activation results from the polarization of the stereocilia of the hair cells on the cristae. In the horizontal canal, the taller ends of the bundles point toward the utricle. Flow of endolymph (relative to the head) toward the ampulla-ampullopetal flow (from Latin *petere*, to seek), therefore excites the horizontal canal afferents, and flow of endolymph away from the ampulla—ampullofugal flow (from Latin *fugere,* "to flee")—inhibits these afferents. Thus, relative to the head, endolymph flow toward the ampulla occurs when the head is turning in the plane of the horizontal canal toward the same side.

The vertical canals, however, have the opposite pattern of hair cell polarization. The taller ends of the bundles point away from the utricle, so that flow away from the ampulla (ampullofugal) excites their afferents. For the left anterior canal, whose ampulla is at its anterior end, turning the head down and rolling it to the left in the plane of the left anterior canal results in relative endolymph flow that is ampullofugal. For the left posterior canal, whose ampulla is at its posterior end, turning the head up and rolling it to the left in the plane of the left posterior canal moves its endolymph away from the ampulla and excites its afferents. The mirror-image rotations would pertain to the right vertical canals.

Fortunately, keeping track of ampullopetal and ampullofugal flows is unnecessary. Instead, one need only recall that a semicircular canal is excited by rotation in the plane of the canal bringing the head toward the *ipsilateral* side. For example, the right horizontal canal is excited by turning the head rightward in the horizontal plane. The right anterior canal is excited by pitching the head nose down while rolling the head toward the right in a plane 45 degrees off of the midsagittal plane. The right posterior canal is excited by pitching the head nose up while rolling it toward the right in a plane 45 degrees off the midsagittal plane. In the case of each semicircular canal on the right, the rotation exciting that canal brings the head toward the right in the plane of the canal. In the case of the horizontal canals, the nose is turned toward the right. In the case of the vertical canals, the top of the head is rotated toward the right.

It should be obvious by now that a semicircular canal is inhibited by rotation in the plane of the canal toward the opposite side. As described previously, the arrangement of canals is such that when head rotation excites one, it inhibits its coplanar mate. Thus, the rotations explained in the last paragraph would produce inhibition of the left horizontal, posterior, and anterior canals, respectively.

Clinical Importance

This principle eliminates the need to memorize the orientations of stereocilia in particular ampullae and whether ampullopetal or ampullofugal flow excites a given canal. In fact, it is easier to deduce the basic anatomy and physiology from this principle than vice versa. For example, rolling the head toward the left and bringing the nose up excites the left posterior canal according to Principle 4. As noted earlier, endolymph flows relative to the membranous canal in a direction opposite to the head rotation. Thus, the left posterior canal is excited when endolymph flows upwards and toward the right in the canal—that is, ampullofugal. The stereocilia of this canal must be polarized with the tall ends away from the utricle. A considerable amount of anatomy and physiology is condensed into this simple principle.

Principle 5: Any Stimulus That Excites a Semicircular Canal's Afferents Will Be Interpreted as Excitatory Rotation in the Plane of That Canal

Anatomic and Physiologic Basis

Perhaps because the VOR is critical to the survival of any vertebrate that needs to see and move about its environment, evolution appears to have placed a high premium on maintaining parsimonious and rapid neural connections of head rotational sensors to eye muscles. This allows for optimal performance when the system is working normally. However, by devoting dedicated lines of communication from the canals to the extraocular muscles, nature has effectively made the eyes slaves to the vestibular system. Designed, as it is, to expeditiously and reliably produce the eye movements needed to counter a sensed head movement, the system cannot help but produce those eye movements when the vestibular afferent firing rate changes from some other cause. Likewise, the systems mediating postural reflexes and perception of spatial orientation will respond to pathologic alterations in peripheral vestibular input in the same way that they do to tilting or translational movement. An important point is that the brainstem (and patient) will interpret any change in firing rate from vestibular afferents as indicating head rotation, tilt, or translation that would normally produce that same change in firing rate. Secondary vestibular neurons relay the same misinformation to other reflex control centers and higher areas of conscious sensation. This leads to autonomic and postural disturbances as well as the noxious sensation of *vertigo*, an illusion of self-motion.

A pathologic asymmetry in input from coplanar canals causes the eyes to turn in an attempt to compensate for the "perceived" head rotation. However, given the mechanical constraints imposed by the extraocular muscles, the eyes cannot continue to rotate in the same direction that the canals command for very long. Instead, rapid, resetting movements occur, taking the eyes back toward their neutral positions in the orbits. The result is *nystagmus*, a rhythmic, slowly forward–quickly backward movement of the eyes. The quick resetting movements (similar to saccades) are *quick phases* of nystagmus, and the vestibular-driven slower movements are *slow phases*. Unfortunately, convention dictates that nystagmus direction is described according to the direction of the quick phases, because these are more dramatic and noticeable. However, an important pont is that the slow phases are the *components driven by the vestibular system*. By focusing on the direction of slow phases, one reduces the number of mental inversions required to identify the pathologic canal causing an observed nystagmus.

This principle holds almost universally true for brief, unpredictable changes in afferent firing, but not necessarily for persistent stable changes. Fortunately, the nystagmus caused by sustained imbalances in afferent vestibular tone eventually abates as brainstem and cerebellar neural circuitry adapt to the imbalance, as discussed later on (Principle 12). Still, this principle's explanation of responses to brief changes in labyrinthine activity provides a powerful clinical diagnostic tool in localizing disease processes to individual canals.

Clinical Importance

Posterior Canal Benign Paroxysmal Positional Vertigo

In the example of PC-BPPV introduced above, we saw how loose otoconia and endolymph flowed in an ampullofugal direction when the affected PC was oriented vertically in the Dix-Hallpike position. From Principle 4, this direction of endolymph flow excites the PC afferents. From Principle 3, the eye movements resulting from excitation of the PC will be in the plane of that PC. Principle 5 predicts the direction of the slow phases of the nystagmus in this plane. Excitation of the PC afferents will be interpreted as an excitatory rotation of the head in the plane of the PC, and the nystagmus generated would be compensatory for the perceived rotation. For the left PC, excitatory rotation consists rolling the head toward the left while bringing the nose up. To keep the eyes stable in space, the VOR generates slow phases that move the eyes down and roll them clockwise (with respect to the patient's head).

The quick phases are opposite; they beat up and counterclockwise with respect to the patient's head.

Superior Canal Dehiscence Syndrome

In another example of a disorder causing isolated stimulation of a single semicircular canal, a young woman complains that exposure of the left ear to loud sound "makes the world flutter up and down." Applying a loud sound to the left ear through a headphone causes her to develop vertigo and nystagmus. When she is directed to look 45 degrees to her left, one observes that the slow phases of her nystagmus move her pupils up and down. When she looks 45 degrees to her right, the slow phases appear to be cyclotorsional movements of her pupils clockwise (from her perspective). As she attempts straight-ahead gaze, the nystagmus becomes a mixture of these vertical and torsional movements. The examiner must think in a canal-fixed coordinate system and recognize that in each case, the eyes rotate around the same axis, or in the same plane. In this case, the eyes are moving in the LARP plane and in the direction anticipated for excitation of the left anterior canal or inhibition of the right posterior canal. Because only the left ear is receiving the sound stimulus, the problem must lie in the left anterior canal.

This is an example of *superior semicircular canal dehiscence syndrome* causing a *Tullio phenomenon*. Tullio[68] experimented with sound as a stimulus for the labyrinth in pigeons after he fenestrated their semicircular canals. He observed that this caused eye and head nystagmus in the plane of the fenestrated semicircular canal, another example of Ewald's First Law. Huizinga[69] proposed that the fenestra created a third "mobile window" in the labyrinth, in addition to the oval and round windows. This window opens another route for sound pressure dissipation in the labyrinth. This new route is along the affected canal, so endolymph moves through the semicircular canal under the influence of sound or other pressure changes applied to the oval or round windows (Fig. 163-19A). By Principle 5, the fenestrated superior canal exposed to loud sound encodes the resulting endolymph flow as it would a head rotation in the plane of the affected canal and toward the affected side. Superior canal dehiscence syndrome was only recently discovered.[70] It was the observation of nystagmus just as described here and the line of reasoning presented by Principles 1 to 5 that led investigators to suspect that the superior canal was the source of the nystagmus, which CT scanning confirmed (see Fig. 163-19B).

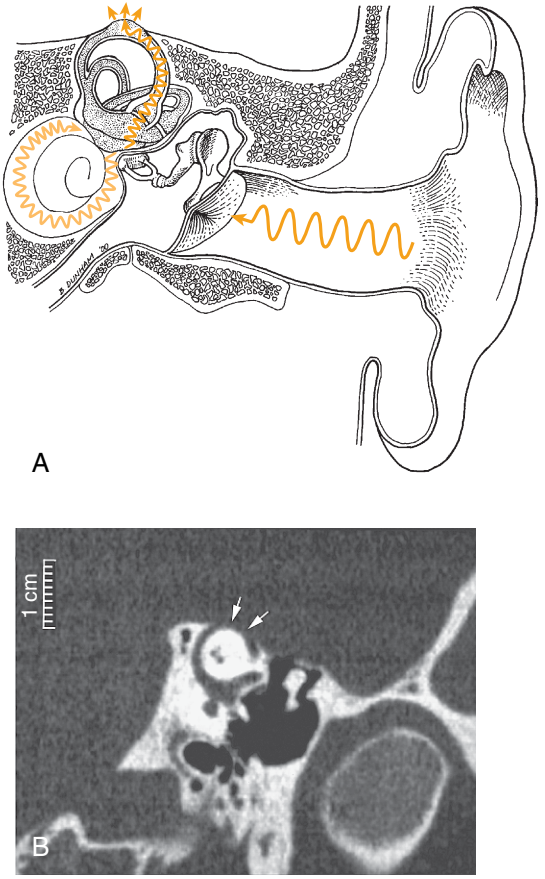

Figure 163-19. A, In superior canal dehiscence syndrome, sound waves can excite the superior canal because the "third mobile window" created by the dehiscence allows some sound pressure to be dissipated along a route through the superior canal in addition to the conventional route through the cochlea. **B,** CT scan demonstrating dehiscence *(arrows)* of the superior canal. *(Illustration courtesy of Dr. B. Dunham.)*

Nystagmus during Caloric Testing

In the caloric test, warm or cool water is irrigated in the external auditory canal. Thermal transfer across the mastoid and eardrum changes the temperature, and therefore density, of the endolymph in the lateral part of the horizontal semicircular canal. That endolymph becomes lighter (by heating) or heavier (by cooling) than the endolymph in the rest of the labyrinth. When the subject is placed supine (with the head up approximately 20 degrees) so as to bring the horizontal canal into a vertical plane, endolymph in the lateral part of the canal made lighter by warming rises toward the ampulla. This is equivalent to the movement caused by turning the head ipsilaterally in the head-horizontal plane. By Principle 4, this manuever excites that canal. By Principle 5, the compensatory eye movements, the slow phases of nystagmus, are in the horizontal canal plane and toward the contralateral side. The quick phases are directed toward the ipsilateral side. By reverse reasoning, for cool irrigation, the horizontal canal is inhibited, and the quick phases are directed toward the contralateral side. (The mnemonic COWS—*c*old *o*pposite, *w*arm *s*ame—can be used to recall the direction of the beating of the nystagmus.) A major advantage of the caloric test is that unlike rotational tests, it applies a truly unilateral stimulus. Diminished caloric responses on one side often help to localize a hypofunctional labyrinth. More details on the caloric test can be found in Chapter 164, Evaluation of the Patient with Dizziness.

Unfortunately, the caloric test has several disadvantages. Testing-predominantly stimulates the horizontal semicircular canal, and little information is provided about other canals and the otolith end organs. Judging from the nystagmus it produces, a caloric stimulus is approximately equivalent to a 5- to 10 degrees/second squared (sec^2) acceleration to a sustained horizontal rotation of approximately 50 to 100 degrees/second. The nystagmus typically persists in one direction for 120 seconds or longer. A comparable head rotation would be a half-cycle of a sine wave with a period of 240 seconds, or a frequency of 1/240 second = 0.004 Hz. This stimulus is well below the ideal operating range of the semicircular canal (see Appendix). Nevertheless, the caloric test remains one of the cornerstones of vestibular evaluation because it gives information about one labyrinth in isolation, which low-frequency rotational tests cannot do.

Principle 6: High Acceleration Head Rotation in the Excitatory Direction of a Canal Elicits a Greater Response than the Same Rotation in the Inhibitory Direction

Anatomic and Physiologic Basis

Ewald made a second important observation in his experiments in which he moved endolymph in individual semicircular canals.[60] Movement of endolymph in the "on" direction for a canal produced greater nystagmus than an equal movement of endolymph in the "off" direction. This observation, *Ewald's Second Law*, indicates an *excitation-inhibition asymmetry*. Excitation-inhibition asymmetries occur at multiple levels in the vestibular system. First, in the hair cells there is an asymmetry in the transduction process. Figure 163-20 shows that in vestibular hair cells there is a larger receptor potential response for stereociliary deflection in the "on" direction than in the "off" direction. A second asymmetry is introduced by the vestibular nerve afferents. Recall that the afferents fire even when the head is at rest, and that this firing is modulated by the hair cell responses to head acceleration after the endolymph and cupula integrate the signal to yield one representing head velocity (Principle 2). Vestibular afferents in mammals

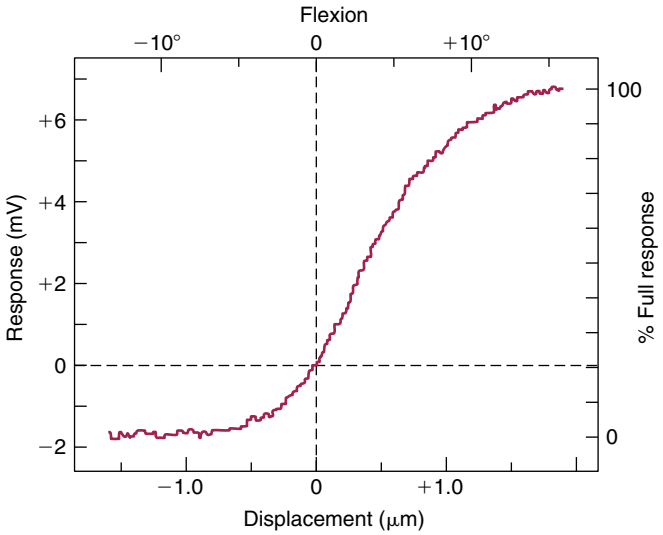

Figure 163-20. Excitation-inhibition asymmetry in the receptor potential of saccular hair cells from the bullfrog. Deflection of stereocilia in the "on" direction produces a larger change in receptor potential than does a comparable deflection in the "off" direction. *(From Hudspeth AJ, Corey DP. Sensitivity, polarity, and conductance change in the response of vertebrate hair cells to controlled mechanical stimuli.* Proc Natl Acad Sci U S A. *1977;74:2407.)*

have baseline firing rates ranging from 50 to 100 spikes/second.[25] Although these firing rates can be driven upwards to 300 to 400 spikes/second, they can be driven no lower than zero. This *inhibitory cutoff* is the most obvious and severe form of excitation-inhibition asymmetry in the vestibular system. Even in the range in which there is no inhibitory cutoff, responses for some vestibular afferents show excitation-inhibition asymmetry, with excitatory rotation causing a greater change in vestibular nerve afferent firing rate than does an equal and opposite inhibitory rotation. Using galvanic currents to stimulate vestibular afferents independent of their hair cells, Goldberg and coworkers[28] showed that this asymmetry is more marked for irregular afferents.

These peripheral asymmetries may be mostly eliminated in the central vestibular connections because of the reciprocal characteristics of signals from one side compared to another. In fact, such a combination of nonlinear sensors acting reciprocally on a symmetrical premotor system can increase the linear range of the vestibular reflexes when both sides are functioning appropriately.[72] However, nonlinearities in the VOR become pronounced when labyrinthine function is lost unilaterally.

Clinical Importance

Aw and colleagues[73] demonstrated that rapid passive rotary head movements elicit markedly asymmetrical VOR responses in humans after unilateral labyrinthectomy. These "head thrusts" are unpredictable, high-acceleration (3000 to 4000 degrees/sec^2) head rotations through amplitudes of 10 to 20 degrees. When the head is thrust in one of the semicircular canal planes so as to excite the canal on the intact side, the VOR that results is nearly compensatory for the head movement (Fig. 163-21, right panels). By contrast, when the head is thrust in one of

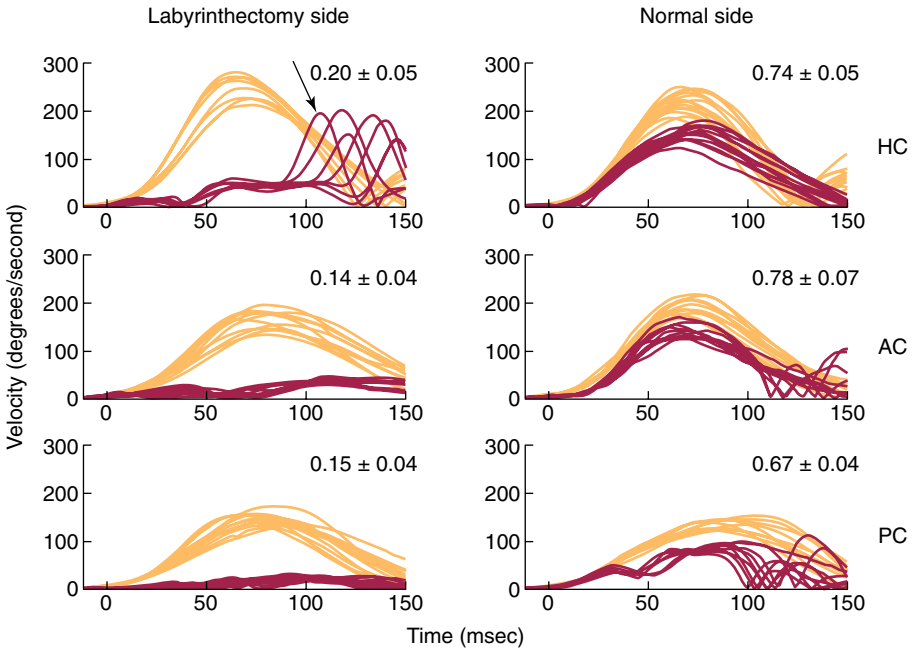

Figure 163-21. Results of head thrust testing of the angular vestibulo-ocular reflexes (aVORs) in a subject after unilateral labyrinthectomy. The examiner manually rotated the subject's head in one of the canal planes during each trial. The subject was instructed to keep his gaze fixed on a small stationary visual target 1.2 m directly in front of him. Eye and head velocities were measured with magnetic search coils. Each panel shows data for 8 to 15 trials exciting one canal. For example, the *top left panel* contains data for rotations in the plane of the horizontal canals (HCs) toward the side of the labyrinthectomy. Head velocity traces are shown in orange, and eye velocity traces are shown in red. For ease of comparison, all velocities are shown as positive values. Gain of the aVOR was defined as the peak eye velocity/peak head velocity ratio during a 30-msec window leading up to the peak head velocity. The gain (mean ± SD) for the respective canal is given in the *upper right corner* of each panel. Note that head thrusts that excited the canals on the normal side were accompanied by nearly compensatory eye movements. By contrast, head thrusts toward the labyrinthectomy side generated very minimal VORs in the period up to peak head velocity. After approximately 90 msec, the visual system registered the retinal slip and triggered a visually guided eye movement to reset gaze on the target *(arrow)*. AC, anterior canal; PC, posterior canal. *(Data from Carey JP, Minor LB, Peng GC, Della Santina CC, Cremer PD, Haslwanter T. Changes in the three-dimensional angular vestibulo-ocular reflex following intratympanic gentamicin for Meniere's disease. JARO. 2002;3:430.)*

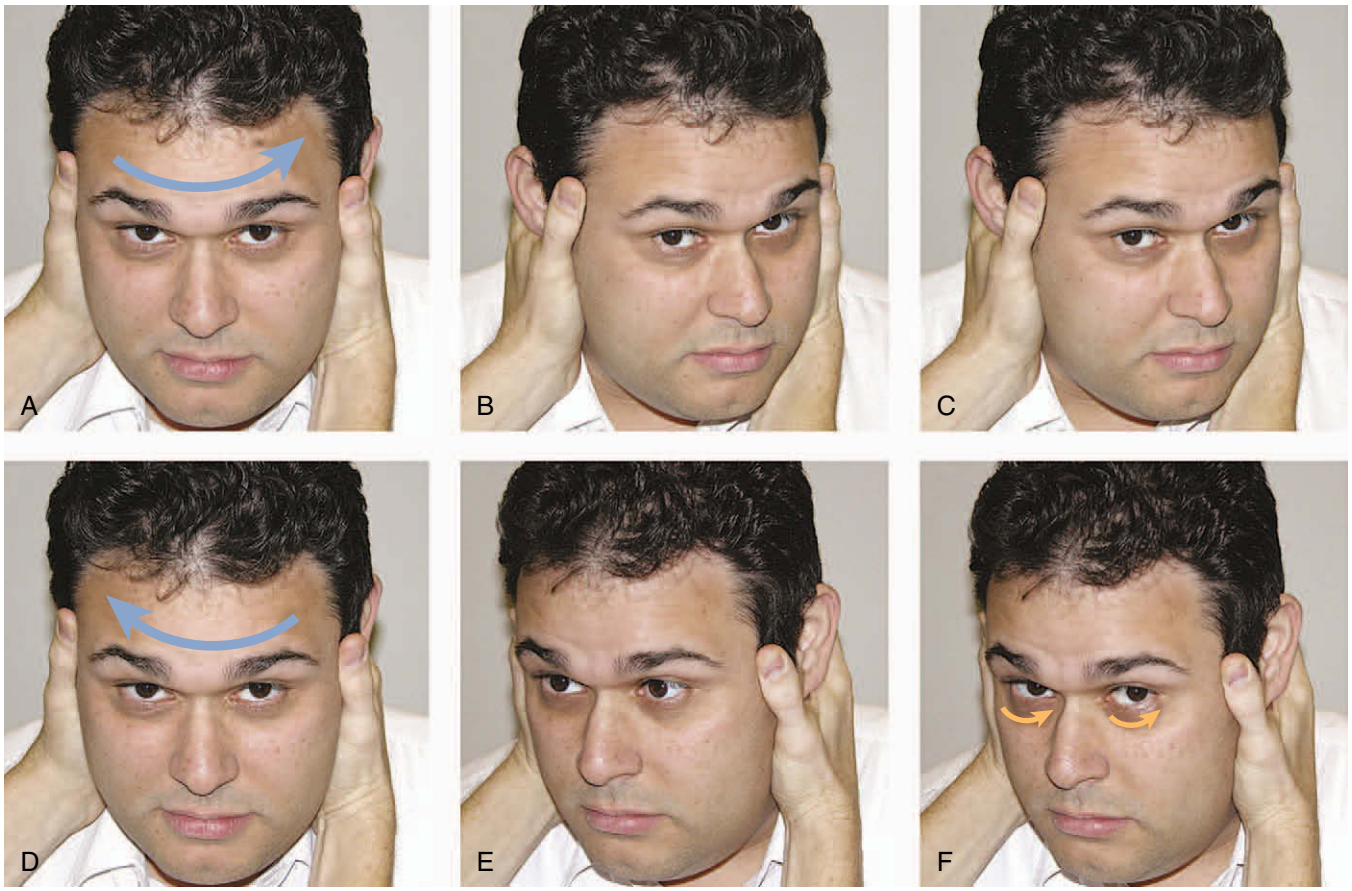

Figure 163-22. In the clinical version of the head thrust test, the examiner asks the subject to fix the gaze on the examiner's nose. The examiner rapidly turns the subject's head, but only by approximately 10 to 15 degrees; larger angles of rotation are unnecessary and may risk injury to the neck. The acceleration must be 3000 degrees/second squared (sec^2) or greater, and the peak velocity must be 150 to 300 degrees/second, meaning that the rotation must be finished in 150 msec. Photographs **A** to **C** show a head thrust to the left, exciting the left horizontal canal (HC). The eyes stay on the examiner's nose throughout the maneuver, indicating normal left HC function. Photographs **D** to **F** show a head thrust to the right, exciting the right HC. The eyes do not stay on target, but move with the head during the head thrust (**D** and **E**). A refixation saccade brings the eyes back on target after completion of the head movement (**F**). This is a "positive" head thrust sign for the right HC, indicating hypofunction of that canal.

the semicircular canal planes so as to excite the canal on the lesioned side, the VOR that results is markedly diminished (see Fig. 163-21, left panels). Although head rotation produces an excitatory contribution from the ipsilateral horizontal canal and an inhibitory contribution from the contralateral one, these contributions are markedly asymmetrical under these conditions. The inhibitory contribution from the intact canal is insufficient to drive a compensatory VOR when the head is thrust toward the lesioned side. Note that Figure 163-21 shows that there is a small VOR response for the head thrust toward the lesioned side. This is the inhibitory contribution from the intact canal. On the other hand, the excitatory contribution from the intact canal that is obtained when the head is thrust toward the intact side is almost adequate to drive a fully compensatory VOR by itself. Such a marked asymmetry may not be evident for low-frequency, low-velocity rotations, which are not dynamic enough to cut off responses in the inhibited nerve.[74]

The head thrust test (HTT) has become one of the most important tools in the clinical evaluation of vestibular function. In its qualitative, "bedside" form, the examiner simply asks the subject to stare at the examiner's nose while the examiner turns the subject's head quickly along the excitatory direction for one canal (Fig. 163-22). If the function of that canal is diminished, the VOR will fail to keep the eye on target, and the examiner will see the patient make a *refixation saccade* after the head movement is completed. If the patient has compensated well for the loss of function, the refixation saccade may even occur while the head is completing its movement, and it may take some experience to spot the saccade while the head is still in motion. By contrast, when the head thrust is in the excitatory direction of an intact canal (and nerve), the patient's gaze remains stable on the examiner's nose throughout the movement.

The HTT can localize isolated hypofunction of individual semicircular canals. Figure 163-23 shows an example of the quantitative head thrust test applied to all of the canals in a patient with a large (5-mm) dehiscence of the right superior canal. The VOR gain is reduced only for the affected superior canal, probably because large dehiscences allow the brain and dura to completely compress the membranous canal, thereby blocking endolymph motion in the canal.[75] The appearance of such a large dehiscence on computer tomographic (CT) scanning is shown in Figure 163-19B.

Principle 7: The Response to Simultaneous Canal Stimuli Is Approximately the Sum of the Responses to Each Stimulus Alone

This principle allows an intuitive approximation of the direction and magnitude of nystagmus caused by excitation (or inhibition) of any combination of semicircular canals.

Anatomic and Physiologic Basis

From Principle 3 and Principle 4, it should be clear that rotation of the head purely in one of the canal planes produces eye movements in

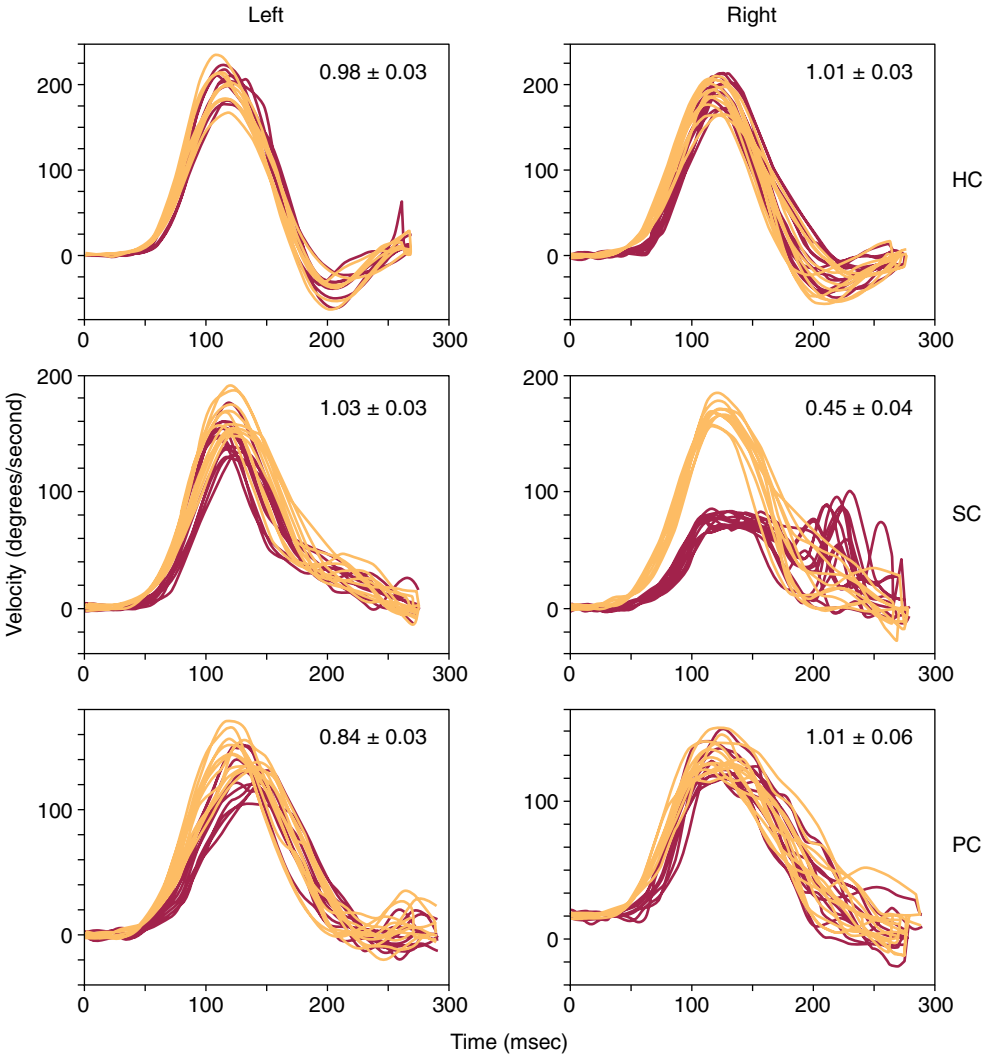

Figure 163-23. Results of head thrust testing of the aVOR in a subject with right superior semicircular canal (SC) dehiscence. Data are presented in the format described in Figure 163-21. Note the isolated loss of function in the right SC. This loss of rotary sensory function is presumably due to complete occlusion of the membranous canal by the brain and dura herniating into the lumen of the canal as shown on the CT scan *(inset)*. AC, anterior canal; HC, horizontal canal.

that canal plane. In reality, few natural head movements align solely with one canal plane, and most rotations stimulate two or even all three of the pairs of canals. How much is each canal stimulated in such a rotation? The motion of the endolymph in each canal (relative to the canal) will determine the degree to which the hair cells in that canal are stimulated. The endolymph motion in each canal is proportional to the component of the head's rotational velocity acting in the plane of that canal. A convenient way to view this is by the use of vector notation to describe the rotations.

The rotation of an object can be represented graphically with a vector that has direction and magnitude that uniquely describe the rotation. The vector lies along the axis about which the object is rotating. The direction of the vector along this axis is given by the right-hand rule (Fig. 163-24A). If the right hand were wrapped around that axis with the ends of the fingers pointing in the direction of the object's rotation, the thumb would point in the direction of the arrow of the vector. The length of the vector describes the magnitude of the rotation (e.g., degrees of angular displacement or degrees/second of angular velocity).

Using vector notation, the rotations that maximally excite each of the semicircular canals can be depicted as shown in Figure 163-24B to D. The axis of each of these rotations is perpendicular to the plane of the canal and is called its *sensitivity axis*. In the case of a head rotation that is not confined along one of these axes, the component of head velocity acting on each of the canals can be determined by graphically projecting the head velocity vector onto each of the sensitivity axes. For example, in Figure 163-24E, a head rotation to the left with the head upright mostly stimulates the left horizontal canal. The component of head rotation operating on the horizontal canal is the projection onto the horizontal canal's sensitivity axis. However, note that the projections onto the sensitivity axes of the superior and posterior canals indicate an excitatory stimulus acting on the ipsilateral superior canal and an inhibitory stimulus acting on the ipsilateral posterior canal. Mathematically, the magnitude of the stimulus projected onto the canal's sensitivity axis is the magnitude of the head velocity vector times the cosine of the angle between the axis around which the head rotates and the sensitivity axis of the canal.

Because the canal planes are approximately orthogonal to each other, the sensitivity axes are also approximately orthogonal. The pattern of activity induced in the ampullary nerves therefore effectively decomposes a head rotation into mutually independent simultaneous components along the sensitivity axes. The actions of pairs of extraocular muscles are similarly combined. The extraocular muscles are arranged in pairs that approximately rotate the eyes around axes in the orbit that parallel the sensitivity axes of the canals. Simultaneous activation of extraocular muscle pairs in proportions similar to the propor-

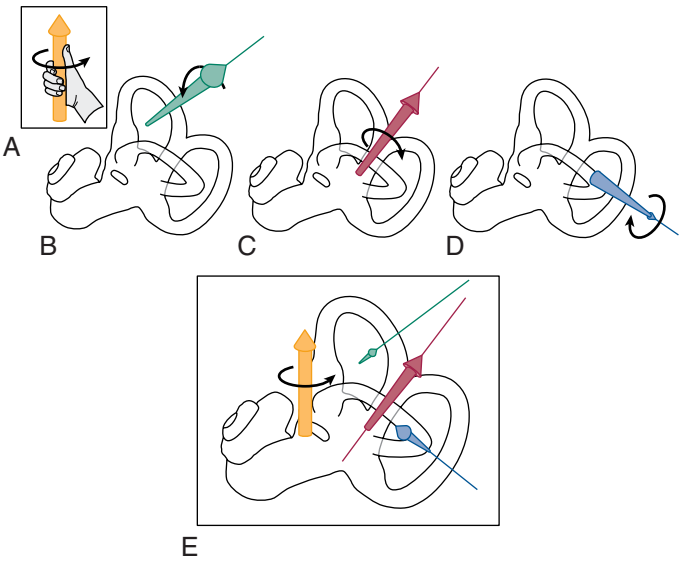

Figure 163-24. Vector representation of head velocity acting to stimulate the individual semicircular canals. **A,** The right-hand rule. The vector describing a rotation is oriented along the axis of rotation, pointing in the direction toward which the thumb of the right hand would point if the fingers wrapped around the axis and pointed in the direction of rotation. The magnitude of the vector represents a measure the rotation, either angular displacement or velocity. **B,** The sensitivity axis of the left superior canal lies perpendicular to the plane of that canal. Excitatory head rotation in that plane down and toward the left is depicted by a vector along the sensitivity axis. **C** and **D,** The sensitivity axes of the horizontal and posterior canals, each with a vector denoting the rotation that maximally excites it. **E,** The contribution of each canal in response to an upright horizontal head rotation to the left (orange vector). The bulk of the head velocity acts on the horizontal canal (HC), as shown by the projection (in red) along its sensitivity axis. The HC is not truly horizontal in this condition. Consequently, the rotation also acts on the superior canal (green vector) and posterior canal (blue vector). The SC receives a small excitatory stimulus. Note that the projection onto the PC's sensitivity axis is in its negative direction, meaning that the PC is inhibited under these circumstances.

tions of canal activation will result in eye rotation around an axis parallel to that about which the head rotates, but in the opposite direction. This, of course, is the goal of the angular VOR.

Given its ability to immediately sort incoming stimuli (head rotations) into spatially independent, minimally redundant channels of information, the labyrinth can be thought of as a "smart sensor" that not only measures stimuli but encodes them immediately in a maximally efficient way for downstream use in driving the angular VOR. In this respect, it is analogous to the cochlea, which segregates sounds into separate bins of the frequency spectrum, and the retina, which spatially maps the world into a retinotopic space.

Just as head rotations rarely stimulate only one pair of semicircular canals, labyrinthine pathology rarely affects only one canal. The brain perceives the simultaneous activation of several canals as the head rotation that would produce the same component of activation along each canal's sensitivity axis. These components are linearly combined to produce an eye movement that would compensate for the perceived head movement. By *observing the axis of the nystagmus*, the examiner can deduce which combination of canals are being excited (or inhibited). This *linear superposition* of the canal signals for simultaneous stimulation of multiple canals was confirmed in an elegant series of experiments by Cohen and associates.[63,76-78] These workers used both cineoculography of eye movements and electromyographic recordings from extraocular muscles in cats while electrically stimulating ampullary nerves alone and in combinations. They observed that even highly nonphysiologic combinations of ampullary nerve stimuli caused eye movements and extraocular muscle activity that could be predicted as the vector summation of responses to each stimulus alone (Fig. 163-25). Individual stimulation of the left semicircular canals caused eye movements that were rightward (for the left horizontal canal), upward and clockwise (for the left anterior canal), or downward and clockwise (for the left posterior canal) with respect to the animal's head. In a canal frame of reference, each of these eye movements is in the plane of the stimulated canal, as predicted by Ewald's First Law (Principle 3). Simultaneous stimulation of the left horizontal and anterior canals caused eye movements that were rightward, upward, and clockwise. In a canal frame of reference, the axis of these eye movements is a weighted vector sum of the responses of stimulated horizontal and anterior canals. Simultaneous stimulation of the left horizontal and posterior canals caused eye movements that were rightward, downward, and clockwise—that is, around an axis given by the sum of two equal vectors along the sensitivity axes of the horizontal and posterior canals. Simultaneous stimulation of the left anterior and left posterior canals caused eye movements that were clockwise, as would be expected from cancellation of the pitch (up and down) response components when vectors along the sensitivity axes of these two canals are summed. Finally, simultaneous stimulation of the all three left canals caused eye movements that were rightward and clockwise, again the prediction from a sum of equal vectors along the sensitivity axes of these canals.

Clinical Implications

This last experiment, by Suzuki and coworkers,[76] models what occurs when all of the canals on one side become excited from their baseline firing rates. The slow phase of the observed nystagmus has a horizontal component toward the contralateral side and a torsional component that moves the superior pole of the eye toward the contralateral side. The nystagmus beats to the ipsilateral side both horizontally and torsionally. There is no vertical component to this nystagmus. This *irritative nystagmus* can be seen when the labyrinth is irritated, for example, early in an attack of Meniere's disease, after stapedectomy procedures, and early in the course of viral labyrinthitis.

The same static imbalance in firing rates between sides occurs with unilateral labyrinthine hypofunction. Consider the case of left unilateral labyrinthectomy, in which case all three canals on that side are ablated. Unopposed activity of the right lateral canal contributes a leftward slow phase component. Unopposed activity of the right anterior canal contributes an upward and counterclockwise slow phase component. Finally, unopposed activity of the right posterior canal contributes a downward and counterclockwise slow phase component. These components combine, with the up and down components canceling each other, and with the net result being a leftward and counterclockwise slow phase (rightward- and clockwise-beating) nystagmus.

Quantitative application of this principle has yielded important information about the pathophysiology of vestibular neuritis. Fetter and Dichgans[79] measured three-dimensional eye movements in 16 patients with spontaneous nystagmus 3 to 10 days after the onset of vestibular neuritis. Their spontaneous nystagmus axes clustered between the direction expected from hypofunction of the horizontal canal and the direction expected from hypofunction of the anterior canal on the affected side. Hypofunction of the posterior canal did not seem to contribute to the nystagmus, and head thrusts in the plane of the ipsilateral posterior canal showed preserved function. These investigators proposed that vestibular neuritis is therefore usually a disorder of the organs innervated by the superior vestibular nerve—that is, the horizontal and anterior canals and the utricle. In support of this hypothesis is the observation that vestibular-evoked myogenic potentials (VEMPs) (a test of saccular function—see Principle 11) usually are preserved in these patients.[80] Furthermore, the frequent (approximately 21%) occurrence of ipsilateral posterior canal BPPV in these patients makes sense under this hypothesis: Function remains intact in the posterior canal, which can mediate BPPV if damage to the utricle releases otoconia into that canal.[80]

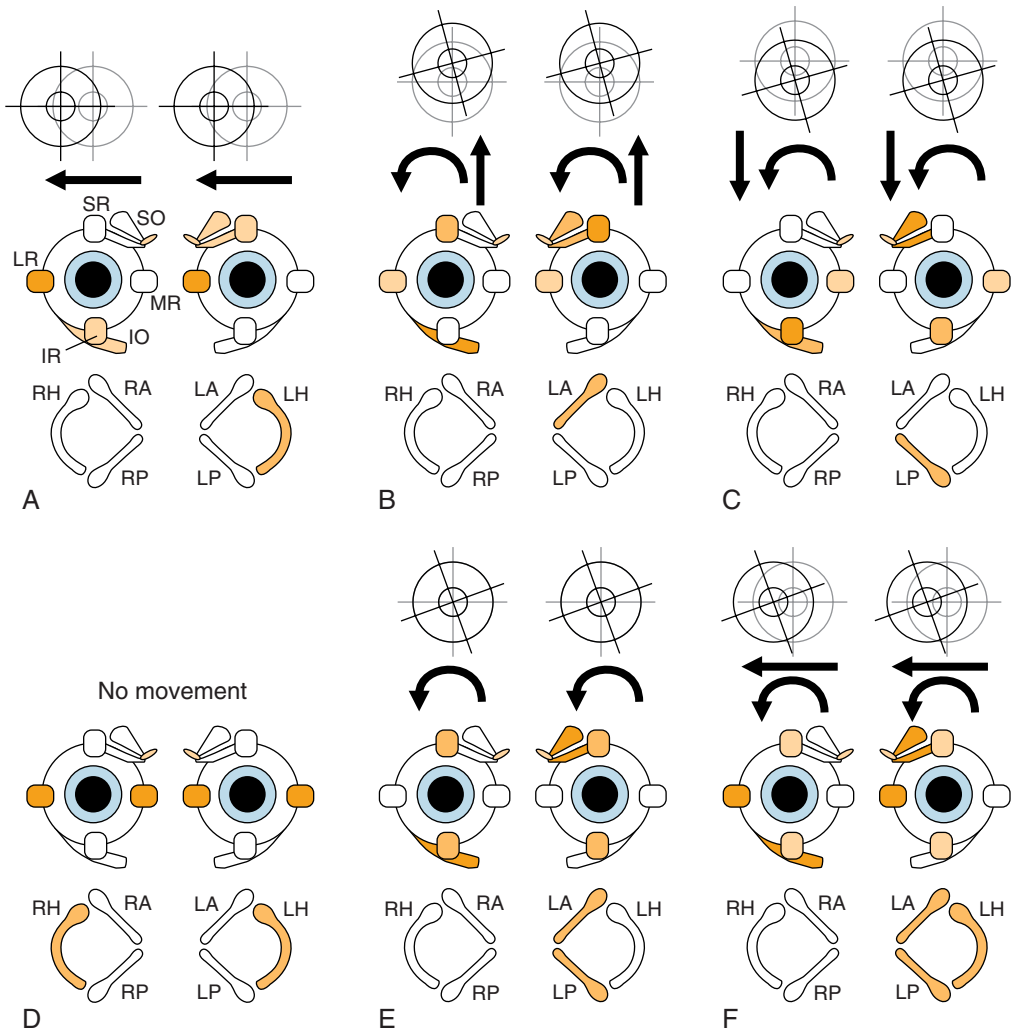

Figure 163-25. Nystagmus slow phases observed for excitation of individual semicircular canals. In the *bottom row* of each panel, *shading* indicates the excited canal(s). LA/LH/LP, left anterior, horizontal, and posterior canals; RA/RH/RP, right anterior, horizontal, and posterior canals. In the *middle row*, a cartoon of the extraocular muscles depicts which muscles are activated (darker shading indicates stronger activation). LR/MR/SR/IR, lateral, medial, superior, inferior rectus; SO/IO, superior/inferior oblique. In the *top row*, the resultant yaw, pitch, and/or roll eye movements are indicated. **A,** Excitation of the left horizontal canal causes rightward slow phases due mainly to strong activation of right LR and left MR. **B,** Excitation of the left anterior canal causes upward/clockwise (from patient's perspective) slow phases, due to combined action of the right IO and SR and the left SO and SR. **C,** Excitation of the left posterior canal causes downward/clockwise (from patient's perspective) slow phases, due to combined action of the right IO and IR and the left SO and IR. **D,** Equal stimulation of LH and RH canals elicits antagonistic contraction of MR and LR bilaterally, yielding no nystagmus. **E,** Combined equal excitation of LA and LP canals excites muscle activity that is the sum of each canal's individual effect; upward and downward pulls cancel, resulting in a purely clockwise nystagmus. **F,** Combined equal excitation of all three left canals causes a right-clockwise slow phase, the expected result of summing activity for each individual canal. *(Adapted from Cohen B, Suzuki J-I, Bender MB. Eye movements from semicircular canal nerve stimulation in the cat.* Ann Otol Rhinol Laryngol. *1964;73:153; data adjusted to human head frame of reference.)*

Principle 8: Nystagmus Due to Dysfunction of Semicircular Canals Has a Fixed Axis and Direction with Respect to the Head

Anatomic and Physiologic Basis

The concept of a fixed axis of nystagmus for stimulation of an isolated semicircular canal has already been demonstrated for posterior canal BPPV, under Principle 3. In that case, the eyes always rotated about the sensitivity axis of the affected posterior canal. Having the patient direct gaze orthogonal to and along the sensitivity axis of the posterior canal showed that there was really no change in the direction of nystagmus when considered in the canal-fixed reference frame (despite the dramatic change in the eye-fixed reference frame).

This principle extends that concept to any axis of rotation resulting from stimulation or inhibition of any combination of semicircular canals. Consider again the patient with acute unilateral hypofunction of all of the right semicircular canals. There is relative excitation of all the left canals. As demonstrated previously, the nystagmus will beat toward the left both horizontally and torsionally. Changing gaze direction does not change the leftward direction of the fast phases of this nystagmus. Thus, it is a *direction-fixed* nystagmus. In general, peripheral nystagmus has a fixed axis and direction.

Clinical Implications

This principle helps to distinguish nystagmus from a peripheral vestibular disorder from nystagmus due to a central disorder. In the case of the latter, the axis or direction of nystagmus may change depending on the direction of gaze.[81] It is important to note that the *magnitude* of the nystagmus is *not* fixed depending on gaze. The reason for this is discussed in the next principle.

Principle 9: Brainstem Circuitry Boosts Low-Frequency VOR Performance through Velocity Storage and Neural Integration; Failure of These Mechanisms Suggests Central Pathology

The description of the VOR up to this point has depicted little role for brainstem and cerebellar signal processing, other than passing on the vestibular signals to the appropriate ocular motor nuclei. This "direct pathway" is the classical three-neuron reflex arc. However, the brainstem does more than serve as a conduit for the vestibular afferent signals. An "indirect pathway" through the brainstem circuits also must account for the poor performance of the vestibular endorgans at low frequencies and the need for further integration of the incoming head velocity signal to generate fully compensatory eye movements. The brainstem accomplishes these tasks through processes called *velocity storage* and *velocity-to-position integration*. These two processes also lead to several important clinical phenomena, such as post-rotatory nystagmus, post–head-shaking nystagmus, and Alexander's Law. The last of these is another one of the cardinal signs that differentiates peripheral from central causes of nystagmus.

Anatomic and Physiologic Basis

Velocity Storage

For head rotations at frequencies below approximately 0.1 Hz, the vestibular nerve afferent firing rate gives a poor representation of head velocity (see Appendix). In response to a constant velocity rotation, the cupula initially deflects but then returns back to its resting position, with a time constant of approximately 13 seconds.[82] Thus, nystagmus in response to a constant-velocity rotation would be expected to disappear after approximately 30 seconds (see Fig. 163-10B).

In fact, the situation would be made somewhat worse because canal afferent neural responses also tend to decay for static or low frequency responses. This adaptation of afferent firing is a property of the neuron itself, and it is especially pronounced for irregular afferents. The effect of adaptation is to make afferents respond more transiently to static and low frequency cupular displacements. Thus, some canal afferents end up carrying a transient signal in response to low frequency and constant velocity rotations. This signal more closely reflects the rate of change of head velocity—that is, acceleration—than velocity itself.

Despite these tendencies for the peripheral vestibular signals to decay prematurely, experimental observations in humans have shown that the time constant of the decay of the angular VOR for constant velocity rotation is about 20 seconds, longer than would be expected based on the performance characteristics of the canals alone.[83] Neural circuits in the brainstem seem to perseverate canal signals, stretching them out in time. The important physiologic consequence of this effect (historically called *velocity storage*, because it appears to "store" the head velocity information for some period of time) is that it allows the vestibular system to function better at low frequencies. Because of velocity storage, the lower corner frequency of the system is extended to approximately 0.08 Hz. This allows sufficient overlap between the VOR and lower-frequency gaze-stabilizing systems (smooth pursuit and optokinetic nystagmus) to avoid having a region of frequency in which neither system works well.[12]

Robinson[84] proposed that velocity storage could be accomplished by a feedback loop operating in a circuit including the vestibular nuclei. Lesion studies in monkeys suggest that velocity storage arises from neurons in medial vestibular nucleus (MVN) and descending vestibular nucleus (DVN) whose axons cross the midline.[85]

Velocity-to-Position Integration

A second problem arises in matching the signals coming out of the semicircular canals to those needed to act on the eye muscles. For all eye movements, in order to move the eye, the contraction of an extraocular muscle must not only overcome the force of viscous drag (friction), which is proportional to eye velocity. It also must overcome the elastic restoring force that arises principally from stretch of the antagonistic extraocular muscle with which it is paired. This elastic restoring force is significant, even though the antagonist muscle receives an inhibitory command. This force, analogous to that produced by a spring, is proportional to the eye's displacement or position. Experimental evidence shows that the oculomotor neurons receive a signal that includes signal components for both the desired eye velocity $\dot{E}(t)$ and the instantaneous eye position $E(t)$:

$$\textit{firing rate} = kE(t) + r\dot{E}(t) \qquad \text{Eq. 163-12}^{86}$$

In making a horizontal saccade, for example, a velocity command is generated by an excitatory burst neuron in the paramedian pontine reticular formation (PPRF) (Fig. 163-26). This command is a pulse of neural activity, which is sent along a direct path to the abducens and oculomotor nuclei. Alone, it would provide only the term proportional to desired eye velocity, and the eye would slide back to its neutral position in the orbit without the ongoing pull from the muscle to overcome the elastic restoring force. The ongoing pull from the term proportional to eye position is obtained by way of an indirect path through neurons that mathematically time-integrate the pulse (a transient or phasic command) to yield a step (a tonic command). The final signal carried by the oculomotor neuron is thus a pulse-step (phasic-tonic) signal of the form of Equation 163-12.

For the VOR as well, the oculomotor neurons need to receive both an eye velocity and eye position command (Fig. 163-27). The desired eye velocity $\dot{E}(t)$ is easily obtained; it is simply equal and opposite to the head velocity $\dot{H}(t)$, a quantity approximately provided by the signals from the semicircular canals. The estimate of eye position $E(t)$ is provided by the brainstem *velocity-to-position integrator*, which integrates the velocity signal provided by the canals to give an estimate of position. All types of conjugate eye movements—the VOR, optokinetic nystagmus, saccades, and pursuit—are initiated as velocity commands that are passed both directly to the oculomotor neurons and indirectly through this shared neural integrator.[87] This brainstem integrator likely is a circuit of recurrently connected neurons in which signals reverberate and produce synaptic changes, a form of short-term memory.[88,89] For horizontal eye movements, the integrating neurons lie in the nucleus prepositus hypoglossi region of the pons.[90,91] For torsional and vertical eye movements, they lie in the interstitial nucleus of Cajal.[92]

Clinical Implications

Pre- and Post-rotatory Nystagmus

Velocity storage is responsible for the prolonged nystagmus that occurs after sustained constant-velocity rotation in one direction (Fig. 163-28). Rotation to one side generates a positive change in afferent firing on the ipsilateral side and a negative change on the contralateral side. Because of the excitation-inhibition asymmetry inherent in the semicircular canal signals (Principle 6), the net result is not zero change in the afferent firing rate sensed by the brainstem, but rather a net excitation on the ipsilateral side. The velocity storage mechanism perseverates this net excitation beyond the time that the cupula deflection has returned to zero (see Fig. 163-10B). The brainstem thus perceives that the head continues to rotate toward the same side, and it generates an angular VOR for that perceived rotation. The slow phases of nystagmus are directed toward the contralateral side, and the fast phases are directed toward the ipsilateral side. This nystagmus decays exponentially as the velocity storage mechanism discharges with the time constant of approximately 20 seconds.

Head-Shake Nystagmus

If the head is rotated side to side in the horizontal plane in normal subjects, the velocity storage mechanism is charged equally on both sides. There is no post-rotatory nystagmus as the stored velocities decay at the same rate on either side. However, nystagmus does occur after head shaking in subjects with unilateral vestibular hypofunction.[93] In the clinical head-shaking test, the examiner passively rotates the subject's head horizontally at 1 to 2 Hz for 10 to 20 cycles of rotation. Once the rotation stops, the eyes are observed under Frenzel lenses in order to prevent visual suppression of the nystagmus. As the head is shaken from the lesioned side toward the intact side, net excitation is stored by the velocity storage mechanism. In fact, the *net* excitation

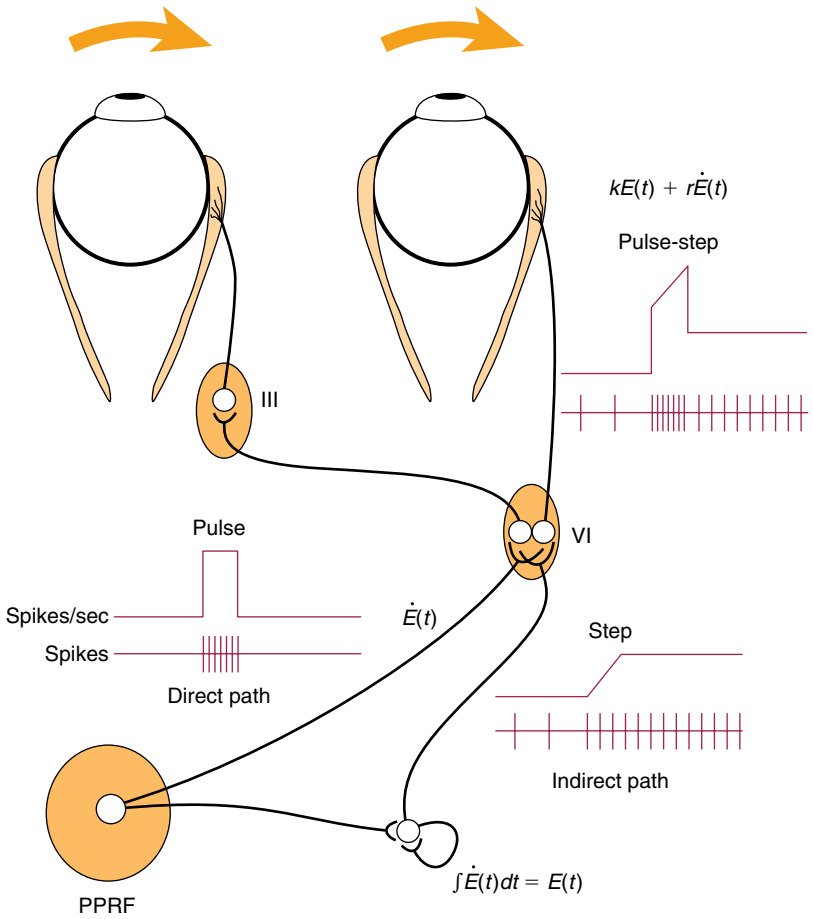

Figure 163-26. The motor command for the saccade originates in the paramedian pontine reticular formation (PPRF) as a pulse of neural firing. This activity is transmitted along a direct path to the ocular motor nuclei as a pulse. The pulse also is integrated into a step of neural discharge and transmitted to the ocular motor nuclei along an indirect path. The final motor signal is thus a pulse-step combination, as required by the dynamics of the eye muscles.

is greater than in normal subjects because there is no inhibitory signal coming from the lesioned labyrinth. When the head is turned and rotated toward the lesioned side, there is no excitatory stimulus sent to the brainstem from that side, and only a small inhibitory stimulus from the intact labyrinth. After multiple cycles of back-and-forth rotation, a marked asymmetry develops in the velocity storage mechanism, one that signals illusory continued rotation toward the intact side. As a result, when the head stops rotating, the nystagmus is as would be expected for continued rotation toward the intact side: The slow phases go toward the lesioned side, and the fast phases toward the intact side. This pattern may even reverse after several seconds, presumably because neurons affected by velocity storage adapt to the prolonged change in firing from their baseline rates.

The head shaking test provides another very useful means of localizing labyrinthine loss, one that complements the information derived from caloric testing and head thrust testing. As noted previously, caloric testing measures the function of an isolated semicircular canal at relatively low frequency. The head thrust test uses rapid, brief rotations with frequency content in the range of 3 to 5 Hz. By providing information about the function of the labyrinth at 1 to 2 Hz, the head-shaking test may provide information not available from the other two tests.

Alexander's Law

The brainstem integrator also manifests characteristic findings in vestibular pathology. In the acute period after loss of unilateral labyrinthine function, the integrator becomes dysfunctional or "leaky." In part, this may be an adaptive strategy by the brain to minimize nystagmus. As we have already seen, integration of the vestibular signal increases the drive to the extraocular muscles that pull the eye in the direction of the slow phases. By shutting down the integrator, the brain may decrease the slow-phase velocity of nystagmus. However, because the integrator is shared by other oculomotor systems, including the saccadic system, the ability to hold the eye in an eccentric position in the orbit is impaired when the integrator is leaky. As a result, the eyes tend to drift back to the center position in the orbits (Fig. 163-29). This centripetal drift has an important effect on the observed nystagmus. When the eyes look toward the direction of the fast phase of nystagmus, the drift due to the "leakiness" of the integrator adds to the slow-phase velocity due to the vestibular imbalance, and as a result the nystagmus slow-phase velocity increases. However, when the eyes look toward the direction of the slow phase, the centripetal drift due to the leaky integrator subtracts from the slow-phase velocity due to the vestibular imbalance, and the nystagmus slow-phase decreases or may disappear. This observation has come to be known as *Alexander's Law*.[94] Although occasionally seen in central lesions, peripheral types of nystagmus generally will obey Alexander's Law, making it an important neuro-otologic examination finding in distinguishing nystagmus of central origin from that of peripheral origin.

Interpreting Rotary Chair Tests

Dysfunction of the neural integrator and velocity storage can also be seen in the results of rotary chair testing. Rotary chair testing may consist of either steps of constant-velocity rotation or sinusoidal harmonic oscillations, typically from 0.01 to 0.6 Hz. Velocity steps may be delivered by suddenly starting the rotation of the chair from zero velocity to a sustained constant velocity in one direction (as in Fig. 163-8B). Alternatively, the equivalent stimulus may be obtained by braking the chair after a prolonged constant velocity rotation in the

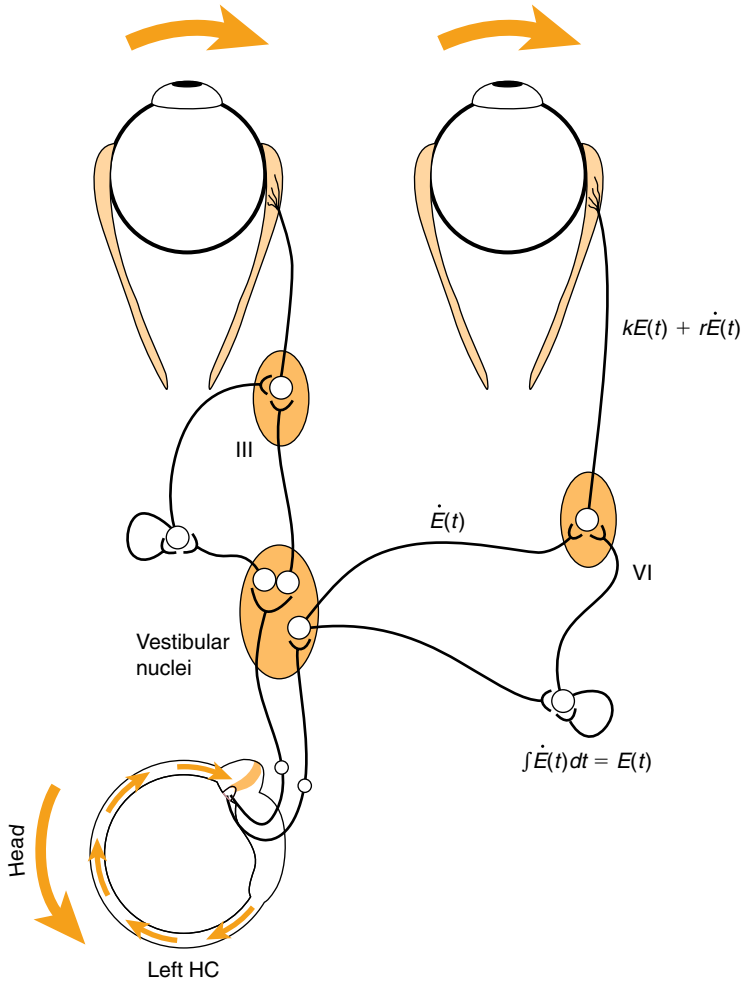

Figure 163-27. Signals from the canals also pass through direct and indirect pathways to the ocular motor nuclei. The direct excitatory pathway for the horizontal vestibulo-ocular reflex (VOR) is depicted in detail in Figure 163-15. The indirect pathway through the velocity-to-position integrator provides the final ocular motor signal with a component proportional to eye position. HC, horizontal canal.

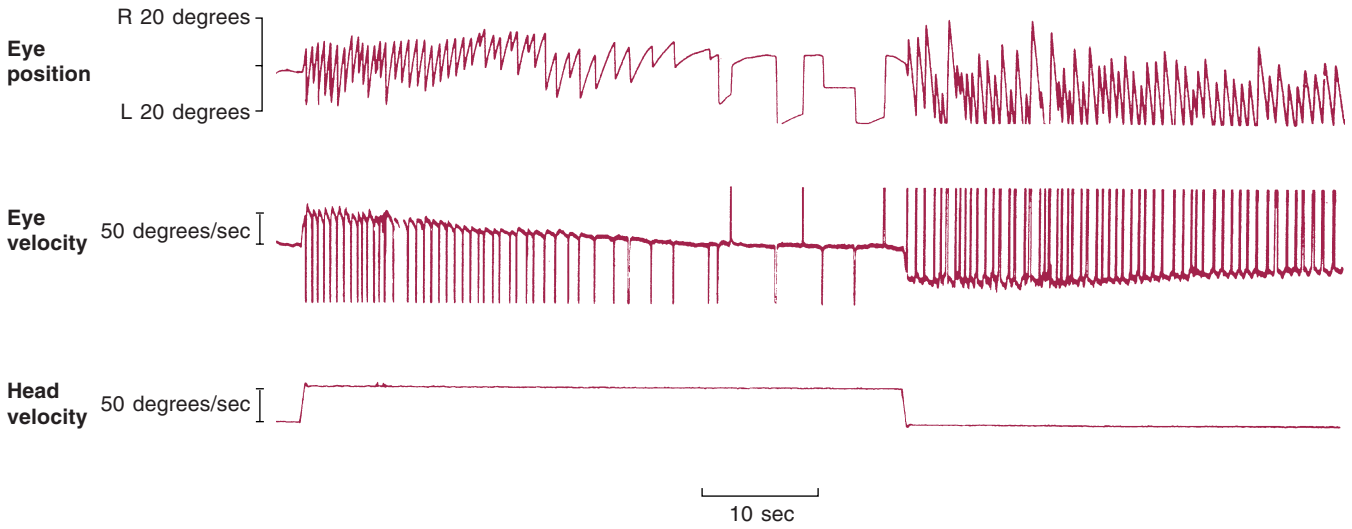

Figure 163-28. Per- and post-rotatory nystagmus in a monkey in response to a step of head velocity to 50 degrees/second. While the chair continues to rotate at 50 degrees/second constant velocity, the initial nystagmus decays more slowly than would be predicted based on the cupula's time constant. After the chair rotation stops, the nystagmus appears again but in the opposite direction. This after-nystagmus also decays more slowly than would be anticipated. The prolongation of the nystagmus after rotation is a manifestation of velocity storage. *(Modified from Cannon SC, Robinson DA. Loss of the neural integrator of the oculomotor system from brain stem lesions in monkey.* J Neurophysiol. *1987;57:1383.)*

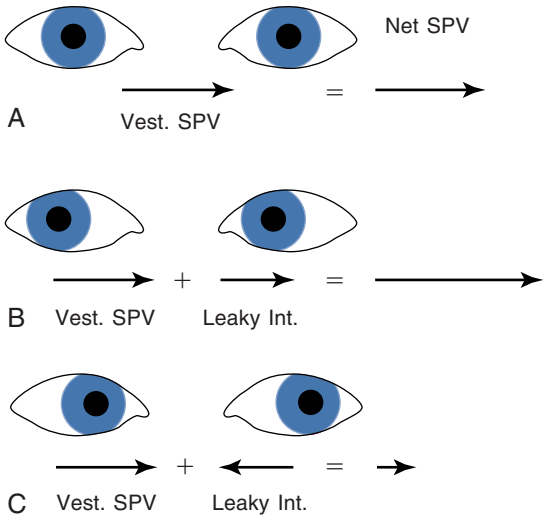

Figure 163-29. Alexander's law. The interactions of the vestibular slow phase velocity (Vest. SPV) and a leaky integrator (Int.) are demonstrated for a case of left acute vestibular hypofunction. In neutral gaze (**A**), the vestibular slow phase alone is manifest. When the gaze is in the direction of the fast phase (*right*, **B**), the leaky integrator causes the eyes to drift to the left. This drift adds to the vestibular slow-phase signal, and the net slow-phase velocity increases. When the gaze is in the direction of the slow phase (*left*, **C**), the leaky integrator causes the eyes to drift to the right. This drift subtracts from the vestibular slow-phase signal, and the net slow-phase velocity decreases.

other direction. The horizontal canals' endolymph and cupulae tend to keep moving in the direction that the chair had been moving, so that the stimulus is equivalent to a velocity step in the direction opposite to that in which the chair had been turning. In the case of unilateral loss of labyrinthine function, the magnitude of post-rotatory nystagmus in response to a velocity step expected to excite the lesioned horizontal canal may be low in comparison to that for velocity steps expected to excite the intact side. However, a decrement in nystagmus may not be detectable in subjects with compensated unilateral loss of labyrinthine function because, as explained in Principle 6, the relatively low frequencies and accelerations involved in rotary chair testing may not elicit much excitation-inhibition asymmetry. Instead, the only abnormality may be that the time constant of post-rotatory nystagmus is shortened. The impairment of the brainstem's velocity storage mechanism secondary to the loss of peripheral function decreases this time constant. For bilateral loss of labyrinthine function, nystagmus in response to steps is likely to show decreased gains and decreased time constants.

When sinusoidal rotary chair testing is performed in subjects with unilateral loss of labyrinthine function, the *gain* of the VOR (the ratio of eye velocity/head velocity; see Appendix) may be lower as the head is rotated toward the lesioned side. More commonly, however, the gain will be low bilaterally or even normal, especially once the individual has compensated for the loss of unilateral function. Often, however, the *phase* of the VOR will remain advanced relative to head velocity at low frequencies.[95] Again, this reflects the limitations of the semicircular canal in producing a response that encodes head velocity at low frequencies (see Appendix). These limitations, which are mitigated by velocity storage and neural integration, become manifest when velocity storage and integration are disrupted by a loss of peripheral vestibular function.

Principle 10: The Utricle Senses Both Head Tilt and Translation, but Loss of Unilateral Utricular Function Is Interpreted by the Brain as a Head Tilt toward the Opposite Side

Anatomic and Physiologic Basis

The utricle senses linear accelerations that are tangential to some portion of its curved surface. Most of the utricle is approximately in the plane of the horizontal canal, although its anterior end curves upward from this plane. The baseline firing of utricular afferent fibers is therefore best modulated by linear accelerations in the horizontal plane—that is, fore-and-aft or side-to-side. Hair cells in the utricle are polarized such that stereociliary deflections toward the striola excite the hair cells, and deflections away from the striola inhibit them. Because the orientations of the stereociliary bundles vary over the surface of the utricle, the organ's overall pattern of responses to a given linear acceleration can be quite complex (see Fig. 163-7). Linear accelerations in different directions probably activate unique ensembles of activity in the afferents of the utricle, with some areas being excited and others inhibited. These ensemble responses may encode the direction of head acceleration.[17]

Excitation or inhibition of *all* regions of the utricle does not occur under normal conditions of vestibular stimulation. Thus, predicting what the brain will perceive during pathologic conditions resulting in stimulation of the whole utricle is less straightforward than was the case for the semicircular canals, whose hair cells are all polarized in the same direction. However, studies in cats[96] and monkeys[97] have demonstrated a 3:1 predominance of afferents arising from the medial aspect of the utricle, which is sensitive to accelerations produced by ipsilateral tilts. Thus, the brain interprets a tonic increase in firing from the utricle on one side as a net acceleration of the otoconial mass toward the ipsilateral side. Conversely, the brain interprets a decrease or loss in firing from the utricle on one side as a net acceleration of the otoconial mass toward the contralateral or intact side.

However, the brain must still decide how to interpret this signal representing a net acceleration of the otoconial mass to one side. Such acceleration could be produced by an ipsilateral tilt or by a contralateral translational movement of the head. There is little physical difference between the shear forces acting on the hair cells of the otolith organs in these two circumstances, but the expected reflexive response of the vestibular system would be quite different depending on the interpretation. If tilt is perceived, then the appropriate compensatory reflexes would be counter rolling deviations of the eyes and head. If translation is perceived, the appropriate reflexes would be horizontal eye movements.

Just how the brain distinguishes utricular signals due to tilt from those due to translation remains one of the ongoing controversies in vestibular physiology. The equivalence of tilt and translation provides the brain a seemingly irresolvable ambiguity in the utricular afferent signals. Nevertheless, the brain is somehow able to correctly resolve the source of the ambiguous stimulus under normal conditions, so that an interaural translation produces horizontal eye movements with little or no roll movements. By contrast, when the same net acceleration acts on the utricles during tilting movements of the head, the eyes counter-roll appropriate to the tilt, but do not turn horizontally as they would for an interaural translation. One way to resolve these different stimuli might be based on the frequency content. Low-frequency or static linear accelerations acting on the otolith organs might be interpreted as gravitational accelerations resulting from tilt, whereas transient linear accelerations might be interpreted as linear translations.[98,99] An alternative hypothesis is that the central nervous system integrates information from the semicircular canals with information from the otolith organs to distinguish tilts (which also transiently activate canals) from translations (which activate only the otolith organs). In support of this hypothesis, experiments in rhesus monkeys in which the semicircular canals were inactivated by plugging demonstrated that in the absence of canal signals, modulation of otolith activity by roll tilts led to eye movements that would instead be compensatory for perceived interaural translations.[100] Thus, the brain appears to need the additional signals from the canals to distinguish tilts from translations.

Whether the brain uses the frequency content of the incoming utricular signal or the concomitant signals from the canals, the perception of a static decrease in the firing rates of utricular afferents on one side should be interpreted as tilt toward the opposite side, not translation toward the same side. From the point of view of frequency content, the static nature of the firing rate change would mimic the static (low-frequency) change due to a head tilt. From the point of view of the

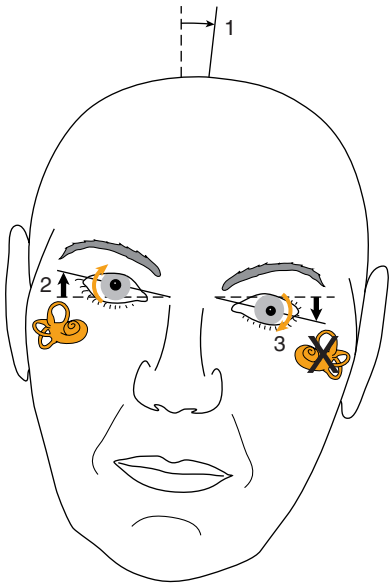

Figure 163-30. The otolith tilt reaction for loss of left utricular function consists of (1) head tilt to the left, (2) elevation of the right eye and depression of the left eye, and (3) roll of the superior pole of each eye to the patient's left.

canal signals, recall that loss of unilateral labyrinthine function leaves a relative excess of signals from the contralateral vertical canals that would be perceived as rolling of the head toward the intact side. This would be the expected concomitant canal signal for a head tilt toward the intact side. Thus, the loss of unilateral utricular function is interpreted by the brain as a head tilt toward the *opposite* side.

Clinical Importance

An isolated loss of utricular nerve activity elicits a stereotypical set of static responses called the *ocular tilt reaction*, which comprises (1) a head tilt toward the lesioned side, (2) a disconjugate deviation of the eyes such that the pupil on the intact side is elevated and the pupil on the lesioned side is depressed (a so-called skew deviation), and (3) a static conjugate counter-roll of the eyes rolling the superior pole of each eye away from the intact utricle[101] (Fig. 163-30). Each of these signs can be understood as the brain's compensatory response to a perceived head tilt toward the intact utricle. This perception arises from the excess of ipsilateral tilt information coming from the intact utricle. The ocular tilt reaction can also occur from interruption of central otolithic pathways as, for example, in multiple sclerosis.[102,103] The full ocular tilt reaction is not often observed with peripheral vestibular lesions because the brainstem compensates for some aspects very rapidly. However, the otolaryngologist will occasionally encounter the postoperative complaint of vertical diplopia after resection of an acoustic neuroma or sectioning of the vestibular nerve. By alternately covering the eyes and observing the opposite vertical shifts that occur for each eye, the skew deviation quickly becomes apparent.

Although the full ocular tilt reaction may not persist for very long after an acute lesion, the static roll of each eye toward the lesioned side may be detected for weeks to months afterward.[104,105] This can be shown with careful fundus photography, but a more practical method is with the perceptual test of subjective visual vertical (SVV) or subjective visual horizontal (SVH). Subjects with recent unilateral loss of otolith function will consistently displace a lighted line in a dark room so that it is tilted off the desired vertical or horizontal orientation toward the lesioned side. In fact, a close correlation has been noted between the absolute torsional deviation of the eyes and the angular displacement of the line from vertical or horizontal.[106] The tilt in SVV or SVH usually decreases over months after a loss of unilateral vestibular function, but for severe lesions such as vestibular nerve section some deviation persists permanently.[104]

Principle 11: Sudden Changes in Saccular Activity Evoke Changes in Postural Tone

Anatomic and Physiologic Basis

The saccule is almost planar and lies in a parasagittal orientation. Hair cells of the saccule, polarized so that they are excited by otoconial mass displacements away from the striola, can sense accelerations fore or aft (along the naso-occipital axis) or up and down. Most afferents from the saccule have a preferred up or down direction.[97] Moreover, only the sacculus can sense linear accelerations up or down, whereas naso-occipital accelerations will activate some utricular as well as saccular afferents. Thus, the sacculus has a unique role of sensing upward or downward accelerations.

When the head is upright in the gravitational field, the acceleration due to gravity (9.8 m/sec^2) constantly pulls the saccular otoconial mass toward the earth. Afferents in the inferior half of the saccule, whose hair cells are excited by this downward acceleration, have lower firing rates and lower sensitivities to linear accelerations than do those afferents in the upper half of the utricle.[97] The afferents in the upper half are excited by relative upward acceleration of the otoconial mass, such as might occur when the head drops suddenly, e.g., when one is falling. Thus, sudden excitation of hair cells across the saccular macula probably would be interpreted by the brain as a sudden loss of postural tone, as in falling. The appropriate compensatory reflex would be one that activates the trunk and limb extensor muscles and relaxes the flexors to restore postural tone. Accordingly, the saccular afferents project to the lateral portions of the vestibular nuclei, which give rise to the vestibulospinal tract, in contrast to the utricular afferents, which project more rostrally to areas involved in the VORs.[106]

Clinical Importance

Saccular excitation probably underlies the test of VEMPs. VEMPs are transient decreases in flexor muscle electromyographic (EMG) activity evoked by loud acoustic clicks or tones applied to the ear. Sufficiently loud sounds applied to the ear excite saccular afferents.[107,108] The predicted reflexive response as noted earlier would include relaxation of flexor muscles. The EMG activity averaged over multiple acoustic stimuli from a tonically contracting flexor muscle will demonstrate a biphasic short latency relaxation potential. The EMG activity can be recorded in many different flexor muscles, but the sternocleidomastoid (SCM) responses have been best described.[109] Because the saccule mediates sound-evoked VEMP responses in the normal labyrinth, absence of VEMP responses may indicate saccular dysfunction. However, transmission of the VEMP acoustic stimulus is very sensitive to any cause of conductive hearing loss in the middle ear, and VEMPs are usually absent in the presence of conductive hearing loss. Interestingly, the preservation of VEMP responses in the face of conductive hearing loss implies an abnormally low acoustic impedance of the labyrinth, such as occurs in superior canal dehiscence syndrome[110] or with enlarged vestibular aqueduct syndrome.[111]

Another example of the postural tone changes that may be related to saccular activity is the drop attack. Also known as the "otolithic crisis of Tumarkin," the drop attack is a dramatic loss of postural tone that can occur in Meniere's disease independent of other vestibular symptoms at the time of the fall.[112] It is not clear what causes the sudden loss of postural tone, but sudden deformations of the saccular macula associated with the hydropic changes of the labyrinth have been invoked.

Principle 12: The Normal Vestibular System Can Rapidly Adjust Vestibular Reflexes in Accordance with the Context, but Adaptation to Unilateral Loss of Vestibular Function May Be Slow and Susceptible to Decompensation

Anatomic and Physiologic Basis

As emphasized throughout this chapter, the vestibular system is efficiently designed to give stereotypical motor reflex outputs that compensate for the movements of the head. Yet a stereotypical output appropriate for one context may be inappropriate for another. For example, redirection of gaze is accomplished by turning first the eyes,

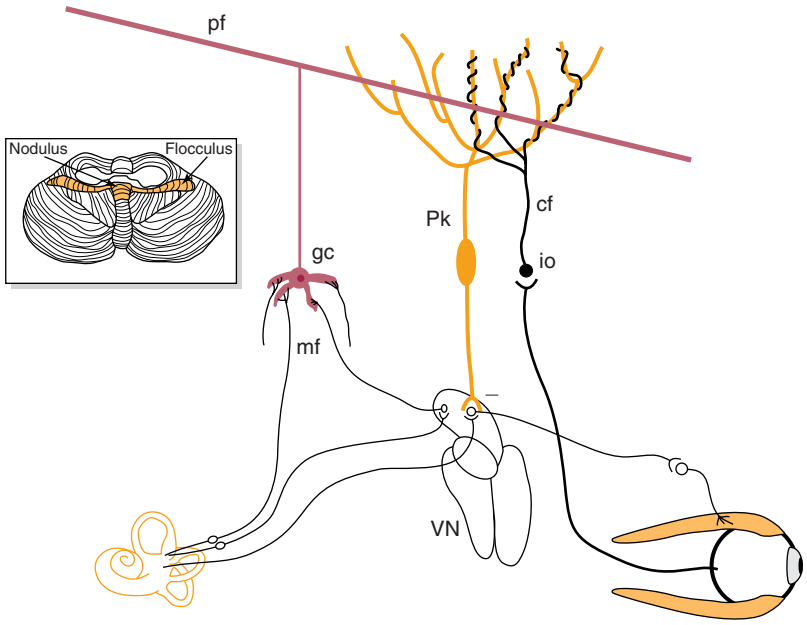

Figure 163-31. Circuitry of the cerebellum involved in modifying the vestibulo-ocular reflex (VOR). Inputs from primary vestibular afferents and secondary vestibular neurons (VN) form mossy fiber (mf) inputs to cerebellar granule cells (gc). Parallel fibers (pf) originating from these synapse weakly with Purkinje cells (Pk), causing a highly tonic inhibitory output of simple spikes from the Purkinje cells onto secondary vestibular neurons controlling the VOR. Climbing fiber (cf) input from the inferior olive (io) carries sensorimotor error information such as retinal slip. Climbing fibers make extensive and strong synapses onto Purkinje cells. Climbing fiber activity leads to complex spikes in the Purkinje cells, which can alter the efficacy of the parallel fibers' synapses onto the Purkinje cells—a form of learning.

then the head, toward a new visual target. During the gaze shift, there is a period during which both the eyes and head must move in the same direction. The VOR must actually be turned off during this period; otherwise, the eyes would stay fixed on the original target. This *cancellation* of the VOR is measurable in secondary vestibular neurons as a decrease in VOR gain when gaze is being redirected.[113,114] The mechanism by which the VOR can be canceled is not clear, but secondary vestibular neurons may receive "efference copies" of the commands going to the eye muscles. These oculomotor signals may, through inhibitory connections, decrease the responses of secondary vestibular neurons participating in the VOR reflex arc.

Under other circumstances, the VOR gain may need to be increased. For example, when the eyes are verged to view a target near the nose, they must rotate through a larger angle than that fore head rotation, in order to stay on target. In fact, as head rotation brings one eye closer to the target and takes the other eye farther away from it, each eye will require a *different* VOR gain value. Viirre and coworkers[115] showed that the VOR performs as needed under these demanding conditions to stabilize images on the retina, and it appears to do so within 10 to 20 msec of the onset of head movement—faster than could be explained by the use of any visual feedback information to correct the VOR. These investigators suggested that otolith interactions with canal signals could provide a means to constantly update an internal map of the visual target in space, allowing adjustments to the gain of the VOR for each eye.

Other contextual changes in the vestibular reflexes take place more slowly. For example, the VOR gain needs to be adjusted for changes in visual magnification when someone begins wearing spectacles. Long-term changes in vestibular reflexes, a form of motor learning, depend heavily on the cerebellum, specifically the flocculonodular lobe of the cerebellum. The basic wiring of the cerebellum as it relates to the VOR reflex arc is shown in Figure 163-31. The output of the cerebellar cortex comes from Purkinje cells, which have an inhibitory effect on their target neurons in the vestibular nuclei. Purkinje cells have two distinct patterns of activation. Simple spikes occur at high rates and are triggered by inputs from many parallel fibers. These parallel fibers arise from granule cells, which in turn receive inputs from mossy fibers. The latter convey a variety of motor and sensory signals. Input from many parallel fibers, each of which synapses weakly onto Purkinje cells, leads to a high tonic output of simple spikes from the Purkinje cells. By contrast, the climbing fibers from the inferior olive carry sensorimotor error signals—for example, retinal slip. Each climbing fiber makes numerous synapses with the dendrites of a Purkinje cell, so that one climbing fiber has a strong effect on the Purkinje cell. This effect generates complex spikes at low rates. In the classical model of cerebellar learning, repetitive and synchronous activation of climbing fiber and parallel fiber inputs causes a gradual reduction in the strength of parallel fiber synapses onto Purkinje cells—so-called long-term depression.[116] In the context of the VOR, weakening the parallel fiber input would diminish the tonic inhibition of the Purkinje cells on the secondary vestibular neurons. The VOR gain would increase as needed to correct the error signal carried by the climbing fibers. It is likely that learning in the cerebellum is much more complex than this, with changes occurring at multiple synapses. An important point is that error signals such as retinal slip may be necessary to drive the motor learning that underlies some compensatory changes in the vestibular system. This phenomenon is the basis for many physical therapy interventions for loss of unilateral vestibular function.

After unilateral loss of vestibular function (e.g., labyrinthectomy), a profound imbalance develops in the firing rates of the vestibular nuclei, with most second-order neurons on the ipsilateral side going silent.[116-125] The static imbalance results in the nystagmus and ocular tilt reaction described earlier. This static imbalance is corrected within 1 week of labyrinthectomy in alert guinea pigs[122] and within 3 weeks in the monkey.[126] Some component of the recovery of resting activity in secondary vestibular neurons is intrinsic.[127] On the other hand, subsequent lesions in other parts of the central nervous system (CNS), such as the spinal cord[128] or inferior olive,[129] can cause transient decompensation and recurrence of symptoms of static imbalance. Two important points emerge from these observations: First, an astonishing compensation for static vestibular imbalance can occur but may require a period of weeks. Second, this compensation may be disrupted by other changes in the CNS at later times, causing a recurrence of symptoms due to static vestibular imbalance. It bears repeating that despite the recovery of static central vestibular imbalance, asymmetries in dynamic responses to head movements persist, to some degree, perma-

nently, after unilateral loss of vestibular function. This is exemplified by the head thrust test discussed in Principle 6.

Clinical Implications

Vestibular compensation requires there to be a stable (although reduced) level of peripheral vestibular function over time. The compensatory mechanisms must also be presented with sensory error signals, and their ability to sense and process these signals must not be compromised. These requirements have three important clinical consequences.

Static Loss of Vestibular Function Can Be Compensated, but Fluctuating Loss Cannot

There are important clinical correlates to the observations that the vestibular system adapts slowly to loss of unilateral function and that changes elsewhere in the CNS or further changes in vestibular function can cause decompensation. Disease states that cause static, stable loss of peripheral vestibular function are typically much less debilitating than are losses than fluctuate over minutes to hours. When there is an acute, fixed loss of unilateral vestibular function, such as after labyrinthectomy, vestibular neurectomy, or some cases of viral labyrinthitis, patients typically have several days of vertigo and nystagmus. Most patients with normal contralateral function compensate for unilateral loss remarkably well over 1 to 2 weeks.[130] Spontaneous nystagmus resolves within a few days, although nystagmus induced by head-shaking and lateral gaze toward the contralesional side may persist longer (see Principle 9). Again, it should be emphasized that sudden, rapid head rotations to the ipsilateral (nonfunctioning) side will always cause transient failure of the VOR if there is not recovery of ipsilateral peripheral function (see Principle 6). Within 2 weeks after acute unilateral loss of function, most patients no longer have vertigo at rest, and can walk, although they may require assistance. By 1 month later, most are walking unassisted and returning to normal daily activities.

In contrast to the relatively benign and predictable course after a permanent total unilateral loss of vestibular function, the fluctuating function typical in Meniere's disease and BPPV can cause intense and debilitating vertigo and nystagmus with each attack. These disorders cause a fluctuating perturbation of peripheral vestibular function on an hour-to-hour or even minute-to-minute basis. The brain simply cannot complete its compensatory work in this time frame, before peripheral function returns to normal. The compensatory mechanisms are effectively faced with a "moving target."

Perhaps the least symptomatic loss of vestibular function occurs with the slow growth of vestibular schwannomas. As the vestibular nerves are slowly infiltrated or compressed, the brain compensates for the gradual loss of function imperceptibly, and patients may have no symptoms save for the occasional off-balance feeling when turning the head rapidly toward the tumor side—a natural equivalent to the head thrust test. Patients with such loss of peripheral function may have little postoperative vertigo, whereas those with preserved function up until the time that one or both vestibular nerves are cut in removing the tumor often have severe vertigo, nystagmus, and the ocular tilt reaction.[130]

The disparity between typical responses to stable and fluctuating losses underlies the rationale behind use of ablative therapies such as intratympanic gentamicin, vestibular neurectomy, and labyrinthectomy for intractable Meniere's disease. After the initial period of compensation, patients who had previously suffered frequent bouts of vertigo usually have relatively few and tolerable vestibular symptoms, so long as contralateral function is intact and stable (reviewed by Blakley[131]).

The difference between stable and fluctuating losses also has diagnostic importance. Because stable vestibular deficits generally do not cause ongoing vertigo, recurrent vertigo in the setting of a well-compensated vestibular loss should be seen as a sign of further fluctuation in vestibular function. This fluctuation may be due to a reactivation of a quiescent disease process such as Meniere's disease, or the appearance of a new labyrinthine problem. A relatively common example of the latter is occurrence of posterior canal BPPV in 15% to 30% of patients who previously had vestibular neuritis.[132,133] As noted in the clinical implications of Principle 7, vestibular neuritis usually involves the superior vestibular nerve and its endorgans, sparing the saccule and posterior canal, which are supplied by the inferior vestibular nerve. It is thought that the damage to the labyrinth can cause release of otoconia from the utricle, and that these otoconia then settle in the posterior canal, precipitating BPPV. Typical posterior canal BPPV can develop in an ear that had vestibular neuritis even months after the onset of the neuritis.

The Effect of Suppressive Drugs on Vestibular Compensation

Patients with the acute syndrome of unilateral vestibular hypofunction are commonly given medications to alleviate their distressing symptoms: benzodiazepines (e.g., diazepam), anticholinergic agents (e.g., meclizine), and antiemetic agents (e.g., promethazine). Although these drugs are invaluable for the acute relief of these distressing symptoms, they can be counterproductive to vestibular compensation if continued for too long. Recall that central adaptation is partially driven by error signals, the sensory mismatch that occurs, for example, between the vestibular signals and visual signals when the VOR fails. These sensory mismatches cause a sense of vertigo in patients with recent-onset unilateral hypofunction as they begin moving once the static symptoms have abated. Suppressing this vertigo with the continued use of some medications can prolong or even prevent vestibular compensation. Studying the effects of medications on vestibular compensation after unilateral labyrinthectomy in cats, Peppard[134] found that the commonly used vestibular symptom suppressants diazepam, scopolamine and dimenhydrinate could hinder the rate and extent of compensation. Meclizine probably has similar effects. Conversely, a combination of a stimulant (amphetamine) and a general antiemetic (trimethobenzamide) had a beneficial effect in enhancing compensation, perhaps because increased physical activity corresponded to more head movements that challenged the system and drove compensation.

The Basis of Vestibular Rehabilitation

A variety of rehabilitation regimens have been constructed around the principle that vestibular compensation is driven by sensory mismatches, particularly between the visual and vestibular systems. Not only do these mismatches drive changes in the gain of remaining vestibular reflexes, but they also engender compensatory changes in other motor systems to replace lost vestibular functions. Examples are the central preprogramming of eye movements and of postural responses, the potentiation of the cervico-ocular reflex, and modification of saccadic eye movements. Sensory substitution of visual and somatosensory cues for the lost vestibular cues may also contribute to overall compensation.[135]

Although controlled studies of vestibular rehabilitation are difficult to perform, these programs generally do improve the subjective sense of balance in persons with fixed loss of vestibular function and often improve their objective performance on balance tests, as well as returning them to many of their activities of daily living.[136-138]

Appendix

Experimental and clinical vestibular tests often employ sinusoidal head rotations at different frequencies as stimuli, and report results in terms of VOR *gain*, *phase*, and *time constant*. These terms describe the *frequency response* of the system. The concept of the frequency response of a system is familiar to anyone who has used a graphic equalizer on a stereo system (Fig. 163-32A). Setting the sliders determines how much attenuation of the incoming signal is applied to each frequency band. The resulting output can be graphically described by the *Bode plot* (see Fig. 163-32B). In the example shown in Figure 163-32, the equalizer is set up as a low-pass filter, letting through low frequencies but attenuating high frequencies. The goal of the following analysis is to derive the frequency response—the Bode plot—for the semicircular canal.

Equation 163-8, which describes the movement of the cupula, can be written as

$$\ddot{\Theta}(t) = \ddot{H}(t) - \frac{B}{I}\dot{\Theta}(t) - \frac{K}{I}\Theta(t) \qquad \text{Eq. 163-13}$$

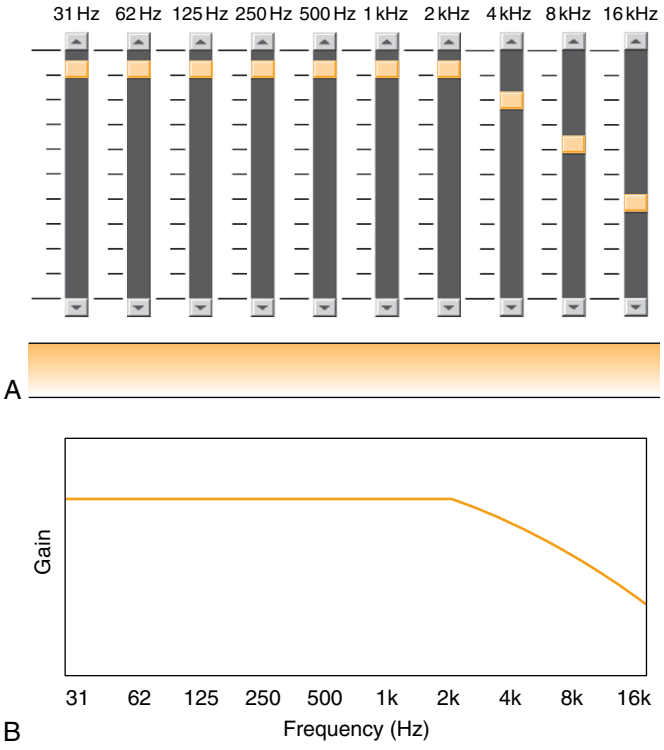

Figure 163-32. **A,** The graphic equalizer provides a means of setting signal strength (gain) across frequencies. **B,** The analytical expression of this is the Bode gain plot.

This differential equation is expressed as a function of time, or *in the time domain*. Although it can be solved as a function of time, our principal interest is to determine this system's frequency dependence. Thus, it is useful to transform this equation into the *frequency domain*. The French mathematician Laplace (1749-1827) devised a method to transform differential equations in the time domain to algebraic equations in the frequency domain. The latter are much easier to solve, and once the solution is obtained, tables can be used to look up the time-domain equivalent if it is needed. The power of Laplace's technique, however, is that it immediately gives the frequency response of the system in the form of a *transfer function* in the frequency domain. Transfer functions, which describe the input-output characteristics of systems across frequencies, are fundamental to the study of the auditory and vestibular systems.

The Laplace transform is

$$f(s) = L\{F(t)\} = \int_0^\infty e^{-st} F(t)\,dt, \text{ where } s = \sigma + j\omega. \qquad \text{Eq. 163-14}$$

The Laplace transform essentially converts signals that vary in time into those that vary in frequency by using complex exponentials. This works because most natural signals can be represented as some combination of functions that have exponential growth or decay and sinusoidal oscillations. Equations of the form $F(t) = Ae^{\sigma t}$ describe exponential growth or decay. Those of the form $F(t) = Ae^{j\omega t}$ describe sinusoidal oscillations, because

$$Ae^{j\omega t} = A(\cos\omega t + j\sin\omega t) \qquad \text{Eq. 163-15}$$

Thus, the complex exponential term $e^{-(\sigma+j\omega)t}$, encompasses most signals.

The following two features of the Laplace transform make it of such practical use in converting differential equations to algebraic ones. If $L\{Y(t)\} = y(s)$,

1. $$L\{\dot{Y}(t)\} = sy(s) - Y(0) \qquad \text{Eq. 163-16}$$

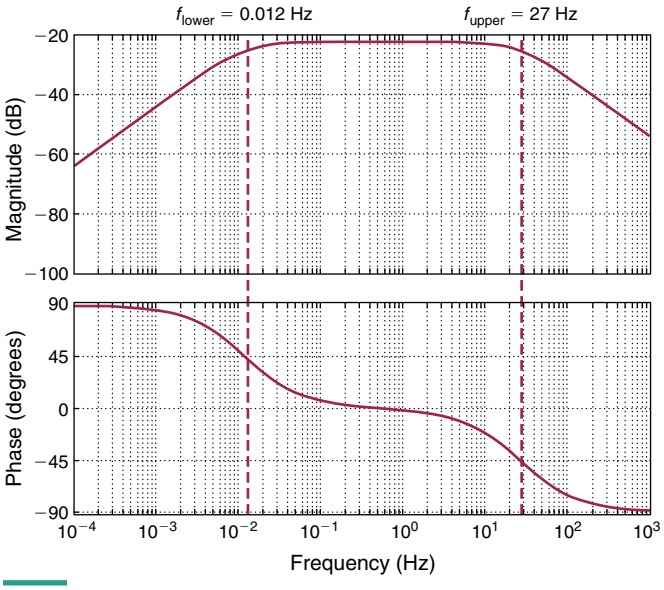

Figure 163-33. Gain (**A**) and phase (**B**) plots for the semicircular canal transfer function relative to head velocity as given in Equation 163-20. Upper and lower corner frequencies (*f*) are indicated.

That is, the Laplace transform of a derivative is just *s* times the Laplace transform of the function, minus the value of the function at time zero. The value at time zero often is 0. Thus, *differentiation* in the *time* domain becomes *multiplication* by *s* in the *frequency* domain.

2. $$L\left\{\int Y(t)\,dt\right\} = \frac{y(s)}{s} \qquad \text{Eq. 163-17}$$

That is, the Laplace transform of an integral is just the Laplace transform of the function divided by *s*. Thus, *integration in the time domain becomes division by s in the frequency domain.*

Using these features, Equation 163-13 can now be written in the frequency domain:

$$s^2\Theta(s) = s\dot{H}(s) - s\frac{B}{I}\Theta(s) - \frac{K}{I}\Theta(s) \qquad \text{Eq. 163-18}$$

or

$$\frac{\Theta(s)}{\dot{H}(s)} = \frac{s}{s^2 + s\frac{B}{I} + \frac{K}{I}} = \frac{I}{K} \times \frac{s}{\frac{I}{K}s^2 + \frac{B}{K}s + 1} \qquad \text{Eq. 163-19}$$

Combining the different constants gives

$$\frac{\Theta(s)}{\dot{H}(s)} = \frac{\tau_1\tau_2 s}{(\tau_1 s + 1)(\tau_2 s + 1)} \qquad \text{Eq. 163-20}$$

where $\tau_1\tau_2 = {}^{1}\!/_{K}$ and $\tau_1 + \tau_2 = {}^{B}\!/_{K}$. Values for these time constants have been estimated at $\tau_1 \approx 0.006$ second and $\tau_2 \approx 13$ seconds.[82]

Note that Equation 163-20 gives the desired relationship between the motion of the endolymph (output) and the head velocity (input). This input-output relationship is the transfer function of the semicircular canal. The shown or frequency response of this transfer function can be obtained by standard engineering mathematics and is shown in Figure 163-33. This plot shows that the expected endolymph motion is indeed in phase with head velocity and has a constant gain over a wide frequency range, from approximately 0.012 to 27 Hz. Thus, over this frequency range, the *semicircular canal approximately encodes head velocity*.

Although this range encompasses most natural head movements, it should be noted that the canal is not a particularly good encoder of head velocity for very low frequency rotations. For example, whereas a slow turn at 0.02 Hz is sensed with little attenuation (1.4 dB below the

flat midfrequency gain), the phase shift is approximately 32 degrees. This deficiency in the performance of the canals at low frequencies is improved by the central mechanism of *velocity storage* (see Principle 9).

Acknowledgments

We would like to thank Dr. Philip Cremer (Sydney, Australia) for the inspiration to explain vestibular physiology with a few fundamental principles. Principle 4 is directly attributed to him. We also thank Dr. Thomas Haslwanter (Linz, Austria) for comments on the manuscript.

CHAPTER ONE HUNDRED AND SIXTY-FOUR

Evaluation of the Patient with Dizziness

Timothy E. Hullar

David S. Zee

Lloyd B. Minor

Key Points

- Imbalance can be due to dysfunction of either the peripheral or the central vestibular system.
- A careful clinical history is critical for determining the cause of imbalance; identification of symptom duration and triggers is key.
- The bedside examination often offers clues to the diagnosis, especially in patients who are asymptomatic at the time of the visit.
- Evaluation of eye movements and hearing assessment are the central parts of the physical examination.
- Laboratory tests must be used judiciously to investigate specific diagnostic entities suggested by the clinical history and bedside examination.
- Determination of treatment options depends on an accurate diagnosis.
- Specific exercises can help patients adapt to long-term balance deficits.

Background

Dizziness is the ninth most common complaint leading patients to visit their primary care physicians, rising to third among those 65 to 75 years of age and first among older patients.[1,2] Despite its frequency, symptoms of dizziness can be difficult for the patient to describe and for the physician to categorize. *Dysequilibrium*, *unsteadiness*, *vertigo*, and *lightheadedness* all are terms that patients may use to describe their sensations. Evaluation of balance signals from peripheral vestibular nerve afferents, the visual system, and somatosensory and proprioceptive receptors normally occurs below a patient's level of awareness, making symptoms particularly difficult to describe.

This chapter outlines an approach to the evaluation of patients with dizziness that builds on an understanding of the pathophysiology of dizziness to develop an organized method for history taking and physical examination leading to the identification of specific abnormalities. A description of some of the physiological and functional principles underlying the symptoms and signs of vestibular disorders is presented first. (A comprehensive description of these topics is provided in Chapter 163.) Using an approach based on these considerations, the clinical evaluation, including the history, physical examination, and quantitative tests of vestibular function, is described next. Finally, the adaptive capabilities of the vestibular system and principles of vestibular rehabilitation are reviewed.

Fundamentals of Vestibular Function

Peripheral Anatomy and Physiology

The vestibular receptors are located in the labyrinth and consist bilaterally of three orthogonally oriented semicircular canals and two otolith organs. The semicircular canals sense angular acceleration and are arranged in roughly parallel pairs: the two horizontal (also called "lateral") canals, the left anterior and right posterior canals, and the right anterior and left posterior canals. The orthogonal geometry of the semicircular canals in each labyrinth permits three-dimensional rotational head movements to be represented as the vector sum of components in each plane. Most vestibular nerve afferents have a spontaneous firing rate between 10 and 100 spikes/second. When the head is still, primary afferents in the right and left vestibular periphery discharge tonically at the same rate. During horizontal head rotation, the horizontal semicircular canal is stimulated in the ipsilateral labyrinth and inhibited in the opposite. During vigorous horizontal head rotations, many afferents and central vestibular neurons on the inhibited side are silenced.[3,4]

Over the physiologic range of head movements (0.1 to 15 Hz), the intrinsic mechanical properties of the semicircular canals integrate this acceleration signal into a velocity signal. This signal is further modified by individual afferents, providing central vestibular neurons with an array of signals carrying velocity and acceleration information. Activity in the vestibular nerve is the major source of sensory input to the vestibular nuclei, with almost 30,000 afferents projecting from each labyrinth to the brainstem in humans.[5] Neurons in the vestibular nuclei typically receive bilateral inputs from the coplanar semicircular canals (direct projections from afferent nerve fibers on the ipsilateral side and commissural projections from central vestibular neurons that cross from the contralateral side), with excitation of peripheral afferents causing increased firing rates of the neurons in the ipsilateral vestibular nucleus.

Eye Movements

Vestibular information is vital to controlling both eye movements and body posture, but eye movements are the more easily studied and the

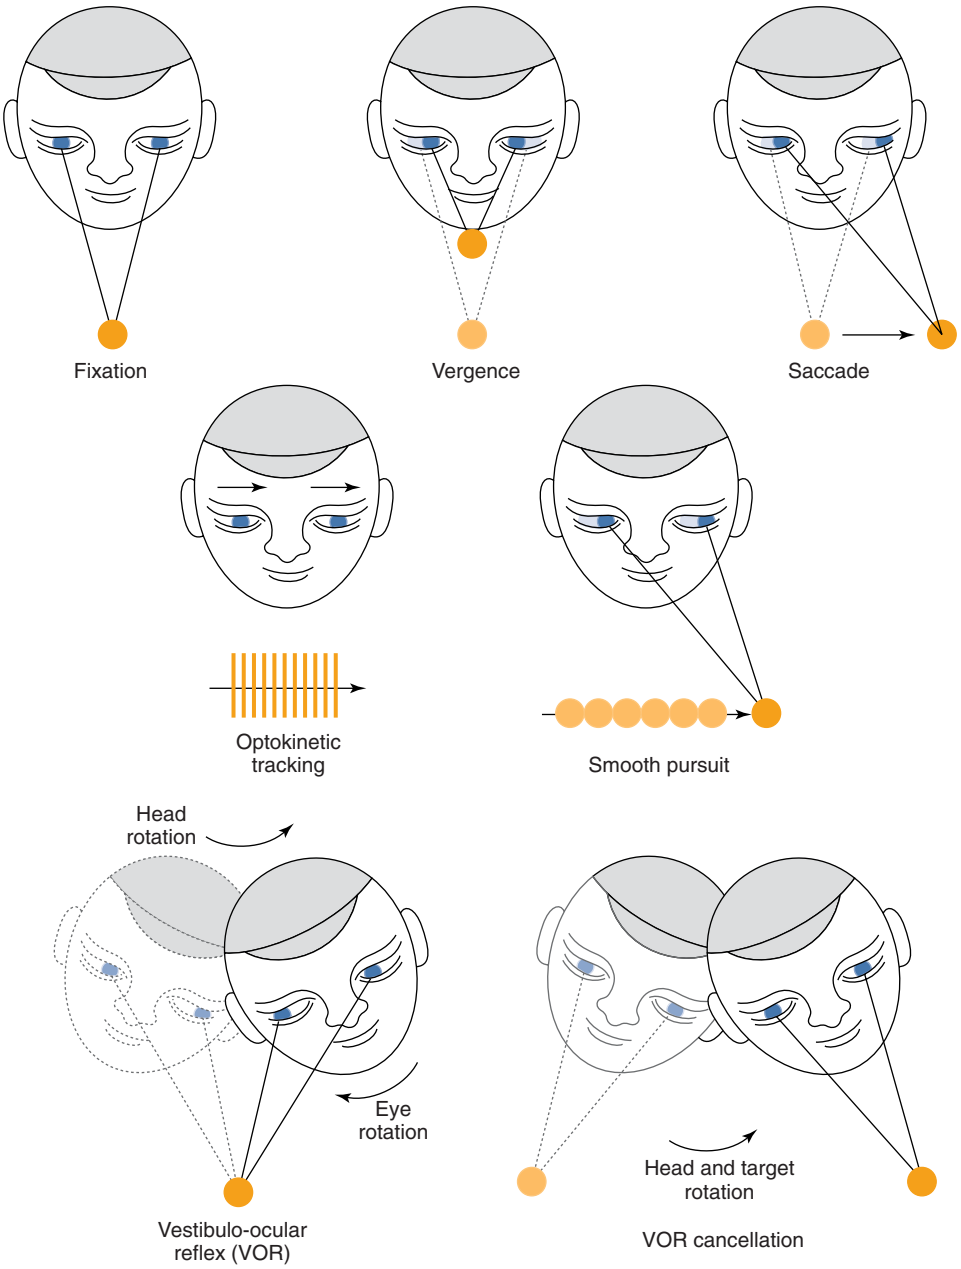

Figure 164-1. Schematic depiction of the functional classes of eye movements. Basic research in the neurophysiology of oculomotor control and clinical studies of eye movement disorders have been enhanced by the recognition of functionally distinct subsystems. Seven types of eye movements are shown.

better understood of the two. All eye movements are aimed at ensuring optimal visual acuity (Fig. 164-1). Vestibular and optokinetic eye movements work to hold eye position in space (i.e., *gaze*) constant by producing compensatory eye movements that keep images stable on the retina during head movements. Saccadic, pursuit, and vergence eye movements change gaze so that images of objects of interest are brought to or kept on the fovea, where visual resolution is highest. Saccades rotate the eye to bring an image onto the fovea, whereas pursuit maintains that image on the fovea as it moves across the visual field. Vergence movements are disjunctive, causing the eyes to move in opposite directions to place the image of an object simultaneously on both foveae during movements of the head or the object (Table 164-1).

Visual acuity is degraded if images slip across the retina even as slowly as 2 to 3 degrees/second.[6] Vestibulo-ocular reflexes (VORs) are responsible for maintaining binocular fixation and stabilizing binocular foveal images during head movements.[7] The VORs are divided into two types: angular and translational. *Angular* reflexes are initiated by activation of the semicircular canals. The canals are aligned with the pulling directions of the three pairs of extraocular muscles,[8] so that activation of a single semicircular canal (as in benign positional vertigo or canal dehiscence) leads to motion of the eyes about an axis that aligns with the axis of the semicircular canal (Fig. 164-2). The latency of the angular reflex is approximately 7 msec in humans.[9]

Translational VORs are driven by otolith afferents and can be grouped into two categories according to the eye movement responses: *tilt* responses, which compensate for lateral head tilt with respect to gravity, and *translational* responses, which produce eye movements compensatory for linear movements of the head (Fig. 164-3). Lateral head tilt produces ocular counter-rolling, a torsional movement of the eye about the line of sight. The torsional deviation of the eyes in response to 60- to 75-degree static head tilts is 6 to 8 degrees.[10] The small amplitude of eye movement produced by relatively large tilts of

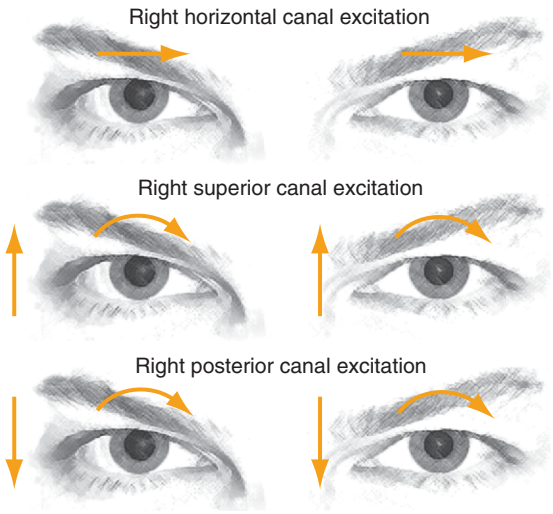

Figure 164-2. Relationship of individual canals and eye movements. Activation of individual canals leads to stereotypical eye movements. The horizontal canal is activated by head rotation in the horizontal plane, whereas pure activation of the posterior canal may be seen in benign positional vertigo, and pure activation of the superior canal is seen in superior canal dehiscence syndrome. All *arrows* represent direction of slow phase eye movements. *(From Hullar TE, Minor LB. The neurotologic examination. In: Jackler RK, Brackmann DE, eds.* Neurotology. *2nd ed. St Louis: Mosby; 2004:215-277.)*

Table 164-1

Functional Classes of Human Eye Movements

Class of Eye Movement	Main Function
Visual fixation	Holds the image of a stationary object on the fovea
Vestibular	Holds images of the seen world steady on the retina during brief head rotations
Optokinetic	Holds images of the seen world steady on the retina during sustained head rotations
Smooth pursuit	Holds the image of a moving target on the fovea
Nystagmus	The repetition of a compensatory slow phase and quick phase resetting movement of the eyes; in quick phases, gaze directed toward the oncoming visual scene
Saccades	Bring images of objects of interest onto the fovea
Vergence	Moves the eyes in opposite directions so that images of a single object are placed simultaneously on both foveas

the head appears to indicate that ocular counterrolling is a vestigial response with little compensatory function, but during lower-amplitude sinusoidal head rolls, the torsional gain is significantly greater. Compensatory eye movements in these situations seem to result largely from canal-related reflexes, although the otolith organs also are

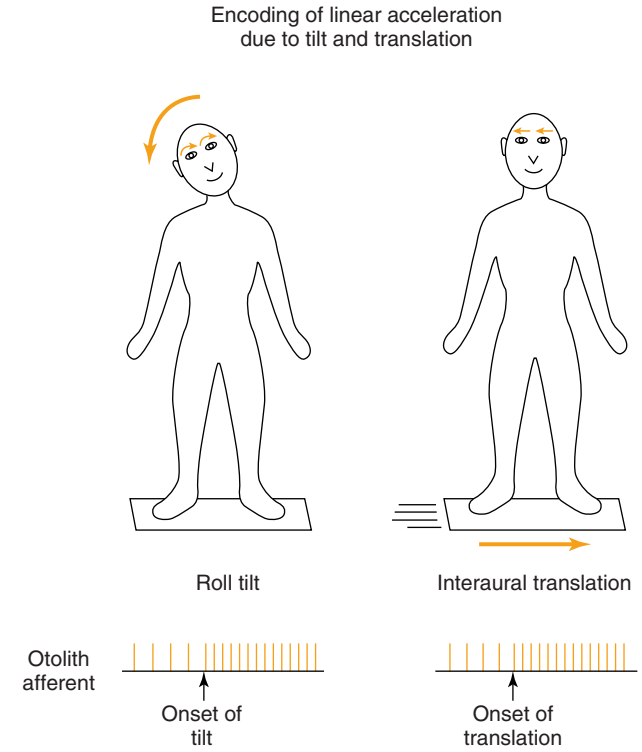

Figure 164-3. Otolith afferents respond to linear acceleration. Identical changes in otolith afferent activity can result from head movements that change the orientation of the head relative to gravity (roll tilt) and from linear translational movement (interaural translation). There is no way for otolith afferents to distinguish whether a translation or a tilt produced the modulation in otolith afferent activity. The compensatory eye movements evoked by these two types of head movements are quite different, as shown on the diagram. Central processing of signals in the brainstem must be responsible for resolution of the so-called translation-tilt ambiguity. *(From Minor LB. Physiological principles of vestibular function on earth and in space.* Otolaryngol Head Neck Surg. *1998;118:54.)*

activated.[11] Translational VORs produce eye movements that maintain the point of binocular fixation for each retina during linear head movements.

Otolith afferents cannot distinguish between tilt and translation. Information from the semicircular canals, comparison of the phasic and tonic components of modulation in otolith afferent activation, frequency-selective organization of otolith-mediated responses, or other sensory signals such as vision or proprioception must be involved in determining appropriate reflex responses. For example, tilting of the head involves both canal and otolith activation, and the combined activation of these receptors provides cues to the brain that the modulation in otolith activity is due to a tilt and not to a linear head movement. Frequency-selective filtering of otolith afferent signals provides another complementary mechanism. Head movements that change slowly with respect to gravity (frequency content less than 0.25 Hz) may be interpreted as tilt stimuli, whereas those with higher frequency content lead to responses that are directed to maintaining stable gaze during linear head movements.[12,13]

Head Movements

Compared with the relatively simple task of the six muscles moving each eye, the 20 muscles moving the neck must contend with more complicated planar relationships, the substantial inertia of the head, and the effect of stretch reflexes and muscular co-contraction. The situation is even more complicated because the trunk and lower extremities are involved in maintaining posture and upright stance. Two reflexes are important for stabilizing the head. The vestibulocollic reflex

(VCR) governs the activation of neck muscles in response to vestibular input,[14] and the cervicocollic reflex (CCR) governs the activation of neck muscles in response to stretch receptors.[15] Studies of head stability during locomotion in humans have shown that the peak velocity of these rotational head perturbations generally does not exceed 150 degrees/second, but their predominant frequency can be as high as 5 Hz, with a frequency for some components of head movements up to 15 Hz.[16-19] Studies of head movements in patients who have lost vestibular function indicate that head stability can be achieved by way of the mechanical properties of head and neck muscles, rather than neural reflexive factors.[20,21] The CCR, consisting of compensatory eye movements during head-on-body rotation caused by neck proprioception, contributes little to gaze stability in healthy people, although it may become more important if labyrinthine function is lost.[22,23]

Combinations of eye and head movements are used to acquire and track a target of interest, as well as to stabilize gaze in response to perturbations of the body. Voluntary eye-head movements can be thought of as either saccadic or pursuit in nature. During small eye-head saccades (less than 30 degrees), the shift of gaze may be achieved by superposition of an internal saccadic command and the VOR.[21] For larger eye-head saccades (more than approximately 40 degrees), the VOR appears to be "turned off" or "disconnected." Nevertheless, the vestibular signal caused by the head movement is still available so that an accurate gaze change can be achieved.[24] During smooth eye-head tracking, more than one mechanism may operate to override the VOR so that gaze follows the moving target smoothly. Evidence suggests that an internal smooth pursuit signal partly cancels the VOR, and that an additional mechanism may be reduction in the activity or partial suppression of the VOR during such eye-head tracking.[25-28] Disorders causing impairment of smooth pursuit usually, but not always, also cause deficits of smooth, combined, eye-head tracking.[29] Patients who have lost vestibular function, on the other hand, often show combined eye-head tracking that is superior to ocular pursuit.[26]

Posture

Active processes for control of the body's center of gravity are involved in maintaining postural stability in healthy subjects. The center of gravity is located in the lower abdominal area and slightly forward of the ankle joints in a healthy person standing erect. In humans, the goal of postural control is to maintain sway within the limits of stability for different body positions and activities. The limits of stability are defined by a horizontal ellipse measuring approximately 12.5 degrees from front to back. The lateral dimension of limits of stability depends on the subject's height relative to spacing between the feet. For a person 70 inches tall with feet placed 4 inches apart, the lateral dimension of the "limits of stability" ellipse is approximately 16 degrees from left to right.

Postural responses to perturbations (movement of the support surface or body) are organized into discrete patterns about the ankles and hips. The pattern(s) to be used depends on structure of the support surface and position of the center of gravity relative to limits of stability. Movements of the body about the ankle joints are the effectors of the *ankle strategy.* The ankle strategy is effective when the center of gravity moves slowly and within the limits of stability, and the support surface is longer than the feet and strong enough to resist torque about the ankles. When it is not possible to exert an adequate amount of torque around the ankle joint, healthy subjects invoke a *hip strategy*. This strategy consists of exerting a horizontal shear force on the support surface by counterphase leg and trunk movements about the hip. The hip strategy also is effective when the center of gravity moves rapidly or approaches the limits of stability.

Contributions of the Brainstem and Cerebellum

The cupula of the semicircular canal returns to neutral position with a time constant of approximately 6 seconds, but the associated decay in eye movements is closer to 15 seconds in normal humans because of the effect of a process termed *velocity storage*. The neural center responsible for this process is located in the brainstem. This mechanism improves the capability of the system to respond to low-frequency head motion[30] and to orient vestibulo-ocular responses to gravity.[31,32] Velocity storage is (transiently) lost in cases of acute unilateral vestibular loss and remains diminished in the long term.

The *neural integrator* is another brainstem mechanism vital for proper eye movements.[33] It produces a steady command to the extraocular muscles to hold the eyes eccentrically, instead of allowing them to drift back to neutral gaze position because of the elastic restoring forces of the orbital tissues. Proper function of the neural integrator also is necessary for the VOR to have the appropriate phase (timing) relationship to head rotation. The neural integrator is not able to hold gaze appropriately in cases of acute unilateral deafferentation.

The cerebellum plays an important role in immediate and long-term adaptive ocular motor control.[34] Lesions of the flocculus impair smooth pursuit and VOR cancellation, which normally allows the eyes to move with head rotations to follow a target.[35] Floccular lesions may cause horizontal gaze-evoked nystagmus, downbeat nystagmus, rebound nystagmus, increased or decreased amplitude (gain) of the VOR, and postsaccadic drift, or *glissades*.

The vestibulocerebellum also is important for ensuring that the eyes rotate in a plane parallel to head rotation so that images can be stabilized appropriately on the retina.[36] The dorsal vermis and underlying fastigial nuclei are important in the control of saccadic amplitude and smooth pursuit; lesions here produce saccadic inaccuracy (dysmetria) and impair the ability to make long-term adaptive adjustments in saccade accuracy.[37] Other "cerebellar" eye signs, which cannot be localized precisely, include square-wave jerks, defective convergence, divergence nystagmus, and alternating hyperdeviation (skew) on lateral gaze.[38]

Approach to the Patient with Dizziness

History

In many cases a specific cause for a patient's dizziness can be determined from an accurate history alone. Taking the history of a patient with a complaint related to dizziness must begin in an open-ended fashion, allowing the patient to describe the symptoms with minimal direction from the clinician. The process can be facilitated by asking the patient to complete and return a questionnaire about symptoms before the first appointment.

From the history, the clinician should have a general idea of whether the symptoms are attributable to a vestibular disorder and, if so, whether this disorder is central or peripheral in origin. An outline of diagnostic possibilities based on symptoms and signs is shown in Figure 164-4.

- Does the patient have vertigo? Vertigo is an illusory sense of motion. The patient can feel as if the motion is internal or that objects in the surroundings are moving or tilting. The sense of motion can be rotatory, linear, or a change in orientation relative to the vertical. Vertigo indicates a problem within the vestibular system, although the abnormality can be located anywhere within the system. Lightheadedness, as opposed to vertigo, may indicate presyncope. Although often related to neural factors, such as vasovagal syncope, it also can reflect cardiac disease, especially in older patients. Generalized imbalance may reflect more central processes, including mal de débarquement or migraine. Some conditions, such as migraine, can manifest with nonspecific imbalance symptoms in addition to acute vertigo.

- What happened the first time the imbalance occurred? The onset of symptoms with straining can be indicative of a disorder such as semicircular canal dehiscence or perilymphatic fistula. Straining also can lead to presyncope in a vasovagal reaction. In women, the association of symptoms with menstrual periods can indicate migraine. A correlation of symptoms with a large salt load should raise suspicion for Meniere's disease. The onset of symptoms after head trauma may indicate benign paroxysmal positional vertigo.

- Are the symptoms episodic or continuous, and if episodic, how long do they last? Most vestibulopathies cause fluctuating or episodic symptoms, although a constant sense of dysequilibrium may be

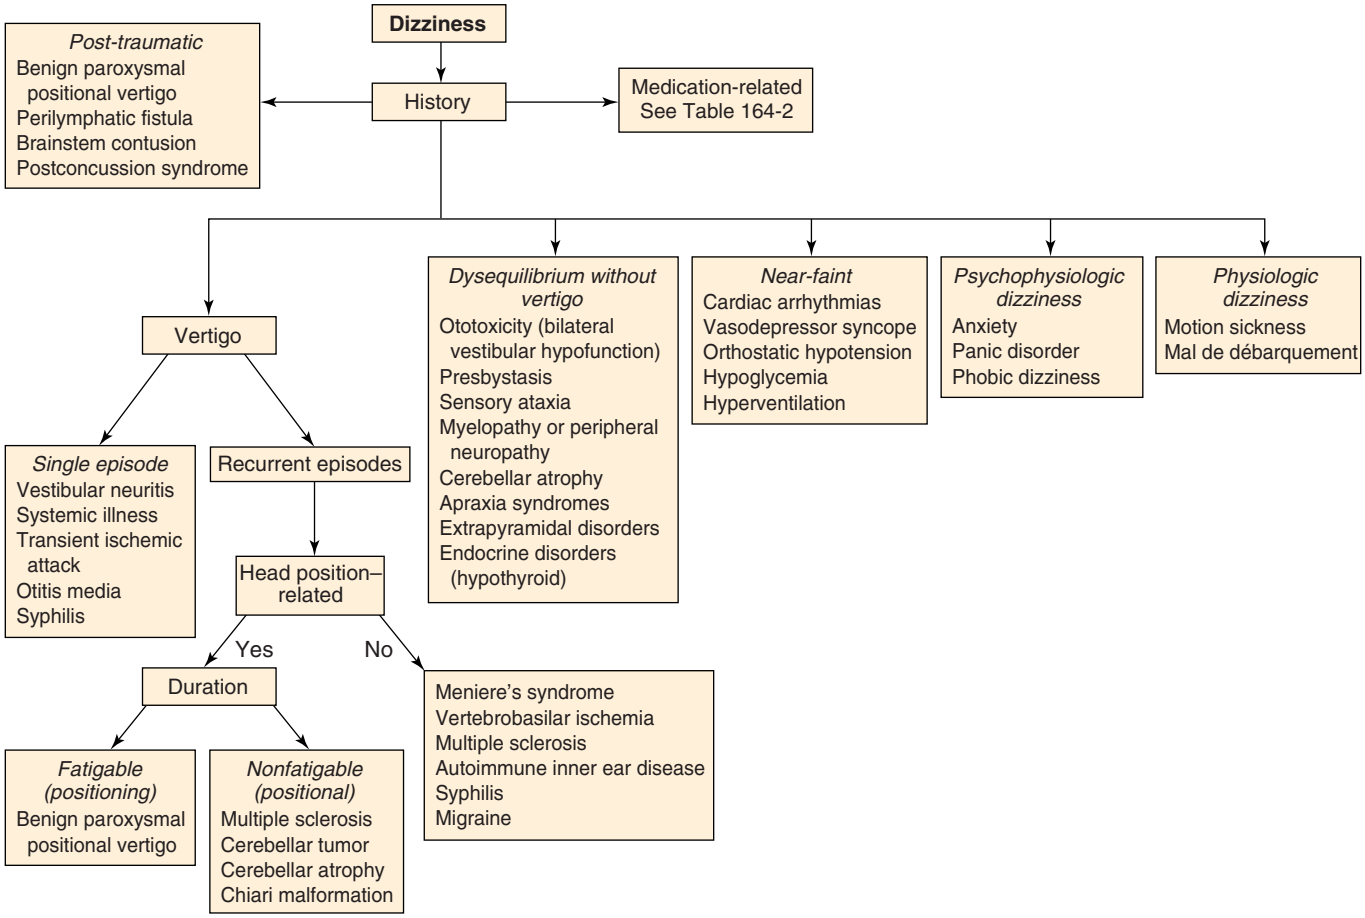

Figure 164-4. Algorithm for the differential diagnosis for dizziness, based on information from the patient's history. *(Modified from Baloh RW, Fife TD, Furman JM, Zee DS. The approach to the patient with dizziness. In: Mancall EL, ed.* Continuum: Lifelong Learning in Neurology. *Vol 2. Cleveland: Advanstar Communication; 1996:25-36.)*

present in addition to the more variable elements of the symptom complex. Migraine tends to be episodic, with each episode lasting hours to days. Benign paroxysmal positional vertigo (BPPV) is episodic but lasts a short time, although patients may note that they are "susceptible" to head motion for weeks and then not susceptible at other times. Continuous symptoms may reflect a condition such as mal de débarquement, migraine, or psychogenic dizziness.

- What brings on the problem? The diagnosis of certain vestibulopathies is strongly suggested from events or movements that trigger symptoms.
  - *Movement of the head*. BPPV of the posterior canal classically begins on rolling over in bed or tilting the head backward and toward the affected ear. BPPV of the horizontal canal can be brought on by lying with the head flat on the bed then turning it to the side. Rapid head movements may uncover vestibular hypofunction by producing a sensation of *oscillopsia* (an illusion of motion for objects that are known to be stationary). When induced by head movements, oscillopsia often is a sign of vestibular hypofunction. Brief (5 to 10 seconds) periods of vertigo, either spontaneous or sometimes induced by certain head movements, may be a sign of vascular compression of the eighth cranial nerve complex.
  - *Lifestyle*. Patients with vestibular migraine may report that certain foods such as caffeine, cheeses, wine, and other foodstuffs can bring on symptoms. The symptoms also may be induced by stress or lack of sleep.
  - *Environment*. Changes in the weather, menses, or motion stimulation such as ceiling fans or video games may bring on problems for patients who have vestibular migraine. Fluorescent lights also may cause a problem. In patients with canal dehiscence, symptoms may be brought on by loud sounds or by maneuvers that change middle ear or intracranial pressure. Changes in seasons also may provoke symptoms in patients with Meniere's disease or migraine, possibly as a result of allergy.
  - *Pressure*. Patients with semicircular canal dehiscence, perilymphatic fistula, or enlarged vestibular aqueduct may have problems with acute pressure changes such as in performing a Valsalva maneuver, coughing, or straining.
- What other signs and symptoms are associated with the dizziness or vertigo? A sensation of aural fullness and tinnitus can precede an attack of vertigo in patients with Meniere's disease. Sweating, dyspnea, and palpitations often accompany panic attacks but also may indicate a cardiogenic cause for presyncope manifesting as imbalance. Migraine-related vertigo may or may not be accompanied by an aura or headache. Other neurologic signs may indicate central mass effect or vascular pathology.
- Is there a family history of imbalance or headache? Migraine-related vertigo can run in families, and the same may be true for Meniere's disease. Otosclerosis, which can be accompanied by imbalance, also has a genetic component. Some genetic conditions, such as CHARGE syndrome (i.e., *c*oloboma, *h*eart anomalies, choanal *a*tresia, *r*etardation of growth and development, and *g*enital and *e*ar anomalies), have a prominent vestibular phenotype.
- Are there other, psychogenic disorders that may be responsible for the patient's symptoms? Anxiety disorders, panic syndromes, and agoraphobia can lead to episodic vertigo that mimics a vestibulopa-

thy. These conditions are frequent in patients with dizziness. Patients with psychogenic dizziness often describe generalized imbalance that lasts for long periods.

- Are there underlying medical problems that may cause or exacerbate the patient's symptoms? Thyroid disease, diabetes mellitus, anemia, autoimmune diseases, infections such as syphilis or Lyme disease, hypoperfusion of the brain from postural hypotension, and cardiac arrhythmias all can lead to dizziness or vertigo. Patients with migraine are more likely to experience BPPV than are those who do not have migraine. Medications also can produce symptoms that mimic vestibular disorders (Table 164-2).

Physical Exam

The physical examination is goal-directed at testing hypotheses made from the history. Each physician will develop an individual approach, with elements of the examination tailored to specific symptoms reported by the patient. A careful bedside examination, including a general otolaryngologic exam, often can be sufficient for appropriate vestibular diagnosis. In some cases, laboratory tests or quantitative methods for evaluation of vestibular function, or both, are important to help make the diagnosis or to document pathophysiologic changes or recovery during the clinical course.

Bedside Exam

No clinical test can directly measure the function of the vestibular periphery. Instead, inferences must be made about vestibular function on the basis of the performance of "downstream" processes. The most important and well-studied of these are eye movements. Use of *Frenzel lenses* (magnifying lenses that prevent the patient from using visual fixation to suppress any spontaneous nystagmus) can increase the examiner's sensitivity for nystagmus and is vital to a thorough ocular examination.

Nystagmus

Eye movements indicative of a vestibular disorder commonly take the form of nystagmus. Several different types of nystagmus are recognized (Table 164-3). The most common is *jerk nystagmus*, which consists of

Table 164-2

Type and Mechanism of Dizziness Associated with Commonly Used Drugs

Drug(s)	Type(s) of Dizziness	Mechanism(s)
Aminoglycosides, cisplatin	Vertigo, dysequilibrium	Damage to vestibular hair cells
Tranquilizers	Intoxication	Central nervous system depression
Antiepileptics	Dysequilibrium	Cerebellar toxicity
Antihypertensives, diuretics	Near-syncope	Postural hypotension, reduced cerebral blood flow
Amiodarone	Dysequilibrium and oscillopsia	Unknown
Alcohol	Intoxication, dysequilibrium, positional vertigo	Central nervous system depression, cerebellar toxicity, change in cupular and endolymphatic specific gravity
Methotrexate	Dysequilibrium	Brainstem and cerebellar toxicity
Anticoagulants	Vertigo	Hemorrhage into inner ear or brain

Table 164-3

Clinical Observations and Causes of Nystagmus

Observation	Cause(s)
Sinusoidal oscillation without fast phases: "pendular nystagmus"	Multiple sclerosis, toluene intoxication, or brainstem infarction with inferior olivary hypertrophy (the syndrome of palatomyoclonus)[a,b] Acquired pendular nystagmus frequently disconjugate; may even be horizontal in one eye and vertical in the other May be responsive to memantine[c]
Purely torsional nystagmus	Intrinsic brainstem involvement within the vestibular nuclei; suggestive of syringomyelia[d]
Downbeat nystagmus	Arnold-Chiari deformity or degenerative lesions of the cerebellum[e] Treated with 4-aminopyridine
Upbeat nystagmus	Lesions at the pontomedullary or pontomesencephalic junction or within the fourth ventricle[f]
Horizontal jerk nystagmus that changes direction approximately every 2 minutes: "periodic alternating nystagmus"	Lesions in the nodulus of the cerebellum[g,h] Treated with baclofen
Nystagmus on attempted eccentric gaze and with slow phases that show a declining exponential time course	Side effect of certain medications, especially anticonvulsants, hypnotics, and tranquilizers, and in patients with disease of the vestibulocerebellum or its brainstem connections in the medial vestibular nucleus and nucleus prepositus hypoglossi[i]

Table 164-3

Clinical Observations and Causes of Nystagmus—cont'd

Observation	Cause(s)
Accelerating slow phases accentuated by attempted fixation, decreased by convergence or active eyelid closure, associated with a head turn, and sometimes accompanied by "reversed" smooth pursuit: "infantile" or "congenital" nystagmus	May be related to central or peripheral deficits[j] May be associated with albinism, retinal diseases, and early visual deprivation May be responsive to neurontin or memantine[j,k]
Gaze-evoked nystagmus that may dampen and actually change direction ("centripetal nystagmus") and often is followed by rebound nystagmus (slow phases are directed toward the previous position of eccentric gaze) when the eyes return to the primary position	Peripheral vestibular lesions, drug intoxication, and cerebellar lesions[l] Rebound nystagmus associated with many cerebellar lesions, including olivocerebellar atrophy[m]
Slow phases with exponentially increasing waveforms	Congenital nystagmus and acquired lesions of the cerebellum
Nystagmus of greater intensity or present only in the abducting eye: "dissociated nystagmus"	Commonly occurs in patients with internuclear ophthalmoplegia (INO) Mechanism unknown for abducting nystagmus in INO[n]
One eye goes up and the other goes down: "seesaw nystagmus"	Midbrain lesions May be related to an imbalance of activity in structures that receive projections from the labyrinthine otolith organs[o]
Slow phases directed centrally and with retraction of the eye into the orbit: "convergence-retraction nystagmus"	Midbrain lesions May be a failure of saccades or of vergence[p] Usually coexists with upgaze paralysis (Parinaud's syndrome)
Skew deviation and the ocular tilt reaction (one half-cycle of seesaw nystagmus)	Occurs with acute peripheral vestibular (otolith organ) lesions and with lesions in the medulla, the pons, and the midbrain Often associated with head tilt[q]
Nystagmus occurring in a plane other than that of vestibular stimulation: "perverted nystagmus"	Central vestibular disorders; multiple sclerosis[r]

so-called slow phases, which represent vestibular signals for eye movements, and fast phases, which represent resetting actions bringing the eyes back toward the center of the orbit but are not as relevant for diagnostic purposes. The direction of nystagmus often is named for the direction of the fast phases, because the fast phases are more obvious on clinical examination. The trajectory of the slow phases should be scrutinized for the following characteristics of individual slow phases: (1) an increase in velocity, as is commonly found with congenital nystagmus; (2) a decrease in velocity, as is seen in patients with cerebellar lesions; and (3) a constant velocity, as is typical for vestibular disturbances.

Spontaneous nystagmus of vestibular origin arises from an imbalance in tonic levels of activity mediating the VOR. The spontaneous nystagmus resulting from unilateral vestibular hypofunction is a jerk nystagmus and is present when the head is still, is reduced by visual fixation, and is increased or becomes apparent only when fixation is eliminated during use of Frenzel lenses. A horizontal-torsional nystagmus typically is observed acutely after unilateral loss of vestibular function. The horizontal component beats toward the "stronger" (intact) ear, and the torsional component involves beating of the superior poles of the eyes toward the intact ear.

The characteristics of nystagmus when the eyes are directed away from center often adds additional diagnostic information. The patient is asked to maintain eccentric horizontal and then vertical positions of gaze (approximately 30 degrees from center orientation). Minimal drift normally should be encountered for periods up to 15 seconds. Nystagmus arising from peripheral lesions and some central lesions is more intense (slow-phase velocity is higher) when the eyes are turned in the direction of the quick phase.[39] This effect, known as *Alexander's law* (Fig. 164-5), is due to the combination of gaze-evoked nystagmus (caused by the initial loss of the neural integrator after a peripheral lesion) and with the vestibular nystagmus caused by the static asymmetry of the lesion itself. The two factors add on looking away from the lesion and cancel each other on looking toward it. *Bruns' nystagmus*, found in patients with cerebellopontine angle tumors, is a combination of gaze-evoked nystagmus with low-frequency, large-amplitude, fast phases on looking toward the side of the lesion and jerk nystagmus with high-frequency, small-amplitude, fast phases on looking the other way.[40] The gaze-holding component of the nystagmus may represent an adaptation to the jerk nystagmus caused by vestibular imbalance.[41] Horizontal gaze–evoked nystagmus is a hallmark of lesions in the medial vestibular nucleus and nucleus prepositus hypoglossi complex. Low-amplitude gaze-evoked nystagmus often is a side effect of many types of medications, including hypnotics, sedatives, and anxiolytics. Many healthy persons may exhibit some physiologic, horizontal, end-gaze nystagmus. It usually disappears once the target is brought back into view of both eyes (i.e., at approximately 30 degrees of eccentricity).

The effect of vergence should be noted, because it may intensify or cause a change in direction of some central forms of vestibular nystagmus or may dampen congenital nystagmus.

Skew Deviation and Ocular Tilt Reaction

Skew deviation is a vertical misalignment of the eyes that cannot be explained on the basis of an ocular muscle palsy (Fig. 164-6). It is the hallmark of an imbalance in tonic levels of activity along peripheral or central pathways mediating otolith-ocular reflexes.[42] Patients with skew deviation often complain of vertical diplopia and sometimes torsional diplopia (one image tilted with respect to the other). The *alternate cover test* is used to detect skew deviation: The examiner covers one eye of the patient with a card and then moves the cover to the patient's other eye while looking for a vertical corrective movement as an index of a vertical misalignment. A skew deviation also can be detected by covering one eye with a red glass (Maddox rod) to dissociate images seen in the two eyes and inquiring whether the patient sees one image above the other, indicating vertical misalignment. The effect of position of the eye in the orbit and of left and right head tilt on the skew also should be examined. Skew deviations tend to be relatively comitant (i.e., the degree of misalignment changes little with different direction

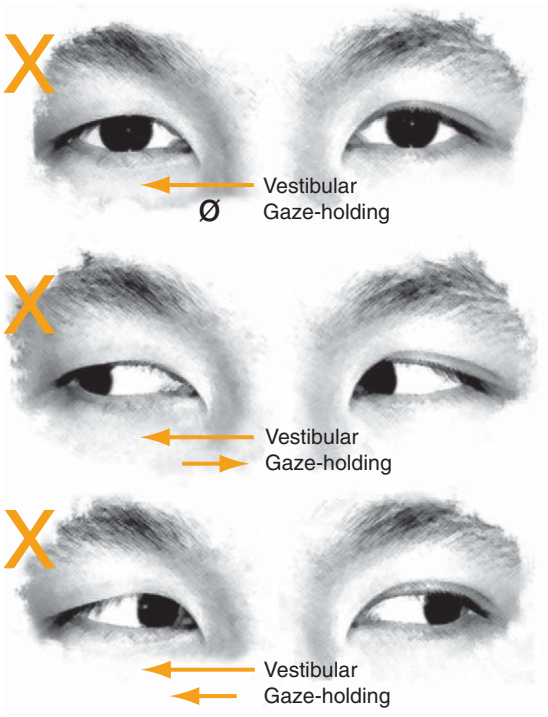

Figure 164-5. Alexander's law. With an acute deficit of the right labyrinth, vestibular input drives the eyes to the right (slow-phase component of nystagmus). A defective neural integrator (caused by the unilateral loss) tends to bring the eyes back to neutral position. With the eyes directed toward the lesion, the two effects cancel. With the eyes directed away from the lesion, they add. *(From Hullar TE, Minor LB. The neurotologic examination. In: Jackler RK, Brackmann DE, eds.* Neurotology. *2nd ed. St. Louis: Mosby: 2004:215-227.)*

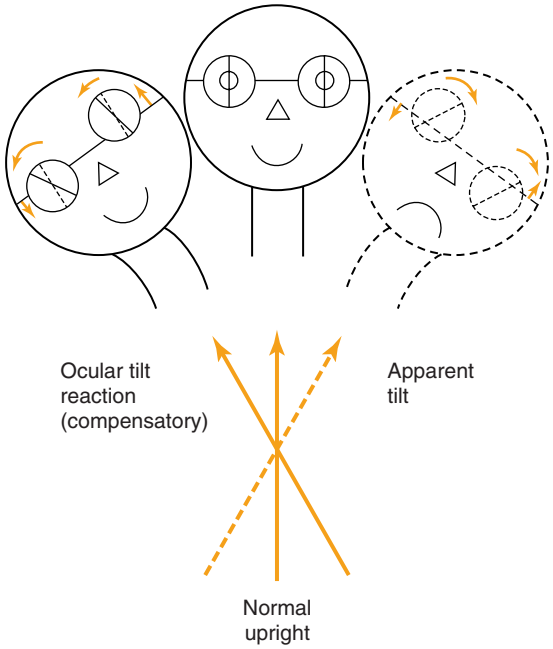

Figure 164-6. The ocular tilt reaction depicted as motor compensation to a lesion-induced apparent eye-head tile *(dashed line)*. The compensatory head tilt is in a direction opposite to the apparent head tilt *(solid line)*. Eyes and head are continuously adjusted to the orientation that the brain computes as being vertical. *(From Brandt T, Dieterich M. Pathological eye-head coordination in roll: tonic ocular tilt reaction in mesencephalic and medullary lesions.* Brain. *1987;110:649.)*

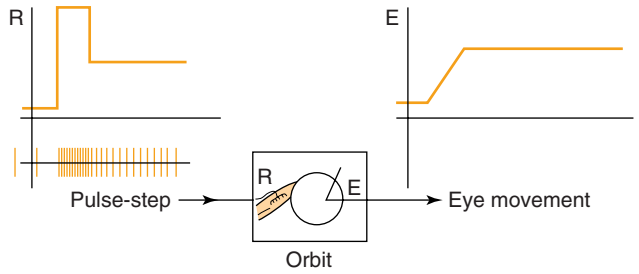

Figure 164-7. The neural signal for a saccade. At *right* is shown the eye movement: E is eye position in the orbit; the abscissa scale represents time. At *left* is shown the neural signal sent to the extraocular muscles to produce the saccade. The *vertical lines* indicate the occurrence of action potentials of an ocular motoneuron. The *graph* above plots the neuron's discharge rate (R) against time (firing frequency histogram). It shows the neurally encoded pulse (velocity command) and step (position command).

of gaze), whereas a fourth cranial nerve palsy causes a vertical misalignment that is greatest with the affected eye down and medial. The adducting eye is higher and the misalignment is greater with the head tilted toward the side of the higher eye. Skew deviations in otolith-ocular imbalance do not show such a clear relation to changes in eye and head position, although they may be decreased or disappear when the affected person is supine.[43] The lower eye is on the side of the lesion with peripheral or vestibular nucleus lesions. Otolith-ocular pathways cross at the level of the vestibular nucleus, so lesions above the decussation result in the higher eye being on the side of the lesion (such as with lesions of the medial longitudinal fasciculus causing internuclear ophthalmoplegia). The head usually is tilted toward the side of the lower eye. Skew deviations also can occur with cerebellar lesions.

Saccades

Rapid changes in gaze from one target to another are achieved by *saccades*. The neural signal for a saccade includes a *pulse* of activity, which brings the eye to its new position, and a *step*, which is a constant neural signal holding the eye at its new position in the orbit (Fig. 164-7). Saccades are examined by asking the patient to alternately fixate (with the head still) on the examiner's nose and then on the finger, held at different locations at approximately 15 degrees away from primary position. Measures of saccades such as accuracy, velocity, and stability represent the effects of the neural pulse, the step, and the match between pulse and step.[44] An error in the pulse amplitude creates overshoot or undershoot dysmetria. This is characteristic of disorders of the dorsal vermis or the fastigial nuclei of the cerebellum, although it appears with lesions in other parts of the nervous system. *Wallenberg's syndrome* produces a specific pattern of saccadic dysmetria: Saccades overshoot to the side of the lesion, undershoot away from the side of the lesion, and, with attempted purely vertical saccades, show an inappropriate horizontal component toward the side of the lesion. Lesions of the superior cerebellar peduncle produce just the opposite: Saccades overshoot when directed away from the side of the lesion.[45]

Normally, saccades follow a relatively invariant relationship between peak velocity and amplitude termed the *main sequence*.[46] A decrease in the height of the saccadic pulse causes slow saccades. Slow horizontal saccades usually imply disease of the pons such as olivopontocerebellar atrophy (spinal cerebellar atrophy type 2 [SCA2]). Slow vertical saccades usually imply disease affecting the midbrain such as progressive supranuclear palsy, Huntington's disease, or Niemann-Pick disease. A mismatch between the size of the pulse and step produces brief (several hundred milliseconds) postsaccadic drift, or glissades. Postsaccadic drift occurs with disease of the cerebellar flocculus. The combination of slow, hypometric saccades and postsaccadic drift also occurs in patients with internuclear ophthalmoplegia, oculomotor nerve palsies, myasthenia gravis, and ocular myopathies. Hypermetric saccades with macrosaccadic oscillations (large saccades about the position of the target) typically are found in patients with lesions in the midline deep cerebellar nuclei.[47] Saccadic oscillations without an intersaccadic interval (back-to-back, to-and-fro saccades) are called *ocular flutter* when they are limited to the horizontal plane and *opsoclonus* when they are multidirectional (horizontal, vertical, torsional). Either type of oscillation may occur in patients with various types of encephalitis or postinfectious immune-mediated processes, as a paraneoplastic remote effect of neuroblastoma or other tumors, or in association with toxins. Ocular flutter also may be voluntarily elicited by some normal people.[48]

The normal saccadic latency is approximately 200 msec, but this latency is increased by disorders of saccadic initiation. Impaired saccadic initiation has been reported in patients with a variety of conditions, including frontal lobe lesions, congenital or acquired oculomotor apraxia, Huntington's disease, progressive supranuclear palsy, and Alzheimer's disease. Patients with bilateral frontal lobe lesions or Parkinson's disease also have difficulty in rapidly alternating gaze between two stationary targets. Patients with Huntington's disease show a characteristic defect in initiating more voluntary, as opposed to more reflexive, saccades. They have particular difficulty in predictive tracking and are unable to suppress inappropriate saccades to the visual target.[49]

Inappropriate saccades disrupt steady fixation.[50] They include *square-wave jerks,* which are small-amplitude (up to 5 degrees) saccades that take the eyes off target and are followed within 200 msec by a corrective saccade. Square-wave jerks may occur in healthy elderly persons or in patients with cerebral hemisphere lesions but are especially prominent in patients with progressive supranuclear palsy and cerebellar disease. Square-wave jerks may be an exaggeration of the microsaccades that occur in healthy people during fixation and can be detected most easily by ophthalmoscopy when the patient is instructed to fixate on a target seen with the other eye. Macro square-wave jerks (10 to 40 degrees in amplitude, with a short intersaccadic interval) have been observed in patients with multiple sclerosis and olivopontocerebellar atrophy.

Smooth Pursuit

The tracking movements of the eyes used to follow an object moving across the field of view, caused by either motion of the object or motion of the viewer, are mediated by the smooth pursuit system. This requires that other gaze-stabilizing inputs, such as vestibular or optokinetic, be suppressed. Smooth pursuit is tested by having the patient follow targets moving no faster than 20 degrees/second. Asymmetries in horizontal tracking, as reflected by the presence of more corrective saccades in one direction, are more helpful in identification of an abnormality than is an overall symmetrical decrease in smooth tracking unless it is profound. Smooth pursuit mechanisms assist visual fixation, suppressing nystagmus from peripheral but not central lesions.

Patients with lesions affecting the temporo-occipital region have been reported to have selective defects in motion detection[24] and are unable to make accurate smooth pursuit or accurate saccadic eye movements because of this deficit.[51] Patients with posterior cortical lesions exhibit a unidirectional (ipsilateral) deficit for smooth pursuit and also a defect of motion detection in the contralateral hemifield.[51] Experimental lesions of dorsolateral pontine nuclei also cause an ipsilateral deficit of smooth pursuit tracking.[52] Lesions of frontal eye fields impair pursuit eye movements,[53] and lesions within the flocculus impair smooth pursuit, especially for ipsilateral tracking. The flocculus projects to the ipsilateral vestibular nuclei, and lesions of this area, including those associated with Wallenberg's syndrome, mainly impair contralateral smooth pursuit.[54]

In addition to the asymmetric deficits of pursuit that may occur with focal lesions, a variety of conditions may bilaterally impair smooth pursuit. A common cause of impaired smooth pursuit is the effect of medications such as anticonvulsants and sedatives. Smooth pursuit is performed less well by elderly persons and is impaired in patients with a variety of neurologic conditions such as Parkinson's disease, progressive supranuclear palsy, and Alzheimer's disease and in those with schizophrenia. In patients with congenital nystagmus, smooth pursuit may appear "reversed," with slow phases directed opposite to the motion of the target.[55] The pathomechanism for this apparent reversal of smooth pursuit is controversial.[56] Disease of the cerebral hemisphere

may produce a low-amplitude horizontal nystagmus in primary position with constant-velocity slow phases directed toward the intact hemisphere. Slow-phase velocity is not decreased by fixation. This nystagmus may result from an imbalance of pursuit tone.

Optokinetic

During sustained rotations, the vestibular signal decays and becomes a poor indicator of head motion. This effect is well known to pilots, who are trained not to trust the vestibular system during prolonged turns. The optokinetic system drives the eyes to follow the visual surround during low-frequency (sustained) head movements. Optokinetic nystagmus (OKN) is a response to motion of the entire visual field, rather than to a particular target (for which the smooth pursuit system is used), and is responsible for effects such as automatic visual tracking of a picket fence seen from a moving car. Use of a bedside optokinetic tape is a convenient way to elicit OKN. Because smooth-pursuit tracking contributes to the generation of optokinetic responses, many of the abnormalities resulting in smooth pursuit deficits also lead to impaired OKN.

Vestibulo-Ocular Reflex Cancellation

The ability of a patient to maintain steady gaze on a target moving in tandem with the head is attributable to cancellation of the VOR. The patient is instructed to fixate on an object (such as the examiner's finger) that moves with the patient's head. A deficit of VOR cancellation is interpreted in conjunction with results obtained from evaluating VOR amplitude.

Vergence

Vergence eye movements, found in frontal-eyed animals such as humans, are disjunctive (opposite direction) responses to changes in gaze. They are necessary, for example, when a target is brought nearer to the viewer and the gaze of each eye converges to keep its image aligned on both retinas. Vergence can be generated volitionally or reflexively and, with accommodation of the lens and papillary constriction, is one element of the "near triad" for close viewing. Eye movements involved in vergence are under the control of several groups of neurons near the oculomotor nuclei.[57] Insufficient vergence causing diplopia at near viewing may be due to aging, stress, or head trauma.[58] Convergence spasm (which may be functional) or divergence paralysis has been mistakenly diagnosed as bilateral sixth nerve palsy. Divergence paralysis has been described with intracranial hypertension[59] or hypotension,[60] with lesions of the midbrain,[61] cerebellum, or in association with medication.[62]

Eye-Head Coordination

Unilateral labyrinthine loss may lead to a head tilt and counterrolling of the eyes.[42] Other disorders causing instability of the head include tremors such as those caused by Parkinson's disease and abnormal postures caused by dystonia and torticollis.[63] Patients with congenital nystagmus sometimes have a head tremor. Such head tremors usually do not compensate for the ocular oscillations, and both are likely to be caused by the same underlying disorder.[64] Intermittent head tremor also is a feature of spasmus nutans, which affects infants and young children.

Other features of this condition include head tilts and turns and nystagmus. The nystagmus is characteristically intermittent, of small amplitude and high frequency, and is typically asymmetric in the two eyes.[65] Any child seen with a monocular form of nystagmus requires a complete ophthalmologic examination and consideration of imaging studies to exclude a tumor of the anterior visual pathways. Disorders of eye-head saccades include involuntary head turning associated with focal epileptic seizures[66] and paresis of voluntary head turning associated with conjugate gaze palsy secondary to an acute lesion of one cerebral hemisphere. *Ocular motor apraxia*, which is characterized by the impaired ability to make voluntary eye movements, often is characterized by thrusting head movements by which the patient is able to shift gaze. These head movements are more conspicuous in the congenital form of ocular motor apraxia, which exclusively affects horizontal eye movements.[66,67] Acquired ocular motor apraxia is associated with bilateral frontoparietal hemispheral deficits, and horizontal and vertical head movements are affected.[68] Disorders causing impairment of smooth pursuit usually, but not always, cause commensurate deficits of smooth, combined, eye-head tracking.[29] Patients who also have lost vestibular function, on the other hand, often show combined eye-head tracking that is superior to smooth ocular pursuit, because no VOR occurs to cancel.[26]

Low-Frequency Vestibulo-Ocular Reflex

An abnormal VOR is indicated by the presence of corrective (catch-up) saccades during head rotations in the light. These can be identified by oscillating the patient's head smoothly left and right (yaw), followed by up and down (pitch) and then right-ear-down to left-ear-down positions (roll) at approximately 0.5 Hz. Because visual stimuli have little ability to generate torsional slow phases, responses to rotations of the head in roll reflect primarily labyrinthine (and possibly neck afferent) stimulation. Absence of torsional fast phases in one direction of head rotation in the roll plane points to a lesion in the rostral interstitial nucleus of the medial longitudinal fasciculus.[69]

Head-Shaking Nystagmus

Head-shaking nystagmus is a test of imbalance in dynamic vestibular function. With Frenzel lenses in place, the patient is instructed to shake the head vigorously approximately 30 times horizontally. Head shaking is stopped abruptly, and the examiner looks for any nystagmus. Healthy persons usually exhibit no or occasionally just a beat or two of head-shaking nystagmus. With a unilateral loss of labyrinthine function, however, a vigorous nystagmus is typical, with slow phases initially directed toward the lesioned side and then a reversal phase with slow phases directed oppositely.[70] The initial phase of head-shaking nystagmus arises because of asymmetry of peripheral inputs during high-velocity head rotations: More activity is generated during rotation toward the intact side than toward the affected side. This asymmetry leads to an accumulation of activity within central velocity storage mechanisms during head shaking. Nystagmus after head shaking reflects discharge of that activity.

The amplitude and duration of the initial phase of head-shaking nystagmus depend on the state of the velocity-storage mechanism. Because velocity storage typically is disabled during the immediate period after an acute unilateral vestibular loss, the primary phase of head-shaking nystagmus may be absent or attenuated in these circumstances. The reversal phase of head-shaking nystagmus reflects short-term adaptation, probably originating in the vestibular nerve and central pathways,[71] and may still be present in acute loss. With unilateral peripheral lesions, vertical head shaking may lead to a low-amplitude horizontal nystagmus, with slow phases directed toward the intact ear. Central lesions (such as those caused by cerebellar dysfunction) also may lead to head-shaking nystagmus, often with a vertical nystagmus after horizontal head shaking. It also is likely that head-shaking nystagmus may result from mechanical disturbances in the labyrinth (e.g., debris adherent to the semicircular canals) or an abnormality of the cupula itself.

Vibration

Vibration-induced nystagmus has been used as a diagnostic tool for patients with superior canal dehiscence. Application of a vibrator to the suboccipital area on the side of the dehiscence can induce a prominent vertical-torsional nystagmus consistent with activation of the dehiscent canal.[72] Vibration also has been shown to induce nystagmus with fast phases toward the intact side in patients with unilateral loss due to vestibular neuropathy or Meniere's disease.[73]

Head Impulse Test

The head impulse maneuver is uniquely able to examine individual canals and to test their responses to high-acceleration, high-frequency motions, whose pathology may be significantly different in genesis and effect from that in lower-frequency losses such as those identified on caloric testing.[74] Brief, high-acceleration horizontal head impulses in the excitatory direction of each canal are applied while the patient is instructed to look carefully at the examiner's nose (Fig. 164-8). A slow phase of abnormally low amplitude will be evoked in response to head

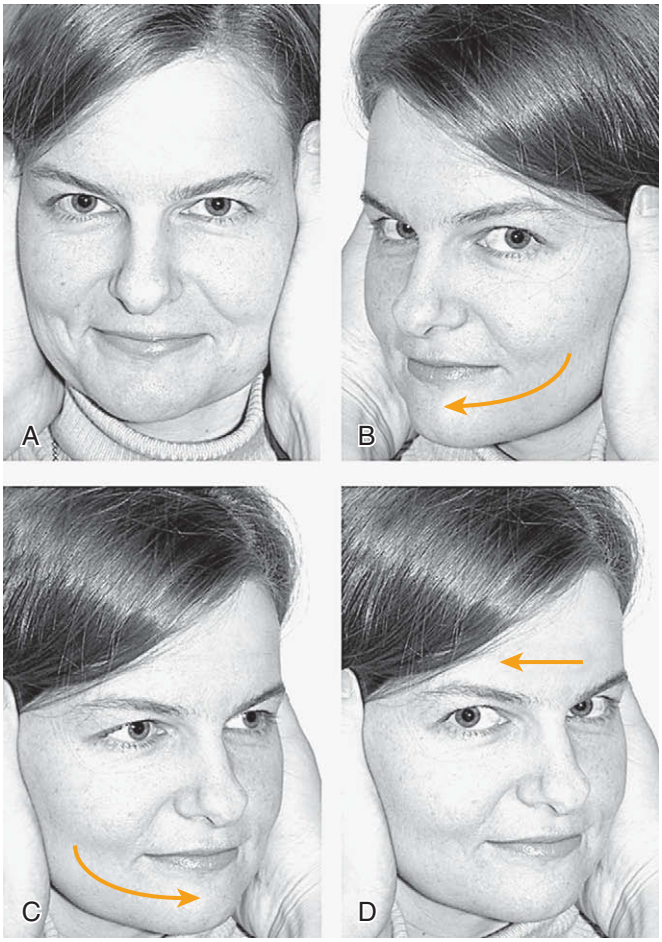

Figure 164-8. The head impulse sign. Starting from neutral position (**A**), a rapid head impulse to the right in the horizontal plane elicits compensatory eye movements to the left, and the patient's eyes remain stable on the examiner (**B**). With a similar movement to the left, a hypoactive labyrinth (**C**) results in a delayed catchup saccade (**D**) to maintain gaze. The *arrow* in **D** shows the direction of the catchup saccade. *(From Hullar TE, Minor LB. The neurotologic examination. In: Jackler RK, Brackmann DE, eds.* Neurotology. *2nd ed. St. Louis: Mosby: 2004:215-227.)*

impulse toward a lesioned or hypoactive labyrinth. A corrective rapid eye movement, required to bring the eyes back to the intended point of fixation, is seen in such cases. A full examination of the labyrinth involves head impulses in each of the three planes of the canals (horizontal, left anterior/right posterior, and right anterior/left posterior) in both directions for each plane. Detection of diminished function in the vertical canals through clinical observations on the head impulse test can be considerably more difficult than for the horizontal head impulse test.

Positional Testing

Positional (sustained) and positioning (transient) nystagmus are best observed with the patient wearing Frenzel lenses. Dix-Hallpike positioning for identification of posterior canal benign paroxysmal positional vertigo (BPPV) is performed first. The patient sits upright on an examination table. For testing to detect the presence of right posterior canal BPPV, the head is turned 45 degrees such that the chin is toward the right shoulder. The patient is then rapidly brought straight back into a right head-hanging position (Fig. 164-9). This position is maintained for at least 30 seconds. The nystagmus characteristic of BPPV begins after a latency of 2 to 10 seconds (although sometimes longer), increases in amplitude over approximately 10 seconds, and decreases in velocity over the next 30 seconds. Posterior canal BPPV results in a vertical-torsional nystagmus, with slow phases directed downward, with intorsion of the lower eye and extorsion of the higher eye. Because of the orientation of pulling directions for the oblique and vertical rectus muscles, the planar characteristics of the nystagmus relative to the orbit change with direction of gaze: on looking to the dependent ear, it appears more torsional and on looking to the higher ear, more vertical.

A horizontal canal variant of BPPV has been described. In these patients, a strong horizontal nystagmus builds up and declines over the same time course as for posterior canal BPPV. In some patients, the nystagmus beats toward the dependent ear (geotropic); in others, it beats away from the dependent ear (apogeotropic). The standard Dix-Hallpike maneuver may not elicit nystagmus in cases of horizontal canal BPPV. Such a nystagmus can be identified by bringing the patient backward into the supine, head-hanging position and then turning the head left-ear-down or right-ear-down. The nystagmus seen with horizontal canal BPPV may last longer than that seen in posterior canal BPPV. Such patients also may exhibit a small amount of spontaneous nystagmus when sitting upright, which varies as the head is pitched forward or backward. Anterior canal BPPV also has been described but is relatively rare. A sustained, usually horizontal positional nystagmus of low velocity is a common finding in patients with central or peripheral vestibular lesions and also may be present in asymptomatic human

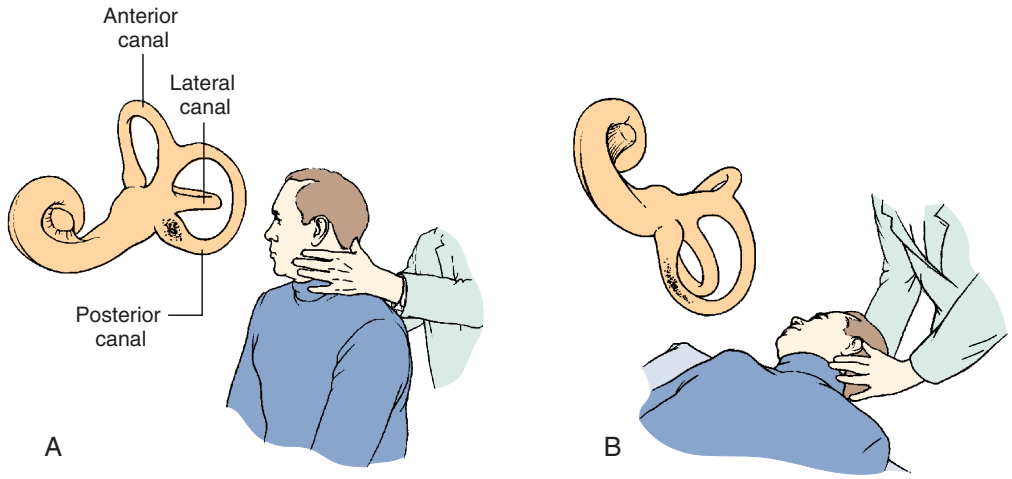

Figure 164-9. The Dix-Hallpike maneuver. Lowering the patient's head backwards and to the side allows debris in the posterior canal (**A**) to fall to its lowest position, activating the canal and causing eye movements and vertigo (**B**). *(From Hullar TE, Minor LB. Vestibular physiology and disorders of the labyrinth. In: Glasscock ME, Gulya AJ, eds.* Surgery of the Ear. *5th ed. Toronto: BC Decker; 2003.)*

Positive pressure in the external auditory canal causes bulging of the membranous canal into the cranial cavity and ampullofugal flow (*arrows*). **B,** Negative pressure in the external auditory canal causes bulging of the cranial contents into the superior canal and ampullopetal flow (*arrows*). *(From Minor LB, Solomon D, Zinreich J, Zee DS. Sound- and/or pressure-induced vertigo due to bone dehiscence of the superior semicircular canal.* Arch Otolaryngol Head Neck Surg. *1998;124: 249-258.)*

subjects.[75] A central lesion is most likely when positional nystagmus is purely vertical or purely torsional or if the patient exhibits a sustained unidirectional horizontal positional nystagmus of high enough intensity to be observed without Frenzel lenses. Positional testing also may exacerbate a spontaneous nystagmus.

Dynamic Visual Acuity

Persons with normal vestibular function typically show no more than a one-line decline in visual acuity on the Snellen chart with head movement, whereas those with vestibular hypofunction (particularly bilateral hypofunction) may show up to a five-line decline in acuity with head movement.[23] To test for this effect, the patient's ability to read a Snellen chart with the head stationary is compared with acuity during horizontal head oscillations at a frequency of approximately 2 Hz. Patients with corrective lenses are instructed to wear their glasses or contact lenses during this testing. Quantitative analysis of dynamic visual acuity has revealed that retinal slip velocities of as little as 2 to 3 degrees/second result in oscillopsia and consequent loss of acuity.[6]

Vertical dynamic visual acuity also may be tested. The test can be improved by use of a computerized display, which prevents patients from seeing the Snellen chart when their head movements drop below a critical velocity at the ends of each oscillation.[76] Dynamic visual acuity also has been measured during rapid head movements and may, in some situations, serve as a useful proxy for quantitative measurement of angular VOR gain during these rapid head movements.

Eye Movements Evoked by Sound or Changes in Middle Ear Pressure

Changes in pressure in the inner ear can be induced by the Valsalva maneuver with the glottis closed (increasing intracranial pressure) and glottis open using a nose pinch (increasing middle ear pressure through the eustachian tube). In patients with superior canal dehiscence, nystagmus may be evoked by either or both maneuvers. The Valsalva maneuver with the glottis closed increases intracranial pressure and exerts force directly at the site of the dehiscence, causing deflection of the cupula of the superior canal toward the ampulla, in its "off" direction. On release of the pressure, the cupula is deflected in its preferred "on" direction, causing stimulatory nystagmus[77] (Fig. 164-10). The plane in which the eyes move during this nystagmus typically aligns with the plane of the affected superior canal. Craniocervical junction anomalies (e.g., Arnold-Chiari malformation), perilymph fistulas, and other abnormalities involving the ossicles, oval window, semicircular canals, or otolith organs also may cause vertigo with the Valsalva maneuver.

Tullio's phenomenon is the occurrence of vestibular symptoms and eye movements with exposure to sound. Motion of the tympanic membrane and ossicular chain can induce vertigo and nystagmus (*Hennebert's sign*) in patients with otic syphilis, perilymph fistula, and dehiscences of the semicircular canals. Superior semicircular canal dehiscence syndrome, caused by lack of bone covering the superior semicircular canal and arcuate eminence, may feature sound-evoked or pressure-evoked vertigo and conductive hearing loss.[78,79] If suspected, these causes should be investigated by moving the tympanic membrane with tragal compression or insufflation through a Siegle's speculum. Pure tones can be given over a range from 250 to 4000 Hz at intensities of 100 to 110 dB. The characteristic nystagmus evoked by activation of the superior canal is a vertical-torsional nystagmus with slow phases that are directed upward in the vertical plane and that involve motion of the superior pole of the eye away from the affected ear in the torsional plane. The eye movements evoked by sound or pressure stimuli in superior canal dehiscence typically are conjugate. Depending on the stimulus parameters and the effect of the dehiscence in individual patients, the evoked eye movements may be brief in duration and may not involve a sustained nystagmus.

Hyperventilation

Patients with anxiety or phobic disorders may sometimes hyperventilate and experience symptoms but usually do not show signs of nystagmus. Patients with demyelinating lesions on the vestibular nerve (such as an acoustic neuroma or compression by a small blood vessel) or with a central distribution (such as in multiple sclerosis) may show an excitatory (due to restoration of function) hyperventilation-induced nystagmus.[80] In the case of a peripheral lesion, the slow phase is away from the involved ear. Hyperventilation-induced nystagmus (usually a paretic nystagmus, with the slow phase toward the involved ear) rarely is noted in patients with pathologic conditions of the vestibular end organs alone.[81]

Vestibulospinal Function

Static imbalance in vestibulospinal reflexes is identified from Romberg testing, tandem walking, evaluation of past pointing, and the stepping test. The *Romberg test* is used to assess sway with feet together and tandem in eyes opened and closed condition. Falls during *tandem*

walking are suggestive of horizontal canal dysfunction. *Past pointing* of the arms to previously seen targets with eyes closed also may be a sign of vestibulospinal imbalance. It is best elicited by having the patient repetitively raise both arms over the head, with index fingers extended, and then bring them down, with eyes closed, toward the examiner's index fingers (but without actually touching them) located at waist level. For the *stepping test*, the patient, with eyes closed and arms outstretched, steps in place for at least 30 seconds.[82,83] A patient with acute labyrinthine asymmetry may turn to the weak side, in the direction of the slow phase of the nystagmus. This test sometimes is augmented with caloric stimulation.[84] Dynamic vestibulospinal function is assessed by observing postural stability during rapid turns or in response to external perturbations imposed by the examiner (i.e., a gentle shove forward, backward, or to the side). A complete examination of (1) gait, (2) strength, reflexes, and sensation in the legs, and (3) cerebellar function is essential for the interpretation of postural instability and dysequilibrium.

Sensory Integration

Balance relies on collection of vestibular, visual, and proprioception information and also on their appropriate central integration. The Clinical Test of Sensory Integration and Balance (CTSIB) is a simple series of bedside tests designed to evaluate these processes.[85,86] This test simulates the test conditions of dynamic computed posturography, detailed later on, with the patient standing on foam to disrupt proprioception and wearing a large paper lantern over the head, to simulate posturography's sway-reference condition. Results of the CTSIB correspond with dynamic posturography findings.[87]

Quantitative Testing

Quantitative tests of physiologic processes under vestibular control can be useful in identifying the cause of a patient's symptoms, confirming clinical findings, planning therapy, and monitoring the response to treatment.

Methods of Eye Movement Recordings

Three techniques can be used for quantitative measurement of eye movements. *Electronystagmography* (ENG) remains the most practical laboratory test to evaluate patients with dizziness or imbalance.[88] ENG can be helpful when the clinical picture suggests unilateral or bilateral vestibular hypofunction; disorders of oculomotor control such as deficits of smooth pursuit, saccades, or optokinetic eye movements; Meniere's disease or endolymphatic hydrops; BPPV; recurrent vestibulopathy; or migraine-associated dizziness. The quantitative information from ENG enables the clinician to monitor progression of or recovery from disorders affecting vestibulo-ocular control.

Electro-oculography (EOG) is based on the corneoretinal potential (difference in electrical charge potential between the cornea and the retina). The eye acts as an electrical dipole oriented along its long axis. Movement of this dipole relative to the surface electrodes produces an electrical signal corresponding to eye position. Surface electrodes are placed about each eye as shown in Figure 164-11. Horizontal eye movements typically can be resolved to an accuracy of 0.5 degree. Even under optimal recording conditions, however, the sensitivity of EOG is less than that of direct visual inspection (approximately 0.1 degree). Visual inspection of small-amplitude eye movements either directly or with the aid of Frenzel lenses or an ophthalmoscope is important for documentation of low-amplitude nystagmus. Vertically aligned electrodes sense voltage associated with eye and lid movement, so EOG cannot be used in the quantitative assessment of *vertical* eye movements. It is adequate, in most instances, for qualitative clinical assessment of vertical eye movement disorders and provides a useful monitor of eye blinks.[89] Torsional eye movements cannot be measured with EOG. For this reason, it is important for the examiner to look at the patient's eyes, either directly or with Frenzel lenses in place, during positioning testing so that the vertical-torsional nystagmus caused by posterior canal BPPV is not missed.

The *magnetic search coil technique* is based on the principle that voltage changes are induced in a coil of wire moving in an oscillating magnetic field.[89a] A minute wire is embedded in a plastic annulus that is inserted surrounding, but not actually touching, the cornea. Eye movements in three dimensions—horizontal, vertical, and torsional—can be resolved to an accuracy of approximately 0.02 degree (1-minute arc) and at speeds of up to 1000 samples per second. The technique also can be used to measure combined eye and head movements. The main disadvantage of search coil recordings is the level of expertise, in comparison with other techniques, required to set up the apparatus and conduct the recording sessions. Topical anesthetic drops are required to insert the search coil on the patient's eye. The risk of corneal abrasion is low when proper coil insertion and removal techniques are used.

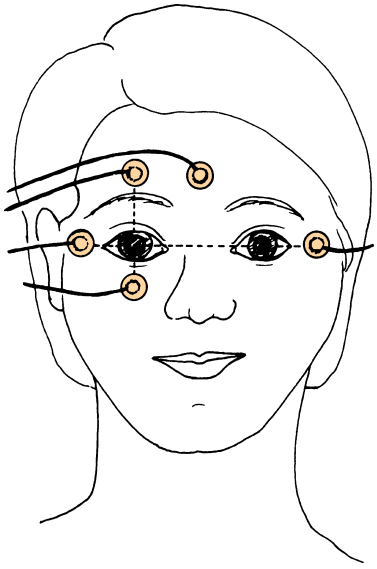

Figure 164-11. Surface electrodes are placed at outer canthi for recording horizontal eye movements and above and below one eye for recording vertical eye movements throughout the electronystagmographic procedure. A ground or reference electrode is placed on the forehead. If recordings are to be made of each eye independently, additional electrodes are placed at the inner canthus of the eye to be recorded.

Infrared video can monitor movement of the cornea or pupil. This technique can be used to record eye movements in three dimensions. Advantages are that the technique is noninvasive, requires little setup time, and is not associated with the position drifts (requiring repeated calibrations) seen with EOG. Disadvantages are that, although procedures and algorithms are improving at a rapid pace, image fitting and analysis techniques still do not work properly for some patients. The time resolution of these methods is poorer (lower sampling rates) than that available with search coil techniques.

Nystagmus

Eye movements are recorded with eyes closed and with eyes open and viewing a stationary visual target. A spontaneous nystagmus and effects of fixation suppression on this nystagmus are thereby determined. Effects of eye position on this nystagmus and the presence of gaze-evoked nystagmus are then assessed by asking the patient to look left, right, up, and down, much as in bedside testing as previously described. The recording of eye movements in darkness is a standard part of ENG testing.

Saccade Testing

The patient is instructed to fixate (with eye movements while keeping the head stationary) on a series of randomly displayed dots or lights at eccentricities of 5 to 30 degrees. Saccades typically begin with a latency of 180 to 200 msec after presentation of a target. Saccade velocity increases linearly with amplitude up to approximately 20 degrees but remains relatively constant for higher amplitudes (Fig. 164-12). Healthy persons consistently undershoot the target for saccades by more than 20 degrees. Asymmetries in saccade amplitude or peak

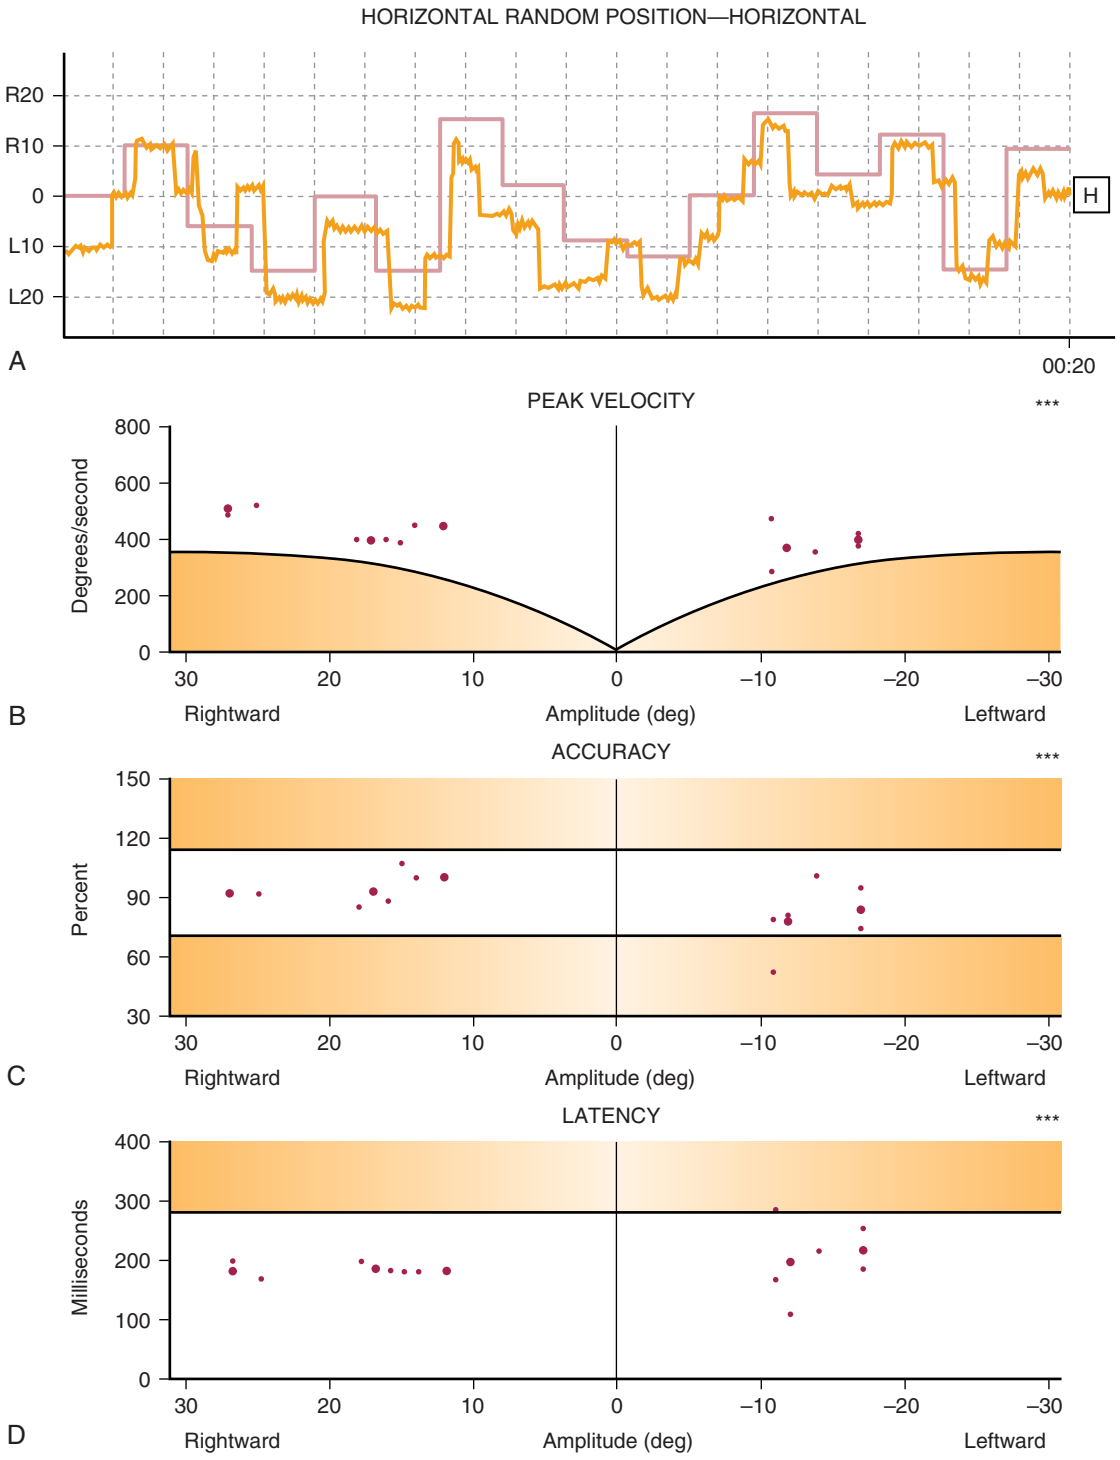

Figure 164-12. Electronystagmographic recordings of saccades. **A,** Eye tracings. **B,** Plot of speed versus amplitude. **C,** Accuracy. **D,** Latency. *Yellow* denotes areas of abnormal responses. See text for causes of inaccurate saccades.

velocity can provide localizing information. With EOG, the speed of abducting saccades seems to be lower than that of adducting saccades, although recordings with search coil and infrared techniques suggest the opposite.

Smooth Pursuit

The patient is asked to watch a target that moves horizontally in a sinusoidal fashion at a low frequency (0.2 to 0.7 Hz) with a position amplitude of 20 degrees in each direction. Inspection of the waveform of the tracking eye movement often is of greater diagnostic use than are absolute measures of gain and phase (Fig. 164-13). "Catch-up" saccades typically are seen when pursuit responses are decreased. Saccadic pursuit is characterized by the occurrence of these saccades in a "stair-step" pattern. Such patterns are seen in cerebellar disease and also may occur with the decreases in pursuit gain that occur with aging.

Optokinetic Testing

Testing is often performed with the subject surrounded by a visual scene that moves in one direction at velocities of 30 to 60 degrees/

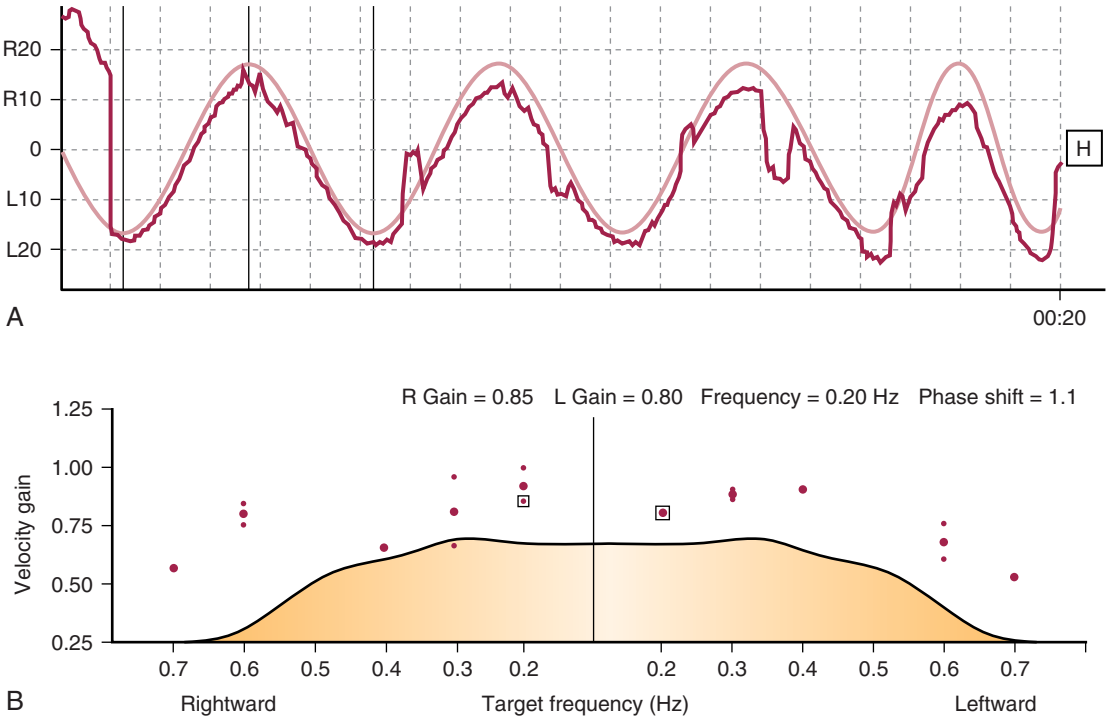

Figure 164-13. Electronystagmographic recordings of smooth pursuit. **A,** Smooth sinusoid, target motion; irregular tracing, eye movements. **B,** Gain in response to moving target at various frequencies. *Yellow shaded area* represents abnormally low responses.

second. The optokinetic tracking response is a nystagmus in the plane of motion of the visual scene. Response gain (the ratio of slow-phase eye velocity to velocity of the visual scene) is measured, and the profile of slow-fast component interaction is assessed. In general, slow-phase abnormalities on optokinetic tests parallel those detected with smooth pursuit testing, whereas fast-phase abnormalities are correlated with those detected on saccade testing. During sustained rotations, the vestibular signal decays and becomes a poor indicator of head motion. To maintain ocular fixation during low-frequency or sustained head movements, the optokinetic system drives the eyes to follow the visual surround. Optokinetic reflexes are a response to motion of the entire visual field rather than of a particular target (for which the smooth pursuit system is used) and are responsible for effects such as automatic tracking of a picket fence seen from a moving car.

Optokinetic afternystagmus (OKAN) is the perseveration of nystagmus after an optokinetic stimulus has been eliminated. OKAN is characterized by its initial eye velocity, time constant of declining eye velocity, cumulative eye position, and symmetry.[38] Velocity storage is believed to be the neural mechanism responsible for maintaining the nystagmus after an optokinetic stimulus. Because smooth pursuit tracking movements contribute to the generation of the slow phases of OKN and confound the assessment of the nystagmus response to optokinetic stimuli, OKAN is the best measure of the action of the portion of the optokinetic responses generated through the vestibular nuclei. If optokinetic reflexes are impaired, OKAN will not be generated even if smooth pursuit is preserved. Optokinetic reflexes are absent in persons with bilateral peripheral vestibular loss but also may be deficient in some normal subjects. OKAN declines with age,[90] and as with the effects of velocity storage caused by vestibular stimulation, its time constant can be reduced with repetition.[91] OKAN is modified in microgravity environments, and its duration is reduced by tilting the head, implying that the otolith organs are important to its genesis. Asymmetries in OKAN have been reported in patients with unilateral vestibular hypofunction induced by removal of an acoustic neuroma. Responses are greater in amplitude and longer in duration for stimulus and eye movement toward the side of the lesion.[92]

Caloric Testing

Caloric testing remains the most useful laboratory investigation for determining the responsiveness of the labyrinth. It is one of the few modalities that allow one labyrinth to be studied independently of the other. Caloric testing relies on stimulating (with a warm stimulus) or inhibiting (with a cool stimulus) the vestibular system by alternately changing the temperature of the external auditory canal with water or air. The horizontal canal is affected most by such temperature changes because it is located closest to the external auditory canal and is oriented in the plane of the temperature gradient that results in the temporal bone from irrigation with water.

Caloric testing causes a response in two ways. The first is a convective component, with the temperature gradient across the horizontal canal resulting in a density difference within the endolymph of the canal (Fig. 164-14). When the horizontal canal is oriented earth-vertically (by elevating the head 30 degrees from the supine position or 60 degrees backward from the upright position), the more dense fluid sinks to the lower position in the canal and the less dense fluid rises to the upper part of the canal. In the presence of gravity, a flow of endolymph occurs from the cooler (more dense) region to the warmer (less dense) region. This movement of fluid within the canal (convective flow) deflects the cupula, thereby leading to a change in the discharge rate of vestibular nerve afferents. Endolymph flows toward the ampulla (resulting in an increase in vestibular nerve afferent discharge) for warm irrigations and away from the ampulla (resulting in a decrease in afferent discharge) for cold irrigations. This effect depends on head position (Fig. 164-15).

The second component does not vary with head position and results in an excitation of the horizontal canal when the ear is warmed and in an inhibition when it is cooled. The nonconvective component may be a result of a direct temperature effect on hair cells or vestibular nerve afferents[93] or cupular displacement resulting from pressure changes in the membranous duct.[94] Direct evidence for the existence of a nonconvective component came from demonstration that a caloric nystagmus can be elicited in the microgravity environment of orbital space flight under conditions in which convection is absent.[95] The

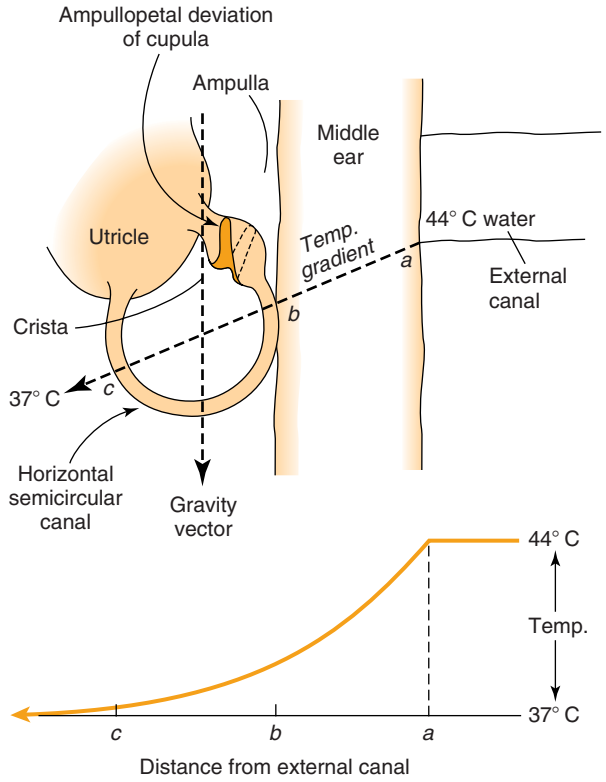

Figure 164-14. Top, Convective flow mechanism of the caloric response. Irrigation with warm or cold water (or air) results in a temperature gradient across the horizontal semicircular canal. With the horizontal canal oriented in the earth-vertical plane, gravity induces the convective flow of endolymph from the cooler area of the canal, in which endolymph is more dense, into the warmer area of the canal, in which endolymph is less dense. For the warm caloric irrigation used for this diagram, ampullopetal deflection of the cupula results from this flow of endolymph. Vestibular nerve afferents innervating the horizontal semicircular canal are excited, and a horizontal nystagmus with slow phase components directed toward the opposite ear is produced. A cold caloric stimulus results in an oppositely directed response with ampullofugal deflection to the cupula, inhibition of horizontal canal afferents, and a nystagmus with slow-phase components directed toward the ear to which the cold caloric is applied. **Bottom,** Graph showing temperature at locations *a*, *b*, and *c*, indicated above. *(From Baloh RW, Honorubia V.* Clinical Neurophysiology of the Vestibular System. *2nd ed. Philadelphia: F.A. Davis; 1990.)*

convective component accounts for 75% of the caloric response in the conventional testing position. Convective and nonconvective components are, in the squirrel monkey, affected by a position-dependent, otolith-mediated modification of velocity storage mechanisms.[96]

An otoscopic examination should be performed before caloric testing. Cerumen should be removed to obtain clear visualization of the tympanic membrane. Testing of caloric nystagmus is performed with eyes opened in darkness, behind Frenzel lenses, or in a dimly illuminated room with the patient looking at a Ganzfeld or nonpatterned background. Concentration tasks such as mental arithmetic are used to maintain alertness. EOG calibrations typically are checked after each or every other stimulus. Water calorics should be avoided in cases of tympanic membrane perforation. Improved stimulus reproducibility can be obtained by direct visualization of the position of the irrigation source within the external canal at the time of the stimulus.

Alternate binaural, bithermal caloric testing is the most commonly used testing protocol.[97] Cool water (30° C) and warm water (44° C) are administered for 60 to 90 seconds to each ear in a set order such as right warm, left warm, right cold, left cold. Such a stimulus results in a heating effect in the temporal bone that lasts for 10 to 20 minutes, although nystagmus frequently decays over a much shorter time course (2 to 3 minutes) because of the effects of adaptation.[98] The prolonged heating effect of a single temperature irrigation requires that at least 10 minutes be allowed between successive irrigations. Biphasic caloric irrigations can reduce patient nausea and shorten the wait between stimuli to approximately 2 minutes by using irrigation with water at 43.5° C for 45 seconds, 30.5° C for 65 seconds, and 43.5° C for 23 seconds.[99,100]

Eye movements are recorded for a period of several seconds before onset of an irrigation, during the irrigation, and until the nystagmus has ended. Standard computer algorithms exist for distinguishing fast from slow components of nystagmus and for determining the velocity of each slow component. A plot of slow component velocity is then formed (Fig. 164-16), and the maximum slow component is determined on the basis of three to five slow components with highest velocity. Data are interpreted in terms of unilateral weakness (UW) and directional preponderance (DP), according to formulas described by Jongkees and colleagues[101]:

$$UW = 100\% \times [(R30° + R44°) - (L30° + L44°)]/(R30° + R44° + L30° + L44°)$$

$$DP = 100\% \times [(R30° + L44°) - (R44° + L30°)]/(R30° + L44° + R44° + L30°)$$

Normative values are established for each laboratory. A UW value greater than 20% and DP value greater than 25% usually are considered significant. UW is a sign of decreased responsiveness of the horizontal semicircular canal or the ampullary nerve that provides its innervation. DP commonly is seen in patients with spontaneous nystagmus. For example, a right-beating spontaneous nystagmus will commonly lead to a DP for right-beating responses on caloric testing. The spontaneous nystagmus simply adds to or subtracts from each response to caloric irrigation depending on its direction. In the absence of spontaneous nystagmus, DP may be a central sign indicating asymmetrical sensitivities of central vestibular neurons to inhibitory-excitatory stimuli or asymmetries in the inputs from these central vestibular neurons to extraocular motoneurons. An increased warm and a diminished cold response, as can occur in an ear affected with Meniere's disease, can result in a DP. Caloric nystagmus can be suppressed with visual fixation in healthy persons. Failure of fixation suppression of caloric nystagmus can be seen in central disorders such as cerebellar disease.

Rotatory Chair Testing

Unlike caloric tests, rotational tests analyze the responses of both semicircular canals together. They require a high-torque motor-driven chair and specific software to analyze the results. Rotatory chair testing is useful in assessing vestibular function in patients with suspected bilateral vestibular hypofunction, in patients receiving vestibulotoxic medications, and in children who may not tolerate caloric testing. Clinical situations in which findings on rotatory chair testing in pediatric patients may provide useful information include determining whether a failure to achieve normal developmental milestones is based in part on absent vestibular function, evaluating vestibular function after meningitis, and determining the presence or absence of vestibular function in patients undergoing a genetic evaluation for hearing loss.

Rotational testing does not depend on delivery of a stimulus directly to the inner ear, as with the caloric test, so results are therefore not susceptible to variables such as size or shape of the external auditory canal. Rotational testing is less bothersome to some patients than is caloric testing (although nausea and vertigo associated with calorics can be decreased considerably with the use of temperature switch techniques as described). Most commercially available rotational testing systems administer low-frequency sinusoidal rotations and analyze eye movement responses to the input stimulus. The patient's head typically is aligned with the chin pitched 30 degrees nose down such that horizontal semicircular canals are in the plane of rotation. Approximately 10 cycles of the sinusoidal head velocity stimulus are recorded for five to eight test frequencies over the range of 0.01 to 0.7 Hz, with the

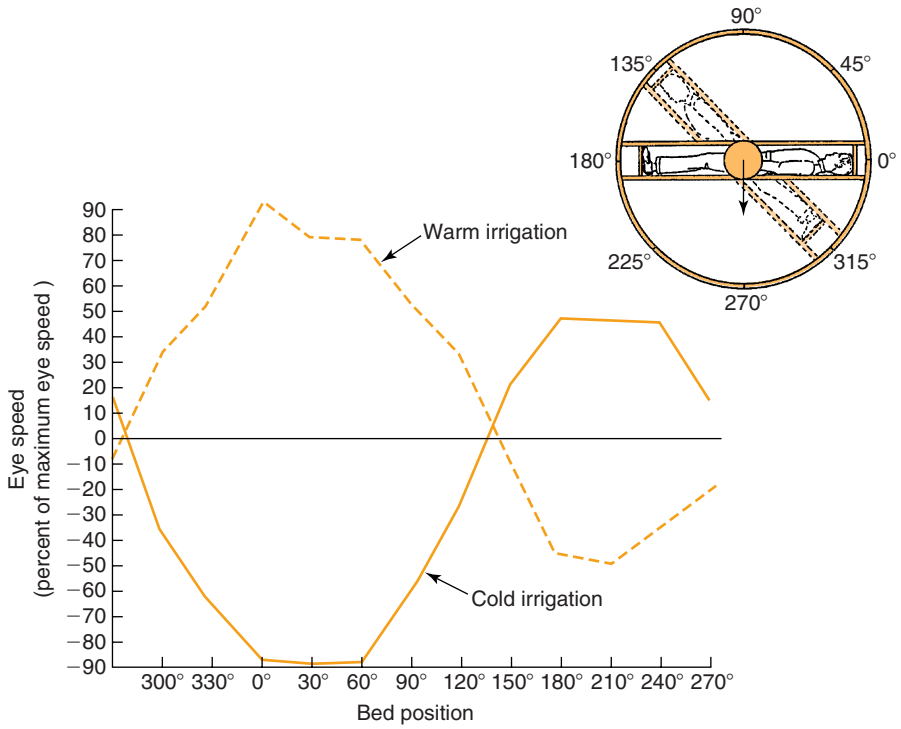

Figure 164-15. Average slow-phase eye velocity in response to warm (44° C) and cold (30° C) irrigations with subjects oriented in different bed positions. Subjects were lying on a Stryker bed that could be moved through 360 degrees in the pitch plane (see *inset*). For each subject, the percent of the maximum value in the curve (which usually occurred at the 30-degree position, at which the horizontal canal is in the earth-vertical plane) was determined at each of the positions tested. These percentages were then averaged for all subjects to obtain the composite plots shown. Four observations are apparent: (1) Caloric responses in the face-up positions are consistently greater in intensity than those in the face-down positions. (2) "Face-up" responses cover a larger segment of the 360-degree arc than the "face-down" responses. (3) The curves appear to approximate a sine function. (4) The findings are similar for warm and for cold irrigations. *(Modified from Coats AD, Smith SY. Body position and the intensity of caloric nystagmus.* Acta Otolaryngol (Stockh). *1967;63:515.)*

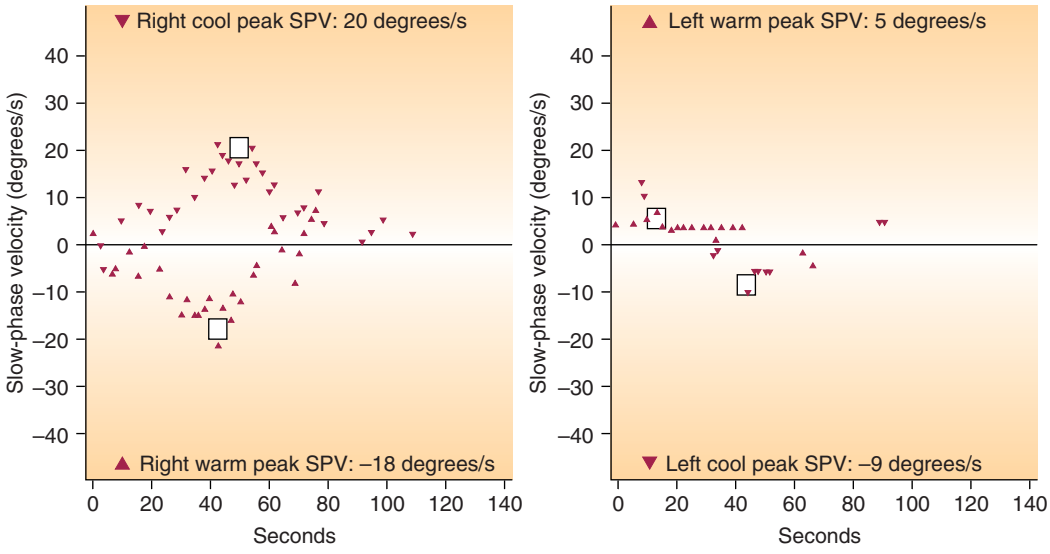

Caloric weakness: 46% in the left ear
Directional preponderance: 4% to the right

Figure 164-16. Caloric responses in a patient with unilateral labyrinthine hypofunction. The patient had no response in the left ear, although right ear responses to warm and cold irrigations were normal. SPV, slow component velocity.

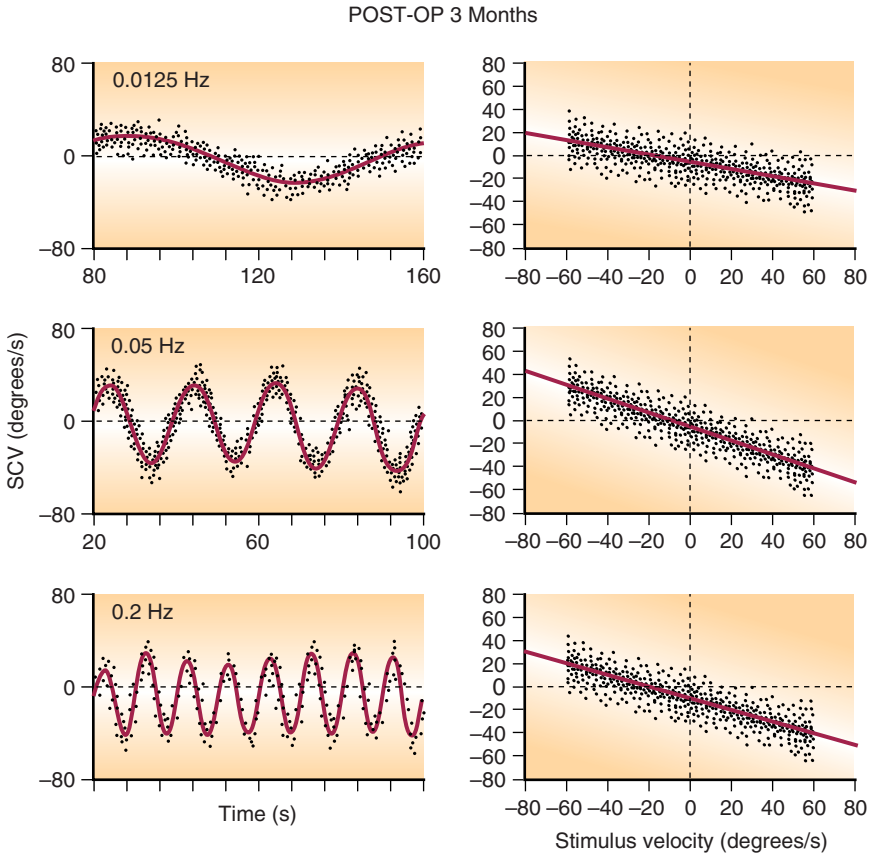

Figure 164-17. Rotational chair responses 3 months after unilateral vestibular deafferentation. Vertical axis = ocular response in degrees/second. Note that at the low frequencies tested here, the patient's responses *(dots)* closely follow the chair's movement *(solid line)*, indicating compensation from the lesion. Head impulse signs at this stage are likely to remain pathologic. The bottom stimulus-velocity curve *(lower right)* shows a slight bias (i.e., the line does not pass exactly through the origin). SPV, slow component velocity. *(From Jenkins HA. Long-term adaptive changes of the vestibulo-ocular reflex in patients following acoustic neuroma surgery.* Laryngoscope. *1985;95:1224.)*

patient in darkness. The results are averaged over successive cycles, and gain, phase, asymmetry, and bias velocity are calculated. *Gain* refers to amplitude of the maximum slow-phase eye velocity divided by amplitude of the maximum stimulus velocity. *Phase* is the temporal shift in eye velocity relative to head velocity. For a perfectly compensatory VOR, eye velocity should be equal in amplitude but opposite in direction to head velocity. This would correspond to a VOR gain of 1.0 and phase shift of 180 degrees (meaning that eye velocity would lag head velocity by 180 degrees).

Cerebellar abnormalities produce specific changes in responses that can be evaluated with rotatory chair testing. Velocity storage mechanisms that are responsible for prolonging the VOR time constant relative to that of vestibular nerve afferents are sensitive to the orientation of the head with respect to gravity. In healthy persons, tilting the head downward at the onset of post-rotatory nystagmus results in an immediate suppression of the stored velocity response, but patients with midline cerebellar lesions near the uvula and nodulus have VOR time constants that are normal in the upright position and are not affected by post-rotatory tilt.[102] Patients with cerebellar lesions such as caused by the Arnold-Chiari malformation exhibit tilt suppression intermediate between that of healthy persons and that of patients with midline cerebellar lesions. Abnormally high gain on rotational testing also has been noted in cases of cerebellar atrophy.[103] However, the presence of post-rotatory nystagmus evoked by this test is influenced by the level of vestibular function and by the status of velocity storage mechanisms, and the nystagmus can be suppressed by visual fixation. Because of the many processes involved, the test results have proved to be variable and difficult to correlate with specific pathologic processes.

Directionally dependent asymmetries can indicate relative weakness of function in one labyrinth compared with the other.[104] In the case of a patient with absence of vestibular function on the right, head rotation to the left continues to evoke a normal VOR, whereas rotations to the right may produce a weaker response, with gain decreasing as velocity increases. These asymmetries are thought to occur because vestibular neurons have an approximately three-fold higher range for excitation than for inhibition. The effects of these asymmetries are not seen when both labyrinths are functioning symmetrically, presumably because the brain is able to compensate for the loss of signals on the side being driven into inhibitory cutoff by use of signals from the excited side. The asymmetries are, however, more pronounced for rotational velocities and frequencies greater than those typically used in conventional clinical testing. Patients with compensated unilateral vestibular loss frequently exhibit normal gain and phase with minimal asymmetries on standard sinusoidal rotatory chair tests[105] (Fig. 164-17).

A further indication of unilateral deficiency of vestibular function is seen as a bias velocity in responses to sinusoidal rotations. Spontaneous nystagmus causes a bias velocity by adding the slow-phase velocity of the nystagmus to the response to sinusoidal stimulation, but such a bias also can be seen after spontaneous nystagmus has resolved. The direction of bias alone does not identify the affected ear, because both irritative lesions (such as Meniere's disease, serous labyrinthitis, labyrinthine fistulas, and acoustic neuromas) and ablative lesions can cause bias (but in opposite directions).

Step changes in head velocity can be used instead of sinusoidal rotations to identify vestibular hypofunction. The patient is seated in the rotatory chair apparatus, and eye movements are recorded with EOG. Testing is performed in darkness. The chair accelerates rapidly to the right or to the left, reaching its peak velocity (typically 60 or 240 degrees/second) in 1 second. A horizontal nystagmus is recorded. Response gain and VOR time constant are determined by the time after

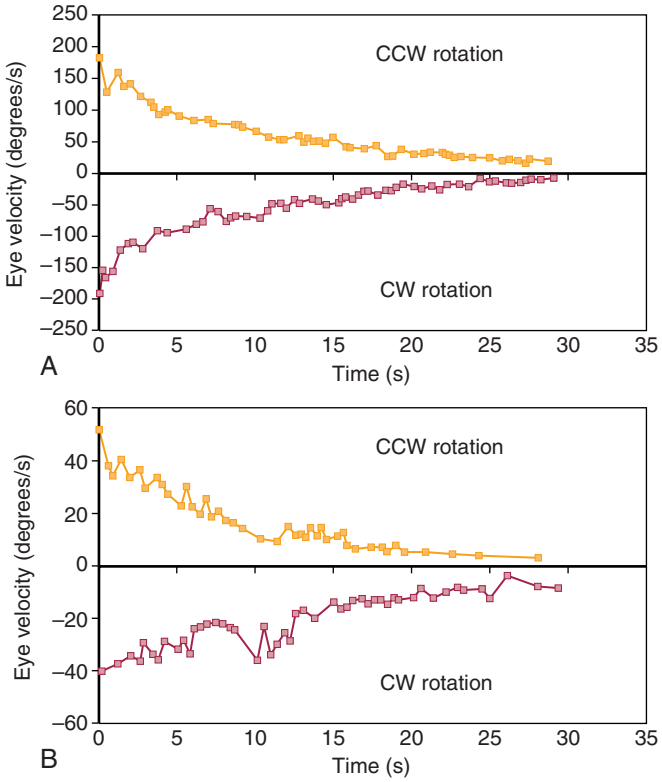

Figure 164-18. Velocity of horizontal slow-phase components of nystagmus evoked by velocity steps of 240 degrees/second (**A**) and 60 degrees/second (**B**). The subject is seated in a rotatory chair with the head positioned in approximately the horizontal canal plane (chin tilted downward 30 degrees from ambient position of the head) in **A** and in the ambient position (30 degrees upward from the horizontal canal plane) in **B.** Testing is conducted in darkness. Chair rotations in the counterclockwise (CCW) direction evoke slow phases to the right, whereas rotation in the clockwise (CW) direction evokes slow phases to the left. Gain is determined from the responses in **A** by dividing the velocity of the first slow phase in response to the stimulus by the head velocity. Gain measures approximately 0.80 in these data and is symmetrical for clockwise and counterclockwise rotations. Time constant is measured from responses to 60-degrees/second rotations as the time required for slow-phase velocity to decline by 63% of its initial value. In the data shown for CW rotation in **B,** the initial eye velocity is 40 degrees/second and falls to 15 degrees/second (a decline of 63% from the initial value) 20 seconds after the stimulus onset. The time constant of the response is therefore 20 seconds.

onset of the stimulus at which slow-phase eye velocity has decreased by 67% of its initial value (Fig. 164-18). A further procedure has been used to improve test sensitivity in identifying unilateral vestibular hypofunction: A rotation of 240 degrees/second is given with the patient's head aligned in the 30-degree chin-down position (to bring the horizontal canals into the plane of rotation) and with the head pitched 30 degrees upward.[106] The effect of the rotational stimulus on the horizontal semicircular canals varies with the cosine of the angle of the canal to the plane of rotation. Thus, the stimulus causes only approximately 60% of maximal activation with the head in the 30-degree pitched-upward position. Vertical semicircular canals are brought more into the plane of rotation in these pitched positions. In cases of unilateral vestibular hypofunction, gain asymmetries caused by the inhibitory cutoff effects are more likely to be seen with the horizontal canals aligned in the plane of rotation.

Electrocochleography

Electrocochleography (ECOG) may be useful in the diagnosis of Meniere's disease, although interpretation of the findings remains a

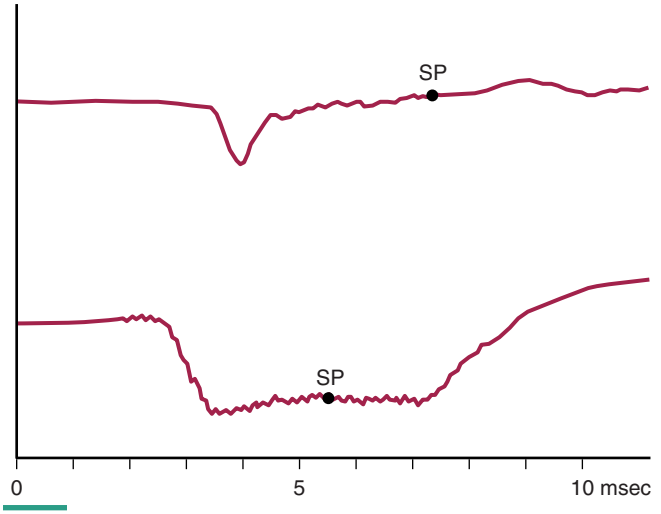

Figure 164-19. Transtympanic electrocochleography. *Top line*, Normal response to tone burst stimulus. *Bottom line*, Pathologic response, with shifted summating potential line (SP) relative to the baseline.

topic of controversy. The cochlea responds to repeated presentation of sound with auditory evoked potentials, which can be represented as an action potential (AP) and a summating potential (SP) (Fig. 164-19). A ratio between the two (SP/AP ratio) greater than 0.4 and an AP duration longer than 3 msec are indicative of endolymphatic hydrops.[107] This effect is believed to be due to the altered physical properties of the basilar membrane because of endolymphatic hydrops. ECOG can be performed with tone bursts or clicks. Recent studies regarding the safety and efficacy of transtympanic ECOG indicate that this technique may be superior to simply placing the electrode in the external canal.[108] The utility of ECOG in the identification of Meniere's disease has been questioned.

Subjective Visual Vertical

The subjective visual vertical is a useful measure of otolith function. Patients sit in a darkened area and focus on a line that they manipulate by use of a dial until they perceive it as vertical. Patients with acute utricular lesions usually leave the line tilted 10 to 15 degrees toward the side of the lesion. Deficits in subjective visual vertical also are seen in patients with brainstem infarctions.[109]

Quantitative Head Impulse Testing

Quantitative head impulse testing allows recording of responses for later analysis and detection of short-latency or small eye movements that may be missed under bedside conditions. Eye movements generally are recorded using scleral search coil technology. Quantitative head impulse testing allows accurate titration of intratympanic gentamicin treatment for intractable Meniere's disease[110,111] and to show that vestibular neuritis preferentially spares the inferior vestibular nerve serving the posterior semicircular canal.[112] These methods also have shown that plugging of the superior canal as used in the treatment of superior canal dehiscence typically causes reduction in function of the plugged canal with preservation of function in the other canals.[113]

Active Head Movement Analysis Techniques

Active head movement analysis techniques have been developed to evaluate the VOR in response to higher-frequency head rotations than those customarily used in rotatory chair testing. This broader range of stimulus frequencies is possible because the test subjects make the head movements actively, using their own neck musculature to rotate the head. In these cases, head velocity is measured by a transducer mounted directly to the head. In one of the more commonly used commercial systems (Vestibular Autorotation Test, Western Systems Research, Inc., Pasadena, California), a computer-generated metronome cues head movements for an 18-second trial period over a swept-frequency band from 2 to 6 Hz. Broad-band cross-spectral analysis is used to determine

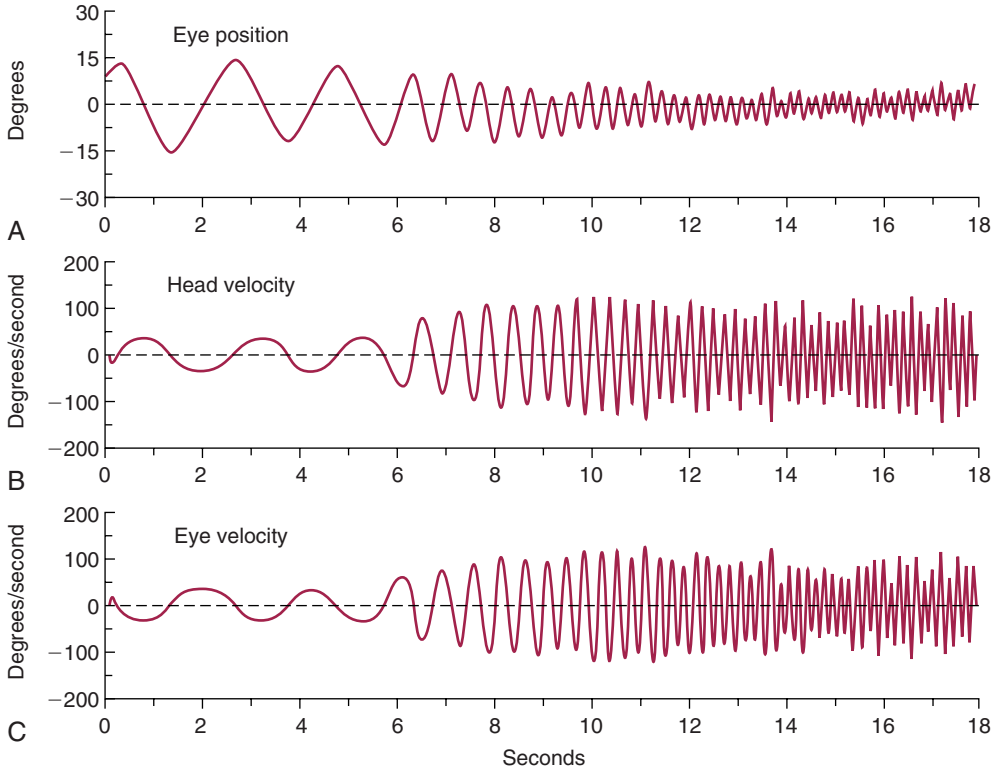

Figure 164-20. Horizontal eye position (**A**), head velocity (**B**), and eye velocity (**C**) during active head movement testing with the Vestibular Autorotation Test. *(From Fineberg R, O'Leary DP, Davis LL. Use of active head movements for computerized vestibular testing.* Arch Otolaryngol Head Neck Surg. *1987;113:1063.)*

all harmonic contributions that occur at each frequency. Results are computed and reported as gain and phase values at 12 selected frequencies over the range of 2 to 6 Hz (Fig. 164-20). Testing is performed with the room illuminated, while the patient fixates on a stationary target that does not move with the head. The range of frequencies tested exceeds that over which smooth pursuit typically is active, so responses are a result of the VOR. Normative data have been obtained for patients of various ages (see Fig. 164-20).[114,115] The vertical VOR can be evaluated in a similar fashion.

Active head movement testing of the VOR has been applied in monitoring patients receiving vestibulotoxic medications such as cisplatin.[116] Asymmetries in responses have been shown to be correlated directionally with the side of lesion in patients with unilateral labyrinthectomy and with the side of lesion in patients with acoustic neuroma.[115] Many patients with Meniere's syndrome also were noted to have abnormalities when these testing procedures were applied.[117] The sensitivity of active tests such as the vestibular autorotation test may be somewhat less than that of passive tests such as head impulse testing, because of the patient's ability to preprogram his or her eye movements during active head movements.[118]

Vestibular Evoked Myogenic Potentials

Recent studies have demonstrated that healthy subjects exhibit a relaxation of the ipsilateral sternocleidomastoid (SCM) muscle in response to auditory stimulation (100- to 200-msec rarefaction clicks, 95-dB sound pressure level [SPL] or tone bursts).[119] These cervical vestibular evoked myogenic potential (VEMP) responses are recorded with electromyelography (EMG) and occur at a short latency (12 msec) relative to onset of the click stimulus (Fig. 164-21). The responses are abolished on the side of surgery after unilateral vestibular neurectomy.[120] VEMP responses are a result of selective activation of vestibular nerve afferents innervating the sacculus. In addition to aiding in diagnosis of otolith function, patients with superior canal dehiscence syndrome also seem to have lower thresholds and increased amplitude[121] and patients with Meniere's disease may have higher thresholds for responses to VEMPs.[122]

Variants of the test include the use of a reflex hammer to produce a sharp tap on the patient's forehead. With this modification, VEMPs were evoked in a small series of patients with conductive hearing loss, while the selectivity of the test was maintained in patients with unilateral vestibular loss.[123] Bone-conducted stimulation with pure tones may be more sensitive than air-conducted sounds.[124] VEMPs also may be recorded from the extraocular musculature.[125] Ocular VEMPs may be superior to cervical VEMPs for detection of superior canal dehiscence.[126]

Posturography

Techniques for postural assessment in patients have been developed in an attempt to provide a quantitative assessment of processes involved in maintaining upright stance under static and dynamic conditions. These tests have conceptual appeal, because they provide a potential mechanism for evaluation of all sensory systems (vestibular, visual, and somatosensory) that provide information important for maintaining balance.

The most commonly used system for clinical postural assessment is computerized dynamic posturography (CDP) (e.g., Equitest, NeuroCom International, Clackamas, Oregon). The test subject stands on a computer-controlled movable platform with a movable visual surround. The platform and visual surround can be fixed or move independently or concomitantly with postural sway. Anterior-to-posterior sway of center of gravity is monitored with pressure-sensitive gauges located in each quadrant of the platform (Fig. 164-22). The standard CDP test battery includes assessment of automatic postural responses to platform movements—the motor control test—and determination of effects of manipulations of visual and somatosensory information on standing balance—the sensory organization test (SOT).

Motor Control Test

The platform administers sudden sagittal movements to the feet, and "toes-up" and "toes-down" platform rotations of 4.0 degrees in 500 msec also are presented. Strain gauges for each foot are then used to calculate the following: weight symmetry (distribution of weight over

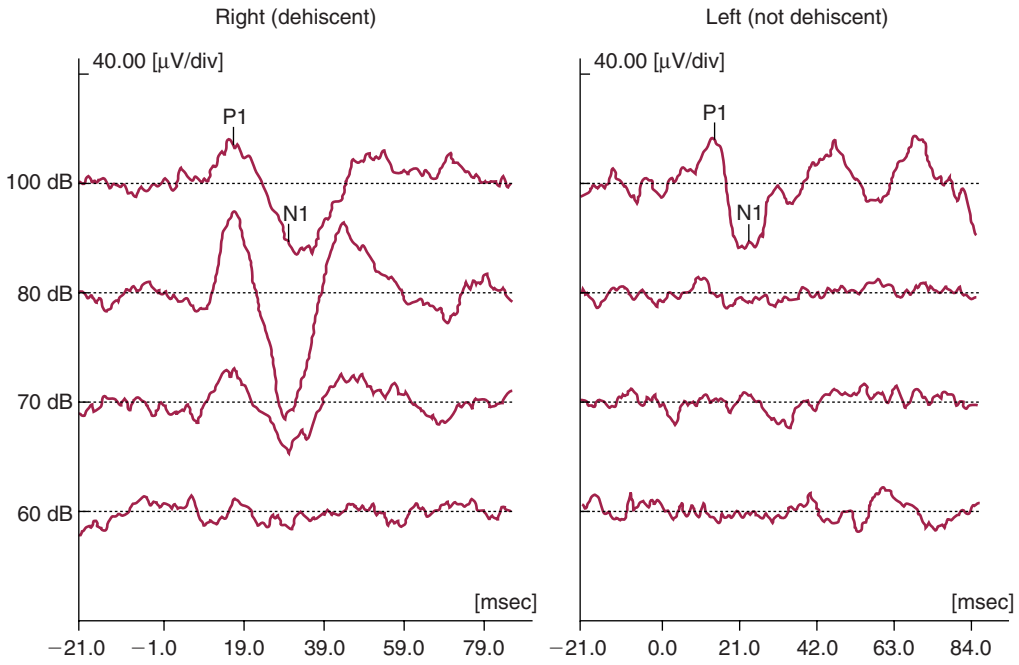

Figure 164-21. Vestibular evoked myogenic potentials (VEMPs) in a patient with unilateral semicircular canal dehiscence responding to clicks. Stimulus was presented at time = 0 msec. The evoked potential peaks at approximately 16 msec and is evident bilaterally at 100 dB *(top tracing)*. On the dehiscent side *(right)*, the potential is still present at 70 dB, but on the normal side *(left)*, no VEMP is present below 100 dB. div, division.

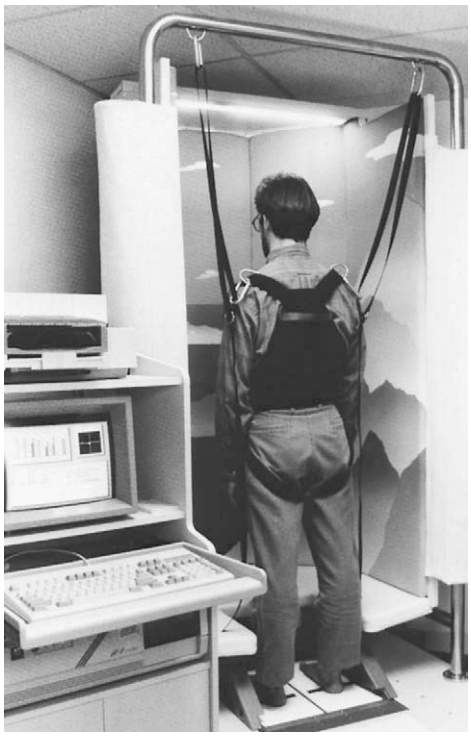

Figure 164-22. Photograph of the NeuroCom International Equitest system shows a subject standing on a platform surrounded by a visual scene. Pressure-sensing strain gauges beneath the platform surface detect patient sway by measuring vertical and horizontal forces applied to the surface. A safety harness is attached to the patient in case loss of balance occurs. The platform surface and the visual surround are capable of moving independently or simultaneously.

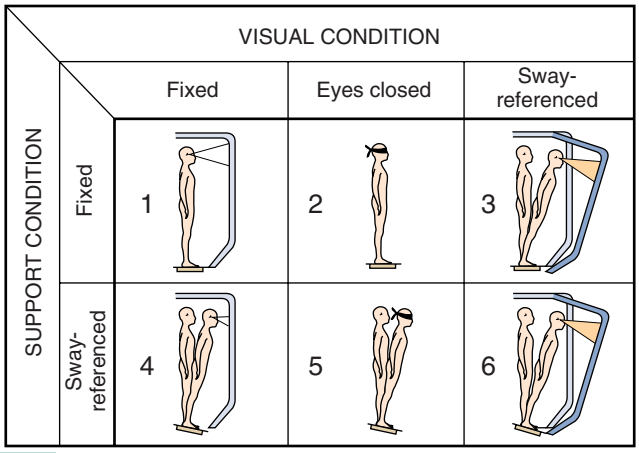

Figure 164-23. The sensory organization test protocol showing the six test conditions. *(From Nashner LM. Computerized dynamic posturography. In: Jacobson GP, Newman CW, Kartush JM, eds.* Handbook of Balance Function Testing. *St. Louis: Mosby; 1996:280-307.)*

both feet during movement), amplitude scaling (distribution of force through legs during platform movement), latency (time from onset of platform movement to discernible response and relationship to amplitude of movement), and adaptation (relationship between response amplitude and stimulus repetition).

Sensory Organization Test

Six test conditions comprise the SOT test battery (Fig. 164-23). The platform remains fixed under the first three test conditions, providing the patient with stable reference for somatosensory information. The visual surround also remains fixed in test condition 1, making this the condition for optimal stability. The patient's eyes are closed in test condition 2, and anteroposterior (AP) sway is controlled by vestibular and somatosensory information. Balance is controlled mainly by somatosensory information during this test condition, so patients with

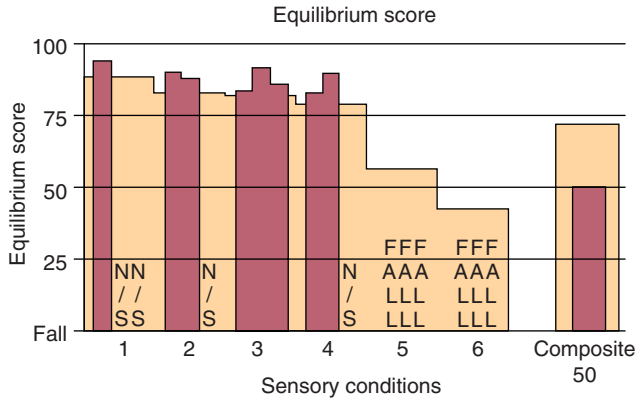

Figure 164-24. Vestibular dysfunction (5-6) pattern. Distortion of somatosensory cues (conditions 5 and 6) and distortion (condition 6) or elimination of visual cues (condition 5) force the patient to rely on vestibular information for balance and posture. This pattern can be seen with acute unilateral or bilateral vestibular lesions, in cases of poor compensation in response to peripheral vestibular lesions, and occasionally with central vestibular system disease. Patients with compensated unilateral peripheral vestibular lesions typically exhibit normal performance on the sensory organization test. During actual test conditions, a stimulus repetition may be deferred if the preceding presentation of that stimulus gives a normal response. The label FALL indicates trials in which the sway in response to the stimulus was outside the limits of stability and would have resulted in a fall had the patient not been secured with a harness. N/S, no stimulus.

deficient vestibular function typically show minimal unsteadiness on this test condition, provided that somatosensory function is normal.

The visual surround moves in reference to AP body sway in test condition 3. "Sway referencing" of the visual surround results in distorted visual inputs to systems controlling balance. Maintaining balance requires the brain to disregard these inaccurate visual inputs and select vestibular and somatosensory cues for balance. As in condition 2, somatosensory inputs are most important for postural control in these situations, so patients with vestibular deficits (but normal somatosensation) tend to do well.

The platform moves to follow the AP sway of the patient in test conditions 4, 5, and 6, thereby providing distorted somatosensory inputs to the brain. Inaccurate proprioceptive cues must be suppressed in these cases, with vestibular and visual inputs used to maintain postural stability. The visual surround remains fixed in condition 4, which permits visual and vestibular inputs to be used in maintaining balance. Patients with vestibular deficits tend to do well in this condition, provided that their vision is intact. The patient's eyes are closed in condition 5, and the platform is sway referenced. Only vestibular cues can be used to maintain balance in this condition, and patients with bilateral vestibular hypofunction or uncompensated unilateral vestibular hypofunction sway excessively. The platform and visual surround are sway referenced in condition 6. Vestibular inputs must now be selected over inaccurate somatosensory and visual cues to maintain balance in this situation. Responses are quantitatively assessed in each condition and compared with age-related norms. Balance strategies (hip or ankle) also are measured. Specific profiles for SOT findings are shown in Figure 164-24.

Use of Posturography

The role of CDP in the diagnosis and management of dizziness continues to be a topic of debate.[127] Rather than serving as a screening test for making a diagnosis in all patients with unidentified problems affecting posture or balance, CDP may be beneficial in three specifically defined clinical situations[128]:

1. *Planning and monitoring a course of postural rehabilitation*. Diagnoses for which posturography can be useful include unilateral or bilateral vestibular hypofunction, brainstem stroke, cerebellar ataxia, extrapyramidal disorders, and vestibular schwannomas and cerebellopontine angle neoplasms. Vestibular rehabilitation programs that are specifically designed for a patient's profile of deficits have been shown to be more effective at alleviating symptoms than generic physical therapy measures.[129] CDP can be useful in the selection of exercises included in a patient's rehabilitation program and in monitoring responses to the therapeutic regimen. For example, patients with dysequilibrium after a unilateral loss of vestibular function can demonstrate dependence on somatosensory or visual information to maintain balance. Patients with somatosensory reliance are given exercises that include walking on uneven surfaces to promote use of visual or vestibular cues to balance, whereas those with visual dependence do exercises that involve intermittently closing the eyes to promote use of somatosensory and vestibular cues.

   The organization of an exercise program on the basis of data obtained from posturography has been demonstrated to have a beneficial effect on functional outcome. Patients showed a significant reduction in postural sway on SOT conditions 5 and 6 in patients with peripheral vestibulopathy who received vestibular rehabilitation compared with those of a control group who only received vestibular-suppressant medication.[130] Patients with a variety of peripheral and central vestibular disorders show improvements in subjective and objective measures of functional outcome after receiving an exercise regimen organized around abnormalities on SOT.[131] Evaluation of CDP prelesion and postlesion can also be useful in defining the expected outcome and end point of vestibular rehabilitation for each patient. Patients undergoing vestibular neurectomy for intractable vertigo who showed preoperative abnormalities on CDP showed persisting abnormalities even after a postoperative recovery period, whereas patients with normal findings preoperatively returned to normal.[132]

2. *Determination of the need for high-volume cerebrospinal fluid (CSF) drainage with lumbar punctures or shunting in patients with dysequilibrium or gait disturbances caused by processes resulting in abnormal CSF pressure dynamics*. These patients develop dysequilibrium and ataxia with increased CSF accumulation. CDP is useful in quantifying their improvement after CSF draining and in predicting their response to ventriculoperitoneal shunting.[133]

3. *Documentation of postural responses when malingering, exaggeration of disability for compensation, or conversion disorder is suspected*. CDP can identify inconsistencies between symptoms and performance parameters that have been shown to indicate a functional deficit as in malingering or conversion disorder.[134,135] Patients with these disorders often show patterns on CDP that are described as aphysiologic (e.g., poorer performance on SOT conditions 1 and 2 than on 5 and 6). Identification of such patients can be useful in making recommendations about disability status and the need for psychiatric intervention.

Audiogram

Audiometric findings may indicate the cause of imbalance and guide its therapy. Sensorineural hearing loss may accompany peripheral vestibular loss caused by Meniere's disease or aminoglycoside vestibulotoxicity. A Stenger test may help identify malingering. Conductive hearing loss may accompany superior canal dehiscence and enlarged vestibular aqueduct syndrome. Auditory reflex testing helps distinguish these conditions from others, such as otosclerosis, that may have similar balance-related symptoms.

High-Resolution Temporal Bone Computed Tomography

Advances in radiologic techniques have allowed improved diagnosis of many otologic disorders. Superior canal dehiscence syndrome is characterized by sound-induced or pressure-induced vertigo or apparent conductive hearing loss, or both, due to incomplete covering of the superior semicircular canal in the arcuate eminence. In affected patients, eye movements in the plane of the superior semicircular canal often can

be induced by loud noises and by maneuvers that change middle ear or intracranial pressure. Confirmation of this diagnosis requires thin-slice computed tomography (CT) images of the temporal bone in the plane of the superior semicircular canal. Scanners with 0.5-mm slice thickness had a 93% positive predictive value, compared with only 50% with a 1.0 mm slice thickness, because of partial volume averaging in the coarser scan.[136]

Magnetic Resonance Imaging

Dysarthria, diplopia, and paresthesias may accompany the vertigo seen in cases of vertebrobasilar insufficiency. Other neurologic signs including cranial neuropathies and seizure activity may indicate a primary intracranial process.

Serologic Tests

Serologic abnormalities are rare in patients with symptoms of imbalance but in some cases may indicate severe disease. Syphilis, Lyme disease, or Susac syndrome may manifest with hearing loss or imbalance. Antiphospholipid syndrome recently has been associated with inner ear disease, and treatment may prevent significant embolic events.[137] *Cogan's syndrome* is an inflammatory condition characterized by severe visual and vestibular symptoms. In some cases, life-threatening systemic vasculitis may develop.[138] Rare paraneoplastic syndromes associated with breast cancer or Hodgkin's lymphoma may be associated with imbalance.[139]

Adaptive Capabilities of the Vestibular System

The clinician must consider adaptive changes when evaluating the results of vestibular testing. Unilateral loss of vestibular function creates two general types of deficits for which a correction is required: *static imbalance*, related to differences in the levels of tonic activity of neurons in the vestibular nuclei, and *dynamic disturbances*, related to responsiveness to motion. For the VOR, spontaneous nystagmus with the head stationary is an example of the former type of disturbance, whereas decreased amplitude and asymmetry of eye rotation during head rotation are examples of the latter. For a fixed (nonfluctuating) unilateral loss of vestibular function, resolution of static signs such as spontaneous nystagmus and the ocular tilt reaction usually occurs within days, but dynamic processes return toward baseline levels over the course of several weeks. Some processes such as the function of velocity storage and responses to high-frequency, high-acceleration head movements toward the hypoactive labyrinth may not recover.

Adaptive mechanisms are most likely to involve increasing sensitivities of central vestibular neurons to signals they receive from the intact vestibular nerve or adjustments in the level of modulation in neurons that connect the vestibular nuclei from one side to the other. Experimental evidence indicates that once acquired, these adaptive and compensatory changes require continued sensory exposure for maintenance of appropriate responses. In addition to the central mechanisms that promote normalization of vestibular processes after labyrinthine or central injuries, the brain can substitute other strategies for generating responses involved in sensing and controlling motion. These substitutions can involve other sensory inputs for driving the same motor response (e.g., substitution of the cervico-ocular reflex or the optokinetic reflex for labyrinthine-evoked VOR). Other strategies can be based on prediction or anticipation of intended motor behavior (e.g., gaze overshoots during combined eye and head movements in labyrinthine-defective persons can be prevented by preprogramming compensatory slow phases and decreasing saccade size in anticipation of a head movement). A consequence of such an adaptive capability is that a vestibular disorder reflects the "pure" effects of a lesion only when history-taking and patient examination are done immediately after change in vestibular function.

Specific vestibular rehabilitation exercises constitute the appropriate treatment for patients with unilateral or bilateral vestibular loss. These exercises are designed to assist the brain's intrinsic adaptive processes to compensate for loss of peripheral function. A successful rehabilitation program usually is carried out in partnership with a physical therapist. Some exercises are designed to increase the gain of the hypoactive vestibular system by maintaining fixation on a target while moving the head. Others attempt to habituate the patient to disturbing symptoms by mildly and repetitively provoking them. Rehabilitation is effective in patients with acute vestibular loss, as well as in patients with more chronic symptoms. Patients with bilateral vestibular loss generally enjoy less benefit from rehabilitation than that observed in patients with unilateral loss. Despite the benefits of rehabilitation, many patients will never achieve the same level of activity that they had before their vestibular loss. Some patients who do not improve after vestibular exercises may have problems such as benign positional vertigo or superior canal dehiscence that are better treated with more specific therapies.

CHAPTER ONE HUNDRED AND SIXTY-FIVE

Peripheral Vestibular Disorders

Benjamin T. Crane

David A. Schessel

Julian Nedzelski

Lloyd B. Minor

Key Points

- The peripheral vestibular system transduces head movement, playing key roles in stabilizing vision and ambulation.
- The history of vertigo symptoms provides definitive insights into underlying diagnosis and pathophysiology; the first step is to differentiate peripheral from central vestibular disorders.
- Peripheral vestibular disorders are highly prevalent, affecting 1 in 13 people during their lifetime.
- Benign paroxysmal positional vertigo (BPPV) produces characteristic symptoms of position sensitivity and fatigability and often is effectively diagnosed with the Dix-Hallpike maneuver and treated with the Epley maneuver.
- The diagnosis of vestibular neuritis is suggested by dramatic, sudden-onset vertigo with vegetative symptoms.
- The diagnosis of Meniere's disease is based on a history of episodes of vertigo lasting up to 24 hours, fluctuating sensorineural hearing loss, tinnitus, and aural fullness. If followed for 2 years, more than half of Meniere's patients will have a spontaneous cessation of vertigo symptoms.
- Treatments for Meniere's disease include low-sodium diet, diuretics, and intratympanic injection of dexamethasone or gentamicin. More advanced cases not responsive to initial therapy may be treated with nerve section or labyrinthectomy.
- Superior canal dehiscence syndrome is caused by absence of bone over the superior canal. Symptoms include vertigo induced by loud sound or high pressure, conductive hearing loss, pulsatile tinnitus, and autophony.
- Cogan's syndrome is characterized by interstitial keratitis, hearing loss, and vestibular symptoms. Systemic steroids are the accepted treatment.
- Perilymph fistula is a controversial diagnosis with presenting symptoms of dizziness and hearing loss.
- Bilateral vestibular hypofunction can manifest with oscillopsia and gait disturbance. Aminoglycosides are the most common cause.
- Enlarged vestibular aqueduct syndrome usually manifests with hearing loss in childhood, but vertigo often develops later in life.

Basic Principles of Peripheral Vestibular Physiology

The peripheral vestibular system depends on the sensory receptor structures, which are responsible both for sensing motion and position of the head in space and for converting this sensory stimulus into an electrical signal. These sensory signals are carried to the central nervous system (CNS) in the form of neural activity.

Vestibular receptors are organized to detect head motion in a specific direction or plane. Horizontal head rotation (yaw) produces a stimulus to the horizontal semicircular canals. Pitching of the head from front to back, as well as roll from side to side, is detected by the superior and posterior semicircular canals. Linear acceleration such as gravity as well as motion along a straight trajectory are sensed by the otolith organs located in the utricle and saccule.

All receptors are tonically active. A resting, spontaneous, continual outflow of action potentials from the vestibular portion of the eighth cranial nerve has been recognized. With head motion, this spontaneous activity is modulated up or down. For example, turning the head to the right in the upright position produces an increase in activity in the nerve coming from the right horizontal semicircular canal, whereas left turns decrease activity below the resting rate from the same canal. These paired labyrinths (one in each ear) behave in a "push-pull" fashion. The CNS compares the inputs coming from both ears. When the inputs are equal, the system is balanced, with no sense of movement. When inputs are asymmetrical, the CNS interprets this finding as a head rotation and as a result generates compensatory eye movements and postural adjustments, all of which lead to a conscious sensation relative to the perceived movement of the head.

Of great importance, the CNS is capable of rebalancing itself—that is, compensating after an injury to the peripheral receptor. This compensation is thought to occur as a result of the organism's ability to compare other sensory, visual, and kinesthetic inputs to vestibular

input and, when the inaccuracy of the latter has been recognized, to readjust the central response. As a consequence, the point of balance is reset. CNS compensation in an otherwise healthy person results in near-normal clinical recovery even if complete unilateral vestibular loss has occurred. However, compensation takes time, on the order of days.

Abrupt vestibular imbalance created by a labyrinthectomy leads to severe vertigo, nausea, and ataxia that gradually resolve over ensuing days. On the other hand, a slowly progressive lesion of the vestibular system, such as occurs with acoustic neuromas, rarely causes vertigo. Although vestibular function is destroyed, because the damage has been incurred gradually, ongoing central adaptation masks the developing asymmetry between the ears.

As opposed to acute unilateral peripheral vestibular loss, bilateral vestibular loss, exemplified in the patient who has suffered ototoxicity, results in permanent clinical disability. Because peripheral vestibular input is lacking, the CNS is unable to make the required adjustments to head movements. If the loss is simultaneous and symmetrical, no significant vertigo results. The patient complains of worsened balance, especially in the dark. Fixed objects appear to jump with any head movement (oscillopsia). The symptoms are due to a now inefficient vestibulo-ocular and vestibulospinal system. An important point is that so long as vestibular input is symmetrical, vertigo symptoms will not arise even in the case of complete absence of any vestibular activity.

Clinical Relevance

The lifetime prevalence of vestibular vertigo is 7.4%.[1] In 80% of affected persons, vertigo resulted in a medical consultation, interruption of daily activities, or sick leave. Of patients who present to emergency departments with falls of unknown cause, 80% have vestibular impairment, and 40% complain of vertigo.[2] Thus, peripheral vestibular disorders constitute a significant medical problem. The most important clinical feature in the diagnosis of peripheral vestibular dysfunction is its pattern of presentation or history.

Vertigo is the illusion of motion, either of self (subjective) or of the environment (objective). Although the thorough neuro-otologic examination is beyond the scope of this chapter, a minimum vertigo history should address the following: (1) the duration of the individual attack (e.g., hours vs. days); (2) frequency (e.g., daily versus monthly); (3) the effect of head movements (e.g., worse, better, or no effect); (4) specific position–induced (e.g., rolling onto the right side in bed); (5) associated aural symptoms (e.g., hearing loss and tinnitus); (6) concomitant ear disease (e.g., otorrhea, previous surgery, trauma).

One of the most important features of the pattern of presentation of peripheral vestibular disorders is the duration of vertigo. Based on this parameter, the following classification of peripheral vestibular disease can be used:

1. Vertigo lasting seconds (benign paroxysmal positional vertigo)

2. Vertigo lasting minutes to hours
   a. Meniere's disease
   b. Migraine-associated vertigo (covered in Chapter 166)
   c. Otic syphilis
   d. Cogan's disease

3. Vertigo lasting days to weeks (vestibular neuritis)

4. Vertigo of variable duration
   a. Inner ear fistula
   b. Labyrinthine concussion
   c. Blast trauma
   d. Barotrauma
   e. Familial vestibulopathy
   f. Superior semicircular canal dehiscence syndrome
   g. Bilateral vestibular hypofunction

Historical Background

Before the 1860s, dizziness and balance problems were thought to be exclusively central disorders, often referred to collectively as "cerebral congestion" or lumped in with epilepsy. As early as the 1820s, post-rotation nystagmus was observed in mental patients after rotation in cages as a means to subdue them. Jan E. Purkinje hypothesized that this effect was central in origin. Vertigo symptoms during this period often were treated with leaching, purging, and cupping. Around this time emerged the first hints that equilibrium may have a peripheral component. Pierre Flourens noticed that pigeons would fly in circles in the same orientation as an ablated semicircular canal.[3]

The existence of peripheral vestibular disorders was proposed by Prosper Meniere in 1861.[4] Meniere was the director of a large deaf-mute institution in Paris who probably saw patients in whom both vertigo and hearing loss developed immediately after trauma to the ear, allowing him to conclude that both symptoms have a common inner ear origin.[5] To support his conclusion he presented the results of an autopsy of a young girl in whom sudden hearing loss and acute vertigo developed after such injury. On autopsy, her brain was found to be normal but the inner ear was filled with blood. It is ironic that this patient probably had leukemia, and not endolymphatic hydrops. Because of this finding, it was commonly believed well into the 20th century that Meniere's disease was caused by hemorrhage. Before 1940, "Meniere's disease" was used as a generic term for any peripheral vertigo, especially if it involved hearing loss. The first insight into the true pathophysiology of Meniere's disease came a decade after his initial report, with Knapp's hypothesis that inner ear hydrops was similar to ocular glaucoma.[6]

Early treatments of peripheral vertigo focused on destruction of the end organ. In 1904 the techniques of both eighth cranial nerve section[7] and labyrinthectomy[8,9] were described. The concept of drainage of the endolymph was first reported by Portmann in 1926.[10] Dandy also proposed selective vestibular nerve sectioning using a suboccipital approach during the 1930s, by which he treated more than 600 patients.[11] In this early period these procedures carried a high risk of deafness and facial nerve paralysis, as well as significant mortality rates. It was not until 1938, after examination of nerve section specimens taken from two patients who died in the perioperative period, that Hallpike and Cairns were able to report dilatation of the endolymphatic system in patients with Meniere's disease. This finding was hypothesized to reflect a disruption of the resorptive mechanism.[12] This pathologic feature also was independently observed by Yamakawa.[13]

Treatment of Meniere's disease that focuses on reversing endolymphatic hydrops has continued to evolve through the present day, with several variations on the Portmann shunt being proposed, such as transmastoid decompression,[14] subarachnoid drainage,[15] and cochleosacculotomy.[16] All of these procedures have had incomplete success in treating vertigo symptoms and carry a risk of hearing loss. A randomized controlled trial has suggested that these procedures have an efficacy similar to that for the placebo effect of surgery,[17] although a more recent analysis of these data has suggested that endolymphatic shunts may have a real effect.[18] Accordingly, these procedures continue to evolve and be performed.

BPPV is the most common cause of peripheral vertigo. BPPV was first described by Bárány in 1921, and he attributed the disorder to otolith disease.[19] After Bárány's initial description, scattered contradictory and confusing reports of BPPV appeared in the literature.[20] The clinical diagnosis of this disorder was not well defined until Dix and Hallpike described the classic positioning which causes a characteristic nystagmus in 1952.[21] Like Bárány, however, they believed it was due primarily to otolith disease. It was noted that the disease could be cured by a chemical labyrinthectomy[22] and eighth nerve section.[23] Schuknecht observed granular deposits on the cupula of the posterior semicircular canal in temporal bone specimens and proposed the "cupulolithiasis" theory to explain the pathophysiology.[24] This theory provides a basis for understanding the disorder, although more recent work has shown that the disorder is more commonly due to free-floating particles in the semicircular canal ("canalithiasis"), rather than cupulolithiasis. Gacek proposed transection of only the posterior ampullary nerve for relief of BPPV, confirming the posterior canal origin.[25] In most patients, however, the Epley canalith repositioning maneuver is adequate treatment,[26] and no surgery is required.

The most recently described etiologic disorder with peripheral vertigo is superior canal dehiscence.[27] Affected patients often exhibit a

Tullio phenomenon (nystagmus with loud noise) or *Hennebert's sign* (eye movements caused by pressure on the external auditory canal). This dehiscence acts as a third window into the middle cranial fossa, which can be plugged using a middle cranial fossa approach[28] or a transmastoid approach.[29]

Tremendous progress has been made in understanding the causes of peripheral vertigo and developing treatments. However, even today, vertigo is a symptom whose cause often cannot definitely be attributed to a known single disease process. Further developments in our understanding will no doubt occur and will modify the medical and surgical treatments of peripheral vestibular disorders.

Benign Paroxysmal Positional Vertigo

The most common peripheral vestibular disorder generally is agreed to be BPPV. The hallmark of the disease is brief spells (lasting seconds) of often severe vertigo that are experienced after specific movements of the head. The head movements that most commonly cause symptoms are rolling over in bed and extreme posterior extension of the head as if looking under a sink. Current understanding of this disease has evolved such that specific therapies based on accepted theories have been developed and proved successful in controlling symptoms.

The disorder initially was described in 1921 by Bárány.[19] He recognized several of the cardinal manifestations of BPPV, including vertical and torsional components of the nystagmus, the brief duration of the nystagmus, and the fatigability of the nystagmus and vertigo. Bárány did not, however, correlate the onset of the nystagmus with the positioning maneuver. He erroneously concluded that an abnormality in the encoding of head position by the otoliths was responsible for the symptoms and signs that he had noted. In 1952, Dix and Hallpike[21] reported this entity in a large group of patients. They described their now well-known maneuver for eliciting the classic pattern of nystagmus and its associated symptoms. They recognized the important features of the nystagmus occurring in BPPV, including its latency, directional characteristics, brief duration despite maintaining the offending head position, reversibility upon returning the patient to a seated position, and fatigability from repeated testing. They correctly identified the offending labyrinth but incorrectly concluded that BPPV results from an otolithic disturbance.

Schuknecht[30] reviewed the previous studies of BPPV, including the temporal bone histology of several patients who had experienced the disorder. He noted extensive utricular destruction in these patients and damage to other structures supplied by the anterior vestibular artery. This observation and the failure of electrical stimulation of the utriculus or sacculus to produce discrete patterns of nystagmus in laboratory animals led Schuknecht to conclude that abnormal stimulation of the otoliths was not responsible for the disorder. He suggested that the posterior canal crista was the probable source of the dysfunction. According to Schuknecht, BPPV was caused by loose otoconia from the utricle that, in certain positions, displaced the cupula of the posterior canal. Deposition of otoconia on the cupula of the posterior canal, known as "cupulolithiasis," was later proposed by Schuknecht as the mechanism of BPPV.[24] However, this mechanism poorly explained the brief duration of the nystagmus and the reversal of the nystagmus on return to a sitting position.

The suggestion that the mechanism of BPPV could result from deflection of the posterior canal cupula by the movement of debris in the posterior canal was revisited by Hall and colleagues.[31] These investigators suggested that the nonfatigable form was due to fixed deposits on the cupula, whereas the fatigable form was attributed to the motion of free-floating material within the lumen of the posterior semicircular canal. In most cases, BPPV-associated nystagmus is most commonly due to motion of material in the lumen of the posterior canal.

This latter theory is consistent with the five typical features of posterior canal BPPV: (1) The canalithiasis mechanism explains the latency of nystagmus as a result of the time needed for motion of the material within the posterior canal to be initiated by gravity. (2) The nystagmus duration is correlated with the length of time required for the dense material to reach the lowest part of the canal. (3) The vertical (up-beating) and torsional (top of the eyes beating toward the lowermost ear) components of the nystagmus are consistent with eye movements evoked by stimulation of the posterior canal nerve in experimental animals. (4) The reversal of nystagmus when the patient returns to the sitting upright position is due to retrograde movement of material in the lumen of the posterior canal back toward the ampulla, with resulting ampullopetal deflection of the cupula. (5) The fatigability of the nystagmus evoked by repeated Dix-Hallpike positional testing is explained by dispersion of material within the canal.

Incidence

BPPV is the most common cause of vertigo in patients seen by the otolaryngologist, accounting for 20% to 40% of cases of peripheral vestibular disease[32]—making it almost twice as frequent as Meniere's disease. The incidence is difficult to estimate because of the benign, typically self-limited course of the disease. It is thought to range from 10.7 per 100,000 to 17.3 per 100,000 population in Japan[33] and has been reported as 64 per 100,000 in a population study from Minnesota.[34]

The mean age at onset is in the fourth and fifth decades, but BPPV also may occur in childhood.[35] In a study of pediatric patients with BPPV, an association with migraine was suggested, leading to the hypothesis that migraine-induced ischemia may be responsible for the release of otoconia in some cases.[36] Overall, the incidence increases with age,[37] and BPPV is twice as common in women.[35]

Diagnosis

History

The patient with BPPV experiences severe vertigo associated with change in head position. The most frequently cited occurrence of this symptom follows rolling over or getting into bed and assuming a supine position. Frequently a specific side is identified as being associated with symptom onset (e.g., "the dizziness comes when I roll over to my right side but not to the left"). Patients also will experience similar symptoms on arising from a bending position, looking up to take an object off a shelf, tilting the head back to shave, positioning the head in the hairdresser's chair, or turning rapidly.

Symptoms occur suddenly and last on the order of seconds but never in excess of a minute.[35] The subjective impression of attack reported by the patient frequently is longer.

Episodes of vertigo frequently are clustered in time and separated by remissions lasting months or more. The patient also may report that periods of active disease may be associated with constant feelings of lightheadedness, worsened by head movement.[38] These chronic balance problems may be worse on awakening.

In most cases of BPPV, no specific etiologic disorder can be identified. In a large survey by Baloh and colleagues, no cause was identified in 48% of cases.[35] The most common known cause was closed head injury, followed by vestibular neuritis. In our experience, BPPV will eventually develop in nearly 15% of patients suffering from vestibular neuritis. Other cited predisposing events include infections and certain surgical procedures, including stapedectomy[35] and insertion of a cochlear implant.[39] Prolonged bed rest and Meniere's disease also are predisposing factors.

Findings on Examination

The diagnosis of BPPV is made by observing the classic eye movements in association with the Dix-Hallpike maneuver, combined with a suggestive history. The *Dix-Hallpike maneuver* is carried out as follows (Fig. 165-1). The patient is positioned supine on an examination table with the head extending over the edge. The patient is lowered with the head supported and turned 45 degrees to one side. The eyes are carefully observed. If no abnormal eye movements are seen, the patient is returned to the upright position. The maneuver is repeated with the head turned in the opposite direction and finally with the head extended supine.[40]

The pattern of response consists of the following: (1) The nystagmus is a combined vertical up-beating and rotary (torsional) component beating toward the downward eye (the superior poles of the eyes beat toward the downward ear). Pure vertical nystagmus is not BPPV.[35] (2) A latency of onset of nystagmus (seconds) is common. (3) Duration

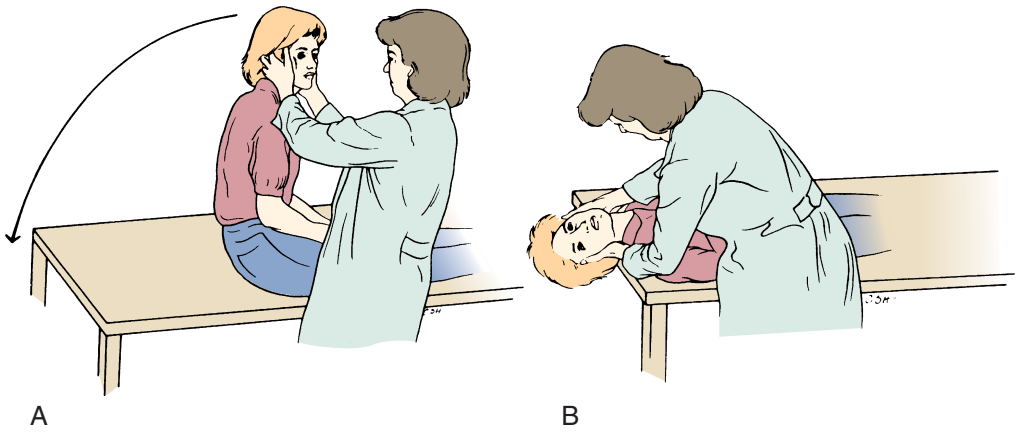

Figure 165-1. Right Dix-Hallpike maneuver for eliciting nystagmus and vertigo due to posterior canal benign paroxysmal positional vertigo (BPPV). The patient's head is first turned 45 degrees to the right (**A**). The patient's neck and shoulders are then brought into the supine position with the neck extended below the level of the examination table (**B**). The patient is observed for nystagmus and assessed for symptoms of vertigo. The patient is next returned to the upright position. *(From Herdman SJ, ed.* Vestibular Rehabilitation. *Philadelphia: F.A. Davis; 1994. Used with permission.)*

of nystagmus is short (less than 1 minute). (4) Vertiginous symptoms are invariably associated. (5) The nystagmus disappears with repeated testing (i.e., it is fatigable). (6) Symptoms often recur with the nystagmus in the opposite direction on return of the head to the upright position.[38]

Canalithiasis of the posterior semicircular canal is the most frequent cause of BPPV. Posterior canal BPPV rarely may be bilateral.[41] If the head is not positioned correctly during testing (i.e., not positioned with the head in the plane of the posterior canal during testing of the unaffected side), debris on the affected side may come to rest against the cupula, simulating an excitatory nystagmus from the unaffected ear.[42] The lateral semicircular canal has been identified as the affected structure in approximately 12% of cases, with a significant fraction of these being induced by the repositioning maneuver for posterior canal BPPV.[43] Lateral canal BPPV can be detected by a variation of the Dix-Hallpike maneuver: The patient is first brought to the supine position with the head resting on (not hyperextended below) the examining table. The head is then turned rapidly to the right so that the patient's right ear rests on the table. Eye movements are monitored with Frenzel lenses for 30 seconds. The patient is then returned to the supine position (looking upward) and the head is turned rapidly to the left so that the left ear rests on the table. Eye movements are again monitored.

The nystagmus with lateral canal BPPV is horizontal and may beat toward (geotropic) or away from (ageotropic) the downward ear. It often begins with a shorter latency, increases in magnitude while maintaining the test position, and is less susceptible to fatigue with repetitive testing than the vertical torsional nystagmus of posterior canal BPPV. The increased amplitude and duration of the horizontal nystagmus may reflect action of the central velocity storage mechanisms (which perseverate signals from the vestibular periphery, especially those arising from the lateral canal). Cupulolithiasis, arising either independently or in combination with canalithiasis, is more likely to be involved in the etiology of lateral canal BPPV than is the case for posterior canal BPPV. Cupulolithiasis can be differentiated from canalithiasis by minimal or absent latency to the onset of nystagmus. Cupulolithiaisis also can persist for minutes or even as long as the patient remains in the provocative position.[44] If the nystagmus is geotropic, the particles are likely to be in the long arm of the lateral canal relatively far from the ampulla. If the nystagmus is ageotropic, the particles may be in the long arm relatively close to the ampulla or on the opposite side of the cupula, either floating within the endolymph or embedded in the cupula.

The superior semicircular canal is affected in only 2% of cases of BPPV.[45] The nystagmus expected in cases of superior canal BPPV would be downbeat and torsional. Such a nystagmus can be elicited by standard Dix-Hallpike positioning testing. The right posterior canal lies in roughly the same plane as that of the left superior canal, and vice versa. Placement of the head into the right Dix-Hallpike position will therefore bring the left superior and right posterior canals into the plane of gravity. A nystagmus resulting from the left superior canal BPPV would, in this position, be expected to be downbeat, with a torsional component directed such that the superior part of each eye beats toward the upward ear. Note that this nystagmus is opposite in vertical and torsional direction from that resulting from right posterior canal BPPV.

Test Results

The bedside Dix-Hallpike test[21] combined with an appropriate history is key to making the diagnosis. Standard electro-oculography (EOG) and the many videonystagmography devices do not record the torsional eye movements associated with BPPV. The eye movement tracings obtained with these standard devices used for clinical testing reflect solely the associated vertical and horizontal components of the eye movements. The observation of these patterns may be facilitated by the use of Frenzel lenses.

Treatment with Repositioning

First-line therapy for BPPV is organized around repositioning maneuvers that, in cases of canalithiasis, use gravity to move canalith debris out of the affected semicircular canal and into the vestibule. For posterior canal BPPV, the maneuver developed by Epley[26] is particularly effective (Fig. 165-2). The maneuver begins with placement of the head into the Dix-Hallpike position, to evoke vertigo. The posterior canal on the affected side is in the earth-vertical plane with the head in this position. After the initial nystagmus subsides, a 180-degree roll of the head (in two 90-degree increments, stopping in each position until any nystagmus resolves) to the position in which the offending ear is up (i.e., the nose is pointed at a 45-degree angle toward the ground in this position) is performed. The patient is then brought to the sitting upright position. The maneuver is likely to be successful when nystagmus of the same direction continues to be elicited in each of the new positions (as the debris continues to move away from the cupula). The maneuver is repeated until no nystagmus is elicited. In our experience, when administered in this way, the Epley maneuver is effective in more than 90% of cases in eliminating BPPV. Medications are not usually given, but a low dose of meclizine or a benzodiazepine 1 hour before may be appropriate if the patient is unusually anxious or susceptible to nausea and vomiting with vestibular stimulation.

The Semont maneuver also is effective for posterior canal BPPV[46] but is more difficult to perform and is less effective than the simpler, more comfortable Epley maneuver.[47] The patient is moved quickly into the position that provokes the vertigo and remains in that position for 4 minutes. The patient is then turned rapidly to the opposite side, ear down, and remains in this second position before slowly sitting up.

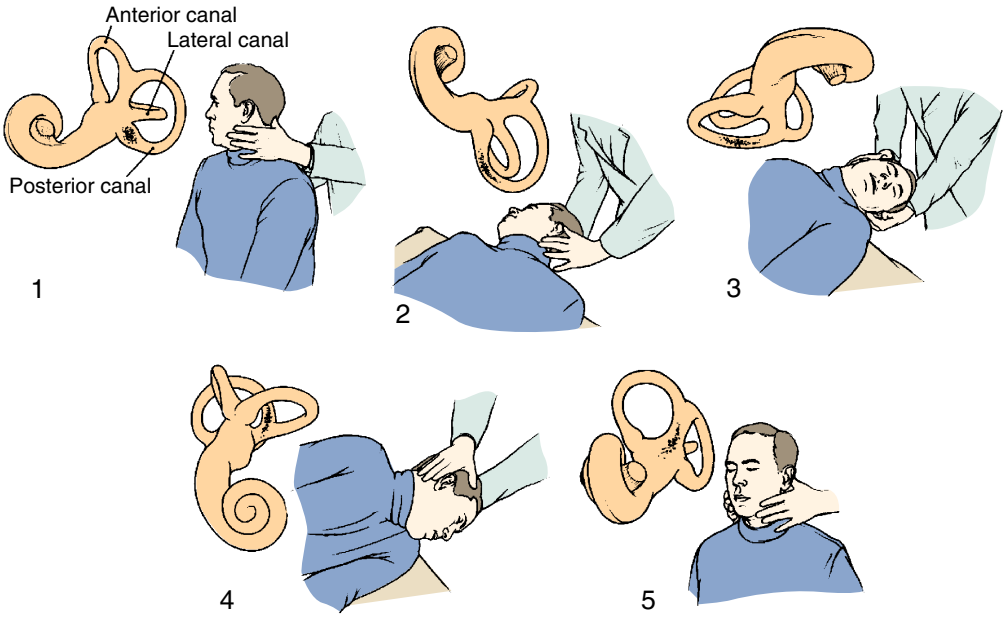

Figure 165-2. Canalith repositioning maneuver for treatment of benign paroxysmal positional vertigo (BPPV) affecting the posterior canal of the right ear. **1,** The patient's head is turned to the right at the beginning of the canalith repositioning maneuver. The *inset* shows the location of the debris near the ampulla of the posterior canal. The diagram of the head in each inset shows the orientation from which the labyrinth is viewed. **2,** The patient is brought into the supine position with the head extended below the level of the gurney. The debris falls toward the common crus as the head is moved backward. **3,** The head is moved approximately 180 degrees to the left while keeping the neck extended with the head below the level of the gurney. Debris enters the common crus as the head is turned toward the contralateral side. **4,** The patient's head is further rotated to the left by rolling onto the left side until the patient is face down. Debris begins to enter the vestibule. **5,** The patient is brought back to the upright position. Debris collects in the vestibule. *(Illustration by David Rini. From Hullar TE, Minor LB: Vestibular physiology and disorders of the labyrinth. In: Glasscock ME, Gulya AJ, eds.* Surgery of the Ear. *5th ed. Hamilton, Ontario: B.C. Decker; 2003.)*

For both Epley and Semont maneuvers, gravity is the stimulus that moves the particles within the canal, so turning the head on the body is unnecessary. En bloc movement of the head and body to the extent possible is the preferred treatment pattern. Some physicians also use a small handheld vibrator over the mastoid and claim slightly better results, although the results do not seem significantly different.[48] Mastoid vibration should be avoided in patients who have had retinal detachment or who may be susceptible to such a detachment because of high myopia. Some investigators recommend having the patient sleep with the head elevated for 1 to 2 days after the maneuver, but this has not been shown to have a significant effect.[49]

The following observations support the effectiveness of these maneuvers for treatment of posterior canal BPPV: (1) Patients who have been symptomatic for years can be cured; (2) BPPV involving one canal can convert to BPPV involving another canal as a result of treatment; (3) patients in whom the wrong side was treated and post-treatment instructions were given show no improvement; and (4) randomized trials have shown the effectiveness of the treatment maneuvers. Because BPPV commonly resolves in a few weeks to a month, a repositioning maneuver may seem to be no better than placebo in an unselected group of patients with BPPV in whom spontaneous recovery is common. In more intractable cases, however, the treatment will almost certainly be determined to be effective.

Treatment maneuvers also have been suggested for the lateral canal variant of BPPV. In cases that involve geotropic nystagmus, lying on one side with the affected ear up for 12 hours has been reported to be effective in the vast majority of cases.[50]

Treatment maneuvers for superior canal BPPV should follow the same principles. The head initially should be moved into a dependent position wherein the ampulla is superior, then rotated by 180 degrees, and then brought back to its initial position. Data on treatment of superior canal BPPV have not been reported, no doubt owing to its relative rarity.[51]

Some events that can occur during repositioning maneuvers are worthy of discussion. Posterior canal BPPV can be converted to lateral canal BPPV during the Epley maneuver. The lateral canal BPPV usually resolves in several days. Posterior canal BPPV can occasionally be converted into a presumed anterior canal BPPV (i.e., symptoms worsen when the offending ear is up). An obstruction of canalith material may occur at the common crus during the Epley maneuver, resulting in a sustained pure torsional nystagmus (both the superior and posterior canals are excited simultaneously, so the opposing vertical components cancel and the torsional components add).

Surgical Treatment

The vast majority of patients with BPPV will be cured by repositioning maneuvers, but surgical therapy remains an option for the rare patient with disabling persistent disease.

Singular neurectomy to treat refractory BPPV was proposed by Gacek.[25] During the three decades since it was described, the procedure has been performed at least 342 times, of which 252 were by Gacek himself.[52] Although the procedure generally is effective, it is technically difficult and the risk of hearing loss from the procedure may be as high as 41%.[53]

Posterior semicircular canal occlusion was introduced as a treatment for BPPV in 1990.[54] This technique blocks the canal lumen so that it becomes unresponsive to angular acceleration. At total of 97 cases have been reported in the literature. Although the procedure was associated with brief postoperative vertigo, 94 of the 97 patients were cured of their BPPV.[55] The procedure is associated with a postoperative hearing loss that usually recovers over several weeks.

Vestibular Neuritis

Vestibular neuritis typically manifests with dramatic, sudden onset of vertigo and attendant vegetative symptoms.[56] Typically, the dizziness lasts for days, with gradual, definite improvement throughout the course. Balance-related complaints, particularly caused by or related to

rapid head movements, may be present for months after resolution of the acute disease. Paroxysmal positional vertigo occurs subsequently in a small percentage of patients.[57,58] Vestibular neuritis has been known to recur, with some patients reporting similar, usually less intense attacks for years.[58] Bilateral disease has been described and must be considered in the differential diagnosis for bilateral vestibular loss. Vestibular neuritis is not associated with subjective change in hearing or with any focal neurologic complaints.[21] Although historically the terms *vestibular neuritis* and *labyrinthitis* were used interchangeably, *vestibular neuritis* is now considered the more accurate term for cases that do not involve hearing loss. The term *epidemic vertigo* has also been used historically and is synonymous with vestibular neuritis; the term reflects the observation that the vertigo often is preceded by upper respiratory infection.[58]

Subjectively, hearing remains normal. When sudden sensorineural hearing loss accompanies vertigo with a vestibular neuritis–like pattern, classification as a sudden sensorineural hearing loss should be considered. In such cases, treatment appropriate for sudden sensorineural hearing loss should be instituted and the evaluation should include evaluation for a retrocochlear lesion, such as acoustic neuroma.

A documented caloric response reduction or positive head thrust test in the direction of the involved side can be used to identify the side of involvement.[56] Head thrust testing in the canal plane may have the advantage of localizing the pathology to the inferior or superior vestibular nerve.[59] However, inferior vestibular nerve involvement is unusual, so VEMP testing is rarely useful.[60] Lateralization also has been reported with use of magnetic resonance imaging (MRI) with gadolinium enhancement.[61]

Histopathologic studies of temporal bones from patients believed to have experienced this clinical entity reveals vestibular nerve degeneration with sparing of the peripheral receptor structure.[58] Human pathologic studies also have demonstrated signs of more chronic inflammation in the rare case manifesting a more chronic or recurrent course of disease. A postinfectious syndrome has been suggested in these cases. Opinion holds that the superior vestibular nerve is more commonly involved in this disease than the inferior. It is postulated that this predilection may be secondary to the longer and narrower bony canal traversed by the superior nerve, making it more susceptible to compressive swelling.[62] It also is possible that isolated inferior vestibular nerve neuritis is not diagnosed owing to normal horizontal head thrust and caloric testing.[63]

The cause of the degeneration is not established. Infection with one of the neurotropic viruses, such as herpesvirus, is thought to be responsible. *Borellia* infection also has been noted in some instances. In most cases, the responsible virus is never identified.

Treatment has historically been supportive and symptomatic for vertigo and related vegetative symptoms. Recently, methylprednisolone and valacyclovir have been investigated as possible therapeutic agents in a placebo-controlled, double-blind study.[64] Patients given methylprednisolone experienced significantly more improvement after 1 year. Valacyclovir was not shown to have any affect. As in all acute peripheral vestibular losses, early ambulation is encouraged.

Meniere's Disease

Meniere's disease (idiopathic endolymphatic hydrops) is a disorder of the inner ear associated with a symptoms consisting of spontaneous, episodic attacks of vertigo; sensorineural hearing loss which usually fluctuates; tinnitus; and often a sensation of aural fullness. Despite this well-known symptom complex, Meniere's disease remains a controversial and often difficult condition to diagnose and treat. This is in part due to the dramatic variability that is the hallmark of this disease. This discussion concentrates on current thought concerning Meniere's disease as well as indicates some of these underlying controversies.

History

Prosper Meniere first described the symptom complex in 1861 and proposed the pathologic site to be in the labyrinth. It was Meniere along with Flourens who recognized that vertiginous symptoms could originate in the inner ear. However, hemorrhage into the inner ear, which Meniere himself believed to be the pathophysiology, has proved to be erroneous. Knapp advanced the hypothesis that hydrops was similar to ocular glaucoma,[6] although this was not histologically demonstrated until 1938.[12,13] Before that time, "Meniere's disease" was used as a generic term for any peripheral vertigo. Understanding of Meniere's disease has advanced considerably since these initial descriptions, yet the cause of the underlying hydrops remains elusive and controversial despite seventy years of active research.

Incidence

Wide variation exists in the published rates for incidence of Meniere's disease. These range from 17 per 100,000 in the Japanese population[65] to a high of 513 per 100,000 in the population of southern Finland,[66] with several studies reporting intermediate values. Some of the variation may be explained by the diagnostic criteria used and by access to health care in a population. The disease seems to be more prevalent among whites,[67] with a male-to-female ratio of approximately 1. The peak age at onset is in the fourth and fifth decades of life, although presentation can be at almost any age.

The frequency of bilateral disease is unclear, and the incidence in published reports is from 2% to 78%.[68] The rate depends on the duration of follow-up and the diagnostic criteria. The studies at the extreme ends of this range were from before 1980, when standardized diagnostic criteria were not in use. The true incidence probably is in the range of 19% to 24%.[67,68] Symptoms of bilateral disease may appear many years or decades after onset of the unilateral symptoms.[69]

Familial occurrence of Meniere's disease has been reported in 10% to 20% of cases.[70] An autosomal dominant mode of inheritance has been suggested,[71] although the mode of inheritance can be variable. Migraine is strongly associated with Meniere's disease in familial cases.[72] The incidence is elevated in persons with specific major histocompatability complexes (MHCs). Human leukocyte antigens (HLA) B8/DR3 and Cw7 have been associated with Meniere's disease.[73,74] The etiology of the disease in persons with these HLAs may be autoimmune.[75]

Pathogenesis

Meniere's disease is characterized by recurring attacks of vertigo, sensorineural hearing loss, tinnitus, and, in some affected persons, a fluctuating sense of fullness in the ear. Acute attacks are superimposed on a gradual deterioration in sensorineural hearing in the involved ear, typically in the low frequencies initially. Over time, a reduction in responsiveness of the involved peripheral vestibular system occurs.

The pathologic basis thought to underscore these findings is a distortion of the membranous labyrinth. The hallmark of this distortion is endolymphatic hydrops.[12] This condition reflects the changes in the anatomy of the membranous labyrinth as a consequence of the overaccumulation of endolymph. Such changes occur at the expense of the perilymphatic space (Fig. 165-3).

Traditional thought has held that endolymph, which is produced by the stria vascularis in the cochlea and by the dark cells in the vestibular labyrinth, circulates in both a radial and a longitudinal fashion.[76] In the case of hydrops, the underlying pathophysiology is controversial, but inadequate absorption of endolymph by the endolymphatic sac is the prevalent theory.[77] The endolymphatic duct may act as a valve to regulate endolymph homeostasis.[78] Temporal bone histologic equivalents of hydrops have been produced in animals as a consequence of disruption of the endolymphatic sac, thereby supporting the above theory of pathogenesis.[79]

Histopathologic studies of the human sac in the hydrops patient remain controversial. Some investigators have reported perisaccular fibrosis[80] and decreased endolymphatic duct size.[81] However, the underlying cause of these histologic findings is not certain.

Imaging studies in patients with Meniere's disease also identify abnormalities of the endolymphatic drainage system. Such studies suggest hypoplasia of the endolymphatic sac and duct, reflected in the decreased visualization of the vestibular aqueduct and reduction in periaqueductal pneumatization on computed tomography (CT) imaging.[82] Persons with Meniere's disease have significantly smaller and

shorter endolymph drainage systems, as measured by the distance between the posterior semicircular canal and the posterior fossa on magnetic resonance images.[83] These anatomic variations are apparent by the age of 3 years and may predispose affected persons to later development of Meniere's disease. Enhancement of the endolymphatic sac[84] (Fig. 165-4) and perilymphatic space[85] has been demonstrated on MRI after gadolinium enhancement. However, significant individual variation has been observed, so imaging studies are neither diagnostic or predictive for Meniere's disease. The main role of imaging in the diagnosis of Meniere's disease is to exclude other possible causes of dizziness and unilateral hearing loss, such as a vestibular schwannoma.

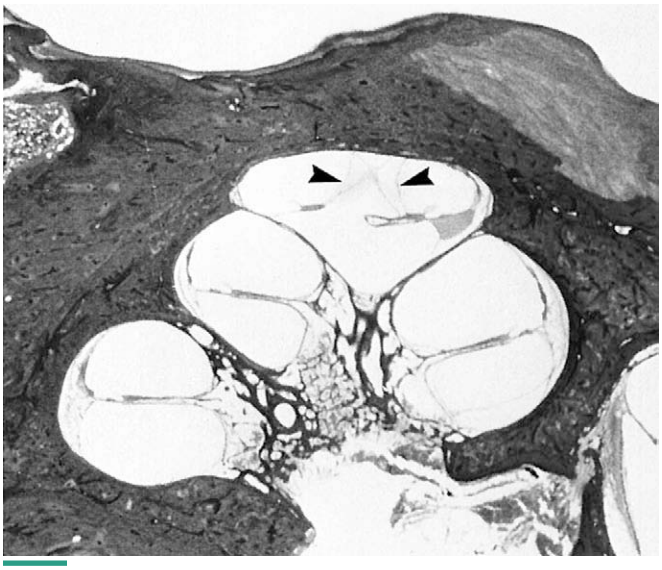

Figure 165-3. Photomicrograph of a cross section of human cochlea demonstrating endolymphatic hydrops in a patient with Meniere's disease. Note the distention of Reissner's membrane into the scala tympani in the apical turn of the cochlea *(arrowheads)*. *(Courtesy of Drs. J. Rutka and M. Hawke, University of Toronto.)*

Endolymphatic hydrops has been uniformly observed in the temporal bones from persons with Meniere's disease. However not all patients found to have hydrops, had a history of Meniere's disease.[86,87] Hydrops also is a postmortem finding after labyrinthitis, otitis media, head trauma, mumps, and meningitis. Asymptomatic hydrops also has been described.[88]

Ruptures in the membranous labyrinth of the patient with Meniere's disease are thought to be significant to the pathophysiology of the disorder. Membranous ruptures have been found in nearly all parts of the inner ear. Healed scars, presumably after rupture, also have been identified.[89,90] Their presence has supported one of the more prominent theories of the pathogenesis of Meniere's disease. Schuknecht postulated that ruptures in the membranous labyrinth allow leakage of the potassium-rich endolymph into the perilymph, bathing the eighth cranial nerve and lateral sides of the hair cells.[91] High concentrations of extracellular potassium depolarize the nerve cells, causing their acute inactivation. The result is a decrease in auditory and vestibular neuronal outflow consistent with the hearing loss and features of acute vestibular paralysis seen in a typical Meniere's attack. Healing of the membranes is presumed to allow restitution of the normal chemical milieu, with termination of the attack and improvement in vestibular and auditory function. The chronic deterioration in inner ear function presumably is the effect of repeated exposure to the effects of the potassium. This theory remains somewhat controversial, because some investigators have suggested that these ruptures rarely occur and do not adequately explain the observed symptoms.[92]

Etiology

The triad of hearing loss, tinnitus, and vertigo constitutes Meniere's syndrome. If the cause is unknown, it is defined as Meniere's disease.[93] However, if a disease entity that is known to cause endolymphatic hydrops is associated with the syndrome, the diagnosis is one of secondary endolymphatic hydrops (i.e., otosclerotic foci causing mechanical endolymphatic blockage[94]). Obstruction of the endolymphatic duct is the basis for development of hydrops in experimental animals. This is accomplished by any lesion that can produce failure of duct function, including mechanical blockage, chemical fibrosis, viral inoculation, immunologically induced inflammation, and ischemia.[95] However, these animal models cannot be interpreted to explain the actual cause of the human disease. These models also do not completely reproduce the clinical and pathologic entity experienced by humans.

Note enhancement of the endolymphatic sac. *(Courtesy of Dr. D. Fitzgerald, Washington, DC.)*

Antibodies directed against normal inner ear elements have been suggested. Patients with Meniere's disease have an increased incidence of specific types of human leukocyte antigens.[70,96] However, most autoimmune processes, including those that affect the ear, such as Cogan's syndrome, have histopathologic findings including infiltration of white blood cells and cellular destruction. If an autoimmune mechanism is responsible, it would have to have a more indolent course or be intermittent and absent at the time of tissue sampling.

Viral infection also has been a suggested pathomechanism for Meniere's disease.[89] The observed occurrence of symptomatic hydrops many years after unexplained deafness, so-called delayed endolymphatic hydrops, suggests that subclinical viral infection could cause hydrops many decades later.[97] However, no virus has been conclusively identified, and comparison of patients with Meniere's disease with control subjects has demonstrated no difference in response to herpes simplex virus.[98]

Ischemia of the endolymphatic sac or inner ear has also been proposed as a underlying mechanism of Meniere's disease.[99] Such a common vascular mechanism may link migraine and Meniere's disease.[72,100,101]

Numerous factors have been implicated as causative for Meniere's disease. Although this lack of specificity in part reflects the current lack of understanding, it also suggests that Meniere's disease may be multifactorial or may represent the common end point of a variety of injuries or anatomic variables. A number of processes seem to be associated with the development of hydrops (e.g., trauma, acute otitis media, labyrinthitis, congenital inner ear deformity, idiopathic processes), but these are not always associated with the development of symptoms.[86] It is possible that Meniere's disease is precipitated by a variety of events such as autoimmune, viral, traumatic, or vascular or ischemic and may even be the result of congenital anatomic and molecular variations that may act as triggers for the later development of symptomatic hydrops (see Chapters 149 and 153).

Diagnosis

No single test is available to make the diagnosis of Meniere's disease. Rather, the most important aspect of the diagnostic process is a complete history, including a detailed description of the pattern of disease presentation, supported by quantitative testing. The most recent definition of the disease has been established by the Committee on Hearing and Equilibrium of the American Academy of Otolaryngology–Head and Neck Surgery (AAO-HNS) and is summarized in Table 165-1.[102]

Clinical Presentation

The typical history consists of recurring attacks of vertigo (96.2%) with tinnitus (91.1%) and ipsilateral hearing loss (87.7%).[103] Attacks often are preceded by an aura consisting of a sense of fullness in the ear, increasing tinnitus, and a decrease in hearing. The attacks may, however, be sudden in onset, with little or no warning. Acute attacks typically last from minutes to hours, most commonly 2 to 3 hours.[104] Attacks lasting longer than a day are unusual and if present should cast doubt on the diagnosis.

The classic presentation as just described is not always detailed by the patient. This is particularly true in the early phases of the disease. Often in retrospect, the disease seems to manifest with a predominance of either vestibular or auditory complaints.[105] In the series reported by Kitahara and associates, 50% of patients presented with vertigo and hearing loss together, 19% with vertigo only, and 26% with only deafness.[106] These variable initial presentations have led to the usage of the terms *cochlear* and *vestibular* Meniere's disease. These subtypes are not widely used, however, and are considered by the AAO-HNS Committee on Hearing and Equilibrium[102] to be an inappropriate application of the diagnosis.[106] Furthermore, no pathologic correlation for these subtypes has been found.[86] The terms *recurrent vestibulopathy* and *atypical Meniere's disease* have been used to describe the condition on persons with less than the classic triad of hearing loss, vertigo, and sensation of aural fullness or tinnitus.

The clinical course of Meniere's disease is highly variable. Patients often have a cluster of attacks separated by long remissions. Silverstein and coworkers[107] found that vertigo ceased spontaneously in 57% of patients in 2 years and in 71% after 8.3 years. Attacks often are clustered in time. Severity of symptoms ranges from minimal inconvenience to complete incapacitation; the AAO-HNS has provided staging guidelines[102] (Table 165-2). In addition to the incapacitating effects of the physical manifestations of Meniere's disease (vertigo, dysequilibrium, hearing loss, tinnitus, and pressure), the disease is emotionally disabling.[108]

History

Incapacitating, spinning vertigo, usually in the horizontal axis, is the most distressing complaint of the affected patient.[93] As is typical of peripheral vestibular dysfunction, the symptoms are exacerbated with any head movement. Accompanying symptoms and signs may include nausea, vomiting, diarrhea, and sweating. Between attacks, patients

Table 165-1

AAO-HNS Criteria for Meniere's Disease Diagnosis

Major Symptoms

Vertigo
- Recurrent, well-defined episodes of spinning or rotation
- Duration from 20 minutes to 24 hours.
- Nystagmus associated with attacks
- Nausea and vomiting during vertigo spells common
- No neurologic symptoms with vertigo

Deafness
- Hearing deficits fluctuate
- Sensorineural hearing loss
- Hearing loss progressive, usually unilateral

Tinnitus
- Variable, often low-pitched and louder during attacks
- Usually unilateral
- Subjective

Diagnosis

Possible Meniere's disease
- Episodic vertigo without hearing loss *or*
- Sensorineural hearing loss, fluctuating or fixed, with dysequilibrium, but without definite episodes
- Other causes excluded

Probable Meniere's disease
- One definitive episode of vertigo
- Hearing loss documented by audiogram at least once
- Tinnitus or sense of aural fullness in the presumed affected ear
- Other causes excluded

Definite Meniere's disease
- Two or more definitive spontaneous episodes of vertigo lasting at least 20 minutes
- Audiometrically documented hearing loss on at least one occasion
- Tinnitus or sense of aural fullness in the presumed affected ear
- Other causes excluded

Certain Meniere's disease
- Definite Meniere's disease, *plus* histopathologic confirmation

AAO-HNS, American Academy of Otolaryngology–Head and Neck Surgery.

Table 165-2

AAO-HNS Criteria for Meniere's Disease Severity

Vertigo

a. Any treatment should be evaluated after at least 24 months.
b. Formula to obtain numeric value for vertigo: ratio of average number of definitive spells per month after therapy divided by definitive spells per month before therapy (averaged over a 24-month period) × 100 = numeric value
c. Numeric value scale:

Numeric Value	Control Level	Class
0-40	Complete control of definitive spells	A
41-80	Limited control of definitive spells	B
81-120	Insignificant control of definitive spells	C
>120		D
Secondary treatment initiated		E

Disability

a. No disability
b. Mild disability: intermittent or continuous dizziness/unsteadiness that precludes working in a hazardous environment
c. Moderate disability: intermittent or continuous dizziness that results in a sedentary occupation
d. Severe disability: symptoms so severe as to exclude gainful employment

Hearing

a. Hearing is measured using a four-frequency pure-tone average (PTA) of 500 Hz, 1 kHz, 2 kHz, and 3 kHz.
b. Pretreatment hearing level: worst hearing level during 6 months before surgery
c. Post-treatment hearing level: poorest hearing level measured 18-24 months after institution of therapy
d. Hearing classification:
   i. Unchanged: ≤10-dB PTA improvement or worsening or ≤15% speech discrimination improvement or worsening
   ii. Improved: >10-dB PTA improvement or >15% discrimination improvement
   iii. Worse: >10-dB PTA worsening or >15% discrimination worsening

In 1996, the Committee on Hearing and Equilibrium reaffirmed and clarified the guidelines, adding initial staging and reporting guidelines:

Initial Hearing Level

Stage	Four-Tone Average (dB)
1	≤25
2	26-40
3	41-70
4	>70

Functional Level Scale

Regarding my current state of overall function, not just during attacks:

1. My dizziness has no effect on my activities at all.
2. When I am dizzy, I have to stop for a while, but it soon passes and I can resume my activities. I continue to work, drive, and engage in any activity I choose without restriction. I have not changed any plans or activities to accommodate my dizziness.
3. When I am dizzy I have to stop what I am doing for a while, but it does pass and I can resume activities. I continue to work, drive, and engage in most activities I choose, but I have had to change some plans and make some allowance for my dizziness.
4. I am able to work, drive, travel, and take care of a family or engage in most activities, but I must exert a great deal of effort to do so. I must constantly make adjustments in my activities and budget my energies. I am barely making it.
5. I am unable to work, drive, or take care of a family. I am unable to do most of the active things that I used to do. Even essential activities must be limited. I am disabled.
6. I have been disabled for 1 year or longer and/or I receive compensation because of my dizziness or balance problem.

AAO-HNS, American Academy of Otolaryngology–Head and Neck Surgery.

may be entirely asymptomatic or may describe periods of dysequilibrium, lightheadedness, and tilt.

Sudden unexplained falls without loss of consciousness or associated vertigo occasionally are described. Tumarkin[109] attributed these events to acute utriculosaccular dysfunction—so-called otolithic crises of Tumarkin, or drop attacks. It is thought that an abrupt change in otolithic input generates an erroneous vertical gravity reference. This in turn generates an inappropriate postural adjustment by way of the vestibulospinal pathway, resulting in a sudden fall.[110,111] Attacks are so sudden that injury can occur. The patient often describes a feeling of being pushed or "the world moving." The spells are brief with little associated vertigo. Drop attacks have been reported in 2% to 6% of persons with Meniere's disease. They tend to occur in clusters and then spontaneously remit.

Lermoyez described an unusual clinical presentation in which tinnitus and hearing loss precede and worsen with the onset of vertigo. When the vertiginous episode occurs, the tinnitus and hearing loss dramatically resolve. The temporal bone studies in a patient with such attacks noted hydrops and membrane ruptures isolated to the basal turns of the cochlea and the saccule.[112]

Acute Meniere's attacks are rarely observed by physicians. Horizontal nystagmus is the cardinal finding, but the direction varies over the course of the attack, so it is not useful in determining the involved ear.

Hearing Loss and Tinnitus

The sensorineural hearing loss in Meniere's disease typically is fluctuating and progressive. It often occurs coincident with the sensation of fullness or pressure in the ear. A pattern of low-frequency fluctuating loss and a coincident nonchanging, high-frequency loss is described, resulting in a "peaked" or "tent-like" tracing on the audiogram. This peak classically occurs at 2 kHz. Over time, the hearing loss normalizes across frequencies and becomes less variable.[105] In only 1% to 2% of patients does the hearing loss progress to profound deafness.

Additional features include diplacusis, a difference in the perception of pitch between the ears (43.6%) and recruitment (56%).[93]

Tinnitus tends to be nonpulsatile and variously described as whistling or roaring. It may be continuous or intermittent. Tinnitus often begins, gets louder, or changes pitch as an attack approaches. Frequently a period of improvement follows the attack.

Investigations

Electronystagmography

Electrooculographic recordings of eye movements after caloric and rotational stimulation are a commonly available and reliable method of assessing vestibular function. The caloric test often can localize the involved ear. A significant caloric response reduction is found in 48% to 73.5% of patients with Meniere's disease.[113] Complete absence of caloric response is reported in 6% to 11% of patients.

Head Thrust Testing

The head thrust test popularized by Halmagyi is very sensitive for detection of unilateral vestibular dysfunction.[114] However, in Meniere's disease, the asymmetry is subtle and present in only 29% of the patients.[115]

Electrocochleography

The summating potential (SP), as recorded by electrocochleography in patients with Meniere's disease, is larger and more negative. This is thought to reflect the distention of the basilar membrane into the scala tympani, causing an increase in the normal asymmetry of its vibration. The most commonly used value is the ratio of amplitudes of the SP and the eighth cranial nerve action potential (AP), the SP/AP ratio. This is based on the observed variability in the amplitude of the SP, considering variables such as recording technique and electrode placement. The SP/AP ratio has been used to reduce the intertest variability, resulting in a more linear response. The SP becomes relatively larger in hydrops; accordingly, the SP/AP ratio increases.[116] It is not a definitive test, because ratios are elevated in 62% of patients with Meniere's disease and in 21% of control subjects. Because of the difficulty in obtaining reproducible recordings and the variability of the wave amplitudes noted with patient age, hearing loss, and stage of disease, as well as the availability of reliable, less invasive diagnostic methods, electrocochleography is now infrequently used for this purpose.[117,118]

Dehydrating Agents

The assumption that an increase in endolymph volume, with its effect on labyrinthine membrane behavior, produces, in part, the hearing loss and vestibular deficit in Meniere's disease has led to the administration of dehydrating agents (e.g., urea, glycerol, furosemide). The goal is to reduce the volume abnormalities in the inner ear and produce a measurable change in response. Improvement has been measured with audiometrics, reduction in SP negativity (as recorded with electrocochleography), or a change in the gain of the vestibulo-ocular response to rotational stimulation. The reported sensitivity and specificity rates for the test vary widely. Klockhoff reports a 60% sensitivity in cases of known Meniere's disease.[119] Psychological factors constitute a significant source of variability, leading some authorities to question the usefulness of the test.[117,120]

Vestibular Evoked Myopotentials

VEMPs are generated by playing loud clicks in the ear, which move the stapes footplate and stimulate the saccule. This is the start of a disynaptic pathway that passes through the vestibular nuclei and then to synapses that relax the sternocleomastoid muscle. The saccule is the second most common site affected by hydrops, which has caused VEMPs to be investigated as a potential diagnostic tool. In the normal ear, the best response is near 500 Hz. Ears affected by Meniere's disease have elevated VEMP thresholds with flattened tuning.[121] The interaural amplitude difference in the response has been implicated as a staging tool for Meniere's disease.[122] Although these tests show differences between populations, they currently have limited diagnostic value owing to the large individual variation in responses.

Treatment

Therapy of Meniere's disease is aimed at the reduction of its associated symptoms. The optimal curative treatment should stop vertigo, abolish tinnitus, and reverse hearing loss. Unfortunately, long-term hearing impairment does not seem amenable to treatment.[108] Currently, almost all proven therapies are directed at relieving vertigo, which usually is the most distressing symptom.

Evaluating treatments for vertigo in patients with Meniere's disease has been made difficult by the natural history of the disease, which includes spontaneous improvement in 60% to 80% of cases, and because many treatments have a significant placebo effect.[96,123,124] This is further supported by the 71% reduction in symptoms by patients who refused surgery,[107] and placebo-controlled studies of endolymphatic sac surgery[17,125] and medical therapy.[126] The large variety of Meniere's disease treatments reflect the extreme variability in clinical response and the inherent difficulty in assessing effectiveness.

Dietary Modification and Diuretics

Salt restriction and diuresis may be the best initial therapy for Meniere's disease.[127,128] The goal of salt restriction and diuretics is to reduce endolymph volume by fluid removal or reduced production. Despite the popularity of these treatments, neither salt restriction[129] nor use of diuretics[130,131] has had its efficacy confirmed by double-blind, placebo-controlled studies. Carbonic anhydrase inhibitors such as acetazolamide were recommended on the basis of the localization of carbonic anhydrase to the dark cells and the stria vascularis. However, these agents have not proved to be clinically more effective than other diuretics.[132] Despite the lack of hard evidence of their efficacy, we feel that a low-salt diet and diuresis constitute an appropriate and effective treatment for Meniere's disease with a low risk of side effects.

Vasodilators

In the belief that Meniere's disease was the result of strial ischemia, vasodilating agents have been used. Betahistine, an oral preparation

of histamine, is one such medication.[133] It has proved to be effective in treatment of Meniere's disease in a placebo-controlled study.[133,134] Such studies have flaws, however, which continues to raise doubts about the efficacy of betahistine over placebo.[135] The medication has become a popular treatment for Meniere's disease in Europe.[136] The drug is available through compounding pharmacies in the United States but often is not covered by insurance and is infrequently prescribed.

Symptomatic Treatment

Antivertiginous medications, antiemetics, sedatives, antidepressants, and psychiatric treatment have been reported to be beneficial in reducing the severity of the vertigo and vegetative symptoms and in improving tolerance of Meniere's symptoms.[137]

Local Overpressure Therapy

A relatively recent approach to decrease hydrops is by pulsing pressure in the middle ear. As long ago as 40 years, overpressure in the middle ear was reported to decrease Meniere's symptoms during acute vertigo attacks.[138] The mechanism of vertigo reduction is unclear, although it may facilitate endolymph absorption.[139]

Since 2000, the Meniett device has been approved for use by the U.S. Food and Drug Administration (FDA). This device is a handheld air pressure generator that the patient self-administers. The pressure is delivered in complex pulses of up to 20 cm of water, over a 5 minute period. The device requires a ventilation tube to be placed in the tympanic membrane before initiation of therapy. A randomized controlled trial demonstrated that patients using the Meniett device experienced a significant decrease in vertigo symptoms for the first 3 months of therapy but that findings afterward were similar to those with placebo.[140] The placebo device in these cases was an inactive device that did not administer pressure. Long-term treatment with the Meniett device has shown results similar to the natural course of Meniere's disease.[141]

Of note, simple placement of a ventilation tube with no additional therapy also has been reported to control vertigo symptoms in many patients with Meniere's disease.[142,143]

Intratympanic Injection

Intratympanic injection commonly is performed with either dexamethasone or gentamicin for control of vertigo symptoms. The term *chemical labyrinthectomy* often is applied to intratympanic gentamicin treatment, but it may not be an appropriate assessment of the effect of gentamicin on the labyrinth in titrated therapy. Instillation of aminoglycosides into the middle ear was described by Schuknecht in 1957 with streptomycin injection through a microcatheter placed through the tympanic membrane.[144] Control of vertigo was achieved in these patients, but severe hearing loss in the treated ear also occurred in most patients.

Gentamicin has a vestibulotoxicity that is high relative to its cochleotoxicity; accordingly, it can be used to control vestibular symptoms while sparing hearing. The gentamicin can be administered through either a tympanostomy tube or directly injected through the tympanic membrane. Peripheral vestibular deficits are evident on head thrust testing after even a single dose of gentamicin[145] (Fig. 165-5). The concentration of the medication used and frequency of injection vary by series. The risk of hearing loss also varies greatly by series, depending on the dose and frequency of treatment. Lange[146] reported elmination of vertigo in 90% of 92 patients, but the incidence of hearing loss and level of vestibular function were not specified. Beck and Schmit[147] sought to determine if complete ablation of vestibular function, as measured with ice water caloric response, was needed for vertigo control. They found that it was not, and that this end point led to severe to profound hearing loss in 58% of treated patients. Wu and Minor[148] found complete control of vertigo in 90%, with profound sensory neural hearing loss in only 3% of patients. Nedzelski and associates[149] found that control of vertigo was achieved in 83% of patients, with substantial control in the remaining subjects. A 10%

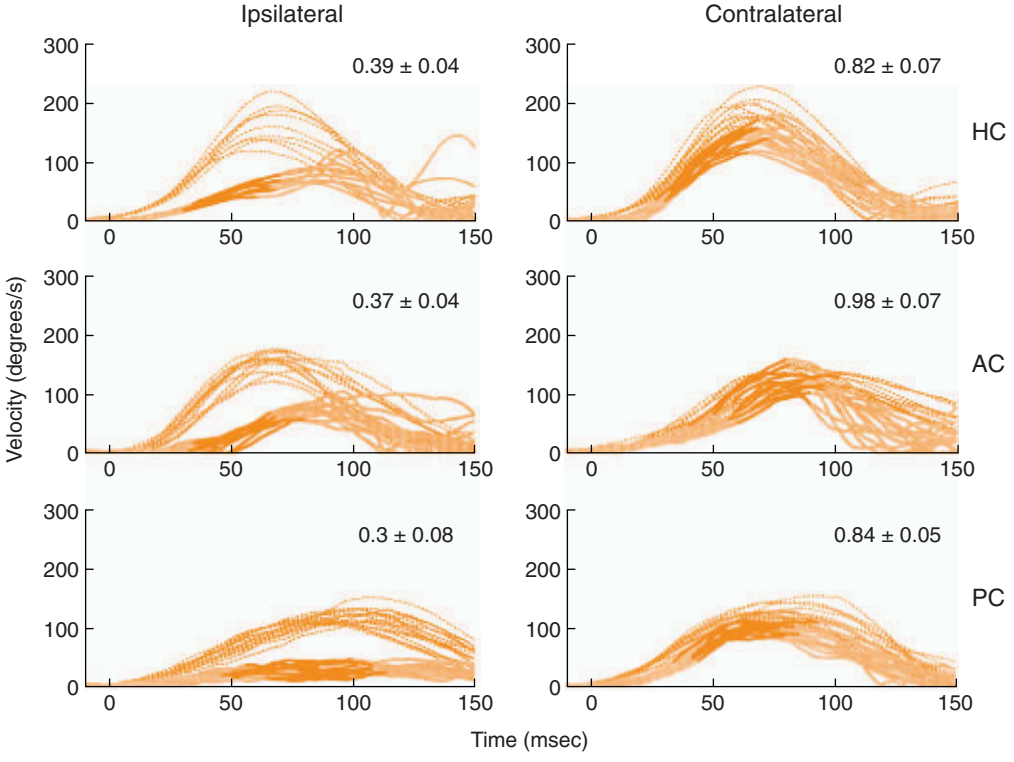

Figure 165-5. Response to head thrusts that excited each of the six semicircular canals in a typical subject measured 49 days after a single intratympanic injection of gentamicin in the right ear. AC, anterior canal; HC, horizontal canal; PC, posterior canal. *(Reproduced from Carey JP, Minor LB, Peng GC, et al. Changes in the three-dimensional angular vestibulo-ocular reflex following intratympanic gentamicin for Meniere's disease.* J Assoc Res Otolaryngol. *2002;3:430.)*

incidence of profound hearing loss in the treated ear was noted. The current trend is away from multiple doses of gentamicin and toward a single-injection regimen, with additional doses only if needed to control symptoms (so-called titration therapy). The risk of hearing loss with gentamicin using many current protocols is similar to that with the natural history of Meniere's disease.[127,148]

Intratympanic injection of dexamethasone is considered by many experts to be a reasonable procedure to offer when vertigo is intractable but the patient still has some functional hearing. The mechanism for steroid effect on vertigo symptoms is not currently clear. Some evidence suggests that Meniere's disease has an autoimmune component, which the steroids may address. Several studies have reported a beneficial effect of intratympanic injection of dexamethasone in the control of vertigo from Meniere's disease,[150,151] although the effect on hearing loss and tinnitus is minimal. The risk of hearing loss or other complications from the steroid injection appears to be low. A small randomized trial has shown complete resolution of vertigo symptoms in 82% of patients receiving dexamethasone, compared with 57% receiving saline injection.[152] Dexamethasone injections may need to be repeated every 3 months to maintain the patient free of vertigo symptoms, although the optimal dosing frequency is variable and unknown. Concentrations used have varied from 2 to 24 mg/mL.

Endolymphatic Sac Surgery

Surgical decompression of the endolymph for Meniere's disease was first described by Portmann in 1926.[10] During the more than three fourths of a century during which this technique has been practiced, numerous variations on the concept have been devised. Despite significant investigation into techniques to decompress the endolymph, the etiology of endolymphatic hydrops as part of the pathophysiology of Meniere's disease is still an active area of controversy and debate. Several theories have been proposed: release of external compression on the sac, neovascularization of the perisaccular region, allowing passive diffusion of endolymph, and creation of an osmotic gradient out of the sac.[153]

Several variations of endolymphatic sac surgery have been described. Simple decompression, wide decompression that includes the sigmoid sinus,[154] cannulating the endolymphatic duct, endolymphatic drainage to the subarchnoid space, drainage to the mastoid, and removal of the extraosseous portion of the sac[155] all have been advocated. A variety of prostheses also have been proposed, ranging from simple Silastic sheets to tubes and one-way valves designed to allow flow selectively in either the mastoid or the subarachnoid direction.

In a double-blind, placebo-controlled study by Thomsen and coworkers, a mastoidectomy alone had the same efficacy as that of an endolymphatic shunt in a group of 30 patients, with 15 randomly selected for each operation.[17] The efficacy of the procedure remains controversial, with other workers re-examining the data of Thomsen and colleagues and claiming that a significant result would have been found if a different criterion for success had been used[156] or if different statistical methods were applied.[18]

Nerve Section

Several approaches to sectioning of the vestibular nerve have been described. The earliest approach was the retrosigmoid, with the first large series accumulated by Walter Dandy in the 1930s.[11] The terms *retrosigmoid* and *suboccipital* are now used interchangeably. The middle fossa approach to the internal auditory canal and superior vestibular nerve was developed by William House[157] and later modified to include sectioning of the inferior vestibular nerve.[158] A retrolabyrinthine approach has also been described.[159]

Vestibular nerve section achieves a complete vertigo control rate of approximately 85% to 95%, with 80% to 90% of patients maintaining their preoperative hearing after the procedure.[160-162] The procedure offers much greater vertigo control rates than those reported for endolymphatic shunt procedures but also is more invasive and technically challenging. Vestibular nerve section has been argued to carry a lower risk of hearing loss when compared with gentamicin injection,[161] although the risk of hearing loss with gentamicin seems to be most significant with high-dose protocols.

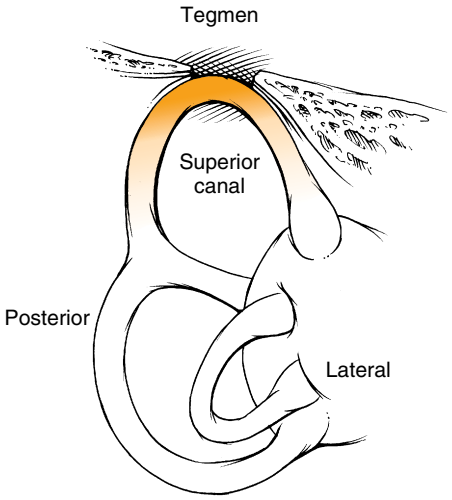

Figure 165-6. Superior canal dehiscence. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

Labyrinthectomy

The most destructive procedure for treatment of Meniere's disease is labyrinthectomy, owing to the uniform destruction of hearing and vestibular function. Ideal candidates for the procedure are pateints who have no functional hearing and in whom more conservative treatments such as gentamicin injection have failed. Despite the associated morbidity, the procedure has a higher rate of vertigo control than that typical for vestibular neurectomy[163] and has been reported to improve quality of life in 98% of operated patients.[164] The procedure is most commonly performed through a transmastoid exposure but can be done using a transcanal approach.

Superior Canal Dehiscence Syndrome

Superior canal dehiscence syndrome (SCDS)[27] is the result of the absence of bone over the superior canal (Fig. 165-6). This bony dehiscence creates a third mobile window that allows the abnormal movement of endolymph during presentation of loud sounds (Tullio phenomenon[165]), tragal compression, nose-blowing, or other mechanisms for creation of a pressure gradient between the ear and middle fossa. Loud sound or increased pressure often causes nystagmus in the same plane as that of the superior canal on the affected side.[166] The nystagmus is a combination of vertical and torsional rotation aligning with the superior canal, as predicted by Ewald's first law.[167] When gaze shifts 45 degrees toward the side of the dehiscence, the pupil will move in a vertical direction. During gaze 45 degrees in the contralateral direction, the eye will rotate about an axis through the pupil. The Tullio phenomenon is not observed in all cases of SCDS. In addition to dizziness and nystagmus, SCDS may be characterized by autophony (sensation of increased loudness of the patient's own voice), conductive hearing loss that is not due to middle ear pathology, or pulsatile tinnitus.[168] High-resolution CT scans with reconstructions in the plane of the superior canal and orthogonal to that plane should be done to confirm the diagnosis.

The pathophysiology of superior canal dehiscence can be understood in terms of the effects of the dehiscence in creation of a third "mobile window" into the inner ear. Under normal circumstances, sound pressure enters the inner ear through the stapes footplate in the oval window and, after passing around the cochlea, exits through the round window. The presence of a dehiscence in the superior canal allows this canal to respond to sound and pressure stimuli. The direction of the evoked eye movements supports this mechanism. Loud sounds, positive pressure in the external auditory canal, and Valsalva maneuver against pinched nostrils cause ampullofugal deflection of the superior canal, which results in excitation of afferents innervating this canal. The evoked eye movements can include a nystagmus that has slow components directed upward with torsional motion of the supe-

rior pole of the eye away from the affected ear. Conversely, negative pressure in the external canal, Valsalva maneuver against a closed glottis, and jugular venous compression cause ampullopetal deflection of the superior canal, which results in inhibition of afferents innervating this canal. The evoked eye movements typically are in the plane of the superior canal but in the opposite direction (downward with torsional motion of the superior pole of the eye toward the affected ear) (Fig. 165-7).

The severity of a patient's symptoms and the impact of these symptoms on lifestyle are major determinants in the discussion of surgery for superior canal dehiscence.[168] Some patients are discovered to have SCDS as an incidental finding on CT scan and do not have symptoms. In other patients, only autophony or conductive hearing loss may be noted. A decision about surgical plugging of the superior canal to alleviate symptoms should be based on the impact of symptoms on a patient's lifestyle and a consideration of the risks of surgery.

Confirmation of dehiscence of bone overlying the superior canal in patients with the syndrome has been obtained with high-resolution CT scans of the temporal bones.[28,169-171] Conventional temporal bone CT scans are performed with 1.0-mm collimation, and images are displayed in the axial and coronal planes. These scans have a relatively low specificity (high number of false-positive results) in the identification of superior canal dehiscence because of the effects of partial volume averaging. The specificity and positive predictive value of these scans are improved when 0.5-mm-collimated helical CT scans are performed with re-formation of the images in the plane of the superior canal.[171] The scans also are reformatted radially around the canal in the plane perpendicular to the superior canal, so that the cross section of the canal can be evaluated (Fig. 165-8). Of note, even the best CT scan may be misleading, because very thin bone may be below the resolution of the scanner; accordingly, diagnosis should never be based on the CT scan alone.

CT studies have shown that the thickness of bone overlying the intact superior canal in a patient with unilateral dehiscence is significantly thinner than in patients without superior canal dehiscence.[172] This finding and observations from a review of 1000 histologically

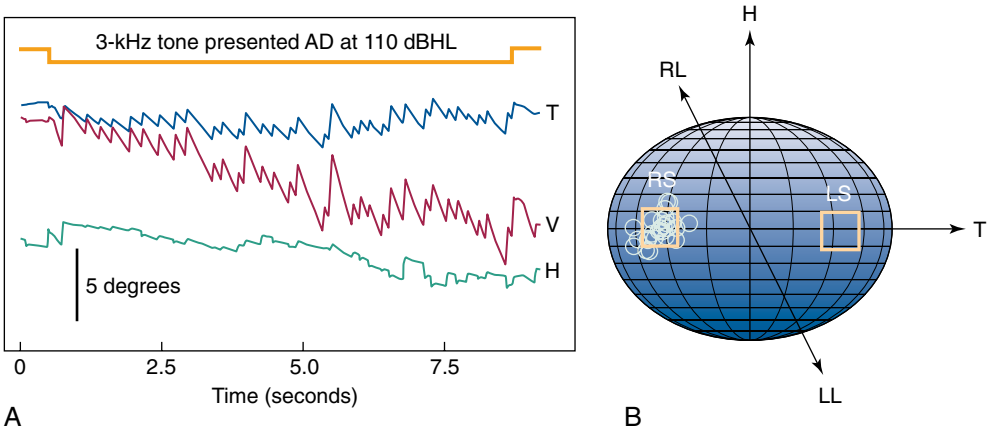

Figure 165-7. Ocular responses to sound in the superior canal dehiscence (SCD) syndrome. Nystagmus induced by a 3-kHz tone at an intensity of 100 dB in the right ear (AD [*auris dextra*]) of a 33-year-old woman with right SCD syndrome. **A,** Torsional (T), vertical (V), and horizontal (H) eye position recorded with the scleral search coil technique from the right eye. The time during which the tone was presented is indicated by the *yellow bar* at the top. Positive direction for horizontal is left, vertical is down, and torsional is clockwise (from the patient's perspective, so rotation of the superior pole of the patient's eye is to the patient's right). In response to the tone in her right ear, the patient developed a nystagmus with upward, counterclockwise slow phases consistent with excitation of the right superior canal. **B,** The axis of slow-phase eye velocity corresponded to the data plotted in **A.** The sphere represents the patient's head, as viewed from the right. The positive direction of the horizontal axis (H) travels upward from the top of the head, the torsional axis (T) straight ahead from the patient's nose, and the vertical axis (obscured by the sphere) from the patient's left ear. The anatomic axis of each of the right superior (RS), left superior (LS), right lateral (RL), and left lateral (LL) semicircular canals is shown. The box around the axis of each superior canal indicates the region (±2 SD) from the mean orientation of that axis. Each *light circle* represents the mean eye velocity axis for one slow phase of nystagmus. *(Reproduced with permission from Minor LB, Cremer PD, Carey JP, et al. Symptoms and signs in superior canal dehiscence syndrome.* Ann N Y Acad Sci. *2001;942:259-273.)*

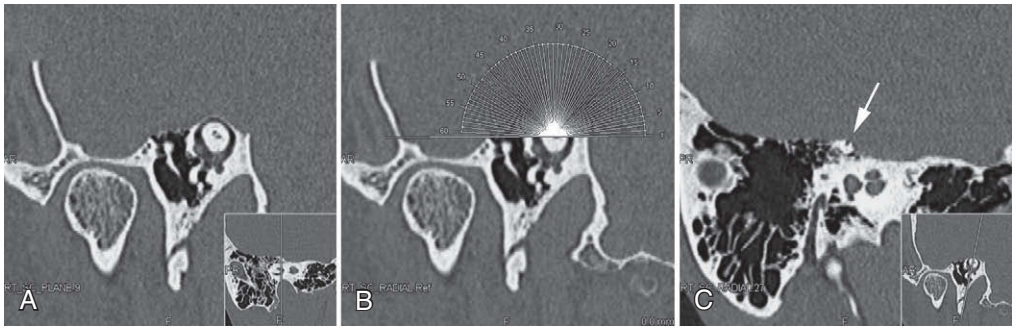

Figure 165-8. Computed tomography (CT) of the right superior semicircular canal demonstrating dehiscence. **A,** CT image is reconstructed in the plane of the torus of the right superior canal. **B,** The center of the superior canal is identified, and radial orthogonal reconstructions are performed at 3-degree intervals. **C,** The radial reconstructions are sequentially examined along the course of the superior canal, and dehiscence in the canal is identified if bone does not appear to completely cover the canal *(arrow)*. The *inset* at lower right in **A** and **C** shows the plane of section of this radial reconstruction relative to the superior canal plane.

processed temporal bones sectioned in a plane parallel to the petrous ridge[173] suggest an underlying developmental or congenital abnormality that leads to the development of the syndrome. The onset of symptoms and signs associated with this syndrome typically has been during adulthood. Patients in whom a normal thickness of bone fails to develop may then acquire the syndrome when the abnormally thin layer of bone is disrupted by trauma or is eroded over time as a consequence of the pressure from the overlying temporal lobe.

Vestibular evoked myogenic potentials (VEMP) responses have been useful in assessing for the presence of superior canal dehiscence syndrome.[174-176] In this test, short-latency relaxation potentials evoked by clicks or by tone bursts are recorded from surface EMG electrodes placed on the skin over the ipsilateral sternocleidomastoid muscle while that muscle is tonically contracted. These responses arise from the vestibular end organs, most likely the sacculus.[177,178] The threshold for eliciting the VEMP response is lower in an ear affected with superior canal dehiscence than in a normal ear.[174,176]

Some patients with the vestibular symptoms and signs indicative of superior canal dehiscence syndrome also have been noted to have auditory manifestations of the disorder. The Weber tuning fork test typically lateralizes to the affected ear, and patients also may hear a tuning fork placed on the lateral malleolus of the foot.[168,179] Patients may present with seemingly bizarre complaints, such as "hearing" their eye movements or their pulse. Bone conduction thresholds on audiometry can be below 0 dB normal hearing level (NHL). Therefore, an air-bone gap may be present even when air conduction thresholds are normal.[180] This conductive hearing loss may be caused by formation of a third window by the dehiscence, which causes a dissipation of acoustic energy transmitted through air conduction mechanisms. For some patients, autophony or a disturbing sound of their own voice can be the primary symptom.[181] The clinical manifestations of superior canal dehiscence include vestibular signs and symptoms in some patients, vestibular and auditory abnormalities in others, and exclusively auditory findings in others.

Patients who experience only mild effects of the symptoms and signs associated with superior canal dehiscence may not require any specific treatment other than avoidance of the stimuli that evoke these effects. Placement of a tympanostomy tube may be beneficial in some patients with principally pressure-induced symptoms. For patients who are debilitated by symptoms associated with the syndrome, surgical repair of the superior canal dehiscence by plugging the superior canal through a middle cranial fossa approach can be effective in alleviating or attenuating the vestibular signs and symptoms.[28,182]

Cogan's Syndrome

Cogan's syndrome was first described in 1945 and is characterized by interstitial keratitis, "low-frequency unilateral" hearing loss, and vestibular symptoms as well as nonreactive tests for syphilis.[183] The syndrome was later divided into typical and atypical forms on the basis of specific ocular findings.[184] The typical form includes interstitial keratitis, whereas the atypical form has ocular features of scleritis, episcleritis, papilledema, and retinal detachment.[185] Ten percent of patients with Cogan's syndrome have the atypical form. Multisystem involvement, including CNS manifestations and inflammatory vascular disease, is a feature of Cogan's disease. Of the two forms, systemic features are noted more commonly in atypical Cogan's disease. In the typical form, the heart and lungs are the usual site of systemic involvement, including aortitis, pleuritis, pericardial effusion, coronary arteritis, and myocardial infarction. In atypical Cogan's disease, systemic features arise from a systemic vasculitis (e.g., polyarteritis nodosa, arthritis, glomerulonephritis, gastrointestinal problems).

Ocular and inner ear changes appear concurrently or within 6 months of each other. Ocular complaints include photophobia, blurred vision, lacrimation, and pain. These symptoms and signs may be unilateral or bilateral. Onset usually is sudden, and resolution is gradual. Recurrences over years are not uncommon. Ocular pathologic changes include infiltration of the cornea with lymphocytes and plasma cells as well as corneal neovascularization.

Balance-related symptoms are similar to those of Meniere's disease and consist of sudden attacks of true vertigo with ataxia and vegetative symptoms. Progression to the complete absence of vestibular function, manifested by ataxia and oscillopsia, is common.

Hearing loss is sensorineural in type and is bilateral in 44% of patients.[186] The loss is progressive without spontaneous improvement, frequently becoming profound. In bilateral cases, hearing loss frequently begins on one side.

Cogan's syndrome is thought to be of autoimmune basis. This suspected etiology is based on lymphocyte transformation tests, migration inhibition to inner ear tissues, the association with rheumatologic diseases, and presence of lymphocytes and plasma cells in the ear and eye, as well as the clinical response to systemic steroids.

Clinically, patients often report having had an upper respiratory infection within 7 to 10 days of initial onset of Cogan's syndrome.[184] Raised IgG and IgM titers to *Chlamydia* are reported in association with active Cogan's syndrome. Furthermore, antibody titers are noted to decrease with remission of disease. For this reason, it has been suggested that an acute infection, perhaps with *Chlamydia*, promotes sensitization of the immune system to "self" and leads to immune-mediated disease.[184]

Systemic corticosteroids are the accepted treatment. An initial dose of 1 mg/kg per day of prednisone usually is recommended, followed by a slow taper. The probability of hearing improvement is thought to be better the sooner the steroids are started.[185] In addition, cyclophosphamide and methotrexate have been recommended by some authorities if systemic vasculitis is present.

Otosyphilis

Syphilis is a sexually transmitted disease that can become disseminated and affect almost any organ system. Although it is thought to be a rare condition in the modern era, the diagnosis is difficult to confirm, and many cases may be misdiagnosed as other conditions.[187] Thirty percent of patients suffering from congenital syphilis and 80% of symptomatic neurosyphilis patients experience significant hearing loss.[188]

Otologic involvement can be grouped into two categories: early syphilis, symptoms occurring within 2 years of exposure, and late otosyphilis, when the disease becomes symptomatic after 2 years. Vestibular symptoms are less frequent in early otosyphilis; they most commonly manifest as a sudden hearing loss. Late otosyphilis presents similar to Meniere's disease with episodes of vertigo combined with progressive hearing loss and tinnitus, which often is unilateral.[185,189] Late-stage otologic syphilis, whether acquired or congenital syphilis, can manifest up to 50 years or more after exposure. Systemic symptoms frequently overshadow the otologic ones and include signs of meningitis. In the case of early congenital syphilis, systemic involvement may prove to be fatal.

Interstitial keratitis is a feature of 90% of patients with late-onset otologic syphilis, whether congenital or acquired. The triad of sensorineural hearing loss, interstitial keratitis, and notched incisors—*Hutchinson's triad*—is an exclusive feature of late congenital syphilis.[188]

Hennebert's sign (nystagmus and vertigo produced by pressure change on the ear, thought to be due to deformation of a softened, gummatous otic capsule) and Tullio phenomenon (nystagmus and vertigo caused by loud noise), although often encountered in syphilis, are not pathognomonic for the disease and also are common findings in superior canal dehiscence.

The Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) nontreponemal tests are easily performed and relatively inexpensive. Sensitivity varies with the stage of disease. In view of the fact that otologic symptoms occur in late-stage disease, nontreponemal tests detect only 70% of cases of otosyphilis.[190] These tests are useful in following therapeutic response, by change in titer and loss of reactivity. On the other hand, treponemal tests—such as free treponemal antigen absorption, FTA-ABS, and microhemagglutination *Treponema pallidum* [MHATP] assays, which detect the presence of the organism—are far more sensitive; these tests detect 95% or more of cases of late-stage disease. The FTA or MHATP and their variations are the tests of choice for the detection of otologic syphilis.[190] Lumbar puncture is not necessarily warranted because results are positive in only 5% of cases of otosyphilis.[185]

Treatment of otologic syphilis varies. Some investigators feel that in the early stages of the disease, treatment with antibiotics alone (i.e.,

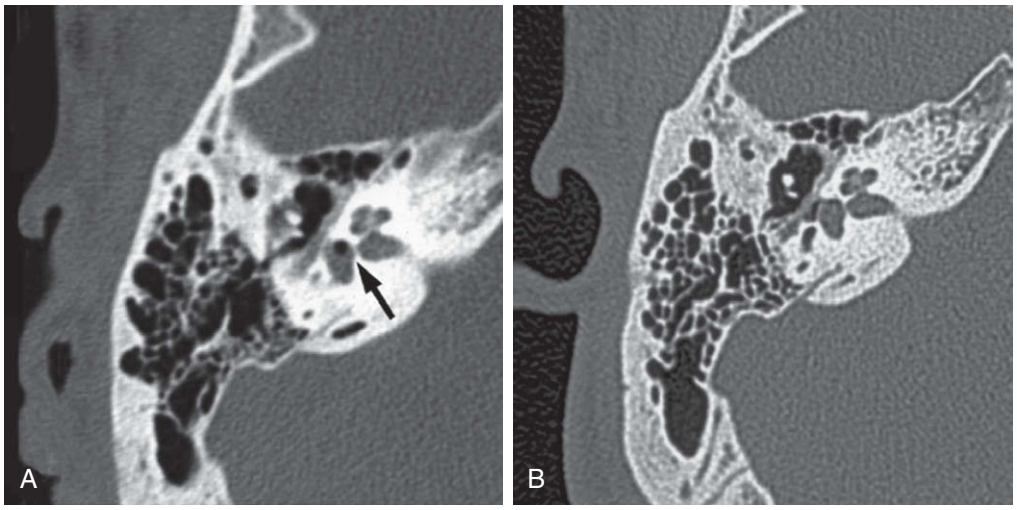

Figure 165-9. **A,** Axial CT scan of the temporal bone of a 15-year-old patient in whom pneumolabyrinth developed immediately after penetrating trauma to the left ear. This patient also presented with vertigo, a mixed hearing loss, nausea, and vomiting. The vestibular and auditory symptoms resolved with conservative management in the days after the injury, and no air was seen on a CT scan obtained 4 days later **(B)**. Within 5 months of the event, sensorineural hearing improved by 40 dB. *(Reproduced from Lao WW, Niparko JK. Assessment of changes in cochlear function with pneumolabyrinth after middle ear trauma.* Otol Neurotol. *2007;28:1013.)*

penicillin 2.4 million units IM) provides a cure, frequently resulting in hearing improvement.[188] Additional use of a 10-day course of steroids is advocated. Although consensus is lacking regarding exact drug treatment for late-stage disease, it generally is agreed that protracted therapy with both antibiotics and steroids is indicated. Difficulty in eradication of the infection, despite adequate antibiotic therapy, is ascribed to prolonged dividing time for the treponeme in late-stage disease. Antibiotic regimens of variable duration have been suggested. A recommended neurosyphilis treatment protocol consists of 1.8 million units of penicillin IM daily with 500 mg of oral probenicid four times daily for 3 weeks. It is suggested that otic syphilis and neurosyphilis are comparable with respect to response to treatment.[188] Prenisone (40 to 60 mg per day) is given for at least 2 weeks before tapering. Steroids are used in part to minimize the potential damage to the ear by the inflammatory response in the early treatment of syphilis. Improvement in hearing, particularly of speech discrimination, is noted in 35% to 50% of cases, along with resolution of vestibular symptoms.[188]

Perilymph Fistulas

Inner ear fistulas are abnormal communications between the labyrinth and surrounding structures. The labyrinth normally is covered by dense bone. Labyrinthine fistulas can be organized into three main categories: (1) leakage of perilymph from the inner ear to the middle ear, (2) disruption of the bony labyrinth by disease such as cholesteatoma, and (3) idiopathic bony dehiscence of the semicircular canals (i.e., superior semicircular canal dehiscence syndrome and posterior canal dehiscence). These disorders manifest with similar symptoms of hearing loss and episodic vertigo despite their differing etiology.[191] Idiopathic bony dehiscence of the semicircular canals creates problems of pressure transfer, as noted previously, but not fluid mixing.

The clinical presentation of inner ear fistula may range in severity from mild and inconsequential to severe and incapacitating. Sensorineural hearing losses vary from an isolated high-frequency loss to a low-frequency or flat one. Speech discrimination test results are not characteristic. Both the pure-tone threshold and speech discrimination scores have been noted to fluctuate. Isolated mild conductive losses have been noted.[192] Glasscock and colleagues, in a series of patients who had undergone surgical exploration for fistulas, were unable to identify differences in audiometric profile for patients with proven fistulas and those without.[193] Vestibular symptoms also are variable and may include episodic incapacitating vertigo (equivalent to a Meniere's disease attack), positional vertigo, motion intolerance, or occasional dysequilibrium. (Disequilibrium with increases in CSF pressure such as with nose blowing or lifting has been noted, as has Tullio's phenomenon (occurrence of vertigo during) exposure to loud noises).

Definitive leakage of perilymph from the inner ear to the middle ear can be caused by trauma[194] or may be noted after stapedectomy.[195] Spontaneous fistulas are rare except in cases of Mondini malformation and other congenital abnormalities.[196] CT may reveal pneumolabyrinth[194] (Fig. 165-9). In definitive cases of leakage, patching with a tissue graft can achieve the goal of hearing preservation and relief of vertigo, although even definitive cases can resolve with conservative management and without surgery.[194] However, many cases of vertigo or hearing loss alleged to be caused by perilymph fistula are much more ambiguous, with equivocal surgical findings.[197-199]

A fistula can be through fissula ante fenestram, or a fissure from the round window niche with the ampulla of the posterior canal may be seen. Fissures in these areas tend to be common, and their clinical significance is not clear.[200] It is difficult to ascertain whether small amounts of fluid seen during surgical exploration are truly perilymph. An assay for beta-2 transferrin (a protein unique to cerebrospinal fluid) has been suggested, but it has a low sensitivity for detection of small amounts of fluid.[201]

The absence of observed leakage during surgery has been interpreted to mean either that no fistula exists, that the fistula may be intermittent, or that the fistula may be present but too small to be detected. In cases of negative findings on exploration, it is unclear if patching of the oval and round windows is of any value. Criteria for determining when a middle ear exploration for perilymph fistula may be beneficial have been difficult to establish, because no definitive test is available to make the diagnosis and interobserver concordance is low.[202] Applying pressure in the external auditory canal to see if eye movements are evoked (Hennebert sign) has been used. Measuring postural sway during pressure to the external auditory canal also has been proposed as a diagnostic test for fistula.[202] Even if a fistula exists, spontaneous resolution may occur. Recently, many patients who initially were diagnosed with fistulas have been found to have superior canal dehiscence.[191]

Chronic ear disease can cause a bona fide fistula. Long-standing otitis media can lead to cholesteatoma formation, with consequent erosion of the dense bone around the labyrinth. Patients in whom fistulas develop usually have a multiyear history of chronic ear disease, sometimes requiring several operations. In a recent review of 375 surgical procedures done for chronic otitis media, labyrinthine fistulas were

identified in 29 cases, 25 of which involved canal-wall-down mastoidectomies.[203] The overall incidence of fistulas after canal-wall-down mastoidectomies was 13%. All of these patients experienced vertigo symptoms. However, of the 19 tested, only 14 exhibited a Hennebert sign with positive pressure. The horizontal semicircular canal was the most common site of fistula formation (76%), followed by oval window and promontory. In these cases, surgical closure of the fistula is recommended.

Trauma

Vertigo and ataxia are common sequelae of head trauma. Vestibular-related complaints can arise from cervical trauma and CNS trauma, as well as peripheral vestibular damage. Only symptoms resulting from peripheral vestibular damage are considered here. Mechanisms by which damage can be inflicted include blunt concussive trauma, penetrating trauma, explosive blast, and barotrauma. Similar lesions can result with different mechanisms of injury. Hence, labyrinthine concussion can follow blunt trauma as well as barotraumas.

Nonpenetrating Trauma

Labyrinthine Concussion

Injuries of the labyrinth that do not result in violation of the otic capsule or the intralabyrinthine limiting membranes are classified as *labyrinthine concussion*.

Vestibular-related symptoms, although variable and not well characterized, generally are thought to include mild vertigo, imbalance, visual confusion, and vegetative symptoms (e.g., nausea and vomiting). These symptoms typically are short-lived and gradually subside over a period of days to weeks. Examination of the patient with active symptoms may demonstrate nystagmus directed toward the side of the lesion acutely (i.e., over hours), followed by more typical contralateral beating nystagmus. Past pointing and falling in the direction of the slow phase of nystagmus have been reported. Vestibular testing may demonstrate a reduction in the caloric response and abnormality of vestibulo-ocular reflex gain and phase after rotational testing.[204]

Benign positional vertigo also is a common sequel of blunt head trauma.[204] Diagnosis and management of this entity are discussed earlier in this chapter.

Hearing loss and tinnitus often are reported. When present, the most common pattern of hearing loss is similar to that of a noise-induced hearing loss, with a loss most apparent at 4 kHz.[205]

Both the vestibular and the auditory complaints usually are transient, with spontaneous resolution occurring over a matter of days to weeks.[204] However, symptoms also have been reported to persist and worsen over time.

Blast Trauma

Explosive blasts can produce pressure waves greater than 200 dB sound pressure level (SPL).[206] The ear, which exists to capture and amplify this energy, frequently is injured when exposed to such a noise. Blast trauma would include that incurred by such mechanisms as an open-handed slap to the ear, as well as actual explosions. Perforation of the tympanic membrane, ossicular disruption, or both may occur; however, inner ear damage is more likely when the conductive mechanism remains intact. Auditory loss is common and often recovers spontaneously but can be permanent.[207] Dizziness is present in 15% of patients.[208]

Penetrating Trauma

Acute vertigo and sensorineural hearing loss heralds inner ear damage. Nystagmus beats in the direction of the healthy ear owing to the acute loss on the affected side. Vegetative symptoms typically are present. Vertigo will gradually subside over the ensuing days to weeks. Hearing loss, when present, can range in severity from mild and transient to profound and permanent.

Barotrauma

Damage to the inner ear resulting from pressure changes is known as barotrauma. Historically thought to be a fairly rare problem, barotrauma is now believed to be a fairly frequent injury among divers. Inner ear dysfunction can be produced by rapidly changing air pressure, as in atmospheric barotrauma, by elevated or asymmetric middle ear pressure, as in alternobaric trauma, or by bubble formation within the labyrinth or its blood supply in the case of inner ear decompression sickness and isobaric gas counter diffusion sickness.

Alternobaric vertigo is most prominent in divers during ascent to the surface and in fliers during ascent of the aircraft. Both scenarios involve decreasing ambient pressure. Vertigo is relieved by equilibration of middle ear–ambient pressure differences, as well as by repressurization (i.e., by descending several meters in the case of divers). As many as 26% of divers and 10% to 17% of pilots have admitted to experiencing alternobaric-like vertigo.[209]

Susceptibility to alternobaric vertigo is thought to be a consequence of individual variations in the pressure required within the middle ear to force open the eustachian tube. Conditions that alter eustachian tube patency (e.g., mucosal turgescence) such as upper respiratory infection are known to contribute. The effects of alternobaric trauma on the inner ear are temporary. In most cases, vertigo, hearing loss, and tinnitus are described as resolving in 10 to 15 minutes. The occurrence of alternobaric trauma can be minimized by frequent equilibration of middle ear pressure during diving, the use of topical nasal decongestants before the dive, and the avoidance of diving during periods of increased upper respiratory obstruction (e.g., upper respiratory infection, sinusitis).[210]

Atmospheric barotrauma is caused by extremes of pressure or abrupt changes in middle ear pressure, which are capable of damaging middle ear and inner ear structures. Damage to the latter is reflected by auditory and vestibular dysfunction. As opposed to alternobaric trauma, barotraumatic injury frequently is long-lasting or permanent. Hearing loss and tinnitus are universal complaints, whereas vertigo tends to be less common (35%) and rarely is the primary complaint.[211] When present, vertigo resolves within a few weeks even without treatment. The hearing loss ranges in severity from a mild, high-frequency sensorineural type to complete deafness. Suggested treatment of inner ear barotrauma is similar to that recommended for perilymph fistula. Bed rest, head elevation, and close monitoring of hearing and balance-related symptoms are suggested. Symptoms usually resolve spontaneously in a matter of hours to days with conservative management.[212]

Inner ear decompression sickness (IEDS) has become more common as a consequence of the increased use of mixed gas, oxyhelium, for deep water diving. Although damage produced by these disorders is not restricted to the inner ear, it now represents the most common decompression injury experienced by persons diving to depths greater than 100 m.[213] In a recent series it was found to account for 33% of diving-related ear injuries.[214] In IEDS, vertigo is almost always the primary symptom, and hearing loss when present usually is unilateral and often manifests later, after the vertigo begins to resolve.[211] Otologic symptoms often are the sole feature of decompression sickness, particularly in cases in which oxyhelium is used. When the inner ear is affected, vestibular and auditory dysfunction often is permanent, particularly if treatment is delayed. One study claims that significant improvement is achieved only when hyperbaric oxygen therapy is started within 68 minutes.[215] In some reports, however, improvement has been obtained when hyperbaric oxygen was started 24 hours after the injury.[211]

Familial Vestibulopathy

The rare syndrome of familial vestibulopathy with autosomal dominant inheritance is characterized by sudden attacks of vertigo followed by chronic dysequilibrium. The vertigo typically lasts on the order of minutes, with several hours of subsequent dysequilibrium. These spells recur at variable intervals for many years. Some patients have reported that spells seemed to be triggered by stress. Patients also have described the gradual onset of chronic dysequilibrium and oscillopsia due to vestibular insufficiency.[216] Auditory symptoms including tinnitus are absent. It is notable that all affected persons also experience migraine headaches, although headache was not associated with the spells of vertigo. An autosomal dominant mode of inheritance was defined.

Findings on quantitative testing in these patients include imaging results that are normal except for bilateral vestibular responses on caloric testing and low gains with shortened time constants on rotary testing—all of which are consistent with damage to the peripheral vestibular system.

In all cases, spells of vertigo were successfully terminated with the administration of acetazolamide. The mechanism of action in this case is unknown; however, in a seemingly related condition, familial periodic vertigo and ataxia, the acetazolamide effect is presumed to be that of a reduction in acidity of the brain.

More recently, another familial syndrome associated with migraine headaches, essential tremor, and vertigo was identified.[217] In this syndrome, vertigo lasts minutes to hours. As in the familial vestibulopathy already described, headaches were unassociated with the spells of vertigo. Spells were triggered by stress, exercise, and lack of sleep. The long-term progressive vestibular deficit noted in the familial vestibulopathy syndrome was not noted in this latter disease. As in the former disease, acetazolamide was proved to be effective at curtailing spells of vertigo as well as the migraines. Although clustering of migraine and episodic vertigo occurs in many families, the search for a single gene remains elusive. It is likely that multiple genes and possible environmental factors are responsible.[218]

Migraine itself may contribute to permanent damage of the vestibular end organs. (Migraine-associated vertigo is discussed in Chapter 166). However, the disorder also may have a peripheral component in some patients. Caloric paresis in patients with migraine occurs at a rate of 15% to 35%.[218,219] Vasospasm and small artery infarction have been suggested as potential mechanisms.[220]

Bilateral Vestibular Hypofunction

Bilateral loss of vestibular function leads to oscillopsia with head movements, as well as to disturbances of gait of variable severity. Hypofunction most commonly is induced by the vestibulotoxic effects of aminoglycoside medications. In 1952, a physician published a classic description of the symptoms of vestibular hypofunction that developed 2.5 months into a course of intramuscular streptomycin injections to treat sepsis of his right knee.[221] He also described oscillopsia and dysequilibrium of sudden onset and worsening over 2 to 3 days. By then he had to stabilize his head on bars in order to read, because even his pulse induced enough head motion to produce oscillopsia. His balance improved as he learned how to use visual and somatosensory information to make up for his loss of vestibular function.

It is estimated that vestibular injury develops in up to 3% of patients who receive gentamicin.[222] The vestibulotoxicity usually is not detected until the patient leaves the hospital and does not correlate with peak or trough levels or with dosage levels.[223,224] A genetic predisposition to increased sensitivity for aminoglycoside toxicity has been identified as linked to mutation of a mitochondrial ribosomal protein.[225] Thus, aminoglycosides are not recommended when an alternative is practical. If gentamicin is used, bedside tests of vestibular function including assessment of dynamic visual acuity and the head thrust test should be performed daily, when feasible, so that the medication may be stopped at the first signs of vestibulotoxicty.[226]

Other causes of bilateral vestibular loss include degenerative diseases of the cerebellum, meningitis, systemic autoimmune diseases, trauma, and bilateral Meniere's disease. No underlying cause is identified in approximately 20% of cases.[227]

Enlarged Vestibular Aqueduct

The vestibular aqueduct is an aperture in the posterior ridge of the petrous bone that contains the endolymphatic duct and sac. Enlargement of this structure probably occurs as a result of dilation of the endolymphatic duct during embryogenesis.[228] Patients usually present with hearing loss that begins in early childhood and often progresses with minor head trauma. The onset of vestibular symptoms in these patients often is delayed until adulthood, with episodes of vertigo that last between 15 minutes and 3 hours.[229] Childhood vestibular symptoms also have been described.[230] On testing, patients have been found to have impaired vestibulo-ocular reflex function and decreased VEMP thresholds.[231] Diagnosis is based on the CT finding of a vestibular aqueduct width greater than 1.5 mm at the midpoint; in most patients, this is similar to the width of the horizontal semicircular canal (Fig. 165-10). Experience in treatment of vertigo associated with enlarged vestibular aqueduct has been limited, but symptomatic and supportive treatment is suggested.

CHAPTER ONE HUNDRED AND SIXTY-SIX

Central Vestibular Disorders

Benjamin T. Crane

Scott D. Z. Eggers

David S. Zee

Robert W. Baloh

Key Points

- Determining a central versus a peripheral origin for vertigo requires a careful assessment of symptoms and presenting circumstances, as well as physical findings.
- Appreciation of migraine as a common etiologic disorder in patients presenting with dizziness and other vestibular symptoms is essential to optimal clinical management of this highly prevalent disorder.
- The diagnosis of migraine-associated vertigo relies critically on the history and can be substantiated by monitoring the response over time to diet manipulation and medical management.
- Effective, definitive treatment of migraine-associated vertigo requires the patient's understanding of the importance of lifestyle modification to promote compliance.
- Migraine-associated vertigo is best treated with beta-blockers, tricyclic antidepressants, serotonin reuptake inhibitors, or anticonvulsants.
- Meniere's disease and benign paroxysmal positional vertigo (BPPV) are commonly associated with migraine.
- Vascular disorders are a common cause of vertigo in the elderly population.
- Several types of strokes can manifest with vertigo but almost always are associated with multiple neurologic deficits.
- Neoplasms can manifest with vertigo; vestibular schwannoma is the most likely tumor to present with this symptom, although tumors in the brain stem and cerebellum also can cause vertigo. Screening for neoplasm should be considered in patients with progression of symptoms, particularly when another cranial nerve or central nervous system disorder is present.
- Disorders of the craniovertebral junction can cause vertigo symptoms and should be considered when cervical motion is impaired or radiculopathy is suspected.
- The otolaryngologist should be aware that multiple sclerosis, normal pressure hydrocephalus, focal seizure disorders, and cerebellar ataxia syndromes can produce vertigo.

Dizziness can be classified into *vertigo* (a sense of motion, either of the person or of the visual surround), *dysequilibrium without vertigo*, *presyncope* (near-faint, lightheadedness), and *psychophysiologic dizziness* (often associated with extreme motion sensitivity, anxiety and panic, and phobic behavior). Dizziness, often with motion sickness, can occur in normal persons when they are exposed to unnatural patterns of motion—for example, during sea and car travel. Overlaid on all types of dizziness can be the psychological consequences of extremely distressing symptoms, and vice versa: Dizziness can be a symptom of a psychiatric disorder such as panic and anxiety syndromes and depression. Many conditions of central nervous system origin can cause each of these types of dizziness.

The first task of an otolaryngologist in examining a patient with dizziness is to determine if the symptom is of central or peripheral origin[1] (Table 166-1). Some central causes of acute vertigo can be life-threatening and may necessitate immediate intervention.[2] The differentiation can almost always be made by physical examination based on the type of nystagmus, result of head thrust test, severity of imbalance, and presence or absence of other neurologic signs.

Spontaneous nystagmus of peripheral origin typically is horizontal, or horizontal with a torsional component, and does not change direction with direction of gaze. Spontaneous nystagmus of central origin also can be purely horizontal but often is purely vertical or torsional and usually changes direction with changes in gaze.[1]

The *head thrust test* is performed as follows: The examiner grasps the patient's head and applies a brief, high-acceleration head rotation, first in one direction and then the other.[3] During these maneuvers, the patient fixates on the examiner's nose and the examiner watches for corrective rapid eye movements (saccades), which are a sign of decreased vestibular response (i.e., the eyes move with the head, rather than remaining fixed in space). If a "catch-up" saccade occurs after head thrusts in one direction but not in the other, a peripheral (including the labyrinth and the eighth cranial nerve on its course from the brainstem) lesion on that side is likely.

Patients with an acute peripheral vestibular lesion typically can stand but may demonstrate sway toward the side of a lesion. By contrast, patients with vertigo of central origin often are able to stand

Table 166-1

Differentiation of Central and Peripheral Vertigo

Feature	Central Origin	Peripheral Origin
Imbalance	Severe	Mild to moderate
Neurologic symptoms	Frequent	Rare
Nystagmus	Changes direction No change with fixation	Unidirectional Decreases with fixation
Hearing loss	Rare	Frequent
Nausea	Variable	Severe
Recovery	Slow	Rapid

Box 166-1

Diagnostic Criteria for Migraine

Migraine without Aura

A. At least five attacks fulfilling criteria B to D
B. Headache lasting 4 to 72 hours when untreated
C. Headache with at least two of the following characteristics: unilateral location, pulsating quality, moderate or severe intensity, aggravation by physical activity
D. During the headach, either nausea and vomiting or photophobia
E. Not attributable to another disorder

Typical Aura with Migraine Headache

A. At least two attacks fulfilling criteria B to D
B. Fully reversible visual, sensory, or aphasic aura symptoms with no motor weakness
C. At least two of the following: homonymous positive features or unilateral sensory symptoms; for at least one symptom, gradual development over more than 5 minutes; duration of 5 to 60 minutes for each symptom
D. Headache following aura after a symptom-free interval of less than 60 minutes
E. Not attributable to another disorder

without support. Associated neurologic signs such as dysarthria, incoordination, numbness, or weakness suggest a central origin.

Dizziness and vertigo can be caused by diverse pathologic conditions of the central nervous system (CNS). Differentiation of these disorders from those of peripheral labyrinthine origin requires familiarity with the associated signs and symptoms of CNS processes, their natural history, and their appearance. Definitive diagnostic evaluation and management usually involve cooperation with neurologists or neurosurgeons. A classification of CNS disorders associated with vestibular symptoms includes intracranial complications of suppurative otitis, vascular disorders, neoplasms, disorders of the craniovertebral junction, multiple sclerosis, familial ataxia syndromes, and focal seizure disorders.

Intracranial Complications of Otitic Infections

Epidural or subdural abscesses, as well as those of the temporal bone, petrous apex, or cerebellum, can cause vestibular signs and symptoms. Such processes usually are associated with other signs of infection, such as fever or sepsis, and are rare in the modern era of antibiotics.

Migraine

Migraine is characterized by recurrent headaches associated with nausea, vomiting, hypersensitivity to light, sound, and smell.[4] This clinical entity is an important consideration in the diagnosis because patients with migraine often present with dizziness. Neurologic aura symptoms are present in one third of migraine patients. Migraine affects nearly 25% of women, 15% of men,[5,6] and 5% of children.[7] In the prepubertal period, boys with migraine slightly outnumber girls, but at puberty, migraine decreases in boys and increases in girls, so that a 2:1 female preponderance is established by adulthood.[8] Migraine typically begins in young adulthood, with onset of symptoms after the age of 40 in only 10% of sufferers.

The diagnosis and classification of migraine and other headache disorders have been a controversial issue. The most recent effort of the Headache Classification Committee of the International Headache Society (IHS)[4] sets up criteria that allow meaningful comparisons of groups of patients between centers. The IHS classifies the most common type of migraine as migraine with and migraine without aura (Box 166-1); other classified types of migraine headache have been designated but are not considered in this chapter because they will only rarely be encountered by the otolaryngologist.

The definition of migrainous vertigo also has been controversial. Neuhauser and colleagues[9] proposed criteria for *definite migrainous vertigo* as follows: (1) episodic vestibular symptoms (rotational vertigo, other illusory self or object motion, positional vertigo, head motion intolerance) of at least moderate severity; (2) migraine according to IHS criteria; (3) at least one of the following migrainous symptoms during at least two vertiginous attacks: migrainous headache, photophobia, phonophobia, visual or other auras; and (4) other causes ruled out by appropriate investigations. *Probable migrainous vertigo* was the designation chosen for patients who did not meet definite criteria but were still believed to have migrainous vertigo as the most likely diagnosis. This definition requires criteria 1 and 4 from the foregoing list, plus at least one of the following: migraine according to IHS criteria; migrainous symptoms during vertigo; migraine-specific precipitants of vertigo (e.g., specific foods, sleep irregularities, hormonal changes); and response to antimigraine drugs. A diagnostic algorithm[10] for definite and probable migrainous vertigo (Fig. 166-1) has been proposed.

To elicit a history adequate to make the diagnosis, an understanding of the various components of the aura is essential. In descending order of frequency, these features are (1) scotoma or blind spots; (2) teichopsia, or fortification spectra (a zig-zag pattern in the visual field resembling a fort); (3) flashing or colored lights; and (4) paresthesias.

Vestibular Symptoms

Nonspecific Dizziness

Nonspecific dizziness occurs frequently in patients with either tension or migraine headaches and does not in itself differentiate between the two groups, although dizziness is more common and more severe in migraine sufferers.

Vertigo

Vertigo is extremely common in patients with migraine and occurred in 26.5% of Kayan and Hood's group of patients with migraine, compared with 7.8% of those with tension headache ($P < .001$).[11] Some studies have found the incidence of vertigo in classic migraine sufferers to be as high as 42%.[12] The severity of vertigo in patients with migraine tends to be greater than in those suffering from tension headaches. Vertigo severe enough for the patient to seek medical attention for relief occurred in 5% of those with migraine but in less than 1% of those with tension headache.[11]

The temporal relationship of vertiginous spells to migraine headaches is important to ascertain. Vertigo does not usually manifest as an aura immediately preceding the headache as a prodrome. Of the 53 patients with vertigo and migraine interviewed by Kayan and Hood,[11]

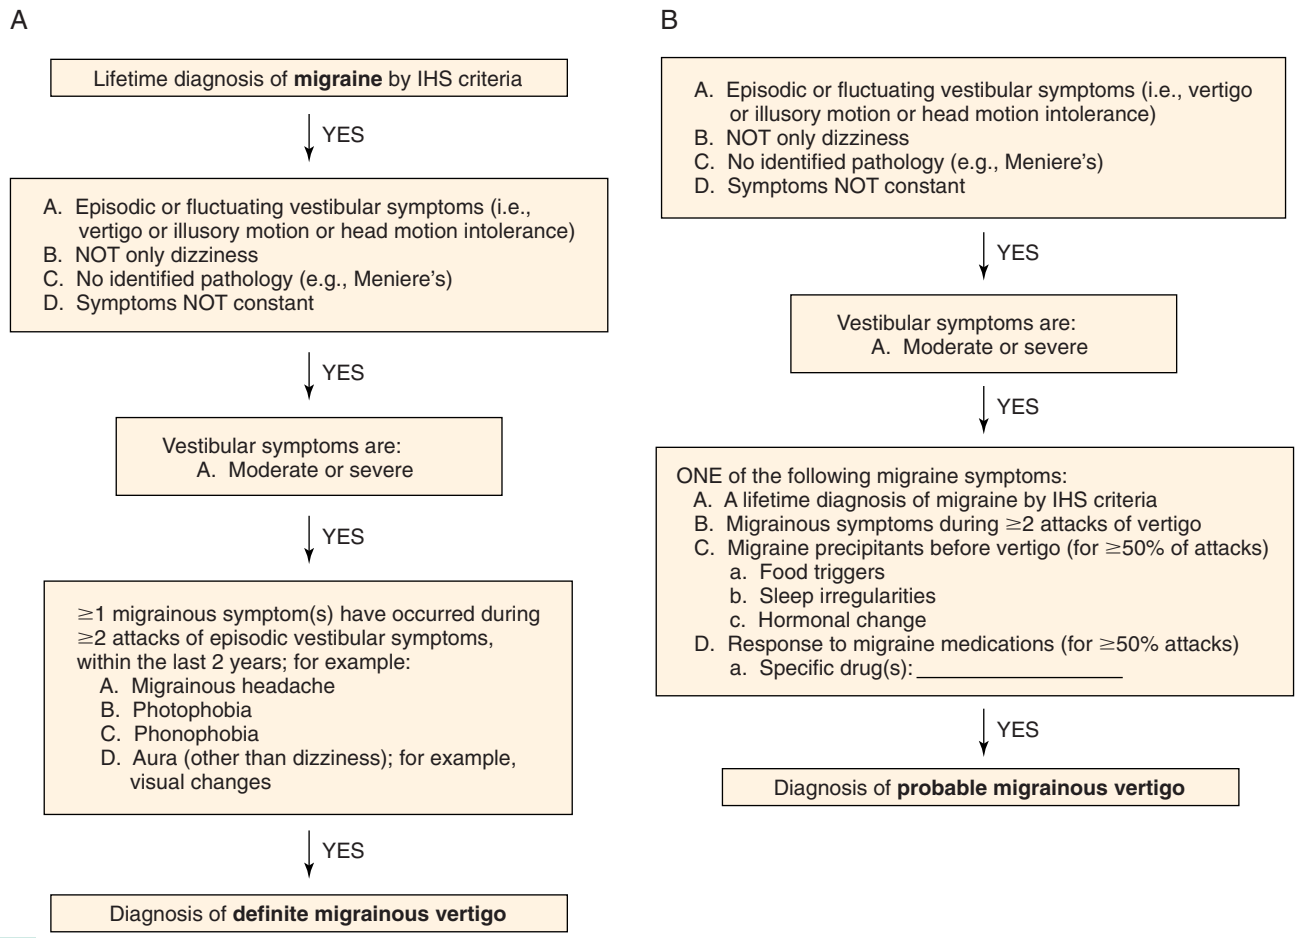

Figure 166-1. Diagnosis of definite (**A**) and probable (**B**) migrainous vertigo. "Moderate" vestibular symptoms interfere with daily activities, and "severe" vestibular symptoms prohibit daily activities. "Head motion intolerance" is the sensation of imbalance or illusory self or object motion provoked by head motion. IHS, International Headache Society. *(From Furman JM, Marcus DA, Balaban CD. Migrainous vertigo: development of a pathogenetic model and structured diagnostic interview.* Curr Opin Neurol. *2003;16:5-13. Adapted from Neuhauser H, Leopold M, von Brevern M, et al. The interrelations of migraine vertigo and migrainous vertigo.* Neurology. *2001;56:436-441.)*

the vertigo immediately preceded the headache in only 15%, whereas it occurred during the headache in 47% and during the headache-free interval in 36% of patients. In a series of 50 patients with basilar migraine, Olsson[13] and Cuttler and Baloh[14] also found vertigo to occur more often during the headache-free interval than as a prodrome before the headache.

Motion Sickness

The relationship between migraine and motion sickness is well established. In his seminal study of 9000 Swedish schoolchildren, Bille[15] matched children with more pronounced migraine to children in a similar group without migraine. Severe motion sickness was present in 49% of the children with migraine and in only 10% of the control group. Barabas and colleagues found that 45% of 60 children with migraine experienced at least three episodes of motion sickness culminating in vomiting, compared with 5% to 7% of three similar-sized control groups of subjects with non-migraine headaches, seizure disorders, and learning disabilities or neurologic perceptual impairments.[16] In adults, a similarly significantly greater incidence of motion sickness has been observed in patients with classic migraine than in patients with tension and cluster headaches.[12] In the Kayan and Hood[11] series of 200 unselected patients with migraine, 51% reported motion sickness, compared with 20% of the patients with tension headache.

A subset of migraine sufferers experience disabling motion sickness. These patients limit their head motion to a minimum, limit their daily activities accordingly, frequently rest during the day, and when symptomatic may need to remain motionless for up to an hour until symptoms abate. If they cannot avoid vestibular stimulation, a full-blown migraine attack can be triggered. Caloric responses in these patients tend to be symmetrical and very brisk, often culminating in emesis. If treatment provides a dramatic response, the patients often are surprised to recognize how much they had restricted their lifestyle. Often, neither the patient nor the physician suspects that the migraine had any relationship to the other symptoms. Patients often discuss only the vestibular symptoms and ignore or discount any effects of the underlying problem. Prophylactic migraine therapy often yields dramatic clinical improvement with a decrease in symptoms.

Auditory Symptoms

Of the patients studied by Kayan and Hood,[11] 20% complained of hearing loss, tinnitus, or pitch distortion, and one fourth of the 20% had multiple auditory symptoms. In descending order of frequency, the temporal patterns for occurrence of these symptoms were during the headache, during the headache-free interval, and immediately before the headache. The temporal relationship of these symptoms mirror the relationship of vertigo to headache in this same series.

Hearing Loss

The association of hearing loss to migraine is reported to be approximately 7%.[11] Hearing loss is a more prominent symptom in patients with basilar migraine. In Olsson's study,[13] 52% of the patients noticed a change in hearing as part of the aura immediately preceding the migraine headache and 50% had a fluctuating low-frequency sen-

sorineural hearing loss. A group of migraine patients in whom hearing loss thought to be due to vasospasm has been reported.[17]

Tinnitus

Tinnitus was experienced by 15% of migraine patients, but none with tension headache,[11] and in more than 60% of basilar migraine patients.[13]

Distortion

Although distortion was noted by only 4% of patients in the Kayan and Hood series,[11] its actual prevalence may be higher. More attention may be given to more bothersome symptoms, and auditory distortion may be ignored by physicians and patients alike as unimportant.

Phonophobia

Loud noise aversion distinguishes patients with migraine from those suffering other types of headaches. Only 12% of tension headache sufferers experienced phonophobia, but 81% of those with migraine had the symptom.[11] Olsson[13] detected phonophobia in patients with basilar migraine at a rate of 70% during headache and 76% during headache-free intervals. Furthermore, he documented an abnormal loudness discomfort level in 78% of these patients, whereas only 14% had abnormal speech reception thresholds.

Migraine Associated with Neuro-otologic Symptoms

Basilar Migraine

Bickerstaff[18] described a form of migraine ascribed to ischemia in the distribution of the basilar artery. This syndrome currently is known as *basilar migraine*, replacing "basilar artery migraine" and "posterior fossa migraine," which occasionally appear in the older literature. This subtype of migraine was similar to classic migraine in that it consisted of an aura followed by a severe headache. However, a majority of affected patients were adolescent girls, in whom the migraine attacks often occurred premenstrually. Later observers emphasized other aspects of the clinical picture such as stupor,[19] loss of consciousness,[20] neurologic symptoms,[21] hearing loss, and vertigo.[22] These symptoms are thought to be due to involvement of the brainstem, cerebellum, cranial nerve nuclei, and occipital lobe cortex.

Migraine without Headache

Migraine should not be eliminated as a cause for vertigo just because headaches are not present. Whitty[23] reported on a series of patients with symptoms typically experienced during a migraine aura but no headaches. In these patients, typical headaches sometimes developed later in life, or auras that were only intermittently related to headaches were noted. Other observers have described similar patients using the term *migraine equivalent*[24-26] or *migraine accompaniments.*[27] A history of motion sickness, premenstrual clustering of attacks, or headaches associated with some of the attacks is frequent. Personal or family history of migraine also is helpful in diagnosing these patients.

Etiology

Historically migraine headache was thought to result from dilation of intracranial and dural arteries causing stretching of pain fibers in the walls of the arteries. The complex phenomena associated with migraine cannot be fully explained by a vascular theory. More recently, neurally based spreading of depression activity has been implicated,[28,29] although the neurophysiology is far from completely understood.

A family history of migraine is present in approximately 40% to 90% of affected persons, compared with 5% to 20% of unaffected subjects. When migraine sufferers with and without aura are examined separately, patients who have migraine with aura are more likely to have affected family members. When twins are studied, conconcordance rates for migraine are only 10% to 34%, depending on the country, suggesting that both genetic and environmental factors play a role.[30]

Familial hemiplegic migraine (FHM) is a rare type of migraine that affects only 0.01% of the general population.[31] However, the underlying cellular cause is relatively well understood. Unlike most types of migraine, FHM has a clear autosomal dominant pattern of inheritance. Thus far, mutations have been found in three different genes that determine neuronal excitability.

Management

Treatment of migraine has historically been focused on headache symptoms. Management of migraine headache can be divided into two categories: symptomatic and prophylactic. Some interventions are useful in ameliorating the symptoms of the acute attack, whereas others are designed to reduce the frequency or severity of attacks. Symptomatic management includes analgesics, antiemetics, antivertiginous drugs, sedatives, and vasoconstrictors. In many patients, over-the-counter analgesics such as ibuprofen, aspirin, or acetaminophen and rest are all that is needed to relieve headache symptoms. Decreased gastric motility occurs during and between migraine attacks, which may decrease absorption of oral drugs, contributing to nausea and vomiting.[32] Metocopramide promotes normal gastric motility and may improve absorption of oral medication.

Nutrition may play a significant role in the frequency and severity of migraine headaches and migraine-associated dizziness. Riboflavin (vitamin B_2) has been shown to be more effective than placebo in reducing the frequency of migraine headache when given in a dose of 400 mg daily.[33] High-dose magnesium also has been found to have a therapeutic effect on migraine; suggested mechanisms have included inhibiting platelet aggregation, counteracting vasospasm, stabilizing cell membranes, and anti-inflammatory effects.[34] Patients suffering from migraine symptoms have been found to have lower levels of magnesium, and infusion of magnesium can relieve symptoms.[35] Magnesium given orally in a dose of 600 mg daily also has been shown to decrease headache symptoms[36]; however, diarrhea is a potential side effect at these doses.

Food sensitivity may be a migraine trigger in a significant number of patients with migraine symptoms.[34] Although some patients have observed that consuming a certain food will reliably provoke a headache, the effect of diet is more subtle. Foods that should be avoided include red wine, aged cheeses, beer, chocolate, caffeine, and yogurt.[37] Alcohol itself does not seem to be a trigger, because vodka consumption does not provoke attacks.[38] Dietary modification may be considered as first-line therapy for migraine prophylaxis (Fig. 166-2).

Vestibular migraine symptoms often are not directly related to the headache symptoms, and in some cases, dizziness as a manifestation of migraine can be present nearly continuously. Treatment of vestibular migraine has tended to mirror that of traditional migraine symptoms, and medications that alleviate headache symptoms also tend to be effective for vertigo symptoms.[39] However, because the migraine-associated dizziness often is much more frequent than the headaches, prophylaxis usually is necessary.

Sumatriptan (Imitrex), a 5HT1D receptor agonist, has become the principal drug to abort severe migraine headache. Initial trials indicate that in 90% of cases the drug effectively aborts migraine headache symptoms within an hour of their onset when it is given subcutaneously; in 70% to 85%, symptoms may be aborted within 2 hours.[40] Common side effects include sensations of heaviness and pressure in the chest, with coronary artery vasospasm more rarely reported. Although sumatriptan is remarkably effective in relief of early migraine headaches, breakthrough is common, and the drug has limited efficacy for concurrent vestibular symptoms.

Propranolol (Inderal) is the drug most commonly used for preventing migraine episodes. Approximately 50% to 70% of patients with headache symptoms derive benefit from prophylactic propranolol therapy, which also may be beneficial for vertigo symptoms.[21] The medication is contraindicated in patients with asthma, congestive heart failure, peripheral vascular disease, diabetes, or hypothyroidism. Principal side effects include fatigue, lethargy, and dizziness, which usually occurs on rising from a seated or supine position. Side effects are minimized by slowly increasing the dose from a low starting level. Doses of 80 to 180 mg per day usually are effective. The medication should be continued for at least 2 to 3 months at the highest level of tolerance before it is considered a failure. On discontinuation, the drug should be gradually tapered over several days.

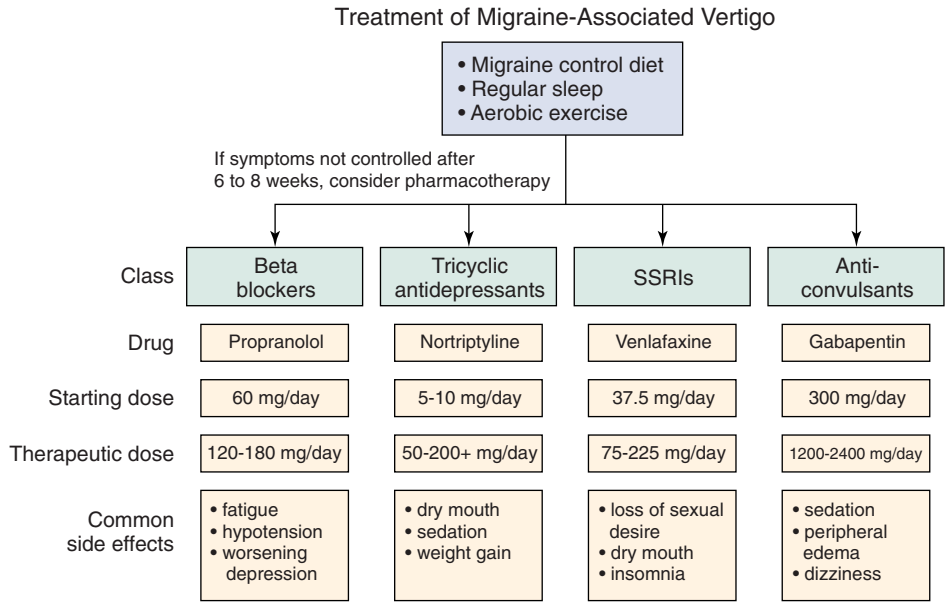

Figure 166-2. Flowchart of suggested migraine treatment. Lifestyle modification usually is a good first option because it is not associated with side effects and will provide symptomatic improvement in most patients. Pharmacotherapy should be considered if more conservative measures fail.

A variety of beta-adrenergic agents also have been used for migraine prophylaxis. Atenolol (Tenormin), metoprolol (Lopressor), nadolol (Corgard), and timolol (Blocadren) probably are as effective as propranolol. However, a number of other beta-adrenergic antagonists (e.g., acebutolol, oxprenolol, alprenolol) do not appear to be effective in migraine prophylaxis. It has been suggested that pure beta-adrenergic antagonism without intrinsic sympathomimetic activity is required for efficacy.

Calcium channel blockers (nifedipine, verapamil) also have been reported to reduce the frequency of migraine attacks, but the effect is likely to be only modest.[41] Diltiazem (Cardizem) does not seem to have any effect on migraine prevention.

Tricyclic antidepressants also have been shown to decrease the frequency and severity of migraine attacks. Amitriptyline is perhaps the most-studied drug in this category, with several studies showing its efficacy.[42] Starting doses usually are 10 to 25 mg, which usually is given at bedtime, to avoid the side effects of sedation and anticholinergic activity. Weight gain is a side effect that limits patient compliance with therapy in some populations. Therapeutic doses usually are 50 to 100 mg, with some patients who also suffer from depressive symptoms requiring doses of up to 400 mg. Nortriptyline is less sedating than amitriptyline and has a dosage profile similar to that of amitriptyline.

The role for selective serotonin reuptake inhibitors (SSRIs) for treatment of migraine remains controversial. Some evidence shows that they seem to be less effective than tricyclic antidepressants[43] for headache symptoms. However, in patients with chronic subjective dizziness as their primary symptom, SSRIs seem to be effective.[44]

Clinical trials have shown gabapentin (Neurontin) to be effective at dosages of 1200 to 2400 mg per day,[45] which usually is divided into three doses daily. Dizziness, peripheral edema, and somnolence are common side effects.

Valproic acid derivatives such as divalproex (Depakote) are effective in migraine prevention. However, the need to monitor levels and the side effect profile of these medications, which includes nausea, fatigue, weight gain, teratogenicity, hepatic toxicity, and tremor, have made them infrequently used.

Acetazolamide (Diamox) has been shown to be effective in preventing migraine headaches and episodic vertigo in families who also exhibit essential tremor.[46] However, it has not been shown to be of benefit in larger migraine headache populations.[47] It may be effective in ameliorating motion-induced vestibular symptoms in patients with migraine.

Vestibular Disorders Associated with Migraine

Benign Paroxysmal Positional Vertigo

BPPV is the most common cause of peripheral vertigo. The disorder probably is due to free-floating particles in the semicircular canal (canalithiasis), which usually collect in the posterior semicircular canal owing its low point with respect to gravity. Classic symptoms include brief episodes (lasting less than 1 minute) of vertigo when the head is tilted backwards or during rolling over in bed. An extensive discussion of diagnosis and treatment of this common disorder is outside the scope of this chapter. Of note, however, migraine and motion sickness are three times more common in patients with BPPV than in the general population, with 59% of patients having a family history of migraine.[48]

Meniere's Disease

Meniere's disease classically manifests with unilateral low-frequency fluctuating hearing loss, a sense of aural fullness, and dizziness lasting several minutes to hours.[49] However, the presence and severity of these symptoms are variable, which can overlap with those of migraine.[50] Unselected patients with migraine have a 7% incidence of hearing loss and 26% incidence of vertigo.[11] In patients with Meniere's disease, the lifetime incidence of migraine is 56%, versus only 25% in controls.[51] The frequent co-occurrence of Meniere's disease and migraine suggests a pathophysiologic link between the two syndromes.[52] Alternatively, the diseases may be separate processes that cause similar symptoms. It is likely that both Meniere's disease and migraine are not homogeneous disorders but may be caused by a spectrum of genetic and environmental influences—so both explanations may be correct: Migraine may be one of many risk factors for Meniere's disease, and vice versa.

Vestibular Disorders Related to Migraine

Benign Paroxysmal Vertigo of Childhood

Basser[53] described a clinical entity in children younger than 4 years of age that he called *benign paroxysmal vertigo*. This should not be confused with the much more common benign paroxysmal positional

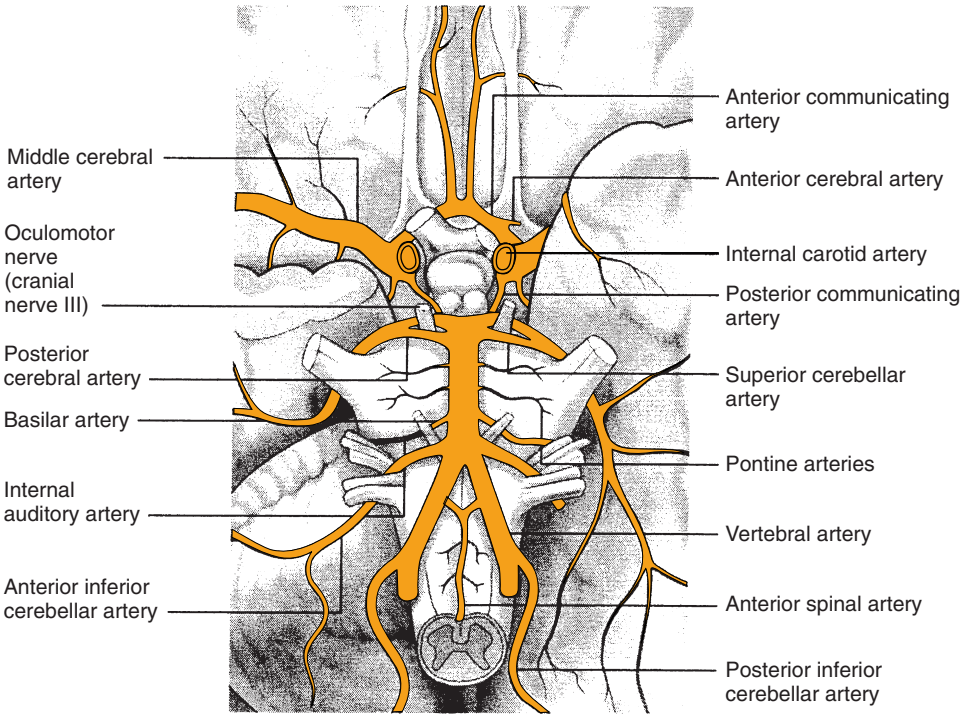

Figure 166-3. The blood vessels supplying the brain. The brainstem is supplied by branches of the vertebral arteries and basilar artery. Note that although this figure shows the internal auditory artery arising directly from the basilar artery, it more commonly branches off the anterior inferior cerebellar artery instead. *(Adapted from Kandel ER, Schwartz JH, Jessell TM.* Principles of Neural Science. *New York: McGraw-Hill; 2000:1303.)*

vertigo (BPPV), which also is referred to as benign positional vertigo. Children with this disorder usually become suddenly frightened, cry out, cling to the parent, stagger as though drunk, and exhibit pallor, diaphoresis, and frequent vomiting. Symptoms are worsened by head motion. The episodes last less than 5 minutes, after which the child is normal again. The symptoms usually manifest at the age of 2 to 3 years and gradually decrease until they resolve before age 8. When the clinical picture is clear, treatment is not needed. On long-term follow-up, classic migraine eventually developed in six of seven patients with this disorder.[54]

Paroxysmal Torticollis

Snyder[55] described a series of 12 infants who experienced recurrent attacks of head tilt before the age of 8 months. The spells lasted from a few hours to 3 days and occasionally were accompanied by pallor, vomiting, and agitation. Subsequent observers have suggested a familial occurrence[56] and that symptoms also may involve the trunk and extremities.[57] The spells usually stop spontaneously by age 5, and no treatment is needed.

Vascular Disorders

Abnormalities of blood flow to the vestibular system are relatively common causes of vestibular symptoms and often are difficult to distinguish from well-known end organ disorders. Clinical presentations vary for many reasons. Functional deficits may be restricted to one or both end organs or their structures or may involve the vestibular nuclei or other peripheral or central regions. Diverse abnormal processes can result in permanent or temporary loss of function. Permanent losses typically result from arterial occlusion or from hemorrhagic infarction. Transient effects may accompany arterial stenosis, vascular spasm, inadequate perfusion pressure, or reversed arterial flow with shunting such as in subclavian steal syndrome. Many symptom complexes are possible, but defined clinical entities are more common.

The blood supply to the inner ear, brainstem, and cerebellum arises from the vertebrobasilar system. Vertigo can occur from occlusion of any of the three major circumferential branches of the vertebral or basilar arteries: the posterior inferior cerebellar artery, the anterior inferior cerebellar artery, and the superior cerebellar artery (Fig. 166-3).

Specific Disorders

Vertebrobasilar Insufficiency

Vertebrobasilar insufficiency is a significant cause of vertigo in the elderly population.[58,59] Vertigo due to vertebrobasilar insufficiency is of abrupt onset, usually lasts several minutes, and frequently is associated with nausea and vomiting. Presentation with vertigo symptoms alone is extremely uncommon and occurs in less than 1% of patients.[60] Usually multiple symptoms are present, which often include headache, diplopia, ataxia, numbness, weakness, or oropharyngeal dysfunction. Repeated episodes of vertigo without other symptoms suggest another diagnosis.

Atherosclerosis of the subclavian, vertebral, or basilar arteries usually is the underlying cause of vertebrobasilar insufficiency. The distribution of large-artery atherosclerosis differs according to race and gender.[61] European men tend to have atherosclerosis at the origin of the vertebral arteries near the subclavian. Intercranial large-artery atherosclerosis is more common among African Americans, Asians, and women. Hypertension increases the risk of lipohyalinotic thickening of these vessels, which increases the risk of infarction.

Rarely, occlusion or stenosis of the subclavian or innominate artery just proximal to the origin of the vertebral artery results in *subclavian steal syndrome*. In patients with this syndrome, vertebral insufficiency results from siphoning of blood down the vertebral artery from the basilar system to supply the upper extremities. Vertigo and other symptoms are precipitated by exercise of the upper extremities.

If the patient is suspected to have had a stroke, a CT scan should be ordered to rule out the possibility of a hemorrhagic event. If a patient has presented within 3 hours after the onset of symptoms, the National Institute for Neurological Disorders and Stroke (NINDS) guidelines recommend administration of t-PA intravenously. However, recommendations in this area are rapidly evolving, and in the acute phase, patients should be treated by a neurologist familiar with stroke.

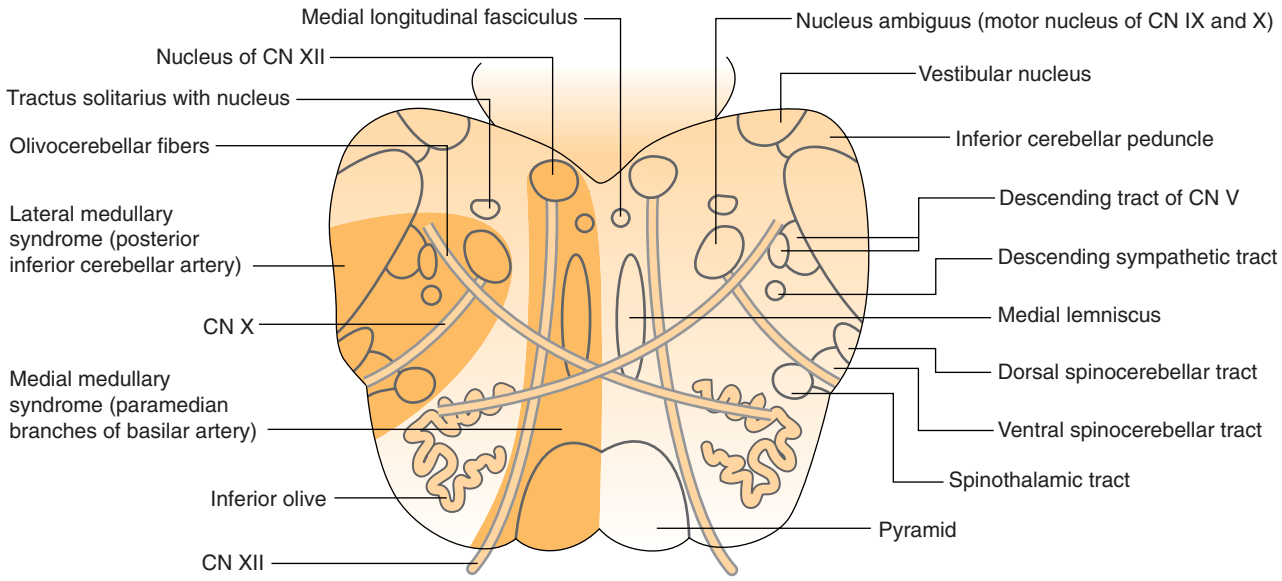

Figure 166-4. Medulla cross section with anatomic structures labeled on the *right* and vascular lesions on the *left*. CN, cranial nerve. *(Adapted from Kandel ER, Schwartz JH, Jessell TM.* Principles of Neural Science. *New York: McGraw-Hill; 2000:1303.)*

In most patients with nonacute presentations, treatment consists of controlling risk factors such as diabetes, hypertension, and hyperlipidemia. In patients with symptomatic intracranial stenosis with 50% to 99% occlusion, aspirin and warfarin are equally effective, but warfarin carries a higher risk of hemorrhagic events,[62] so aspirin is the agent of choice. Anticoagulation with warfarin should be considered if the patient has previously had an embolic stroke of cardiac origin.[58] Stenting of vertebral artery stenosis has been tried, with mixed results. Endarterectomy for extracranial vertebral artery disease also has been successfully performed, but indications for such procedures are still evolving.

Lateral Medullary Syndrome

The zone of infarction producing the lateral medullary syndrome (Wallenberg's syndrome) consists of a wedge of the dorsolateral medulla just posterior to the olive (Fig. 166-4). The syndrome usually results from occlusion of the ipsilateral vertebral artery and rarely from occlusion of the posterior inferior cerebellar artery.[63] The classic presentation includes sensory deficits affecting the trunk and extremities on the opposite side of the infarct and sensory and motor deficits affecting the face and cranial nerves ipsilateral to the infarct. Characteristic symptoms include vertigo, ipsilateral facial pain, diplopia, dysphagia, and dysphonia. Neurologic examination may reveal a ipsilateral Horner's syndrome, ipsilateral dysmetria, dysrhythmia, spontaneous nystagmus, and contralateral loss of pain and temperature sensation.

Hearing loss does not occur because the lesion is caudal to the cochlear nerve entry zone and cochlear nuclei.

Some patients exhibit a prominent motor disturbance that causes the body and extremities to deviate toward the lesion site as if being pulled by an invisible force.[64] This so-called lateral pulsion also affects the oculomotor system, producing excessively large saccades directed toward the side of the lesion and abnormally small saccades away from the lesion. Most patients with Wallenberg's syndrome have major residual neurologic deficits months or even years after the acute infarction.

Lateral Pontomedullary Syndrome

Ischemia in the distribution of the anterior inferior cerebellar artery results in infarction of the dorsolateral pontomedullary region and the inferolateral cerebellum.[65] The middle cerebellar peduncle typically is the core of the affected territory (Fig. 166-5). Because the labyrinthine artery originates from the anterior inferior cerebellar artery in 80% of patients, infarction of the membranous labyrinth is a common accompaniment. Severe vertigo, nausea, and vomiting are common initial symptoms. Other signs and symptoms include ipsilateral hearing loss, tinnitus, facial paralysis, and cerebellar asynergy. Spontaneous nystagmus is common. Contralateral loss of pain and temperature sensation may be caused by crossed spinothalamic fibers. Onset of symptoms is acute, followed by gradual improvement. Vertigo may persist for several weeks owing to damage of the central compensation mechanisms.

Cerebellar Infarction

Occlusion of the vertebral artery, the posterior inferior cerebellar artery, the anterior inferior cerebellar artery, or the superior cerebellar artery may result in infarction confined to the cerebellum without brainstem involvement[66] (Fig. 166-6). Initial signs and symptoms are severe vertigo, vomiting, and ataxia. Lack of typical brainstem signs may cause an incorrect diagnosis of an acute peripheral labyrinthine disorder. The key to the diagnosis is the presence of prominent cerebellar signs such as gait ataxia and paretic gaze nystagmus. The diagnostic modality of choice is magnetic resonance imaging (MRI). After a latent interval of 24 to 96 hours, some patients exhibit signs of progressive brainstem dysfunction caused by compression by a swelling cerebellum. Progression to quadriplegia, coma, and death may follow unless surgical decompression is performed.

Cerebellar Hemorrhage

Spontaneous intraparenchymal hemorrhage into the cerebellum causes neurologic symptoms that often rapidly progress to coma and death.[67-69] The initial manifestations are severe vertigo, vomiting, and ataxia. As with cerebellar infarction, brainstem signs may not initially be present, which may cause the condition to be confused with a peripheral vestibular problem. Modern imaging studies such as computed tomography (CT) and MRI have revolutionized the diagnosis of this condition (Fig. 166-7). Mortality rates range from as low as 20%[70] up to 74%, depending on the series. The value of and indications for surgical intervention remain controversial and probably depend on the size and location of the hematoma as well as the patient's symptoms.[67]

Evaluation and Management

Cerebrovascular disease is a primary consideration in the differential diagnosis for acute spontaneous vertigo, particularly if the patient has vascular risk factors. If the history and examination findings suggest a vascular disorder, immediate neuroimaging is necessary. CT of the brain without contrast often is the first imaging test because it is widely available and shows intraparenchymal or subarachnoid blood. Hemorrhage can mimic any of the ischemic stroke syndromes and must be

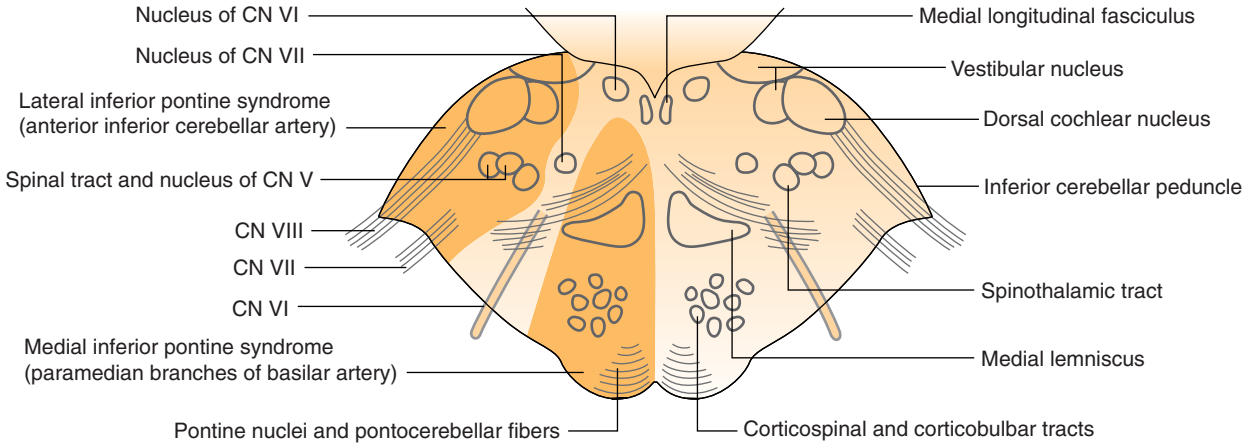

Figure 166-5. Lower pons cross section with anatomic structures labeled on the *right* and vascular lesions on the *left*. CN, cranial nerve. *(Adapted from Kandel ER, Schwartz JH, Jessell TM.* Principles of Neural Science. *New York: McGraw-Hill; 2000:1303.)*

excluded with thin-section CT through the cerebellum, brainstem, and fourth ventricle. MRI and magnetic resonance angiography (MRA) are superior to CT for viewing the vertebrobasilar vessels and their supplied structures, because CT scans often are normal in appearance with cerebellar or brainstem infarction. MRI, on the other hand, detects ischemic strokes in the brainstem and cerebellum early on, as well as edema. Diffusion-weighted imaging with MRI can now detect infarcts within the first hour of ischemia (Fig. 166-8). MRA has begun to replace conventional angiography in certain circumstances. Vertebral artery dissection and vertebral or basilar artery stenosis or occlusion generally can be identified with MRA of the cervical vessels performed with contrast (Fig. 166-9).

Neoplasms

Space-occupying lesions can induce vestibular symptoms by compressing or by destroying neural tissue within the temporal bone, in the cerebellopontine angle, or intra-axially within the brainstem and cerebellum. Symptoms also can be produced or increased by vascular compression.

Vestibular Schwannomas

Vestibular schwannomas can manifest with vertigo symptoms, which can be disabling in some patients,[71] although such symptoms are present in less than 20% of patients with these tumors.[72] Hyperventilation-induced vertigo also may occur in the absence of hearing loss.[73] Discussion of the diagnosis and treatment of vestibular neuromas can be found in Chapters 149 and 153.

Brainstem Neoplasms

Gliomas of the brainstem usually grow slowly and infiltrate the brainstem nuclei and fiber tracts, producing progressive symptoms and signs. The typical history is one of relentlessly progressive involvement of one brainstem center after another, often causing death with the destruction of the vital cardiorespiratory centers of the medulla. These tumors are 5 to 10 times more common in children than in adults. Vestibular and cochlear signs and symptoms occur in approximately one half of patients, but the spectrum of findings usually makes a brainstem origin clear. In the modern era, imaging studies such as CT or MRI usually are performed to investigate the initial manifestations, making the diagnosis obvious.

Tumors originating in the pons or midbrain initially are likely to cause long tract signs, cranial nerve deficits, and ataxia. Although uncommon, tumors that originate in the medulla are likely to cause recurrent vertigo and vomiting. Irradiation is the treatment of choice, because surgical resection of this area is associated with significant morbidity.

Tumors originating in the fourth ventricle and compressing the vestibular nuclei in its floor also can produce vestibular symptoms.

Medulloblastomas, occurring primarily in children and adolescents, are rapidly growing, highly cellular tumors that originate in the posterior midline or vermis of the cerebellum and invade the fourth ventricle and adjacent cerebellar hemispheres. Headaches and vomiting occur early from obstructive hydrocephalus and associated increased intracranial pressure. An attack of headache, vertigo, vomiting, and visual loss may result from a change in head position, producing transient cerebrospinal fluid (CSF) obstruction (Bruns' syndrome). Positional vertigo and nystagmus may be the presenting manifestations.[74,75] Other fourth ventricle tumors that produce a similar clinical picture include ependymomas, papillomas, teratomas, epidermoid cysts, and cysticercosis. The diagnosis of a fourth ventricular mass is made readily with MRI and CT scanning, but frequently the exact nature of the tumor cannot be determined before surgical exploration and biopsy. Complete removal of tumor should be achieved when possible. Medulloblastomas are particularly sensitive to radiotherapy.[76]

Figure 166-7. Noncontrast computed tomography scan of a cerebellar hematoma within the vermis. Surrounding edema and effacement of the superior aspect of the fourth ventricle are evident. Resulting obstruction of cerebrospinal fluid outflow may lead to hydrocephalus. *(Courtesy of K. D. Flemming.)*

Cerebellar Neoplasm

Clinical manifestations of posterior fossa tumors include dizziness in 81% and vertigo in 44% of patients.[77] One half of patients with posterior fossa tumors exhibit spontaneous nystagmus, and a third lack caloric responses. Other common symptoms and signs of cerebellar tumors include tinnitus, hearing loss, headache, nausea or vomiting, and ataxia. Gliomas of the cerebellum may be relatively silent until they become large enough to obstruct CSF circulation or compress the brainstem.[78] Positional vertigo occasionally is the initial symptom of a cerebellar tumor.[79,80] Paroxysmal positional nystagmus, when present, is atypical, because it can be induced in several different positions and is nonfatigable. Tumors that can produce these signs and symptoms include gliomas, teratomas, hemangiomas, and hemangioblastomas. Each of these tumors has a characteristic appearance on MRI and CT scans, although occasionally the exact tumor type cannot be determined before surgical biopsy.

Cervical Vertigo

Dizziness caused by disorders of the neck and cervical spine is poorly understood and relatively uncommon. Neck afferents are recognized to have a role in the coordination of eye, head, and body spatial orientation. Perception of head rotation can be driven by vestibular, proprioceptive, or visual inputs. Cervical vertigo must be by definition proprioceptive in nature, because the other inputs that cause vertigo do not exist in the neck. Laboratory experiments in humans that eliminate visual input with darkness and vestibular input by holding the head still have shown that trunk motion can produce the sensation of head turning[81]; however, this has not been shown to occur in more ordinary situations. Several studies have provided limited evidence for the existence of cervical vertigo. Unilateral local anesthesia of the cervical roots can cause ataxia and nystagmus in animals and ataxia without nystagmus in humans.[82] Patients with chronic cervicobrachial neck pain also have worse results on posturography tests.[83] These results are difficult to interpret because trauma that causes neck pain also can cause brain injury and damage to peripheral otolith organs. In clinical practice, it is necessary to exclude neurologic, vestibular, and psychosomatic disorders before a disorder of the craniovertebral junction can be given serious consideration. The diagnosis of cervical vertigo remains largely theoretical.[84,85]

Disorders of the Craniovertebral Junction

Disorders of the craniovertebral junction are poorly understood and relatively uncommon. The patients frequently are referred for

Figure 166-8. Figure 166-9. Contrast-enhanced magnetic resonance angiogram showing stenosis of the cervical vessels. **A,** Frontal view. **B,** Lateral view. Severe stenosis can be seen at the junction of the left vertebral artery *(long arrow)* and the basilar artery *(short arrow)*. The right distal vertebral artery also is occluded *(arrowhead)*. *(From Lee H. Sudden bilateral simultaneous deafness with vertigo as a sole manifestation of vertebrobasilar insufficiency.* J Neurol Neurosurg Psychiatry. *2003;74:540.)*

surgical evaluation because of brainstem or lower cranial nerve signs and symptoms such as tinnitus, vertigo, hearing loss, pharyngeal dysfunction, hoarseness, or airway obstruction. Physical examination can be difficult and misleading, and radiographic findings often are not sufficient to establish a diagnosis. An understanding of these disorders may facilitate appropriate evaluation and prevention of inappropriate management such as middle ear exploration and endolymphatic sac surgery.

Pathophysiology

The physiologic problem common to these disorders is physical compression of the CNS at the level of the upper spinal cord and medulla (cervicomedullary compression).[86-88] The rostrocaudal area of compression is variable, and the impingement can be ventral or dorsal, or (rarely) both. A second but uncommon potential mechanism is vascular insufficiency of the anterior spinal or vertebral arteries from angulation, stretching, or extrinsic obstruction.[89,90]

Classification

Basilar Impression

Basilar impression is an upward indentation or invagination of the clivus or posterior fossa floor.[86,91] This defect causes the upper cervical spine to migrate cephalad toward the brainstem, as the floor of the skull collapses under the weight of the head. The normal anatomy of the foramen magnum, first cervical vertebra (atlas), second cervical vertebra (axis), and its odontoid process (dens) can become altered by disease, trauma, or congenital deformities. When a softening of the skull base results, the skull literally descends onto the spinal column and odontoid. As the odontoid projects intracranially, it compresses the ventral aspect of the medulla.

Associated erosive changes of the occipital condyles and atlas accentuate the protrusion of the odontoid, narrow the diameter and circumference of the foramen magnum and spinal canal, and provide mechanisms for dorsal cervicomedullary compression. The odontoid not only projects above the foramen magnum but also occupies a large portion of its circumference.

Disorders known to cause basilar impression include Paget's disease, rheumatoid arthritis, osteomalacia, osteogenesis imperfecta, cretinism, and rickets.[86] The diagnosis is confirmed when lateral radiographic views of the skull demonstrate that the tip of the odontoid either extends above Chamberlain's line (a line extending from the posterior edge of the hard palate to the posterior lip of the foramen magnum)[92] or projects posterior to Wackenheim's clivus-canal line. The term *platybasia* has been used synonymously with *basilar artery impression* by some authors. Although the two conditions coexist, platybasia itself causes no symptoms.

Assimilation of the Atlas

Assimilation of the atlas (also called *occipitalization of the atlas*) is a bony union between the first cervical vertebra and the skull.[93] The amount of union varies, but motion between the two structures does not occur. As a result, the odontoid often impinges on the effective anteroposterior diameter of the foramen. A frequent associated finding is fusion of the axis to the third cervical vertebra. The condition is frequently developmental in origin and is found in association with abnormalities of the jaw, cleft palate, auricular deformities, cervical ribs, and urinary tract anomalies.[94] Klippel-Feil syndrome is one of the most common causes of cervical vertebral fusion.

Signs and symptoms of this syndrome are variable and typically appear fairly late and progress slowly. Symptoms may involve the brainstem, cerebellum, spinal cord, or lower cervical nerve roots or the vascular supply to these structures. These symptoms frequently precipitate a visit to a neurologist, but vertigo, facial paresis, dysphagia, hearing loss, and tongue atrophy may bring some patients to an otolaryngologist for initial evaluation. Although the disorder can be diagnosed with CT reconstructions, the key to diagnosis often is MRI, which allows direct coronal and sagittal imaging.[95]

Atlantoaxial Dislocation

During flexion and extension of the neck, congenital fusion of the occiput to the atlas increases the strain on the structures that normally restrict the motion of the atlas on the axis, especially if fusion of other cervical vertebrae also is present. The transverse ligaments that normally secure the odontoid against the anterior aspect of the arch of the atlas may weaken because of this repeated strain, and the resultant laxity allows the odontoid to move posteriorly into the lumen of the foramen magnum with neck flexion. Flexion or extension of the neck may then produce symptoms, depending on whether the predominant neural compression is anterior from the odontoid or posterior from the posterior arch of C1. When the atlas or congenital cervical fusion has been assimilated, the transverse odontoid ligament is sometimes hypoplastic, which makes laxity and atlantoaxial dislocation even more likely.

Atlantoaxial instability is associated with a number of congenital and acquired disease processes. It occurs in 10% to 30% of patients with Down syndrome when diagnosed radiographically, with an atlantodens interval of 4 to 5 mm.[96,97] The condition also is associated with spondyloepiphyseal dysplasia, Hurler's syndrome, and Morquio syndrome, and in those with achondroplastic dwarfism. A high incidence of atlantoaxial instability, resulting from destruction of the normal

Eighth nerve signs in a case of multiple sclerosis.* Am J Otolaryngol. *1989;10:376-381.)*

stabilizing mechanisms by inflammatory tissue, has been reported in patients with rheumatoid arthritis.[98] Similarly, ligamentous laxity can result from inflammatory conditions affecting the retropharyngeal soft tissues or cervical bony structures, such as osteitis, retropharyngeal abscess, or lymphadenitis. Atlantoaxial instability in association with pharyngeal infection has come to be known as Grisel's syndrome.[99] It is rare in adults and associated with pain and dysphagia.

Most patients with atlantoaxial instability of developmental origin are asymptomatic, and the instability does not usually worsen with time.[97] Symptoms and signs develop in only 1% to 2% of patients with Down syndrome and usually appear between the ages of 5 and 15 years. Neck pain, sensory deficits, and difficulty with bladder control have been described; more subtle manifestations include decreased activity tolerance, changes in gait, and hyperreflexia.

Chiari Malformation

Chiari malformations are a group of developmental hindbrain and spinal cord abnormalities characterized by hernation of the contents of the posterior cranial fossa caudally through the foramen magnum into the upper cervical spine. These patients may present with symptoms related to the vestibular system such as ataxia, nystagmus, or vertigo.[100] Chiari malformation can be divided into two forms, type I and type II. The Chiari type I malformation is more common and more mild. Symptoms of Chiari type I usually are delayed until the age of 25 to 35 years. Affected persons often have subtle neurologic symptoms that are not associated with other developmental defects. Diagnosis is made by CT or MR images reconstructed in the sagittal plane, which may demonstrate deformation of the cerebellar tonsils more than 5 mm caudally through the foramen magnum (Fig. 166-10). The Chiari type II malformation manifests in the first few months of life with associated hydrocephalus and other CNS malformations such as meningomyelocele.

Classic presentation symptoms of Chiari type I malformation include upper extremity weakness, sensory loss, and pain. Occipital headaches that are exacerbated by coughing sneezing, bending over, or lifting also are a common presenting feature. Ataxia and nystagmus are reported in 24% of patients, with vertigo being a complaint in only 8%.[101] Patients also may have a vestibular test profile consistent with peripheral dysfunction but remain asymptomatic.[100] These patients also may present to the otolaryngologist with difficulty swallowing, aspiration, or hoarseness due to involvement of the lower cranial nerves (cranial nerves IX through XII).

Multiple Sclerosis

Multiple sclerosis (MS) is an inflammatory demyelinating CNS disorder of idiopathic origin with the onset in early adulthood. The disease affects women twice as often as men. The key to diagnosis is the presence of disseminated signs of CNS dysfunction manifested in an alternating and remitting and exacerbating course. Many symptoms can occur, depending on the location of the lesions. Vertigo is the initial symptom of MS in only approximately 5% of patients, although the symptom may be present in as many as one half of these patients at some point in the course of the disease.[102] Lesions within the vestibular nuclei and in the entry zone of cranial nerve VIII represent the most common locations for demyelinating activity to cause vertigo in patients with MS[103] (Fig. 166-11). However, benign paroxysmal positional vertigo remains the most common cause of vertigo in these patients,[104] as in the general population.

The diagnosis of MS remains a clinical one, with no definitive imaging study or laboratory tests.[105] Abnormalities in CSF can be identified in as many as 90% of patients with MS at some point in the course of the disease. Findings included increased gamma globulin level, oligoclonal banding of gamma globulin, and increased myelin basic protein. MRI demonstrates white matter lesions in more than 90% of patients, although similar lesions occasionally are seen in patients without MS.[106]

MS is treated with disease-modifying and symptomatic therapies. Intravenous methylprednisolone 500 to 1000 mg/day for 3 to 5 days is commonly used to hasten recovery from acute exacerbations. Drugs such as interferon-beta 1a and 1b and copolymer 1 are immunomodulating drugs that alter the natural history of MS. They reduce the relapse rate and the appearance of new MRI lesions and slow the progression. Other medications are used to treat symptoms of spasticity, neurogenic bladder, and fatigue.

Cerebellar Ataxia Syndromes

Recurrent or progressive ataxia is the primary neurologic deficit in several well-defined hereditary and sporadic degenerative disorders. Abnormal nystagmus is common and may be one of several categories,

including gaze paretic nystagmus and rebound nystagmus. The central nature of this symptom is almost always clear owing to the gait disturbances, dysarthria, tremor, and bradykinesias; accordingly, these patients rarely present to otolaryngologists. Impaired vestibular function usually is not symptomatic, although it may be found on clinical tests.

Friedreich's ataxia, the most common hereditary ataxia, is of autosomal recessive inheritance and usually is caused by a GAA repeat expansion in the frataxin gene. The onset of symptoms usually is before 20 years but may be as late as the sixth decade. Classically, its distinguishing features include an axonal sensory neuropathy with areflexia, Babinski sign, dysarthria, diabetes, and cardiomyopathy, although genetic testing has expanded the phenotypic range. Reduced vestibulo-ocular reflex gain is common, and saccadic intrusions (square-wave jerks) are characteristic. Rarer causes of recessively inherited ataxias include ataxia-telangiectasia, abetalipoproteinemia, and Refsum's disease. Ataxia is a feature of many other inborn metabolic and mitochondrial disorders.

Spinocerebellar atrophy encompasses a group of disorders in which cerebellar ataxia is a prominent feature. Many different genetically inherited subtypes have been identified by genetic linkage analysis.[107]

Cerebellar atrophy is characterized by gradual onset of ataxia, without other associated signs, beginning later in life. The disorder can be genetic or sporadic. Vestibular testing often reveals rebound nystagmus and spontaneous vertical nystagmus.[108]

Familiar episodic ataxia is an uncommon ataxia with a dominant inheritance pattern characterized by recurrent vertigo and ataxia. Episodes of ataxia often are triggered by stress, last minutes to hours, and begin between early childhood and early adulthood. Symptoms are markedly reduced or eliminated by acetazolamide.[109]

Paraneoplastic cerebellar degeneration (PCD) typically manifests as a subacute, rapidly progressive cerebellar syndrome. The development of anti-Purkinje cell antibodies (PCAs) in patients with undiagnosed and otherwise asymptomatic malignancies may result in the syndrome of PCD. PCD typically begins fairly abruptly and progresses rapidly through several months, with cerebellar-type ocular motor and vestibular abnormalities, dysarthria, and severe appendicular and gait ataxia. The cerebellum is not directly invaded by tumor, but the tumor produces remote effects on the cerebellum that probably are immune-mediated. It most commonly occurs in patients with carcinoma of the lung (small cell), breast, ovary, and Hodgkin's lymphoma. However, the neurologic symptoms usually appear before the cancer is identified.[110]

Focal Seizure Disorders

Vertigo can be part of an aura of a focal seizure. Smith[111] studied a group of patients with vestibular symptoms as part of their aura. The most common vestibular symptom was a sense of spinning, which occurred in 55% of these patients, followed by a sense of linear translation in 30%. However, episodes of vertigo as isolated manifestations of a seizure disorder occur rarely, if ever.

Normal Pressure Hydrocephalus

Idiopathic normal pressure hydrocephalus classically manifests with the triad of dementia, urinary incontinence, and gait or balance disturbance. However, these symptoms represent the more severe end of the clinical spectrum, and more subtle cases can manifest with only mild gait or balance symptoms.[112] Cognitive symptoms also are common but may be mild. Patients usually become symptomatic after the age of 60 years. Diagnosis requires an imaging study that demonstrates nonobstructive ventricular enlargement disproportionate to the degree of cerebral atrophy.

Physiologic Dizziness

Physiologic dizziness refers to phenomena that occur in normal persons as a result of physiologic stimulation of the vestibular, visual, or somatosensory system. Typically a mismatch among sensory signals causes disorientation, imbalance, and vegetative symptoms.

Motion Sickness

Motion sickness is a common form of physiologic dizziness. The main symptoms are dizziness, fatigue, pallor, cold sweats, salivation, and finally nausea and vomiting. It usually is caused by prolonged vestibular stimulation but also may occur with visual stimulation. The key symptom is nausea, a term derived from the Greek *naus*, "ship." Motion sickness may develop aboard a ship, in a car, on an airplane, or in space. Symptoms generally are worse when subjects are not able to visualize the movement, thereby creating a visual-vestibular conflict. Relief may be gained on a ship by standing on the deck and focusing on the horizon or land, rather than sitting in an enclosed cabin. When riding in a car, riding in the back seat or reading may make symptoms worse than sitting in front and looking off into the distance. Susceptibility among affected persons varies considerably. Patients with migraine generally are more prone to motion sickness, and bouts of motion sickness during childhood may be the first symptom of migraine.

Physical measures may help prevent motion sickness. In the long term, repeated gradual exposure to motion causes protective habituation, which may be the most effective therapeutic measure. Minimizing conflicting sensory inputs by restricting unnecessary head movement (such as pressing the head firmly against the headrest of a car) is helpful, as is minimizing any visual-vestibular mismatch, as described earlier.

Anti–motion sickness drugs are aimed at modulating the histaminic, cholinergic, and noradrenergic neurotransmitters that are thought to be important in the neural processes of motion sickness. These drugs work by blocking the emetic response, reducing the size of the sensory mismatch by promoting habituation, or blocking conflicting sensory inputs.

Mal de Débarquement Syndrome

Mal de débarquement (MDD), "sickness of disembarkment," refers to inappropriate sensations of movement after exposure to motion. Although this unusual syndrome typically follows a sea voyage, MDD may occur after extended train, air, or car travel.[113] The characteristic symptom is a sensation of persistent rocking or swaying of the body without rotational vertigo. Vague dysequilibrium or unsteadiness also may be a feature. MDD is distinguished from motion sickness in that patients with MDD are mostly symptom-free during the period of motion. Although many normal persons experience similar symptoms of "land sickness" for up to 48 hours after exposure to prolonged motion, most experts define MDD as a syndrome persisting for at least a month. During symptomatic periods, patients typically report improvement while in a moving vehicle or while walking that is lost when they stop moving, when symptoms worsen. MDD affects predominantly women, with a mean age at onset in the 40s. Symptoms may last for months to years. Some investigators have hypothesized that MDD is caused by a multisensorimotor adaptation and habituation to a new or abnormal motion environment. Benzodiazepines such as clonazepam or diazepam or amitriptyline may have a beneficial effect, but meclizine and scopolamine were ineffective.[113]

CHAPTER ONE HUNDRED AND SIXTY-SEVEN

Surgery for Vestibular Disorders

Steven A. Telian

Key Points

- The otologist should recognize the vulnerability of patients with refractory vertigo, shelter them from nonvalidated treatments, and seek to guide them toward the most effective surgical options.
- Some operations seek to correct a pathologic process that is unique to a particular diagnosis, while preserving or restoring inner ear function. Success in this setting hinges on making an exact diagnosis and selecting procedures with proven efficacy.
- If a labyrinthine lesion is unstable or rapidly progressive in nature, central vestibular compensation is not possible unless the ear is first stabilized by medical or surgical management.
- The patient with recurrent vertigo refractory to conservative treatment is a candidate for a procedure that will ablate the residual vestibular function in the involved ear.
- Labyrinthectomy and vestibular nerve section will reliably ablate peripheral vestibular function and may be applied in the management of any unstable peripheral vestibular disorder.
- The endolymphatic sac is simply a specialized portion of the posterior fossa dura containing resorptive epithelium. Operations for decompression of the sac, with or without shunting, have a low efficacy rate but produce favorable results in some cases.
- It is not certain whether the observed benefits from sac decompression operations are due to a nonspecific effect of surgery or the decompression itself. Thus, if it is difficult to identify the sac, the prudent surgeon should never hesitate to terminate the procedure rather than risk a complication.
- Transmastoid labyrinthectomy is the gold standard procedure for surgical relief of vertigo from inner ear pathology but generally is reserved for patients who already have poor hearing in the involved ear.
- If hearing preservation is desired, selective vestibular nerve section procedures provide proven relief of vertigo for properly selected patients.
- If a patient describes a severe vestibular crisis at initial onset, without equally intense symptoms on any occasion since the original event, an uncompensated stable peripheral lesion is likely. Such patients are best treated with vestibular rehabilitation.
- Unilateral fluctuating or progressive sensorineural hearing loss is a strong indication of unstable inner ear function and is useful for lateralizing the offending ear.
- If uncertainty exists regarding which ear is causing vertigo, ablative surgery is not recommended. If the patient reports that vertigo spells are associated with auditory symptoms in the better ear, the second ear may have become involved, and surgery is ill-advised.

The otolaryngologist frequently is asked to evaluate a patient with intense vertigo or severe balance disturbance who has tried multiple medical treatments without success. Those who consider themselves disabled by their symptoms are eager, and often desperate, for relief. Although it is proper to consider surgical treatment in this setting, the physician should recognize that an unsuccessful surgical intervention may greatly aggravate the patient's discouragement regarding the disease, with the potential for alienation from the surgeon and from the medical profession in general. Recognizing the vulnerability of this patient population, the astute clinician seeks to guide the patient toward rational and effective surgical options when available, and to shelter them from nonvalidated medical or surgical treatments.

This chapter reviews the surgical procedures that are available for the management of vestibular disorders, with an emphasis on principles that promote understanding of the proper role and limitations of each procedure. Clinical application of these principles in patient selection can be expected to result in satisfactory outcomes in a high percentage of surgical procedures performed for dizziness.

Rationale for Surgery

When vertigo results from acute disturbances of the peripheral vestibular system, the patient will experience intense symptoms that gradually subside. If the lesion is self-limited and stable (e.g., acute viral labyrinthitis), it will not produce fluctuating or progressive dysfunction in the system. In this setting, the process of central vestibular compensation will reliably relieve dizziness in most patients by adjusting to the altered sensory inputs from the periphery. Similarly, ongoing vestibular compensation can minimize symptoms of vestibular loss from lesions that produce an insidious progressive deterioration, such as vestibular schwannoma. However, if the lesion is unstable or rapidly progressive in nature, central compensation is not possible unless the ear can be stabilized by medical or surgical management. Meniere's disease is the

prototypical disorder in this category, wherein the ear fluctuates between normal labyrinthine function and dramatic cochleovestibular pathology. Accordingly, vestibular system surgery is most likely to succeed when it is undertaken to stabilize an unstable ear, either by correcting a defect that underlies the disorder or by ablating function in the pathologic ear.

Certain surgical procedures are applicable only for one particular diagnosis. Some of these operations are widely accepted as both rational and effective, such as repair of a superior semicircular canal dehiscence or operations for intractable benign paroxysmal positional vertigo. Other disease-specific operations, such as endolymphatic sac surgery for Meniere's disease, repair of perilymph fistula, and microvascular decompression of the eighth nerve, continue to generate controversy. All of these operations have as their unifying feature the goal of correcting a pathologic process that is unique to the particular diagnosis, while preserving or restoring inner ear function. Success in this setting hinges on making an exact diagnosis and selecting operations with proven efficacy. On the other hand, procedures such as labyrinthectomy and vestibular nerve section are designed to ablate unilateral vestibular function and may be applied in the management of any peripheral vestibular disorder. In this setting, an etiologic diagnosis is less critical. Instead, the physician must be certain that the problem is attributable to ongoing fluctuating or rapidly progressive labyrinthine dysfunction and that the pathologic ear has been correctly identified.

Procedures for Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo (BPPV) most often affects the posterior semicircular canal. Variations of this condition affecting any of the three semicircular canals have now been recognized, as discussed in Chapters 164 and 165. BPPV seems to be caused by displaced otoconial debris within the membranous labyrinth. The original pathogenic hypothesis proposed that otoconial debris became lodged within the ampulla of the posterior semicircular canal (cupulolithiasis), rendering it sensitive to gravity. In the early 1990s, evidence accumulated to support the concept of otoconia floating freely in the membranous canal (canalithiasis).[1-3] These particles within the semicircular canal are purported to cause a transient flow of endolymph after a change in head position, producing a deviation of the cupula and triggering a change in the neural firing rate in the vestibular nerve. The brain perceives this change as rotation in the plane of the semicircular canal, with resulting vertigo and nystagmus. This theory is largely confirmed by the favorable results of particle repositioning maneuvers and the posterior canal occlusion procedure. It also better satisfies the conceptual framework for the biomechanics of BPPV originally suggested in the 1970s by McCabe and Ryu.[4] Although cupulolithiasis may certainly result in vestibular symptoms, this entity occurs much less frequently.

Before surgical procedures for BPPV are considered, it should be recognized that this condition has a high rate of spontaneous resolution and also is highly responsive to management by physical therapy interventions. Surgery is rarely required and should be reserved for refractory or multiply-recurrent cases. Nonsurgical management options[5] include traditional habituation exercises, Brandt-Daroff exercises, the liberatory maneuver of Semont, and particle repositioning techniques popularized by Epley and Parnes. A detailed discussion of these management options is provided in Chapters 163 and 165.

Singular Neurectomy

Gacek and Gacek[6] have advocated the singular neurectomy procedure for BPPV. This procedure involves selective transection of the branch of the inferior vestibular nerve innervating the posterior canal ampulla. The nerve is interrupted within the singular canal, which travels from the posterior portion of the internal auditory canal to the posterior canal ampulla (Fig. 167-1). This procedure is a highly rational choice for management of intractable posterior canal BPPV, because it is safer and more specific than a complete section of the vestibular nerve. However, this procedure is demanding technically and should not be undertaken unless the surgeon has mastered the approach in the temporal bone dissection laboratory. Gacek has performed 74% of the reported cases in the world literature, with preservation of hearing in 97% of the operated patients; other investigators report poor hearing results with this procedure.[7]

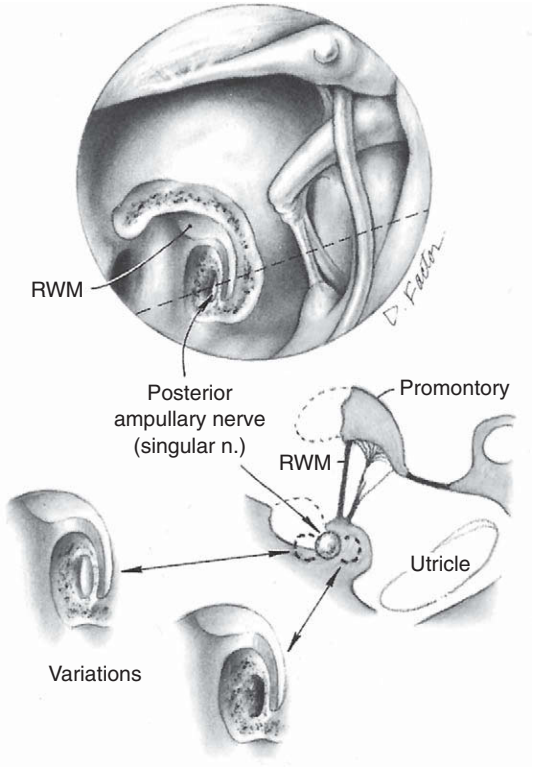

Figure 167-1. Singular neurectomy. After exposure of the round window membrane (RWM), the singular nerve is exposed inferior to the posterosuperior portion of RWM. Three variations in location of the nerve are illustrated in the vertical section taken along the broken line.

For this procedure, a tympanomeatal flap is elevated using a transcanal approach, and the bony lip of the round window niche is removed to visualize the round window membrane itself. The surgeon approaches the singular canal by drilling at a site inferior to the round window. Ideally, the nerve is transected just before its point of entry into the ampulla. The ampulla itself and the vestibule are at risk for injury during the procedure, and injury of either structure may result in severe vertigo and sensorineural hearing loss. One study suggested that the nerve measures approximately 5 mm in length and is best accessed by drilling approximately 0.7 mm posteroinferiorly to the posteromedial margin of the round window membrane after saucerization of the niche.[8] This study also found that whereas the average depth of the nerve was 1.5 mm, the posterior canal ampulla, the cochlear aqueduct, and the inferior cochlear vein were all within 2 mm of the preferred drilling point, which highlights the dangers of this approach. Another study showed that the nerve was always at least 0.7 mm from the edge of the exposed round window membrane, with an average depth of 1.3 mm.[9] Transtympanic access was believed to be straightforward in only 20% of specimens and impossible in 28%. This procedure has largely been supplanted by the technically simpler semicircular canal occlusion procedure.

Posterior Semicircular Canal Occlusion

Parnes and McClure[2] introduced the concept of surgical occlusion of the posterior semicircular canal for the relief of BPPV. Conceptually, the canal occlusion procedure is based on the assumption that otoconial debris, originally from the macula of the utricle, settles into the endolymphatic space of the posterior semicircular canal and produces the signs and symptoms of BPPV.

The surgery is conducted to obstruct the bony lumen of the dome of the posterior semicircular canal without disruption of the membra-

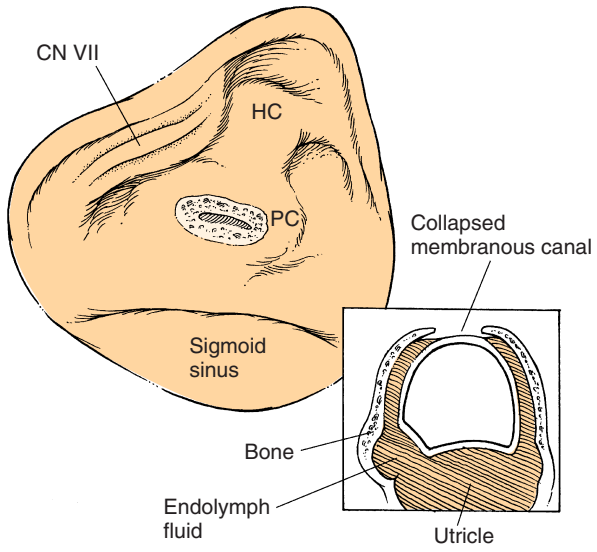

Figure 167-2. Posterior semicircular canal occlusion. After transmastoid exposure of the posterior semicircular canal, the bony lumen is opened and obstructed, with care to avoid disrupting the collapsed membranous canal (inset). CN VII, seventh cranial nerve; HC, horizontal semicircular canal; PC, posterior semicircular canal with fenestration.

nous labyrinth (see Fig. 167-2). After a complete mastoidectomy is performed, the horizontal semicircular canal is identified. The dome of the posterior semicircular canal is then identified between the horizontal canal and the posterior fossa dural plate. The lumen of the posterior canal is approached with a diamond drill until it is visible as a dark line through a thin layer of residual bone. The lumen is opened by removing the remaining thin bone over the canal lumen using delicate instrumentation, with care taken to avoid damaging the membranous canal or suctioning fluid from the perilymphatic space. The perilymph is gently removed by placing a wick of absorbent material near the labyrinthotomy site, causing the membranous semicircular canal to collapse against the deep wall of the bony canal lumen. The canal may then be occluded by placing small plugs of periosteum into the canal, one toward the ampulla and one toward the common crus. The labyrinthotomy is repaired by filling the lumen with wet bone dust harvested during the mastoidectomy. This material can be secured in position by placing bone wax or a piece of connective tissue over the dome of the canal.

The patient may have mild to moderate unsteadiness after the procedure but usually is fit for discharge from the hospital within 24 to 48 hours. A small risk of reactive labyrinthitis and sensorineural hearing loss is associated with the need to open the bony labyrinth. Approximately 15% of patients have protracted postoperative dysequilibrium, but vertigo control rates approach 100%, and hearing loss is uncommon.[10] Dizziness Handicap Inventory scores are reduced significantly, and patient satisfaction is 85%.[11]

Surgery for Superior Semicircular Canal Dehiscence

Minor[12] first described the syndrome of superior semicircular canal dehiscence (SSCD) in 2000. Further detailed characterization and recommendations for treatment have evolved since that ground-breaking report. Morphometric evidence indicates that SSCD may be associated with generalized reduction in the thickness of the squamous portion of the temporal bone,[13] which would predispose affected patients to middle fossa superior semicircular canal defects and explain the frequent association with natural dehiscences of the tegmen tympani and mastoideum. Aural pressure and unusual sensitivity to bone-conducted sounds are common complaints. Patients frequently report autophony, so this condition must be distinguished from the patulous eustachian tube. Vestibular symptoms typically are transient and are induced by loud sounds or any activity that leads to a transient increase in intracranial pressure. Some patients also report chronic dysequilibrium. Eye movements that are characteristic of superior semicircular canal stimulation may be seen in response to applied pressure stimuli—specifically, a torsional downward deviation of the eye. Vestibular evoked myogenic potential (VEMP) thresholds are reduced and amplitudes elevated in the setting of open dehiscence. Auditory findings include an apparent conductive or mixed hearing loss with a significant low-frequency conductive component. The apparent conductive hearing loss is believed to be caused by shunting of air-conducted acoustic energy away from the basilar membrance within the cochlea toward the dehiscence, which is functioning as a third mobile window.[14] It is essential to distinguish this condition audiometrically from otosclerosis by requesting testing for supranormal thresholds (often better than 0 dB) on bone conduction audiometry, and for the presence of acoustic reflexes.[15]

In cases in which clinical symptoms and test results suggest this diagnosis, high-resolution computed tomography (CT) of the temporal bone is indicated in an effort to visualize a dehiscence of the canal at the dural interface in the floor of the middle cranial fossa. These studies should be performed in a parasagittal plane orthogonal to the superior canal (Fig. 167-3). Generally, the dehiscence is repaired through a middle cranial fossa craniotomy, and evidence is mounting that disrupting the canal by obstructive plugging is superior to a simple repair ("resurfacing") of the defect.[16] Plugging of the SSCD reliably relieves vertigo symptoms and reduces the gain of the angular vestibulo-ocular reflex (VOR) by an average of 44% for the superior canal, along with a modest 10% reduction for the ipislateral posterior canal.[17] The procedure will resolve most of the auditory symptoms, but results are less predictable than those for vestibular symptoms. Care should be taken to avoid suctioning perilymph from the dehiscence during surgery; plugging may be accomplished with tissue plugs supported by bone chips or bone paté. In carefully selected patients, it may be possible to repair the dehiscence using a transmastoid approach, obviating the need for a craniotomy.[18]

Repair of Perilymphatic Fistula

Perilymphatic fistula is a controversial diagnosis that centers on the phenomenon of perilymph leaking from the inner ear into the middle ear cleft through the oval window, round window, or other abnormally patent fissures in the bony labyrinth.[19] A perilymph fistula may develop after stapedectomy surgery, penetrating middle ear trauma, head trauma, or barotrauma.[20] Uncertainty regarding the clinical criteria for the diagnosis and the inability to document the presence of a microfistula at surgery contribute to the problematic nature of this diagnosis.[21] Most authors agree that acute perilymph fistulas generally heal spontaneously, so a 2- to 3-day period of bedrest initially is appropriate. With suspected fistula after penetrating trauma, early exploration is indicated to preserve residual hearing, unless complete hearing loss is already present at diagnosis. In suspected chronic cases, a trial of vestibular rehabilitation before middle ear exploration may be appropriate if the diagnosis is uncertain, particularly if the hearing is stable.

Some investigators have attempted to use β-2 transferrin in fluids collected from the middle ear to support a clinical diagnosis of perilymph fistula, but results have been conflicting using this protein as a marker for perilymph.[22,23] Unpublished data from my laboratory suggest that assays for β-2 transferrin used for identification of cerebrospinal fluid leak are not sensitive enough to detect this protein in only 1 to 2 μL of perilymph. On the other hand, exquisitely sensitive assays will detect trace amounts that are present in serum, which could lead to false-positive results. Accordingly, use of this technique in an effort to confirm this diagnosis is not recommended.

An exploratory tympanotomy for perilymph fistula should be undertaken with use of local anesthesia and mild sedation whenever possible, so that the patient may be enlisted to perform the Valsalva maneuver to help identify perilymph leaks. After a tympanomeatal flap is elevated, bone is removed from the posterior superior wall of the bony external auditory canal until the oval window is completely visible. Likewise, it may be wise to remove any mucosal folds and the

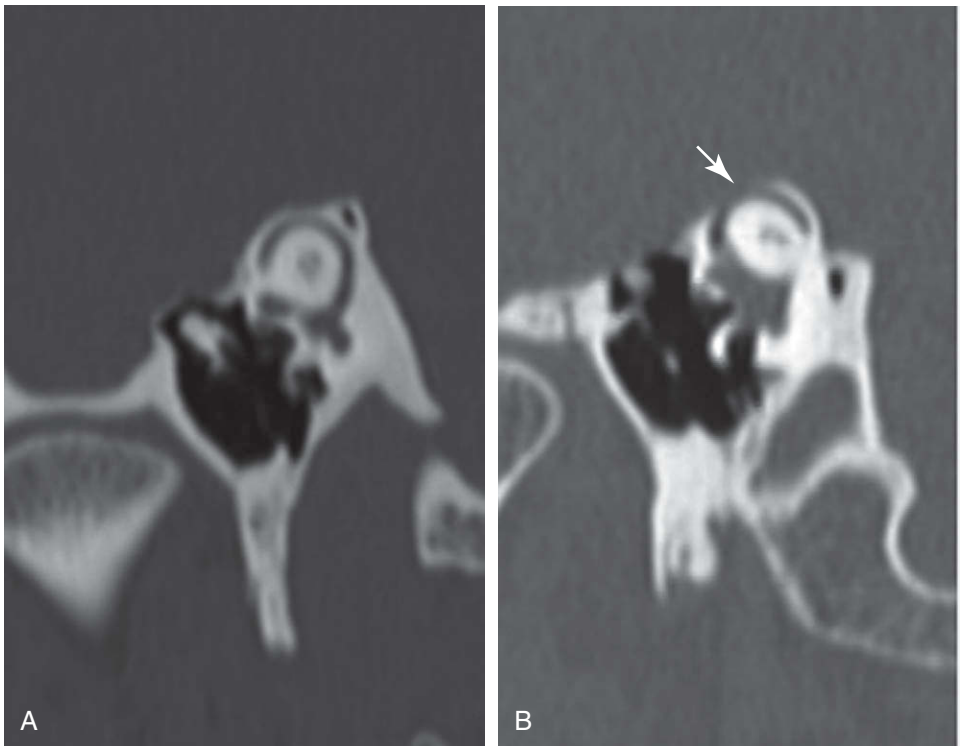

Figure 167-3. Superior canal dehiscence is best confirmed on a parasagittal computed tomography (CT) image obtained in the plane orthogonal to the superior canal. **A** shows a normal canal, with the *arrow* in **B** indicating a dehiscence.

bony overhang of the round window niche to better visualize the round window membrane. It is rare to see a dramatic defect in the oval or round window in routine perilymph fistula explorations. Fluid may be suctioned from the niche to see if it reaccumulates, although this phenomenon is common and does not verify that a perilymph fistula is present. Poe and Bottrill[24] have added credence to the suggestion that pooling of clear fluid in the oval or round window is due to transudation or to dependent accumulation of local anesthetic solutions. They performed transtympanic endoscopy of the middle ear before raising a tympanomeatal flap, and documented that fluid was not evident in the windows until after injection of the local anesthetic solution. In fact, endoscopic visualization of the middle ear could supplant formal tympanotomy for diagnosis of this disorder. The ear also should be inspected for abnormally patent fissures in the bony labyrinth, especially anterior to the oval window and inferior to the round window. Any suspicious defect should be repaired by removing surrounding mucosa and patching with connective tissue, secured by packing. My own practice is to routinely patch the round window niche in explorations with negative findings, but a more conservative approach is indicated in the oval window region to avoid the risk of an iatrogenic conductive hearing loss.

Specific Operations for Meniere's Disease

Meniere's disease is characterized clinically by the complex of recurrent episodic vertigo, fluctuating sensorineural hearing loss, tinnitus, and a subjective sense of aural fullness. If the diagnosis is uncertain, the indications for surgical procedures designed to address this specific disorder are less straightforward. The general teaching is that surgery is reserved for patients with "intractable vertigo in whom medical therapy has failed." Experience suggests that otologists differ significantly in their standards for determining medical failure. Some clinicians require that the patient experience 6 to 12 months of frequent and severe spells of vertigo before surgery is undertaken; others are willing to proceed more quickly. These differences are important to consider in evaluating uncontrolled clinical studies of surgical efficacy, especially in light of the spontaneous remissions that characterize this disorder.

A less invasive alternate treatment for Meniere's disease, intratympanic gentamicin injection, has become an accepted alternative to ablative surgery.[25-27] Uncontrolled reports of success with intratympanic corticosteroids are accumulating, but higher-quality studies of efficacy in this disorder are needed.[28] Therapy with a novel mechanical device, the Meniett device (Medtronic Xomed, Jacksonville, Florida), has demonstrated a significant reduction of episodic vertigo among surgical candidates in a placebo-controlled randomized clinical trial.[29] This therapy involves insertion of a tympanostomy tube in the affected ear, with subsequent application of intermittent pulsatile overpressure to the inner ear in 5-minute treatment cycles three times daily. Sustained remissions were typical, and only 24% elected to proceed to surgical treatment within 2 years.[30]

When a decision is made to proceed with surgery, questions arise regarding the choice of operation. Although vestibular nerve section or labyrinthectomy should reliably relieve vertigo related to Meniere's disease, these procedures ablate residual function in the affected ear. The ideal procedure for Meniere's disease would restore normal function, or at least preserve residual function, while stabilizing the ear. As discussed next, two operative procedures have been proposed to achieve this goal: cochleosacculotomy and endolymphatic sac surgery.

Cochleosacculotomy

The cochlear endolymphatic shunt procedure, usually referred to as *cochleosacculotomy*, is designed to create a permanent communication to equilibrate endolymphatic and perilymphatic pressures in the hydropic ear.[31] The goal is to create a small permanent fistula in the osseous spiral lamina within the basal turn of the cochlea. This is performed by elevating a tympanomeatal flap and exposing the round window niche. A 3-mm right-angle pick is inserted through the round window membrane and directed toward the oval window niche, hugging the lateral wall of the inner ear (Fig. 167-4), and fracturing the osseous spiral lamina. As might be expected, the operation has been associated with a 25% incidence of high-frequency sensorineural hearing loss and a 10% incidence of profound deafness.[32] Despite reports of 70% success with long-term relief of vertigo, the operation

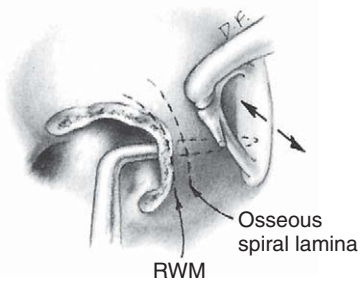

Figure 167-4. Cochleosacculotomy. Bony overhang of round window niche is removed to allow insertion of 3-mm, right-angle hook through the osseous spiral lamina of the basal end of the cochlea. Penetration of the tip of the hook can be monitored by movement of the stapes footplate. RWM, level of round window membrane.

has enjoyed only limited application. In one series of elderly patients with Meniere's disease, vertigo control was documented in almost every patient, but hearing was almost universally worse.[33] The study authors recommended that this operation be used as an alternative to labyrinthectomy in elderly patients with preexisting severe hearing loss.

Endolymphatic Sac Surgery

Although the specific physiologic defect causing Meniere's disease is unclear, many investigators report a beneficial effect in uncontrolled studies of surgical intervention directed toward the endolymphatic sac in patients with Meniere's disease. The first operative procedure on the endolymphatic sac was performed by Portmann.[34] Many modifications have been proposed, including bony decompression of the sac by Shambaugh,[35] placement of an endolymphatic-subarachnoid shunt by House,[36] and an endolymphatic-mastoid shunt by Shea.[37] Complications of endolymphatic sac procedures include hearing loss, cerebrospinal fluid leak, and facial nerve paralysis, although they are infrequent.

The efficacy of endolymphatic sac procedures has been widely questioned and debated. Some investigators suggest that the operation is ill-conceived and that the reported results may be biased or reflect a nonspecific effect of the operative undertaking or the natural history of this spontaneously remitting condition.[38,39] Evidence of a nonspecific effect of anesthesia on Meniere's disease has been provided by Gates,[40] who documented in a prospective observational trial that administration of a potent neuroleptic analgesic (Innovar) provided lasting relief of vertigo for most patients in whom medical management had failed to produce improvement. Advocates of sac surgery argue that a 50% to 70% success rate improves on the anticipated natural history in this patient population, making an endolymphatic sac procedure preferable to immediate use of an ablative procedure.[41] One uncontrolled observational study suggested that vertigo and vestibular disability could be largely corrected in 90% of patients evaluated 2 years after wide bony decompression of the sac and sigmoid sinus.[42] An important randomized clinical trial performed in Denmark during the 1970s compared endolymphatic sac decompression with a "sham" cortical mastoidectomy operation. The patients and those evaluating the outcomes were blinded to group assignment. Multiple subsequent reports were published, culminating with a 9-year follow-up report.[43] Both surgical groups demonstrated improvements that were not statistically different, and the investigators concluded that clinical improvement with decreased vertigo was attributable to a "placebo effect." The conclusions of this study have been widely debated, with proponents of sac surgery arguing that the sample size was too small to detect clinically important differences and pointing out that both groups did improve, thus arguing in favor of the operation even if the effect was nonspecific. Welling and Nagaraja[44] reanalyzed the data from this study by more sophisticated modern statistical methods. They demonstrated from the original data set that, even with the small sample size, the sac surgery group showed statistically significant reductions in postoperative vertigo, nausea and vomiting, and tinnitus compared with the mastoidectomy control group. Unfortunately, because the study did not include a nonsurgical control group, the potentially important influence of disease natural history on the reported efficacy could not be assessed. The Danish group performed another small controlled study comparing endolymphatic sac decompression and insertion of a tympanostomy tube, demonstrating that both groups had similar levels of improvement.[45] Again, a nonsurgical control group was not used.

One difficulty in performing vertigo outcome studies has been a lack of validated metrics for measuring treatment outcome. A previously validated medical quality-of-life instrument, the SF-36, has been demonstrated to correlate well with the 1995 disease reporting classification[44] proposed by the American Academy of Otolaryngology–Head and Neck Surgery (AAO-HNS).[46] The study showed that preoperative patients scored well below population norms, and that those achieving AAO-HNS class A or B outcomes (vertigo relief) normalized their scores. Alternative metrics have been proposed for future prospective studies that are more specific to Meniere's disease.[47,48]

In the absence of properly controlled clinical trials, the otologist should perform a critical review of the literature before recommending endolymphatic sac procedures. Several specific issues warrant consideration: Is endolymphatic sac surgery sufficiently efficacious for control of vertigo in patients who are eager for reliable results? If so, do the results deteriorate over time? Is the efficacy of sac surgery reported in uncontrolled observational studies inflated, in view of the retrospective nature of the studies? Is most of the observed benefit attributable to the placebo effect or to another nonspecific effect of surgery? The available evidence seems to indicate that endolymphatic sac surgery has not been demonstrated to be a sufficiently reliable surgical treatment for Meniere's disease. Continued uncertainty about these issues after decades of clinical experience underscores the need for properly controlled multi-institutional clinical trials to address the role of endolymphatic sac surgery in Meniere's disease.

The surgical approach to the endolymphatic sac begins with a cortical mastoidectomy. Once the antrum is exposed, it is wise to copiously irrigate the cavity and temporarily obstruct the aditus ad antrum to prevent bone dust from accumulating in the middle ear, which can result in a delayed conductive hearing loss from fixation of the ossicular chain. The bony labyrinth, particularly the posterior semicircular canal, should be positively identified before any bone is removed from the posterior fossa dura.

The endolymphatic sac is simply a specialized portion of the posterior fossa dura that contains the resorptive epithelium of the membranous labyrinth. It is connected to the vestibule by the endolymphatic duct, which travels in the vestibular aqueduct through the bony labyrinth medial to the posterior semicircular canal and then parallel to the common crus of the posterior and superior semicircular canals. The entrance of the endolymphatic sac into the vestibular aqueduct is a helpful surgical landmark in seeking to identify the sac. It is located roughly at the point where a hypothetical line parallel to the horizontal semicircular canal bisects the dome of the posterior semicircular canal (Donaldson's line). In seeking to identify the sac, this critical landmark should be remembered, because the endolymphatic sac is always inferior to this line. As indicated by my own experience performing surgical procedures after previous "endolymphatic sac decompression" failures, a not uncommon finding in such cases is that this area of the temporal bone was not previously dissected, so that the sac was never actually identified or decompressed.

The endolymphatic sac is bounded superiorly by Donaldson's line, posteriorly by the sigmoid sinus, anteroinferiorly by the jugular bulb, and laterally by the descending (mastoid) portion of the facial nerve. This region of the temporal bone may be poorly pneumatized, because there seems to be an association between Meniere's disease and underdevelopment of this portion of the mastoid process. Such an operative finding not only makes proper identification of the sac difficult but also increases the danger of injury to the facial nerve and the sigmoid sinus. To avoid injury to these structures, the surgeon should widely remove bone posterior and lateral to the sigmoid sinus. The digastric ridge should be identified inferiorly and followed toward the stylomastoid foramen. This will allow the surgeon to open any retrofacial air cell tract that is present and thus to identify the level of the facial nerve. After these structures are positively identified, the posterior

Endolymphatic sac surgery. **A,** Endolymphatic sac exposed by transmastoid approach and incised. **B,** Endolymphatic sac–mastoid shunt involves placing Silastic sheeting or a shunt into the lumen of the sac. **C,** Endolymphatic sac–subarachnoid shunt placement requires penetration of the deep layer of the sac lumen (posterior fossa dura) into the subarachnoid space. CN VII, seventh cranial nerve; HC, horizontal semicircular canal; PC, posterior semicircular canal.

fossa dura behind the sinus and the sinus itself should be decompressed with a large diamond drill. The surgeon then may retract the sinus and dissect bluntly between the bony dural plate and the presigmoid posterior fossa dura (containing the endolymphatic sac). After the sinus and the dura are safety retracted, the bony dural plate inferior to Donaldson's line can be removed down to the level of the jugular bulb. Dissection may proceed anteromedially into the retrofacial air cell tract until the site of the endolymphatic duct's entry into bone medial to the posterior semicircular canal is seen. Care should be taken not to injure the medial surface of the facial nerve or the dome of the posterior canal while drilling in this region. This portion of the dissection is greatly facilitated by the dural decompression that has already been accomplished.

Once the sac has been identified, the surgeon should decide whether to terminate the procedure, having accomplished a wide bony decompression, or to open the lumen and place a shunt. Reported series of wide bony decompression without shunting[49] compare favorably with those series that included shunt procedures. Some experts have recommended placing a pressure-sensitive valve into the endolymphatic duct after the sac lumen has been opened and followed into the duct.[50] Other surgeons have failed to achieve the positive results originally reported with this procedure.[51] It often is difficult or impossible to identify one predominant lumen of the sac, and foreign material placed into the sac has been shown to become rapidly encapsulated with fibrous tissue. Despite these considerations, most surgeons who perform endolymphatic sac surgery choose to place a shunt from the sac into the mastoid cavity (Fig. 167-5A and B). On the other hand, use of an endolymphatic sac–subarachnoid shunt[36] (Fig. 167-5C) carries a higher risk of cerebrospinal fluid leak. Beyond this consideration, the procedure seems to be conceptually flawed, because the pressure in the subarachnoid space will always exceed that in the endolymphatic space, even in an ear with significant endolymphatic hydrops. In general, the more the sac is surgically manipulated, the greater the risk of cerebrospinal fluid leak postoperatively. When it is difficult to identify the sac or its lumen, the prudent surgeon will never hesitate to terminate the procedure rather than risk a serious complication.

Patient Selection in Ablative Vestibular Surgery

The patient with recurrent vertigo that has been refractory to medical or conservative surgical treatment is a candidate to undergo a procedure that will ablate the residual vestibular function in the involved ear. In this setting, the patient willingly sacrifices the residual function in the diseased ear in order to eliminate the spontaneous episodes of vertigo that result from fluctuating inputs from the labyrinth to the central nervous system. A successful outcome hinges on the patient's ability to compensate centrally for the unilateral loss of function.

The transmastoid labyrinthectomy is the gold standard procedure for surgical relief of vertigo from inner ear pathology. Because complete loss of residual hearing is inevitable after this operation, it is reserved for those patients who have poor hearing in the affected ear. When hearing must be preserved, a selective vestibular nerve section procedure may be undertaken. Although more risky and slightly less reliable, vestibular neurectomy enjoys a proven track record in the surgical relief of vertigo in properly selected patients. Both of these procedures ideally will produce a total loss of afferent input from the offending vestibular periphery. Although these procedures are applied most often in persons with Meniere's disease, they may be effective in patients with any unstable peripheral vestibular disorder.[52,53]

The Priority of Distinguishing Poor Compensation from Unstable Labyrinthine Disease

Although the specific etiology of dizziness is at times elusive, it usually is possible to distinguish on clinical grounds those patients whose symptoms are caused by an uncompensated stable lesion from those with unstable or progressive disease in the vestibular system. It generally is believed that an operation designed to ablate unilateral vestibular function can effectively relieve vertigo caused by labyrinthine dysfunction of any cause. However, failure to recognize that the patient's symptoms result from poor vestibular compensation for a stable lesion may lead to inappropriate and fruitless surgical intervention.[54] This categorical distinction has important management implications, especially as current understanding of vestibular compensation has evolved. Before the availability of vestibular rehabilitation programs, surgery to ablate vestibular function was offered to any patient whose vestibular injuries were clearly peripheral in nature and could be lateralized to one ear. Subsequently, however, it was demonstrated that the results obtained with vestibular rehabilitation are markedly superior to those with vestibular nerve section for the control of symptoms caused by uncompensated vestibular neuritis (Table 167-1). Thus, surgery is rarely recommended for this indication today. With uncompensated lesions, both surgeon and patient should be aware that the prognosis for success is dramatically lower than that reported for disorders characterized by fluctuating or deteriorating unilateral labyrinthine function.

The methods available to help the clinician distinguish uncompensated patients with a stable vestibular lesion from those with unstable labyrinthine pathology include recognition of key features in the clinical history, the use of vestibular testing, and, when appropriate, the use of a therapeutic trial of vestibular rehabilitation.

Clues in the Clinical History

It often is argued that a complete neurotologic history is the most important component in the diagnostic evaluation of the patient with a balance disorder. This also is true in the assessment of the patient's compensation status. Certain clues in the history will suggest that the patient has incomplete compensation, despite the fact that the vestibular lesion is stable. If the patient describes a severe vestibular crisis at onset without equally intense symptoms on any occasion since that time, an uncompensated lesion is more likely, and the patient is best treated with vestibular rehabilitation. Poor compensation is particularly likely to be the cause of continuous unsteadiness or mild recurring motion-provoked vertigo after recovery from the severe crisis. However, if the current spells are just as severe or more severe than the initial insult, an unstable or progressive vestibular lesion is strongly suggested. In such cases, the patient is best treated with medical or surgical measures designed to stabilize labyrinthine function, once the possibility of a central pathologic process has been eliminated.

The documentation of fluctuating or progressive sensorineural hearing loss also provides a strong indication of unstable inner ear function. Sometimes the patient is uncertain about the nature of an

Table 167-1

University of Michigan Treatment Results in Uncompensated Vestibular Neuritis

Outcome	Vestibular Nerve Section ($n = 16$)	Vestibular Rehabilitation ($n = 59$)
Complete improvement	None	25%
Dramatic improvement	25%	47%
Mild improvement	45%	13%
No improvement	25%	15%
Worse	5%	None

associated hearing loss. A review of serial audiograms may be helpful in this setting. Occasionally, it is desirable to obtain an audiogram during an episode of vertigo to determine whether subtle changes in auditory function are occurring that may be imperceptible to the patient.

The Role of Vestibular Testing

A complete battery of vestibular tests may be helpful in assessing compensation status or in explaining poor compensation by identifying pathologic processes in the central nervous system. The specific vestibular test results that may be helpful in these distinctions are summarized in Box 167-1.

Clinically significant spontaneous nystagmus, positional nystagmus, or a directional preponderance on electronystagmography (ENG) or videonystagmography (VNG) studies provides evidence for failure of physiologic compensation in the VOR. Rotational chair phase or gain abnormalities may identify a pathologic change in the VOR but do not assess compensation within the central nervous system. However, persistent asymmetry in VOR responses strongly suggests that the peripheral lesion is physiologically uncompensated. For head rotation toward the paretic side, the maximum eye velocity induced by the VOR is reduced from normal. This fact results in the observed asymmetry of VOR gain for rightward versus leftward rotations. This asymmetry usually resolves as the compensation process proceeds, at least in the subphysiologic range tested by rotational chair technology. A persisting VOR asymmetry even in well-compensated patients may be identified using the head thrust test above frequencies of 1 Hz.

Dynamic posturography provides adjunctive functional information about the balance system. Sometimes a patient whose major complaints are related to the vestibular system will have normal findings on ENG and rotational chair testing. Posturography may help to demonstrate continued functional impairment despite relatively normal physiologic responses in both inner ears. Patient age and preoperative posturography score have been shown to correlate strongly with postoperative Dizziness Handicap Inventory score.[55] Any evidence of a malingering pattern on postural control testing also may inform the clinician of previously unsuspected psychosocial issues complicating the patient's care.

Box 167-1

Clinical Usefulness of Vestibular Test Results

Evidence for Peripheral Labyrinthine Dysfunction
Unilateral caloric weakness
Spontaneous or positional nystagmus with normal oculomotor findings
Rapid positioning nystagmus after Dix-Hallpike maneuver
Rotational chair phase or asymmetry abnormality
Reduced VOR gain on rotational chair (bilateral weakness)

Evidence for Central Nervous System Pathology
Vertical or perverted nystagmus
Oculomotor test abnormalities
Failure of visual fixation suppression of nystagmus
Motor coordination test abnormalities on dynamic posturography, without musculoskeletal disorder

Evidence for Uncompensated Status
Persistent spontaneous or positional nystagmus
Post–head-shaking nystagmus
Rotational chair asymmetry
Sensory organization test abnormalities on dynamic posturography

Evidence for Improved Compensation Status after Treatment
Resolution of nystagmus
Resolution of rotational chair asymmetry
Improved performance on posturography

VOR, vestibulo-ocular reflex.

Therapeutic Trial of Vestibular Rehabilitation

Ultimately, even with the best clinical history and vestibular test capabilities, the clinician often is faced with diagnostic uncertainty when treating patients with dizziness. As an extreme example, a head injury patient who has a mix of spontaneous and motion-provoked symptoms exhibits evidence of central and peripheral vestibular dysfunction; chronic headache, impairment of cognitive function, and reactive depression also are present. In such patients, it may be difficult or impossible to identify the primary cause of ongoing disability. In settings of diagnostic uncertainty, a program of supervised vestibular rehabilitation may be helpful from a diagnostic standpoint.[5] The patient may make outstanding progress, suggesting that the primary problem was poor compensation for a stable lesion in the vestibular system. If the patient fails to improve, or seems to be worse after 4 to 6 weeks of therapy, an unstable lesion of the labyrinth is considerably more likely. Such an outcome would add credibility to a clinical diagnosis such as post-traumatic endolymphatic hydrops or perilymphatic fistula.

Identification of the Offending Labyrinth

If if there is any uncertainty regarding the ear that is causing vertigo, ablative surgery should not be considered. Reliable lateralizing features include fluctuating or progressive unilateral sensorineural hearing loss and a consistently reproducible unilateral reduction of responsiveness to caloric irrigations. An asymmetrical hearing loss in one ear is the best indicator of the abnormal side.[56] Preexisting hearing loss of extended

duration need not dissuade the physician from incriminating the involved ear as the cause of vertigo.[57,58] To illustrate the importance of this point, one study demonstrated 100% relief of vertigo in 13 patients with delayed-onset endolymphatic hydrops beginning up to 60 years after the onset of hearing loss.[59] Less reliable features include tinnitus, subjective sense of aural fullness, direction of observed spontaneous or positional nystagmus, and rotary chair asymmetries. Although audiologic and vestibular test results usually are reliable in determining the involved ear, they should always be interpreted in light of the entire clinical presentation, to avoid a serious error in diagnosis. For example, with significant unilateral sensorineural hearing loss and a unilateral vestibular weakness on the same side, the clinician usually can be confident that the suspect labyrinth is pathologic. However, if the patient reports that the vertigo spells are associated with roaring tinnitus or hearing fluctuations in the better ear, it is most likely that the second ear has become involved. In this case, surgery would be ill advised.

Identification of Intracranial Pathology

Acoustic neuroma and other lesions of the posterior fossa may manifest with clinical features indistinguishable from those of classic vertigo syndromes.[60] Therefore, it is appropriate to perform a definitive radiographic imaging study before vestibular surgery of any type is undertaken. Magnetic resonance imaging (MRI) of the posterior fossa with gadolinium enhancement provides a reliable means of detecting tumors of any size, early stages of demyelinating disease, and subtle ischemic lesions of the brainstem.

Consideration of Other Potential Treatments

Although labyrinthectomy and vestibular nerve section may be applied in any peripheral vestibular disorder, certain patients may be effectively treated by simpler procedures. The use of transtympanically injected aminoglycosides for chemical suppression or ablation of labyrinthine function is particularly appropriate for the management of Meniere's disease in those patients who would be poor surgical candidates.

Brackmann and associates[61] performed 25 eighth nerve microvascular decompression procedures for vertigo in 20 patients over one decade. This procedure was limited to patients who did not have episodic vertigo but had disabling motion-induced dizziness unrelieved by vestibular rehabilitation exercises or conventional medications. The diagnosis was confirmed when these symptoms were associated with radiographic evidence of a vessel loop impinging the nerve. The investigators reported significant improvement in 80% of patients. This procedure offers the potential to reduce vestibular symptoms without destruction of vestibular function in properly selected patients.

Residual Hearing and Selection of Procedure

Generally, labyrinthectomy is reserved for patients with extremely poor residual hearing in the involved ear. Rather than setting a specific hearing threshold or speech discrimination score as the criterion for suggesting a vestibular nerve section instead of a labyrinthectomy, most surgeons prefer to consider each case on an individual basis. Ultimately, the patient's perception of the usefulness of the residual hearing is the most important factor. Some patients insist that they receive benefit from hearing aid use in ears that the medical community would deem useless compared with the better ear. Others fail to recognize any functional utility from an ear that should provide benefit with proper amplification. Clearly, such perceptions must influence the choice of surgical procedure. It is appropriate to perform a labyrinthectomy instead of a selective vestibular nerve section if the contralateral ear is stable, if the patient is convinced that the involved ear is functionally useless, or if the incremental risks of intracranial surgery are unacceptable. A vestibular neurectomy is appropriate when hearing in the involved ear is deemed useful by the patient, especially when the hearing in the involved ear is unlikely to deteriorate in the near future. However, because the cochlear efferent fibers travel with the vestibular nerve, it must be recognized that a vestibular neurectomy may contribute to undesirable hearing symptoms in Meniere's disease: Sound intolerance and reduced speech discrimination in noise may be evident, even if the pure-tone detection and discrimination scores in quiet are unchanged.[62]

Some investigators argue that labyrinthectomy should never be performed if any hearing remains, fearing the unlikely scenario that the better ear may develop a hearing loss greater than the current loss in the diseased ear. If this rare outcome should occur, a cochlear implant in the most recently deafened ear would almost certainly rehabilitate the patient successfully. Insisting on the preservation of minimal residual hearing in a functionally useless poorer ear is too dogmatic to be practical, especially when the additional risks of vestibular nerve section, such as intracranial hemorrhage, meningitis, and cerebrospinal fluid leak, are considered. Beyond this, the available evidence suggests that preserved hearing often will continue to deteriorate and eventually provide no benefit for the patient.[63,64]

Ablative Procedures for the Control of Vertigo

Surgery for control of vertigo symptoms is virtually always elective. Patients should decide when their vertigo has produced sufficient disability in their lifestyle to outweigh the consequences and risks of surgery. A patient who has come to this decision without coercion by family or the physician is most prepared to face the surgery and the recovery period with a positive outlook.

Labyrinthectomy

Labyrinthectomy may be performed when persistent or recurrent labyrinthine symptoms of any etiology are attributed to dysfunction in an ear with severe to profound sensorineural hearing loss. All residual hearing sensitivity is sacrificed by this procedure. The operation may be undertaken using a transcanal or transmastoid approach. The transcanal labyrinthectomy, also known as oval window labyrinthectomy, retains some popularity. It can be performed quickly by approaching the inner ear through the external auditory canal, although complete ablation of vestibular neuroepithelium cannot reliably be accomplished.[65] The procedure begins by elevating a tympanomeatal flap to enter the middle ear and then accessing the vestibule of the bony labyrinth by removing the stapes from the oval window. Some surgeons advocate removing bone from the promontory below the oval window toward the round window to improve visualization of the vestibule (Fig. 167-6A). The saccule and utricle are identified and removed. An attempt may be made to reach and remove the ampullae of the horizontal and superior semicircular canals, although this step requires blind manipulation with a long right-angled instrument medial to the facial nerve. Augmenting this procedure by a selective section of the nerve to the posterior semicircular canal ampulla should help to prevent residual posterior canal function. To accomplish this, the bony exposure of the vestibule can be extended by drilling near the round window until the nerve to the posterior ampulla is identified and divided. Because the primary shortcoming of the transcanal labyrinthectomy is the inability to visualize all neuroepithelial elements of the inner ear, many surgeons supplement their mechanical efforts by filling the vestibule with absorbable packing soaked with an ototoxic aminoglycoside antibiotic, which enhances the likelihood of success. Although this procedure reliably eliminates vertigo, postoperative imbalance is seen in more than 60% of patients, a rate almost three times higher than after transmastoid labyrinthectomy in the elderly population.[66]

Transmastoid labyrinthectomy (Fig. 167-7) is the gold standard procedure for surgical ablation of vestibular function. The transmastoid approach allows complete visualization and removal of the entire semicircular canal system, utricle, and saccule, resulting in highly reliable relief of vertigo.[67,68] Success is nearly universal and the improvement in quality of life is remarkable for properly selected patients.[69] This transtemporal procedure requires precise knowledge of the anatomy of the bony vestibular labyrinth and other structures in the temporal bone that are medial to the tympanic and mastoid portions of the facial nerve. The neurotologic surgeon who is familiar with transtemporal surgical approaches generally is very proficient operating in this region and can be expected to safely accomplish a complete labyrinthectomy by way of a transmastoid approach. Those surgeons who are less familiar with the anatomy of the temporal bone medial to the facial nerve

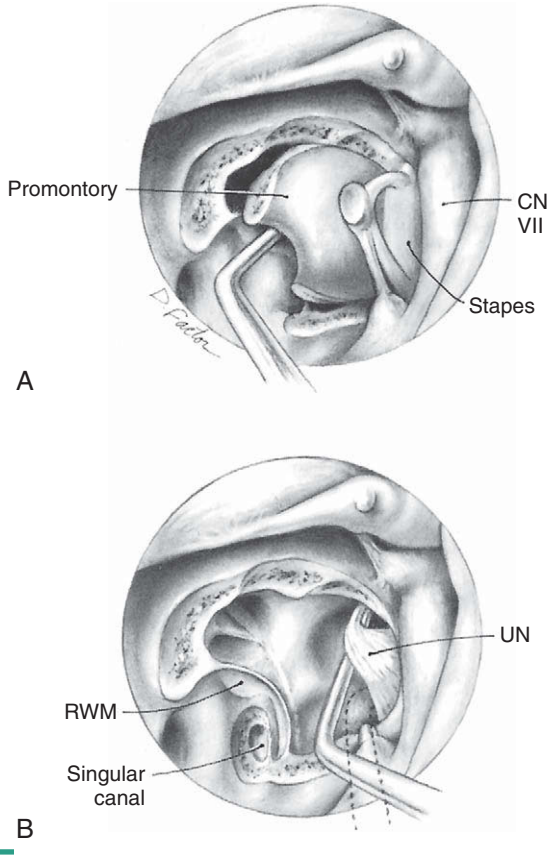

Figure 167-6. Transcanal labyrinthectomy. **A,** Removal of promontory bone and stapes provides wide exposure of vestibule. **B,** Right-angle hook is used to extract utricular neuroepithelium (UN) from the elliptical recess on the roof of the vestibule. Singular canal has been opened and the nerve to the posterior canal ampulla divided. CN VII, seventh cranial nerve; RWM, round window membrane.

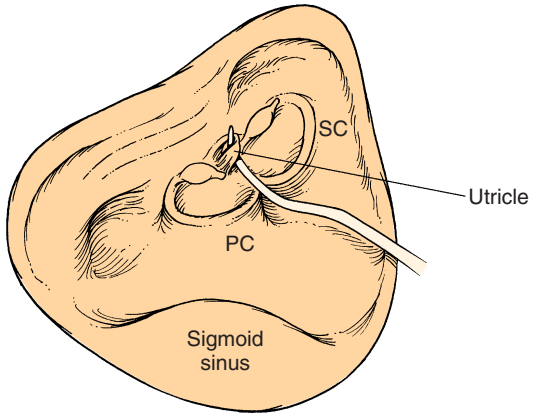

Figure 167-7. Transmastoid labyrinthectomy (left ear). Exposure of the ampullated ends of all three semicircular canals and the vestibule is accomplished, and all neuroepithelium is removed under direct vision. Care is taken to skeletonize but not expose the facial nerve. PC, posterior semicircular canal; SC, superior semicircular canal.

should familiarize themselves with this approach in the temporal bone laboratory before undertaking this procedure in the clinical setting.

The procedure begins with a cortical mastoidectomy performed through a postauricular approach. After the central mastoid air cell tract and the antrum are identified, the cavity should be widely beveled to improve exposure. Special attention should be paid to beveling the bone over the middle fossa dura and the sinodural angle; otherwise, the angle of visualization medial to the facial nerve may not be adequate to allow safe opening of the vestibule and the posterior canal ampulla. Rarely, a limited decompression of the middle fossa dura or the sigmoid sinus is required in a poorly pneumatized mastoid. After the mastoidectomy is completed, the dome of the horizontal semicircular canal is visible at the depth of the antrum. The largest burr or coarse diamond drill bit that will fit safely between the middle fossa dura and the dome of the horizontal canal (usually 4 mm) should be selected. Proper use of continuous suction-irrigation allows the surgeon to prevent injury to soft tissue structures that limit the margins of dissection, such as dura, the superior petrosal sinus, and the facial nerve. Drilling of the labyrinth should commence by deepening the "solid angle" between the three bony semicircular canals before the lumen of any canal is opened. The surgeon will then sequentially open the lumen of the bony semicircular canals, bivalving the internal surface of each canal toward the center of an ever deeper and wider bony cup that is developed as labyrinthine bone is removed.

Generally, the horizontal canal lumen is opened first and used as a landmark to protect the tympanic segment of the facial nerve. The equator of the rotating drill bit should never be allowed to come lateral to the inferior lip of the bony cup, because this would cause the drill to slip into the facial nerve. It is especially dangerous when a right-handed surgeon is operating in the right ear with the drill rotating clockwise. Some surgeons elect to reverse the direction of drill rotation for this part of the procedure in the right ear, to allow better control of the drill. After the horizontal canal lumen is identified, it is followed posteriorly toward the nonampullated end until the dome of the posterior canal is opened. This canal is then followed to the common crus, where the superior canal lumen can also be identified. By progressively deepening and widening the bony cup, it is possible to follow the superior canal toward its ampullated end. During this portion of the dissection, minor bleeding from the subarcuate artery is to be expected. Although this may be a nuisance, it is best to press ahead and completely open the arch of the superior canal and then control the vessel once in an definitive fashion, rather than stopping to address the bleeding several times.

The superior canal ampulla is adjacent to the horizontal canal ampulla, which is opened next. To approach the ampullated end of the posterior semicircular canal, the nonampullated end of the horizontal canal will have to be progressively transgressed until the posterior portion of the vestibule is open. The surgeon should stay within the cup and follow the internal surface of the posterior canal lumen as it passes medial to the second genu of the facial nerve. Care should be taken to avoid injury to the medial surface of the nerve by undercutting it with the drill. To prevent this injury, the surgeon should bevel the cup laterally over the second genu of the nerve and not allow an overhang of bone to develop that may potentially obscure visualization. It is safe and perhaps even desirable to carefully identify the nerve sheath through a thin layer of intact bone, a technique known as "skeletonizing" the nerve. This allows the surgeon to visualize and securely verify the position of the nerve. Whenever the nerve is being skeletonized, it is important to use a gentle polishing drill motion that parallels the direction of the nerve, along with copious irrigation so that the nerve can be seen through the bone before the sheath is exposed or injured. A smaller drill (usually 3 mm) is required to work safely between the skeletonized facial nerve and the posterior fossa dura. After the posterior canal ampulla has been opened, bone can be removed over the vestibule by connecting the three ampullated ends. Then sufficient access has been achieved so that all elements of the membranous labyrinth may be removed, including the cupula of each semicircular canal, the utricle, and the saccule. Care should be taken not to perforate the thin bone at the lateral end of the internal auditory canal during removal of neuroepithelium.

Disadvantages of labyrinthectomy include complete ipsilateral loss of hearing and a period of postoperative vertigo. Nystagmus usually is brisk and may persist for several days. Generally, the patient walks unassisted by the second or third postoperative day. Although vestibu-

lar compensation is mostly complete by 2 months postoperatively, further gradual improvement over 12 to 18 months may be anticipated. In some patients, significant dysequilibrium persists. Rare complications of labyrinthectomy that should be discussed with patients include facial nerve injury, cerebrospinal fluid leak, and disabling chronic dysequilibrium. In experienced hands, the overall occurrence of surgical complications is infrequent. Because the operation should not violate the dura of the posterior cranial fossa or the internal auditory canal, the risk of meningitis or cerebrospinal fluid leak is slight.

Vestibular Nerve Section

Success rates for control of vertigo by all approaches to the vestibular nerve ranges from 80% to 95%, notably poorer than with labyrinthectomy. In most cases, a vestibular nerve section procedure is selected in an effort to relieve episodic vertigo without sacrificing the patient's residual hearing. However, a complete discussion of the subject must at least mention two rarely used approaches for vestibular nerve section that, like labyrinthectomy, do sacrifice residual auditory function. These are the translabyrinthine vestibular neurectomy[70] (Fig. 167-8) and the transcochlear cochleovestibular neurectomy[71] (Fig. 167-9). Each of these operations supplements one of the two common labyrinthectomy procedures by adding an intradural dissection of the eighth cranial nerve within the internal auditory canal. The rationale used to justify adding a vestibular neurectomy after the labyrinthectomy has been completed is to accomplish division of the vestibular nerve medial to Scarpa's ganglion in the internal auditory canal. In the translabyrinthine vestibular neurectomy, a transmastoid labyrinthectomy is completed, and the internal auditory canal dura is then identified and opened, exposing the neural contents of the canal. Both the superior and inferior divisions of the vestibular nerve may then be avulsed from the lateral end of the canal and sectioned medial to the ganglion. Similarly, the transcochlear cochleovestibular neurectomy extends the transcanal labyrinthectomy to open the cochlea and the distal end of the internal auditory canal to section the cochlear nerve along with the vestibular nerve. The cochlear neurectomy is added in an effort to decrease tinnitus after the procedure. This approach currently has few adherents, because most reports of cochlear nerve section for tinnitus have shown a dismal success rate, thus failing to justify the additional risk associated with opening the internal auditory canal.

The rationale for these two extensions of labyrinthectomy procedures is dubious because of the excellent results obtained with transmastoid labyrinthectomy alone,[72] especially in view of the increased risk of cerebrospinal fluid leak and meningitis associated with intradural dissection.

Most often, vestibular nerve section is performed in an effort to eliminate disordered vestibular function while preserving useful hearing in the symptomatic ear. In this setting, selective section of the vestibular nerve is the primary goal, with intent to preserve the labyrinth, auditory nerve fibers, and cochlear blood supply. The best surgical approach for selective vestibular nerve section remains a controversial issue. The three conventional approaches that are used are the middle fossa approach, the retrolabyrinthine approach, and the retrosigmoid approach.

The middle fossa approach, popularized in the 1970s by Fisch[73] and Glasscock,[74] is the most technically demanding. It permits the most definitive section of the vestibular fibers by specifically identifying the superior and inferior vestibular nerves within the lateral portion of the internal auditory canal. In this location, they have separated anatomically from the auditory fibers of the eighth nerve (Fig. 167-10). Although this approach provides a better opportunity to avoid injury to the cochlear nerve fibers, it carries a risk for injury to the cochlear blood supply, because the labyrinthine artery ramifies in the distal portion of the internal auditory canal, in close proximity to the inferior vestibular nerve. If the surgeon elects to avoid this risk by choosing not to transect the inferior vestibular nerve, episodic vertigo may persist. In addition, this operation involves the highest rate of injury to the facial nerve among conventional approaches for vestibular neurectomy (with temporary paresis rates as high as 33%) and a significantly higher rate than in labyrinthectomy.[75,76]

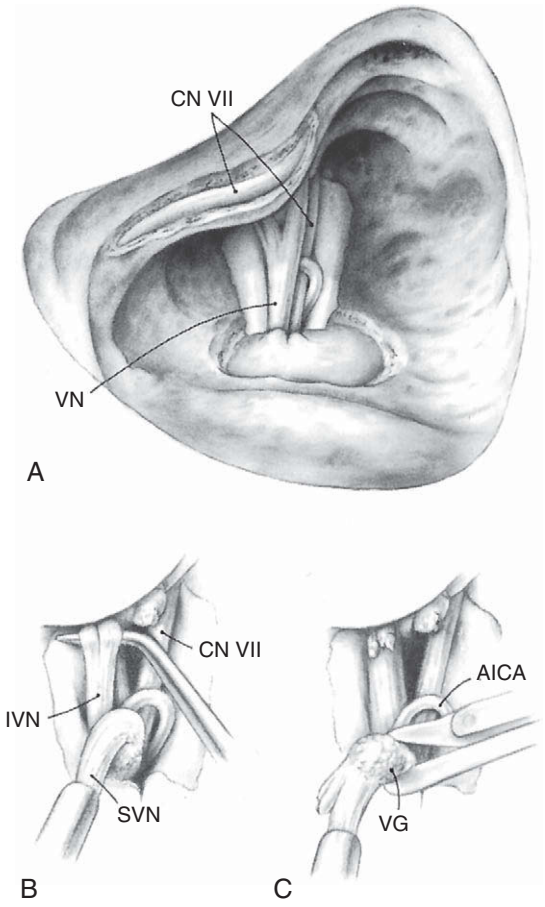

Figure 167-8. Translabyrinthine vestibular nerve transection. **A,** Nerves of internal auditory canal are exposed. **B,** Traction on the transected end of the superior division of the vestibular nerve (SVN) permits exposure of the inferior division of the vestibular nerve (IVN). **C,** Transection of the nerve trunk proximal to the vestibular ganglion (VG) completes excision of vestibular neurons. Anterior inferior cerebellar artery (AICA) is occasionally visualized. CN VII, seventh cranial nerve; VN, vestibular nerve.

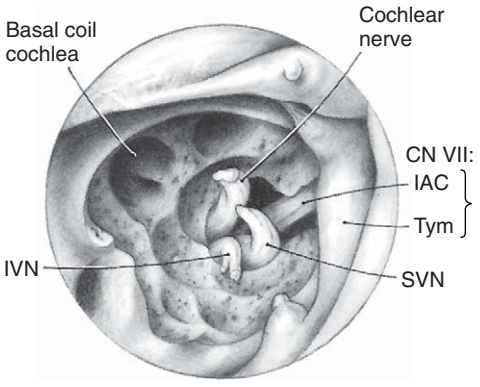

Figure 167-9. Transcochlear vestibular nerve transection. Medial wall of vestibule and lateral cochlear wall are removed to expose distal end of internal auditory canal (IAC). Cochlear and vestibular nerve branches are transected at their distal ends. SVN and IVN, superior and inferior divisions, respectively, of the vestibular nerve; Tym, tympanic segment of cranial nerve VII (CN VII).

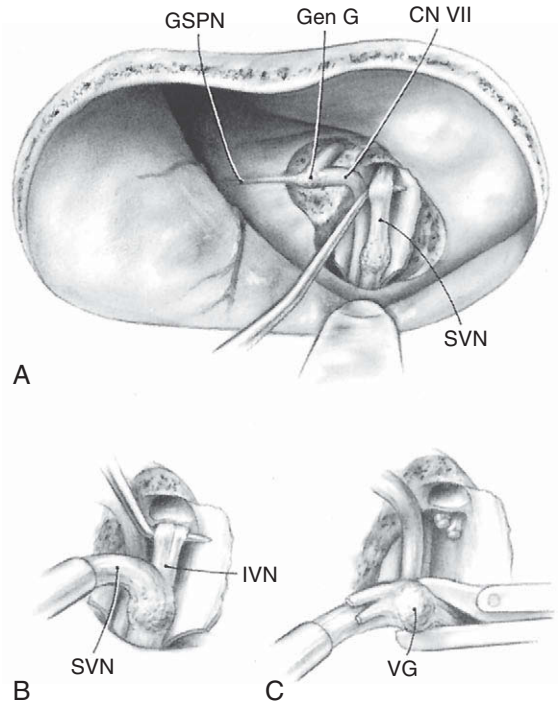

Figure 167-10. Selective transection of vestibular nerve (middle fossa approach). **A,** Vestibular and facial nerves are exposed in the superior compartment of the internal auditory canal. The superior division of the vestibular nerve (SVN) is avulsed distally with a right-angle hook. Gen G, geniculate ganglion; GSPN, greater superficial petrosal nerve. **B,** Traction on the distal end of the SVN with a suction tip permits exposure of the inferior division of the vestibular nerve (IVN). **C,** After lateral transection of the IVN, the vestibular nerve trunk is transected proximal to the vestibular ganglion (VG).

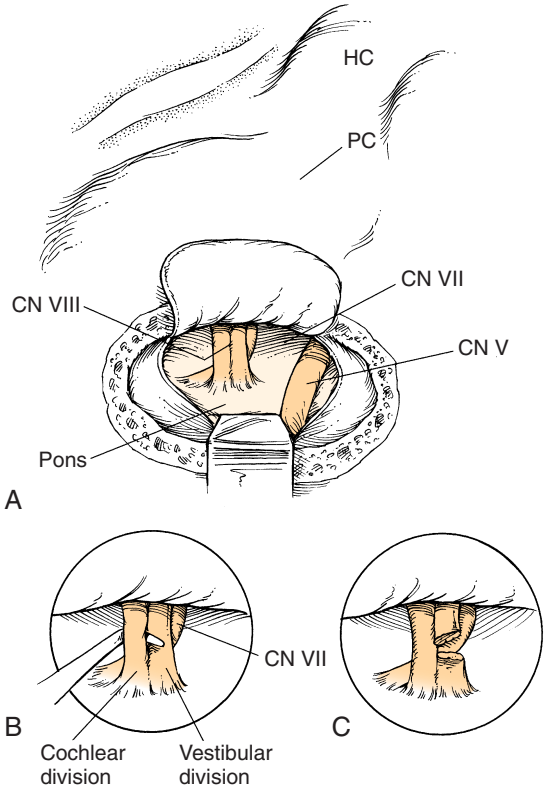

Figure 167-11. Retrolabyrinthine vestibular nerve transection. **A,** After a flap of posterior fossa dura including endolymphatic sac has been elevated, the retractor exposes the seventh and eighth cranial nerves (CN VII, CN VIII). **B,** Vestibular nerve fibers are separated from the cochlear nerve with sharp and blunt instruments. **C,** The vestibular nerve is transected. CN V, trigeminal nerve; HC, horizontal semicircular canal; PC, posterior semicircular canal.

With the middle fossa approach, the operation begins with a temporal craniotomy centered above the external auditory canal. The middle fossa dura is elevated from the surface of the temporal bone, and the temporal lobe is retracted extradurally with a specially designed retractor. Then the contents of the internal auditory canal are skeletonized, with care taken not to injure the cochlea, the superior semicircular canal, or the labyrinthine portion of the facial nerve. An effort should be made to dissect almost 180 degrees around the internal canal, so that its contents will be easily visible after the dura is opened (see Fig. 167-10A). It is not necessary to completely expose the labyrinthine segment of the facial nerve, although confirming its location will help with orientation. With continuous intraoperative monitoring of the facial nerve and auditory evoked potentials, the dura is incised, and the facial nerve is positively identified within the internal canal by electrical stimulation. The superior vestibular nerve then may be avulsed from its lateral attachments and sectioned (see Fig. 167-10B). The same procedure is repeated with the inferior division of the vestibular nerve, with care taken to avoid the cochlear blood supply and adjacent fibers of the auditory nerve that are traveling to the basal turn of the cochlea (see Fig. 167-10).

In the 1980s, several otologists reported series of retrolabyrinthine vestibular nerve section procedures, establishing this as a reliable approach with a lower incidence of hearing loss and facial nerve injury.[77-79] The retrolabyrinthine approach is also technically simpler than the middle fossa operation. The primary drawback is that the eighth cranial nerve (cranial nerve VIII) is exposed only in the cerebellopontine angle, between the porus acousticus and the brainstem, where it may be difficult to reliably separate auditory fibers from the vestibular fibers. The surgical view of cranial nerve VIII that is afforded by the retrolabyrinthine approach (Fig. 167-11) is somewhat constricted, particularly if the surgeon is not careful to follow several technical points designed to maximize exposure through the temporal bone.

The retrolabyrinthine exposure requires wide decompression of the posterior fossa dura both anterior and posterior to the sigmoid sinus. The dura should be exposed for approximately 1.5 cm posterior to the sinus to allow easy retraction. The bone anterior to the sinus then is removed until the bony labyrinth is outlined and until the entire endolymphatic sac area is exposed. The jugular bulb is the inferior limit of dissection. Because inferior bone removal is critical to satisfactory intracranial exposure, the surgeon should make every effort to open the retrofacial air cell tract and expose the sac until the jugular bulb is skeletonized. Care should be taken to prevent entry of bone dust into the middle ear while drilling, because this may lead to delayed fixation of the ossicular chain. The dura and the endolymphatic sac then are incised, and a flap of dura is retracted forward, exposing the posterior fossa. The cerebellum is gently retracted, and the cerebrospinal fluid of the cerebellopontine angle cistern is released by incising the arachnoid membrane. The trigeminal nerve and the tentorium cerebelli are identified superiorly for orientation. The eighth nerve complex then is identified inferiorly. Because the angle of vision is parallel to the posterior face of the petrous bone, the porus acousticus is not visible. If the inferior bony exposure is exceptionally good, the small multiple fibers of the intracranial portions of cranial nerves IX and X may be visible. Often, the flocculus of the cerebellum must be retracted to improve visualization of the eighth nerve. The facial nerve should be positively identified by electrical stimulation, which usually requires

minor retraction of the eighth nerve. The superior (caudal) half of the eighth nerve complex contains the vestibular fibers, which should be divided from the inferior portion and then sharply sectioned. Ideally, the vestibular component is completely divided without injury to the nervus intermedius or facial nerve. The dura then is approximated, and the closure is augmented with a piece of temporalis fascia. The aditus ad antrum is blocked with an additional piece of fascia, and the mastoid defect is filled with an abdominal fat graft. It is best to place a small bone chip harvested during the mastoidectomy between the mastoid contents and the ossicle heads to prevent prolapse of the graft material into the middle ear.

A disadvantage of the retrolabyrinthine approach is uncertainty about the plane between the cochlear and vestibular nerve bundles. Thus, this approach is associated with a risk for incomplete vestibular neurectomy and some chance that auditory neurons may be inadvertently divided. Nevertheless, use of this approach is satisfactory if the hearing results are equivalent to those reported with other methods. A slightly higher risk of cerebrospinal fluid leak has been attributed to the difficulty of reliably closing the posterior fossa dura anterior to the sigmoid sinus.

In the 1930s, two neurosurgeons, Dandy[80] and McKenzie,[81] each reported a series of cranial nerve VIII section procedures for vertigo using a lateral suboccipital craniotomy approach. Long-term follow-up evaluation of Dandy's suboccipital vestibular nerve section procedures demonstrated a 90% rate of complete relief of vertigo.[82] This approach, now commonly called the retrosigmoid approach, allows for selective sectioning of the vestibular nerve in roughly the same location encountered in the retrolabyrinthine approach. Many neurotologists prefer this approach today, because no temporal bone dissection is required to expose the eighth nerve complex, improving the speed and perhaps the safety of the procedure. In addition, because a watertight closure of the retrosigmoid dura usually can be accomplished, the incidence of cerebrospinal fluid leak presumably will be lower. Disadvantages include poorer proximity to the nerve from the depth of the wound, the need for increased intradural retraction of the cerebellum, and a significant incidence of troublesome postoperative headaches. The headache problem may be ameliorated to some degree by avoiding intradural drilling, constraining the spread of bone dust in the subarachnoid space, and making efforts to prevent postoperative attachment of the deep skull base musculature to the exposed retrosigmoid dura.

One group of neurotologic surgeons reported a modification of the retrosigmoid approach in which 60 to 90 mL of cerebrospinal fluid is removed by means of a lumbar drain to decompress the posterior fossa before the operation.[83] They were then able to perform the procedure by use of a 2-cm craniotomy and reported a short operative time, no cerebrospinal fluid leaks, and a very low incidence of postoperative headache. Some surgeons prefer the retrosigmoid approach or even a combined retrolabyrinthine-retrosigmoid approach, because these provide the opportunity to remove bone behind the internal auditory canal to better distinguish between the auditory and vestibular fibers, providing a more reliable ablation of vestibular function.[84,85]

The infralabyrinthine approach[86] for vestibular nerve section is rarely used. As the name implies, the surgeon approaches the internal auditory canal by outlining the posterior semicircular canal and working through the retrofacial air cell tract inferior to the intact bony labyrinth. This approach offers the theoretical advantages of a highly selective vestibular nerve section, facial nerve safety, and a rather limited intradural dissection confined to the distal portion of the internal auditory canal. Of note, however, this technically demanding exposure can be accomplished only in extensively pneumatized temporal bones. It also requires substantial dural decompression and sigmoid sinus retraction inferiorly, where the sinus wall may be less durable.

Although intracranial approaches for the control of vertigo all are associated with the potential for catastrophic complications, the overall complication rate is low. Stroke, subdural hematoma, facial nerve paralysis, meningitis, and wound infection have been reported. Postoperative facial nerve paralysis is infrequent, especially with posterior fossa approaches. In most series, the incidence of sensorineural hearing loss is less than 10%. Vestibular nerve section should not be expected to eliminate the auditory symptoms of ongoing endolymphatic hydrops. The addition of a concurrent endolymphatic sac decompression procedure does not appear to increase the chance of a good hearing outcome after vestibular neurectomy.[87] After vestibular nerve section, most patients return to their usual activities within 2 to 4 months. Rates of control of vertigo by all approaches to the vestibular nerve range from 80% to 95%—notably poorer than with labyrinthectomy. In cases in which a neurectomy in the posterior fossa has failed to relieve the vertigo, a middle fossa approach may theoretically be used to accomplish a more selective vestibular neurectomy in the lateral portion of the internal auditory canal. One study reported only a 55% success rate in this setting, which again emphasizes the priority of differentiating disordered residual cranial nerve VIII function from inadequate compensation.[88]

Postoperative Vestibular Compensation

After any ablative vestibular procedure, there is always a requisite period of vestibular compensation. In counseling preoperative patients, an important point is that vestibular compensation is variable and somewhat unpredictable. Not all patients will compensate fully for the loss of unilateral vestibular function, and up to 30% may be left with considerable chronic dysequilibrium or motion-provoked vertigo. The phenomenon of incomplete or delayed postoperative compensation explains many of the unsatisfactory outcomes after vestibular surgery. One study documented that although most post-labyrinthectomy patients are relieved of vertigo, only 50% return to work.[89] This suggests that functional recovery is more complex than simply achieving relief of vertigo spells. It has long been the impression of some surgeons that recovery from vestibular nerve section is more protracted and more frequently incomplete than after labyrinthectomy.[75] One study showed that post-neurectomy patients had a higher incidence of prolonged postoperative ataxia (11%) than that experienced by post-labyrinthectomy patients (2%), as well as a longer delay of return to work.[75] Eisenman and colleagues[63] compared long-term compensation 3 to 10 years after these two operations in patients who had satisfactory relief of their episodic vertigo symptoms. No differences were found between the groups in self-assessment of balance abilities or functional balance performance. Both groups showed evidence of incomplete physiologic compensation in a majority of subjects, suggesting that recovery of vestibular function after seemingly successful ablative surgery is not as comprehensive as was previously believed.

The routine use of vestibular exercises may help to optimize balance function after any operation that results in unilateral loss of labyrinthine function. It is appropriate for the rehabilitation therapist to offer counseling and instruction in a generic exercise program to all postoperative patients, and any patients who demonstrate poor progress toward recovery should be promptly referred for a customized program of therapy. Persons at particular risk for poor recovery include patients with additional sensory deficits or other complicating neurologic conditions, those using centrally sedating medications, and any who may have a poor psychological motivation for recovery. Such patients should be encouraged to pursue a customized program of vestibular rehabilitation early in the postoperative course.

If a relapse of vestibular symptoms occurs beyond the acute phase of recovery, it may be difficult to distinguish among disease progression, involvement of the contralateral ear, and central decompensation. The phenomenon of decompensation may occur after an initially satisfactory recovery from any peripheral lesion, including vestibular surgery. Early failures after labyrinthectomy are best attributed to incorrect diagnosis, incomplete surgical removal of the neuroepithelium, or inadequate initial vestibular compensation. Late failures may be a result of central decompensation, which should respond briskly to vestibular rehabilitation.[54] Failures after vestibular nerve section may be caused by an incomplete division of the vestibular fibers. A labyrinthectomy or a revision procedure to complete the neurectomy may be required in this setting. However, a therapeutic trial of vestibular rehabilitation is always appropriate before additional surgery is considered if decompensation or incomplete compensation is a possibility.

CHAPTER ONE HUNDRED AND SIXTY-EIGHT

Vestibular and Balance Rehabilitation: Program Essentials

Neil T. Shepard

Steven A. Telian

Audrey B. Erman

Key Points

- Vestibular compensation is the normal physiologic response of a healthy central nervous system to vestibular pathology.
- In many patients with chronic imbalance and dizziness, the symptom complex is a result of incomplete compensation after a vestibular insult.
- The compensation process hinges on the neurologic phenomenon of adaptive plasticity, with reorganization of perceptual and motor output responses to altered sensory inputs.
- Patients who avoid the inciting movements that provoke sensorimotor conflicts or continually use vestibular suppressant medications are at particular risk for delayed or incomplete compensation.
- Confounding central neurologic disease or an unstable peripheral lesion also can lead to ongoing symptoms.
- Individualized vestibular rehabilitation programs constitute a safe and effective treatment option for a large percentage of patients with complaints of imbalance and dizziness.
- Referrals are based on symptomatic complaints, rather than specific etiologic diagnoses or test results.
- Benign paroxysmal positional vertigo (BPPV) is an inner ear disorder that is particularly responsive to physical therapy interventions.

Vestibular exercises were first described in the early 1940s by Drs. Cooksey and Cawthorne for the treatment of surgically induced vestibulopathies. Their simple eye, head, and body movements assist in habituation and are still in use today. Modern vestibular and balance rehabilitation therapy (VBRT) programs have evolved into multidisciplinary efforts in which physicians and therapists collaborate in a team approach, frequently in association with sophisticated vestibular testing facilities. A sufficient number of prospective, controlled studies have now been conducted to demonstrate both the efficacy and cost-effectiveness of vestibular rehabilitation.[1] Accordingly, this treatment has become widely available and is the primary management technique for a large proportion of patients with complaints of imbalance and dizziness.

The two overall goals in a VBRT program are (1) to advance the central vestibular compensation process (Fig. 168-1), resulting in reduction in symptoms under static and dynamic conditions, and improvement in the function of the vestibulo-ocular reflex (VOR); and (2) improvement in the functionality of static and dynamic balance and gait. This second goal can be a process that is achievable independent of complete central compensation.

To accomplish these goals, a variety of different exercise techniques may be used. Each has specific subgoals within the overall structure of a VBRT program. Not all available techniques are used with every patient. The various techniques and their goals are as follows:

- *Adaptation exercises*: to improve the functional performance of the VOR[2-4] (Fig. 168-2).
- *Habituation exercises*: to reduce or eliminate dysphoric responses to a specific stimulus by repeated exposure to a sensory conflict situation.[5,6]
- *Sensory substitution exercises*: to allow for the use of alternative sensory inputs or central nervous system preprogramming and motor output paths in the acquisition of control for gaze stabilization during head movements, and for postural and gait control.[7-11]
- *Balance exercises*: improved performance in both static and dynamic postural control. Practice of tai chi or similar activities may be an effective adjunct in this setting, especially for patients with complaints of continuous imbalance when standing.

- *Gait exercises*: improvement in ambulation by use of both short and long courses. As the patient progresses in the program, these gait activities are combined with habituation and adaptation exercises through the use of head rotations during walking.

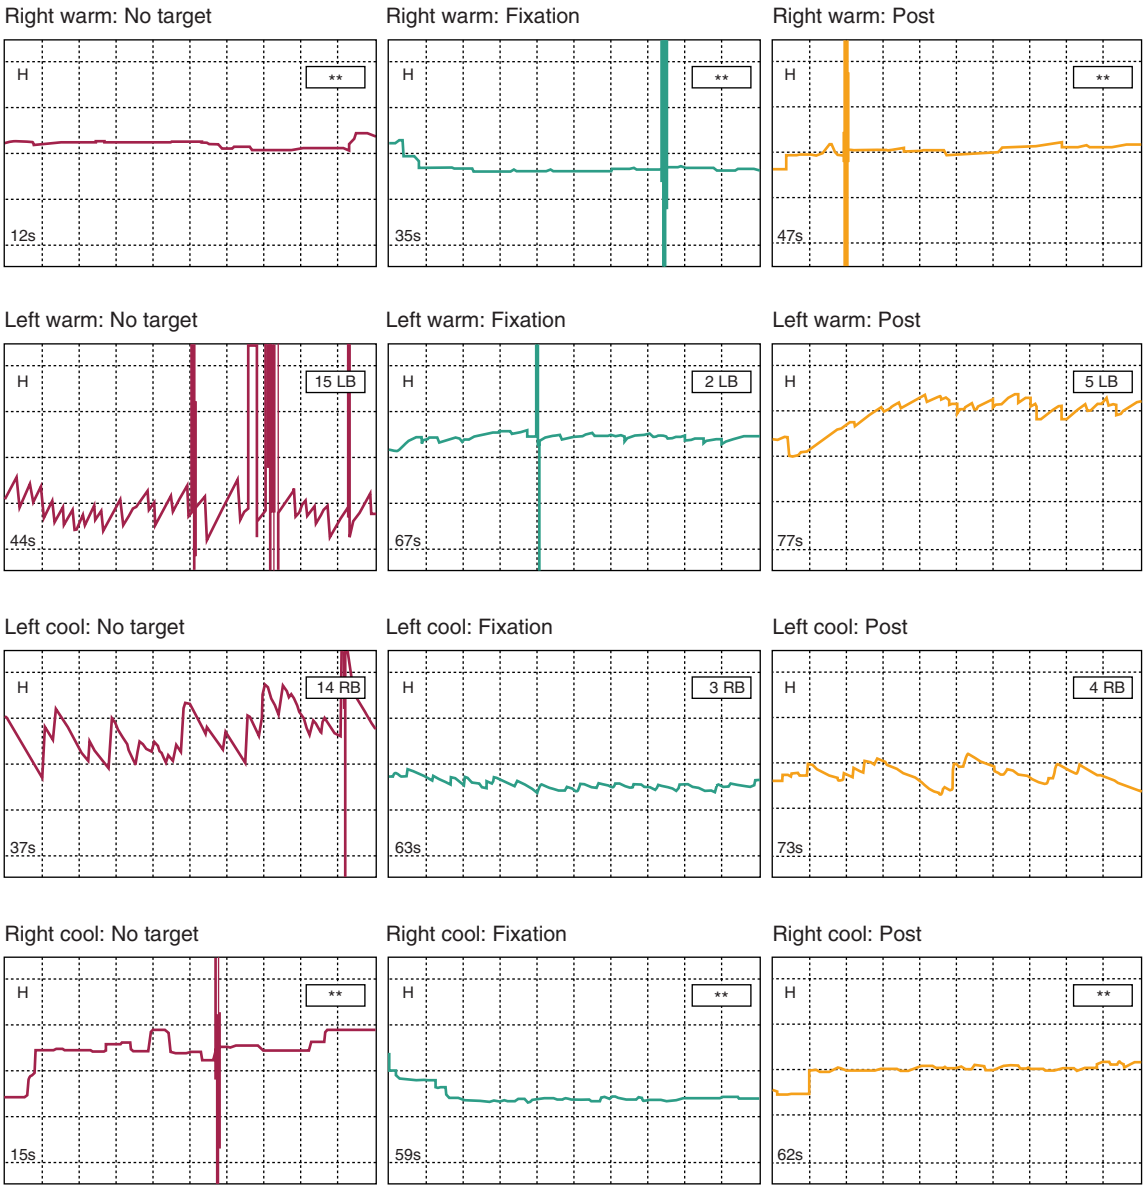
- *General conditioning*: to achieve lifestyle changes to increase activity and fitness.

- *Maintenance program*: to allow for continued exercise activity without the rigor of a formal program, yet to maintain the accomplishments achieved during the active treatment phase. This is especially important in certain central nervous system disorders.[12]

These elements form the basis for the programs discussed in this chapter. A full, in-depth discussion of all of the aspects of a VBRT program is available in Herdman's definitive work on vestibular rehabilitation.[13]

Physiologic Rationale for Vestibular and Balance Rehabilitation

A unique feature of the central nervous system is its ability to adjust to asymmetries in peripheral vestibular inputs and, to a lesser degree, to fix insults within the central vestibular pathways.[14] This adjustment process is referred to as vestibular compensation and occurs naturally after most vestibular insults, provided that the affected person resumes an active lifestyle. Such adaptive plasticity requires active neuronal changes in the cerebellum and the brainstem nuclei in response to the sensory conflicts produced by central or peripheral vestibular pathology. In most instances, this process will reliably relieve vestibular symptoms, provided that the lesion is either stable or producing only gradual progressive deterioration. The underlying physiologic components of this process are the foundations of vestibular and balance rehabilitation. At least four distinct components of vestibular compensation are recognized: *static compensation*, which occurs regardless of movement,



A

Figure 168-1. Videonystagmography test results from a patient with uncompensated right unilateral vestibular system hypofunction. **A,** Results of bithermal alternating open loop water irrigations. The *left column* shows the maximum nystagmus response to right warm, left warm, left cool, and right cool irrigations. The *center column* shows the suppression of nystagmus with a fixation target, and the *right column* shows return of nystagmus after ("post") suppression.

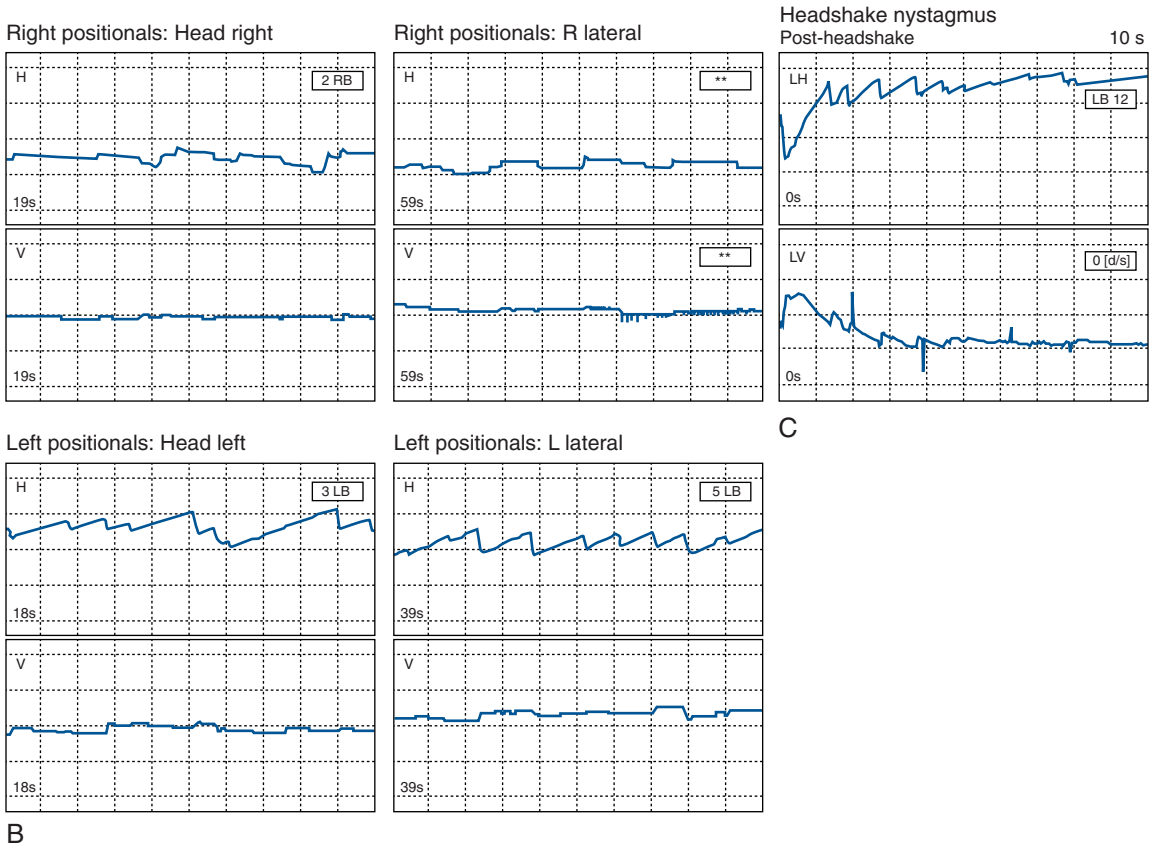


Figure 168-1. **B,** Results from positional testing. In the *top row*, the eye movement recordings for horizontal are shown in the *top box*, with vertical eye movements shown in the *lower box*, from positions of head turn right from supine and right lateral positions. In the *lower row*, the eye movement recordings are shown for the positions of head turn left and left lateral. Left-beating nystagmus ranging from 3 to 5 degrees/second slow-component eye velocity is noted, with no significant nystagmus in the head right and right lateral positions (not shown are three additional positions, also with left-beating nystagmus). **C,** Result of the post-headshake nystagmus test. The *top box* shows the significant left-beating nystagmus that resulted from horizontal headshaking. Minor up-beating nystagmus is seen in the *lower box*.

and three dynamic compensatory processes, *adaptation*, *habituation*, and *sensory substitution*, each of which is promoted by various exercise techniques targeted in VBFT.

Static Compensation for Peripheral Vestibular Lesions

Vertigo of acute onset is accompanied by nystagmus and a variety of neurovegetative symptoms, such as nausea and vomiting. This symptom complex is a result of a persistent asymmetry of vestibular input, often seen after ablative surgical procedures or with acute insults to the peripheral system. The acute or static phase of recovery is mediated by tonic rebalancing of the resting activity in the vestibular nuclei. These changes minimize side-to-side discrepancies between the tonic firing rates in the second-order neurons originating in the nuclei and occur without the need of head movement or vision.[14-18] This activity generally provides relief from the most intense symptoms of vertigo and vomiting within 24 to 72 hours. Nevertheless, the patient continues to experience considerable dysequilibrium, because the system is unable to respond appropriately to the dynamic aspects of vestibular input produced by normal head movements. Thus, even after the intense vertigo has been controlled, continued motion-provoked vertigo is common until dynamic compensation is achieved.

Dynamic Compensation

To eliminate persisting dysequilibrium and residual motion-provoked vertigo after a vestibular lesion, the system must adjust to produce accurate responses to head movements. The dynamic compensation phase seems to be accomplished by reorganization of brainstem and cerebellar pathways, without modulating the neural input to the vestibular nuclei from the peripheral system.[14] This process is much slower than static compensation and typically requires reprogramming of eye movements and postural control responses to head movements. The necessary reprogramming is accomplished by exposure to stimuli that challenge both the gaze stabilization and postural control systems. Because of the brainstem commissural pathways connecting the vestibular nuclei, appropriate central vestibular responses can be produced from inputs arriving from one functioning labyrinth. This feature of the compensation process is critical to recovery after extensive pathologic insults or ablative vestibular surgery, such as labyrinthectomy or vestibular nerve section. As discussed next, three major areas are active in the process of dynamic compensation: adaptation, habituation, and sensory substitution.

Adaptation is the neurologic mechanism that allows for long-term changes in the neuronal response to head movement-provoked gaze stabilization. The neural signals that induce the adaptation are generated primarily by "retinal slip" of the visual image on the retina. This phenomenon is generated by a disordered VOR response, when a head movement produces a perceived motion of a stable object in the visual environment. The resulting error signal can lead to fairly prompt and long-term changes in the functional performance of the VOR.[4] This process of adaptation produced by retinal slip seems to be context-dependent, so that specific adjustments must be made for movements of different frequency, directions of head movement, eye position in the orbit, and distances from the visual target.[3,19] The complexity of the adaptation process helps explain why residual symptoms are almost unavoidable even in a fairly well-compensated patient. Postural stability also is improved by reducing abnormal visual influences on postural control mechanisms secondary to retinal slip.

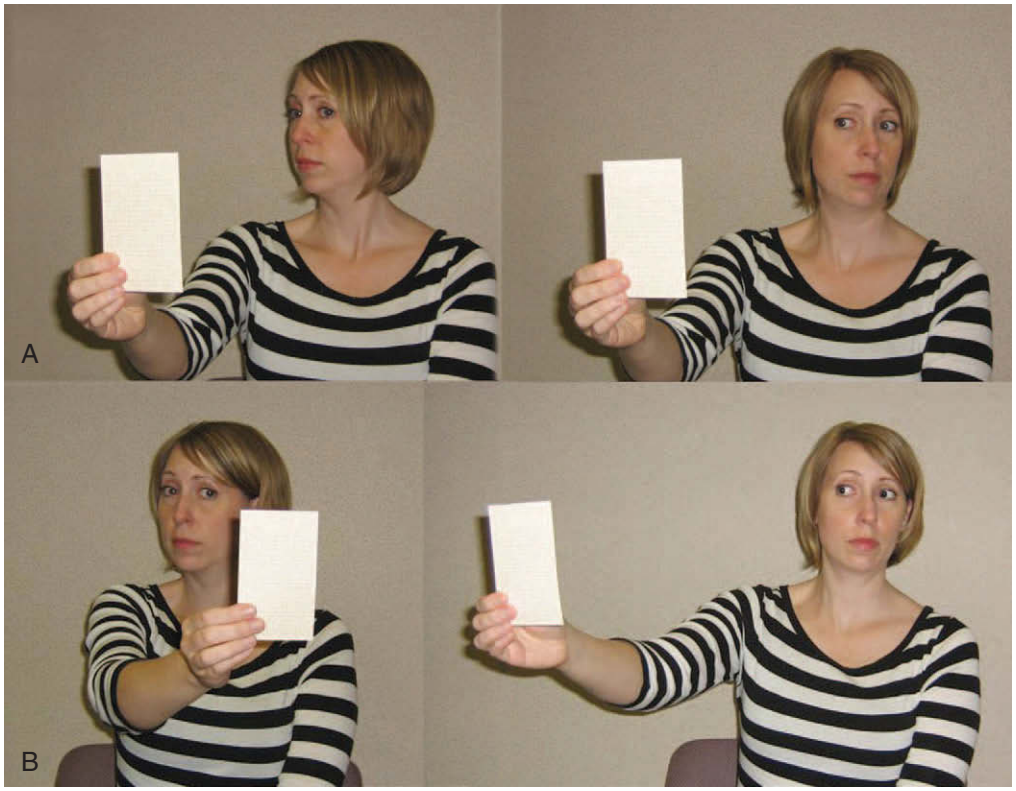

Figure 168-2. Adaptation exercises given to the patient whose videonystagmography results are shown in Figure 168-1. **A,** The "times 1" adaptation exercise. In the times 1 viewing, the target is held still and the patient focuses on a letter on the card and oscillates her head in a small arc in the horizontal plane as fast as she can while maintaining clear visual imaging of the target. **B,** Progression to a "times 2" viewing exercise. In the times 2 viewing, the task is the same, of maintaining clear visual imaging on the letter on the card; however, this time, as the head is moved to the right, the target is moved to the left, doubling the amount the eyes have to move for the same head movement shown in **A**.

Habituation is the long-term reduction of a response to a noxious stimulus resulting from repeated exposure to the stimulus.[20] This phenomenon seems to be context-dependent and does not generalize well from one head movement to another. This mechanism is essential for a variety of conditions that can produce sensitivity to head movement or motion in the visual surroundings. Although peripheral asymmetry is one common cause of these symptoms, other common causes are central lesions, anxiety disorders, and migraine disorders.[5] Although the adjustments produced by habituation are made fairly quickly and are reasonably accurate, the central system requires consistency in the inputs to use them properly for habituation. For this reason, it is essentially impossible to "compensate" for an unstable vestibular lesion such as Meniere's disease.

The primary goals of both adaptation and habituation are to produce gaze stability and postural stability in both static and dynamic situations. The response frequency ranges for gaze and postural stability are very different. To achieve gaze stability, the responsible mechanisms must function properly in a range from static position (no motion) up to movements that correlate with head motions as quick as 10 Hz. Postural stability is predominantly a task that requires responsiveness only below 4 Hz.[21,22]

In addition to adaptation and habituation, another critical component of dynamic compensation involves *sensory substitution*. This process requires the adoption of alternate strategies for gaze and postural control, in order to replace the compromised sensory function. For example, the patient with bilateral loss of peripheral vestibular function becomes dependent primarily on visual or proprioceptive inputs to maintain postural stability. Although these mechanisms may need to be fostered in a therapeutic setting, many patients will have developed some of these out of necessity before coming for evaluation. Although sensory substitution may be helpful, it may be maladaptive in some environmental settings. For example, a patient may be overly dependent on vision and therefore cannot use proprioceptive and residual vestibular inputs to successfully navigate in darkness. In addition to the common substitution of visual and proprioceptive inputs, some of the other mechanisms that may be invoked in the setting of vestibular loss include (1) activation of the cervico-ocular reflex, which is not particularly active in healthy persons[10]; (2) use of the smooth pursuit tracking system[11]; and (3) use of anticipatory or corrective saccades. Patients with both unilateral and bilateral vestibular deficits use corrective saccades to adjust for the reduction of VOR-induced eye movements after head movement. With central preprogramming through exposure to specific eye-head coordinated movements, these eye movements can be applied automatically to help maintain gaze stability when the VOR is deficient.[7,8]

Research findings suggest that initial central vestibular compensation for a peripheral lesion can be enhanced by head movement but is delayed by inactivity.[23-26] It also is hampered by central vestibular dysfunction of any cause.[27] Medications that typically are used for acute symptoms of vertigo, such as meclizine, scopolamine, and benzodiazepines, all cause sedation and central nervous system depression. Although they may provide helpful symptomatic relief during the initial stages of an acute labyrinthine crisis, their effects are potentially counterproductive with respect to vestibular compensation, especially with use over extended periods.[24,28] In addition, chronic anxiety or other psychiatric disorders may delay or disrupt the compensation process.[29,30]

Although remarkably reliable, vestibular compensation seems to be a somewhat fragile, energy-dependent process. Even after it is apparently complete, periods of symptomatic relapse may occur because of decompensation. A period of inactivity, extreme fatigue, change in medications, general anesthesia or an intercurrent illness may trigger these relapses. A relapse of vestibular symptoms in this setting does not imply ongoing, progressive, or new labyrinthine dysfunction.

These features of vestibular compensation suggest that avoidance of movements and body positions that provoke vertigo, as well as the traditional practice of prescribing vestibular suppressants, may be inappropriate. Because the stimulus for recovery seems to be repeated exposure to the sensory conflicts produced by movement, the patient's medications should be discontinued once the acute symptoms are resolved, and an active program geared toward recovery should be encouraged. For most affected persons, recovery will be rapid and nearly complete. For some, the symptoms of vestibular dysfunction may persist. Although the latter patients are candidates for vestibular rehabilitation programs, starting a formal vestibular rehabilitation program as early as possible for patients whose symptom presentation suggests a high likelihood of benefit from such programs can help to avoid the persistence of symptoms.

Assessment of Vestibular Compensation

Role of the Clinical History

A complete neuro-otologic history probably is the single most important component of the diagnostic evaluation of the patient with a balance disorder. Balance function study results must be interpreted in light of the presenting symptoms and medical history.[31] In general, the information sought should include the onset of symptoms and their characteristics at that time, the progression of symptoms over time, the nature and duration of typical spells, any predisposing factors in the medical history, and use of medications or other management strategies. Complicating features of anxiety, depression, or excessive dependence on medications should be addressed. Some effort should be extended to identify the degree of disability produced by the patient's vestibular complaints with respect to his or her professional and social activities. The stability and commitment of the patient's psychological support system also should be assessed.

Ongoing complaints after a peripheral vestibular insult indicate that compensation is incomplete. The history and presenting symptoms are used to determine whether these continuing sensations may be a result of a fluctuating or progressive labyrinthine disorder. In the case of the unstable lesion, poor compensation results because the central nervous system cannot react to unpredictable peripheral inputs. In the history, an unstable periphery is suspected if symptoms are spontaneous in onset. In the stable cases, the symptoms are much more likely to be consistently provoked by head or eye movements. It is the patients with stable lesions who are most likely to benefit from vestibular and balance rehabilitation. The patients in the group with unstable lesions may have VBRT as part of their management, but it is not likely to be the primary modality of treatment.

Role of Vestibular Testing

The most traditional purpose of balance function studies is site-of-lesion localization addressing the sensory inputs, motor output elements, and neural pathways that may be involved in producing the reported symptoms. Balance function studies also may assess the patient's functional ability to use sensory input systems in an integrated fashion, as in maintenance of stance before and after induced sway and coordination of head and eye movements during gaze activities. The third assessment goal is to evaluate, in a limited manner, the current degree of physiologic and functional compensation.[32]

Although a wide variety of studies may be used to assess the balance system in the broadest sense, tests that are used to determine the extent and site of vestibular lesions are unable to predict the type of vestibular symptoms, the magnitude of those symptoms, or the level of disability in an individual patient. When the predictive utility of the vestibular test battery is reviewed, no significant correlation is found between test results and performance of high-level activities of daily living in the chronically dizzy patient. Thus, a therapist can and must proceed with an evaluation of these factors, irrespective of the vestibular test results.

Although specific subtests within videonystagmography (VNG), rotary chair, and postural control testing can give indications of compensation status, the value of such tests is somewhat limited. Typically, the information obtained from these studies relates more to the static phase of compensation than that of the dynamic phase. Clinically significant spontaneous nystagmus, positional nystagmus, and a directional preponderance on the VNG provide evidence for failure of physiologic compensation in the control of eye movements. Rotational chair testing stimulates the horizontal semicircular canals and their afferent inputs over a broad range of frequencies and accelerations. Although this is a physiologic rather than a functional evaluation, it provides information about the vestibulo-ocular system that is not obtained from the VNG. In general, although abnormalities in the timing (phase lead) or amplitude (gain) of the eye movements produced by the VOR provide evidence for peripheral vestibular dysfunction, these physiologic measures do not assess the level of compensation within the central system.[14] On the other hand, persistent asymmetry (bias) in the slow-phase eye velocity responses produced by rightward versus leftward rotation strongly suggests that the peripheral lesion is physiologically uncompensated.

Dynamic posturography provides information about balance system function that is not available through the other vestibular testing modalities. The sensory organization portion of dynamic posturography is primarily a test of functional capabilities, rather than a site-of-lesion evaluation. By measuring the degree of postural sway under several test conditions, this test determines whether the patient is able to make proper use of sensory inputs from the visual, vestibular, and somatosensory systems for maintaining stable stance. By identifying difficulty in the use of one or more of the input informations, a quantitative estimate of functional compensation is obtained. It is not unusual to document normal sensory organization findings in patients who report motion-provoked symptoms exclusively and show no signs of pathologic nystagmus or significant asymmetry on rotational chair testing. By contrast, some patients will demonstrate significant abnormalities of postural control, reflecting inadequate functional compensation, even when the more physiologic measures (VNG and rotational chair) suggest a reasonably complete physiologic compensation process.

The movement coordination battery of dynamic posturography may be used to assess the automatic motor output responses from the central nervous system in response to perturbations of stance. Abnormalities detected may help to explain findings in the sensory organization test, especially the somatosensory and vestibular dysfunction pattern. It also may provide indications of previously undiagnosed peripheral neuropathy or biomechanical deficits resulting from known musculoskeletal conditions.[33,34] This protocol does not provide any information about the status of compensation.

Vestibular Rehabilitation: Patient Selection Criteria

Vestibular Rehabilitation as a Primary Treatment Modality

The use of VBRT in the treatment of BPPV is well accepted. The use of noncustomized programs such as Cawthorne exercises has a long and fairly successful history for the management of this problem.[19,23,35] However, for many patients, the commonly prescribed Cawthorne program is too intensive and often provokes intense vestibular symptoms, sometimes accompanied by nausea or vomiting. This discourages the patient from continuing. A preferred noncustomized program for BPPV that addresses the needs of most patients is the Brandt-Daroff program.[23] An alternate approach for the treatment of classic BPPV caused by otoconia floating free in one of the semicircular canals (canalithiasis) is to perform an appropriate particle repositioning maneuver.[36] When these techniques are insufficient to bring relief, the patient should be referred to a vestibular therapist for a customized program.[6] For a complete discussion of BPPV and particle repositioning maneuvers, please refer to Chapters 163-165.

The use of VBRT as the primary treatment recommendation is appropriate in any condition characterized by a stable unilateral peripheral or central vestibular deficit when the patient's natural compensation process is incomplete. This is a symptom-driven indication that is determined from the patient's presenting symptoms. The report of spontaneously occurring symptoms or documented fluctuations in

hearing or vestibular function suggests an unstable lesion. If the patient's evaluation reveals no evidence of a progressive or fluctuant (unstable) process, it is likely that VBRT will produce a satisfactory resolution of symptoms. This intervention is certainly preferable to the protracted use of vestibular suppressants. In most patients with stable peripheral lesions, there is no role for the use of long-term vestibular suppressants. However, they may be useful at the outset of VBRT to reduce symptoms to a level that allows the patient to perform the prescribed exercise program.[37]

The final indication for the use of VBRT as a primary treatment modality is for disorders characterized by multifactorial balance difficulties, such as those seen in the elderly.[38] This option becomes especially important when other treatment options are unavailable or have been exhausted. These patients may benefit greatly from postural control exercises and individualized conditioning programs. Frequently, the relationship with the therapist assumes a strong counseling function, and the use of assistive devices for safety in ambulation can be introduced as needed.

Vestibular Rehabilitation as an Adjunctive Modality

Several situations may require the use of VBRT interventions as an adjunctive treatment modality. The use of routine or selective VBRT is helpful in optimizing the outcome after vestibular surgery, such as vestibular schwannoma removal, labyrinthectomy, or vestibular nerve section, and after intratympanic aminoglycoside administration for Meniere's disease. When a patient with an unstable vestibular condition undergoes an ablative procedure, a more profound, yet stable, unilateral vestibular lesion is created. The process of acute and chronic compensation must begin anew. It is possible that many of the unsatisfactory outcomes after vestibular surgery can be attributed to incomplete or delayed postoperative compensation. All patients should be instructed regarding the importance of central compensation for the success of any ablative vestibular procedure. Those individuals who are at particular risk for poor recovery because of complicating central nervous system conditions, sedating medications, or poor motivation for recovery should be encouraged to pursue a customized program of VBRT early in their postoperative course.

Vestibular rehabilitation may play a role in other conditions that include a component of balance complaints.[5,39] Frequently, patients who have had head injuries have significant disability from vestibular symptoms. Because their condition often includes cognitive and central vestibular involvement, along with the peripheral labyrinthine component, VBRT techniques are best used as a supplement to a comprehensive, multidisciplinary head injury program rather than as the primary rehabilitative measure. Similarly, patients with anxiety disorders often seek management of ill-defined vestibular symptoms. After a suitable evaluation is performed, VBRT may be recommended as an adjunctive measure for the anxiety disorder. If the anxiety is mild, VBRT functions as a behavioral intervention, similar to exposure therapy for treatment of phobias. If the anxiety component is significant, and particularly if panic attacks are frequent, psychiatric intervention will be required as well. The use of VBRT can be of assistance in situations of migraine-associated dizziness, provided that appropriate treatment for migraine is given concurrently.[5,13]

Patients with Meniere's disease may complain of positional vertigo or other chronic vestibular symptoms between their definitive attacks. Although such patients are candidates for VBRT, they need to recognize that the prognosis for lasting relief of chronic symptoms is reduced if the typical severe attacks of Meniere's disease occur more than monthly. If the attacks are rare, or the Meniere's disease is inactive, the prognosis is considerably improved.

Vestibular Rehabilitation as a Therapeutic Trial

At times, the physician may be uncertain whether a patient's complaints are due to stable vestibular disease with inadequate compensation or to an unstable labyrinthine disorder, such as perilymphatic fistula. In this setting, a trial of VBRT is appropriate if the hearing is stable and may assist in the diagnosis by clarifying this important distinction. Failure to improve in VBRT lends further credibility to the diagnostic impression that the lesion is unstable or progressive. It is then advisable to proceed with appropriate surgical management, provided that the symptoms are severe enough to warrant the procedure and they are believed to emanate from the end organ. This conservative treatment course is particularly appropriate before surgical interventions are considered for controversial diagnoses such as spontaneous perilymph fistula.[40]

It is sometimes difficult to determine whether a postoperative relapse of vestibular symptoms represents disease progression or merely central decompensation.[41] Decompensation may be observed as a late sequela after initially complete compensation for any peripheral lesion, including vestibular surgery. For example, many surgeons consider transmastoid labyrinthectomy to be a definitive procedure for the control of vertigo of peripheral origin. Thus, an explanation of why failures are reported to occur is warranted. Early failures are best attributed to incorrect diagnosis, incomplete removal of the neuroepithelium at the time of surgery, or inadequate initial central nervous system compensation. Late failures have been hypothesized to result from "post-labyrinthectomy neuromas."[42,43] Although there is little reason to expect that such lesions could produce symptoms, some surgeons would advocate performing a vestibular neurectomy in this setting. An alternate explanation for these recurrent symptoms after a complete labyrinthectomy would be late central decompensation, which should respond briskly to VBRT. Instead of proceeding to additional surgery, a therapeutic trial of VBRT is suitable whenever the possibility of incomplete compensation or decompensation remains.

Inappropriate Candidates

Patients whose symptoms occur strictly in spontaneous, discrete episodes, such as are seen with Meniere's disease, are unlikely to benefit from VBRT. If no provocative movements or body positions are found to reliably produce spells and no postural control abnormalities are noted during the evaluation, the patient is best managed with alternative medical or surgical strategies. Nonetheless, such patients should be encouraged to remain active and optimize their general health through physical activities performed at a level that is appropriate for their age and general health.

Role of Balance Function Studies in Patient Selection

It needs to be recognized that VBRT is a symptom-driven treatment program. The principal features that suggest use of VBRT for primary or adjunctive management are complaints related to motion-provoked symptoms or dysfunction with balance and gait. Is there a role for the use of balance function studies for determination of which patients would be appropriate candidates for VBRT? Do these tests play any role in the monitoring of the program's outcome?

Of the main balance function studies, *dynamic posturography* has the highest likelihood of suggesting that VBRT may be appropriate and guiding the treatment prescribed by the therapist. Some patients have a symptom presentation that does not suggest the use of therapy as a management option, yet performance on dynamic posturography shows clear deficits in maintenance of upright stance during challenging conditions. Such a patient would then be a highly appropriate candidate for VBRT to improve performance and reduce the potential for falls. Dynamic postural control evaluations in patients for whom VBRT is to be used can assist in the design and monitoring of the customized VBRT program.[19,33,37]

The VNG and rotary chair studies do not provide information that assists in deciding who is an appropriate candidate for VBRT. However, if a patient is otherwise an appropriate candidate for VBRT, these studies can be used to reinforce the use of a specific form of exercise in the therapy program. Indications of deficits in the VOR provide support for the use of adaptation exercises as a means for improving the VOR gain and, thereby, the functional performance of the VOR. Neither of these studies holds any significant utility with respect to the monitoring of the progress of a VBRT program. However, if the patient is not improving as expected, repeating portions of the VNG or rotary chair protocol may be useful in determining whether the vestibular system pathology has progressed in a way that would adversely affect the patient's progress.[44]

Table 168-1

Common Techniques for Vestibular Rehabilitation

Vestibulopathy	Rehabilitative Strategy
Acute uncompensated unilateral peripheral lesion *Example*: immediate postoperative status or recent crisis	Generic vestibular rehabilitation program to start Customized program if patient does not make satisfactory progress
Stable uncompensated unilateral peripheral lesion *Example*: previous crisis with continuous symptoms	Habituation and adaptation exercises Postural control activities if abnormalities detected during testing
Bilateral peripheral lesions	Sensory substitution with visual-vestibular interaction Postural control activities if abnormalities detected Screening for other comorbid conditions that may aggravate balance problems
BPPV	Particle repositioning maneuver Habituation exercises if repositioning fails
Vertiginous migraines Anxiety-provoked symptoms Head injury	Sensory substitution activities potentially of benefit with chronic dizziness related to vertiginous migraine Vestibular rehabilitative adjuvant treatment as part of a multidisciplinary approach

BPPV, benign paroxysmal positional vertigo.

Vestibular Rehabilitation: Common Techniques

The vestibular rehabilitation therapist uses a variety of techniques when providing a program customized to the needs of the individual patient (Table 168-1). For a complete discussion of the diagnostic and therapeutic interventions that may appropriately be performed by the therapist, the interested reader is referred to other resources for further reading.[13,45] This section of the chapter reviews several general categories of exercise techniques that are used in a customized program of VBRT.

Adaptation Exercises

The principal goal of adaptation exercises is improvement in the functional performance of the VOR and accompanying gaze stability for those who demonstrate a VOR deficit physiologically and who have predictable symptoms provoked by head movements. Evidence of a VOR deficit may include a caloric response asymmetry on VNG and/or an abnormal time constant on rotary chair testing. The functional impact of a physiologic VOR deficit is realized through the use of Dynamic Visual Acuity (DVA) testing, which assesses the ability to accurately resolve a visual target while the head is in motion.[13] The activities involve primarily eye-head coordinated movements called VOR *times 1* and *times 2* viewing exercises (see Fig. 168-2), described elsewhere.[5,13] Using eye movement recordings during the head thrust, test pilot data have been able to show an actual increase in the gain of the VOR correlating with functional improvement as reflected in the DVA in patients with unilateral hypofunction. However, the gain was more consistently increased for active (patient-initiated) head thrusts than for passive (unexpected examiner-initiated) head thrusts.[46] The implication of this work is that to appreciate an actual change in physiologic gain of the system, the task must have direct relevance to the patient. This is the first study to show a mechanistic change as a result of the vestibular rehabilitation adaptation exercises. Of interest is that even though the underlying mechanism for VOR adaptation may not as yet be well understood, the prescribed exercises do result in measurable changes in the VOR functional performance.[1,13,14]

Habituation Exercises

For most patients with positionally provoked symptoms, the primary goal is to extinguish residual pathologic responses after incomplete or disordered compensation.[47] The therapist identifies the typical movements that produce the most pronounced symptoms and provides the patient with a limited but progressive program of exercises that reproduce these movements. Typically, these are performed two to three times daily, with the duration and number of repetitions varying according to the severity of nausea or dizziness they produce. Patients are counseled that symptoms are aggravated by the exercises at first but that gradual improvement will follow. Patients often are encouraged by experiencing short-term habituation at the end of an exercise session. If they can persevere with their program, most patients will begin to note dramatic relief of positional vertigo within 4 to 6 weeks.

There is obviously significant overlap between these and the adaptation activities. Differences exist in the details of the techniques relative to speed, visual target, number of movements, and repetition. The underlying principle of habituation exercises is that of brief repeated exposures. This technique also can be used to reduce sensitivity to visual motion–provoked symptoms, although that is a more difficult task.

Substitution Exercises

As the name implies, substitution exercises teach the patient to use alternative strategies and sensory inputs to make up for those that are deficient or absent. There is clearly a limit to how much vision or proprioception can substitute for the vestibular system, or how much vestibular information can substitute for proprioception. These limits are secondary to the differences in the frequency range over which each of these inputs and the various motor and perceptual outputs function.[21,22] Notwithstanding the limitations, this technique can be successful in promoting changes in performance for both gaze stability and postural control by means of the mechanism of central preprogramming.[9,48]

Postural Control and Gait Exercises

When abnormalities of postural control are detected in the assessment, these may be specifically addressed in the prescribed exercise program. Programs can be designed to correct weight-bearing asymmetries, limited mobility about the center of gravity, and sensory input selection problems. For example, if the patient is found to depend on somatosensory input despite the availability of accurate visual cues, the program may involve exercises that require balancing on thick foam. This would be performed initially with eyes open and eventually with eyes closed.

Although working on static balance is one dimension of therapy, more complex gait activities over a short course (such as a 10- to 20-foot walk) often are prescribed and combined with other, more complex movements. These may involve specific activities such as stepping over objects or incorporating reciprocal head movements. The patient also

may be asked to practice walking on different types of surfaces such as a compressible soft carpet or an irregular gravel parking lot. These activities are designed to enhance stability in daily activities. Patients with bilateral loss of vestibular function may be instructed to perform exercises that help with sensory substitution. These may include walking in progressively more challenging, dimly lit environments to facilitate somatosensory substitution and balancing on more challenging support services to facilitate visual substitution.[13]

Conditioning and Maintenance Activities

Most patients with vertigo and balance disorders have adopted a sedentary lifestyle to avoid precipitating their symptoms. Although such a response is understandable, the inactivity contributes to their ongoing disability and delays their recovery. Thus, all patients who receive customized VBRT programs also are provided with suggestions for a general exercise program that is suited to their age, health, and interests. For most patients, this would involve at least a graduated walking program. For many, a more strenuous program is suggested that may include jogging, treadmill, aerobics, or bicycling. Activities that involve coordinated eye, head, and body movements such as golf, bowling, handball, or racquet sports may be appropriate. Swimming is approached cautiously because of the disorientation experienced by many patients with vestibular dysfunction in the relative weightlessness of the aquatic environment.

Maintenance of Initial Results

Once the patient has completed the initial period of treatment, progress is assessed and adjustments are made in the program. Exercises that no longer produce symptoms are eliminated and replaced by others that were not originally included because of lower priority. This process is continued until the improvements begin to plateau. When this point is reached, it is important to provide the patient with counseling and a program of maintenance exercises to secure the benefits gained from the active treatment program. The maintenance program typically includes continuing the prescribed conditioning exercises, as well as any unique postural control activities that were required. The patient is instructed to resume exercises if a relapse of symptoms should occur. For central nervous system lesions involving the cerebellum, indications are that the active program needs to be continued indefinitely to maintain benefits.[12]

Role of Therapist in Patient Education

A key role of the therapist in the management of the patient with a balance disorder is to educate the patient about the illness.[12] The patient often has acquired considerable misinformation that must be addressed. This supportive function of the therapist is particularly essential for the management of patients with a less favorable prognosis. A patient who is well educated regarding the nature of vestibular or balance dysfunction will understand the rationale for vestibular rehabilitation. The patient will recognize that these measures are simply a management technique instead of a cure for the underlying deficits. This orientation takes the patient from a passive role toward an active role in his or her own recovery.

Vestibular Rehabilitation: Expected Results

A 2-year prospective clinical trial including all patients undergoing VBRT at the University of Michigan suggested that a reduction of symptoms can be expected in approximately 85% of cases. In this trial, 80% of patients also showed improved scores on a disability rating scale after therapy.[37] A subsequent randomized controlled clinical trial provided evidence that VBRT programs customized to the unique needs of the individual patient provided results that are superior to those obtained with generic programs of therapy.[49] A recent review from the Cochrane collaboration evaluated 21 randomized trials of vestibular rehabilitation for unilateral peripheral vestibular dysfunction. Overall, the results strongly support vestibular rehabilitation as an effective tool in the management for unilateral vestibular dysfunction over medications, placebo or sham interventions, or no intervention.[50] Whitney and Rossi[1] also have provided a useful review of multiple published studies of VBRT efficacy. In their review, they classify the works by the presence or absence of control groups and the prospective or retrospective nature of the studies. Overall, the studies reviewed demonstrate significant evidence supporting the efficacy of VBRT as a major management tool for patients with balance and vestibular disorders. This summary also demonstrates that VBRT is highly beneficial after unilateral surgical ablation of vestibular function. Similar results may be expected in treating fixed unilateral lesions such as vestibular neuritis and labyrinthitis. Treatment of canalithiasis causing classic BPPV with the particle-repositioning maneuver is effective in more than 90% of cases, but the condition may recur in up to 30% of patients. Habituation exercises have been reported to yield similar results but do not offer relief as promptly. Patients with bilateral vestibulopathy treated with VBRT show significant improvement in speed of ambulation and stair negotiation, postural stability, and reaching distance compared with control subjects.

In general, the patients who have a poorer prognosis for improvement with VBRT include those with severe bilateral peripheral lesions, combined central and peripheral vestibular deficits and headache syndromes after head injury, and those with established long-term disability. For those in whom migraine or anxiety disorders are the primary source for symptoms, VBRT can be effective if used with treatment for the primary disease process.[5] Although some elderly patients may progress poorly because of irreversible multisensory dysfunction, the overall experience with this age group has been favorable.

The concurrent use of vestibular suppressant medication or other centrally acting agents has been shown to delay the time course of recovery during VBRT. Whenever possible, these medications should be tapered to lower doses or discontinued completely. On the other hand, they may be continued if they are essential for treatment of complicating medical conditions or for relief of symptoms during the VBRT program, because their use does not seem to dramatically reduce the chances of a satisfactory ultimate outcome.

Facial Nerve Disorders

CHAPTER ONE HUNDRED AND SIXTY-NINE

Tests of Facial Nerve Function

Rodney C. Diaz

Robert A. Dobie

Key Points

- History and physical examination are the most important tools in evaluation of facial nerve function and in diagnosis of dysfunction.
- The House-Brackmann grading system is the most commonly used method of categorizing and documenting long-term facial nerve function after insult, injury, or surgery.
- Topognostic testing correlates specific functional deficits with corresponding anatomic branch points to determine the site of the lesion along the course of the facial nerve; it has been largely superseded by electrodiagnostic testing.
- The four types of electrodiagnostic testing are the nerve excitability test (NET), the maximum stimulation test (MST), electroneuronography (ENoG) (also called electroneurography), and electromyography (EMG). Each has its advantages and disadvantages.
- Electrodiagnostic testing of the facial nerve can differentiate neurapraxia from neural degeneration, but it cannot distinguish between different degrees of neural degeneration.
- Electrodiagnostic testing can provide prognostic information regarding the likelihood of complete or good recovery versus severely incomplete or poor recovery; threshold criteria for predicting poor recovery are used by some surgeons in patient selection for surgical exploration and decompression of the facial nerve.
- Intraoperative facial nerve monitoring has been shown to be a valuable adjunct in surgery for acoustic neuroma and other tumors of the cerebellopontine angle, as well as in revision parotidectomy for recurrent pleomorphic adenoma. Multiple factors can affect accuracy and performance; therefore, responses from a monitoring device should not supplant surgical knowledge and experience in intraoperative decision making.
- Unconventional forms of facial nerve monitoring, under development, may provide additional information for evaluating facial nerve integrity intraoperatively beyond standard methods of intraoperative monitoring.

In facial paralysis, as in most medical problems, history and physical examination usually provide more useful information than laboratory tests. Sometimes, however, a more objective evaluation of facial nerve function is indicated to detect a facial nerve lesion; to measure its severity; to localize it to a particular intracranial, intratemporal, or extratemporal site; to assess the prognosis for recovery; to assist in treatment decisions; or to detect and avoid surgical injury. Quantitative tests of facial nerve function are then used.

Useful diagnostic tests add information to what is already known, influence the choice of therapy, and ultimately improve clinical outcomes.[1] This chapter discusses several tests for evaluation of the facial nerve that can be helpful—as well as several that have not been shown to be helpful—in various clinical scenarios. Intraoperative monitoring of electrical activity of muscles innervated by the facial nerve is by far the most well-established, clinically useful means of assessing facial nerve function, other than physical examination. Outpatient electrical testing of facial nerve function makes sense in clinical settings in which surgical repair or decompression is under consideration, such as after temporal bone fracture or Bell's palsy. Of note, however, most of the tests described in this chapter have very limited proven clinical usefulness.

Facial nerve imaging also is briefly discussed. Although magnetic resonance imaging (MRI) is the modality of choice when a tumor is suspected to be the cause of facial paralysis, it seems not to be useful in Bell's palsy.

Physical Examination

Facial weakness can be extremely subtle, apparent only to a trained examiner (and perhaps to the patient). Paradoxically, mild unilateral facial weakness sometimes can be more easily detected by comparison with a normal contralateral side by having the patient perform nominal rather than maximal volitional movements. Rapid repetitive blinking also can unmask a mild facial weakness, which will manifest as slowed or reduced blink frequency compared with that on the normal side. By contrast, when facial paralysis is total or near-total, the diagnosis is obvious; such impairment can be devastating to the patient on functional, social, and psychologic levels.

Attempts have been made to standardize measurement of facial function, using techniques as simple as measurements with hand-held calipers and as complex as digital photographic and videographic documentation.[2,3] Whereas caliper methods have been shown to demonstrate a high intertest variability, digital photographic methods appear to be much more reliable.[4]

Several systems of clinical measurement of facial nerve function have been devised, but since the mid-1980s, the House-Brackmann system has been most widely used and has been endorsed by the

American Academy of Otolaryngology–Head and Neck Surgery.[5] In the House-Brackmann system, grade I is normal function, grade VI is complete absence of facial motor function, and grades II to V are intermediate (Table 169-1).

The House-Brackmann system is least ambiguous at its extremes and most prone to intertest variability at its intermediate grades II to V: Multiple regional descriptors of facial movement within each scale can overlap, leading to confusion in assigning the appropriate grade. Alternatively, major functional criteria can be used to create unambiguous categories of progression of deficit correlated with each grade (Fig. 169-1).

Similarly, examiners do not always agree among themselves, even when using the same formal grading system. In two studies, each with more than 100 patients with various degrees of facial weakness, examiners unanimously agreed on the House-Brackmann grade as often as 80% (three examiners in one study) and as seldom as 33% (five examiners in the other study).[6,7] Of course, the probability of disagreement should increase as more examiners are used; the probability of any two examiners disagreeing is as low as 13%[8] (on the assumption that in all cases of three-examiner disagreement, two choose one grade and the third choose another grade) and as high as 40% (on the assumption of maximum dispersion of examiner judgments across House-Brackmann categories).[9] It would be interesting to know how much of this variability is caused by individual examiners' test-retest variability (i.e., the tendency of an examiner to assign different scores to the same patient on repeated examination) and how much is attributable to consistent differences among examiners (e.g., between "strict" and "lax" graders).

The wide acceptance of the House-Brackmann system has not prevented many others from proposing new systems. For example, Burres and Fisch[10] described a method requiring multiple measurements of movement in different parts of the face; Croxson and colleagues[6] showed the expected correlation between Burres-Fisch and House-Brackmann in 42 patients, but considerable variability of Burres-Fisch scores was observed for House-Brackmann grades III and IV. Murtry and coworkers[9] proposed and tested the Nottingham system of subjective estimation of movement at each of several points on the face. This method correlated better with House-Brackmann than did Burres-Fisch, and it was simpler to perform. Newer systems include those devised by Ross and associates at Sunnybrook (Ontario, Canada)[11] and Coulson and colleagues in Sydney, Australia.[12] both of which place particular emphasis on the degree of synkinesis in facial movement. These systems demonstrate good overall test-intertest reliability and correlation with the House-Brackmann system, but subjective evaluation of degree of synkinesis is much more variable.[12,13]

Neely and associates[14] showed the feasibility of computer-assisted image analysis for measuring facial movement. Other objective measurement systems have been proposed by Johnson[15] and Jansen[16] and their coworkers. These methods are promising, particularly for research and for the assessment of weakness affecting only a single region of the face (e.g., forehead, lower lip).

An occasionally overlooked limitation of the House-Brackmann grading system is in the evaluation of acute facial paralysis. The differentiation among House-Brackmann grades II, III, IV, and V rests partly on the presence and severity of synkinesis, contracture, hemifacial spasm, and asymmetry at rest—all sequelae of long-term facial nerve dysfunction and hence all absent in the setting of acute facial paralysis. This inherent restriction extends to most other alternative grading systems as well.

The House-Brackmann system applied in its strictest sense is well suited for evaluation of long-standing facial nerve dysfunction but not acute facial paralysis.[17] Nonetheless, this system can be informally rethought for use in the acute setting, in terms of graduated degrees of facial weakness: grade I, normal or 100% function, grade II, mild weakness or 75% to 99% function; grade III, moderate weakness or 50% to 75% function; grade IV, moderately severe weakness or 25% to 50% function; grade V, severe weakness or 1% to 25% function; and grade VI, complete paralysis or zero function. The obvious disadvantage of this technique is in the reversion to a coarse, imprecise, unweighted method of scaling facial function. However, although not canonical, this method allows for continued use of a six-scale grading system to track facial nerve function through the entire clinical course, from acute onset of the paralysis to long-term outcome.

Table 169-1

House-Brackmann Facial Nerve Grading System

Grade	Description	Characteristics
I	Normal	Normal facial function in all areas
II	Mild dysfunction	Gross: slight weakness noticeable on close inspection; may have very slight synkinesis At rest: normal symmetry and tone Motion—Forehead: moderate to good function Motion—Eye: complete closure with minimum effort Motion—Mouth: slight asymmetry
III	Moderate dysfunction	Gross: Obvious but not disfiguring difference between two sides; noticeable but not severe synkinesis, contracture, or hemifacial spasm At rest: normal symmetry and tone Motion—Forehead: slight to moderate movement Motion—Eye: complete closure with effort Motion—Mouth: slightly weak with maximum effort
IV	Moderately severe dysfunction	Gross: obvious weakness and/or disfiguring asymmetry At rest: normal symmetry and tone Motion—Forehead: none Motion—Eye: incomplete closure Motion—Mouth: asymmetric with maximum effort
V	Severe dysfunction	Gross: only barely perceptible motion At rest: asymmetry Motion—Forehead: none Motion—Eye: incomplete closure Motion—Mouth: slight movement
VI	Total paralysis	No movement

The best system would be reliable, easy to use, and correlate well with patient self-assessment. Kahn and coworkers[18] developed a 15-item questionnaire for patient self-assessment of facial paralysis; questionnaire results in 76 patients correlated fairly well with both House-Brackmann and the Sunnybrook Facial Grading System.[11] The American Academy of Otolaryngology–Head and Neck Surgery committee on facial nerve disorders has been in the process of developing a standardized grading system for facial nerve function, but this has not yet been formalized.[19] For now, House-Brackmann still seems the most reasonable and widely used choice.

Topognostic Tests

Topognostic tests were intended to reveal the site of lesion by use of a simple principle: Lesions below the point at which a particular branch

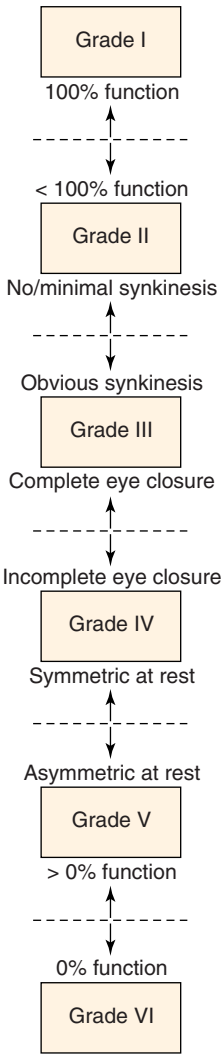

Figure 169-1. Schematic diagram of functional progression in assigning House-Brackmann grade to degree of facial paralysis.

leaves the facial nerve trunk will spare the function subserved by that branch. Accordingly, injury to the nerve in the face cannot affect lacrimation, salivation, taste, or the stapedius reflex. Conversely, the combination of facial paralysis and decreased lacrimation can theoretically be caused only by a lesion in the segment of the nerve in which voluntary motor fibers and parasympathetic fibers to the lacrimal gland run together (i.e., from the cerebellopontine angle to the geniculate ganglion).

In complete focal lesions, which often are the result of trauma, topognostic tests are reliable but usually are unnecessary, because clinical examination and imaging suffice to describe the site of lesion. Bell's palsy, on the other hand, usually is a mixed and partial lesion with varying degrees of conduction block and degeneration changes within different fibers and fascicles of the nerve trunk; therefore, topognostic tests are not expected to provide precise information about the level of the lesion. Many investigators have noted paradoxic and misleading results in applying topognostic testing principles in the evaluation of patients with Bell's palsy. In recent years, otologists use these tests only rarely.

Lacrimal Function

Schirmer's test has the advantages of simplicity, speed, and economy: The physician places a folded strip of sterile filter paper into the conjunctival fornix of each eye and compares the rate of tear production of the two sides. Normally, the portion of the filter paper in contact with the conjunctiva acts as an irritant, stimulating an increased flow of tears, which are then wicked along the filter paper strip by capillary action. The length of the wetted portion of the strip after a fixed interval (usually 5 minutes) is measured and is proportional to the volume of tears produced. A defect in the afferent (the trigeminal nerve along the opthalmic division, or V_1) or efferent (the facial nerve by way of the greater superficial petrosal nerve) limb of this reflex may cause a reduced flow. The reflex is consensual (i.e., a unilateral irritating stimulus in either eye causes tearing in both eyes, and a unilateral sensory deficit in either eye will reduce tearing bilaterally). However, unilateral corneal anesthesia reduces tearing asymmetrically, with a greater reduction on the anesthetized side; therefore, when a sensory deficit is present, presence of bilateral corneal anesthesia should be considered, and stimulation of lacrimation by other noxious stimuli (e.g., inhalation of ammonia) should be performed instead of the conventional Schirmer's test.[8]

Schirmer's test usually is considered positive if the affected side shows less than one-half the amount of lacrimation seen on the healthy side. This corresponds well to the normative data of Fisch,[20] who found that 95% of healthy persons had relatively symmetric responses (the lesser response was less than 54% of the greater response). Fisch[20] also pointed out that tearing often is reduced bilaterally in Bell's palsy (perhaps because of subclinical involvement of other cranial nerves). Thus, both the symmetry of the response and its absolute magnitude are important; a total response (sum of the lengths of wetted filter paper for both eyes) of less than 25 mm is considered abnormal.

Fisch[20] correlated the results of Schirmer's test and ENoG (see later under "Electrodiagnostic Testing") in patients with Bell's palsy and herpes zoster oticus and found that all cases with 90% or greater degeneration by ENoG had an abnormal result on Schirmer's test. However, the Schirmer's test result did not indicate degeneration earlier than ENoG and was abnormal in several cases in which ENoG correctly predicted a good spontaneous recovery.

May[21] added Schirmer's test to the salivary flow test and MST (see later under "Electrodiagnostic Testing") in a battery of prognostic tests. A decrease to 25% of normal in any of these was associated with a 90% chance of a poor recovery.

Stapedius Reflex

The nerve to the stapedius muscle branches off the facial trunk just past the second genu in the vertical (mastoid) part of the nerve. In patients with hearing loss, acoustic reflex testing is used to assess the afferent (auditory) limb of the reflex, but in cases of facial paralysis, the same test is used to assess the efferent (facial motor) limb. An absent reflex or a reflex that is less than one-half the amplitude of the contralateral side is considered abnormal.

The reflex can be elicited by ipsilateral or contralateral acoustic stimulation or, in cases of bilateral severe hearing loss, by tactile or electrical stimulation. It is absent in 69% of cases of Bell's palsy (in 84% when the paralysis is complete) at the time of presentation; the reflex recovers at about the same time as for clinically observed movements.[22] The prognostic value of this test therefore seems limited.

Taste

Because the chorda tympani carries fibers subserving taste from the anterior two thirds of the tongue, many investigators have studied abnormalities of taste in Bell's palsy. Psychophysical assessment can be performed with natural stimuli, such as filter paper disks impregnated with aqueous solutions of salt, sugar, citrate, or quinine, or with electrical stimulation of the tongue.[23] The latter modality, termed *electrogustometry* (EGM), has the advantages of speed and ease of quantification. EGM involves bipolar or monopolar electrical stimulation of the tongue, with current delivery on the order of 4 μA (−6 dB) to 4 mA (34 dB). Threshold responses are denoted by the current level's imparting a subjective sensation of one of the four cardinal tastes or of buzzing or tingling. In healthy persons, the two sides of the tongue have similar thresholds for electrical stimulation, rarely differing by greater than 25%.[24] Older studies demonstrated little usefulness of taste testing, because results were abnormal in almost all patients who were in the acute phase of Bell's palsy; accordingly, EGM could not be used to identify patients with a poor prognosis.[25,26] A newer

study suggests better predictive value for the test: Of a cohort of 50 patients with complete idiopathic facial paralysis, 18 demonstrated abnormal EGM responses (defined as no response or a threshold difference greater than 20 dB across sides), and 7 demonstrated no response on NET, all of whom were in the abnormal EGM responses group. Of these 7, 5 demonstrated incomplete recovery of facial nerve function on long-term follow-up.[23] Taste function appears to recover before visible facial movement in some cases, so if the results of electrogustometry are normal in the second week or later, clinical recovery may be imminent.

Salivary Flow Test

The salivary flow test requires cannulation of the submandibular ducts and comparison of stimulated flow rates on the two sides. It is time-consuming and unpleasant for the patient, especially if performed repeatedly; this latter drawback is one good reason it is not widely used. Reduced submandibular flow implies a lesion at or proximal to the point at which the chorda tympani nerve leaves the main facial trunk; this is variable and may be anywhere in the vertical (mastoid) portion of the nerve.

Ekstrand[27] stated that reduced salivary flow (less than 45% of flow on the healthy side after stimulation with 6% citric acid) correlates well with worse outcome in Bell's palsy. Complete or incomplete recovery could be predicted with 89% accuracy. It is unclear whether these data, all collected within 10 days of onset of paralysis, provide an earlier or more reliable indication of prognosis than electrical or other tests.

May and Hawkins[28] noted that salivary flow decreases sooner than do threshold changes in NET (see under "Electrodiagnostic Testing" later on) in idiopathic facial paralysis. These workers argued that a flow rate of 25% or less of that on the contralateral, unaffected side is an indication for surgery.

Salivary pH

At least one report[29] showed that a submandibular salivary pH of 6.1 or less predicts incomplete recovery in cases of Bell's palsy. Presumably only the duct on the affected side needs to be cannulated, because in this study, all of the control sides had pH levels of 6.4 or more. The overall accuracy of prediction was 91%. Unfortunately, the reported experience with salivary pH is very limited; it is unknown whether this test gives an earlier prognosis than other tests.

Imaging

Magnetic resonance imaging (MRI) with intravenous gadolinium contrast has revolutionized tumor detection in the cerebellopontine angle and temporal bone and is currently the study of choice when a facial nerve tumor is suspected (e.g., in a case of slowly progressive or long-standing weakness).[30] However, enhancement also occurs in most cases of Bell's palsy and herpes zoster opticus, usually in the perigeniculate portions of the nerve.[31,32] This enhancement may persist for more than 1 year after clinical recovery; can be distinguished from neoplasm by its linear, unenlarged appearance; and has no apparent prognostic significance. Computed tomography (CT) is valuable for surgical planning in cholesteatomas and temporal bone trauma involving facial nerve paralysis but probably is less useful than MRI in the investigation of atypical idiopathic paralysis. Unfortunately, even MRI fails to detect a substantial number of malignant parotid tumors.[33]

MRI shows the greatest utility in predicting location and depth of parotid gland tumors, but even in this capacity it is no better than simple manual palpation alone. The MRI appearance of tumor indistinct from surrounding parotid parenchyma has a positive predictive value for malignancy of only 0.48; accordingly, fine needle aspiration biopsy continues to be the "gold standard" modality for preoperative evaluation of parotid masses.[34]

Pathophysiology

Sunderland[35] provided a simple, five-category histopathologic classification of peripheral nerve injury based on a schematic framework proposed by Seddon[36] (Fig. 169-2). Some investigators have since expanded this classification to include a sixth category involving mixed forms of injury proposed by MacKinnon and associates.[37] This classification of

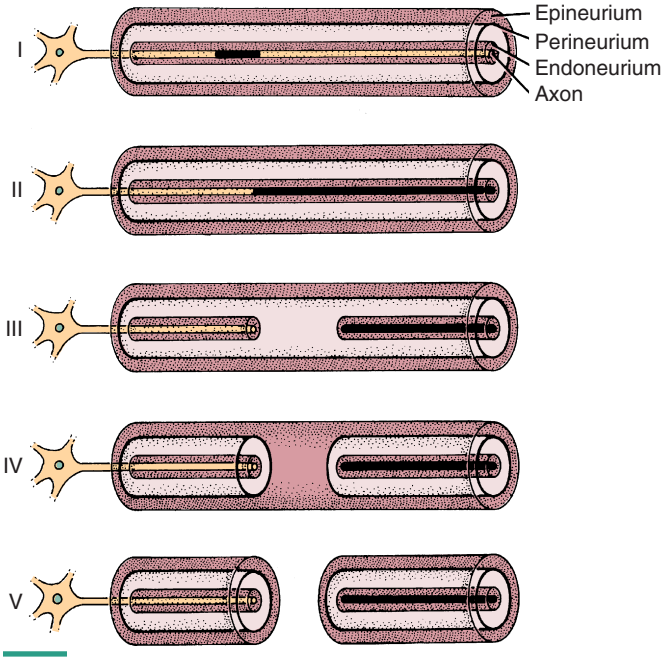

Figure 169-2. Sunderland histopathologic classification of peripheral nerve injury. Roman numerals I to V at *left* denote the Sunderland class corresponding to the degree of injury depicted in the diagram.

nerve trunk injury is helpful in understanding and interpreting the results of electrical tests.

Class I: Pressure on a nerve trunk, provided that it is not too severe, causes conduction block, termed neurapraxia by Seddon. No physical disruption of axonal continuity occurs, and supportive connective tissue elements remain intact. When the pressure or other insult (e.g., local anesthetic infiltration) is removed, the nerve can recover quickly. During conduction block, no impulses can cross the area of the lesion, but electrical stimulation distal to the lesion still produces a propagated action potential and a visible muscle twitch at all times after injury. An example of a Sunderland class I injury is the neurapraxia of an arm or leg that has "gone to sleep."

Class II: A more severe lesion, whether caused by pressure or some other insult (e.g., viral inflammation), may cause axonal disruption without injury to supporting structures. Wallerian degeneration occurs and propagates distally from the site of injury to the motor end plate and proximally to the first adjacent node of Ranvier. In a class II injury, the connective tissue elements remain viable, so regenerating axons may return precisely to their original destinations. Removal of the original mechanism of insult permits complete recovery, but this is considerably delayed, because the axon must regrow from the site of the lesion to the motor end plate at a rate of approximately 1 mm/day before function returns. A class II injury is an *axonotmesis*.

Class III: If the lesion disrupts the endoneurium, wallerian degeneration occurs as in a class II injury, but the regenerating axons are free to enter the wrong endoneurial tubes or may fail to enter an endoneurial tube at all; this aberrant regeneration may be associated with incomplete recovery, manifested as an inability to make discrete movements of individual facial regions without involuntary movement of other parts of the face—an abnormality termed *synkinesis*. Sunderland class III to V nerve injuries, in which aberrant regeneration can occur, are *neurotmesis* injuries.

Class IV: Perineurial disruption implies an even more severe injury, in which the potential for incomplete and aberrant regeneration is greater. Intraneural scarring may prevent most axons from reaching

the muscle, resulting in not only greater synkinesis but incomplete motor function recovery.

Class V: A complete transection of a nerve, including its epineurial sheath, carries almost no hope for useful regeneration, unless the ends are approximated or spanned and repaired.

Class VI: Insults to the facial nerve trunk, whether compressive, inflammatory, or traumatic in origin, can be heterogeneous in nature, with differing degrees of injury from fascicle to fascicle. Such mixed injury involving both neurapraxia and a variable degree of neurodegeneration has been advocated as an additional class of injury.

A patient with a conduction block (class I injury) cannot move the facial muscles voluntarily, but a facial twitch can be elicited by transcutaneous electrical stimulation of the nerve distal to the lesion. The twitch can be observed visually, or the electrical response of the facial muscles may be recorded. Because no wallerian degeneration occurs, this electrical stimulability distal to the site of lesion is preserved indefinitely in isolated class I injury.

In classes II to VI, once wallerian degeneration has occurred, electrical stimulation of the nerve distal to the lesion will fail to produce a propagated action potential and muscle contraction. However, before axonal degeneration, the distal segment is still electrically stimulable. Wallerian degeneration begins immediately after injury but progresses slowly. Histopathologic degeneration of the distal segment becomes apparent approximately 1 week after insult and continues for the ensuing 1 to 2 months.[38] In the case of the facial nerve, this delay in degeneration results in continued electrical stimulability of the distal segment for up to 3 to 5 days after injury.[39] Thus, during these first days after an insult, electrodiagnostic testing of any form cannot distinguish between neurapraxic and neurodegenerative injuries.

After wallerian degeneration, electrical testing can distinguish axonally intact but neurapraxic lesions (class I) from axonally disrupted and neurodegenerative lesions (classes II to V). It cannot, however, distinguish among the different classes of neurodegenerative lesions II, III, IV, and V. An important consideration in the use of such testing is its limited ability to distinguish between pure lesions associated with an excellent prognosis for perfect spontaneous recovery (class II) and those associated with a poor prognosis for useful recovery without surgical repair (class V).

It also is important to recognize that most facial nerve lesions are not pure but probably mixed, with some fibers in conduction block and others disrupted with varying degrees of connective tissue injury. Accordingly, a majority of insults to the facial nerve, whether compressive, inflammatory, or traumatic (except for complete transections), probably are class VI, with a variable threshold of electrical stimulability commensurate with the proportion of neural degeneration across the nerve trunk.

Electrodiagnostic Testing

Tests based on these two principles, electrical stimulation and recording of the electromyographic response, are useful in determining prognosis and sometimes in stratifying patients for nonsurgical versus surgical management. However, they are rarely useful in differential diagnosis. In Bell's palsy and traumatic facial nerve paralysis, electrical tests most often are used to identify patients whose nerves have begun to degenerate, because these patients may be candidates for decompression surgery. In this sense, outpatient evaluation of facial paralysis with electrical testing only needs to be performed if the physician is prepared to recommend decompression in the event that degeneration is discovered. However, intraoperative monitoring of facial nerve function (usually with electromyography) is in widespread use in many types of intracranial and intratemporal surgery.

Nerve Excitability Test

The simplest and best-known test for facial nerve degeneration is the NET introduced by Laumans and Jonkees.[40] The stimulating electrode is placed on the skin over the stylomastoid foramen or over one of the peripheral branches of the nerve, with a return electrode taped to the forearm. Beginning with the healthy side, electrical pulses, typically 0.3 msec in duration, are delivered at steadily increasing current levels until a facial twitch is noted. The lowest current eliciting a visible twitch is the threshold of excitation. Next, the process is repeated on the paralyzed side, and the difference in thresholds between the two sides is calculated.

In a simple conduction block (e.g., after infiltration of the perineural tissues with lidocaine proximal to the point of stimulation), no difference exists between the two sides; the paralyzed nerve is as easy to stimulate distal to the site of lesion as the healthy nerve. After a more severe injury (Sunderland classes II to V) in which distal axonal degeneration occurs, electrical excitability is gradually lost, over a period of 3 to 4 days—even after a total section of the nerve. Findings on the NET (and all other electrical tests involving distal stimulation), therefore, always lag several days behind the biologic events themselves.[41]

In most cases of Bell's palsy with complete paralysis, some degree of neural degeneration occurs, evolving over 1 to 2 weeks.[42] Accordingly, proponents of the NET urge frequent, even daily, examinations, so that severe degeneration can be detected as early as possible. A difference of 3.5 milliamperes (mA) or more in thresholds between the two sides has been proposed as a reliable sign of severe degeneration and has been used as an indicator for surgical decompression. With use of this criterion, complete versus incomplete recovery can be predicted with 80% accuracy.[40] Some investigators insist on conducting two consecutive tests showing differences greater than 3.5 mA to reduce the chance of test error. Lewis and colleagues[43] have reported thresholds in more than 10,000 NETs in cases of Bell's palsy, using the trunk and branches to the eye, forehead, and mouth.

The NET is useful only during the first 2 to 3 weeks of complete paralysis, before complete degeneration has occurred. This test is unnecessary in cases of incomplete paralysis, in which the prognosis is always excellent; in these cases, the test result will be normal when the segment of nerve distal to the lesion is stimulated. If the paralysis becomes total, the test can determine whether a pure conduction block exists or whether degeneration is occurring, as indicated by progressive loss of excitability. Total paralysis for longer than 1 month is almost invariably associated with total loss of excitability. Once excitability is lost and this result is confirmed by repeat testing, further excitability tests are pointless, because clinically evident recovery always begins before any apparent electrical excitability returns. This disparity results because the regenerating axons are smaller, more irregular in size, and fewer in number than before the lesion occurred. Electrical stimulation generally is ineffective in eliciting a synchronous and hence observable twitch in the early stages of regeneration. As these early fibers regenerate, they may regain electrical function individually, while group function, measured as a clinically apparent twitch on electrical stimulation, still is not evident. This phenomenon is termed *early deblocking*, or asynchronous firing of the facial nerve. Similarly, with complete paralysis, if clinical recovery begins before degeneration is noted, continuing testing is unnecessary, because recovery will be rapid and complete.

Partial degeneration and a bad outcome are not synonymous. In a Sunderland class II lesion, nearly complete recovery may occur without serious complications. Laumans and Jonkees[40] state that even patients who show degeneration (threshold difference greater than 3.5 mA) have a 38% chance for complete spontaneous recovery; in the remainder, development of complications such as permanent weakness (not total paralysis) and synkinesis is typical.

Because of relatively large intersubject variations in threshold compared with the small differences between the two sides of the face, stating NET results in proportional terms rather than in absolute threshold differences may be more appropriate. For example, Mechelse and associates[44] used as their criterion for decompression a 150% increase in threshold compared with the healthy side.

Maximum Stimulation Test

The MST is similar to the NET in that it involves visual (i.e., subjective) evaluation of electrically elicited facial movements. Instead of measuring threshold, however, maximal stimuli (current levels at which the greatest amplitude of facial movement is seen) or supramaximal stimuli (even higher current levels) are used. The electrode type and

placement and the nerve-stimulating equipment are the same as in the NET. On the unaffected side, the stimulus current intensity is increased above the threshold level incrementally—with corresponding increases in subjective facial twitch magnitude—until the maximum stimulation level is reached. Stimulation above this level does not elicit any further increase in facial twitch magnitude. This maximum stimulation level is then used to stimulate the affected side, and the degree of facial contraction is subjectively assessed as either equal, mildly decreased, markedly decreased, or without response compared with that on the normal side. With MST as performed by May and coworkers,[45] peripheral branches are the preferred site of stimulation, and the movements on the paralyzed side are subjectively expressed as a percentage (0%, 25%, 50%, 75%, 100%) of the movements on the healthy side.

The theoretic basis of the MST is that by stimulating all intact axons, the proportion of fibers that have degenerated can be estimated; this information should more reliably guide prognosis and treatment than that obtained with the NET. Unfortunately, no good data comparing these or other electrical prognostic tests in the same patients are available, so this claim has not been proved.

According to May and coworkers,[46] when MST results remained normal in Bell's palsy, 88% of patients recovered completely. Reduced movement presaged only a 27% chance of complete recovery. An absence of electrically stimulated movement was always associated with incomplete recovery.

MST is painful for some patients; Molina[47] suggests that the use of a pulse duration less than 0.4 msec (as opposed to the 1 msec proposed by May and coworkers[46]) can eliminate this discomfort, although higher currents are required in some cases.

Electroneuronography

In ENoG, the facial nerve is stimulated transcutaneously at the stylomastoid foramen, as in the NET, although a bipolar stimulating electrode is used. Responses to maximal electrical stimulation of the two sides are compared, as in the MST, but they are recorded in a more objective fashion by measuring the evoked compound muscle action potential (CMAP) with a second bipolar electrode pair placed (usually) in the nasolabial groove. A supramaximal stimulus often is used, and peak-to-peak amplitude is measured in millivolts (mV). The average difference in response amplitude between the two sides in healthy patients has been said to be only 3%.[48] The term "electroneuronography" is actually a misnomer, because it is the facial muscle CMAP that is measured and recorded. Some workers use the term *evoked electromyography* synonymously with *electroneuronography*.

Clearly, this method offers the potential advantage of an objective registration of electrically evoked responses, and the amplitude of response on the paralyzed side can be expressed as a precise percentage of that on the healthy side. For example, if the amplitude of the response on the paralyzed side is only 10% of that on the normal side, an estimated 90% of fibers are said to have degenerated on the paralyzed side. However, this method has some practical difficulties that should be mastered before reliable results can be expected.[49,50] Test-retest errors in the 20% range have been reported by Raslan and associates,[51] despite standardization of electrode positions. Most investigators require a 30% or greater asymmetry (or change over time) for results to be considered abnormal.

The use of ENoG to prognosticate in Bell's palsy has become widespread, although Gates[52] points out the lack of comparative studies showing ENoG to be superior to NET or MST. For example, Coker and coworkers[53] showed good correlation between ENoG and NET (when NET threshold differences exceeded 2 mA, ENoG amplitude on the paralyzed side usually was less than 10% of the normal side), but their study provided no data on clinical outcomes to help choose one test over the other.

The most valid data supporting the use of ENoG would have to come from studies limited to cases of complete paralysis (because incomplete paralysis is known to have an excellent prognosis). In 37 such cases, May and colleagues[45] showed that severe ENoG amplitude reductions (to less than 10% of the unaffected side) were highly correlated with incomplete recovery. Although Canter and associates[54] could find no correlation of final outcome with ENoG in 23 patients with complete paralysis, they did not specifically test the predictive value of the 10% criterion widely used by other authors. More recently, Sillman and colleagues[25] found excellent correlations between ENoG and outcome in Bell's palsy ($n = 66$) but not in traumatic facial nerve palsy ($n = 29$).

Electrical recording of the muscle response also offers the possibility of measuring latency, which is the time elapsed between stimulus and response. Only slight interest in this variable has developed; although slow nerve conduction velocities might be expected to be an early indicator of degeneration, the available data are in conflict. Joachims and associates[55] stated that increased latency in the first 72 hours (before any observable change in threshold or response amplitude) was a reliable predictor of a poor outcome. However, Esslen[48] reported that in 145 patients, latency never increased before the 5th day, and latency changes never preceded changes in evoked potential amplitude; he concluded that latency measurements were of no clinical value. Danielides[42] and Ruboyianes[56] and their coworkers also suggested that latency adds nothing to information provided by ENoG amplitude or MST.

The limitation described for the NET, namely, its inapplicability in cases of partial paralysis after the beginning of clinical recovery and after excitability has been lost, also applies to the MST and to ENoG. In acute facial paralysis, all of these tests are useful only in tracking the early course of a completely paralyzed nerve until clinical recovery begins or the nerve shows complete loss of excitability.

Esslen[48] used ENoG to study the time course of Bell's palsy, finding that the acute phase rarely exceeds 10 days. Decreases in ENoG amplitude after the 10th day were associated with substantial latency increases and were attributed to desynchronization of surviving fibers, rather than to increased degeneration. Accordingly, the time elapsed since the onset of paralysis should be taken into account in the interpretation of ENoG results. Patients reaching 95% degeneration (amplitude of response equals 5% of that on the healthy side) within 2 weeks had a 50% chance of a poor recovery, whereas patients exhibiting a more gradual decrease in ENoG amplitude had a much better prognosis.[57]

Most proponents of ENoG use it mainly to obtain an early prognosis in acute facial paralysis (Bell's or post-traumatic) or to select patients for decompression surgery. Kartush[58] pointed out that ENoG also can document subclinical facial nerve involvement by tumors, especially acoustic neuromas. Patients with acoustic tumors who had ENoG evidence of nerve involvement (despite clinically normal facial movement) were more likely to have postoperative weakness. However, because ENoG amplitude reductions were highly correlated with increasing tumor size (which also predicts poorer facial nerve outcome), it is unclear whether ENoG really adds prognostic information when tumor size is known. ENoG also has demonstrated some success in preoperative detection of facial nerve infiltration by malignant parotid tumors, even when no paresis is seen on clinical examination.[59] Table 169-2 summarizes the three versions of electrodiagnostic testing and commonly accepted threshold criteria for consideration of facial nerve decompression for complete facial paralysis.

Electromyography

EMG is the recording of spontaneous and voluntary muscle potentials using needles introduced into the muscle. Its role in the early phase of Bell's palsy is limited, because it does not permit a quantitative estimate of the extent of nerve degeneration (the percentage of degenerated fibers). However, EMG may be helpful in certain situations. Several authorities who favor decompression for Bell's palsy base their decisions for surgery primarily on the NET or ENoG, but also require confirmatory EMG[40,49]; if it shows voluntarily active facial motor units despite loss of excitability of the nerve trunk, the prognosis for a good spontaneous recovery is excellent.[25,48] This application of EMG in Bell's palsy probably is underused.

After loss of excitability, tests requiring electrical stimulation such as NET and ENoG are no longer useful. However, EMG may give prognostically useful information during this phase of the illness. After 10 to 14 days, fibrillation potentials may be detected, confirming the presence of degenerating motor units; in 81% of patients with such findings, incomplete recovery is the rule.[60] More useful are the polyphasic reinnervation potentials that may be seen as early as 4 to 6 weeks

Table 169-2

Electrodiagnostic Testing Criteria

Test	Criteria to Consider Facial Nerve Decompression
Nerve excitability test (NET)	>3.5-mA threshold difference between sides
Maximal stimulation test (MST)	No response on injured side at maximal stimulation
Electroneurography (EnoG)	>90% degeneration within 14 days

after the onset of paralysis. Presence of these potentials precedes clinically detectable recovery and predicts a fair to good recovery.[48] Grosheva and coworkers noted that EMG performed after 14 days exhibited greater prognostic value for determining good versus poor recovery, with both higher specificity and positive predictive value, than ENoG performed before 14 days using a 75% degeneration cutoff criterion; however, their study included many patients with incomplete facial paralysis.[61]

Because few surgeons advocate decompression surgery for Bell's palsy late in the course of the disease, this use of EMG is uncommon. It may be helpful in the assessment of long-standing facial paralysis, along with muscle biopsy, to determine the possible success of substitution anastomosis or cross-facial anastomosis as a mechanism of restoring facial motion. EMG also can help assess whether a nerve repair (e.g., in the cerebellopontine angle) is unsuccessful. If no clinical recovery occurs and EMG shows no polyphasic reinnervation potentials at 15 months (or at 18 months at the latest), the anastomosis should be considered a failure, and another operation should be considered (e.g., hypoglossal-facial anastomosis).

Facial Nerve Monitoring

During the 1980s, audible EMG monitoring of facial nerve function during acoustic neuroma surgery became routine in many centers, and its application has spread to other operations involving risk to the facial nerve and other cranial nerves.[62] Although it is possible for the surgeon or an associate to watch for facial movements in response to mechanical or electrical stimulation of the nerve, simple observation fails to detect many small muscular contractions and in any case demands constant vigilance. By contrast, electrodes in or near the facial muscles record EMG potentials that can be amplified and made audible with a loudspeaker. Thus, the surgeon's ears can monitor the facial nerve while the hands and eyes operate. Harner and colleagues[63] pointed out that this technique is not really new but has only recently become popular.

Facial nerve monitoring can be performed in many different ways. One approach to categorizing the type of monitoring used is to consider if it is active versus passive.[64] Having a surgical assistant visually monitor the face for twitches during parotid surgery is technically a form of facial nerve monitoring, albeit a coarse and highly variable one. By applying needle electrodes to the facial muscles and recording CMAPs, the activity of the facial nerve can be monitored in a more standardized, precise, and sensitive fashion. Both of these examples are *passive* forms of facial nerve monitoing, whereby facial muscle movement is activated only with direct mechanical, stretch, caloric, or other nonelectrical stimulation of the facial nerve. Facial nerve monitoring electrodes typically are placed in a two-channel montage including the orbicularis oculi and orbicularis oris muscles, although four-channel arrangements can be used as well.

When electrical stimulation of the facial nerve is used along with measurement of facial CMAPs, the technique is termed *active* facial nerve monitoring. Electrical stimulation is delivered by a monopolar or bipolar electrode (e.g., similar to those used for bipolar electrocautery), which is insulated except at the tips. Commercially available monopolar electrodes are flexible with blunt tips, which makes them convenient for access to cramped areas. In addition, electrified instruments with insulated shafts are available that are shaped in the form of traditional otomicroscopic dissectors such as curved needles, sickle knives, round knives, gimmicks, and other elevators. On bipolar stimulation, the current is mostly confined to the tissue between the electrified tips; with wide tip separation, the stimulation is similar to that with use of a monopolar electrode, but with the tips close together, bipolar stimulation is quite specific. Both types are satisfactory if the user understands these differences.

Electrical stimulation activates a surrounding volume of tissue commensurate in size with the delivered current intensity, and modulation of current intensity can provide the surgeon with good sensitivity for locating and mapping the facial nerve. Early in the dissection before the facial nerve has been visually identified, initial stimulation with higher current levels allows the surgeon to stimulate the nerve from afar, without the need for direct contact on the nerve. As dissection is carried closer to the nerve, lowering the current level allows for more precise determination of nerve location. As dissection is continued and the facial nerve (or its candidates) are identified, low-level current stimulation directly on the nerve provides confirmation that the nerve has been positively identified.

When the surgeon stimulates the nerve electrically, a CMAP is recorded from the monitored facial muscles and can be plotted on an oscilloscope (if visual display is being used), and the loudspeaker emits a characteristic thump. Gentle mechanical stimulation (e.g., touching the nerve with an instrument) will produce a similar sound. Tension on the nerve from mechanical stretching or caloric or thermal stimulation of the nerve from irrigation often will produce a prolonged irregular series of discharges that sounds like popcorn popping. Prass and associates[65] termed these two characteristic sounds *bursts* and *trains*, respectively. Learning to identify these sounds is easy, providing instant feedback regarding the location of the facial nerve and concomitant surgical manipulation. Bursts imply near-instantaneous nerve stimulation; trains signify ongoing stimulation of the nerve, which can be potentially more damaging.

Kartush[58] stated that excessive intraoperative train activity predicts poor outcome; Prell and colleagues correlated total train time (the summation of online monitoring time during which trains were recorded) greater than 10 seconds with a higher likelihood of immediate and long-term deterioration in facial function.[66] Hone and associates[67] disagree. Conversely, if at the end of the surgical procedure the nerve can be stimulated successfully near the brainstem with low currents (0.05 to 0.1 mA), all investigators agree that the prognosis for postoperative function is excellent.[68-72] As seen in patients with Bell's palsy or traumatic facial paralysis, patients undergoing resection of acoustic neuromas in whom facial function is intact immediately postoperatively but a delayed paralysis develops subsequently have better long-term facial function than those with immediate weakness or paralysis.[73]

As with any technical aid, a number of pitfalls have been recognized. Failure to obtain audible facial nerve responses can be caused by any of a multitude of possible errors: detached or shorted electrodes, incorrect wiring of electrodes, malfunction of a nerve monitor or stimulator, inadvertent direct anesthesia of the facial nerve from local anesthetic infiltration to the stylomastoid foramen, pharmacologic muscular paralysis from induction agents used in anesthetic management, or even simply a muted speaker, as well as many other complications (including a nonfunctional nerve). Anesthesiologists have shown that the facial musculature is less susceptible to pharmacologic paralysis than somatic musculature and that a moderate degree of paralysis[74,75] (leading to 50% reduction of hypothenar muscle potentials or even "complete" neuromuscular blockage as measured in the thumb)[76] does not necessarily interfere with facial nerve monitoring.

Stimulation of the trigeminal nerve occasionally can cause electrical confusion, or crosstalk; the facial muscle electrodes may pick up EMG signals from the nearby masseter muscle. Similarly, stimulation of the adjacent vestibular or cochlear nerves can sometimes activate the facial nerve as well, leading to a false-positive identification.

Electrode position should always be checked by voluntary movement, transcutaneous electrical stimulation, or most commonly simply

by tapping over the muscular area being monitored before the surgical site is draped. The most useful intraoperative check on the monitoring equipment is the stimulus artifact or warble tone, which is produced when the stimulating electrode touches tissue remote from the facial nerve. Standard neuromonitoring equipment can be set to produce an auditory flag such as a warble tone or a verbal phrase confirming current flow. This auditory notification confirms that the stimulator is delivering current, the electrodes are in place, and the loudspeaker is working and is to be distinguished from the audible bursts and trains indicating true facial nerve stimulation and facial muscle contraction.

The idea that audible EMG monitoring makes acoustic tumor surgery easier, faster, and probably more successful in terms of facial nerve preservation has become widely accepted anecdotally, and several investigators have shown that postoperative facial nerve function is better in patients who have been monitored (at least during operations for resection of large tumors).[77-79] These studies seem to have used historical control groups (i.e., monitoring was adopted for all patients at a particular point in time, with no monitoring for patients operated on before that time). This limitation makes it hard to be sure that some of the improvements were not caused by improvements over time in the surgeon's skill; indeed, one group acknowledged that the monitored group also had profited from evolving surgical techniques (more use of sharp dissection).[80] This finding highlights the role of the monitor as teacher; the surgeon rapidly learns to prefer medial-to-lateral over lateral-to-medial dissection and sharp over blunt dissection (when the tumor is adherent to the nerve). Although most surgeons use EMG monitoring, others have monitored facial contractions with a motion sensor connected to an electronic circuit that produces an audible signal or by the use of small bells that are sutured to facial skin.[72,81,82]

A panel discussion at a meeting of the American Otological Society produced consensus that electrical facial nerve monitoring is valuable in acoustic tumor surgery and may be useful in facial nerve rerouting in skull base surgery.[83,84] A consensus conference on acoustic tumors sponsored by the National Institutes of Health came to a similar conclusion that benefits of intraoperative facial nerve monitoring in acoustic neuroma surgery had been clearly established.[85]

Electrical facial nerve monitoring is now used by a majority of American otolaryngologists performing parotidectomies, although such monitoring has not been shown to improve postoperative facial paralysis rates after primary parotid gland surgery.[86-88] A retrospective study by Makeieff and colleagues did demonstrate an advantage in postoperative facial paralysis rates when intraoperative continuous facial nerve monitoring was used in 14 of 32 patients undergoing revision total parotidectomy for recurrent pleomorphic adenoma.[89]

In adjusting for the probabilities of facial nerve paralysis with or without monitoring, intraoperative facial nerve monitoring has been shown to be cost-effective for both primary and revision middle ear and mastoid surgical procedures, with a higher number of quality-adjusted life-years and lower average cost than for a no-monitoring strategy.[90]

Unconventional Tests of Facial Nerve Function

Acoustic Reflex Evoked Potentials

Hammerschlag and associates[91] reported a scalp-recorded potential at 12- to 15-msec latency in response to acoustic stimulation contralateral to the recording site and attributed this to facial motor pathway activation. The response persisted after paralysis during anesthesia, and these workers proposed its use for intraoperative monitoring of facial nerve function. However, the response was extremely small (much lower in amplitude than that of the auditory brainstem response), which would make it difficult and slow to record, requiring prolonged averaging. This response seems unlikely to be useful, because audible EMG monitoring gives essentially instantaneous feedback for intraoperative assessment of facial nerve function.

Antidromic Potentials

If a motor nerve is electrically or mechanically stimulated at some point between its cell body and its synapse on a muscle fiber, action potentials will be propagated in two directions: An orthodromic or antegrade impulse will travel distally toward the muscle, whereas an antidromic or retrograde impulse will travel proximally toward the cell body. The orthodromic impulse will cross the neuromuscular junction, resulting in an observable muscle contraction and a recordable compound muscle action potential. This *M-wave* is the same potential recorded in ENoG. Although the antidromic impulse will not cross a synapse, it can be recorded by electrodes on the proximal nerve (near field) or at a distance (far field). Tashima and coworkers[92] recorded electrical responses from the geniculate ganglion region in guinea pigs while stimulating the facial nerve at the stylomastoid foramen. These near-field antidromic responses were reliably altered by surgical lesions placed between the stimulating and the recording electrodes. Other modifications for improving the consistency and reliability in producing antidromic potentials involve stimulation of the buccal branch of the facial nerve through Stensen's duct, rather than percutaneous stimulation of the facial nerve branches.[93]

Far-field antidromic potentials have been recorded from the scalp after electrical stimulation near the stylomastoid foramen, in hopes that this would yield a noninvasive test of the integrity of the intratemporal or intracranial portions of the facial nerve. However, these responses are difficult to record and interpret. Metson[94] concluded, on the basis of studies in cats, that the intracranial nerve was the main generator, but Kartush and associates[95] found in dogs that the mastoid segment was primarily responsible.

As previously mentioned, the antidromic impulse will not travel farther "upstream" than the facial nucleus motor neuron, but it can be reflected back along that neuron's axon in an orthodromic direction, eventually reaching the muscle and stimulating a muscle action potential—the *F-wave*—that is delayed relative to the initial M-wave. These F-waves are unusually large in hemifacial spasm,[96] suggesting that facial nucleus hyperexcitability plays a role in that disorder. F-waves are easily disrupted by even the mildest degree of facial paresis.[97] They often are abnormal with delayed latency or decreased amplitude or are absent in patients with acoustic tumors, even when clinical examination of facial nerve function yields normal findings.[98] However, they do not predict postoperative function when tumor size is taken into consideration.[99]

Antidromic stimulation of peripheral branches of the facial nerve has been introduced into intraoperative monitoring, with continuous recording of either near-field potentials from the facial nerve near the brainstem[100] or F-waves from facial musculature.[89] Wedekind and Klug[98,101] believe that F-wave monitoring provides earlier and better prognostic information to the surgeon than that obtained with continuous EMG monitoring.

Blink Reflex

Electrical or mechanical stimulation of the supraorbital branch of the trigeminal nerve elicits a reflex contraction (blink) of the orbicularis oculi muscle, which is innervated by the facial nerve. Two studies found blink reflex abnormalities (recorded by EMG) in many patients with acoustic tumors (far more than were found by ENoG).[102,103] Although this finding suggests that subclinical facial nerve involvement is more common than has been clinically appreciated, neither study offered evidence that blink reflex testing added any prognostic information to that available from tumor size.

Magnetic Stimulation

A rapidly varying magnetic field produced by a surge of current in a coil placed over the skin will induce electrical currents in underlying tissue and can be used to stimulate nerves. This method offers two potential advantages over conventional electrical stimulation of the facial nerve: (1) the nerve can be maximally stimulated without pain or discomfort, and (2) if the coil is placed in the temporoparietal area (transcranial stimulation), the nerve seems to be stimulated in the region of the geniculate ganglion or the internal auditory canal. This functionality, when coupled with electrical stimulation of the facial nerve at the stylomastoid foramen, could obviously be useful for site-of-lesion determination, at least in the earliest phases of paralysis before electrical excitability distal to a lesion is lost.[104-108]

Patients with magnetically stimulable nerves, when tested up to 4 days after onset of Bell's palsy, had a better prognosis than those whose

responses had been lost.[109] Unfortunately, it was unclear whether this test added prognostic information once the severity of the clinically assessed paresis was taken into account. Schriefer and colleagues[109] found no response to transcranial magnetic stimulation in serial follow-up evaluations of two patients with Bell's palsy, even after rapid and complete clinical recovery (2 and 3 weeks, respectively), suggesting that this technique may not be useful for prognostic purposes after the first few days. Rösler[110] and Duckert[111] and their coworkers found that magnetic stimulation offered no unique prognostic information in acoustic tumor cases once tumor size (the best predictor of facial nerve outcome) is considered.

Optical Stimulation

Another method of stimulating the facial nerve without direct tissue contact is by optical excitation. Contact-free optical excitation provides the important potential benefit of neural stimulation without mechanical trauma. Unfortunately, early efforts at optical nerve stimulation using ultraviolet-wavelength excimer laser were successful only at energy densities comparable to the photoablation threshold.[112] Wells and colleagues demonstrated successful optical stimulation of frog and rat sciatic nerve with pulsed short- and medium-wavelength infrared laser light, with neural tissue damage occurring at energy densities 2.5 times neural excitation threshold.[113] More recently, Teudt and coworkers used short-wavelength infrared pulsed laser light to successfully stimulate the extratemporal facial nerve without neural damage seen on histologic examination.[114] Neural tissue injury occurred at an energy density similar to that reported by Wells and colleagues,[113] approximately 1.3 to 3 times that of threshold.

Such optical excitation techniques would have an obvious advantage for use in locations in which mechanical dissection of the facial nerve must be kept to a minimum, such as at the cerebellopontine angle, where the nerve does not yet have a protective layer of epineurium for support. This specific application has not yet been reported.

Transcranial Electrical Stimulation–Induced Facial Motor Evoked Potentials

Current methods of intraoperative facial nerve monitoring allow for active stimulation of the nerve at the level of the hand-held stimulator. Although this technique is beneficial in identifying and confirming the integrity of the nerve at all points distal to the dissection, it cannot test the integrity of the nerve proximal to dissection, which may be vital to know during dissection of a large cranial base tumor, when the facial nerve root entry zone is not readily identified. Antidromic stimulation and F-wave monitoring of the facial nerve can theoretically overcome this drawback. Another more recently developed method involves transcranial electrical stimulation of the cortical facial motor pathway and measurement of the corresponding facial motor evoked potentials (MEPs).

In intraoperative transcranial electrical stimulation, spiral electrodes are placed at Cz and C3/C4 overlying the facial motor cortex contralateral to the side of the lesion being removed. Electrical stimulation of these facial corticobulbar neurons is propagated across the pyramidal decussation to stimulate facial nucleus neurons on the side ipsilateral to the lesion. Lower motor neuron stimulation propagates to the facial musculature, where a muscle action potential is recorded in the standard fashion; this corticobulbar-derived CMAP is the MEP. Thus, the integrity of the entire facial motor tract is tested by this technique. MEP recordings are performed before tumor microdissection (baseline), at regular intervals intraoperatively, and immediately after completion of dissection (final). The final-to-baseline MEP amplitude ratio is calculated to determine the likelihood of an intact or disrupted facial motor tract.[115]

Transcranial excitation of the facial motor cortex is dependent on multipulse stimulation, in contrast with facial nerve stimulation, which adds to the specificity of the technique. However, application of the transcranial electrical stimulation technique is characterized by multiple constraints, including the necessity for nonvolatile anesthesia (only propofol and narcotic infusions are used for maintenance of anesthesia, as volatile agents adversely affect corticobulbar stimulability), use of high stimulus voltages (on the order of 100 to 400 V) and subsequent need to pause surgical dissection during MEP acquisition, and the possibility of epileptic discharge during cortical stimulation.[116]

Nonetheless, the technique has been used with good success by several groups.[117-119] Final-to-baseline MEP amplitude ratios greater than 50% appear to correlate well with good immediate postoperative facial function (reported as House-Brackmann grade I or II); ratios less than 50% correlate with varying degrees of worse function (reported as House-Brackmann grades III to VI). This technique is in its infancy and is likely to undergo continued refinement, with its ultimate utility to be determined.

CHAPTER ONE HUNDRED AND SEVENTY

Clinical Disorders of the Facial Nerve

Douglas E. Mattox

Key Points

- The term *Bell's palsy* should be reserved for abrupt-onset, idiopathic facial paralysis without other identified cause.
- Progressive facial paralysis is not Bell's palsy and should prompt an investigation for neoplasm.
- The etiology of Bell's palsy is reactivation of herpes simplex virus (HSV).
- The mainstay of treatment for Bell's palsy is corticosteroids.
- Ramsay Hunt syndrome (herpes zoster oticus) is caused by varicella-zoster virus (VZV).
- Bell's palsy is common during pregnancy and is managed as for any other facial palsy, in collaboration with the patient's obstetrician.
- Bilateral facial paralysis suggests the possibility of Lyme disease.
- When facial paralysis occurs in the setting of chronic otitis media (suppurative or cholesteatoma), the first line of treatment is to resolve the ear disease; subsequent recovery from the facial paralysis is the usual outcome in this setting.

This chapter describes clinical disorders of the facial nerve (Fig. 170-1). Most of the discussion is devoted to idiopathic paralysis (Bell's palsy); however, disorders of the facial nerve associated with other diseases also are presented. The usefulness of electrodiagnostic testing and the medical and surgical management of Bell's palsy are reviewed as well.

Bell's Palsy: Spontaneous Idiopathic Facial Paralysis

The term *Bell's palsy* should be reserved for cases of facial paralysis in which signs and symptoms are consistent with the disease and in which a diligent search fails to identify another cause for the clinical findings. Every experienced otolaryngologist has seen patients whose facial paralysis was caused by malignancy, facial neuroma, intracranial tumor, infection, or some other manageable cause but was misdiagnosed by another physician. The dictum that "all that palsies are not Bell's" cannot be overemphasized.

Although older literature relegated Bell's palsy to a diagnosis of exclusion, May and colleagues[1] emphasized the diagnosis on the basis of specific clinical features. Taverner[2] outlined the minimum diagnostic criteria for Bell's palsy: (1) paralysis or paresis of all muscle groups of one side of the face; (2) sudden onset; (3) absence of signs of central nervous system (CNS) disease; and (4) absence of signs of ear or cerebellopontine angle disease. The differential diagnosis of facial palsy is shown in Table 170-1.

Incidence

The annual estimated incidence of Bell's palsy is 20 to 30 patients per 100,000 population; it was 20.2 of 100,000 per year in the United Kingdom between 1992 and 1996.[3] The incidence is greater in patients older than 65 years (59 of 100,000) and lower in children younger than age 13 (13 of 100,000).[4-6] The male-to-female ratio for Bell's palsy is approximately equal, except for a predominance in women younger than 20 years of age and a slight predominance in men older than 40 years.[4] The left and right sides of the face are equally involved. Thirty percent of patients will have incomplete paralysis on presentation, and 70% will have a complete paralysis.[7] Bilateral paralysis occurs in 0.3% of patients, and 9% have a history of previous paralysis.[4] A family history of Bell's palsy can be elicited in 8% of patients.[4]

Etiology

Proposed causes of Bell's palsy include microcirculatory failure of the vasa nervorum,[8,9] viral infection, ischemic neuropathy, and autoimmune reactions.[10,11] Of these, the viral hypothesis has been the most widely accepted[4,12]; however, no virus has ever been consistently isolated from the serum of patients with Bell's palsy.[13] Thus, the evidence for the viral hypothesis is indirect, relying on clinical observations and changes in viral antibody titers. Furthermore, although the underlying cause may be viral, the immediate cause of the paralysis itself is debated to be viral neuropathy alone or ischemic neuropathy secondary to viral infection.[14]

Acute facial paralysis can occur as part of many viral illnesses, including mumps,[15] rubella,[16] herpes simplex,[17] and Epstein-Barr virus.[18,19] A viral cause for Bell's palsy also is supported by the finding that it seems to be part of a polyneuritis syndrome in which the facial palsy is the most obvious cranial nerve involved. Careful neurologic examination will reveal other cranial nerve weaknesses in more than 50% of patients with Bell's palsy.[20,21] Adour[22,23] found several affected cranial nerves in most patients (Table 170-2).

A direct link between Bell's palsy and viral infection has been difficult to establish. Serologic studies have examined both seroconversion and prevalence of antigens to suspected etiologic agents in patients with Bell's palsy, especially HSV and VZV. The results have been conflicting and have been dependent on techniques used and popula-

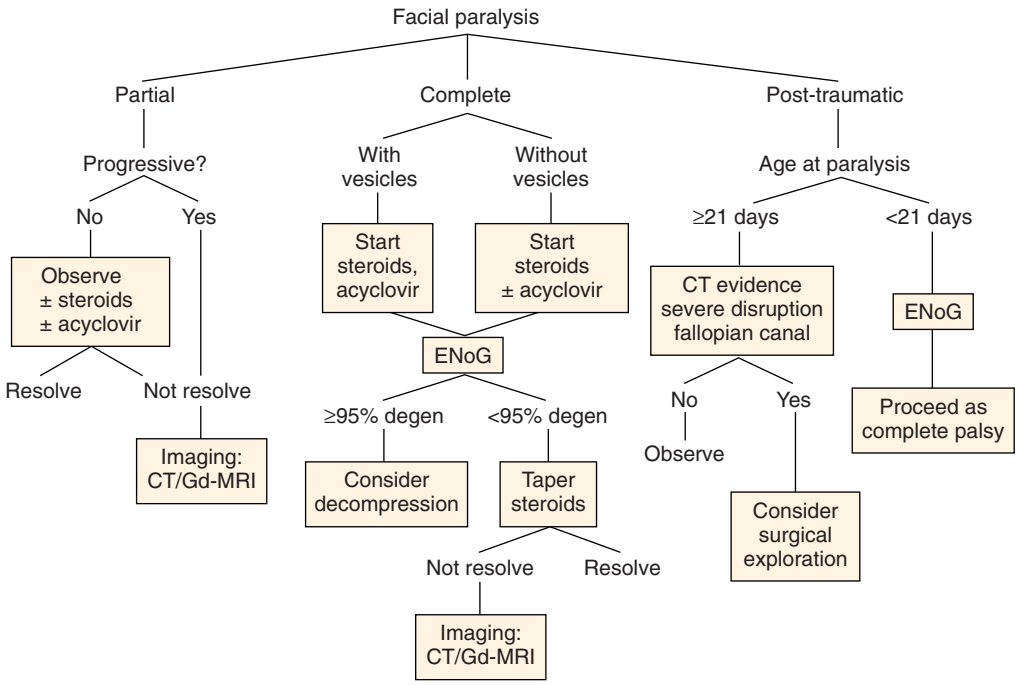

Figure 170-1. Facial paralysis: management algorithm.

Table 170-1
Differential Diagnosis of Facial Paralysis

Acute Paralysis	Chronic or Progressive Paralysis
Polyneuritis	Malignancies
· Bell's palsy	· Primary parotid tumor
· Herpes zoster	· Metastatic tumor
· Guillain-Barré syndrome	Benign tumors
· Autoimmune disease	· Schwannoma
· Lyme disease	· Glomus tumor
· Human immunodeficiency virus infection	Cholesteatoma
· Kawasaki's disease

tions studied.[24,25] One reason for failure of these studies is that they sought for signs of an acute infection immediately preceding the onset of the Bell's palsy. No seasonal predilection or epidemic clustering has been documented, however, so it is much more likely that Bell's palsy is caused by reactivation of a latent virus rather than direct, communicable viral infection.

Morgan and colleagues[26,27] and Vahlne and coworkers[28] support the hypothesis that Bell's palsy is a reactivation of VZV that may be initiated by several stresses, including heterotopic viruses (viruses other than herpesviruses) or physical or metabolic stress. Activation by other agents may explain the diversity and inconsistency of the antibody titers reported in various studies, as well as the epidemicity or clustering of cases. This reactivation can occur without a measurable antibody response to HSV.

The best evidence for reactivation of HSV as the mechanism for Bell's palsy comes from several studies of the geniculate ganglion and facial nerve. Futura[29] and Takasu[30] and their coworkers have demonstrated HSV-1 DNA in both the trigeminal and geniculate ganglia of unselected autopsy specimens. Burgess and colleagues[31] reported a single of case of a patient who died shortly after Bell's palsy developed and in whom HSV-1 genomic DNA was identified in the geniculate ganglion of the facial nerve. Assay of archival control tissue for viral DNA yielded negative findings. In the most important study so far, Murakami and associates[32] looked at endoneurial fluid and postauricular muscle from patients with Bell's palsy or Ramsay Hunt syndrome and control subjects. Polymerase chain reaction (PCR) assay was used to test for HSV-1 DNA and VZV DNA, and the results were confirmed with Southern blot analysis. HSV DNA was detected in 11 of 14 patients with Bell's palsy, whereas VZV DNA was not recovered from any. Conversely, VZV DNA was recovered from all the patients with Ramsay Hunt syndrome, whereas none had HSV-1 DNA. Unaffected control subjects had neither virus DNA. This study suggests a clean distinction between Bell's palsy and Ramsay Hunt syndrome; however, other studies suggest more overlap.

Futura and coworkers[33] studied 142 patients with both clinical Ramsay Hunt syndrome and acute facial palsy. Thirteen were diagnosed as having Ramsay Hunt syndrome on the first visit, and in another eight, vesicular lesions developed subsequent to their initial evaluation. Of the 121 with nonvesicular acute facial paralysis, 35 had VZV DNA detected in their saliva or serologic evidence of VZV reactivation. Yamakawa and colleagues[34] demonstrated how technique-sensitive these studies are. Using two different PCR techniques, these investigators found high but differing rates of VZV DNA detection in patients with Ramsay Hunt symdrome.

A few animal studies also support a viral cause for Bell's palsy. Ishii and coworkers[35] induced facial paralysis in guinea pigs by inoculating the surface of the facial nerve with HSV-1. The severity of paralysis and subsequent degeneration were evaluated histologically and seemed to be worse if the epineurium was removed before inoculation. Of interest, these workers found greater extension of the virus centrally within the nerve than toward the periphery. Sugita and associates[36] induced an acute transient facial paralysis in mice by injecting HSV into the auricles and tongues of mice. The paralysis started 6 to 9 days after inoculation and resolved after 3 to 7 days. Viral antigens were detected in the facial nerve, geniculate ganglion, and facial nerve nucleus. A spontaneously recovering ischemic facial palsy also can be induced in cats by embolization of internal and external maxillary arteries. The onset of the paralysis is immediate after embolization and resolves after 2 months.[37]

Although it is likely that the underlying disease in Bell's palsy is viral polyneuropathy, an unresolved question is why such a profound effect on the facial nerve occurs, in contrast with the relatively minor and transient changes in the other cranial nerves. The major anatomic difference between the facial and other cranial nerves is in its long bony canal. Fisch[38] measured the diameter of the fallopian canal throughout the temporal bone and found that the narrowest point was at the junction of the internal auditory canal and the labyrinthine portion, which he called the *meatal foramen*. The meatal foramen averaged 0.68 mm in diameter, whereas the remainder of the fallopian canal measured 1.02 to 1.53 mm. Fisch reasoned that edema in this narrow segment of the fallopian canal could cause damming of the axoplasmic flow within the facial nerve. This site of lesion in Bell's palsy has been confirmed by clinical observation[39,40] and by intraoperative neuronography.[41,42] A similar site of lesion has been identified electrophysiologically in herpes zoster oticus.[43]

Histopathology

Fowler[16] reported autopsy findings in a patient who died shortly after Bell's palsy developed. The entire intratemporal nerve contained dilated and engorged veins and venules. Fresh hemorrhage was found within the internal auditory canal surrounding the facial nerve that extended as far as the geniculate ganglion. Fowler theorized that the ischemia resulted from microthrombi rather than vasospasm.

Reddy and associates[44] examined a facial nerve 17 days after the onset of spontaneous paralysis. The nerve showed scattered degeneration of the myelin sheaths and axons. From 10% to 30% of facial nerve fibers were surrounded by phagocytic cells. The perivascular areas also showed inflammatory reactive changes and hemorrhage.

Proctor and coworkers[45] examined a patient who died 13 days after the onset of facial paralysis. The facial nerve showed lymphocytic infiltration and phagocytosis of myelin by macrophages throughout the infratemporal course of the nerve. Initially, these findings were interpreted as evidence for a viral cause. However, when McKeever and colleagues[46] reexamined the case, they emphasized that the inflammatory cells were most prominent where the facial nerve was surrounded by bone, especially in the labyrinthine portion of the fallopian canal, but not within the internal auditory canal. These investigators theorized that the histopathologic features suggested a compression-type injury with no evidence of vascular occlusion.

O'Donoghue and Michaels[47] found degeneration of myelin sheaths and axon fibers throughout the intratemporal course of the facial nerve. The nerve was constricted at the meatal foramen, and an osteoclastic giant cell reaction caused resorption of bone around the geniculate ganglion. These workers interpreted the observed changes as consistent with a viral cause, but as pointed out by Jenkins and associates,[40] these findings do not preclude edema and constriction of the facial nerve as the final event leading to the paralysis.

Podvinec[48] found inflammatory infiltrates in the intratemporal portion of the facial nerve 6 months after the onset of the palsy, along with signs of wallerian degeneration and regeneration. He suggested that the persistence of infiltrates for this extended time may result from compromised circulation within the fallopian canal. Jackson and colleagues[49] reported the histopathologic findings from the labyrinthine segment of the facial nerve in a patient 1 year after the onset of a total facial paralysis secondary to herpes zoster. A portion of the nerve within the auditory canal was essentially healthy; however, at the meatal foramen, the nerve became a mixed fibrotic and necrotic acellular mass.

Michaels[50] described the histopathologic findings in an autopsy performed 11 days after the onset of Bell's palsy. As in other studies, histopathologic features included demyelination, compression, bone resorption, and lymphocytic infiltration in the proximal labyrinthine segment of the facial nerve. Michaels cautioned against the overinterpretation of bulging of the nerve in the distal internal auditory canal, because it was found on both the healthy and the pathologic sides.

Another approach to the histologic evaluation of Bell's palsy is with biopsy specimens obtained intraoperatively, including biopsy specimens of the chorda tympani and greater petrosal nerve. Chorda tympani specimens in acute Bell's palsy have shown degeneration of myelinated fibers but no inflammatory response.[51,52] Fisch and Felix[14] examined greater petrosal nerve specimens obtained during middle cranial fossa facial nerve decompression. Their findings included degeneration and demyelination of large axons and lymphocytic infiltration. They found these results to be consistent with wallerian degeneration starting proximal to the geniculate ganglion, probably from the meatal foramen.

In summary, most histologic studies show diffuse demyelination of the facial nerve throughout its intratemporal course, with the most severe changes in the labyrinthine segment and at the meatal foramen.

Central Nervous System Changes

Auditory symptoms, usually in the form of hyperacusis, may be present in up to 30% of patients with Bell's palsy.[53] The cause for these auditory symptoms is unknown. McCandless and Schumacher[54] did not find evidence of a lesion affecting the cochlear nerve in patients with facial paralysis. Many researchers have attributed the hyperacusis to decreased damping of sound secondary to dysfunction of the stapedius muscle. However, most investigators have not found reduced contralateral stapedius reflex thresholds, suggesting that an absence of stapedial damping is not the cause.[55]

On the basis of these observations, many investigators have concluded that the auditory dysfunction results from CNS involvement.[53] A few patients with Bell's palsy have auditory brainstem response (ABR) abnormalities compared with ABRs in age-matched control subjects. These abnormalities include an increase in the wave I to V interval and

the interaural difference for wave V. These changes usually are present bilaterally and resolve with recovery from the facial paralysis.[55] These findings suggested a brainstem abnormality associated with Bell's palsy that the study authors hypothesized is related to the reactivation of HSV. These findings should be interpreted with caution. Other investigators did not confirm the presence of such ABR abnormalities,[56,57] and the findings have not been corroborated by somatosensory evoked potentials or visual evoked potentials.

Several investigators have looked for CNS changes in acute facial paralysis by studying the cerebrospinal fluid (CSF). Again the results are contradictory. Findings of elevated levels of myelin basic protein[58] and pleocytosis[59] in the CSF support CNS involvement in Bell's palsy. Weber and coworkers[60] found a normal total cell count, total protein concentration, blood-CSF permeability, and CSF–to–serum immunoglobulin ratios in most patients with Bell's palsy. Only approximately 10% of these patients demonstrated some pathologic feature of the CSF, including a mild increase in blood-CSF permeability or pleocytosis. These workers concluded that their findings did not support the hypothesis that Bell's palsy was a part of a cranial polyneuropathy.

CNS changes in Bell's palsy also have been suggested by magnetic resonance imaging (MRI). Jonsson and associates[61] found brain or brainstem changes in 5 of 19 patients with Bell's palsy. These areas of increased signal intensity did not correlate with the facial nerve brainstem nucleus or the supranuclear pathways and were interpreted as indicative of unrelated vascular disease.

Electrophysiology and Testing

The multiple branches from the facial nerve, including the greater petrosal nerve, stapedial nerve, chorda tympani, and muscular branches, led to the development of topodiagnostic testing to localize the site of a facial nerve lesion. Schirmer's test evaluates greater petrosal nerve function by measuring the lacrimal secretions accumulating on a piece of filter paper placed under the eyelid at the medial canthus.[62] Stapedial nerve function can be evaluated with stapedial reflex testing. The chorda tympani nerve can be evaluated with taste testing or with the submandibular salivary flow test described by Magielski and Blatt.[63] Unfortunately, the accuracy of localization with topodiagnostic testing has been disappointing.[42] This is not a surprising finding in Bell's palsy, in which the lesion is a diffuse demyelination throughout the nerve. However, topodiagnostic testing also has yielded disappointing results in investigation of tumors in which a sharply defined site of lesion was expected.[64]

Electrodiagnostic tests on the motor branches of the facial nerve also have been used to assess function and predict outcome. All of these tests have a similar shortcoming: Stimulation and recording are performed only distal to the lesion, rather than on opposite sides of the site of injury.[65] Accordingly, such testing should be delayed because it will not demonstrate abnormalities until nerve degeneration has reached the site of stimulation, usually 4 to 5 days after injury.

Nerve Excitability Threshold

The use of electricity as a neurodiagnostic test was described by Duchenne in 1892 and was adapted to the facial nerve by Laumans and Jongkees.[66] Application of the Hilger nerve stimulator is the method of facial nerve evaluation most commonly used by otolaryngologists. The extratemporal portion of the nerve is stimulated with a small-amplitude, pulsed direct current. The face is observed for the lowest current to produce a visible twitch. Although a threshold difference of more than 3.5 mA between the two sides has been considered to be suggestive of nerve degeneration, Gates[67] found that with careful technique, low thresholds were obtained with percutaneous stimulation. The thresholds increased slowly with age and body weight, but nerve excitability thresholds greater than 1.25 mA in the upper division and 2 mA in the lower division were statistically abnormal.

Maximal Stimulation Test

A modification of the minimal excitability test, the maximal stimulation test, attempted to determine the difference between the strength and amount of contraction of the facial musculature caused by a supramaximal electrical stimulus.[68,69] However, the maximal stimulation test is difficult to quantitate and is more subject to interobserver variation than is the minimal stimulation test.[65]

Electroneurography

Electroneurography (ENoG), also called electroneuronography, adds recording of the facial muscle action potential with surface or needle electrodes to the stimulation tests. Esslen[70] introduced the use of bipolar surface electrodes for stimulation and recording of responses. The two electrodes are moved independently to produce the maximum amplitude of response. The response is evaluated by comparing the peak-to-peak amplitude of the maximum response obtained for the two sides of the face.

Electromyography

Electromyography (EMG) measures muscle action potentials generated by spontaneous and voluntary activity. It is distinct from other electrodiagnostic tests in which the activity is generated by active stimulation of the nerve. Denervation potentials are seen 10 days or longer after onset of the palsy; therefore, they are of limited value in determining early prognosis of facial paralysis. However, the loss of voluntary motor unit potentials within the first 3 to 4 days of paralysis suggests a poor prognosis.[65] Conversely, retention of voluntary motor activity past the 7th day suggests that complete degeneration will not occur. Sittel and Stennert[71] found that the detection of spontaneous fibrillation by needle EMG had an 80% accuracy in predicting a poor outcome 10 to 14 days after onset of paralysis. Unfortunately, this is too late to be useful in surgical decision making.

Nerve Conduction Velocity

Nerve conduction velocity can be measured between the stylomastoid foramen and the mandibular branch of the facial nerve. A strong correlation has been found between decrease in nerve conduction velocity and decrease in the compound nerve action potential measured by ENoG during the first 2 weeks after the onset of paralysis.[72] Normal facial nerve conduction velocity ranges between 37 and 58 meters/second, and conduction velocities in this range were associated with uniformly good outcomes. Conduction velocities between 20 and 30 meters/second carry a 50% chance of significant residual paresis or synkinesis, and those less than 10 meters/second were associated with poor outcomes.

Interpretation of Electrical Tests

All electrical stimulation tests have the same fundamental weakness: inferences are made on the basis of tests on the nerve distal to the site of injury within the temporal bone. Therefore, there is an inherent delay between the onset of the injury and the development of sufficient degeneration of the distal segment of the nerve to be discovered by the tests. Only intraoperative monitoring, with stimulation proximal to the lesion, provides direct information about the state of the nerve at the site of the lesion. Newer experimental techniques, including antidromic stimulation and magnetic stimulation, hold some promise for circumventing this limitation.

Excellent recovery of facial function is invariable when the decline in the compound action potential (CAP) as measured by ENoG does not reach 90%, and one half of patients in whom this level of degeneration is documented also have excellent outcomes.[73,74] The problem is how to identify patients who will not achieve a good recovery, and at least a partial answer lies in the combination of ENoG with standard EMG. For patients who maintain recordable voluntary motor potentials despite a severe depression of the CAP, the prognosis is excellent.[74] This finding may be explained by severe desynchronization of the motor units, causing a reduced or absent CAP.

Electromagnetic Stimulation of the Facial Nerve

Facial nerve testing with electromagnetic stimulation also has been explored. Benecke and colleagues[75] were able to stimulate the nerve with cortical (supranuclear) electromagnetic discharges, demonstrating that the nerve could be stimulated trans-synaptically. Direct stimulation of the facial nerve with electromagnetic stimulation also has been described. On the basis of latencies of compound muscle action

potentials from magnetic and electrical stimulation of the facial nerve, investigators concluded that the root entry zone of the facial nerve was the most likely site of excitation with magnetic stimulation.[76] These data are tantalizing because the ideal test of the facial nerve would stimulate the nerve medial to the presumed site of the conduction block in the labyrinthine segment. Meyer and coworkers[77] found an absence of electromagnetic responses to be the earliest sign of nerve conduction block in patients with Bell's palsy, and that electromagnetic stimulation could differentiate between central and peripheral nerve lesions.

It is not yet clear, however, whether magnetic stimulation will be a useful predictive test, because significant discrepancies have been noted between the response to magnetic stimulation and clinical findings. Patients with incomplete palsies may exhibit complete loss of response to magnetic stimulation.[78] Loss of response to electromagnetic stimulation occurs in more patients with Bell's palsy than does loss of electrical stimulation, and this finding may persist after facial function has clinically recovered.[75,79] Nowak and associates[80] tested 65 patients with facial paralysis with both transcranial magnetic stimulation and electrical stimulation of the facial nerve. A severe reduction in muscle action potiental response was observed in both Bell's palsy and herpes zoster and did not correlate with the clinical grade of the palsy. On the basis of current clinical information, electrical stimulation seems to add little to the diagnostic armamentarium in facial palsy.

Imaging of the Facial Nerve

Gadolinium-enhanced MRI has been used to study the peripheral facial nerve in Bell's palsy. Enhancement of the facial nerve is a common finding in healthy persons, making evaluation of facial nerve findings on MRI difficult. The most consistent area of enhancement in Bell's palsy and herpetic palsy is the distal meatal and labyrinthine segments.[81,82] Sartoretti-Schefer and associates[82] hypothesized that the gadolinium enhancement resulted from breakdown of the blood-brain barrier or from venous congestion in the epineurium. However, the location or degree of enhancement does not correlate with the recovery of facial movement.[81,83] In a recent report that used high-resolution gadolinium-enhanced MRI with surface coils, Kress and colleagues[84] were able to differentiate 3 patients with poor outcomes from 17 who recovered on the basis of the wide distribution and intensity of enhancement. The development of more detailed MRI techniques may prove useful in determining the prognosis of Bell's palsy.[85]

Prognosis and Statistics

The prognosis for most patients with Bell's palsy is excellent: 80% to 90% recover completely.[6,53] Peitersen[7] reported that none of 1505 patients followed without management had permanent complete paralysis, and that 17 had moderate to severe sequelae (contracture, synkinesis, palsy). Many large series of patients with Bell's palsy have been analyzed to identify prognostic factors that have a significant impact on outcome. The most important such factor is whether the paralysis is incomplete or complete. The prognosis for affected persons in whom complete facial paralysis never develops is excellent: 95% to 100% recover with no identifiable sequelae.[6,86]

The many reports available in the literature are difficult to compare, because they use different criteria for inclusion and evaluation of outcome. Stankiewicz[87] collated the outcomes from nine reports, including the large series of Park and Watkins[88] and Peitersen.[89] The overall results from these series were 53% complete recovery, 44% partial recovery, and only 3% no recovery. The results in the general population probably are better than those in these studies.

Other factors associated with poor outcome include hyperacusis; decreased tearing; age older than 60 years; diabetes mellitus; hypertension; and severe aural, anterior facial, or radicular pain.[4,90] Abraham-Inpijn and associates,[91] however, compared outcomes in 200 patients by use of several potential prognostic factors, including severity of the facial paralysis, mean arterial pressure, age, clinical or chemical diabetes mellitus, and history of hypertension. Only the severity of the paralysis at its maximum extent and the mean arterial pressure at presentation proved to be statistically significant. Peitersen[7] noted a correlation between sequelae (synkinesis, contracture) and the interval between paralysis and the onset of recovery.

Management

Management of Bell's palsy has had a long, complex evolution that is not yet complete. Methods currently advocated include observation, corticosteroids, surgical decompression, and antiviral agents.

The use of corticosteroids in Bell's palsy was first proposed by Rothendler.[92] Since then, corticosteroid therapy has become the most common approach to management of Bell's palsy.[93] Adour and Wingerd[94,95] stated that although prednisone does not reduce the number of patients with eventual partial denervation or contracture or synkinesis, it reduces the number of patients with eventual complete denervation, therefore making the disease less severe. Numerous prospective and retrospective studies on the effectiveness of corticosteroids in Bell's palsy have been reported. In a meta-analysis, Ramsey and colleagues[96] found two studies with sufficient numbers of patients and rigor for analysis and concluded that treated patients had a 17% better chance of complete recovery than placebo-managed or untreated patients. Their analysis of a larger number of studies concluded that the odds of recovery with steroid treatment ranged between 49% and 97%, versus 23% and 64% for untreated patients. Consensus is lacking regarding the dose or duration of steroid treatment.

The case for steroid treatment in children in less clear. Neither Prescott[97] nor Unüvar and coworkers[98] found a beneficial effect of corticosteroids for Bell's palsy in children. Salman and MacGregor[99] came to the same conclusion in their systematic review of the literature.

Patients with Bell's palsy commonly are treated with antiviral agents in addition to prednisone,[100] although once again, definitive proof of efficacy is lacking. Although initial enthusiasm was high for the use of a combination of steroids and antivirals[101,102] more recent studies have yielded negative results. Sullivan and colleagues[103] conducted a four-armed, multi-institutional trial of prednisolone, acyclovir, a combined regimen of both agents, and placebo. Significant improvement in outcome was observed in both arms containing prednisolone, but no additional benefit from antiviral treatment was found. A similar outcome was described in a study reported from Japan.[104] Current opinion does not support the use of antivirals in Bell's palsy.

Surgical therapy is more controversial, because unlike with corticosteroids, it is associated with the possibility of significant additional injury. Early enthusiasm for transmastoid decompression of the tympanic and mastoid segments of the facial nerve has waned,[105] and the procedure has been abandoned,[1] because randomized trials showed no benefit[1] and because of evidence that the site of the lesion is in the proximal labyrinthine portion of the facial nerve, which is inaccessible through the mastoid.[38]

The efficacy of surgical decompression of the meatal foramen and labyrinthine segment of the facial nerve in patients with poor prognosis as shown by ENoG testing is promising, but it has been difficult to assemble a large enough series to definitively establish its value in randomized trials. Fisch[38] compared outcomes in 14 surgical patients with 90% degeneration or greater as shown by ENoG within 3 weeks of the onset of paralysis with those in 13 similar patients who refused surgery. He found a subtle but statistically significant improvement in the long-term facial recovery in the operative group. Sillman[74] found a shift toward grade I and II recovery in patients with greater than 90% degeneration who underwent surgical decompression versus those managed with corticosteroids alone. In the most well-controlled study of middle fossa decompression of the facial nerve in Bell's palsy, Gantz and colleagues[106] evaluated the outcome when ENoG showed greater than 90% degeneration, and no voluntary motor unit potentials were found on electromyography performed within 2 weeks of onset of paralysis. Ninety-one percent of surgical patients achieved House-Brackmann grade I or II recovery, versus a 42% chance of these same results with steroids alone. Graham and Kartush[107] described six patients with recurrent facial paralysis, one of whom had Melkersson-Rosenthal syndrome. None of these patients experienced recurrent facial paralysis after total seventh nerve decompression from the stylomastoid foramen to the internal auditory canal. Thus, surgical decompression remains in the armamentarium for the management of facial paralysis, but timing and appropriate patient identification remain difficult.

Persistent synkinesis can be a problem for many patients recovering from severe degeneration of the facial nerve regardless of the cause. Chua and associates[108] performed a dose escalation study of botulinum toxin to determine the best treatment for reducing eyelid synkinesia and found the lowest dose, 40 units injected into the orbicularis oculi, to give the best reduction in synkinesia while avoiding ptosis. Borodic and coworkers[109] reported similar results with botulinum toxin in a multi-institutional study.

Special Cases of Facial Paralysis

Ramsay Hunt Syndrome

Ramsay Hunt syndrome (herpes zoster facial paralysis) differs from Bell's palsy, because it is associated with VZV infection (as shown by rising titers of antibodies to VZV) and the presence of skin vesicles on the pinna, retroauricular area, face, or mouth. Compared with Bell's palsy, Ramsay Hunt syndrome generally causes more severe symptoms, and patients are at higher risk for the development of complete nerve degeneration.[110]

Varicella, or chickenpox, is the manifestation of primary infection by VZV (HSV, varicellae) in a nonimmune host. Herpes zoster is the manifestation of this same virus infection in a partially immune host. Serologic and epidemiologic data strongly suggest that varicella-zoster represents the reactivation of a latent virus rather than reinfection. After the primary infection, the virus probably travels to the dorsal root to extramedullary cranial nerve ganglia, where it remains dormant until it is reactivated. Reactivation generally occurs during a period of decreased cell-mediated immunity. VZV infection is the second most common cause of facial paralysis. The incidence of herpes zoster in patients with peripheral facial palsy is 4.5% to 9%.[111] A Mayo Clinic study[112] estimated the annual incidence of herpes zoster as 130 cases per 100,000. The incidence increased dramatically in patients older than age 60; 10% of this population had identifiable risk factors for decreased cell-mediated immunity, including carcinoma, trauma, radiotherapy, and chemotherapy. The increased incidence in the elderly is explained by an age-related decrease in cellular immune response to VZV.[113]

The severity of the paralysis is worse and the prognosis poorer in herpes zoster oticus than in Bell's palsy. Peitersen[114] reported full recovery in only 22% of patients, and Devriese[115] found complete recovery in only 16%. As in Bell's palsy, the recovery is predicted in part by the severity of the paralysis. Complete recovery occurred in only 10% of patients after complete loss of facial function and in approximately 66% after incomplete loss.[111]

The timing of the appearance of the vestibular eruption may have prognostic significance. In most cases, eruption and paralysis occur simultaneously. In approximately 25% of cases, the eruption precedes the paralysis; these patients have a higher likelihood of recovery.[111] Patients with Ramsay Hunt syndrome also are more likely than patients with Bell's palsy to have associated cranial nerve symptoms, including hyperacusis, hearing loss, and pain.[116] Ramsay Hunt syndrome can be misdiagnosed on the basis of initial presentation. In approximately 10% of patients, the vesicular rash appears well after the initial facial paralysis, and many patients demonstrate a rise in antibody to VZV without ever exhibiting cutaneous or mucous membrane vesicles—so-called Ramsay Hunt sine herpete.

Severe ocular complications can occur with herpes zoster ophthalmicus. These complications include uveitis, keratoconjunctivitis, optic neuritis, and glaucoma and are almost always associated with involvement of the ophthalmic division of the trigeminal nerve. Herpes zoster ophthalmicus may be difficult to differentiate from the localized skin rash associated with HSV infection. Although both conditions may cause keratitis, differentiation between them is extremely important, because topical corticosteroids are used to manage herpes zoster but are contraindicated in HSV infection. Ophthalmologic consultation for biomicroscopy, staining, cytologic studies, and viral isolation studies may differentiate these two conditions.[117] Adour[94] stated that aside from concerns about ophthalmic involvement, the development of skin vesicles before or after initiation of prednisone does not contraindicate corticosteroid use.

Management of patients with herpes zoster, including cephalic zoster, consists of systemic corticosteroids.[118] A specific benefit of corticosteroid therapy is a reduction in postherpetic neuralgia. The usefulness of corticosteroids in fostering recovery from the facial paralysis is controversial; however, early institution of corticosteroids seems to relieve acute pain, reduce vertigo, and decrease the incidence of postherpetic neuralgia.[119,120]

The antiviral agent acyclovir also is recommended to treat herpes zoster facial paralysis.[121,122] Acyclovir is a nucleotide analog that interferes with herpes virus DNA polymerase and inhibits DNA replication. The drug is preferentially taken up by HSV-infected cells, making it nearly nontoxic to noninfected cells. Early return of facial function after acyclovir management has been reported by some investigators,[121,122] but no beneficial effects were reported by others.[123] At the least, treatment with acyclovir seems to lessen pain and promote resolution of the vesicles.

Box 170-1

Congenital versus Acquired Facial Paralysis

Congenital

Mononeural agenesis
Congenital facial paralysis
Congenital unilateral lower lip palsy
Facial paralysis with other deficits
Möbius syndrome (cranial nerves VI, VII; bilateral)
Hemifacial microsomia
Oculoauriculovertebral dysplasia
Poland's syndrome (agenesis of pectoralis major muscle)
Secondary to teratogens
Thalidomide
Rubella

Acquired

Birth trauma
Forceps injury
Pressure from maternal sacrum
Pressure from fetal shoulder
Intracranial hemorrhage
Idiopathic
Bell's palsy
Systemic or infectious disease
Melkersson-Rosenthal syndrome
Poliomyelitis
Infectious mononucleosis
Varicella
Acute otitis media
Meningitis

Modified from Harris JP, Davidson TM, May M, Fria T: Evaluation and treatment of congenital facial paralysis. *Arch Otolaryngol*. 1983;109:145.

Congenital Facial Paralysis

The incidence of facial paralysis in newborns has been estimated at 0.23% of live births.[124] The first dilemma in managing facial palsy in an infant or young child lies in differentiating true congenital paralysis from birth trauma. The differential diagnosis of congenital facial palsy is shown in Box 170-1. Birth trauma usually causes isolated facial paralysis and other signs of injury, including facial swelling, ecchymosis, and hemotympanum. Abnormalities of other cranial nerves or abnormalities on brainstem audiometry (prolongation of the I to III or I to V interval) suggest that the facial paralysis is congenital and not traumatic.[125]

Of facial paralysis cases in infants, 78% are related to birth trauma. These cases are equally divided between forceps deliveries and vaginal deliveries plus cesarean sections,[126,127] suggesting that intrauterine facial nerve injury can occur from pressure on the infant's face by the sacral

prominence during birth. Supranuclear palsy secondary to intracranial hemorrhage also has been reported.[128]

The mildest form of congenital facial dysfunction is congenital unilateral lower lip palsy, in which the defect is limited to an absence of depressor labii inferioris muscle activity. It is associated with a lesion of the brainstem.[129]

Möbius' syndrome represents a broad spectrum of clinical and pathologic findings ranging from isolated unilateral facial paralysis (usually associated with sixth cranial nerve paralysis) to bilateral absence of facial and abducens nerve function. Multiple other cranial nerves, including the glossopharyngeal, vagus, hypoglossal, and other extraocular motor nerves, also may be affected.[129a] Forty-three percent of children with Möbius syndrome have a history of some significant event in utero.[130] A majority of patients with Möbius' syndrome demonstrate sparing of the lower face compared with the upper face. Verzijl and coworkers[131] performed electrophysiologic testing on 11 patients with Möbius syndrome and concluded that Möbius syndrome is not a primary developmental disorder of the facial musculature but is a disorder of the rhombencephalon including both motor nuclei and transversing long tracts. MRI evidence suggests evidence of absence of the seventh cranial nerve in the internal auditory canal, implying the lower face receives aberrant innervation from other nerves, including the trigeminal, glossopharyngeal, and hypoglossal nerves.

Multiple cranial nerve palsies including facial palsy are seen in the CHARGE association (*c*olobomata, *h*eart disease, *a*tresia of choanae, *r*etarded growth, *g*enital hypoplasia, *e*ar anomalies and deafness). Of CHARGE-associated cases, 75% have at least one cranial nerve involved, and 58% have two or more cranial nerves involved. The most frequently involved are the auditory nerve in 60%, the facial nerve in 43%, and the glossopharyngeal or vagus nerve in 30%.[132]

Habilitation of the face in congenital facial paralysis usually is accomplished with temporalis muscle transfer, tarsorrhaphy, upper eyelid gold weights, and free muscle transfers. Surgical exploration and decompression of the facial nerve are rarely useful.[133]

Spontaneous Facial Paralysis in Children

Bell's palsy is uncommon in children; 8% of patients in the series by Peitersen[89] and only 2% in the series by Adour and coworkers[4] were younger than 10 years of age. Manning and Adour[134] and Prescott[97] found a female preponderance in this group.

The prognosis for children with Bell's palsy is uncertain. Peitersen,[89] Taverner,[2] and Prescott[97] reported a high rate of spontaneous recovery in children with Bell's palsy, in part related to the high frequency of incomplete paralysis. Inamura and colleagues[135] found that 97% of 58 cases recovered completely and concluded that corticosteroids had no impact on recovery. However, Alberti and Biagioni[136] and Manning and Adour[134] reported that a significant percentage of children did not recover from their facial paralysis. Jenkins and colleagues[40] and Prescott[97] argued that the prognosis was determined by the amount of nerve degeneration revealed by electrophysiologic testing and noted that children and adults with similar electrical testing results had similar outcomes.

Familial Facial Paralysis

Adour and associates[4] reported that 8% of patients with Bell's palsy had a positive family history, and Willbrand and associates[137] reported a 6% incidence. In addition, sporadic reports describe families with several affected members, usually each experiencing several attacks. Cawthorne and Haynes[138] reported the cases of two brothers, one of whom had experienced five episodes of Bell's palsy and the other, three episodes. DeSanto and Schubert[139] reported 10 cases of Bell's palsy in a family over 83 years; Wilbrand and associates[137] reported a family with 29 cases of Bell's palsy over 40 years. Samuel[140] reported a child who experienced four episodes of Bell's palsy involving both sides of the face; the child's father had six episodes of unilateral Bell's palsy. Amit[141] described a family tree in which only women (the index patient and her mother, maternal aunt, and maternal grandmother) had Bell's palsy. In three of the four, onset was during puberty, suggesting that hormonal influence may have been important. The evidence from these sporadic cases is insufficient to determine conclusively a genetic influence. In such cases, however, the paralysis often has an early age at onset and is recurrent, and the prognosis is excellent.

Recurrent Paralysis

Adour and coworkers[4] found that 9.3% of patients with Bell's palsy had a history of previous paralysis. Similarly, Hallmo and colleagues[142] reported that 10.9% of patients had a history of a previous facial paralysis (approximately equally on the ipsilateral and contralateral sides). Prescott[97] reported that 20 of 228 children (9%) with Bell's palsy who were younger than 18 years had a history of previous paralysis on the same side, and 8 had contralateral paralysis. The interval between the two attacks usually was longer than 1 year.[143] Perhaps the record for recurrent facial paralysis was set by a woman who experienced more than 50 episodes of unilateral lower facial paralysis after exposure to the disinfectant chlorocresol.[144] The age distribution for patients with recurrent facial palsy was the same as that for the overall population with Bell's palsy,[4] except for those with ipsilateral recurrent palsies, which may be associated with a younger age at onset.[143] Several reports noted a slight female predominance in recurrent facial palsy.[143,145] Diabetes mellitus was present in 39% of patients with recurrent paralysis in one study[4] but only in 4% in another.[142]

Controversy continues regarding whether the prognosis for recovery from recurrent facial palsy is better or worse on subsequent attacks. Some investigators state that the second attack is associated with a poorer prognosis and therefore constitutes a stronger indication for surgical decompression.[146] Most other workers, however, found no prognostic difference between the primary and subsequent attacks of facial paralysis and no difference whether the second attack occurred on the ipsilateral or contralateral side.[142]

Recurrence of facial palsy should prompt a careful investigation for other etiologic disorders. May and associates[1] found a tumor in 8 of 40 of patients (20%) with a second palsy on the same side.

Bilateral Facial Paralysis

Bilateral idiopathic facial paralysis is much less common than unilateral paralysis and occurs in only 0.3% to 2% of patients.[147] Bilateral facial paralysis is associated with a much higher incidence of systemic causes than unilateral palsy and should spur a diligent search for an underlying disorder.[148] The diseases most commonly associated with bilateral facial paralysis are Guillain-Barré syndrome, Bell's palsy, multiple idiopathic cranial neuropathies, brainstem encephalitis, benign intracranial hypertension, syphilis, leukemia, sarcoidosis, Lyme disease, and bacterial meningitis.[149,150] The possibility of an intrapontine or prepontine tumor also should be excluded.[150] Most of these conditions are associated with other systemic or neurologic signs that suggest the appropriate diagnosis.

Guillain-Barré syndrome is a progressive ascending motor paralysis, occurring after a viral infection, that usually affects the lower limbs. However, rare bulbar, myelitic, and cerebral forms of Guillain-Barré do not affect the limbs. Of the cranial nerves, the facial nerve is the third most commonly affected, after the glossopharyngeal and vagus.[151] The diagnosis is based on the typical clinical picture and the presence of elevated CSF protein but a normal cell count. Other conditions associated with facial diplegia include influenza,[152] infectious mononucleosis,[153] other viral infections,[154] and diabetes.[155] Heerfordt's syndrome (parotid enlargement, iridocyclitis, and cranial nerve palsy) associated with sarcoidosis also can cause bilateral facial paralysis.

The workup for a patient with bilateral facial paralysis should include a careful neurologic examination to detect other cranial neuropathies, a lumbar puncture to obtain CSF for cytologic studies, chemistry, culture, a Venereal Disease Research Laboratory (VDRL) test for syphilis. An MRI scan should exclude space-occupying lesions.[156]

The disability caused by bilateral facial paralysis is dramatically more severe than that from unilateral paralysis. Aggressive eye care with ointment, taping, or patching usually is required, but this approach significantly interferes with visual function. Bilateral paralysis of the lower lip leads to a characteristic speech impairment, oral incompetence, and drooling. In severe cases, inadequate circulation of saliva may have dental sequelae.[157] The psychologic impact can be devastating, because these patients are incapable of voluntary or emotional expres-

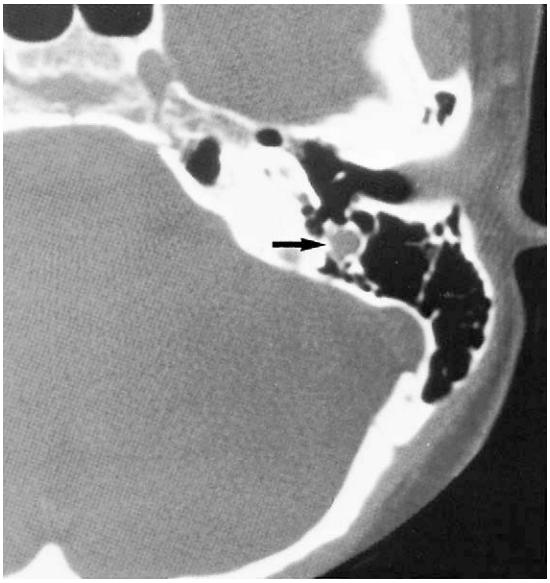

Figure 170-2. Axial CT scan of the right temporal bone shows enlargement of the mastoid segment of the fallopian canal *(arrow)* in the child with progressive facial paralysis. The lesion was a neuroma of the facial nerve.

sion.[158] Recovery in bilateral Bell's palsy is similar to that in unilateral palsy, although one side may recover before the other.[159]

Progressive Paralysis

Slowly progressive facial paralysis is not Bell's palsy. The differential diagnosis includes primary neuromas of the facial nerve (Fig. 170-2); metastases from squamous cell carcinomas and melanomas of the face and scalp; and occasionally distant metastases from kidney, breast, lung, and prostate.[160] Progressive facial paralysis also can occur from other primary temporal bone and cerebellopontine angle lesions and from carotid artery aneurysms.[161] A tumor should be excluded in all of these cases; the investigation should begin with physical examination for neuroma of the peripheral branches of the facial nerve and continue with computed tomography (CT) and gadolinium-enhanced MRI of the infratemporal and intracranial portions of the nerve. If results of these studies are negative, some authorities argue for exploration of the nerve from the peripheral branches through the temporal bone.[162] At the very least, patients with negative findings on initial evaluation require careful serial observation and imaging.

Traumatic Facial Paralysis

The most common causes of infratemporal facial nerve injury are temporal bone fracture, penetrating injuries (typically from a bullet), and iatrogenic injuries.

Injury of the facial nerve in temporal bone fractures can result from compression from bone fragments, intraneural hematomas, entrapment from compression, and loss of continuity. The distal labyrinthine segment and geniculate ganglion are the areas of the facial nerve most susceptible to injury in longitudinal and transverse temporal bone fractures[163] (Fig. 170-3). This portion of the facial nerve is particularly at risk because of its small size and lack of fibrous supporting tissue, and because of traction between the greater petrosal nerve and the geniculate ganglion caused by temporary distraction of the anterior and posterior portions of the temporal bone at the time of the injury.[163] Grobman and colleagues[164] presented a case that featured severe compression, demyelination, and edema of the facial nerve proximal to the site of the injury, with the most severe changes at the meatal foramen, in addition to direct injury to the nerve. These investigators pointed out that histologic changes in the facial nerve were similar to those in Bell's palsy, despite the fact that the initial insult to the nerve was different. High-resolution CT of the temporal bone is the most effective way to identify potential sites of injury of the facial nerve (Fig. 170-4).

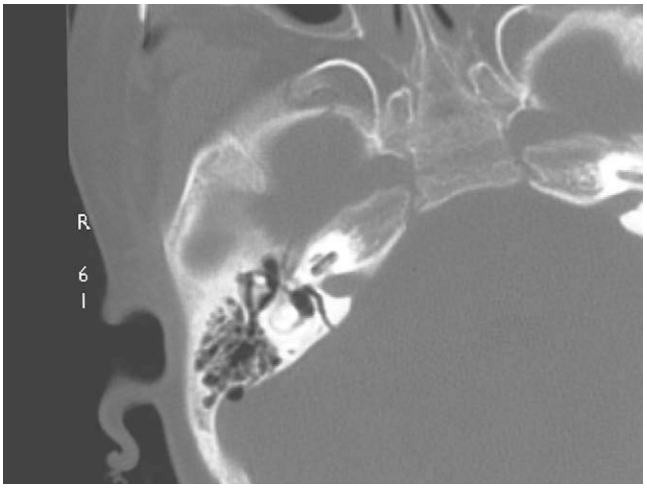

Figure 170-3. An axial CT scan of the temporal bone showing a transverse fracture of the temporal bone through the vestibule and geniculate ganglion.

Figure 170-4. A coronal CT scan of the temporal bone showing a transverse fracture of the temporal bone through the cochlea and traversing the fallopian canal in the tympanic portion of the facial nerve.

Management of facial nerve injury in temporal bone fractures has been controversial. Some authorities recommend observation and symptomatic care only. Maiman and associates[165] followed 45 patients nonoperatively. Twenty-nine had injuries severe enough to be visible on polytomography. Of the 45, 44 achieved satisfactory recovery, and 65% had complete recovery. McKennan and Chole[166] reported excellent recovery in patients with delayed-onset paralysis managed nonsurgically.

In decisions about surgical decompression in specific cases, such cases traditionally have been divided into those with immediate onset and those with delayed onset after the injury; immediate-onset paralysis is associated with severe injuries and poorer outcomes.[166] Conversely, Adegbite and coworkers[167] found the outcome was predicted by the severity of the paralysis but not the time of onset. Fisch,[73] however, advocated surgical intervention on the basis of ENoG results rather than time of onset of the paralysis. He established a criterion of greater than 90% degeneration within 6 days of onset. The timing of surgery, however, does not have to be within 6 days; in fact, some advantage may lie in delaying surgery up to 3 weeks after an immediate paralysis,

to allow resolution of edema and hematoma and to make the surgical field more discernible.[39] Chang and Cass[168] carefully reviewed the literature on surgical versus expectant management of facial paralysis after temporal bone fracture and concluded that the natural history, the appropriate timing, or reporting criteria exist to judge the true efficacy of facial nerve decompression in nonpenetrating injury of the temporal bone.

Long-standing paralysis also is a management problem, because electrical testing is not valid. In such cases, unless CT shows gross disruption of the fallopian canal, it is advisable to wait 12 months and then explore the nerve if clinical or EMG signs of recovery do not appear.

Penetrating injuries (gunshot wounds) often are accompanied by severe injuries, including dural tears, CSF otorrhea, damage of the otic capsule, and vascular injury. Evaluation includes high-resolution CT, carotid arteriography, and facial nerve electrical testing. Telischi and Patete[169] emphasize that extratemporal facial nerve blast injuries may not cause transection of the facial nerve; these workers recommend continued conservative management even if the nerve is severely hemorrhagic and contused.

Iatrogenic facial paralysis is a feared complication of ear surgery. For optimal management, the cases can be divided into those in which the integrity of the facial nerve was a concern intraoperatively and those in which the paralysis was unexpected. In the former group, the nerve should be positively identified by use of landmarks distant from the site of presumed injury. The nerve is traced to the site of injury, the local area decompressed, and disrupted nerve fibers reapposed. If loss of nerve tissue is serious, an onlay or interpositional facial graft can be used. If the landmarks are not discernible, the dissection should be terminated before further injury occurs and an appropriate colleague consulted. In the emotionally and medicolegally charged realm of iatrogenic injury, consultation is often beneficial to all involved. If the facial paralysis is unexpected, it is appropriate for the original surgeon to manage the case. Tight dressings and packing should be released immediately and time allowed for any local anesthetic effects to dissipate. If these measures do not result in recovery of function, urgent reexploration and decompression of the nerve should be performed.

Surgical exploration of the facial nerve after trauma requires the surgeon to be familiar with the entire temporal bone and to be prepared for mastoid, translabyrinthine, and middle fossa exploration and repair of the nerve. Caution is necessary for middle fossa exploration in patients with temporal bone trauma. Jones and associates[170] reported that 14 of 15 patients with CT evidence of temporal bone fracture also had MRI evidence of significant ipsilateral temporal lobe contusion.

Facial Paralysis Associated with Other Conditions

Pregnancy

The possible role of hormonal and fluid changes in the pathogenesis of Bell's palsy has been debated since Bell[171] first suggested an association between idiopathic paralysis and pregnancy in 1830. Bell's palsy is 3.3 times more frequent among pregnant women than among similarly aged nonpregnant women[172] and most commonly occurs in the third trimester or immediately post partum.[4,172] Recurrent palsy with repeated pregnancies and bilateral facial palsies during pregnancy also have been reported.[173]

In a series of 18 patients, Falco and Eriksson[174] reported that preeclampsia was six times more common among patients with facial palsy than in the general population of pregnant women. Facial palsy in pregnant women cannot be correlated with preterm labor, low birth weight, fetal congenital abnormality, or other perinatal abnormality. The prognosis and outcome compared with those in age-matched nonpregnant women are uncertain; some studies indicate no difference,[175] whereas others suggest decidedly worse results.[176] Gillman and coworkers[176] compared 77 women in whom Bell's palsy developed during pregnancy, or immediately post partum, with age-matched nonpregnant women and age-matched men. The pregnant patients had a statistically significant poorer result than either of the comparison groups.[176] Treatment with prednisone is the mainstay of management for the pregnant woman with Bell's palsy, although no significant difference in outcome with or without steroids was found in this study. Prednisone apparently poses minimal risk to the developing fetus, especially in the third trimester.[177]

Melkersson-Rosenthal Syndrome

Melkersson-Rosenthal syndrome consists of a triad of symptoms: recurrent orofacial edema, recurrent facial palsy, and lingua plicata (fissured tongue). The orofacial edema is the defining feature; lingua plicata and peripheral facial paralysis each occur in one half of the patients. The complete triad is present only in one fourth of the patients. Onset of the condition generally is in the second decade of life, and the manifestations usually occur sequentially and seldom appear simultaneously.

The major diagnostic criterion is persistent or recurring nonpitting facial edema that cannot be explained by infection, malignancy, or connective tissue disorder. The oral swelling usually involves the lips and buccal area, but the gingiva, palate, and tongue also can be affected. The swelling can extend to the supraorbital and infraorbital tissues of the cheek.[178] The edematous lips assume a chapped, fissured, red-brown appearance. The swelling usually is transient but may recur at regular intervals.

After numerous recurrences, the lips eventually become permanently deformed. They also may have chronic fissuring that is slow to heal and painful.[179] The extent of the facial swelling varies, ranging from unilateral involvement of the lower lip to bilateral total facial edema.[179] Chronic swelling constitutes a cosmetic problem and may interfere with speaking and eating. The chronic and recurrent nature of the edema distinguishes it from transient angioneurotic edema. Biopsy specimens of the lip reveal noncaseating epithelioid cell granulomas surrounded by histocytes, plasma cells, and lymphocytes.[179] The cause of Melkersson-Rosenthal syndrome is unknown. Some authorities consider it to be a variant of sarcoidosis, but others dispute this theory. Some experts suggest that it is a primary vasomotor disturbance,[180] whereas others suggest it has an allergic cause. Elevation of angiotensin-converting enzyme (ACE), seen in sarcoidosis and some other diseases, has been reported in some cases.[181]

Facial paralysis occurs in 50% to 90% of patients with Melkersson-Rosenthal syndrome, and it has an abrupt onset that is identical to that in Bell's palsy.[182] A history of bilateral sequential paralysis and relapse of paralysis after initial recovery is common. The site of the paralysis usually corresponds with the area of facial swelling.[179] Symptomatic management of the facial paralysis is indicated. No randomized trials of corticosteroids or surgery have been conducted, although cessation of the recurrent facial paralyses has been reported in several series after facial nerve decompression.[107,183]

Human Immunodeficiency Virus Infection

Acute facial palsy can occur at any stage of human immunodeficiency virus (HIV) infection. The palsy can be a direct result of or secondary to HIV disease (e.g., resulting from a secondary infection by herpes zoster virus). Most cases of facial palsy in patients with early-stage HIV infection resemble Bell's palsy in that (1) they have an abrupt onset and (2) no other cause is identifiable. These patients also are at risk for a craniocervical form of Guillain-Barré syndrome.

HIV is neurotropic and has been isolated from the CSF and neural tissues in all stages of HIV infection.[184] Acute facial palsy in acute and chronic HIV infection may result from invasion of the facial nerve or the facial ganglion by the virus.[185] Alternately, it has been suggested that acute facial palsy may be part of an acute inflammatory demyelinating polyneuropathy that occurs in other nerves in early stages of HIV.[186,187]

In later stages of HIV infection, facial nerve involvement may be related to the immunodeficiency, resulting in cephalic herpes zoster or systemic lymphoma. In addition, the facial nerve may be involved along with other nerves in a chronic peripheral polyneuropathy.[188]

The prognosis for idiopathic paralysis in patients with acquired immunodeficiency syndrome (AIDS) is similar to that in the general population.[189] The prognosis for facial paralysis from other causes in patients with AIDS depends on the underlying pathologic process.

Lyme Disease

Lyme disease (Bannwarth's syndrome in Europe) is caused by the tickborne spirochete *Borrelia burgdorferi*. The vectors for Lyme disease are several species of *Ixodes* ticks. The primary reservoirs of infection are the white-footed mouse and the white-tailed deer. The disease occurs in all parts of the United States.

Like syphilis, Lyme disease occurs in several stages. It begins with erythema migrans, an influenza-like illness, regional lymphadenopathy, and general malaise. The erythema migrans is an enlarging, annular, erythematous skin lesion, which may be multiple and is not limited to the site of the bite.[190] The second stage starts several weeks to months later when neurologic abnormalities develop, including meningitis, cranial nerve neuropathies, and other peripheral neuropathies. Early symptoms include headache, neck stiffness, and spinal pain. Stage three occurs months to years later with manifestations of chronic arthritis, neurologic deficits, recurrent meningitis, and subtle mental disorders.[191] Chronic neurologic complications occur in 18% of patients with untreated Lyme disease.[192]

Moscatello and coworkers[193] reviewed the head and neck symptoms in a large series of patients with Lyme disease. Headache, neck pain, and dizziness were the most common head and neck complaints. Facial paresis occurred in 4.5% of patients, may be unilateral or bilateral, and may be the sole neurologic abnormality. Halpern and Golightly[194] emphasized that the facial paralysis may precede serologic evidence of infection, and that facial paralysis may occur in the absence of either erythema migrans or identified tick bite.

Lyme disease is recognized as an increasingly important cause of facial paralysis, especially in children. In endemic areas, Lyme disease is responsible for one half of the cases of facial paralysis seen in children.[195] Facial weakness or paralysis usually resolves completely, although mild or, rarely, severe residual facial weakness has been described.[196] Reik and associates[197] reported the development of facial palsy in 6 of 18 patients with neurologic complications; 3 of these patints had residual weakness after 5 months. Puhakka and colleagues[198] found no difference in facial recovery between borreliosis and VZV infection.

The diagnosis of Lyme disease can be difficult.[199] Only 30% of patients have a recognized tick bite, and an erythema migrans rash fails to develop in 50%. Specific antibody tests may not yield a positive result for several weeks. MRI in children with neurologic symptoms may show hyperintense signal on T2-weighted images of the brain[200] and may be the best modality for following the effect of antibiotic therapy.[201]

Treatment of Lyme disease with neurologic symptoms is with ceftriaxone (2 g/day intravenously for 14 days).[201a] Improvement is not expected for several months after therapy, and recovery is seldom complete.[191]

Kawasaki's Disease

Kawasaki's disease, also known as infantile acute febrile mucocutaneous lymph node syndrome, is a multisystem disease occurring primarily in infants and young children. In addition to involvement of the mucous membranes, skin, lymph nodes, and cardiac system (coronary artery aneurysms), neurologic complications have been reported in up to 30% of patients.[202,203] Aseptic meningitis and irritability are the most common neurologic complications; however, facial palsy has been reported by several groups of investigators.[204-206]

In a review of 17 cases of well-documented facial palsy in the literature, Gallagher[204] reported the median age to be 13 months; no patient was older than 25 months. On average, onset of the paralysis occurred on day 16 of illness, and except for patients who died from cardiac complications, the palsy resolved in 1 to 12 weeks. Histologic examination of patients dying of Kawasaki's disease showed changes typical of arteritis,[207] leading Teresawa and associates[203] to conclude that the facial paralysis resulted from ischemia of the nerve. Treatment of Kawasaki's disease includes supportive care, appropriate management of cardiac failure, if present, and high-dose aspirin.

Sarcoid

Sarcoidosis is a chronic noncaseating granulomatous disease. Manifestations of systemic involvement usually include hilar or peripheral adenopathy (the lungs), polyarthralgias, anergy, hepatic dysfunction, and elevated serum calcium. Heerfordt's disease (uveoparotid fever), a variant of sarcoidosis, is characterized by nonsuppurative parotitis, uveitis, mild fever, and cranial nerve paralysis. Although only 5% of patients with sarcoidosis have cranial nerve involvement, the facial nerve is the most commonly affected.[208] By contrast, 50% of patients with uveoparotid fever have facial paralysis. The paralysis starts abruptly days to months after the onset of the parotitis. Paralysis is thought to be caused by direct invasion of the nerve by the granulomatous process[209] and not by pressure from the swollen parotid gland.[210] Sarcoidosis should be included in the differential diagnosis when the paralysis is bilateral.[147]

The diagnosis can be confirmed by an elevated serum ACE level, in contrast with tuberculosis, cancer, and pulmonary fungal diseases, in which ACE levels are low.[211] Sarcoidosis is treated with corticosteroids, after which the ACE levels are expected to return to normal.[212]

Otitis Media

Facial paralysis from otitis media is rare but can occur in acute or chronic cases. In a recent series, otitis media accounted for only 3.1% of acute facial palsies.[213] Of these 50 cases, only 5 were in children with acute otitis media. The remaining adult cases were divided equally between chronic purulent otitis media and cholesteatomas. Three additional cases were from tuberculous otitis.

Most paralyses were incomplete. Nearly all patients explored surgically were found to have a dehiscence of the bony canal of the facial nerve, usually in the tympanic segment, which presumably allowed spread of the inflammation from the middle ear to the nerve.

Facial paralysis associated with acute otitis media, especially in infants and children, should be treated with parenteral antibiotics and a wide myringotomy for drainage. Surgical manipulation of the facial nerve in acute otitis media is not recommended. Adour[94] also recommended the addition of a 10-day course of corticosteroids in conjunction with myringotomy and antibiotics.

Facial paralysis associated with chronic otitis media suggests a high probability of cholesteatoma, and surgical intervention is appropriate. The mechanism of facial paralysis associated with cholesteatoma may be compression or inflammation. Djeric[214] studied autopsy specimens from patients who had chronic otitis media but no antemortem evidence of facial paralysis. Two of 20 facial nerves had focal areas of demyelination, suggesting that adjacent inflammation may be more important than pressure. The most important hallmark of facial paralysis from cholesteatoma is a gradual onset, which distinguishes it from Bell's palsy. Removal of the cholesteatoma and decompression of the nerve without opening the perineurium will allow recovery from the paralysis in most cases.[215]

Barotrauma

Several investigators have described a curious phenomenon of recurrent facial paralysis with changes in barometric pressure. Woodhead[216] reported the case of a 50-year-old man who experienced repeated episodes of facial paralysis and ipsilateral loss of taste on ascending to 8000 to 10,000 feet while driving in mountainous regions or during air travel. His symptoms resolved on descent. Similar cases have been reported after commercial airline flights[217] and after scuba diving.[218,219] A brief facial palsy also has been reported after forceful nose blowing.[220] Barometric facial paralysis seems to be related to pressure changes in the middle ear transmitted directly to the facial nerve through natural dehiscences in the fallopian canal. Symptoms are relieved with placement of pressure equalization tubes or other means of improving eustachian tube function.[216]

Benign Intracranial Hypertension

The most common symptoms of benign intracranial hypertension are headache and visual disturbances, but occasionally it is associated with cranial nerve palsies, falsely suggesting a localized lesion. The abducens nerve is the most commonly involved, being affected in 10% to 60% of cases.[221] Unilateral and occasionally bilateral facial paralysis has been reported in a few cases of benign intracranial hypertension.[222] These

cranial nerve palsies tend to resolve promptly after reestablishment of normal intracranial pressure through medical means or by shunting.

Metabolic Disorders

Adour and colleagues[223] reported that 17% of patients older than 40 years of age with Bell's palsy had abnormal results on glucose tolerance testing; on this basis, these workers calculated that the development of Bell's palsy is 4.5 times more likely in a person with diabetes than in a person without diabetes. The incidence of diabetes, or at least abnormal glucose tolerance curves, in patients with Bell's palsy is reportedly 10%[95] to 56%.[224] A case-control study by Paolino and associates[225] also found abnormal glucose tolerance curves in 24% of patients with Bell's palsy, compared with 13% of control subjects ($P < .005$). These findings warrant caution in prescribing corticosteroids to patients with Bell's palsy. Reversible facial paralysis has been reported with hypovitaminosis A.[226]

Central Facial Paralysis

Central facial paralysis is caused by a lesion in the parietal motor cortex or the connections between the cortex and the facial nucleus. Lesions in these areas usually are accompanied by other neurologic symptoms referable to the CNS. A supranuclear palsy of the face most severely affects the lower half of the face and spares the forehead. Another important sign is that emotional facial reaction remains intact even though voluntary motion may be severely affected.

Hyperkinetic Disorders

Hemifacial Spasm

Hemifacial spasm is an involuntary twitching and contraction of one side of the face. The spasm usually starts around the mouth and, as the disease develops, comes to involve the entire face.[48] These uncontrollable spasms cause severe functional, social, and psychologic impairment. Although the spasms usually are painless, a rare form of the disease also involves the trigeminal nerve.

The cause of hemifacial spasm is widely debated; in the past, hemifacial spasm was thought to originate somewhere in the peripheral facial nerve. Esslen hypothesized that pressure or ischemia within the fallopian canal could generate spontaneous action potentials.[227] Jannetta[228] thought that compression of the seventh nerve by aberrant blood vessels near its exit from the brainstem (root entry zone) was the cause, although other workers disagree with this conclusion.[229]

An unusual aspect of hemifacial spasm is the lateral spread response first described by Esslen, in which electrical stimulation of one branch of the facial nerve causes a response in muscle innervated by a different branch. This response disappears at the time of vascular decompression.[230] How could vascular compression of the facial nerve cause facial spasms? Two mechanisms have been hypothesized[231]: (1) ephaptic transmission of impulses (electrical side currents allowing the depolarization of adjacent nerve fibers) at the site of the compression or (2) hyperactivity of the facial nucleus secondary to continuous irritation at the site of the compression. Experiments by Kuroki and Møller[231] suggest that a combination of demyelination and arterial compression is required for generation of the symptoms of hemifacial spasm and that the facial nerve becomes hyperactive after long-term irritation of the demyelinated portion.[231]

The best management of hemifacial spasm also has been contested. Many surgeons advocate some form of partial destruction of the peripheral facial nerve—either partial resection of the three main branches[232,233] or resection of involved branches determined by EMG.[234] However, Jannetta and coworkers[235] and Møller and Jannetta[230] advocate separation of the aberrant vessels from the nerves through a posterior fossa craniotomy. The experience of other surgeons confirms the success of microvascular decompression; Samii[236] and Moffat[237] and their colleagues report that 92% of patients were spasm-free 6 months after decompression of the facial nerve. Selection of patients for surgery is difficult, but recent studies with MRI and magnetic resonance angiography suggest that neurovascular contact with the nerve at the root exit zone is producing the associated symptoms.[238]

Blepharospasm

Blepharospasm is an idiopathic progressive involuntary spasm of the orbicularis oculi and upper face (corrugator and procerus muscles). Extension of the spasms to include the lower face is not uncommon.[239] In advanced cases, the eyes may be closed for as much as one third of the patient's waking time, rendering the patient functionally blind.[48] Blepharospasm generally is considered to be central in origin, although the exact mechanism is not yet determined.[43]

Treatment is directed toward selective destruction of the peripheral nerve branches innervating the orbicularis oculi muscles. McCabe and Boles[240] recommend exposing the upper branches of the facial nerve, confirmation with nerve stimulation, and resection of all branches to the orbicularis oculi. Success has been obtained with injection of botulinum toxin. Botulinum A toxin, a neurotoxin produced by *Clostridium botulinum* that interferes with the presynaptic release of acetylcholine, has been used in the management of many facial dystonias, especially blepharospasm. More than 90% of patients have experienced some relief of symptoms, although the average duration of the maximum improvement is only 11 to 14 weeks.[241,242] Systemic complications after administration of botulinum toxin have not been reported. Local complications usually are transient and include lid ptosis, facial weakness, corneal exposure, and diplopia.[243] Long-term improvement is prevented by regeneration of axons after treatment.[244] Periorbital myectomy also may produce acceptable long-term results.[239]

CHAPTER ONE HUNDRED AND SEVENTY-ONE

Intratemporal Facial Nerve Surgery

Bruce J. Gantz

Jay T. Rubinstein

Ravi N. Samy

Samuel P. Gubbels

Key Points

- Appropriate management of facial nerve disorders requires a thorough knowledge of the pathophysiology of the diseases affecting the facial nerve, experience in the interpretation of findings on radiologic and electrophysiologic tests of the nerve, and expertise in multiple neuro-otologic surgical approaches to the facial nerve.
- The middle fossa craniotomy surgical approach provides access to the canalicular, labyrinthine, geniculate and proximal tympanic segments of the nerve while preserving hearing but is technically challenging. The middle cranial fossa approach can be used for facial nerve decompression in palsy, facial nerve tumor decompression or removal, and facial nerve grafting in the internal auditory canal, and to address facial nerve impingement resulting from longitudinal temporal bone fractures.
- A transmastoid approach can be used to address pathologic processes involving the tympanic and mastoid segments of the facial nerve while preserving inner ear function. Total facial nerve decompression can be achieved using the transmastoid approach in combination with a middle fossa craniotomy.
- The translabyrinthine approach provides access to the entirety of the intratemporal facial nerve for decompression, mobilization, or grafting when no usable hearing remains.
- Retrolabyrinthine and retrosigmoid approaches provide access to the cisternal segment of the facial nerve while preserving hearing and can be used for vascular decompression and combined with other approaches for facial nerve grafting at the brainstem.
- Anterior rerouting of the facial nerve from the geniculate to the extratemporal segment, as in the Fisch type A approach, can be performed with normal facial function possible postoperatively.
- The most important element of successful facial nerve repair is a tension-free anastomosis. An interposition graft, using the great auricular or sural nerve, should be used for nerve repair in all cases in which a tension-free end-to-end anastomosis cannot be achieved.
- In general, facial nerve tumors should be observed in patients with House-Brackmann grade I or II function. Surgical decompression is a management option for patients with facial nerve tumors and House-Brackmann grade II or III function. Tumor resection with facial nerve grafting is recommended for patients with House-Brackmann grade IV function or worse due to a facial nerve tumor.

Advances in surgical instrumentation and refinements in surgical strategies have enabled the otologist to expose safely the entire course of the facial nerve from the brainstem to its exit from the temporal bone. Surgical management of facial nerve disorders, however, continues to be as controversial as it was in the days of Cawthorne and Kettel. Successful treatment of the disease processes that cause facial nerve dysfunction requires thorough knowledge of the pathophysiology of the disease process and accurate assessment of the degree of nerve injury. Newer diagnostic tools, such as electroneuronography (ENoG) (i.e., electroneurography), high-resolution computed tomography (CT), and magnetic resonance imaging (MRI), provide more precise assessment and localization of nerve injuries in many disorders. This advance has allowed more accurate preoperative planning and selection of the most expeditious surgical approach to the nerve injury site when surgery is appropriate.

This chapter describes surgical approaches in detail, including the advantages and disadvantages of each.

Surgical Anatomy

Thorough knowledge of the intricate, convoluted course of the facial nerve and its anatomic relationship to other vital structures is essential to the surgeon who plans to operate in this area. The facial nerve (cranial nerve VII) exits the brainstem at the pontomedullary junction approximately 1.5 mm anterior to the vestibulocochlear nerve (cranial

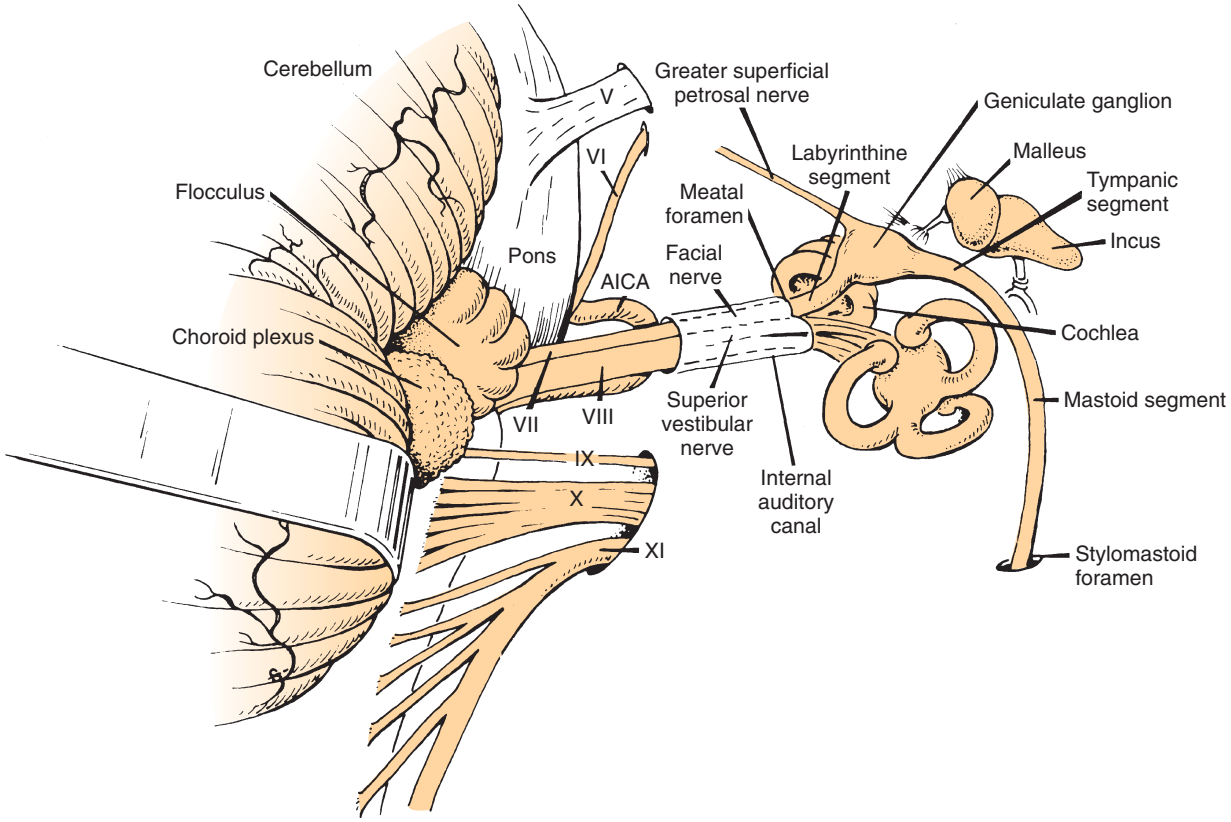

Figure 171-1. Course and relationships of the facial nerve from the pontomedullary junction to the stylomastoid foramen. AICA, anterior inferior cerebellar artery; Roman numerals designate cranial nerves.

nerve VIII). The facial nerve is smaller in diameter (approximately 1.8 mm) than the oval cranial nerve VIII (approximately 3 mm in the longer diameter). A third, smaller nerve, the nervus intermedius, emerges between cranial nerves VII and VIII and eventually becomes incorporated within the sheath of cranial nerve VII. After leaving the brainstem, cranial nerve VII follows a rostrolateral course through the cerebellopontine cistern for 15 to 17 mm, entering the porus of the internal auditory canal of the temporal bone (Fig. 171-1). Other important structures in the cerebellopontine cistern include the anterior inferior cerebellar artery (AICA) and the veins of the middle cerebellar peduncle. The AICA passes near or between cranial nerves VII and VIII; the veins are more variable in position and number. On entering the IAC, the facial nerve occupies the anterosuperior quadrant of this channel for 8 to 10 mm. Then it enters the fallopian canal at the fundus of the internal auditory canal. The internal auditory canal is anterior to the plane of the superior semicircular canal, with which it subtends an angle of approximately 60 degrees. At the entrance of the fallopian canal (meatal foramen), cranial nerve VII narrows to its smallest diameter, 0.61 to 0.68 mm.[1] Only the pia and arachnoid membranes form a sheath around the nerve at this point, because the dural investment terminates at the fundus of the internal auditory canal. Some investigators[2,3] identify the small diameter of the meatal foramen as an important contributory etiologic factor in facial paralysis associated with certain diseases, such as Bell's palsy and Ramsay Hunt syndrome.

Within its intratemporal course, the facial nerve has three distinct anatomic segments: labyrinthine, tympanic, and mastoid. The labyrinthine segment is shortest (approximately 4 mm), extending from the meatal foramen to the geniculate ganglion. This segment travels in an anterior, superior, and lateral direction, forming an anterior medial angle of 120 degrees with the internal auditory canal. Anteroinferior to the labyrinthine segment, the basal turn of the cochlea occupies a close relationship to the fallopian canal. At the lateral end of the labyrinthine segment, the geniculate ganglion is found, and the nerve makes an abrupt posterior change in direction, forming an acute angle of approximately 75 degrees. Anterior to the geniculate, the greater superficial petrosal nerve exits the temporal bone through the hiatus of the facial canal. The hiatus of the facial canal varies in distance from the geniculate ganglion. The greater superficial canal also contains the vascular supply to the geniculate ganglion region.

The tympanic segment of the nerve is approximately 11 mm long, running between the lateral semicircular canal superiorly and the stapes inferiorly, forming the superior margin of the fossa ovale. Between the tympanic and mastoid segments, the nerve gently curves inferiorly for approximately 2 to 3 mm.

The mastoid, or vertical, segment is the longest intratemporal portion of nerve: approximately 13 mm. As the nerve exits the stylomastoid foramen at the anterior margin of the digastric groove, an adherent fibrous sheath of dense vascularized connective tissue surrounds it. The stylomastoid artery and veins are within this dense sheath.

General Surgical Technique

Whenever the facial nerve is to be surgically exposed, several technical principles should be observed. First, a system for monitoring facial nerve function during the operation should be used.[4] One of the simplest monitoring methods is visual observation during critical stages of the operation. Needle electromyography also can be used if the equipment is available. No matter which monitoring technique is used, it is essential that the side of the face on which the nerve is to be exposed be draped in a manner that allows visual observation. The patient's forehead, eye, mouth, and chin should be visible. The endotracheal tube should be secured to the opposite side without taping on the side of the mouth to be observed. Towels drape the posterior, superior, and inferior margins; a fourth towel is placed along the anterior profile. An abdominal transparent plastic drape is placed over the face and operative area (Fig. 171-2). An observer can thus see the entire face during the procedure and determine whether any of the muscles move in response to surgical manipulation of the nerve. If the surgeon asks for

Figure 171-2. Plastic draping with exposure of hemiface allows visualization of facial movements in addition to electromyographic monitoring.

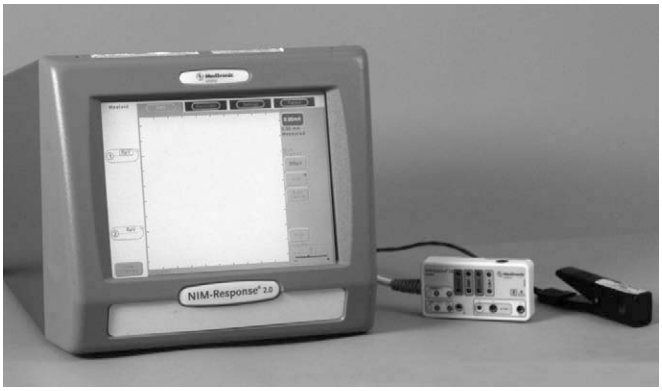

Figure 171-3. A popular commercially available nerve monitoring system. Stimulus intensity to the stimulator probe can be varied, as can the sensitivity of monitoring response.

observation during critical periods of the procedure, the circulating nurse is the best observer.

More precise intraoperative monitoring can be achieved using commercially available needle electromyographic systems (Fig. 171-3). Electromyographic needles are placed in the orbicularis oculi and orbicularis oris muscles, as shown in Figure 171-4. Stimulation of the facial nerve during the operation provides accurate localization of the nerve if the anatomy is distorted by a disease process or congenital abnormality. Constant current or constant voltage stimulators can be used. These systems allow auditory monitoring of facial nerve activity and alert the surgeon when the nerve has been stimulated. Auditory monitoring is especially useful during the removal of tumors adjacent to the facial nerve.

Instrumentation is crucial to successful exposure of the facial nerve. The largest diamond burr that the operative site can safely accommodate should be used when the operator is near the fallopian canal. Cutting burrs have a tendency to catch and jump unexpectedly, with the potential to cause severe injury to the nerve. Continuous suction-irrigation keeps the burr clean and also dissipates heat, which can induce neural damage.

The final layer of bone over the nerve should be removed by blunt elevators designed for this purpose. These instruments are thin but strong enough to remove a thin layer of bone. Stapes curettes usually are too large and can cause compression injury to the nerve. If neurolysis is to be performed, disposable microblades are available (Beaver No. 59-10). Sharp dissection is less traumatic than blunt elevation when the nerve must be lifted out of the fallopian canal. The medial surface of the nerve usually adheres to the bone and contains a rich vascular supply. Cauterization near the nerve should be performed only with bipolar electrocautery and insulated microforceps.

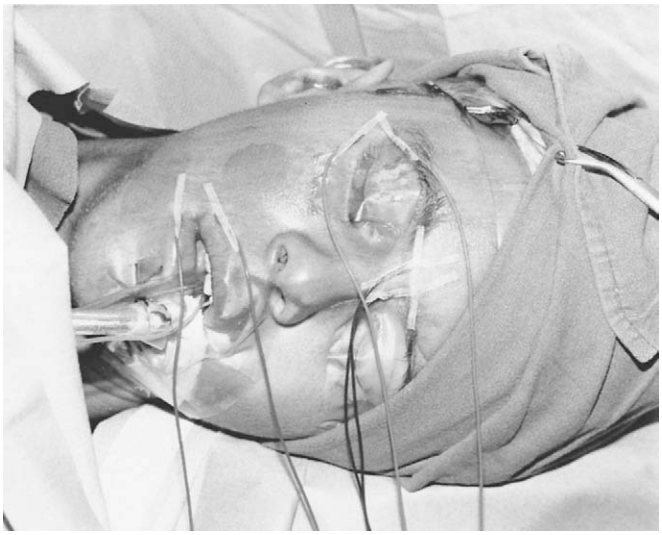

Figure 171-4. Placement of electromyographic electrodes in orbicularis oculi and orbicularis oris muscles. Ground electrodes are placed in the procerus muscle.

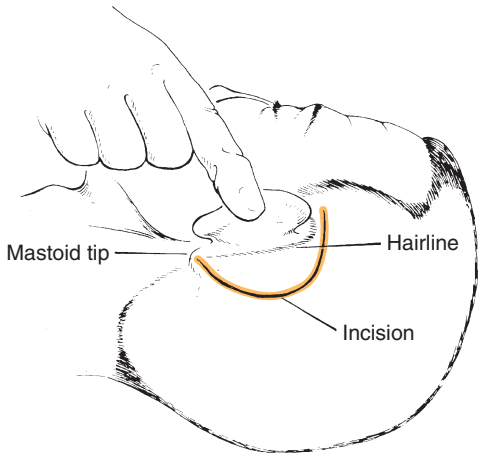

Figure 171-5. Skin incision for the retrolabyrinthine surgical approach.

Surgical Approaches

Retrolabyrinthine Approach: Brainstem to Internal Auditory Canal Porus

Technique

The patient is positioned on an operating table similar to that used for a mastoidectomy. Endotracheal anesthesia is administered, and the anesthetist is positioned at the foot of the table, allowing the surgical nurse to be opposite the surgeon. The hair is removed 4 cm superiorly and postauricularly, and the ear and the left lower abdominal quadrant (for the harvest of fat if necessary) are prepared and draped. An osmotic diuretic (250 mL of 20% mannitol) is administered intravenously at the start of the skin incision. The skin incision is made in the hairline 3 to 4 cm posterior to the postauricular crease and extended down over the mastoid tip (Fig. 171-5). Posterior placement of the skin incision provides access for occipital bone removal, which is necessary for posterior retraction of the sigmoid sinus.[5]

A complete mastoidectomy is performed. In addition, bone is removed over the sigmoid sinus from the sinodural angle to its most inferior extent. The dome of the jugular bulb also is identified. A large diamond burr and suction-irrigation are essential to prevent injury to the sinus and the posterior fossa dura. The cerebellar plate is removed

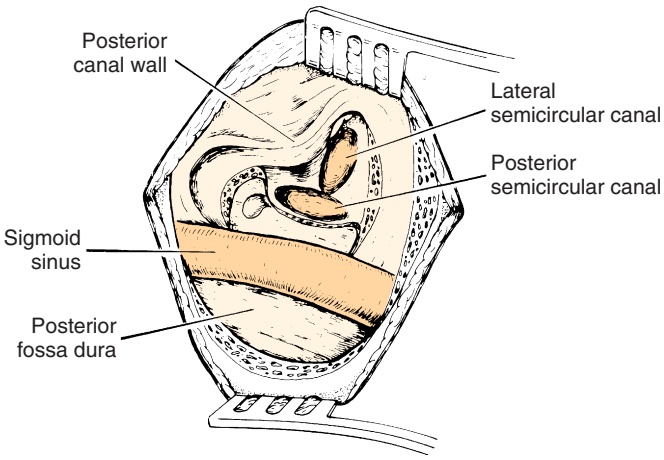

Figure 171-6. Exposure obtained through the left retrolabyrinthine approach before retraction and dural incision, as viewed by the surgeon.

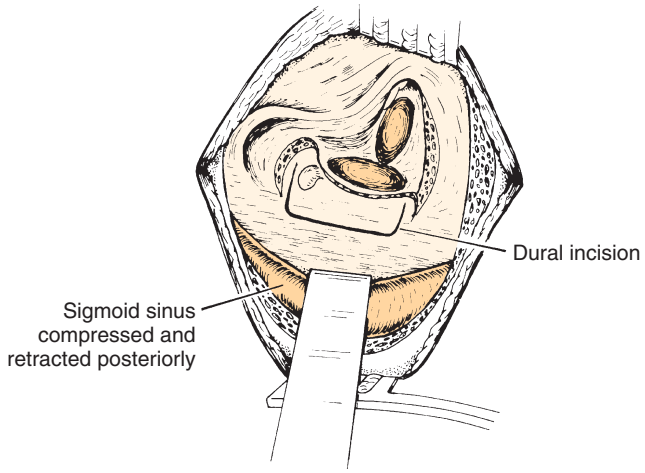

Figure 171-7. Dural incision for left retrolabyrinthine exposure.

from the tegmen mastoideum to the jugular bulb. Anteromedially, the posterior semicircular canal is identified, and inferior to the labyrinth (retrofacial area) the endolymphatic sac is exposed (Fig. 171-6). In a well-aerated mastoid, 2 to 3 mm of bone can be removed between the posterior semicircular canal and the cerebellar dura with the use of small diamond burrs. If the posterior canal is not evident, it should be blue-lined to locate its exact position.

An anteriorly based trapdoor cerebellar dural flap is fashioned with a sharp microscalpel and microscissors (Fig. 171-7). Care should be taken not to injure the small cerebellar arachnoid vessels when the dura is opened. A cuff of dura should be left adjacent to the bony margins, sigmoid sinus, and superior petrosal sinus for placement of sutures during closure. Sutures placed at the corners of the dural flap serve to retract it anteriorly. A malleable self-retaining retractor is used to retract the sigmoid sinus posteriorly. The cerebellum usually falls away from the temporal bone, and minimal, if any, retraction is required. Hyperventilation, in addition to an osmotic diuretic, is useful in obtaining brain shrinkage.

The cochleovestibular facial nerve complex is seen 2 to 3 mm inferior and parallel to Donaldson's line (a line extending posterior from the plane of the lateral semicircular canal). The arachnoid is incised sharply, releasing the cerebrospinal fluid (CSF) from the cistern. Other visible nerves are the trigeminal nerve (cranial nerve V) superiorly and the glossopharyngeal nerve (cranial nerve IX) and possibly the vagus nerve (cranial nerve X) inferiorly (Fig. 171-8). Visualization of cranial nerve VII may be completely blocked by cranial nerve VIII.

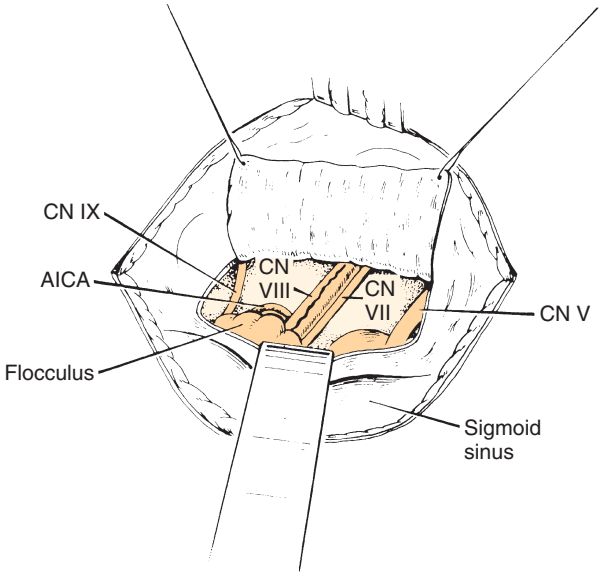

Figure 171-8. Left retrolabyrinthine exposure after retraction of the dural flap. AICA, anterior inferior cerebellar artery; CN, cranial nerve.

Cranial nerve VII usually arises 1.5 mm directly anterior to cranial nerve VIII. A Buckingham mirror aids identification of the facial nerve. The rostral division of the AICA may pass between cranial nerves VII and VIII, along with one or more veins. Approximately 15 mm of the nerve can be inspected in the cerebellopontine cistern.

At the end of the procedure, care should be taken to achieve watertight closure of the dura. Strips of abdominal fat (5 mm × 4 cm) are harvested from a lower abdominal incision, placed subdurally, and incorporated into the suture line. Braided nylon (4-0) sutures are used for closure of the dura. Fat can be placed in the mastoid but should not block the aditus or interfere with the ossicles. The subcutaneous tissues are closed in layers. A mastoid compression dressing is placed.

Retrosigmoid Approach

Technique

Another option for exposure of the facial nerve from the brainstem to the internal auditory canal is through a small retrosigmoid craniotomy. The preparation and incision are similar to those in the retrolabyrinthine approach (see Fig. 171-5). Instead of a complete mastoidectomy, the bone over the sigmoid sinus is removed to identify the posterior margin of the sinus. Bone is removed 4 cm posterior to the sigmoid sinus, exposing the posterior fossa dura (Fig. 171-9). The outline of the transverse sinus is exposed superiorly. A curvilinear incision in the posterior fossa dura is created to expose the cerebellum (Fig. 171-10). Care is taken to incise the dura without injuring the arteries and veins on the cerebellum. Cottonoid sponges lined with rubber glove strips are placed on the cerebellum. Slow, gentle retraction of the cerebellum over 5 to 10 minutes allows exposure of the posterior fossa face of temporal bone and internal auditory canal. Once the cerebellum has been slowly retracted, no external retraction is necessary. The cerebellum should fall away from the temporal bone, allowing viewing of the flocculus, choroid plexus, and the cranial nerve VII and VIII bundle (Fig. 171-11). The posterior lip of the internal auditory canal porus can be removed for additional lateral exposure, but the position of the posterior semicircular canal and its relationship to the posterior lip of the porus acusticus should be ascertained by CT.

Advantages and Uses

The retrolabyrinthine and retrosigmoid approaches provide access to the facial nerve in the cerebellopontine angle without sacrificing inner ear function. These approaches have an advantage over the routine suboccipital approach in that minimal or no cerebellar compression is needed. The procedure can be used in combination with middle fossa

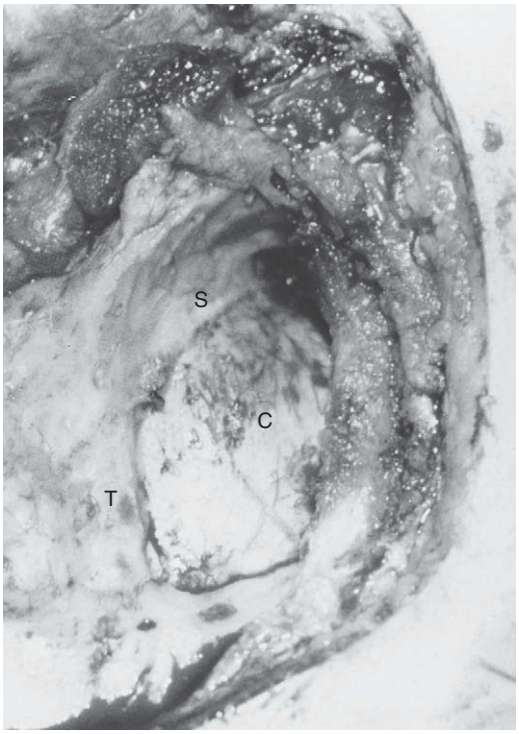

Figure 171-9. Retrosigmoid craniotomy. The skin flap is reflected anteriorly, exposing the mastoid and the cerebellar cortical bone. Craniotomy (approximately 4 × 4 cm), exposing the sigmoid sinus (S) anteriorly, transverse sinus (T) superiorly, and cerebellar dura (C).

Figure 171-10. A dural incision (2 to 3 cm long) can be linear or curvilinear. Here, 4-0 Neurolon suture retracts the anterior leaf of the dural incision.

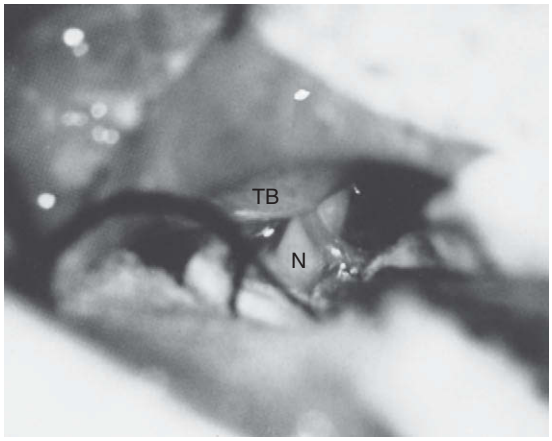

Figure 171-11. Retrosigmoid exposure. The cerebellum has been retracted from the cerebellar plate of the temporal bone (TB), exposing the neurovascular bundle (N). Cranial nerve VII is directly deep and slightly cephalic to cranial nerve VIII.

exposure for tumor removal and grafting of cranial nerve VII near the brainstem. For facial nerve surgery, the retrolabyrinthine technique is most commonly used in some practices for vascular decompression in hemifacial spasm. The AICA, posterior inferior cerebellar artery, and accompanying veins can be easily manipulated through this approach.

Limitations and Potential Complications

Visualization of the facial nerve often is hampered by the location of cranial nerve VIII. Gentle separation of the nerves with a blunt instrument can be accomplished but is associated with increased potential for hearing loss or vestibular complications. Because of the compromised exposure, management of any intracranial vascular complications is limited. If an intracranial complication occurs, rapid removal of suboccipital bone, in combination with a retrosigmoid dural opening, provides additional access.

CSF leakage is a potential problem with this approach, but careful dural reapproximation and use of subdural fat strips have decreased the incidence of this complication.

Middle Cranial Fossa (Transtemporal) Approach: Internal Auditory Canal Porus to Tympanic Segment

The middle cranial fossa approach[6] is used to expose the internal auditory canal and labyrinthine segments of the facial nerve when preservation of existing auditory function is desirable. The geniculate ganglion and tympanic portions of the nerve also can be decompressed using this approach.

Technique

The patient is placed supine on the operating table with the head turned so that the involved temporal bone is upward. The hair is shaved 6 to 8 cm above and anterior to the ear and 2 cm posterior to it. The surgeon is seated at the head of the table, with the instrument nurse at the anterior aspect of the patient's head.

A 6 cm × 8 cm posteriorly based trapdoor incision is marked in the hairline above the ear (Fig. 171-12). If exposure of the mastoid is necessary, the inferior limb of the incision can be extended postauricularly. The skin flap is elevated to expose the temporalis muscle. A 4 cm × 4 cm temporalis fascia graft is harvested for use during closure of the internal auditory canal dural defect. An anteriorly based trapdoor incision is used to elevate the temporalis muscle and periosteum. Staggering the levels of the muscle and skin incisions provides for a double-layer watertight closure at the end of the procedure.

The temporal root of the zygoma is exposed during elevation of the temporalis muscle. This landmark represents the level of the floor of the middle fossa. Stay sutures are placed in the skin and temporalis flaps to be used for retraction. A 3 cm × 5 cm bone flap centered above the temporal root of the zygoma is fashioned with a medium cutting

burr. The anterior and posterior margins of the craniotomy should be parallel to facilitate placement of the self-retaining retractor.

Branches of the middle meningeal artery are occasionally embedded within the inner table of the skull; therefore, the bone flap should be elevated in a controlled manner. Bipolar coagulation and bone wax may be necessary to control bleeding. Elevation of the dura from the floor of the middle fossa can be one of the most difficult steps. Use of blunt dissection and magnification greatly facilitates dural elevation. The dura is elevated from posterior to anterior to prevent accidental injury to an exposed geniculate ganglion and greater superficial petrosal nerve. Bipolar coagulation is used to cauterize dural reflections within the petrosquamous suture before transection with scissors.

The elevation proceeds until the petrous ridge is identified medially and the arcuate eminence, meatal plane, and greater superficial petrosal nerve are revealed anteriorly. No attempt is made to identify the middle meningeal artery and accompanying troublesome bleeding veins. The tip of a self-retaining (House-Urban) retractor is placed at the petrous ridge anterior to the arcuate eminence. A medium diamond burr and a suction-irrigation apparatus are used to identify the blue line of the superior semicircular canal. Review of a Stenvers projection radiograph obtained preoperatively will help to determine the level of the superior semicircular canal in relation to the floor of the middle fossa.

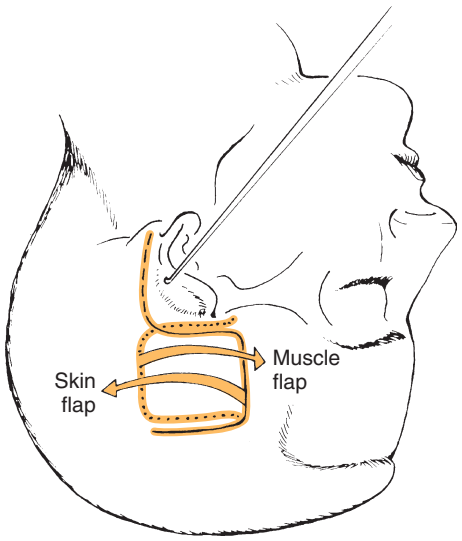

Figure 171-12. Surgical view of a skin incision *(solid line)* for the middle cranial fossa approach.Mastoid extension for total facial nerve exposure *(dashed line)* and extent of the muscle periosteal flap *(dotted line)* also are shown.

Drilling begins posterior to the arcuate eminence over the mastoid air cells and is continued until the dense yellow bone of the otic capsule is identified. Otic capsule bone is slowly removed until the blue outline of the superior semicircular canal is seen. The internal auditory canal is located by removing bone in a line 60 degrees anterior to the blue line of the superior semicircular canal and continuing until approximately 180 degrees of the canal is exposed (Fig. 171-13). Because of the close proximity of the superior semicircular canal and the basal turn of the cochlea, only approximately 120 degrees of the circumference of the internal auditory canal can be safely removed in its lateral 5 mm or more. The facial nerve occupies the anterosuperior portion of the internal auditory canal. Laterally, the vertical crest (Bill's bar) marks the division between the superior vestibular nerve and the meatal foramen.

The segment of the facial nerve at its entrance to the fallopian canal is the narrowest, most delicate portion of the nerve. At the meatal foramen, the facial nerve turns anterior and slightly superior. The basal turn of the cochlea can be within 1 mm inferiorly, and the ampulla of the superior semicircular canal can be directly posterior to the nerve. The labyrinthine segment is followed to the geniculate ganglion. The tegmen tympani is removed with care taken to avoid injury to the head of the malleus and incus. The tympanic segment is easily seen to turn abruptly posteriorly; it is followed to where it courses inferior to the lateral semicircular canal. It is advisable to leave a thin shell of bone covering the nerve until its entire course is identified. The final layer of bone is removed using small blunt elevators. The nerve is tightly confined within the labyrinthine segment of the fallopian canal; use of larger curettes should be avoided to prevent compression injury.

If the nerve is to be decompressed, neurolysis is the final step. A disposable microscalpel (Beaver No. 59-10) is used to slit the periosteum and epineural sheath.

Alternative methods to locate the facial nerve may be necessary, especially in traumatic cases. The greater superficial petrosal nerve can be traced posteriorly to the geniculate ganglion, or the tegmen tympani may be fractured to permit a view of the tympanic segment through the fracture. The tympanic segment is then used to locate the geniculate ganglion and labyrinthine segments.

At the end of the procedure, a corner piece of the bone flap is fashioned to cover the defects in the tegmen tympani and internal auditory canal (Fig. 171-14). This prevents herniation of the temporal lobe into the middle ear. The previously harvested temporalis fascia is placed over the bone plug to help seal the dural defect at the internal auditory canal. The squamous bone plug is replaced, and the temporalis muscle is closed with interrupted absorbable sutures. The skin is closed in layers. No drain is placed. A mastoid type of pressure dressing is applied.

Advantages and Uses

The middle cranial fossa approach is the only method that exposes the entire internal auditory canal and labyrinthine segment with preservation of hearing. In combination with the retrolabyrinthine and trans-

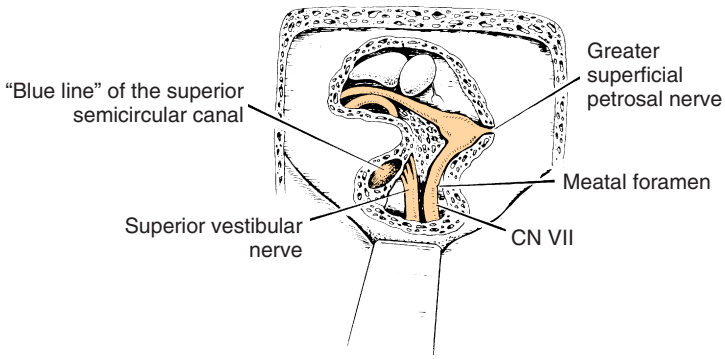

Figure 171-13. Surgical view of the left middle cranial fossa exposure after craniotomy, temporal lobe retraction, and bony exposure are complete. CN, cranial nerve.

mastoid approaches, this approach enables visualization of the entire course of the facial nerve and preserves function of the inner ear. The middle cranial fossa technique is most commonly used for decompression of the facial nerve in Bell's palsy[7,8] and with longitudinal temporal bone fractures.

Limitations and Potential Complications

The anatomy of the floor of the middle cranial fossa is variable and presents difficulty in identification of landmarks. The surgeon should have thorough knowledge of the three-dimensional anatomy of the temporal bone. Many hours in a temporal bone dissection laboratory are required to attain the delicate microsurgical skills necessary for this type of surgery.

Dural elevation can be difficult, especially in patients older than 60 years of age. The dura can adhere to the middle fossa floor and may be thin. A temporalis fascia patch should be used to repair any dural tears to prevent CSF leaks.

Conductive and sensorineural hearing losses can result from middle cranial fossa facial nerve decompression. Conductive hearing loss can be secondary to temporal lobe herniation or ossicular disruption during dissection in the attic. A free bone plug prevents temporal lobe herniation. Sensorineural hearing loss can result from direct injury to the inner ear from the drill during exposure of the cochlea or semicircular canals, or from translational injury incurred when the drill strikes an ossicle. Injury to the internal auditory vessels within the internal auditory canal also can result in loss of inner ear function. Loss of vestibular function can occur by the same mechanisms.

Persistent CSF leakage can lead to meningitis and should be controlled by a temporary lumbar drain. If CSF leakage continues despite an adequate period of lumbar drainage, surgical revision with dural repair may need to be performed.

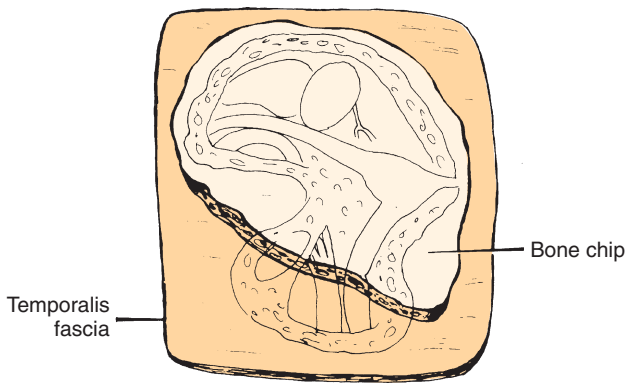

Figure 171-14. Bone chip and temporalis fascia placement for tegmen reconstruction and dural closure of the middle cranial fossa approach.

Uncontrolled bleeding or injury to the AICA poses the most serious complication during the operation. The middle cranial fossa approach does not provide adequate access to the cerebellopontine angle. The AICA and accompanying veins can loop into the internal auditory canal. Control of bleeding of these vessels may require a suboccipital exposure. Injury to the AICA results in brainstem and cerebellar infarction of variable degree, depending on the size and area of terminal arterial supply.

Results with Middle Cranial Fossa Decompression of Bell's Palsy

May and coworkers[9] showed the futility of transmastoid decompression for Bell's palsy. Only middle cranial fossa decompression of the meatal foramen, labyrinthine segment, and geniculate offers any benefit. Although the middle cranial fossa approach is used frequently for acoustic neuroma and vestibular nerve section with minimal morbidity, it is technically challenging even for experienced temporal bone surgeons and carries a significant potential for complications. A 30-dB conductive hearing loss constitutes minimal morbidity for a patient with an acoustic neuroma or intractable Meniere's disease, but it is significant for a patient who may have up to a 50% chance of spontaneous complete recovery. Thus, even with proof of efficacy, decompression is advocated only in centers experienced in the middle cranial fossa approach. As surgical series of middle cranial fossa decompression for Bell's palsy become available, honest appraisals of the statistical and clinical significance of improved facial function will be needed. Slight improvements in facial symmetry do not justify significant rates of conductive or neurosensory hearing loss or CSF leak, or the cost of the procedure and overnight postoperative stay in the intensive care unit.

In a study of middle cranial fossa decompression, Fisch[2] showed statistically significant improvements in outcome with surgery, but it is difficult to assess the degree of improvement in his subject population. Use of the House-Brackmann scale in subsequent reports will make this easier. Table 171-1 summarizes the published data available[3,10] and the experience at the University of Iowa Hospitals and Clinics through 1986 regarding outcome with middle cranial fossa decompression. All patients demonstrated more than 90% degeneration on ENoG within 14 days of onset of total paralysis and no voluntary electromyography potentials. The prognostic studies of Fisch[2] indicated, at best, a 50% rate of spontaneous satisfactory recovery when degeneration exceeded 90%.[11] Sillman and colleagues[12] and Marsh and Coker[13] studied ENoG prognostication using the House-Brackmann scale and verified Fisch's results, showing less than 50% recovery to grade I or II function when ENoG degeneration exceeded 90%.[12] Thus, patients managed with middle cranial fossa decompression are expected to return to grade I or II without surgery less than 50% of the time.

After at least a 7-month follow-up period, 23 of 26 patients returned to House-Brackmann grade I or II (see Table 171-1). Using a binomial distribution and assuming a 50% spontaneous recovery to grade I or II, this result is highly significant ($P < .00005$). No published study showed statistical significance, and none reported on morbidity

Table 171-1

Middle Cranial Fossa Decompression Outcomes in Patients with Bell's Palsy*

of the procedure, but all showed trends for the efficacy of middle cranial fossa decompression. Data for six of the Iowa patients appeared in a previous report.[14] With these additional cases, the Iowa patients had a highly significant recovery rate with middle cranial fossa decompression ($P < .006$). Table 171-2 shows outcome with corticosteroid management alone. Of the Iowa patients, five of eight who did not undergo prompt middle cranial fossa decompression but who met the electrophysiologic criteria for surgery did not recover to grade I or II (see Table 171-1). In the Michigan study, 14 of 25 patients who did not undergo decompression achieved grade III or IV recovery. Even if historical control subjects are not used, Iowa patients who underwent middle cranial fossa decompression improved to grade I or II significantly more often than those managed with corticosteroids alone ($P < .024$; Fisher's exact test).[15]

Transmastoid Approach: Geniculate Ganglion to Stylomastoid Foramen

Technique

A postauricular incision is used to expose the mastoid cortex. A complete mastoidectomy is performed, and the lateral semicircular canal, tegmen mastoideum, sigmoid sinus, and digastric ridge are identified. The lateral semicircular canal and digastric ridge are important landmarks for identification of the facial nerve. The tympanic segment of the nerve is immediately inferior to the lateral canal, and the anterior margin of the digastric ridge marks the location of the stylomastoid foramen. The short process of the incus is identified but should not be disturbed by an instrument or a rotating burr. The facial recess is opened with a small diamond burr (Fig. 171-15). This allows visualization of the tympanic segment of cranial nerve VII in the middle ear. With use of a medium-sized diamond burr and suction-irrigation, the fallopian canal is exposed from the lateral semicircular canal to the stylomastoid foramen. In the mastoid bone, the posterior 180 degrees of the circumference of the fallopian canal is removed. The retrofacial air cells can be removed if additional exposure is required. In the tympanum, a 1-mm diamond burr is used to remove bone to the geniculate ganglion. Again, the drill should not touch the incus. The final thin shell of bone covering the nerve is removed with blunt elevators (Fig. 171-16). Neurolysis is accomplished if desired. The wound is drained for 24 to 36 hours and closed in layers. A mastoid pressure dressing is placed.

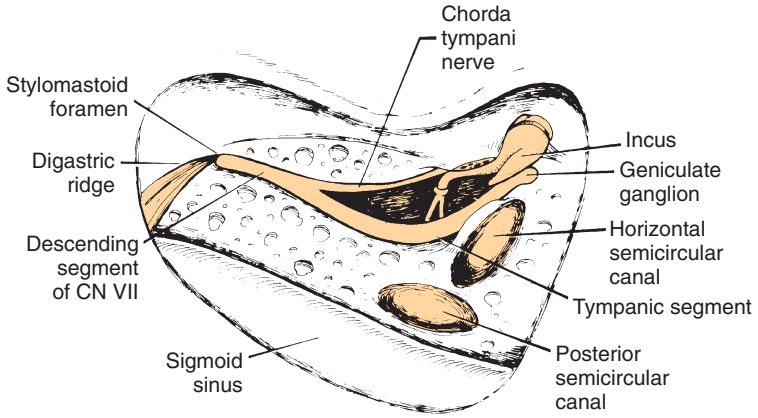

Figure 171-15. Transmastoid facial nerve exposure of the left ear after opening of the facial recess.

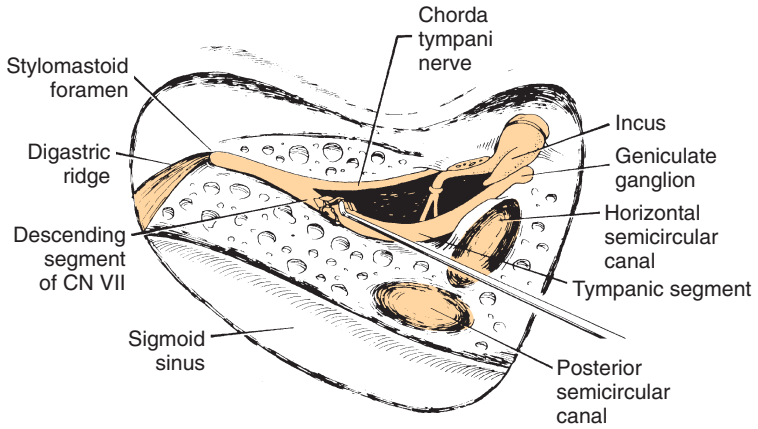

Figure 171-16. The final thin layer of bone covering the facial nerve is removed with a delicate but sturdy blunt elevator.

Advantages and Uses

Transmastoid decompression provides excellent exposure of the mastoid and tympanic segments of the facial nerve. Exposure of the geniculate ganglion requires removal of the incus, which can be replaced at the end of the operation. Conductive hearing loss may occur with this maneuver, and, in general, it is difficult to get adequate decompression of the geniculate segment without a middle fossa craniotomy. The labyrinthine segment cannot be reached through a transmastoid approach unless the ampulla of the lateral semicircular canal is sacrificed.

This route is used to explore the facial nerve when decompression is necessary for rerouting of the nerve and in cases of infection and fractures localized to the mastoid segment of the fallopian canal. Acute or chronic otitis media can induce facial paralysis. The most common sites of involvement are the tympanic segment (dehiscent in more than 25% of healthy persons) and the second genu as the nerve turns into the mastoid. With an isolated mastoid temporal bone fracture or a longitudinal temporal bone fracture that involves the distal geniculate ganglion and tympanic segments, adequate decompression can be accomplished through the mastoid. A longitudinal temporal bone fracture, however, is better managed with the improved exposure provided by a middle fossa approach. During removal of infratemporal fossa tumors, rerouting of the facial nerve frequently is required. Moving the facial nerve provides safer access to the jugular foramen and carotid canal. Transmastoid decompression is used in conjunction with middle fossa and retrolabyrinthine approaches if total facial nerve exposure is required and inner ear function is to be preserved.

Limitations and Complications

The major drawback with transmastoid exposure of the facial nerve is the limited access to the geniculate ganglion and the inability to reach the labyrinthine segment. The labyrinthine portion of the nerve commonly is the primary site of involvement in traumatic paralysis or Bell's palsy. Conductive or sensorineural hearing loss also can be a complication if the incus is removed or touched by a rotating burr during the procedure.

Translabyrinthine Approach: Total Facial Nerve Exposure

Technique

The patient is positioned on the operating table and the head and lower left abdominal quadrant are prepared and draped. An incision is made 3 cm behind the postauricular crease and carried inferiorly over the mastoid tip. Soft tissue is elevated forward off the mastoid cortex to the external auditory canal. A portion of the occipital bone posterior to the sigmoid sinus also should be exposed. An extended complete mastoidectomy is performed.

The bone over the sigmoid sinus is removed, along with 0.5 to 1.0 cm of bone posterior to this structure. The incus is removed, exposing the tympanic segment of the facial nerve inferior to the lateral semicircular canal. The facial recess is opened, further defining the position of the facial nerve in the middle ear and mastoid. A thin layer of bone should remain over the nerve while complete labyrinthectomy is performed. Inferior to the posterior semicircular canal, bone is removed, exposing the jugular bulb, posterior fossa dura, and endolymphatic sac (Fig. 171-17).

Medial to the posterior semicircular canal and lateral semicircular canal, the internal auditory canal appears blue compared with the surrounding yellow otic capsule bone. Bone is removed 180 degrees around the internal canal, exposing the porus acusticus. At the lateral margin of the internal auditory canal, the facial nerve is found medial and slightly superior to the superior vestibular nerve (Fig. 171-18). Bone is removed over the labyrinthine segment to the geniculate ganglion and then distally to the stylomastoid foramen at the anterior limit of the digastric groove. The final layer of bone is removed with blunt elevators.

The dura over the internal auditory canal and cerebellar plate can be opened to expose the cerebellopontine cistern and brainstem. Closure is accomplished with a 4 cm × 4 cm piece of temporalis fascia covering the dural defect and draped over the aditus to separate the mastoid from the middle ear (Fig. 171-19). Abdominal fat is harvested and used to obliterate the mastoid space.

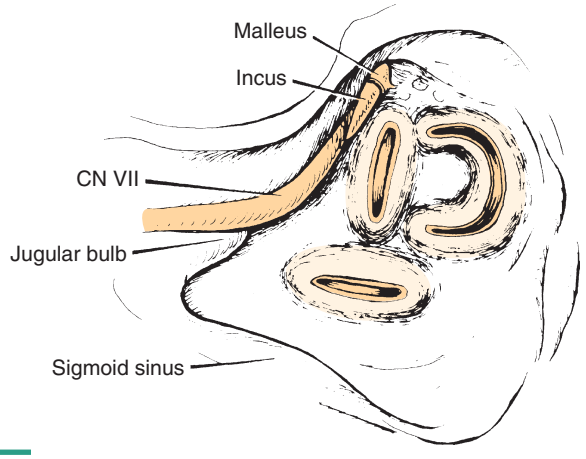

Figure 171-17. Left translabyrinthine exposure of the semicircular canals. CN, cranial nerve.

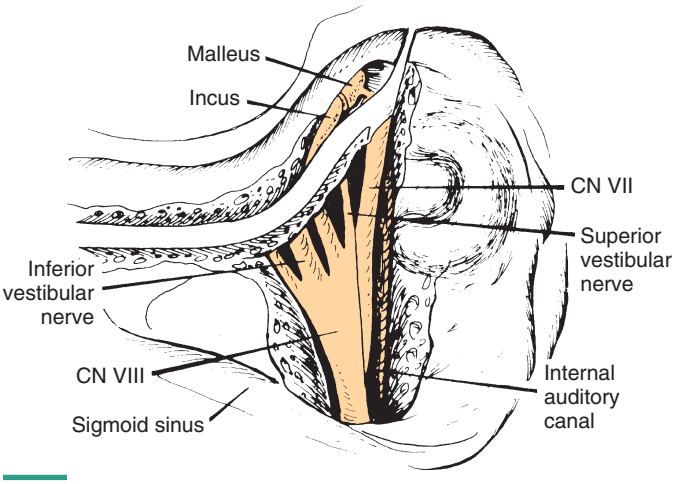

Figure 171-18. Completed left translabyrinthine exposure. CN, cranial nerve.

Advantages and Uses

The translabyrinthine exposure of the facial nerve is used primarily when the cochlear and vestibular functions have been lost preoperatively. The greatest advantage with this technique of facial nerve exposure is the ability to access the entire nerve using one approach. It most often is the approach of choice when facial paralysis has resulted from a transverse temporal bone fracture, an extensive facial neuroma, or a large congenital cholesteatoma that extends into the internal auditory canal. If an interpositional nerve graft is required, the translabyrinthine exposure provides enough working space for anastomosis at or near the brainstem.

Limitation and Complications

The greatest limitation of this procedure is that hearing and balance function must be sacrificed for total exposure of the nerve. When healthy cochlear and vestibular function exists, the surgeon should consider other approaches. Existing hearing and balance functions are destroyed, and the procedure may prevent future use of a cochlear implant device. CSF leakage and infection are the greatest risks with this operation, but the complication rate should be less than 2% if proper fascia graft and fat obliteration are performed.

Combination Approaches

It may be necessary to combine two or more of the approaches described to achieve the exposure dictated by the disease process. Occasionally, middle fossa exposure is combined with the transmastoid approach

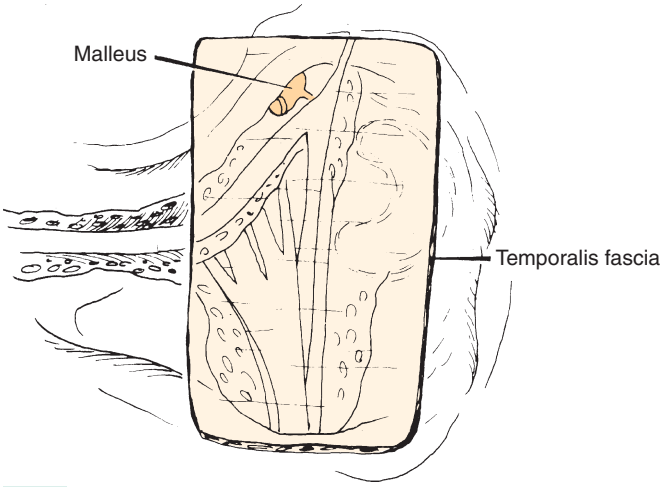

Figure 171-19. Placement of the temporalis fascia at the time of closure of the left translabyrinthine exposure.

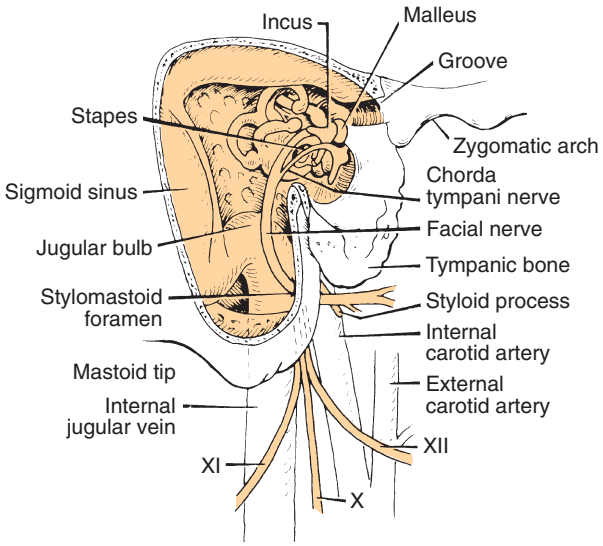

Figure 171-20. Facial nerve exposure for rerouting, as used in glomus jugulare tumor resection. Roman numerals denote cranial nerves.

when total decompression of the fallopian canal is needed. The middle fossa usually is exposed first. In most traumatic injuries, the area of facial nerve involvement is located at or just medial to the geniculate ganglion. If the injury extends distally, the lower limb of the skin incision is carried postauricularly, and a mastoid decompression is accomplished. The middle fossa retractor is left in place until the total nerve is exposed. A fascia graft is used to repair the dural defect in the internal auditory canal, and a portion of the craniotomy flap is placed over the tegmen tympani to prevent temporal lobe herniation. This combination also is useful in patients with facial nerve schwannoma and congenital cholesteatoma.

Retrolabyrinthine exposure also can be added if the disease extends medial to the porus of the internal auditory canal. During this portion of the procedure, the middle fossa retractor should be removed. Combination approaches are useful when a nerve graft is necessary and additional access is required.

Rerouting

Elevation of the facial nerve out of the fallopian canal may be necessary during nerve repair procedures and is essential for removal of sizable neoplasms in the proximity of the jugular foramen and carotid canal. Severe injury to the facial nerve at the geniculate ganglion occasionally occurs in longitudinal temporal bone fractures and can be managed by resecting the geniculate ganglion and reapproximating the labyrinthine and tympanic segments of the nerve through middle fossa exposure. Small tumors at the geniculate ganglion can be similarly managed.

To attain the necessary nerve length, the labyrinthine and transverse segments should be mobilized and elevated out of the fallopian canal. Extreme care should be taken during exposure of the labyrinthine segment of the nerve, because the basal turn of the cochlea can be less than 1 mm inferior and the ampulla of the posterior semicircular canal and lateral semicircular canal directly posterior. Small diamond burrs (0.4 to 0.8 mm) are used to remove the bone over the canal. It is safer to remove more bone anterior to the labyrinthine segment than posterior to it. The final thin layer of bone is removed with blunt microdissectors (Storz). When bone has been removed 180 degrees from the cephalic portion of the nerve, a microelevator is used to elevate the nerve gently out of the canal. Any adhesions to the bone are sharply separated with a microscalpel (Beaver No. 59-10). The tympanic segment of the nerve is mobilized in a similar manner. If the slightest tension would be necessary for reapproximation of the nerve ends, an interposition graft should be placed.

Surgical techniques have been developed to expose lesions near the jugular bulb, carotid canal, and parasellar regions.[8] The descending segment, stylomastoid foramen, and extratemporal course of the facial nerve are directly lateral to these structures. Rerouting the facial nerve greatly facilitates the surgical exposure and eliminates the need to transect the nerve in most instances. Commonly, the nerve is relocated anterior and superior to its original position, requiring the middle ear cleft to be obliterated and the posterior external bony canal to be removed.

A large, C-shaped postauricular skin incision is designed to allow exposure of the mastoid cortex and parotid gland. The skin flap is developed through the external ear canal at the bony cartilaginous junction and carried anteriorly, exposing the periparotid fascia. The extratemporal course of the facial nerve is exposed in the parotid gland in the usual fashion. The dissection of the nerve is carried distal to the pes anserinus, and the inferior division is freed from the surrounding gland for 1 to 2 cm. Additional dissection may be necessary, depending on the exposure required.

A complete mastoidectomy is performed, and the posterior external canal is lowered to the level of the lateral semicircular canal and the digastric ridge. The tympanic ring, malleus, and incus are removed. The tympanic and descending segments of the facial nerve are identified with a diamond burr (Fig. 171-20). Bone is removed 180 degrees around the nerve, leaving a thin shell that is removed with microelevators. Sharp dissection with a microscalpel frees the nerve sheath from the remaining fallopian canal.

An abundant vascular supply frequently is encountered during elevation of the nerve from the canal. Bleeding is controlled with a microtipped bipolar cautery at the lowest effective current.

At the stylomastoid foramen, a thick fibrous sheath strongly adheres to the bone. To prevent trauma to the nerve during elevation of this portion, it is suggested that the entire fibrous sheath be freed and moved with the nerve. Removal of the nerve from the sheath induces unnecessary trauma that may result in temporary paralysis. It also may be difficult to elevate the tympanic segment of the nerve because of the close proximity of the stapes superstructure. The crura and capitulum of the stapes can be removed with a crurotomy scissors. A groove that is larger than the nerve is then milled in the zygomatic root area of the epitympanum to accept the nerve as it is transposed anterosuperiorly at the level of the geniculate ganglion (Fig. 171-21).

Partial Rerouting

Partial rerouting of the facial nerve can be attempted for tumors that do not involve the protympanum, internal auditory canal, or eustachian tube. This procedure allows preservation of middle ear function. When hearing preservation is to be attempted, rerouting of only the mastoid segment of the facial nerve is more limited. The external auditory canal is transected 3 to 4 mm medial to the bony cartilaginous junction, allowing reconstruction of the external auditory canal at the end of the

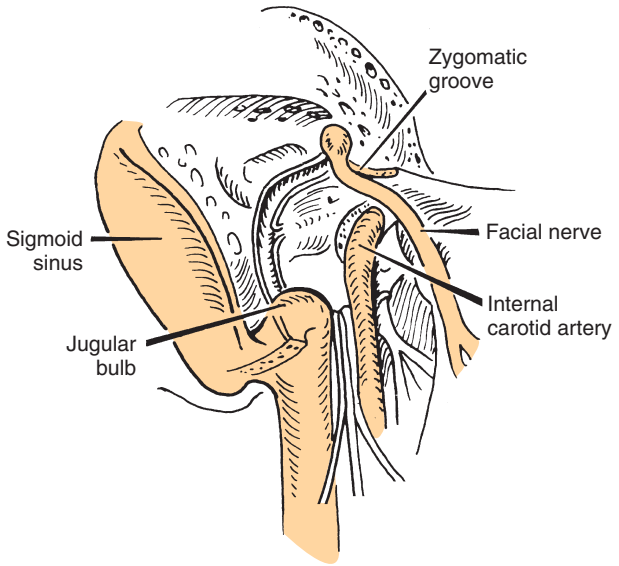

Figure 171-21. Appearance after rerouting of the facial nerve.

procedure. A canal wall-up mastoidectomy with an extended facial recess is created. In addition to thinning the posterior canal wall, the inferior wall or floor is thinned in a similar manner. The facial nerve is skeletonized to the tympanic segment and elevated out of the fallopian canal with sharp dissection. The nerve is sharply dissected with a cuff of tissue at the stylomastoid foramen, as in the total rerouting technique. The facial nerve is temporarily elevated laterally to allow exposure to the jugular foramen and the pars nervosa, containing cranial nerves IX, X, and XI. After tumor removal, the facial nerve is returned to its approximate position. A 1-mm burr is then used to create anchor holes at the lateral extent of the bony canal (one in the floor, two in the posterior wall, and one in the anterior wall). The external canal skin is secured to its position with 3-0 sutures. The sutures are placed into the thick subcutaneous tissue, rather than the skin. The canal is packed with antibiotic ointment–impregnated gauze strip for 1 week. Stenosis of the canal has not occurred in more than 30 partial rerouting procedures. Anchoring the canal skin to the bony canal prevents the formation of external canal mastoid fistula.

Nerve Repair

Whenever the continuity of the facial nerve has been disrupted by traumatic injury, iatrogenic injury, or tumor invasion, every effort should be made to restore its continuity. In some instances, an end-to-end reapproximation can be accomplished, but if any tension occurs at the anastomotic site, an interposition nerve graft confers a better chance of allowing facial movement. All nerve repair techniques produce synkinesis, but sphincteric function of the mouth and eye usually are restored. Newer microsuture techniques and instrumentation should be used to enhance return of function.

In general, the injured ends of the nerve should be freshened at a 45-degree angle. Experimental evidence has shown that cutting the nerve at this angle exposes more neural tubules, with consequently improved regrowth of the nerve.[16] In addition, a fresh razor blade induces less crush to the nerve than does a scalpel blade or scissors. Milesi[17] advocates removing a portion of the epineurium before suturing to prevent connective tissue growth at the anastomotic site. We have found that the perineurium of cranial nerve VII does not hold 10-0 sutures, and attempting to suture it increases trauma to the neural tubules. If the epineurium is cleaned from the end of the nerve for approximately only 0.5 mm, sutures can still be placed in the epineurium for reapproximating the nerve segments. Three or four sutures of 10-0 nylon are placed with jeweler's forceps or longer instruments (19-cm microforceps) for anastomosis in the cerebellopontine angle. At the brainstem, one or two sutures are placed. Within the fallopian canal, a nerve graft can be interposed without sutures if there is no chance of nerve end movement.

When an interposition graft is required, the great auricular nerve or the sural nerve is the preferred graft donor site. The great auricular nerve is readily available near the operative field if it is not involved in resection of a neoplasm and has approximately the same diameter as that of the facial nerve. It is easily located midway and perpendicular to a line drawn between the mastoid tip and the angle of the mandible. If a graft longer than 8 to 10 cm is required, the sural nerve should be used. The sural nerve has another advantage in that the peripheral portion of the nerve has many branches that can be used to reconstruct the branching pattern of the facial nerve. Little discomfort is associated with removal of the sural nerve, because it provides only a small area of sensation to the lateral lower leg. The sural nerve is found immediately posterior to the lateral malleolus, along the saphenous vein. The nerve graft should be 10% to 20% larger in diameter than the facial nerve and long enough to ensure tension-free anastomosis.

Facial Nerve Tumors

Tumors (both benign and malignant) can affect the facial nerve in the intracranial cavity, within the temporal bone, and in the parotid gland. Approximately 5% of cases of facial nerve dysfunction are due to the presence of a tumor. It is essential to differentiate intrinsic from extrinsic facial nerve tumors (e.g., a primary facial nerve tumor versus tumor contiguous with the facial nerve or metastatic disease). Extrinsic tumor involvement is much more common than intrinsic tumor involvement. Numerous benign and malignant neoplasms may occur in and around the temporal bone. Within the temporal bone itself, skull base tumors and metastases from the breast and lung are common neoplastic causes of facial paralysis in adults, whereas hematologic malignancies (leukemia, lymphoma) are common in children.[18] Management of these lesions is beyond the scope of this chapter. It is not possible to list all of the neoplasms, but common ones include facial schwannomas, congenital cholesteatomas, hemangiomas, glomus tumors, vestibular schwannomas (acoustic neuromas), squamous cell carcinomas, and parotid neoplasms. The following discussion is concerned primarily with those lesions of the facial nerve proximal to the stylomastoid foramen.

The classic symptom associated with tumors involving the facial nerve is a progressive paralysis of the face. In some benign lesions, this progression is extremely slow; months or even years may elapse before the paralysis becomes complete. The cause of a facial palsy progressive beyond 3 weeks after onset but with no return of function by 6 months is presumed to be a tumor until proven otherwise. Benign tumors produce facial paralysis by compressing the facial nerve, whereas malignant lesions invade the nerve itself. Therefore, in benign tumor removal, it is sometimes possible to dissect the mass away from the nerve without damage to the nerve itself. In dealing with malignant neoplasms, it is necessary to resect the nerve with the tumor and then perform a reconstruction of the nerve.

Early diagnosis of facial paralysis from a tumor is dependent on a high index of clinical suspicion. In addition to a slowly progressive paralysis, several other clinical features should heighten suspicion for a tumor involving the facial nerve. Twitching of the facial nerve in association with facial palsy is not seen with Bell's palsy. In addition, recurrent palsy also may be associated with a tumor. Pain, although frequently a feature of Bell's palsy or Ramsay Hunt syndrome, also is often a symptom with tumors involving the facial nerve. Involvement of other cranial nerves in addition to the facial nerve should raise concern that a neoplasm is present. A predilection for neoplasms to occur at the geniculate ganglion area, possibly owing to this area's embryologic diversity, has been suggested.[3] Evaluation for a neoplastic etiology for a facial palsy should include radiologic imaging (with both CT and MRI scans).

Acoustic neuromas are benign tumors and are the most common lesions of the internal auditory canal and cerebellopontine angle. Facial paralysis is an unusual manifestation of these tumors and generally signifies an advanced stage of tumor growth. Rarely does an acoustic neuroma actually invade the facial nerve. It also is possible for a patient with an acoustic neuroma and facial palsy to have a concomitant Bell's

palsy as the true etiology of facial nerve dysfunction. In the absence of nerve sheath invasion, the facial nerve generally appears to tolerate gradual pressure stresses well. Facial dysfunction may also occur from local vascular compromise.[19]

Nerve sheath and vascular neoplasms make up the greatest percentage of intrinsic facial nerve tumors (although they are relatively rare as a group). These tumors typically are facial schwannomas (neuromas) but also may include meningiomas, hemangiomas, and glomus tumors.[18] These tumors may manifest relatively early with facial weakness.[19] Overall, facial nerve schwannomas are uncommon, slow-growing neoplasms arising from the nerve sheath, and they may occur anywhere from the cerebellopontine angle to the peripheral branches of the facial nerve.[20] A majority of facial nerve schwannomas are intratemporal, most often involving the labyrinthine segment and geniculate ganglion.[20,21] A retrospective review demonstrated that facial nerve schwannomas were more likely to involve multiple segments than a single segment.[21] One of the largest series of facial nerve tumors to date was published by McMenomey and colleagues in 1994.[22] They reviewed their experience with 32 primary facial nerve tumors between 1975 and 1992. Preoperatively, 38% were thought to be acoustic neuromas.

A facial nerve schwannoma may be misdiagnosed as an acoustic neuroma, especially when the tumor does not enter the meatal foramen or fallopian canal and is instead confined to the internal auditory canal.[22,23] Even with high-resolution MRI, it may be difficult to distinguish preoperatively between an acoustic neuroma and a facial schwannoma. Beyond the clinical examination and clinician suspicion, no useful preoperative evaluation tools are available that can definitively identify the precise nerve of origin of intracanalicular tumors. This limitation emphasizes the need to fully inform the patient preoperatively.[23]

Treatment decisions must be made based on the patient's desires, age, degree of facial function, tumor location, and hearing status.[8,24] The goal in the management of these tumors is to maximize long-term facial nerve function while minimizing morbidity. At most centers, the most common mode of treatment is tumor resection with grafting. Observation is another option for tumors that are not producing facial paresis or are generating minimal symptoms (House-Brackmann grade II). It also is possible that with observation or expectant management, complications such as total hearing loss may occur, particularly when the tumor involves the labyrinthine and internal auditory canal portions of the nerve.[25] Unfortunately, a majority of patients undergoing resection and grafting will have additional facial nerve deficits in the immediate postoperative period, and the long-term results with grafts generally are characterized by poor recovery of forehead motion and mass motion (grade C on the Repaired Facial Nerve Recovery Scale [RFNRS][26]).

A review of the records at House Ear Institute between 1977 and 1994 showed that 93 patients were diagnosed with facial neuromas and 3031 were diagnosed with acoustic neuromas.[27] In four patients in whom the diagnosis was made during surgery, the tumor was not completely resected.[27] Two of the patients underwent decompression using an middle cranial fossa or translabyrinthine approach. Two patients underwent a retrosigmoid craniotomy, one of whom also underwent decompression; for the other, postoperative management consisted of observation of her tumor. Follow-up for these patients ranged from 24 to 62 months. In three of the four tumors, no growth was noted on the MRI scan during the follow-up period (the other showed a 6-mm growth over 5 years). In one patient (who underwent translabyrinthine decompression), facial nerve function improved from grade V preoperatively to grade II postoperatively.

The medical records of 21 patients with facial nerve tumors treated between 1982 and 2002 at the University of Iowa Hospitals and Clinics were retrospectively reviewed. The ages of the patients ranged from 13 to 76 years. Follow-up ranged from 1 month to 22 years.

In 2 of the 21 patients, the tumor was identified on an MRI scan obtained for other medical reasons. Both have normal facial nerve function (House-Brackmann grade I) and undergo periodic MRI. One has been observed for longer than 20 years and continues to have grade I facial nerve function. Twenty-one procedures were performed on the other 19 patients. Of the 21 procedures performed, 11 consisted of resection followed by interposition grafting. Patients in this group presented with conditions classified as House-Brackmann grade IV or worse. All grafting was done using the greater auricular nerve. The other 10 procedures involved decompression, debulking, or both. *Decompression* included removal of the bony confines of the facial nerve either in the internal auditory canal or in the fallopian canal at the site of the tumor and some distance proximal and distal to the tumor. *Debulking* involved removal of portions of the tumor, with the use of intraoperative facial nerve monitoring to reduce the likelihood of inadvertent damage to normal facial nerve fibers.

Table 171-3

Repaired Facial Nerve Recovery Scale (RFNRS)

Score	Function
A	Normal facial function
B	Independent movement of eyelids and mouth, slight mass motion, slight movement of the forehead
C	Strong closure of eyelids and oral sphincter, some mass motion, no forehead movement
D	Incomplete closure of eyelids, significant mass motion, good tone
E	Minimal movement of any branch, poor tone
F	No movement

Facial nerve function was graded using the House-Brackmann scale for the observation and decompression-debulking group. However, owing to the limitations and inadequacies of this grading scale for nerve resections, a different scale, the RFNRS, was used to grade nerve function in the resection and grafting group (Table 171-3). A majority of the tumors in this series were facial nerve schwannomas. All 10 of the tumors in the decompression-debulking group were schwannomas, whereas 7 of the tumors in the resection group were schwannomas. Tumors in the resection group also included 3 hemangiomas and 1 meningioma. In the decompression-debulking group, five patients had grade I function. Three patients had grade II function, one patient had grade III function, and one had grade IV function. None of the patients in this group have had grade V or VI function.

In the resection and grafting group, the best facial function noted postoperatively was grade C, which is roughly equivalent to House-Brackmann grade III, in six patients. Three patients had grade D function. One patient had grade E function and one grade F function. Of significance, none of these patients achieved a preferred grade A or B function.

Observation of intrinsic facial nerve tumors is a possible management approach, especially for patients with House-Brackmann grade I or II facial function. Surgical decompression is an option for patients with House-Brackmann grade II or III facial function. Resection with grafting is recommended for those with grade IV function or worse. Conservative management with either observation or decompression often is an appropriate option, because the best facial nerve function result after resection and grafting is grade C on the RFNRS, owing to the presence of mass motion. Nonetheless, treatment is individualized.

CHAPTER ONE HUNDRED AND SEVENTY-TWO

Rehabilitation of Facial Paralysis

James M. Ridgway

Roger L. Crumley

Jason H. Kim

Key Points

- Paramount to the rehabilitation of facial nerve paralysis is a complete understanding of the nature of the injury, extent of the defect, viability of remaining facial nerve segments, integrity of potential donor nerves and tissues, and the overall patient's health status as well as personal desires and expectations for rehabilitation.
- A detailed history and physical examination should include a description of the mechanism of the injury, time of onset, duration of symptoms, previous surgery or radiation therapy, speech and swallowing function, and previous treatment and rehabilitation.
- Division of the face into upper, middle, and lower thirds allows for a more precise characterization of nerve defects and potential therapeutic options.
- Management of facial paralysis is dependent on the specific cause of the paralysis. Options for facial nerve rehabilitation include spontaneous nerve regeneration (observation), facial nerve neurorrhaphy, facial nerve cable graft, nerve transposition, muscle transposition, microneurovascular transfer, and static procedures.
- EMG is indispensable in determining the existence of denervation atrophy or subclinical innervation. EMG is the single most important test for determining the type of operative procedure to be performed.
- An operative electric nerve stimulator may be used only in acute injuries to identify severed distal nerve segments. Wallerian degeneration with impairment of nerve conduction has occurred by 72 hours after injury, and the surgeon is left to rely on visual identification after this point in time.
- The most desired source for rejuvenation of the paralyzed face is the ipsilateral facial nerve.
- Early protection of the eye in the setting of facial nerve paralysis is of the highest priority, because failure to recognize and treat eyelid dysfunction will result in devastating ocular complications that are entirely preventable.
- Tension-free repair of the facial nerve is critical to the success of nerve anastomosis. When operative circumstance does not permit such an end-to-end anastomosis, cable or interposition nerve grafting is the desired surgical approach to facial muscle reinnervation.
- When grafting to the proximal facial nerve segment is not an option in rehabilitation, attention is then shifted to the muscle (masseter or temporalis) or nerve (hypoglossal) transfer procedure.
- Static techniques are best used in debilitated patients with limited prognostic survival and in those for whom nerve or muscle is not available for dynamic procedures.
- Patients with incomplete recovery from facial nerve paralysis typically present with hyperkinetic, uncoordinated mass facial movements known as synkinesis. Botulinum toxin has dramatically improved the management of this condition and is the current first-line therapy.

Dealing with the consequences of unilateral facial paralysis usually is a devastating emotional ordeal for the patient. The ability to restore symmetry and motion to patients afflicted with facial paralysis is one of the most rewarding skills of the well-trained reconstructive surgeon. This chapter discusses rehabilitation of facial nerve injuries. Many of the diagnostic considerations and surgical techniques described are applicable to otogenic paralyses (intratemporal), as well as injuries and diseases that affect the parotid and facial portions of the facial nerve.

The facial nerve, once damaged, rarely attains full recovery of function. Given the challenges to the patient, counsultations regarding facial nerve paralysis require a clinician's fullest thought and compassion. A realistic approach yields the rewards of patient compliance, understanding, satisfaction, and acceptance of reality. A recent review of all state and federal civil trials alleging malpractice and facial nerve paralysis demonstrates the importance of careful explanation and documentation, as well as the importance of good patient rapport and bedside manner in preventing lawsuits.[1]

Patient Assessment

Complete patient assessment is critical to attain optimal rehabilitation of facial paralysis. It is critical to properly understand the nature of the injury and the resulting defect, to know the viability of the proximal

and distal facial nerve segments, to properly assess the viability of potential donor nerves and facial musculature, and to thoroughly assess both the patient's health status and personal desires for rehabilitation.

An outline of assessment of facial nerve paralysis is presented in Box 172-1.

Box 172-1

Assessment of Facial Nerve Paralysis

History

Type of injury
Time since injury
Age, overall health, and life expectancy
Radiation therapy (past or planned)
Nutritional factors
Previous operative report

Physical Examination

Previous incisions and scars
Integrity of trigeminal, vagal, and hypoglossal nerves
Facial motion (e.g., complete versus partial paralysis)
Status of eye (e.g., lagophthalmos, ectropion)
Facial tone, structure (e.g., habitus)

Testing/Imaging

Electromyography: indicated in all patients who have had paralysis for more than 1 year
Computed tomography and magnetic resonance imaging of temporal bone and parotid: indicated if there is any question about the cause of paralysis

Assessment of the Deformity

Physical examination includes complete head and neck examination with attention to cranial nerve function and the presence of functional masseter and temporalis muscles. The degree of facial nerve function is recorded using the House-Brackmann Facial Grading System[2] (Table 172-1). A number of facial nerve grading scales have been developed, but the House-Brackmann scale was adopted by the Facial Nerve Disorders Committee of the American Academy of Otolaryngology–Head and Neck Surgery in 1985 because of its reproducibility and ease of use.[2] This scale is useful for evaluation of overall function, but it is insufficient for precise assessment of defects affecting one or more branches of the facial nerve, and it does not allow precise measurement of effectiveness of treatments isolated to one region of the face. Therefore, the examination should assess deformity of the upper, middle, and lower thirds of the face independently. This approach allows more precise characterization of defects, aids the decision-making process for rehabilitation, and allows more precise assessment of treatment results. Facial tone also is noted, as is the presence of any reinnervation. Thorough assessment of the eye also is performed. Visual acuity, corneal integrity, eyelid closure, tearing, Bell's phenomenon, lagophthalmos, lower lid laxity, position of the lacrimal puncta, and eyebrow position are noted. Nasal examination focuses on the position of the ala and nasal septum and the presence or absence of nasal obstruction. Oral competence and height and position of the lower lip are carefully reviewed. In long-term paralysis (of more than 1 year's duration), electromyography (EMG) of the facial muscles is performed before reinnervation procedures. Occasionally, muscle biopsy provides additional information about the presence of viable muscle for innervation. If nerve fibrosis is suspected, nerve biopsy occasionally is indicated.

Another important component of the assessment is evaluation of the patient's smile pattern. The smile is created by the muscles of the lips, and smile patterns can be classified into one of three types.[3] The "Mona Lisa" smile is the most common smile pattern (67%). It is

Table 172-1

House-Brackmann Grading System

Grade	Description	Characteristics
I	Normal	Normal facial function in all areas
II	Slight	Appearance: slight weakness noticeable on close inspection; may have very slight synkinesis At rest: normal symmetry and tone Forehead motion: moderate to good function Eyelid closure: complete with minimal effort Mouth motion: slight asymmetry
III	Moderate	Appearance: obvious but not disfiguring weakness between the two sides; noticeable but not severe synkinesis, contracture, and/or hemifacial spasm At rest: normal symmetry and tone Forehead motion: slight to moderate movement Eyelid closure: complete with effort Mouth motion: slightly weak with maximal effort
IV	Moderately severe dysfunction	Appearance: obvious weakness and/or disfiguring asymmetry At rest: normal symmetry and tone Forehead motion: none Eyelid closure: incomplete Mouth motion: asymmetric with maximal effort
V	Severe	Appearance: only barely perceptible motion At rest: asymmetric Forehead motion: none Eyelid closure: incomplete Mouth motion: slight movement
VI	Total	No facial function

From House JW, Brackmann DE. Facial nerve grading system. *Otolaryngol Head Neck Surg*. 1985;93:146.

dominated by action of the zygomaticus major muscle: The corners of the mouth move laterally and superiorly, with subtle elevation of the upper lip. The canine smile (31%) is dominated by levator labii superioris action, appearing as vertical elevation of the upper lip, followed by lateral elevation of the corner of the mouth. The least common smile is the full denture smile (2%), or "toothy smile," produced by simultaneous contraction of the elevators and depressors of the lips and angles of the mouth. Knowledge of facial muscle anatomy and the smile pattern exhibited by the patient is important in considering rehabilitation techniques other than nerve grafting to recreate a balanced facial appearance at rest and the simulation of a symmetric smile.

Considerations in Facial Nerve Rehabilitation

A number of factors come into play in designing a management plan for the patient with facial paralysis. In clinical situations requiring facial reanimation, the technique used often depends on the availability of a viable proximal facial nerve.

Tumor ablation with facial nerve sacrifice (as in radical parotidectomy for parotid malignancy) dictates immediate facial nerve restitution, usually by cable grafting. When the nerve's continuity and viability are in question, however, as may be seen during and after cerebellopontine angle surgery, it is wise to wait 9 to 12 months before an extratemporal facial nerve operative procedure is undertaken. Hence, no modality is universally appropriate for all afflictions of facial nerve function. Static procedures generally are used when no viable reinnervation options exist but also can be integrated with dynamic procedures to provide immediate restoration of facial symmetry.

Generally, however, the order of preference for rehabilitation procedures is as follows:

1. Spontaneous facial nerve regeneration (observation)
2. Facial nerve neurorrhaphy
3. Facial nerve cable graft
4. Nerve transposition
5. Muscle transposition
6. Microneurovascular transfer
7. Static procedures

Time since Transection

A chronic, long-standing paralysis with complete muscle degeneration poses several problems with regard to eventual reinnervation surgery. The facial muscles may undergo denervation atrophy. Severe atrophy renders the reasonably normal muscles incapable of reinnervation and contraction. Such severe atrophy may occur after 18 months of complete denervation, although in some clinical situations, muscles have been known to persist inexplicably for many years without incurring such atrophy.[4] EMG is the most helpful method for assessing facial muscle atrophy and is therefore a preoperative prerequisite for all reanimation candidates if the paralysis is of more than 12 months' duration. The presence of nascent, polyphasic, or normal voluntary action potentials in a patient with facial paralysis indicates the occurrence of reinnervation. If more than 12 months have passed since the facial nerve injury, the situation can be assumed to be stable, and an attempt at surgical reanimation may be warranted. Within the first 12 months, however, the presence of potentials may mean that reinnervation is occurring and that facial movements may return in the next few months. Reanimation surgery should therefore be postponed. Fibrillation or denervation potentials mean that the EMG electrode is positioned in denervated muscle. This is an optimal situation for cable nerve grafting or, when no viable proximal facial nerve is available, for hypoglossal-facial anastomosis.

One of the most significant EMG findings is electrical silence, reflecting denervation atrophy of the facial muscles. The surgical implication is that nerve grafting or transfer is futile and therefore contraindicated. If the facial muscles are absent or atrophied, muscle transfers are indicated.

Another effect of time includes endoneural scarring within distal nerve segments. It is not known whether endoneural scarring acts as an impediment to nerve regeneration, but when associated with muscular atrophy, it probably further precludes nerve grafting or transfer.

Presence of Partial Regeneration

Partial regeneration often is overlooked but is extremely important in determining which operation to perform. If the facial nerve has undergone enough regeneration to permit a few axons to reach the facial muscles, this partial innervation may be sufficient to preserve the muscles for many years, even though they may be totally paralyzed. In these clinical circumstances, results with hypoglossal-facial anastomosis, which generally is preferable to muscle transfer, will be optimized.

Status of the Proximal and Distal Facial Nerve

The optimal source for rejuvenation of the paralyzed face is the ipsilateral facial nerve. Anastomosis or grafting to the ipsilateral nerve has no donor consequence (other than the minor hypesthesia or anesthesia from the harvesting of a nerve graft) and facilitates natural voluntary and involuntary control. Exceptions to this general rule are those cases in which the patient needs prompt relief from corneal exposure or drooling, and a tissue transfer or sling technique may be preferred because its effects are immediate.

Accordingly, the integrity of the proximal facial nerve is critical. As with other motor nerves, no reliable electrical tests exist to confirm the viability of the proximal nerve when it is discontinuous with its distal portion. Factors that affect proximal nerve viability and are therefore important considerations in the clinical evaluation include (1) nature of the nerve injury (e.g., clean transection versus crush), (2) location of injury (proximal versus distal), (3) age (younger nerves tend to regenerate more quickly and fully), (4) nutritional status (which directly affects nerve regeneration), and (5) history of irradiation (which may impede neural regeneration).

The facial nerve distal to the injury site serves as a conduit for neural regeneration to the facial muscles after neurorrhaphy, grafting, or hypoglossal-facial anastomosis. With acute injuries (incurred less than 72 hours previous), the electrical stimulator may be used to identify the distal nerve and the muscular innervation of distal branches. After this "golden period," however, the surgeon must rely on visual identification of the divisions and branches of the distal nerve, because the capability of being stimulated electrically generally is lost after approximately 72 hours. For this reason, transected nerve branches in trauma or tumor cases should be tagged for identification by placing a small colored suture around or adjacent to each nerve branch. Any anatomic or surgical landmarks should be precisely dictated in the operative note. If no suture markers are available, and the golden period has elapsed, careful surgical searching (preferably with use of loupes or an operating microscope) may reveal each of the divisions or branches of the facial nerve. A topographic map is essential in guiding the dissection. A review by Bernstein and Nelson[5] describes the variability with which these branches are placed. The following landmarks are helpful (Fig. 172-1).

- The pes anserinus can be found 1.5 cm deep to a point 1 cm anterior and 2 cm inferior to the tragal cartilage.
- The superior division courses from the pes anserinus to the lateral corner of the eyebrow, convex posterosuperiorly (see Fig. 172-1). Bernstein and Nelson[5] stressed that these temporal branches may be multiple and reach as far posteriorly as the superficial temporal vessels.
- The buccal branch courses superiorly and then anteromedially, passing 1 cm inferior to the inferior border of the zygomatic arch (see Fig. 172-1).
- The marginal mandibular branch passes from the pes anserinus directly over the angle of the mandible and then under the inferior

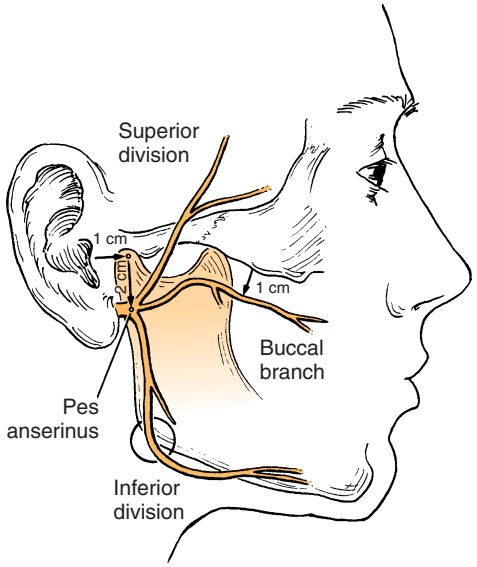

Figure 172-1. Topographic map of distal facial nerve anatomy, useful as a guide in finding nonstimulatable nerve branches for grafting. Pes anserinus is 2 cm inferior to a point 1 cm anterior to tragus. Marginal mandibular branch courses from the pes anserinus to the angle of the mandible: buccal branch parallels the zygomatic arch 1 cm below its inferior border. Superior division arcs from pes anserinus toward lateral end of the eyebrow, under a line that is convex superiorly. *(From House JW, Brackmann DE. Facial nerve grading system.* Otolaryngol Head Neck Surg. *1985;93:146.)*

border of the mandible for approximately 3 cm. It then crosses above the mandible at the level of the facial vessels. Any of several anatomic variations may exist, necessitating ingenuity in nerve grafting. When the facial nerve trunk and pes anserinus are intact, a cable graft (or hypoglossal nerve) should be sutured to that portion of the main nerve trunk. However, certain injuries and surgical procedures may sacrifice important individual portions of the nerve, requiring selective routing of reinnervation to specific divisions. The order of priority for reinnervation of facial nerve branches is as follows: (1) buccal and zygomatic branches (equal), (2) marginal mandibular, (3) frontal, and (4) cervical (the last may be disregarded or excluded).

As an example of selective routing, when a parotid tumor operation results in excision of the pes anserinus and the proximal facial branches, a branched nerve graft may be placed to reinnervate the zygomatic and the buccal branches, excluding unimportant branches. Fisch[6] advises clipping branches of cervical branches in order to route innervation to the more important portions of the face. Data confirming the efficacy of this technique, however, are very limited.

If no nerve branches are found, and EMG shows that denervated facial muscles are present, the nerve graft may be sutured directly to the muscles targeted for reinnervation (muscular neurotization). In these instances, the most important muscles are those of the midface (zygomaticus major and minor, levator labii superioris) and orbicularis oculi muscles. Reinnervation will not be as complete as in routine nerve grafting because the regenerating axons must form new connections to the old motor endplates, or they must create their own.[7]

Viability of Facial Muscles

Four types of EMG responses are observed[8]:

Normal voluntary action potentials indicate that functioning motor axons have connections with and are stimulating motor units of facial muscle.

Polyphasic potentials are seen during reinnervation and may precede visible evidence of reinnervation.

Denervation or *fibrillation potentials* indicate that otherwise normal denervated muscle exists.

Electrical silence, with no potentials seen, indicates atrophy or congenital absence of muscle, provided that the electromyographer has positioned the electrode correctly.

Donor Consequences

Many surgical procedures designed for facial reanimation borrow neural elements or signals from other systems (i.e., the hypoglossal and trigeminal systems). The consequences of sacrificing the donor nerve (known as donor deficit) are most important in planning for the overall needs of the patient. Certainly, the surgeon must assess the donor nerve preoperatively in all cases. The hypoglossal nerve must be tested for strength and vitality before it is transected and anastomosed to the distal facial nerve. Similarly, the trigeminal nerve must be intact and functional when its muscles, either masseter or temporalis, are considered for transposition into the facial muscle system.

The donor effects of facial reanimation surgery may be quite detrimental to the patient's welfare. For example, a patient with previous hypoglossal nerve injury on the opposite side could become an "oral cripple" if the remaining hypoglossal nerve were to be transected for use in a XII-VII anastomosis.

The ideal reanimation procedure is one that yields the following results: (1) no donor deficit; (2) immediate restitution of facial movement; (3) appropriate involuntary emotional response; (4) normal voluntary motion; and (5) facial symmetry. No currently available operative procedure satisfies all of these parameters. In fact, even with a bacteriologically sterile and precise surgical transection and immediate microsurgical repair of the facial nerve, completely normal neurologic function cannot be restored. Therefore, the surgeon must have a clear understanding of all operations available, including potential outcomes and sequelae.

Status of Donor Nerves

The hypoglossal nerve is the most frequently used nerve source for transfer. Reflex and physiologic similarities between the hypoglossal and facial nerves have been described.[9] The integrity of the hypoglossal nerve must be determined before it is transferred for reinnervation. Irradiation of the brainstem, lesions of the skull base and hypoglossal canal, and surgical procedures of the upper neck may affect the integrity and function of this nerve.

The trigeminal nerve has been used for facial reanimation in many ways. The methods currently used most often involve masseter or temporalis muscle transfer (necessitating that the motor portions of the trigeminal nerves be intact). Palpation of the muscle during jaw clenching confirms whether the muscle is functional.

The cross-face nerve graft procedure (faciofacial anastomosis) initially was thought to be the most appropriate and ingenious facial reanimation procedure.[10,11] The procedure is unique in that it borrows appropriate neural input from the contralateral normal side and routes it to the paralyzed side. Such a procedure requires a fully intact (contralateral) facial nerve.

Age

The proximal neuron's ability to regenerate declines with time because of denervation and aging-related changes. The etiologic mechanism probably involves diminishing regenerative vitality of the perikaryon (cell body), although peripheral scarring may play a role. The clinical implication is that facial reanimation surgery should always be performed as soon as possible, provided that the operative procedure does not interfere with or injure existing innervation or ongoing reinnervation.[12]

Health Status

Among patients with diabetes, regeneration of injured nerves is notoriously poor. Microangiopathy is an additional factor that may affect the grafted segment. These factors do not preclude a nerve graft procedure in a diabetic patient, but when combined with radiation, advancing age, and other factors, they may cause the surgeon to con-

sider muscle transfer or a suspensory operation, rather than a neural anastomosis.

Prior Radiotherapy

Radiotherapy, a necessary component of treatment for certain salivary gland malignancies, appears to have a deleterious effect on reinnervation through facial nerve grafts. McCabe[13] demonstrated satisfactory muscle reinnervation from grafting despite irradiation in animals. These investigators subsequently have documented return of facial function in nine patients who received post-grafting radiotherapy. McGuirt and McCabe[13] and Conley and Miehlke[14] have published reports indicating that facial nerve grafts function well even though irradiated, and that nerves are among the most radioresistant tissues of the human body. Pillsbury and Fisch[15] found that radiotherapy reduced the average outcome from 75% to 25% of nerve function recovery in a review of 42 grafted patients. Irradiation probably affects the neovascularization of the nerve graft by decreasing vascularity of the tissue bed and probably injures the proximal and distal segments of the nerve as well. The most radiosensitive portion of the nerve—the pontine nucleus—should be assessed to determine whether it was present in the field of irradiation.

Congenital Paralysis

In a series of 95 infants with neonatal paralysis, Smith and associates[8] found 74 of the cases to be secondary to intrauterine injury or birth trauma, whereas 21 were thought to be congenital. These infants should be studied with nerve excitability and EMG testing early in life to ascertain the status of nerves and muscles. Most patients with injury-related neonatal paralysis recover rapidly, whereas the paralysis associated with other congenital anomalies (such as Möbius syndrome) is permanent. Nerve exploration or transfer generally is futile in the latter cases.

Early Care of Facial Nerve Injury

Failure to recognize and treat acute eyelid dysfunction will result in devastating ocular complications. The ability to prevent, diagnose, and treat paralytic eyelid sequelae before major complications occur is essential in the management of any patient with facial paralysis. An important point is that the outcome of the eyelid paralysis is directly related to patient education and compliance.

Eye Protection: Evaluation and Treatment of Eyelid Paralysis

Paralysis of the orbicularis oculi results in exposure and drying of the cornea. Patients at increased risk for exposure keratitis may be identified by applying the acronym BAD—*a*bsence of Bell's phenomenon, corneal *a*nesthesia, and history of *d*ry eye. An inability to protect the cornea is the result of incomplete eye closure, preventing effective distribution of the tear film across the surface of the eye, and ectropion occurs because the atonic lower lid and lacrimal punctum fail to appose the globe and bulbar conjunctiva. This causes faulty eyelid closure and improper distribution of tears across the cornea.

Epiphora may result from failure of tears to enter the lacrimal punctum, secondary to pooling of tears due to ectropion and the loss of the orbicularis oculi tear-pumping mechanism. The response to abnormal corneal sensation may be reflex tear hypersecretion, which will further increase the epiphora.

Any patient with facial paralysis who demonstrates a poor Bell's phenomenon is at risk for the development of exposure keratitis. Eye pain may herald the onset of keratitis. In patients with diminished corneal sensation, however, exposure keratitis may asymptomatically progress to corneal ulceration. Accordingly, all patients with diminished orbicularis oculi function require ophthalmologic consultation.

Initial eye care is directed toward moisturizing the dry eye and preventing exposure. It is important to communicate to the patient the potential consequences of failure to protect the eye, in hopes of improved compliance. If the eyelid paralysis is temporary or partial, these local measures may be all that are necessary to adequately protect the eye. Regular use of artificial tears commonly is the first-line method used to keep the eye moist. Ointments also may be used, but they are less practical in the daytime because they tend to blur vision.

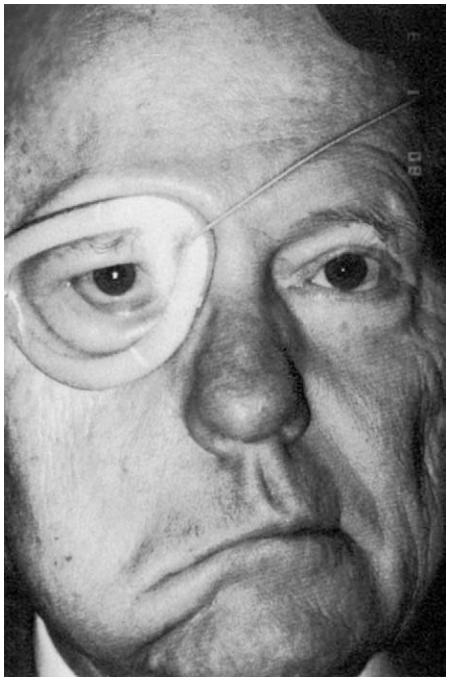

Figure 172-2. Occlusive bubble worn by a patient after acoustic neuroma surgery. The appliance has a foam rubber skin contact surface that is firmly attached to a thin Plexiglas lens. In our experience, patient compliance is relatively high with this type of device. *(Courtesy of Moisture Chamber, Pro-optics, Palatine, Illinois.)*

Lacriserts, contact lenses, and occlusive bubbles commonly are used, although patient compliance may be problematic[16] (Fig. 172-2). The eyelids frequently are patched or taped, but if incorrectly used, these methods may result in corneal injuries. Tape should not be placed vertically across the eyelashes, but applied horizontally above the eyelashes on the upper eyelid, or supporting the lateral canthal portions of the lower eyelid.[17] When an eye patch is used, care must be taken to ensure that the eye cannot open, because this would allow contact between the patch and the cornea.

Procedures to Treat Paralysis of the Lower Lid (Ectropion)

Tarsorrhaphy

The temporary lateral tarsorrhaphy is an expeditious and effective method for protecting the eye in patients with mild lagophthalmos and mild corneal exposure. A horizontal mattress suture of 7-0 silk or nylon is placed laterally to approximate the gray line (mucocutaneous junction) of the upper and lower lids. Tarsorrhaphy sutures will remain effective longer if they are placed through bolsters made of rubber (Robinson) catheters.

For longer-lasting protection, the lid adhesion tarsorrhaphy is preferred. The lid margin (gray line) of each lid is denuded 4 to 6 mm from the lateral canthus, and a similar suture technique is used to approximate the denuded mucocutaneous junctions of upper and lower lids (Fig. 172-3). Like the temporary lateral tarsorrhaphy, this procedure can be reversed if function returns. The cosmetic deformity of tarsorrhaphy and the availability of improved, alternative techniques to rehabilitate the eyelids have reduced the use of tarsorrhaphies.

Wedge Resection and Canthoplasty for Paralytic Ectropion

Wedge resection of all layers of the lower lid is a simple and expeditious procedure, but it can result in notching of the eyelid margin. A more effective option for lower lid laxity is the lateral canthoplasty, which is more reliable, with a less noticeable defect. Several techniques have been described for lid shortening and resuspension. They share the goal of

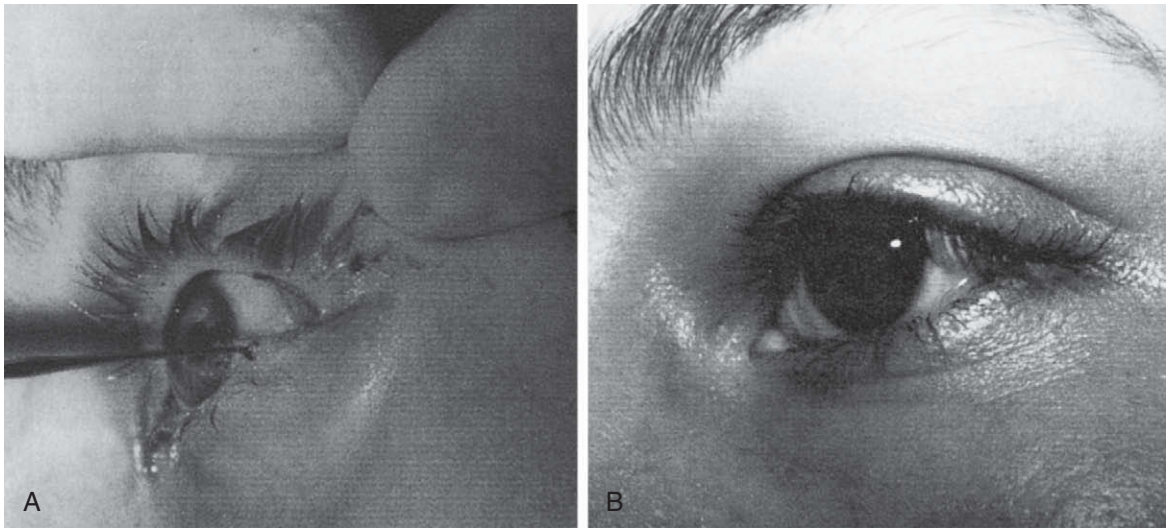

Figure 172-3. **A,** Tiny single skin hook being used to evert the lower lid for denuding of "gray line" (mucocutaneous junction). Note that a gray line of upper lid has been denuded. **B,** Healed tarsorrhaphy at 4 months. Increased eye closure may be achieved by extending the denudation and sutures medially.

eliminating laxity of the lateral canthal tendon by shortening or resuspending (or both) the tendon posteriorly behind and above Whitnall's tubercle.

The modified Bick procedure consists of lateral canthotomy and inferior cantholysis, followed by conservative resection of the lateral canthal tendon and fixation to the medial aspect of the lateral orbital wall above and posterior to Whitnall's tubercle.

The tarsal strip procedure described by Anderson and Gordy[18] modifies the previously described technique by denuding the conjunctiva over the lateral tendon and separating the posterior lamella and the tendon from the anterior lamella. The isolated tarsal strip is then suspended to the lateral orbital rim. In cases of severe ectropion, the lower lid punctum may be everted and displaced laterally after lateral canthoplasty. In these instances, a medial canthoplasty is used to restore the physiologic relationship of the punctum to the globe.[19,20] The lower lid also may be augmented with auricular cartilage to address inadequate support of the medial tarsal plate in cases not amenable to lateral tendon suspension alone.[21]

Procedures to Treat Paralysis of the Upper Lid (Lagophthalmos)

Weights, Springs, and Slings for Lagophthalmos

Gold weight insertion is extremely effective and very popular because of its reliability, minimal cosmetic deformity, and relative ease of insertion. The implant weight used is determined preoperatively by taping a weight to the upper eyelid and assessing eyelid closure. The smallest weight that allows comfortable eyelid closure and does not cause fatigue of the levator muscle is selected.

Under local anesthesia, an incision is made extending equally between the medial and middle thirds of the supratarsal crease, and the skin is elevated to the superior border of the tarsus. A pocket is formed immediately superficial to the tarsus to accommodate the dimensions of the weight. The weight is placed so that its inferior border is parallel to and just above the eyelash line. It is important to create a pocket directly on the tarsal plate, with care taken to preserve a thin cuff of tissue at the lid margin to prevent inferior extrusion of the implant. The implant is secured with clear nylon sutures superior and inferior to the tarsal plate, the orbicularis-levator complex is reapproximated, and the skin is closed.[16]

Gold weights have some disadvantages. A very low incidence of extrusion has been documented with their use even when they are inserted properly. In addition, weights depend on gravity and therefore do not effectively protect the cornea when the patient is supine, so a nighttime ointment is often required. If the weight is placed too far superior, it can result in paradoxical opening of the eye when the patient is in the supine position. Finally, the gold weight can occasionally be noticed by the casual observer as a bump in the eyelid.

Palpebral springs and silicone (Silastic) slings as described by Morel-Fatio and Lalardrie[22] and Arion,[23] respectively, also have been used for lagopththalmos. Silastic slings are used less frequently and are complicated by lateral ectropion.[24] Both types of implants share the disadvantage of extrusion, and they are more difficult to place than eyelid weights. Currently, titanium chain link implants are being used with greater frequency and with excellent results. These implants may be camouflaged to obtain a better cosmetic result, because they conform to the shape of the eyelid. Additionally, the titanium implants have been shown to result in less corneal astigmatism or cornea-altering effect on the globe itself than that typical with gold weights.[25]

Facial Nerve Grafting

Use of cable or interposition nerve grafts frequently is the desired approach to facial muscle reinnervation. The most common setting for this procedure is likely to be in combination with radical parotidectomy and facial nerve sacrifice. The clinical uses of interposition grafts are as follows: (1) radical parotidectomy with nerve sacrifice; (2) temporal bone resection; (3) traumatic avulsions; (4) cerebellopontine angle tumor resection; and (5) any other clinical situation in which viable proximal nerve can be sutured and distal elements of facial nerve can be identified. Tension-free repair is a critical element of successful nerve anastomosis. When tension-free apposition cannot be achieved using existing nerve ends, cable grafts are used.

Facial nerve grafting for acute causes such as parotid malignancy requires the surgeon to customarily identify the distal facial nerve trunk divisions or branches for the distal anastomosis. Nerve restitution should be performed at this time unless extenuating circumstances (e.g., anesthetic complications, intraoperative emergencies) rule out immediate grafting.[26] If grafting is not undertaken at the time of nerve sacrifice, it should be completed within 72 hours thereafter, so that the facial nerve stimulator may be used to identify the distal branches. Conversely, the nerve ends can be tagged for identification at a later time. When grafting is not done, the distal branch becomes nonstimulatable and thus much more difficult to locate and identify.

Surgical Planning

In planning the surgical procedure, the proximal site of nerve transection frequently is found to be in the intraparotid portion proximal to the pes anserinus. This location may present technical difficulties

because the proximal stump may not be adequate for technical ease in suturing. In other instances, the nerve may be transected at the stylomastoid foramen. If it is seen to be transected at the stylomastoid foramen, a mastoidectomy should be performed. Distal to the mastoid portion, the nerve's sheath merges with periosteum of the stylomastoid foramen and temporal bone, making this portion difficult to dissect free for suture. This difficult region exists roughly from 1 cm above to 1 cm below the stylomastoid foramen. Use of the mastoid portion of the facial nerve may require use of the longer sural or medial antebrachial cutaneous nerve, rather than the greater auricular nerve, for a cable graft.

Distally, several situations may be encountered that require some ingenuity in effecting reanimation. When the distal anastomotic site is at or proximal to the pes anserinus, a simple nerve-to-nerve suture will suffice. More frequently, however, after resection for parotid malignancy, several branches or divisions may require anastomosis. In such cases, priority must be given to the zygomatic and buccal branches, sometimes to the exclusion of other, less important facial nerve branches. Frequently, a two-branch graft can be prepared from the greater auricular nerve or the sural nerve. This situation favors suturing of one branch of the nerve graft to the buccal branch and the other graft branch to the zygomatic branch or superior division. This technique will direct innervation to the important orbicularis oculi muscle and the muscles of the buccal-smile complex (Fig. 172-4).

Choosing a Donor Nerve

Four of the nerves most commonly used are the greater auricular nerve, the sural nerve, cervical plexus, and the medial antebrachial cutaneous nerve. Each has distinctive advantages and limitations; the reconstructive surgeon should be familiar with each.

When harvesting the greater auricular nerve, tumor considerations mandate that the ipsilateral nerve not be used. Consequently, the opposite neck should be prepped and draped for harvesting the contralateral nerve in parotid malignancy cases. The nerve is easily identified, arising from the posterior surface of the sternocleidomastoid muscle at Erb's point and traveling obliquely along the sternocleidomastoid muscle toward the ear. The surgical landmarks are well defined: a line drawn from the mastoid tip to the angle of the mandible is then bisected by a perpendicular line that crosses the sternocleidomastoid muscle from inferoposterior to anterosuperior, passing toward the parotid gland. A small horizontal incision in an upper neck skin crease is made along the path of the nerve. The nerve is identified in the subcutaneous tissues and followed superiorly to the parotid gland dissecting each of the three branches, and inferiorly to the posterior border of the sternocleidomastoid muscle. The greater auricular nerve has several advantages: its size and fascicular pattern are similar to the facial nerve, it is easily harvested in familiar anatomy, and it has a favorable distal branching pattern for facial nerve grafting. Unfortunately, the nerve is limited to a maximum of 10 cm for grafting.

In patients who have undergone neck dissection or parotidectomy and in whom the greater auricular nerve is not a viable grafting option, the cervical plexus is the next ideal donor nerve. The cervical plexus can be harvested in the similar fashion to the greater auricular nerve, but requires a longer neck incision. The nerve plexus can be located just posterior and deep to the sternocleidomastoid muscle.

The sural nerve is also commonly used for facial nerve grafting. In contrast to the greater auricular nerve, the sural nerve is the longest donor nerve available, with up to 70 cm of graft available when all branches are dissected into the popliteal fossa. The donor site is located distant from the surgical resection, allowing a second team to simultaneously harvest nerve tissue. Donor site morbidity is low. However, caution should be exercised when working with diabetics or patients with peripheral vascular disease as ischemic pressure necrosis could result in the area of sensory deficit along the lateral aspect of the foot. The sural nerve is of larger diameter than the greater auricular nerve or the facial nerve, and it has more prominent connective tissue than the greater auricular nerve or medial antebrachial cutaneous nerve.

The sural nerve is formed by the junction of the medial sural cutaneous nerve and the peroneal communicating branch of the lateral sural cutaneous nerve between the two heads of the gastrocnemius muscle. The nerve lies immediately deep to and behind the lesser saphenous vein with multiple nerve branches arising near the lateral malleolus. A pneumatic tourniquet should be applied to the thigh and a transverse incision made immediately behind the lateral malleolus. "Stair-step" horizontal incisions along the course of the nerve provide appropriate exposure during the harvesting procedure. The nerve should be harvested immediately before grafting and placed in physiologic solution after débriding away any small pieces of fat or other soft tissue that might interfere with graft revascularization. At all times care is taken to avoid stretching the nerve.

The medial antebrachial cutaneous nerve has been described in the orthopedic literature for peripheral nerve repairs and is used in situ with forearm microvascular flaps for sensory innervation in head and neck cancer reconstruction. This nerve has several properties that warrant consideration for use in facial nerve reconstruction[27]: It has a consistent anatomy, traveling in the bicipital groove immediately adjacent to the basilic vein. Nerve diameter and branching pattern are similar to those of the facial nerve, and donor site morbidity is minimal with nerve harvest. Cheney[27] has described the relevant anatomy in detail.

All of the aforementioned donor nerves are sensory nerves used to lead motor nerve regeneration. This is important as harvesting a motor nerve for grafting material would certainly incur some degree of morbidity to the donor area or muscle. Although there may be theoretic difference between using a sensory nerve versus a motor nerve, further investigation is required to determine if this is of any biologic implication.

Surgical Technique

For the surgical technique of neurorrhaphy, interrupted sutures using 9-0 or 10-0 monofilament nylon are preferred. A straight and a curved pair of jeweler's forceps as well as a Castroviejo needle holder are satisfactory instruments for performing the anastomosis. Both ends of the nerve graft and the proximal and distal stumps should be transected cleanly with a fresh sterile blade.[13] For nerve trunk anastomosis, four simple epineural sutures will usually coapt the nerve ends accurately. However, obvious discrepancies in size or other epineural gaps should be closed with additional sutures. The needle should pass through epineurium only to avoid injury to the fascicular neural contents. The nerve graft should lie in the healthiest possible bed of supporting tissue, with approximately 8 to 10 mm of extra length for each anastomosis. Thus, the graft should lie in a somewhat "lazy S" configuration (see Fig. 172-4), which appears to minimize tension during healing. Suction drainage systems should be placed away from any portions of the nerve graft.

When one division is excised or injured and other portions of the nerve remain intact, it may be desirable to graft from a fascicle within the pes anserinus to a distal branch. To accomplish this, fascicular dissection is performed in parallel and along the plane of the nerve fascicles with curved jewler's forceps into the pes anserinus (Fig. 172-5). The distal buccal branch often has several small filaments, so it may be necessary to select the larger of these for distal anastomosis.

Approximation of the nerve ends using an acrylic glue has been described (Histacryl or cyano-butyl-acrylate)[28] with subsequent investigators revealing that neural anastomosis with tissue adhesive yields results similar to nerve suture. This technique is most helpful in the confined surgical considerations of the temporal bone rather than in distal facial anastomosis.[29] Others have described using biodegradable nerve tubules.

Following temporal bone resection, the nerve may be routed from the tympanic or the labyrinthine portions directly to the face through a bony window near the posterior root of the zygomatic arch. This will shorten the necessary length of the nerve graft. However, when using this technique it is important to ensure the nerve graft's protection from trauma at the temporomandibular joint if the joint is preserved. Conley and Baker[30,31] have reported excellent results using similar techniques.

Millesi[32] introduced interfascicular nerve repair, reasoning that the exact microsurgical approximation of nerve fascicles or fascicle groups may minimize synkinesis or mass movement. It is well known

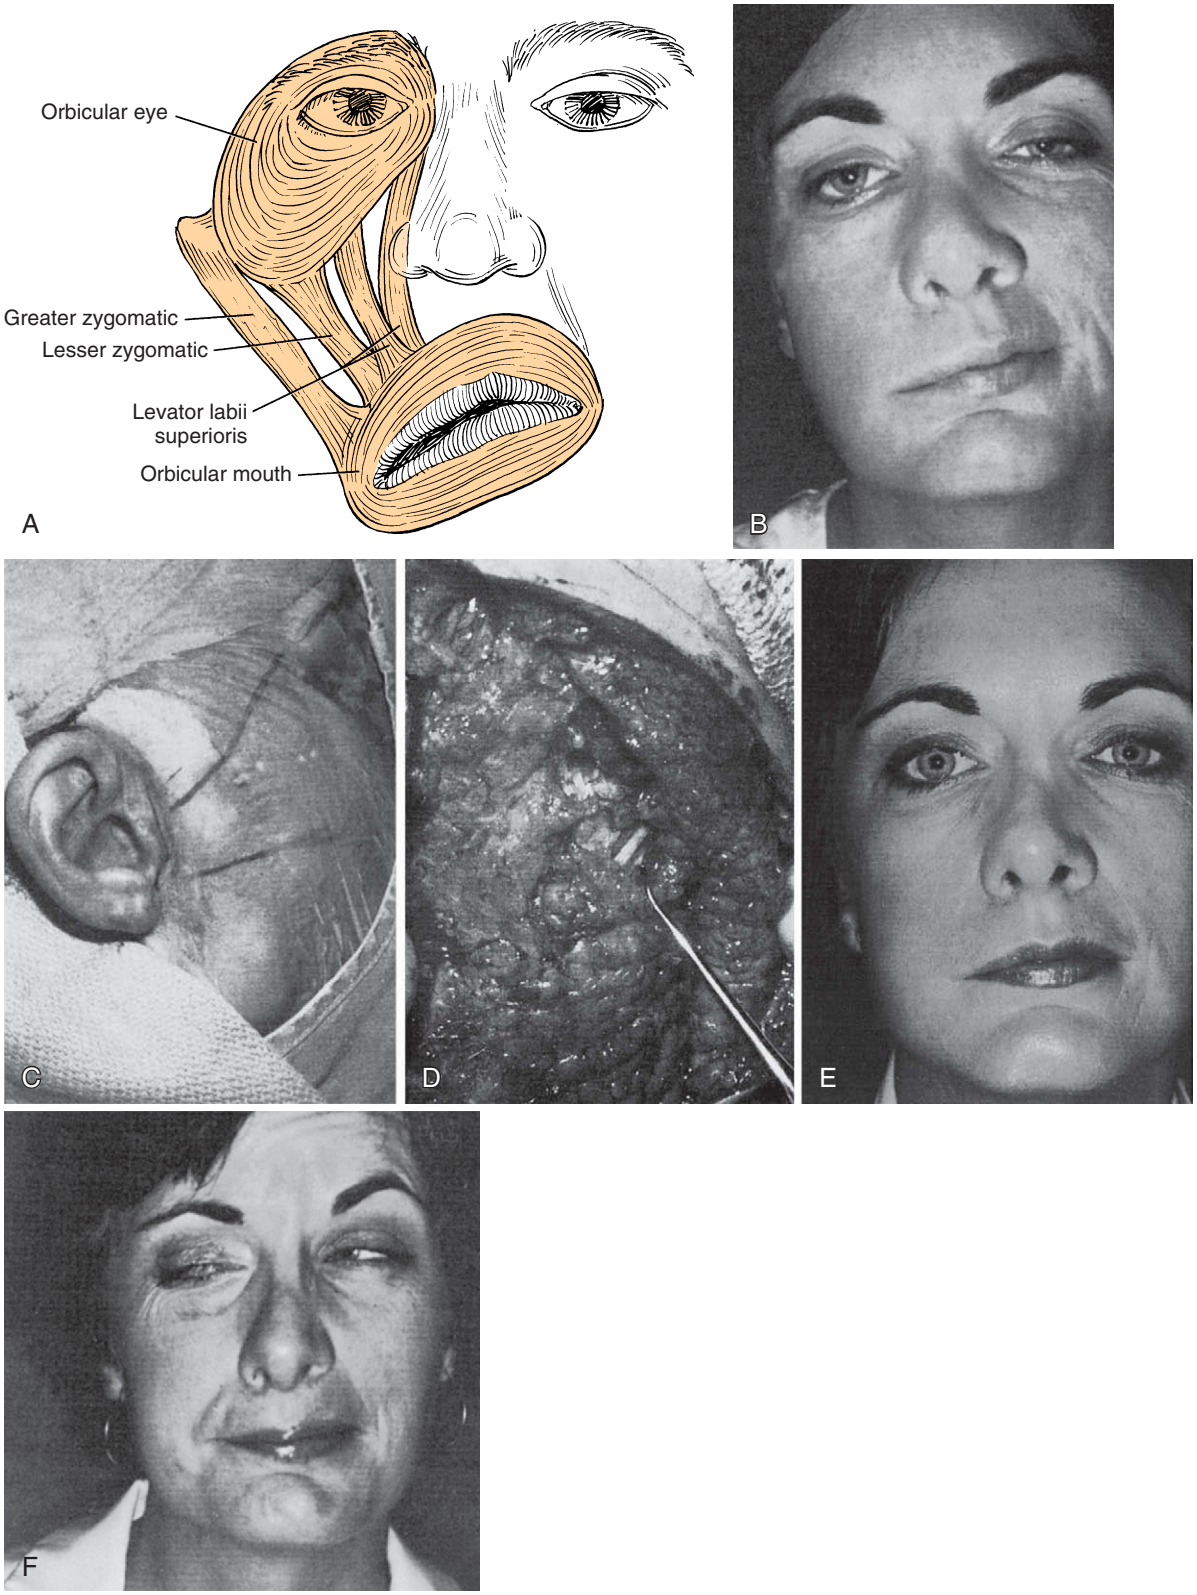

Figure 172-4. Facial muscles. **A,** The most important muscles for reanimation: The levator labii superioris, along with the lesser zygomatic muscle, probably is the most significant muscle for elevation of the upper lip. The greater zygomatic muscle also is critical as the strongest elevator of the oral commissura. **B** to **F,** Example of a delayed nerve graft in a patient in whom a parotid malignancy was removed without immediate reconstruction (because of intraoperative anesthesia considerations). **B,** The patient was referred for nerve grafting after 9 months elapsed. Note elongation of the buccal-smile complex of muscles (greater and lesser zygomatics, levator labii superioris) and paralysis of orbicular eye muscle. **C,** Preoperative surface markings for nerve branches. Nerve stimulator cannot be used to locate distal branches after 9-month time lapse. Markings are for the superior division and buccal branch, based on landmarks described in Figure 172-1 and the previous operative report. **D,** Superior division is found; it is ready for transection and anastomosis to sural graft (from midmastoid nerve segment). **E,** Result at 1 year after operation—typical for a delayed nerve graft. Orbicular eye and buccal branch muscle function is improved, but the muscles are not normally or completely reinnervated. **F,** Voluntary motion in both zygomatic and buccal branches, with synkinesia. This result also is typical for most nerve grafts in that the temporal branch (to occipitofrontal muscle) shows no reinnervation. Note the hairstyle designed to camouflage occipitofrontal muscle paralysis.

that this type of repair is preferred in nerve injuries in the extremities; however, such repairs have not been universally accepted for use in the facial nerve. Several reasons underlie this limited acceptance. The tympanic and, in many cases, the mastoid portions of the nerve have only one or two fascicles, and the intraneural topography is questionable. Few, if any, sensory fibers are present in the extratemporal portion of the facial nerve, so performing sensory-to-sensory fascicular repair is not of value.

Along with May and Miehlke, we have reported (independently) that discrete, spatially oriented fascicles are present in the nerve near the stylomastoid foramen.[33-35] Other authors, notably Sir Sidney Sunderland[36] and Tomander and colleagues,[37] have reported conflicting data demonstrating that various portions of the face are represented in a random fashion in the proximal nerve. At present, it probably is best to perform fascicular repair when the injury obviously lends itself to the technique (e.g., clean lacerations through the pes anserinus and branch nerve grafts that require fascicular dissection in the pes). Basic research has yet to reveal the exact neural topography of the more proximal portions of the nerve.

Cross-Face Nerve Grafting

Overview

The creative and physiologic method of cross-face nerve grafting provides the possibility for facial nerve control of previously paralyzed facial muscles. It is the only procedure with the theoretic capability for specific divisional control of facial muscle groups (e.g., the buccal branch controlling the buccal branch distribution, the zygomatic branch innervating the orbicularis oculi). Originally described by Scaramella[10] and Smith[11] in independent reports in 1971, the technique has not proved to be as advantageous as was first thought. Anderl[38] subsequently described his own results as good in 9 of 23 patients, whereas Samii[39] reported that only 1 of 10 patients had good movement as a result of this technique. A more recent update by Ferreira[40] indicates that those patients operated on within the first 6 months of the paralysis did better than those operated on at a later date. In some of these patients, however, partial spontaneous reinnervation may have occurred, because they appeared to have had lesions without total palsy, and the traditional waiting period of 1 year was not allowed to elapse.

Surgical Technique

The operative technique of cross-face grafting begins with transection of several fascicles, usually of the buccal branch, on the nonparalyzed side through a nasolabial fold incision. One to three sural nerve grafts are approximated to these normal contralateral branches. The nerve grafts are then passed through subcutaneous tunnels, usually in the upper lip. Cross-face grafts for the eye region often are passed above the eyebrow.

As described by most authors, this first surgical stage is performed during the first 6 months of paralysis. Surgery, of course, is not advised unless the paralysis is of known permanence. Tinel's sign often may be elicited after several months of neural ingrowth, because sensory fibers accompany the motor fibers through the cross-face graft. Anastomosis with the paralyzed facial nerve branches is performed by most surgeons during a second stage, 6 to 12 months after the first. At this time, the cross-face graft is explored and sutured to the appropriate branches of the paralyzed side. The approach is through a parotidectomy-rhytidectomy incision and usually is performed within the parotid portion of the paralyzed side.

The cross-face technique suffers from a lack of sufficient axon population and neural excitatory vitality. It is of marginal value when

The superior division is intact and in continuity with proximal facial nerve. **G** and **H,** Strong reinnervation to entire face, 1 year after operation. **G,** Patient uses hypoglossal innervation to buccal branch muscles to enhance eye closure. **H,** Upward movement of oral commissura mediated by hypoglossal nerve, without associated or synkinetic eye closure.

used alone, but when combined with microvascular transfer of muscle (see below), it can provide suitable innervation. Conley[41] and Conley and Baker[42] have discussed the shortcomings and unproven status of cross-face grafting. Cross-face grafting currently is used only in conjunction with free muscle transfers. Reinnervation of paralyzed facial muscles has not been proved to be sufficient to justify use of this procedure without muscle transfer.

Nerve Transposition

Reinnervation by connecting an intact proximal facial nerve to the distal ipsilateral facial nerve generally is the preferred method for facial paralysis rehabilitation. Only when a proximal facial nerve stump is not viable or available should attention be turned to other strategies, such as muscle or nerve transfer.

Hypoglossal Nerve Transfer

Of the various nerves available for anastomosis with the facial nerve, the hypoglossal nerve is preferred, because an anatomic and functional relationship exists between the facial and the hypoglossal nerves. They both arise from a similar collection of neurons in the brainstem, and they also share similar reflex responses to trigeminal nerve stimulation.[9] In addition, the hypoglossal nerve is in close anatomic proximity and is readily available during other operations on the facial nerve. Hypoglossal nerve transection results in less donor disability than that typical with sacrifice of the spinal accessory, phrenic, or other regional nerves that have been used for facial reanimation. The most common criticism of hypoglossal nerve transfer is that it results in a lack of voluntary emotional control. Although this is true, ipsilateral facial nerve anastomosis often is associated with a similar drawback: Mass movements and spasms preclude any voluntary control of eye closure, smiling, or other emotional movements. In our practice, we have used hypoglossal nerve transfer for reanimation of the upper or lower division selectively by performing fascicular dissection in the pes anserinus to identify the specific fascicles that required reinnervation (see Fig. 172-5).

May and coworkers[43] attempted to decrease morbidity from tongue atrophy by performing partial transection of the hypoglossal nerve with use of a jump graft from the partially transected nerve to the distal facial nerve. Decreased effectiveness of partial transection with jump graft has been reported by some investigators.[44]

Recently, "pure" end-to-side anastomosis of the facial nerve or a jump graft into the donor hypoglossal nerve has been rediscovered[45] and reported in a small series of patients.[46] The study investigators performed anastomosis of facial nerve either mobilized from the mastoid or bridged by interposition graft into the intact hypoglossal nerve, without removal of epineurium or perineurium. This technique relies on the presumed axon sprouting across intact epineurium of the hypoglossal nerve. Some evidence indicates lateral axonal growth after

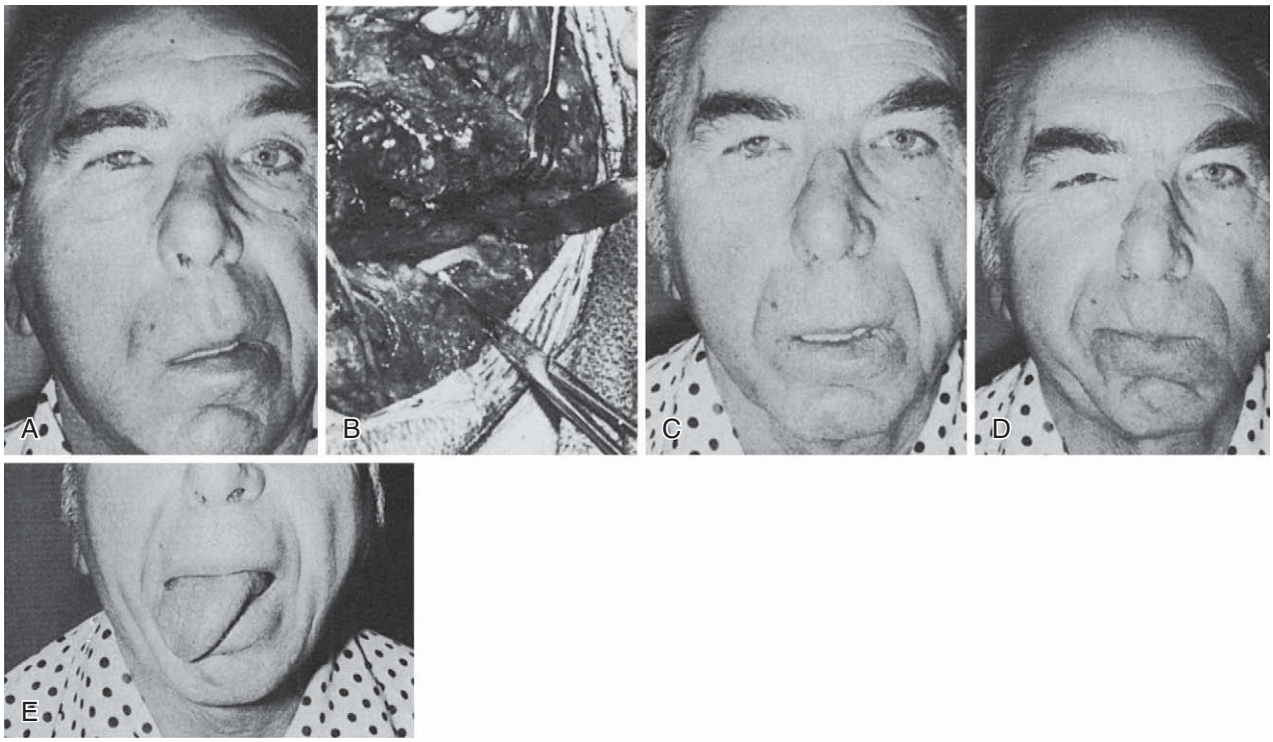

Figure 172-6. **A,** Patient with facial paralysis after acoustic neuroma excision. Lateral tarsorrhaphy is in place. **B,** Exposure of hypoglossal nerve. Note exit of ansa cervicalis branch at *lower right*. This may be transected and sutured to the distal hypoglossal, although preservation of tongue innervation usually is weak with this technique. **C,** Repose. Note elevated commissura and reconstitution of nasolabial fold. **D,** Movement instigated by pushing tongue tip against lingual aspect of mandible in canine region. This maneuver usually results in strongest facial movement after anastomosis of cranial nerves XII and VII. **E,** Typical lingual deviation after the procedure.

end-to-side nerve anastomosis occurs. Rat studies demonstrate axonal penetration of endoneurium, perineurium, and epineurium.[47-49] Whether this technique will be applicable in humans who have decreased nerve regenerative capacity and much thicker perineurium and epineurium than in the rat remains to be seen. It may be more effective to remove an epineurial window and perform the anastomosis without disruption of nerve fibers yet still induce enough axonal regrowth to provide tone and function. Further animal and human studies will be necessary to determine the usefulness and role of end-to-side neurorrhaphy for facial rehabilitation.

Surgical Technique

A modified facelift or parotidectomy incision with an extension made inferiorly toward the hyoid bone usually is used in hypoglossal nerve transfer. The parotid gland is dissected forward from the sternocleidomastoid muscle, and the facial nerve is identified in its trunk–pes anserinus region. The posterior belly of the digastric muscle is then identified, and the hypoglossal nerve is dissected free immediately medial to the tendon of the muscle. The ansa hypoglossi should be identified and dissected free so that, if desired, it may be sutured to the distal hypoglossal stump for reinnervation of the strap musculature. The hypoglossal nerve should be transected as far distally as possible to provide extra length for the anastomosis. After the nerve ends are prepared carefully under high power using a blade, four to eight epineural sutures of 10-0 monofilament nylon complete the anastomosis.

The procedure for the hypoglossal-facial nerve jump graft is similar to that for pure hypoglossal-facial nerve transfer. A greater auricular nerve graft is harvested for use as a jump graft. The facial nerve is transected on the main trunk. The hypoglossal nerve is incised in beveled fashion to expose approximately 30% of the nerve fibers. The jump graft is secured to the proximal edge of the hypoglossal nerve and to the distal end of the transected facial nerve. If the facial nerve is mobilized proximally from the mastoid, it can be directly anastomosed to the partially transected hypoglossal nerve, avoiding placement of a jump graft.

Results

In the largest series to date, involving 137 patients, approximately 95% regained satisfactory tone in repose and regained some mass facial movement.[50] Of these patients, 15% demonstrated hypertonia and excessive movement in the middle third of the face; however, none of these patients requested that the transferred nerve be reoperated. This excessive movement was found to decrease gradually over 10 to 20 years. However, Dressler and Schonle[51] and Borodic and coworkers[52] have had success treating facial hyperkinesia with selective injection of botulinum toxin. Seventy-eight percent of the patients had moderate to severe tongue atrophy, whereas 22% showed minimal atrophy; this wide variability in response of the tongue to hypoglossal nerve transection has been confirmed in other series[53] (Fig. 172-6). Use of the interpositional jump graft with partial hypoglossal nerve preservation preserved tongue function in a majority of patients and provided satisfactory function. In a series of 20 patients, good facial tone and symmetry were observed at follow-up evaluation in all patients, and 13 had "excellent" restoration of facial movement, with development of 12th nerve deficits noted in only 3 patients.[43]

Other Nerve Transfers

The spinal accessory nerve was used before the hypoglossal nerve in nerve transposition techniques. Drobnik performed the first anastomosis of cranial nerves XI and VII in 1879.[9] The phrenic nerve has been similarly used, but this technique causes paralysis of the diaphragm and induces undesirable involuntary inspiratory movements in the facial muscles.[54] The technique is now obsolete.

The neuromuscular pedicle technique described by Tucker transfers a branch of the ansa hypoglossi nerve and a small muscle bloc directly to paralyzed facial muscles. According to Tucker,[55] this proce-

dure is valuable only for the perioral, depressor anguli oris, and zygomaticus muscles. The procedure is described as transferring innervated motor endplates to the denervated facial muscles without the usual delay period seen with free nerve grafts and nerve transfers. The technique allows limited reanimated strength because of the small number of axons present in the donor nerve. In addition, sound electrophysiologic confirmation that the technique produces reinnervation is somewhat lacking, despite a report by Anonsen and colleagues on this topic.[56] Until physiologic data are presented and confirmation by other surgeons is obtained, the procedure has potential but remains unproved.

Neurotropic Factors

With several growth factors known to promote neuronal survival, application and delivery of the these factors constitute an attractive therapy for nerve injury and surgical repair. The trophic effects of nerve growth factor (NGF), glial cell–derived neurotropic factor (GDNF), brain-derived neurotropic factor (BDNF), and insulin growth factors I and II all are under current investigation.[57] In ongoing rat experiments, embryonic stem cells are used to provide the trophic support factors to the host motor neurons in restitution of the neuromuscular junction.[58] These preliminary findings provide a model for motor unit restoration and a potential therapeutic intervention in the treatment of paralysis. However, these studies are limited to the rat model and require further basic and clinical investigation.

Muscle Transfers

Masseter Transfer

Although masseter and temporalis muscle transfer techniques are effective, generally they should be used only if ipsilateral cable nerve grafting is not possible. For most patients with viable facial muscle endplates, a nerve transfer such as hypoglossal facial anastomosis also is preferable to muscle transposition. However, when the proximal facial nerve and the hypoglossal nerve are unavailable, or when facial muscles are surgically absent or atrophied, new contractile muscle must be delivered into the face. A large group of patients who fit into this category are those whose complete paralysis has lasted 2 years or more. These patients usually are characterized by severe denervation atrophy as documented by EMG. In these situations, muscle transfer is the preferred technique of reanimation.

Since the masseter was first used for facial reanimation in 1908, many modifications have been described.[59] Many authors, notably Conley and Baker, prefer the masseter muscle for rehabilitation of the lower face and midface.[30]

The masseter transfer procedure generally is performed for rehabilitation of the sagging paralyzed oral commissure and the buccal-smile complex of muscles. The masseter's upper origin from the zygomatic arch allows a predominantly posterosuperior pull on the lower midface. Transfer of the muscle can be accomplished externally through a rhytidectomy-parotidectomy incision, or intraorally using a mucosal incision in the gingivobuccal sulcus lateral to the ascending ramus of the mandible (Fig. 172-7). The masseter's blood supply is medial and deep, and its nerve supply passes through the sigmoid notch between the condylar and the coronoid processes of the mandible to reach the upper deep surface of the muscle. The nerve supply then ramifies and courses distally and inferiorly, terminating near the periosteal attachments on the lateral aspect of the mandibular angle and body. In general, the external approach is preferred, insofar as the intraoral approach is associated with somewhat limited access, poorer muscle mobilization, and less vascular control.

A generous parotidectomy incision is made and extended inferiorly below the mastoid tip. The parotid gland and masseteric fascia are exposed. The posterior border of the muscle is freed from the mandible's ascending ramus and at the lower border of the mandible. The nerve supply courses along the deep surface approximately midway between the anterior and the posterior borders of the muscle (see Fig. 172-7). It is advisable to preserve the deep fascial layer in dissecting the muscle free from the mandible. Mobilization of the periosteal attachments along the inferior border will provide secure tissue for anchoring sutures and will provide greater length of the transposed muscle.

Dissection is then carried forward to the nasolabial fold in the subcutaneous plane using large Metzenbaum or rhytidectomy scissors. The external incisions are made at or just medial to the nasolabial fold, the lateral oral commissure, and the vermilion cutaneous junction of the lower lip. Each of these incisions is connected to the cheek tunnel, allowing transfer of the masseter muscle. The muscle may be divided into three slips for attachment at these sites, or the entire periosteal end of the muscle may be used to suture the remnants of the orbicularis oris muscle from the lateral upper lip to the commissure and below. These muscle slips are sutured to the dermis and the orbicularis oris muscle using 3-0 clear nylon sutures. The best results depend on gross overcorrection with hyperelevation of the oral commisure, preservation of masseteric nerve supply, secure suture stabilization of the transposed muscle, supportive tape dressing to maintain overcorrection of the oral commissure, and nasogastric feedings to minimize masseteric movement.

Results from the masseteric procedure are quite gratifying and usually yield a high degree of facial symmetry. However, the masseter's arc of rotation will not allow for rehabilitation around the orbit. For this reason, the temporalis transfer can be combined with masseter transfer, or the reanimation of the orbital region can be approached separately with such procedures as canthoplasty and gold weights.

Temporalis Transfer

Although Gillies[60] usually is given credit for introducing the temporalis procedure, Rubin[61,62] deserves much credit for refining the goals of the procedure and the operative technique in the United States. Like the masseter transfer, the temporalis transfer procedure requires an intact ipsilateral V_3 nerve. The nerve supply to the temporalis lies along the deep surface of the muscle. The blood supply comes from the deep temporal vessels from the external carotid artery. Thus, with total parotidectomy, extensive neck dissection, or infratemporal fossa dissection, the neurovascular supply may be tenuous at best. The upper origin of the temporalis muscle is fan-shaped and arises from the periosteum of the entire temporal fossa. The muscle belly converges on a short tendinous portion deep to the zygomatic arch and inserts on the coronoid process. The muscle is best exposed through an incision that passes above the ear, slightly posteriorly, and then in an anteromedial arc. This will expose the entire upper portion of the muscle (Fig. 172-8). A convenient aponeurotic dissection plane exists lateral to the temporalis fascia.

In Rubin's technique, the muscle is dissected free from the periosteum and attached to fascial strips, which are turned down inferiorly to reach the oral commissure and eyelid area. If these fascial strips are omitted, the transposed muscle's length will be insufficient to reach the lateral oral commissure. More recently, Rubin[62] refined his temporalis transfer technique by including a slip of masseter muscle that is sutured to the oral commissure and lower lip. The resulting masseteric pull improves results by providing more posterior and lateral vectors to the oral commissure.

We prefer to use the technique described by Baker and Conley,[50] who describe retaining the integrity of the upper muscle and its overlying fascia. The latter is dissected free and then turned inferiorly for suturing to the oral commissure.

A tunnel at least 1 to 1.5 inches wide must be made over the zygomatic arch to allow the muscle to turn inferiorly and eliminate an unsightly bulge. The attachment of the strip should be just medial to the nasolabial fold so that the natural crease is reproduced by the muscle pull. As with the masseteric procedure, a marked overcorrection is necessary on the operating table. A soft silicone block or a temporoparietal fascia flap may be used to fill the temporal hollow. A modification of this technique by Sherris[63] is performed by extending the transfer into the midregion of the upper and lower lips, to reduce stretching and thinning of the lips over time.

Several modifications of the temporalis transfer have been reported in attempts to avoid folding of the temporalis muscle over the zygomatic arch. Labbé and Huault[64] describe partial inferior mobilization of the temporalis muscle from the skull by elevation of the posterior and superior attachments of the muscle. The coronoid attachments of the muscle are detached, and the muscle is inferiorly mobilized toward the upper lip. The coronoid insertion of the inferiorly displaced muscle is secured to the perioral musculature.

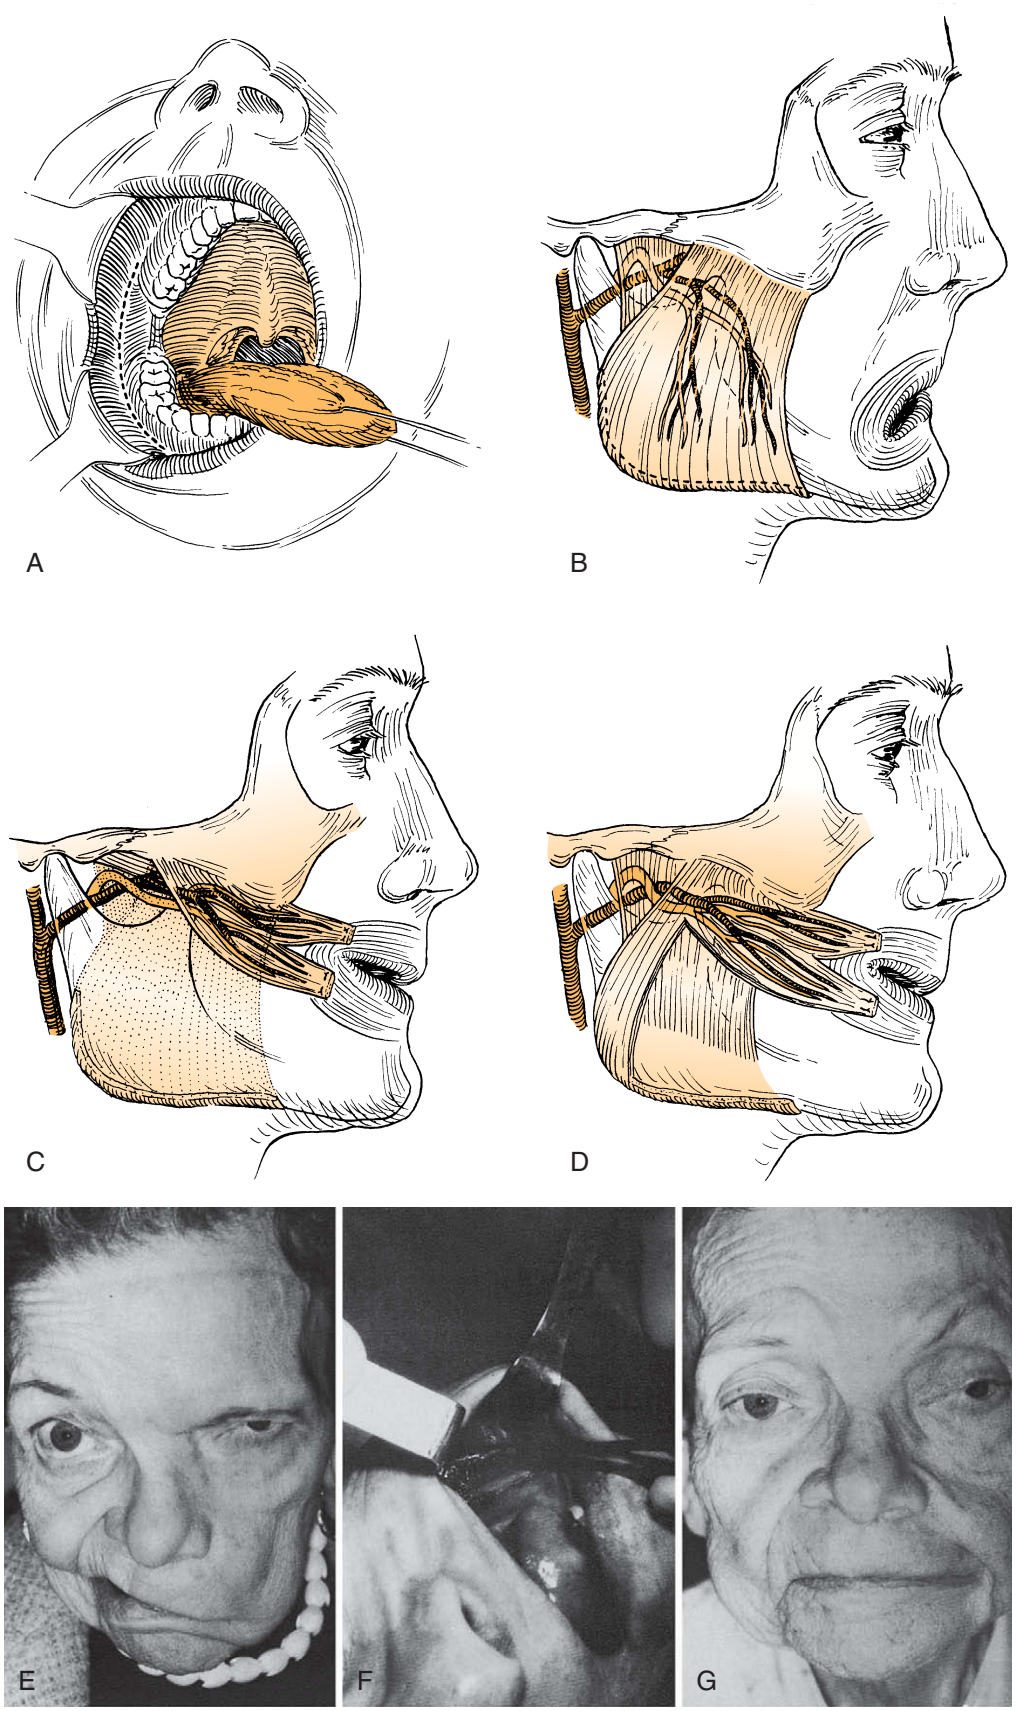

Figure 172-7. Masseter transfer procedure. **A** to **D,** Schematic depiction of key surgical principles. **A,** Intraoral approach to masseter. The procedure is more difficult when performed in this manner; an external approach is preferred. **B,** Correct incisions in muscle and periosteum. Periosteum must be incorporated in the lower portion of the muscle flap to leave the tissue secure for suturing to the lip region. **C** and **D,** Entire muscle, rather than only anterior elements, is transposed, so that the masseteric nerve supply is transferred intact with muscle belly. **E** to **G,** Use of intraoral masseter transfer for correction of complete left peripheral facial paralysis in an elderly woman. **E,** Note severe brow ptosis, medial tarsorrhaphy, and severe redundancy of cheek, paranasal, and lateral lip tissues on the left. **F,** Intraoperative photograph showing intraoral masseter transfer. Large Kelly clamp is used to grasp the inferior portion of the masseter, which will be passed through the cheek tissues to a nasolabial fold incision (see **A** through **D**). **G,** Photograph taken after browlift procedure (tarsorrhaphy has been left for eye safety). Masseter transfer has successfully raised the corner of the mouth and the nasolabial fold. The patient declined further excision of the nasolabial fold for improved cosmesis.

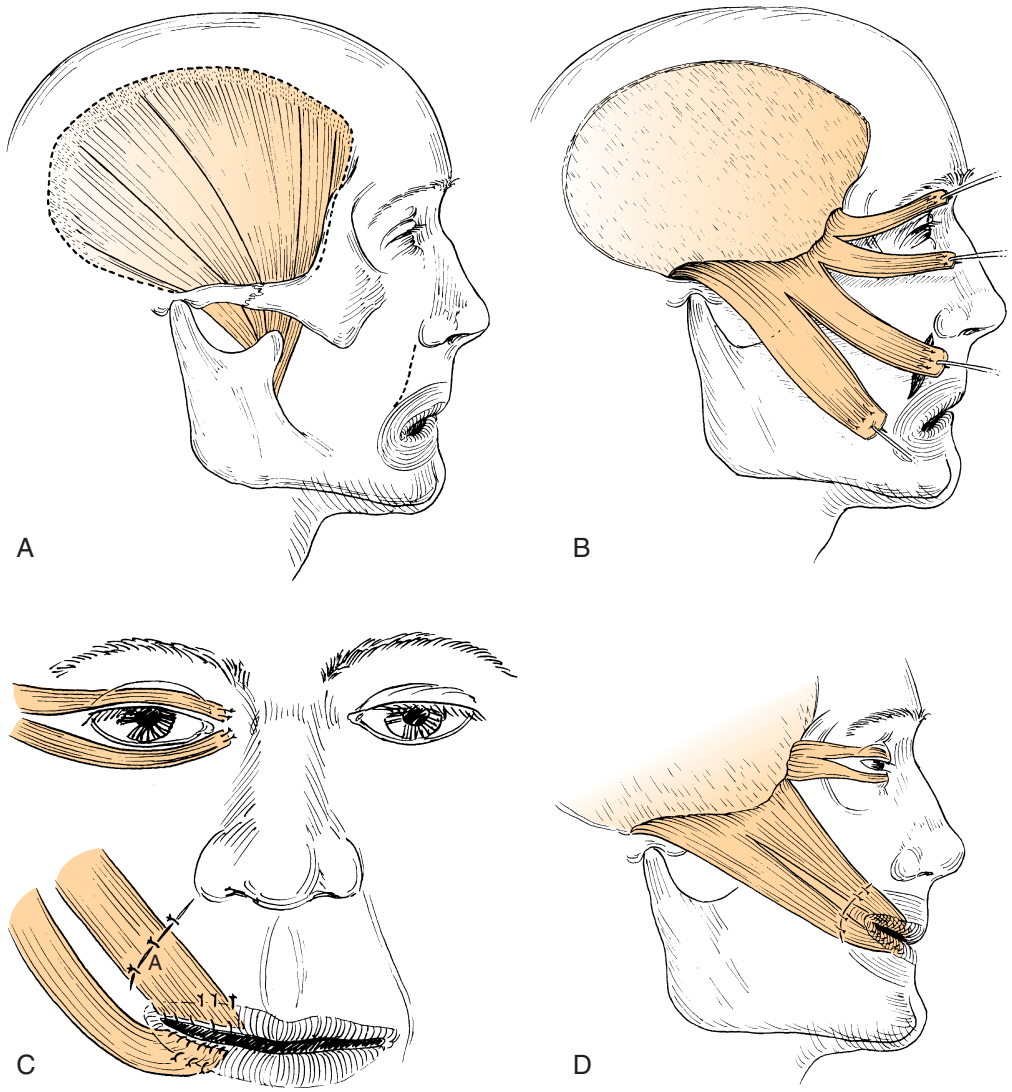

Figure 172-8. Temporalis muscle transposition. **A,** *Dotted line* illustrates the incision in the pericranium peripheral to the edge of the muscle. This results in strong periosteum to hold sutures in the transposed position. Nerve supply on deep side of muscle is not shown. **B,** Temporalis muscle divided into four slips. Note pericranium at the end of the slips sutured to the muscle to reinforce the suture site. Temporal fascia superficial to the muscle can be used in the same way. **C,** Transposed slips sutured to perioral muscles. Creativity and compulsivity are crucial during this portion of procedure. Overcorrection is mandatory. Sutures (A) must be placed in subdermis inferior to incision or in the submucosal portion of the wound deep to the orbicularis oris muscle. **D,** Completed procedure. Wide tunnel over the zygomatic arch precludes an unsightly bulge of muscle, which would otherwise be produced. Superior pull of temporalis muscle is somewhat preferred to posterolateral pull of masseter muscle (see Fig. 172-7).

Although the gold weight–canthoplasty technique often is preferred, the temporalis muscle can be used for orbital rehabilitation. The anterior third of the temporalis muscle is turned laterally into the eyelids (see Fig. 172-8). Subcutaneous tunnel dissection between the paralyzed orbicularis oculi and the eyelid skin allows passage of the fascial strips medially through both eyelids to the medial canthus, where they are sutured. As with any reconstructive procedure, adjustments and suture revisions should be checked carefully on the operating table to ensure proper eyelid contour.

With both masseter and temporalis transfer, facial muscle activation originates from the trigeminal nerve. Patients need to learn, through videotape, biofeedback, or similar methods, the proper way to contract the muscles by chewing or biting. Some younger patients may actually learn how to incorporate these movements into their own facial expressions (e.g., smiles, grimaces). However, patients should be told preoperatively that muscle transfer procedures will not allow any emotional or involuntary reanimation. When performed in the best hands, these techniques provide symmetry and tone in repose, with some learned and induced movements on attempted chewing.

Microneurovascular Muscle Transfer

Microneurovascular muscle transfer was popularized in the 1970s and has been combined with cross-face nerve grafting to restore some facial movement.[65] Because facial movements are highly complex and interrelated, enthusiasm for free muscle transfer was stimulated by the potential to use muscles that may provide isolated or independent segmental contractions, such as for superior elevation of the oral commissure. In patients with absence of facial musculature (such as those with congenital paralysis as in Möbius syndrome), microneurovascular muscle transfer seems to have strong potential.

A number of muscles and their respective nerve supply have been used for microneurovascular transfers. The most popular muscles include the gracilis, latissimus dorsi, and pectoralis minor muscle flaps.[66] Ideally, the proximal stump of the ipsilateral facial nerve is used, but this often is not possible. Traditionally, reinnervation has been

accomplished in two stages, with a preliminary cross-face nerve graft performed approximately 1 year before muscle transfer. Neural ingrowth within the grafted nerve is monitored by recording progression of Tinel's sign along the path of the graft. When reinnervation of the graft has occurred, microvascular muscle transfer is then performed. One-stage procedures using long neurovascular pedicles connected directly to the contralateral facial nerve have been described.[67-70] A recent comparison study found favorable outcomes with the one-stage reconstruction compared to the more traditional two-stage reconstruction.[70] Muscle preservation using implantable intramuscular stimulators is under investigation and may allow preservation of facial muscles while reinnervation occurs.[71] This technique shows promise in management of peripheral nerve injuries, and exploratory studies on the facial nerve have been initiated. When facial nerve input is not available, alternative nerves can be used for input, including the masseteric branch of V_3, ansa hypoglossi, or the hypoglossal nerve.[66,72]

Composite tissue allograft procedures have gained considerable interest over the last 10 years. Devauchelle[73] and Dubernard[74] and their colleagues detailed the preliminary functional improvements of the first human partial face transplant, with the return of light touch, heat and cold perception, and mouth closure. These functional milestones were obtained by 10 months postoperatively; a normal smile was observed at 18 months. As with all tissue transplantation, however, immunosuppression is an essential adjunct and not without consequence. After transplantation, the patient suffered two episodes of acute rejection, two infectious complications (type 1 herpes simplex virus infection and molluscum contagiosum), renal failure, moderate thrombotic microangiopathy, and hemolytic anemia. These preliminary findings reveal a new dimension of reconstructive surgery while also underscoring the inherent benefits of native tissues in facial reconstruction.

Significant advances in microvascular techniques and one-stage microneurovascular facial rehabilitation have greatly improved the functional outcome for appropriately selected patients. These techniques are complex, requiring expertise in both microvascular techniques and facial reconstruction. In general, patients with absent distal facial nerve fibers or intact facial musculature who are motivated to attain dynamic function are potential candidates for these procedures.

Static Procedures

Although reinnervation techniques and dynamic slings (muscular transfers) generally provide the best functional outcomes, a number of static procedures still constitute an appropriate option for selected patients. Use of static techniques is indicated in debilitated persons with poor prognosis for survival and in those for whom nerve or muscle is not available for dynamic procedures. The primary benefit of static procedures is immediate restoration of symmetry in the midface. Success depends on mastering several techniques and selective application using sound clinical judgment. Static suspension relies on elevation and positioning the soft tissues of the oral commissure or nasal ala (or both), most commonly by attaching graft materials, which are elevated and secured to the temporal-zygomatic region. Several major benefits arise from the use of static slings. First, facial symmetry at rest can be achieved immediately. Second, better control of problems associated with ptosis of the oral commissure (e.g., drooling, disarticulation with air escape, difficulty with mastication) is achieved. Finally, nasal obstruction caused by alar soft tissue collapse can be dramatically relieved by resuspension and fixation of the nasal alar complex.

Several materials have been used for static suspension. The most common have been fascia lata[75] and acellular human dermis (Alloderm).[76] In the past, expanded polytetrafluoroethylene (PTFE) (i.e., Gore-Tex) has been used more frequently.[77] The acellular dermis preparation and PTFE have the advantage of avoiding donor site morbidity, but use of foreign materials carries a small risk of infection, which is of greater concern in persons undergoing radiation therapy.

Static Facial Sling

Technique

The implant can be placed through a preauricular or temporal incision. In patients with a well-developed contralateral nasolabial fold, a nasolabial incision may be used instead. Additional incisions are made at the vermilion border of the upper and lower lips, adjacent to the commissure. A subcutaneous dissection plane is created to connect the temporal region to the oral commissure. In selected patients with nasal alar collapse and nasal obstruction from soft tissue ptosis, the dissection is extended to include the midface immediately adjacent to the nasal ala. A single strip of implant material is adequate for the procedure. This is cut to appropriate size and can be split near the end to include slips for attachment to the upper and the lower lips. Permanent sutures are placed to secure the implant to the orbicularis oris muscle and deep dermis. Resorbable sutures are placed in the deep dermis to secure the material just medial to the proposed nasolabial fold. Similar fixation is performed for a strip to the ala if desired. The sling is then suspended and secured with permanent suture to the temporalis fascia, or to the periosteum of the zygoma or zygomatic arch. If fascia lata or acellular human dermis (AHD) is used, overcorrection of the smile is achieved before fixation. Current interest has been developed in the suspension of implant materials along the nasolabial fold with suture anchoring to the deep temporal fascia.[78] In similar fashion, mimicking of the contralateral crease is achieved through suture tension along various points.

Adjunctive Procedures

A number of adjunctive procedures are available to "fine-tune" the results in persons undergoing facial rehabilitative procedures. Optimizing the care of patients with facial paralysis requires a full range of techniques in the surgical armamentarium. Although reinnervation techniques and measures to protect the eye take precedence, a number of options allow "fine-tuning" of results for the patient with facial paralysis. These can be broadly subdivided into procedures to rehabilitate the upper, middle, and lower thirds of the face. Finally, synkinesis can be a major concern, and treatment options for synkinesis are available as well.

Procedures for Upper Third of the Face

Paralysis of the upper third of the face produces significant functional and cosmetic deformities. Brow ptosis may cause superior visual field deficits as well significant facial asymmetry. This asymmetry may be further accentuated after procedures to address the lower face. Browlift techniques to manage paralytic ptosis are the same as for a cosmetic browlift, the only significant technical difference being exercise of restraint to avoid further compromising eyelid closure. Direct, midforehead, endoscopic, and indirect browlifts are all effective. When not overdone, a browlift in conjunction with lid loading or lower eyelid tightening, or both, generally produces satisfactory cosmetic and functional results. Brow ptosis associated with normal aging may be accentuated unnaturally by a unilateral lift, and in older patients, improved results are seen when bilateral browlifts are performed.[79]

Many patients with facial paralysis, particularly older persons, will express interest in additional adjunctive procedures in the periocular region. In patients with excessive redundant eyelid skin, conservative blepharoplasty can decrease superior visual field defects while cosmetically addressing brow ptosis and excessive tissue folds. Extreme caution is necessary in performing blepharoplasty in conjunction with browlift procedures. The risk of further impairing eye closure mandates a conservative approach. A maneuver to help assess the amount of skin to be safely removed consists of manually holding the paralyzed brow in the normal position with observation for impairment of eyelid closure. Similarly, it also is helpful to pinch together the excessive eyelid skin to be resected while holding the brow superiorly and observing its effect on eye closure.

Procedures for Middle Third of the Face

The middle third of the face is most commonly rehabilitated using reinnervation techniques, dynamic slings, or static slings. A number of additional procedures are available to fine-tune the results obtained with these procedures, and selection of the appropriate procedure(s) is determined by both the defect and the desires of the patient.

Nasal obstruction after facial paralysis can occur because of collapse of the alar sidewall from adjacent soft tissue ptosis and loss of intrinsic dilator naris tone. As described, a properly designed static

Figure 172-9. Result with static rehabilitation techniques in a patient with right facial paralysis:. Preoperative **(A)** and postoperative **(B)** photographs. Patient underwent direct browlift, lateral transorbital canthopexy, alloderm facial sling repair, and gold weight placement.

sling may alleviate this problem. Alar batten grafting also may provide relief.

Midface soft tissue laxity and sagging, characteristic of the aging midface, is abnormally pronounced in the paralyzed face. In older patients with significant skin laxity, performing a facelift enhances the results of other treatments for midface deformity. Facelifts can be performed concurrently with other procedures, whether dynamic or static, and some patients will benefit from and prefer a bilateral facelift (Fig. 172-9).

Like the aging patient, the patient with facial paralysis acquires ptotic palpebral-malar and nasojugal sulci, producing a hollowed-out appearance to these areas. The lower eyelid fat may bulge, and the suborbicularis oculi fat (SOOF) and midface complex descend, producing a "double convexity" sign on lateral view. In the youthful patient, the suborbicularis oculi fat typically lies at the inferior orbital rim between the orbicularis oculi muscle and the periosteum. The midface lift repositions the SOOF and associated midface soft tissue superior to its preexisting position. The lift has become a popular technique in facial rejuvenation surgery, and also has shown utility in the treatment of facial paralysis. The midface lift can be performed through a transconjunctival incision, with a lateral canthotomy and inferior cantholysis. The periosteum is incised near the orbital rim and is elevated down to the inferior maxilla, where it is released. It also is important to release the attachment to the masseter muscle. Care is taken to avoid injury to the infraorbital nerve. The periosteum and overlying soft tissue are then elevated and secured superiorly to the deep temporal fascia.

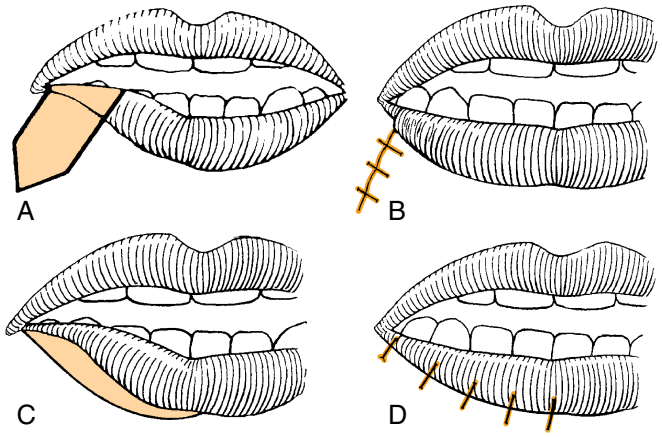

Figure 172-10. Lip wedge excision and cheiloplasty. **A,** Outline of incisions for lip wedge excision. Excision tightens the lower lip and removes part of the denervated muscle. **B,** Appearance after lip resection. Note the intentional asymmetry of vermilion border during closure to evert the lower lip. **C,** Outline of incisions for cheiloplasty. **D,** Appearance of cheiloplasty after resection. Note lowering and outward rotation of the lower lip *(Adapted from Glenn MG, Goode RL. Surgical treatment of the "marginal mandibular lip" deformity.* Otolaryngol Head Neck Surg. *1987;97:464-465.)*

Procedures for Lower Third of the Face

The functional deficits with paralysis of the lower face are dominated by manifestations of oral incompetence. Drooling, air escape with speech, and difficulty with mastication may be present. The asymmetry also produces a significant aesthetic deformity. This is due to the lack of a smile (loss of zygomaticus function) as well as the lack of depressor anguli oris (marginal mandibular nerve) function. These defects can be worsened by performance of static procedures on the middle third of the face, which can produce a troublesome gap in the region of the commissure from elevation of the upper lip.

Reinnervation, free tissue transfer, dynamic slings, and to some degree even static slings assist in repositioning the oral commissure to re-create a more symmetric smile. The asymmetry of depressor function, the so-called "marginal mandibular lip," is more troublesome and difficult to improve. The most commonly used procedures are wedge resection and transposition of the posterior belly of the digastric muscle. The wedge resection, with or without supplemental cheiloplasty technique to improve symmetry and oral competence, has been described by Glenn and Goode.[80] A 2- to 2.5-cm full-thickness excision is performed 7 to 10 mm lateral to the commissure (Fig. 172-10).

The most common dynamic technique for depressor dysfunction is the digastric transposition, first described by Conley and colleagues.[81] The digastric tendon is identified using a submandibular approach. It is released from the hyoid bone, transected near the mastoid tip, transposed superiorly, and attached to the orbicularis oris

through a separate vermilion border incision. Care is taken to preserve the mylohyoid nerve innervating the anterior belly of the digastric muscle. The anterior belly of the digastric muscle may not be available after extirpative cancer surgery, however.[82]

Management of Synkinesis

Patients with incomplete recovery from facial paralysis typically are troubled by both weakness and hyperkinesis, or synkinesis. Synkinesis develops in many patients after facial paralysis of any cause. These uncoordinated mass movements may begin within weeks after paralysis as regeneration occurs. Although the classic description of synkinesis places the etiologic mechanism in aberrant axonal regeneration, it is now known that the sites of pathology are multiple. Synaptic stripping also occurs in the facial nucleus of the brainstem, and ephaptic (non-synaptic) transmission among axons contributes to synkinesis. Future efforts to prevent or treat synkinesis will require addressing each of these areas. Synkinesis ranges in severity from a mild, barely noticeable tic to painful and debilitating mass facial movements.

Careful assessment of each region of the face is performed. It is esssential to identify the patient's most troublesome symptoms and then determine which symptoms result from decreased function and which from synkinesis. The treatment plan can then be individualized to address the patient's needs.

Traditionally, neurolysis has been a mainstay in the management of synkinesis, but it has been largely abandoned as safer and more conservative yet effective techniques have evolved. Such techniques include chemodenervation with botulinum A toxin injections and selective myectomies to target affected muscles.

Botulinum A Toxin

Botulinum A toxin is the most potent poison known to humankind, yet it has been used effectively for more than 2 decades to treat a variety of hyperfunctional disorders including torticollis,[52] blepharospasm,[83] spasmodic dysphonia,[84] strabismus,[85] hyperhidrosis,[86] hyperdynamic skin creases,[87] palatal myoclonus,[88] hemifacial spasm,[89] and facial synkinesis.[90,91] Botulinum toxin causes paralysis by blocking the presynaptic release of acetylcholine at the neuromuscular junction. This typically results in paralysis of the treated muscle for approximately 3 to 6 months. Systemic weakness can occur with doses greater than 200 units. The lethal dose is approximately 40 units/kg.[92]

Botulinum toxin has dramatically improved the management of patients with facial movement disorders. It is now a first-line agent for treatment of facial synkinesis. In most persons, surgical treatment is not necessary or desired. Synkinesis after facial nerve injury can occur in any region of the face, and botulinum toxin can be used to denervate specific muscle groups. The location of the injections is targeted to the muscles causing synkinesis. Typically, 1 to 5 units is injected per site. Initial treatments use conservative doses, which subsequently can be titrated upwards. No anesthesia generally is necessary, but many patients prefer pretreatment of the area with ice or a topical anesthetic. Drug effects are first seen several days after the injection, with a maximal effect observed at 5 to 7 days. Additional toxin can be injected after this time if the initial effect is insufficient.

Adverse effects can occur, related to the diffusion of toxin into surrounding muscles. An example is the development of ptosis after periocular injection. This problem is uncommon, occurring in perhaps 5% of cases. It can be treated with apraclonidine 0.5% drops administered to the affected eye three or four times a day until the ptosis resolves.[93] Apraclonidine causes contraction of Müller's muscle to elevate the upper eyelid. Other complications from botulinum toxin treatment of the face include diplopia, further impairment of eyelid closure, lower eyelid ectropion, brow ptosis, and drooling.

In some patients, the effectiveness of botulinum toxin decreases over time. This diminishing effect may be the result of resprouting of motor endplates or the development of neutralizing antibodies and cannot be overcome with increased doses of the toxin.[94] Patients who do not benefit from botulinum toxin treatments or demonstrate the development of resistance, or who desire a more permanent solution, may be candidates for selective myectomy.

Selective Myectomy

The development of botulinum toxin has significantly expanded the options available to the surgeon caring for a patient with synkinesis. Some patients, however, will prefer something more permanent or may exhibit unsatisfactory results with botulinum toxin injection. These patients may be candidates for selective myectomy.

Neurolysis was for many years the procedure of choice for these patients. Although Fisch[95] reported excellent results, others did not have the same success.[96] Paralytic ectropion, lagophthalmos, lip paresis, oral incompetence, blunted facial expression, and other complications from neurolysis have been reported.[97,98] Myectomy has been offered as a safer, more specific procedure for permanent resolution of synkinesis after facial paralysis.[96] Myectomy results in a more predictable result because the removed muscle does not regrow, a phenomenon that can be seen with neurolysis. In patients desiring no further treatment with botulinum toxin, or for whom botulinum toxin was ineffective, a myectomy may be performed. Selective myectomies can be performed on synkinetic facial muscles.

Summary

A variety of techniques are available for facial nerve rehabilitation after paralysis. The surgeon should know the advantages and disadvantages of the various techniques to apply them properly in each clinical situation. Thorough knowledge of neuromuscular pathophysiology also is important in the understanding of how time affects the available rehabilitative procedures. When properly informed of the limitations of these operative procedures, most patients can be rehabilitated and many of their symptoms can be alleviated.

CHAPTER ONE HUNDRED AND SEVENTY-THREE

Surgical Anatomy of the Lateral Skull Base

Oswaldo Laércio M. Cruz

Key Points

- The temporal bone articulates with five other cranial bones and forms many sutures and foramina through which pass critical neural and vascular structures.
- Along with the greater wing of the sphenoid and a portion of the parietal bone, the temporal bone forms the lateral boundary of the middle cranial fossa.
- The petrous bone is a key element of the osseous anatomy of the middle and posterior cranial fossae.
- Medial and posterior to the foramen ovale the middle meningeal artery enters the middle cranial fossa through the foramen spinosum, and the greater superficial petrosal nerve is located medial to the middle meningeal artery.
- From superior to inferior, the greater superficial petrosal nerve, the tensor tympani muscle, and the eustachian tube all proceed in a similar anteroposterior plane.
- The greater petrosal nerve, the geniculate ganglion, and the labyrinthine segment of cranial nerve VII form an obtuse angle of approximately 120 degrees. The cochlea is embedded in the bone subtended by that angle.
- The cerebellopontine angle is traversed by the intracranial segments of cranial nerve V (superiorly) to cranial nerve IX (inferiorly) and by the premeatal, meatal, and postmeatal segments of the anterior inferior cerebellar artery (AICA).
- The medial aspect of the internal auditory canal is occupied by its four main neural components: the facial nerve (superior and anterior), the superior vestibular nerve (superior and posterior), the cochlear nerve (anterior and inferior), and the inferior vestibular nerve (posterior and inferior).
- The jugular foramen is located at the petro-occipital region and contains several vital neural and vascular components.
- The infratemporal fossa communicates with the orbit through the inferior orbital fissure, with the middle cranial fossa through the foramen spinosum, and with the pterygopalatine fossa through the pterygomaxillary fissure.

The lateral skull base presents a complex and conceptually challenging anatomy. The temporal bone, occupying a central and strategic position in supporting central nervous system (CNS) structures, articulates with five other cranial bones and forms many sutures and foramina through which pass critical neural and vascular structures. Familiarity with this complex anatomy is mandatory for an understanding of pathologic processes arising in the temporal bone and the middle and posterior cranial fossae, and for safe execution of skull base procedures.

This chapter is divided into four sections, on osseous anatomy of the lateral skull base, anatomy of the middle cranial fossa, anatomy of the posterior cranial fossa, and anatomy of the infratemporal fossa.

Osseous Anatomy of the Lateral Skull Base

The temporal bone occupies a central position at the lateral skull base, being the most important anatomic landmark in the lateral skull base anatomy.[1,2]

On lateral view, the squamosa presents a shape reminiscent of an open wing of a bird (Fig. 173-1). From its middle and caudal portions it contributes to the zygomatic arch and forms the superior wall of the external auditory canal. Its articulation with the tympanic bone in the anterosuperior external auditory canal forms the tympanosquamous suture. The zygomatic bone portion contributes to the roof of the glenoid fossa and the anterior part of the tympanic bone forms its posterior wall.

Along with the greater wing of the sphenoid and a portion of the parietal bone, the temporal bone forms the lateral boundary of the middle cranial fossa (Figs. 173-2 and 173-3). This medial aspect of the squamous bone forms the petrosquamous suture, which joins the caudal portion of the squamosa and the lateral superior portion of the petrosa. Anteriorly, at the articulation of the sphenoid with the squamous bone, is located the foramen spinosum, through which passes the middle meningeal artery into the cranium. The sulcus of this artery is easily identified on the medial surface of the squamosa (see Figs. 173-2 and 173-3).

The tympanic bone lies just inferior to the squamous portion and anterior to the mastoid and forms the tympanosquamous and tympanomastoid sutures with them (see Fig. 173-1). It is common for one edge of these suture lines (especially the tympanosquamous suture) to project as a spinous process exteding 1 to 3 mm into the lumen of the external auditory canal.[1,3,4]

The tympanic bone forms the anterior and inferior walls and a portion of the posterior wall of the external auditory meatus and is primarily responsible for the size and shape of the external auditory

Cruz, Helder Tedeschi, and Albert Rhoton.)*

canal. As mentioned, it also composes the posterior wall of the glenoid fossa (see Fig. 173-1).

At the medial extension of the external auditory canal, the tympanic bone ends at the tympanic sulcus or annular sulcus, into which the tympanic membrane inserts (Figs. 173-4 and 173-5; see also Fig. 173-1). On its inferior surface, the tympanic bone articulates with the petrous bone, forming the petrotympanic suture. It also contributes to the formation of the internal carotid artery canal (ascending portion) (see Figs. 173-4 and 173-5). Also, on its inferior aspect and lateral to the carotid canal, the tympanic bone forms the styloid process (see Fig. 173-1). Slightly posterior and medial to this process is the stylomastoid foramen, through which the seventh cranial nerve emerges (see Fig. 173-5).

The osseous anterior wall of the external auditory canal abuts the temporomandibular joint and is of variable thickness. The bony inferior wall is thick and related to the anterior aspect of the jugular bulb (posteriorly) and carotid canal (anteriorly) (Fig. 173-6; see also Figs. 173-1, 173-4, and 173-5). The posterior wall separates the external auditory canal from the mastoid cells and the descending portion of the facial nerve (see Fig. 173-6).[3,5]

The mastoid is a pneumatized bony process located at the most posterior and inferior part of the temporal bone that, in reality, can be considered an extension of the squamosa and a lateral projection of the petrous portion (see Figs. 173-1 and 173-2). It has a somewhat triangular form, with the vertex directed inferiorly and the base superiorly.

Anteriorly, the mastoid process forms the tympanomastoid suture as it joins the posterior portion of the tympanic bone. Above and lateral to the tympanomastoid suture is the suprameatal spine, an osseous elevation of variable size that anchors the nonosseous portion of the external auditory canal and auricle. Immediately posterior to this spine and inferior to the temporal line is a slightly depressed region called the cribriform plate, a multiperforated region that serves as a landmark for surgical access to the mastoid antrum (see Fig. 173-1).

Posteriorly, the mastoid portion presents a relationship with the parietal bone superiorly and the occipital bone inferiorly, forming the parietomastoid and occipitomastoid sutures. These two sutures join the occipitoparietal suture at a point called the asterion, an important surgical landmark for craniotomies to achieve posterior fossa access.

Medial to the mastoid tip, the posterior belly of the digastric muscle at its insertion forms an osseous depression or sulcus, running anterior to posterior. At its anterior termination, this sulcus is a land-

mark for the descending portion of the facial nerve and the stylomastoid foramen (see Figs. 173-1 and 173-6).

Viewed from above and from inside the cranium, the petrous bone is a key element in the osseous anatomy of the middle and posterior fossae. It has a configuration of a three-sided pyramid (see Fig. 173-2). The base of the pyramid constitutes its lateral surface and articulates with the squamous, tympanic, and mastoid portions of the temporal bone (Fig. 173-7; see also Fig. 173-2). Two sides of the pyramid are clearly recognized as medial projections: one superior, which forms much of the floor of the middle cranial fossa, and the medial surface, which faces the posterior cranial fossa, forming most of its lateral wall. The third and inferior side articulates with the occipital bone (see Figs. 173-2 and 173-3). The anterior medial limit of the pyramid (petrous apex) reaches the greater sphenoid wing laterally, the body of the sphenoid medially and superiorly, and the clivus portion of the occipital bone medially and inferiorly (see Figs. 173-2 and 173-3). The petroclival sutures lie on either side of the midline within the circumference of the foramen magnum.

The superior surface of the petrosa forms the major portion of the middle fossa floor and presents key anatomic landmarks for otoneurologic surgery (Figs. 173-8 and 173-9; see also Figs. 173-2 and 173-3). At the most anterior medial portion (apex) is the foramen lacerum, through which passes the end of the horizontal portion of the carotid

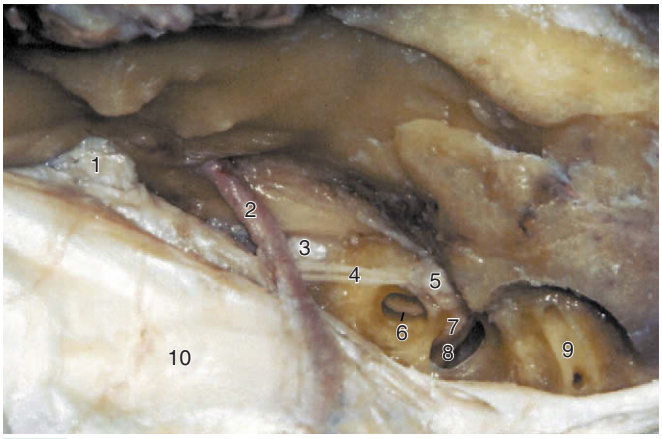

Figure 173-8. Right side view in middle cranial fossa surgical approach. Cruz, Helder Tedeschi, and Albert Rhoton.)*

artery on its way to the cavernous sinus. Medial to the foramen lacerum there is a depression in the bone border (trigeminal impression), where cranial nerve V fibers pass on their way to the Meckel's cave and gasserian ganglion. Lateral and slightly anterior to the ganglion and cave, at the junction to the sphenoid greater wing, is the foramen ovale, through which the third division of the trigeminal nerve (cranial nerve V_3) exits the cranium for the infratemporal fossa (see Figs. 173-2, 173-8, 173-9, and 173-15).

The foramen spinosum is lateral and posterior to the foramen ovale and transmits the middle meningeal artery. The facial hiatus is 10 to 15 mm medial to the foramen spinosum, a bony sulcus that receives the fibers of the greater petrosal nerve coming from the geniculate ganglion (see Figs. 173-2 and 173-3). Posterior and medial to the facial hiatus is the arcuate eminence, related to the most superior aspect of the superior semicircular canal. It is usually, but not always, elevated above the surrounding bone, and the mastoid and tympanic teguments are positioned laterally to it (see Figs. 173-2 and 173-3). The neural and vascular structures of this region are reviewed in the next section, "Anatomy of the Middle Cranial Fossa."

The medial or cerebellar surface of the temporal bone forms the anterolateral wall of the posterior fossa (see Figs. 173-2 and 173-7). Where the superior margin of the medial surface meets the medial margin of the superior surface, a bony sulcus accommodates the superior petrosal sinus on its course between the cavernous sinus and the transition zone between the lateral sinus to the sigmoid sinus. The inferior margin of the medial surface contains another sulcus at the petro-occipital junction for the inferior petrosal sinus, connecting the cavernous sinus and the jugular foramen.

The prominent structure of the petrosa's medial surface is the internal acoustic pore (porus acousticus), which represents the medial limit of the internal auditory meatus (see Fig. 173-7). The meatus ends laterally at the medial wall of the vestibule and the inferior surface of the modiolus and basal cochlear turn (Fig. 173-10; see also Figs. 173-6 and 173-7). A horizontal bony ridge located at the lateral limit divides the meatus into two compartments, superior and inferior. The upper

compartment also is divided into anterior and posterior portions by a small vertical bony crest, commonly known as "Bill's bar" in honor of William House, who first drew attention to its presence and surgical importance. These bony ridges divide the fundus of the internal auditory canal into four quadrants, each carrying its own cranial nerve: an anterior-superior quadrant with the facial nerve, an anterior-inferior quadrant with the cochlear nerve, and posterior-superior and posterior-inferior quadrants occupied by the superior and the inferior vestibular nerves, respectively[6] (see Fig. 173-10A and B).

Posterior to the superior limit of the porus of the internal auditory canal and inferior to the arcuate eminence is the subarcuate fossa, which contains a channel to the subarcuate artery and veins (see Figs. 173-7 and 173-11). Posterior and caudal to the subarcuate fossa is a small bony fissure or depression that indicates the opening of the vestibular aqueduct and the position of the endolymphatic sac in the posterior fossa (see Fig. 173-7).

The inferior surface articulates with the occipital bone forming the petro-occipital suture which is in near continuity with the occipitomastoid suture and the sulcus of the sigmoid sinus. In this region lies the butterfly-shaped jugular foramen with its lateral margin formed by the petrous bone and its medial limits by the occipital bone (see Fig. 173-7). Immediately anterior to the jugular foramen is the petro-occipital sulcus, which contains the inferior petrosal sinus. The inferior petrosal sinus enters the jugular foramen in its anterior compartment.

Cranial nerves IX, X, and XI also exit the cranial cavity through the anterior compartment of the jugular foramen and are completely separated from the venous components by a dural septum and fibrous vascular tissue (as described later under "Anatomy of the Posterior Cranial Fossa") (see Figs. 173-4, 173-5, 173-13, and 173-14). The fossa of the jugular bulb lies superior to the posterior compartment and varies greatly in size (see Figs. 173-4, 173-5, and 173-13). The funnel-shaped opening of the cochlear canaliculus is at the superior border of the anterior compartment (see Fig. 173-7). Just inferior to the anterior compartment is the opening of the hypoglossal canal, through which cranial nerve XII leaves the cranium (see Fig. 173-7).

Lateral and anterior to the anterior component of the jugular foramen is the ascending portion of the carotid artery canal at the petrosa's junctions with the tympanic bone (see Figs. 173-4 and 173-5). Within it are the internal carotid artery and the venous and sympathetic nerve plexuses. Here the carotid artery pursues a cephalic course along the anterior wall of the tympanic cavity, parallel to the anterior portion of the tympanic bone and the glenoid fossa (see Figs. 173-4 and 173-5). Just medial to the tympanic ostium of the eustachian tube and immediately anterior to the cochlea, the carotid canal bends horizontally, forming the carotid "knee," and follows a horizontal course in the middle fossa toward the petrous apex and foramen lacerum (see Figs. 173-5, 173-9, and 173-15).

From an anterior perspective, two small openings are visible lateral to the carotid canal. The superior opening is the canal for the tensor tympanic muscle, and the inferior is the osseous portion of the eustachian tube (see Fig. 173-3).

When viewed from a lateral inferior perspective, the jugular foramen lies posterior and medial to the styloid process, and posterior and lateral to the carotid canal, formed by the medial-inferior aspect of the petrous bone and the occipital bone (see Fig. 173-1).

Anatomy of the Middle Cranial Fossa

This section describes relevant anatomy for the middle cranial fossa surgical approach. After a squamosal craniotomy, the temporal lobe dura is elevated, exposing the floor of the middle fossa (see Fig. 173-8).

The gasserian ganglion is located at the anterior aspect of the petrous apex (see Fig. 173-9). The mandibular division of the fifth cranial nerve (trigeminal nerve), V_1, passes anteriorly through the superior orbital fissure. The maxillary division, V_2, passes through the foramen rotundum, and the ophthalmic division, V_3, through the foramen ovale. Medial and posterior to the foramen ovale, the middle meningeal artery enters the middle cranial fossa through the foramen spinosum (see Figs. 173-2, 173-8, and 173-9). The greater superficial petrosal nerve is located medial to the middle meningeal artery. It is the principal surgical landmark for middle cranial fossa procedures because of its consistency and its intimate relationship with nearby structures[2] (see Figs. 173-2, 173-8, and 173-9).

Lateral to the greater petrosal nerve, semicanal to the tensor tympani muscle lies medial to the middle meningeal artery (see Figs. 173-3 and 173-9). The osseous portion of the eustachian tube parallels the course of the tensor tympani muscle laterally. Thus, from superior to inferior, the greater superficial petrosal nerve, the tensor tympani muscle, and the eustachian tube all proceed in a similar anteroposterior plane (see Fig. 173-3).

The horizontal portion of the carotid artery follows a course just inferior and medial to greater petrosal nerve and inferior to the gasserian ganglion on its way to the foramen lacerum and the cavernous sinus (see Figs. 173-8 and 173-9).

The posterior termination of the greater petrosal nerve is the geniculate ganglion. That ganglion is covered by a thin lamina of bone that is absent in 16% of cases. Medial and posterior to the geniculate ganglion is the labyrinthine segment of the facial nerve emerging from the internal auditory canal. After the superior wall of the internal auditory canal is removed, the facial nerve can be seen in the anterior superior portion of the canal and the superior vestibular nerve in the posterior superior portion (see Fig. 173-9). The greater petrosal nerve, geniculate ganglion, and labyrinthine segment of cranial nerve VII form an obtuse angle of approximately 120 degrees. The cochlea is embedded in the bone subtended by that angle (see Figs. 173-8 and 173-9).

The tegmen tympani and tegmen mastoideum are lateral to the geniculate ganglion. If they are partly removed, the epitympanum, the tympanic segment of the facial nerve, and the incudomalleolar joint are seen anteriorly and the mastoid antrum and the three semicircular canals are seen posteriorly. The groove for the superior petrosal sinus at the superior medial ridge of the petrosa marks the medial limit of the middle fossa approach. The opening of the superior petrosal sinus allows access to the posterior cranial fossa.

Anatomy of the Posterior Cranial Fossa

The cerebellopontine angle is traversed by the intracranial segments of cranial nerves VII and VIII. The posterior fossa also contains many other crucial neural and vascular structures, as shown in Figures 173-11 and 173-12. Also, the posteromedial aspect of the temporal bone contains the internal auditory canal and the jugular foramen, and familiarity with their relationships is essential.

Cerebellopontine Angle

The cerebellopontine angle is delimited as follows[2,6]:

- Anteriorly, by cranial nerve VI and the lateral aspect of the clivus
- Laterally, by the medial surface of the petrosa
- Medially, by the middle cerebellar peduncle, the pons, and the ventral surface of the cerebellum
- Superiorly, by cranial nerve V
- Inferiorly, by cranial nerves IX, X, and XI
- Posteriorly, by the cerebellar floccules

Contained within this space are cranial nerves VII and VIII; the premeatal, meatal, and postmeatal segments of the AICA; and the porus of the internal auditory canal. When cranial nerves VII and VIII leave the brainstem at the bulbopontine sulcus, cranial nerve VII lies 1 to 2 mm anterior to cranial nerve VIII. Both nerves follow a lateral and ascending course to enter the internal auditory canal (see Figs. 173-11 and 173-12). From its origin to the most lateral aspects of the internal auditory canal, cranial nerve VII occupies a more anterior and superior position in relation to cranial nerve VIII (see Fig. 173-10).

Internal Auditory Canal

The internal auditory canal develops a lateral and posterior path in relation to the medial surface of the temporal bone. Its length is 1.2 to

1.4 cm from the porus to the fundus, where it enters the inner ear[6] (see Figs. 173-6, 173-7, 173-9, and 173-10).

The lateral portion of the internal canal is divided into superior and inferior compartments by the falciform or transverse crest (see Fig. 173-10A and B). The superior compartment is further divided into anterior and posterior portions by the vertical crest (Bill's bar). Those four quadrants are occupied by the four main neural components of the internal auditory canal contents: the facial nerve (superior and anterior), the superior vestibular nerve (superior and posterior), the cochlear nerve (anterior and inferior), and the inferior vestibular nerve (posterior and inferior).

The inferior compartment does not have a bony division for the cochlear and inferior vestibular nerves, but the cochlear nerve leaves the internal auditory canal through a multiperforate osseous plate to enter the cochlear modiolus (see Fig. 173-10A). Posteroinferiorly, a small multiperforated region reflects the emergence of the inferior vestibular nerve fibers from the saccular macula, and a short distance away is the singular foramen that transmits the posterior ampullary nerve (singular nerve) from the ampulla of the posterior semicircular canal.

Jugular Foramen

The jugular foramen is located in the petro-occipital region and contains several vital neural and vascular structures (Fig. 173-13 and 173-14; see also Figs. 173-1, 173-3, 173-6, 173-7, and 173-11). The vascular structures include the sigmoid sinus, superior and inferior

petrosal sinuses, jugular bulb, and meningeal branches from the ascending pharyngeal and occipital arteries. The neural components include cranial nerves IX (glossopharyngeal nerve), X (vagus nerve), and IX (spinal accessory nerve) and their respective ganglia. The jugular foramen also receives the opening of the cochlear aqueduct and is in close proximity to the hypoglossal canal and to cranial nerve XII (see Figs. 173-7, 173-11, and 173-14).

Traditionally, the jugular foramen has been divided into two parts: the larger posterior *pars venosa* and the smaller anterior *pars nervosa*. More recently, anatomic division into three compartments has been proposed[7]:

Sigmoid compartment: posterior and receiving the sigmoid sinus

Petrous compartment: anterior and receiving the inferior petrosal sinus

Neural intrajugular compartment: located between the two others and receiving the neural and arterial components

Cranial nerve IX penetrates a dural opening in the neural compartment and courses anteriorly and inferiorly near the opening of the cochlear aqueduct. Within the jugular foramen, cranial nerve IX forms two ganglia. The inferior ganglion gives rise to the auricular branch (Jacobson's nerve), which ascends across the promontory to form a sensory plexus and the lesser superficial petrosal nerve.

Cranial nerves X and XI penetrate the neural compartment inferior to cranial nerve IX and are separated from it by a dural septum. Cranial nerve X also forms a ganglion as it leaves the cranial cavity; the auricular branch of the vagus nerve (Arnold's nerve) arises from it. Arnold's nerve courses superiorly to emerge at the tympanomastoid fissure and provide sensory innervation to the posterior wall of the external auditory canal. Cranial nerve X leaves the jugular foramen and descends vertically posterior to the carotid artery and anterior to the jugular vein, parallel to and in close relationship with the cervical segment of cranial nerve XII immediately after it has left the cranial cavity (see Figs. 173-4, 173-5, 173-13, and 173-14).

Anatomy of the Infratemporal Fossa

The infratemporal fossa is a space delimited as follows (Fig. 173-15; see also Fig. 173-1):

- Anteriorly, by the posterior surface of the maxilla and the inferior orbital fissure
- Posteriorly, by the mastoid and tympanic portions of the temporal bone
- Superiorly, by the inferior surfaces of the greater wing of the sphenoid and the squamous portion of the temporal bone

- Medially, by the pterygoid process of the sphenoid, lateral portion of the clivus, first cervical vertebra, and inferior surface of the petrous portion of the temporal bone
- Laterally, by the zygomatic arch and ascending ramus of the mandible
- Inferiorly, by the the superior limit of the posterior belly of the digastric muscle and the angle of the mandible

The infratemporal fossa communicates with the orbit through the inferior orbital fissure, with the middle cranial fossa through the foramen spinosum, and with the pterygopalatine fossa through the pterygomaxillary fissure (see Figs. 173-1 and 173-15). The lateral and medial pterygoid muscles lie within the infratemporal fossa. The lateral pterygoid muscle is divided into superior and inferior parts. The superior portion arises from the roof of the infratemporal fossa, and the inferior arises from the lateral aspect of the lateral pterygoid process. Both portions insert onto the temporomandibular joint. The medial pterygoid muscle originates from the medial portion of the lateral pterygoid process and inserts on the medial surface of the angle of the mandible and the ascending ramus.

The infratemporal fossa also contains the mandibular division of the trigeminal nerve (V_3) and its branches (see Fig. 173-15), which provide motor innervation to the temporalis, masseter, and medial and lateral pterygoid muscles, as well as sensory innervation through the auriculotemporal, alveolar, lingual, and buccal nerves.

The chorda tympani nerve originates in the mastoid segment of the facial nerve (cranial nerve VII) midway in the descending portion, pursues a course anterior and superior to the posterior superior quadrant of the mesotympanum, passes through the tympanic cavity, and reaches the chorda tympani canaliculus in the petrotympanic fissure. It then passes forward and descends vertically and medially to the lateral pterygoid muscle to join the lingual nerve (see Figs. 173-4, 173-5, and 173-6).

The maxillary artery leaves the external carotid artery posterior to the ascending ramus of the mandible and enters the infratemporal fossa lateral to the lateral pterygoid muscle. It follows a trajectory anterior to the pterygomaxillary fissure and the pterygopalatine fossa (see Fig. 173-15). It divides within the infratemporal fossa. Its principal branches are the middle meningeal artery, the inferior alveolar artery, the deep temporal artery, branches to the pterygoid muscles, the auricular artery, and the anterior tympanic artery.

The venous drainage of the infratemporal fossa occurs by way of the pterygoid venous plexus, which drains posteriorly into the maxillary vein and anteriorly into the facial vein. The plexus also anastomoses with the cavernous sinus, ophthalmic veins, and pharyngeal venous plexus. Infection within the infratemporal fossa thus carries the risk of spread by hematogenous extension, especially to involve the contents of the orbit and cavernous sinus.

CHAPTER ONE HUNDRED AND SEVENTY-FOUR

Surgery of the Anterior and Middle Cranial Base

Colin D. Pero

Rohan R. Walvekar

Bert W. O'Malley, Jr.

Daniel W. Nuss

Key Points

- Advances in oncologic and reconstructive surgery, anesthesiology, radiology, and other related fields have made surgery of the cranial base both technically feasible and therapeutically effective. As a result, surgical resection can be considered the primary management modality for many cranial base lesions previously considered inaccessible or inoperable.
- Symptoms from anterior and middle cranial base lesions may range from headache to impaired cranial nerve and central nervous system functions. These disorders are insidious in that they cause few symptoms until they have reached advanced stages and impinge on cranial nerves, major vessels, or the brain. This paucity of early symptoms makes early diagnosis difficult.
- Operative planning for the removal of lesions of this anatomically complex region requires that laboratory testing, imaging, and vascular interventional procedures be used to their fullest potential to guide the surgical and anesthetic teams, as well as the patient's expectations.
- Operative approaches should attempt to meet principal aims of (1) optimizing exposure, (2) preserving neurovascular structures, (3) implementing the use of image guidance and endoscope assistance to enhance the resection while limiting incision length and removal of normal tissue, and (4) planning surgical techniques that optimize functional and aesthetic reconstruction.
- Postoperative complications may entail serious morbidity and mortality; limiting postoperative neurologic and other complications requires anticipation of potential risks and an aggressive approach to their prevention and management.

The cranial base often is conceptually divided into three anatomic regions that are named for their intracranial relations to the overlying cranial fossae: anterior, middle, and posterior (Fig. 174-1). From a diagnostic and therapeutic point of view, it is useful to consider the anterior and middle cranial base regions together, for several reasons. They contribute to what is commonly referred to as the craniofacial junction, where the neurocranium and the viscerocranium meet (Fig. 174-2). Both share anatomic relationships with the orbits, the nasal airway, and the paranasal sinuses, and they are therefore affected by similar pathologic processes. The anterior and middle cranial base regions have traditionally been approached using craniofacial disassembly techniques, however, endoscopic approaches to the skull base have assumed a growing role in selected cases while minimizing surgical morbidity. Additionally, robotic-assisted surgery has been investigated and holds promise for the future of anterior and middle cranial base surgery. The posterior and lateral cranial base are clinically regarded as a separate region, often approached with combined neurotologic and neurosurgical approaches (Chapters 127, 173, 176, and 177). This chapter focuses on the surgical management of lesions that affect the anterior and middle cranial base.

Surgical Anatomy

Anterior Cranial Base

The anterior cranial base can be defined as that portion of the skull base adjacent to the anterior cranial fossa. It is bounded anteriorly by the frontal bone, which contains two surgically important structures: the frontal sinus and the supraorbital foramina (Fig. 174-3). The anatomy of the anterior cranial base is described in detail in Chapter 175, and briefly reviewed here. The supraorbital foramina, which may be incomplete (and therefore referred to as supraorbital notches), transmit the supraorbital nerves and vessels. These vessels supply the galea and the pericranium of the frontal region, and their preservation facilitates subsequent use in reconstructing anterior cranial base defects.

Superiorly, the anterior cranial base is formed by the frontal, ethmoid, and sphenoid bones (Fig. 174-4). An important visible land-

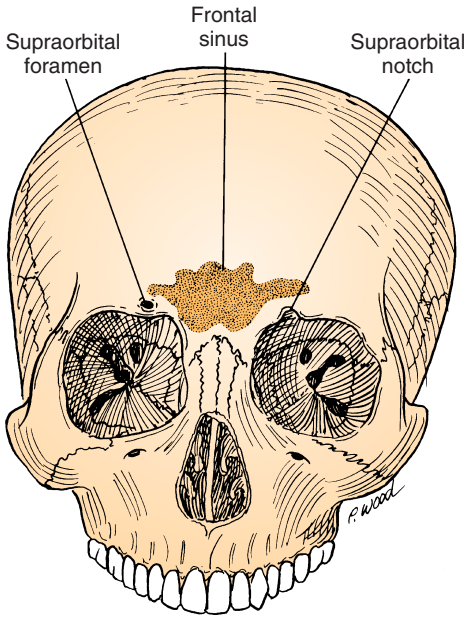

Figure 174-3. Anterior perspective of the anterior cranial base showing the outline of the frontal sinus *(shaded)* and the position of the supraorbital neurovascular pedicle exiting the supraorbital foramen *(left)* and the supraorbital notch *(right)*.

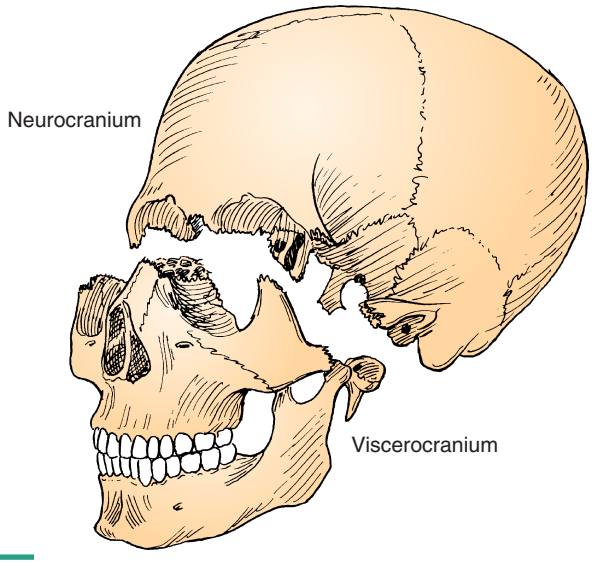

Figure 174-2. Disarticulated skull showing the junction of the neurocranium with the viscerocranium (craniofacial junction). The anterior cranial base forms the roof of the orbits and the nasal cavities, and the middle cranial base makes up the roof of the intratemporal fossa, the pterygopalatine fossa, and the nasopharynx. Operative approaches to the anterior and middle cranial base regions often traverse the viscerocranium.

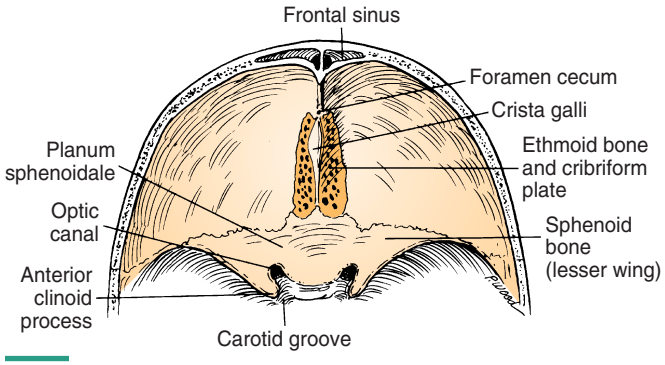

Figure 174-4. Intracranial view of the anterior cranial base and important landmarks.

mark is the foramen cecum, which is the site of a communication between veins of the nasal cavity and the origin of the superior sagittal sinus. The next landmark, the crista galli, protrudes upward from the midline to provide attachment for the falx cerebri. On either side of the crista are the openings of the cribriform plate, through which olfactory nerves are transmitted. Just posterior to the last of these olfactory foramina is a smooth-surfaced area known as the planum sphenoidale; it forms the roof of the sphenoid sinus when the sinus is well pneumatized. The anterior clinoid processes and lesser sphenoid wings delineate the most posterior limit of the anterior cranial base and delineate its boundary with the middle cranial base. Between and slightly below the clinoids are the optic canals and the internal carotid arteries (ICAs).

Extracranially, the anterior cranial base is related to the nasal cavity, the ethmoid and sphenoid sinuses, and the orbits (Fig. 174-5). The floor of the anterior cranial fossa is uneven, with the relatively flat orbital roofs sloping downward as they join the roof of the ethmoid sinuses medially. Thus, the ethmoid roof is lower than the orbital roof. The downward slope becomes even more exaggerated as the ethmoid roof joins the cribriform area (the roof of the nasal cavity), near the midline, which usually is the lowest point of the anterior skull base. The relative relationship of the height of the cribriform plate to the roof of the ethmoid is variable and has been classified by Keros into three categories: class 1, 1 to 3 mm; class 2, 4 to 7 mm; and class 3, 8 to 16 mm.[1]

This nonplanar arrangement of the cribriform area is important during transethmoid extracranial approaches to lesions of the anterior skull base. For example, an axial plane of dissection that is safe along the roof of the ethmoid may risk injury to the dura and frontal lobes if extended medially to encompass the cribriform plate territory.

The orbits contain several landmarks that can help surgical orientation during cranial base operations (Fig. 174-6). The superior orbital fissure transmits the oculomotor, trochlear, ophthalmic, and abducens

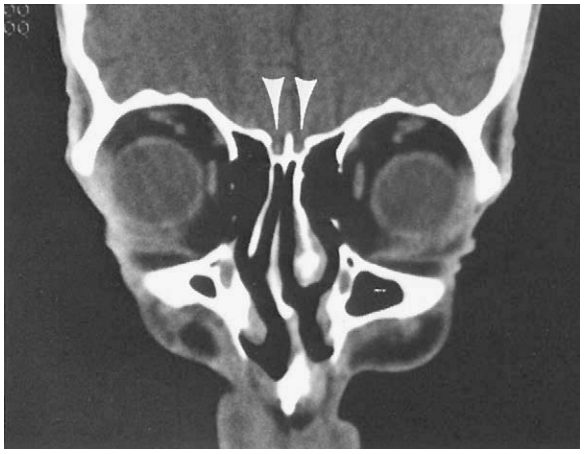

Figure 174-5. Coronal computed tomography scan through the anterior cranial fossa, orbits, and ethmoid region, showing the relationship of the anterior cranial fossa floor with the underlying orbits and sinuses. The cribriform area *(arrows)* is significantly lower than the ethmoid roof and the orbital roof. Extracranial approaches to this region should respect this anatomy to avoid injury to the dura and brain.

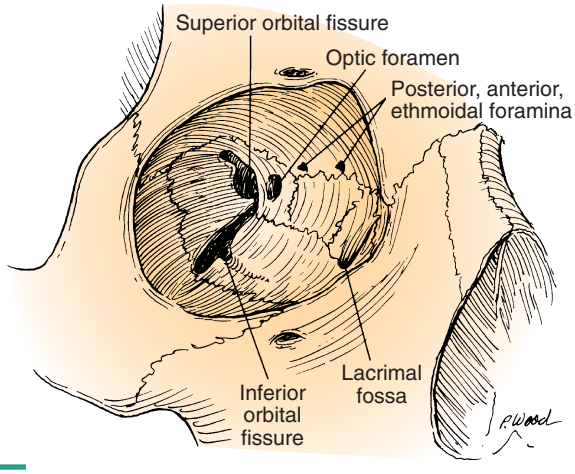

Figure 174-6. Important surgical landmarks of the orbital skeleton.

nerves (cranial nerves III, IV, V1, and VI) and the ophthalmic vein, and it communicates with the middle cranial fossa. The inferior orbital fissure contains the maxillary nerve (V2) and communicates primarily with the pterygopalatine fossa; the lateral end of this fissure is an important landmark for the placement of lateral orbital osteotomies. The optic canal transmits the optic nerve and the ophthalmic artery. The anterior and posterior arteries transmitted through ethmoid foramina should be controlled to reduce intraoperative bleeding in the nasal vault region. More important, these ethmoid foramina mark the position of the frontoethmoid suture line, a valuable guide to the level of the ethmoid roof and the anterior fossa floor. The posterior ethmoid foramen is of additional significance because of its consistent relationship with the optic canal, found 4 to 7 mm posteriorly.

Middle Cranial Base

The middle cranial base forms the floor of the middle cranial fossa. From the intracranial perspective (Fig. 174-7), the middle cranial base begins anteriorly at the posterior edge of the lesser sphenoid wing; posteriorly it ends at the posterosuperior edge of the petrous part of the temporal bone. The intracranial surface of the middle cranial base is formed by the greater wing and body of the sphenoid bone and the petrous and squamous portions of the temporal bone. As such, it forms the roof of the infratemporal fossa, middle ear, mastoid, and condylar fossa and the lateral wall of the sphenoid sinus.

Foramina along the floor of the middle fossa beginning anteriorly are the superior orbital fissure, optic canal, and foramen rotundum (representing the intracranial end of the inferior orbital fissure). Next, the foramen ovale delivers the mandibular nerve (V3) to the infratemporal fossa below, and the foramen spinosum transmits the middle meningeal artery.

The superomedial boundary of the middle cranial base is marked by the petrous part of the temporal bone containing the horizontal petrous ICA and the foramen lacerum. This foramen receives the greater superficial petrosal nerve (GSPN) (parasympathetic fibers from the facial nerve to the lacrimal gland) and conducts it to the pterygopalatine fossa inferiorly. Recognition of this relationship among the GSPN, the foramen lacerum, and the carotid canal often is helpful during surgery because the GSPN, which is readily identifiable, can be followed medially to the distal petrous ICA.

From an extracranial viewpoint, the middle cranial base extends from the posterolateral walls of the maxillary sinuses anteriorly to the petro-occipital sutures posteriorly (Fig. 174-8). It is formed by the greater wing and body of the sphenoid bone and by the temporal bone, including the condylar fossa. As on its intracranial surface, this region also contains numerous openings for major nerves and blood vessels, including the foramina ovale, spinosum, and lacerum and the stylomastoid foramen (cranial nerve VII), the jugular foramen (internal jugular vein, inferior petrosal sinus, cranial nerves IX, X, and XI), and the carotid canal (entrance of ICA into the temporal bone).

Operative approaches in this region often traverse the infratemporal fossa. Here, the muscles of mastication—the temporalis, masseter, and medial and lateral pterygoids—receive their blood supply from branches of the internal maxillary artery, which should be preserved if, for example, the versatile temporalis muscle is to be used as a flap for reconstruction. Both the lateral and medial pterygoid muscles originate in part from the lateral pterygoid plate (of the sphenoid bone), which serves as an excellent landmark owing to the following features: (1) it is a palpable guide for surgical orientation; (2) it can be easily exposed by dissection carried out medially along the greater sphenoid wing; and (3) it is easily identified on radiographic imaging studies, especially computed tomography (CT). The root of this lateral pterygoid plate is situated immediately posterior to the foramen rotundum and anterior to the foramen ovale. It can be used as an index to the positions of the maxillary (V2) and mandibular (V3) divisions of the trigeminal nerve (Fig. 174-9). After the foramen ovale is identified, the foramen spinosum (transmitting the middle meningeal artery) will be found just posterior to it. This leads to the next critical landmark: the spine of the sphenoid.

The sphenoid spine, which is situated just medial to the condylar fossa, serves as a palpable, radiographically identifiable landmark that is important because of its location immediately lateral to the carotid canal (see Fig. 174-8). It helps the surgeon locate the highest portion of the cervical ICA, which can be followed distally to expose and mobilize the petrous ICA. Because the sphenoid spine is just medial to the condylar fossa, the mandibular condyle often is displaced anteroinferiorly or resected to enhance exposure of the ICA as it enters the cranial base.

A thorough and detailed understanding of the regional anatomy of the cranial base is best achieved through the correlative study of dry skulls, cadaveric dissections, and radiographic images.

Preoperative Considerations

The principles of the clinical evaluation of presenting symptoms and physical findings (Chapter 175) and diagnostic imaging[2] (Chapter 135) are considered in detail elsewhere in this book.

Angiography

In many cases, it is important to have information about the vascularity of a given cranial base lesion and the possible involvement of major neighboring blood vessels. For this reason, cerebral angiography often is part of the diagnostic imaging sequence. This type of angiography permits the identification of the blood supply to the lesion and its own vascular pattern while simultaneously clarifying whether the ICA or other major vessels are compromised.

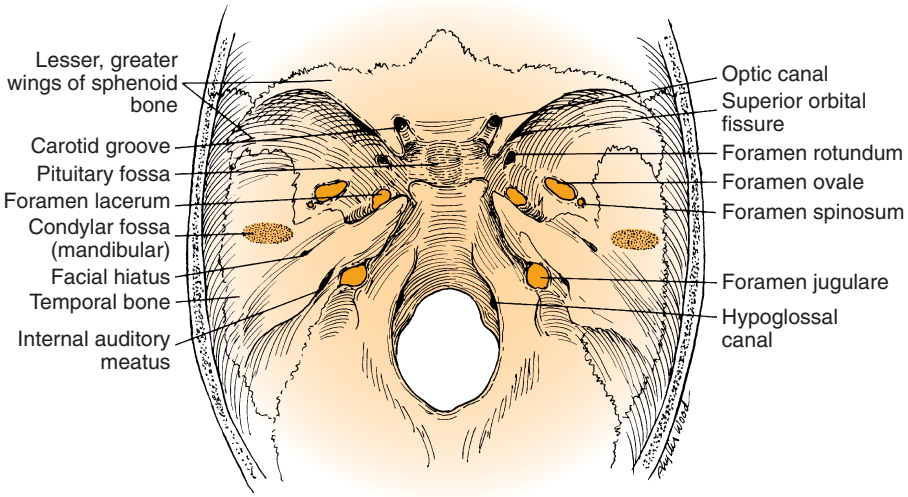

Figure 174-7. Intracranial view of the middle cranial base.

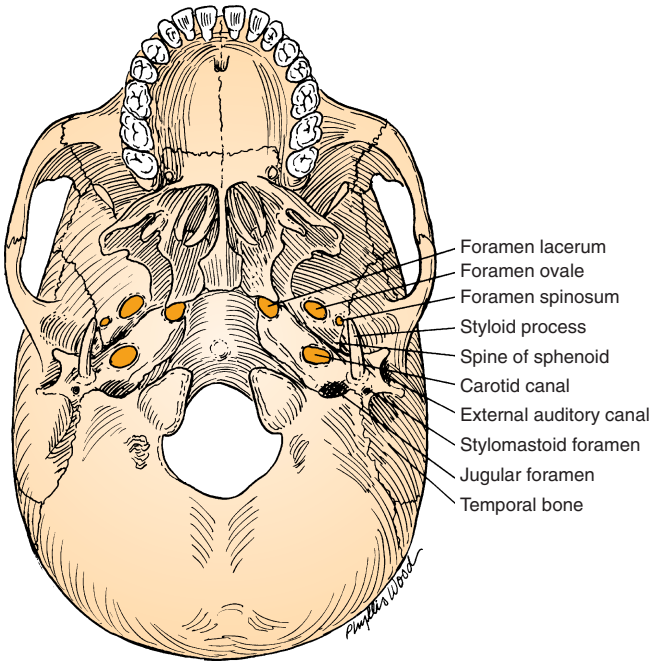

Figure 174-8. Extracranial aspect of the middle cranial base.

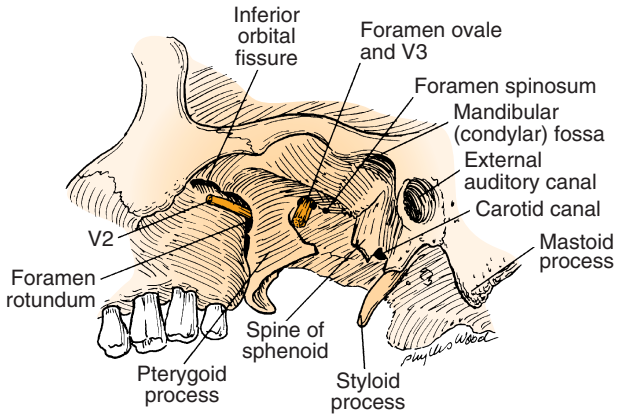

Figure 174-9. Lateral view of the pterygoid process of the sphenoid bone (pterygoid plate), showing the relationship of the foramina rotundum and ovale with associated structures. V2, maxillary nerve; V3, mandibular nerve.

Angiography also gives anatomic information about the integrity of the circle of Willis, existing collateral circulation to the cerebral hemispheres, and other possible anomalous blood supply patterns that may dictate the approach or prudent use of embolization.[3]

Angiography alone, however, does not give sufficient physiologic information about the adequacy of the circle of Willis or other collaterals with regard to supplying circulation to the brain.[4] To obtain detailed physiologic information, cerebral blood flow studies are performed.

Computed tomographic angiography (CTA), magnetic resonance angiography (MRA), and three-dimensional reconstructive technology have added relatively noninvasive options and adjuncts to conventional imaging and angiographic methods. One drawback to these modalities is the inability to incorporate interventional techniques including balloon occlusion and embolization as preoperative workup and adjunctive procedures (as discussed next).

Cerebral Blood Flow Evaluation

If a cranial base lesion involves or impinges on the ICA or if it will be necessary to manipulate the ICA during surgery, cerebral blood flow studies should be considered. These studies give a physiologic index of the adequacy of the circulation to the brain in a quantitative way and are useful for predicting whether a patient can tolerate occlusion of the ICA without major neurologic consequence.[5-8]

The test begins with a temporary occlusion of the ICA by means of a balloon-tipped catheter inflated within the vessel. The catheter is placed percutaneously through the femoral artery and guided into the cervical portion of the ICA under fluoroscopic control, just as is done for routine cerebral angiography. This is performed with the patient awake, and serial neurologic assessments are done during the 15-minute ICA occlusion. If a neurologic deficit develops during this part of the test, occlusion is immediately discontinued. A patient demonstrating such a deficit is considered to have failed the test and is presumed to be highly dependent on the flow in that ICA; thus, the risk for stroke is increased if the carotid is compromised at surgery. If the patient tolerates 15 minutes of ICA occlusion without the development of neurologic deficit, further study uses a quantitative test in which stable xenon gas is inhaled. The inhaled xenon is distributed throughout the circulation and into the brain, where it is visible on CT scanning; this gives a picture of cerebral blood flow distribution (Fig. 174-10). This xenon-enhanced CT scan is performed with the balloon inflated and deflated in the ICA. The uptake of xenon within both cerebral hemispheres is quantitated using the digitized data from the CT scan (when xenon CT is not available, single-photon emission computed tomography [SPECT] imaging can give similar blood flow imaging, although it is not quantitative).

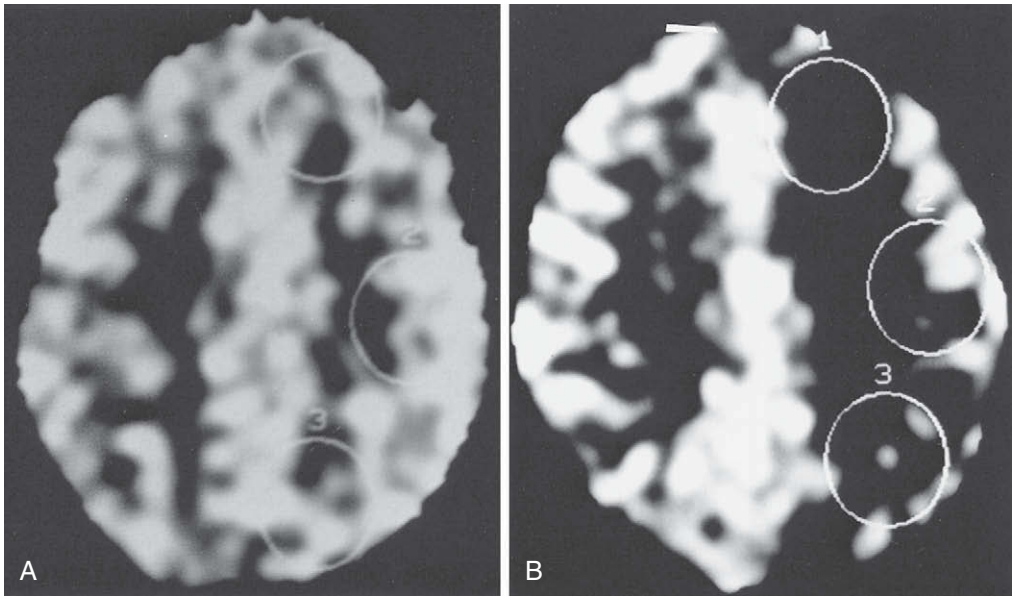

Figure 174-10. Axial slices, xenon-enhanced computed tomography scan through the level of the cerebral hemispheres. **A,** Normal cerebral blood flow distribution with symmetrical bilateral xenon uptake (*dark areas* within each hemisphere represent lateral ventricles). **B,** Significantly decreased hemispheric xenon uptake (on the right side of photograph) after inflation of a balloon within the ipsilateral internal carotid artery. From these xenon studies, cerebral blood flow in specific regions of interest *(circles)* can be quantitated. Such information is useful for predicting the patient's ability to tolerate occlusion of the internal carotid artery at surgery.

The patient who has a significant ipsilateral decrease in hemispheric xenon uptake during ICA occlusion (despite no clinically apparent neurologic deficit during the test) is considered to be at moderate risk for the development of neurologic sequelae should the ICA be occluded during surgery. Such patients would be candidates for extracranial-to-intracranial arterial bypass to enhance the intracranial circulation. Patients who have no drop in xenon uptake during balloon occlusion of the ICA are believed to be at low risk for postoperative stroke, even if the ICA is resected or permanently occluded.

Preoperative Embolization

Another advantage of preoperative angiography is the possibility for elective embolization of vascular tumor beds to help reduce intraoperative bleeding. In addition, the ICA may be electively embolized using detachable intra-arterial permanent balloons if the decision is made preoperatively that the ICA will have to be sacrificed. This is sometimes done to permit the resection of malignant tumors. These procedures are considered in more detail in Chapter 136.

Other Evaluations

For lesions near the orbits, visual acuity should be assessed quantitatively and measurements of the visual fields performed. For lesions near the temporal bone, audiologic and vestibular testing, electronystagmography, and facial electromyography (EMG) should be performed as indicated. These evaluations may help to uncover and quantify cranial nerve dysfunction in some patients. It may also help predict the degree of postoperative cranial nerve morbidity.

For lesions near the pituitary fossa, a complete endocrine evaluation should be performed. It is especially important to identify patients who preoperatively have syndrome of inappropriate antidiuretic hormone, diabetes insipidus, or hypothyroidism, because these conditions can lead to postoperative morbidity if not corrected. Also, abnormal levels of prolactin, growth hormone, or gonadotropins may be of diagnostic significance as indicators of tumors of the pituitary gland. Metastatic workup is conducted in patients with specific malignant tumors.

Pathology and Management Planning

Many disorders can affect the cranial base. Disorders in which surgery has played a significant therapeutic role include basicranial trauma; craniofacial anomalies; congenital syndromes (e.g., hypertelorism, Crouzon's syndrome); spontaneous cerebrospinal fluid fistulas; vascular problems (e.g., petrous carotid artery aneurysms); infectious diseases (e.g., petrositis, malignant external otitis); and neoplasms. Perhaps the widest acceptance and application of cranial base surgery has been in the management of neoplasms, in which the effectiveness of other modalities is limited.

Benign tumors and related lesions affecting the skull base have been reviewed by several authors and are summarized in Box 174-1.[9-11] In general, benign cranial base neoplasms are managed surgically. The surgical technique often involves "piecemeal" removal, with careful progression from one surgical landmark to the next, to permit the maximal preservation of functionally important structures. For larger tumors or those for which removal carries a high risk of damage to neighboring structures, incomplete resection with postoperative irradiation may be indicated.[12]

Malignant skull base lesions are listed in Box 174-2.[10] With some notable exceptions (i.e., leukemia, lymphoma, myeloma, metastases), malignant neoplasms are managed surgically, although in most cases surgery will not be used as the sole modality. Adjuvant management with radiation (by external beam, implantation, or brachytherapy) or chemotherapy is usually included in the therapeutic plan. Single-modality radiation therapy, including sterotactic radiotherapy, has been recommended by some investigators for certain smaller lesions.[13] Malignant lesions are surgically removed en bloc, with margins of uninvolved tissue after broad circumferential exposure whenever possible.[14]

When surgery is considered for tumors and tumor-like disorders of the cranial base, the first question that should be answered involves the biologic behavior of the lesion. As mentioned, an accurate clinical diagnosis often can be made on the basis of information obtained from the history, physical examination, and imaging studies. Whenever possible, this should be supplemented by a histologic diagnosis before definitive management is carried out.

When tumor is present within the nose, paranasal sinuses, middle ear, mastoid, oral cavity, pharynx, or neck, direct biopsy can be performed using standard techniques. When direct biopsy is not feasible, CT-guided needle biopsy may be done in selected cases (e.g., tumors of the infratemporal fossa). Occasionally a tumor may be inaccessible by either of these routes, or biopsy without adequate skull base exposure may be judged to be unsafe because of concerns about injury to nearby

critical structures or because of vascularity of the lesion. In these situations, the surgeon should proceed with an operative approach to the skull base that is designed to provide access to the tumor for safe biopsy before any irreversible ablative steps are taken. Then, if the frozen-section biopsy result contraindicates resection or is questionable, an alternative management plan may be made. On the basis of histologic criteria, extirpative surgery is usually not performed when one of the following conditions is present: (1) a malignant lesion is metastatic from a distant source; or (2) a malignancy is of a type that responds well to other management modalities (e.g., lymphoma).

Anesthesia

Anesthetic management is crucial for determining the outcome of cranial base operations. Techniques of neuroanesthesia are used, with the primary goals of maximal neuronal preservation and simultaneous facilitation of a controlled surgical environment.[15] Maintenance of hemodynamic factors is key in this scheme, because cerebral blood flow cannot be allowed to drop below critical levels for any significant length of time. Thus, close monitoring of arterial pressure, central venous pressure, cardiac function, and urine output is of paramount importance.

Electrophysiologic monitoring, including somatosensory-evoked potentials to assess cortical function and EMG to assess motor cranial nerve function, is another key element for the achievement of neuronal preservation. Appropriate selection of anesthetic agents and limited use of neuromuscular blocking drugs will enhance the reliability of such monitoring.

Cerebral edema, which is a common problem in intracranial surgery, can be minimized with the intraoperative use of colloids (albumin, plasma) rather than crystalloid fluids. It can be minimized by controlled hyperventilation, which, by virtue of decreasing arterial carbon dioxide tension (P_{CO_2}), causes mild cerebral vasoconstriction and a corresponding reduction in intracranial volume. Generally, P_{CO_2} between 25 and 30 mm Hg is desirable for this purpose. Lower arterial CO_2 levels significantly reduce cerebral perfusion and are not recommended. Another technique that is helpful for reducing brain swelling is the preoperative placement of an indwelling lumbar drain, which decompresses the subarachnoid space by removing cerebrospinal fluid (CSF). Lumbar drains also are important postoperatively in selected cases, because short-term CSF decompression can decrease the possibility of CSF fistula formation. Such drains are not used in patients who have major intracranial space-occupying lesions because of the risk of brainstem herniation. Cerebral edema may be lessened with timely use of corticosteroids and diuretics, an especially helpful adjunct if edema is present preoperatively as a result of a mass lesion.

The anesthesia team also is responsible for the infusion of blood products to replenish surgical blood loss, which can be considerable in some cranial base procedures. Dilutional thrombocytopenia and other coagulopathies can occur after multiple transfusions of stored blood. These problems can be successfully managed with the replacement of clotting factors (in the form of fresh-frozen plasma) and platelets in proportion with erythrocyte transfusion. Related issues include the advance donation of autologous blood for transfusion and the use of "cell saver" devices to collect blood intraoperatively and reinfuse it. With concerns surrounding blood transfusion–related infectious diseases, these techniques are becoming increasingly important. One limitation of the cell salvage technique is that it should not be used when there is a risk of reinfusing tumor cells from the operative field.

The anesthesiologist is essential to the success of surgery for cranial base lesions. Optimal anesthetic management depends on close communication between the anesthesiologist and the surgeon before, during, and after the operation.

Operative Techniques

General Considerations

As the field of skull base surgery has evolved, more and more lesions previously thought to be unreachable or unresectable are now able to be addressed surgically. The contraindications to skull base surgery for malignancy as outlined by Donald[16] include anatomic, tumor, and patient factors. Absolute anatomic contraindications include involvement of the brain stem, portions of the cerebrum, superior sagittal sinus, both internal carotid arteries, both cavernous sinuses and certain vital bridging veins. Tumor factors representing contraindications to resection usually include distant metastic disease; although some authors advocate significantly prolonged survival in those with isolated distant metastases after resection of the primary tumor, this has not been well demonstrated in skull base tumors. Certain malignancies typically display aggressive behavior despite treatment, which must be considered before extensive resection. Patients should be well informed and motivated and without medical contraindications to the operation as well.[16]

Overview of Approaches

Surgical treatment of lesions involving the anterior skull base, nasal cavity, and paranasal sinuses has evolved into a single category of craniofacial approaches. A myriad of surgical approaches have been developed for exposure of the anterior and middle cranial base regions; these range from purely intracranial to purely extracranial. However, most approaches for dealing with lesions of the skull base use combined intracranial and extracranial methods. For anterior cranial base lesions, the most commonly used approaches combine frontal craniotomy with some form of transfacial (transnasal, transmaxillary, or transorbital) exposure. Most commonly, a team of neurosurgeons and otolaryngologists performs this procedure resulting in a bifrontal craniotomy from above and a transfacial approach from below. The transfacial approach often involves midfacial degloving, and facial disassembly, requiring facial incisions and facial osteotomies. Lateral rhinotomy, removal of the frontonasal unit, Le Fort I and II osteotomies, and splitting of the maxilla have been described as means of accessing lesions of the anterior cranial base. Janecka and coworkers[17] described the facial translocation approach, which also involves an extensive facial incision and facial disassembly for access to tumors in the anterior cranial base, cavernous sinus, clivus, and infratemporal fossa.

Since the 1990s, endoscopic sinus surgery has virtually replaced the conventional open techniques used by otolaryngologists in treating sinonasal disorders and is discussed in detail in Chapter 175. Use of the endoscope as a supplement to the surgical approaches can alleviate the need for some facial incisions by allowing the surgeon to observe areas hidden from the field of view of the microscope. For those tumors that invade the anterior cranial base, the endoscope may be utilized as an adjunct to the standard bifrontal craniotomy by allowing visualization of paranasal extension into the sphenoid, ethmoid, frontal, and maxillary sinuses. From nasal or maxillary portals, the endoscope allows visualization of all of the paranasal sinuses. As the technology of endoscope optics and video systems improves, the role of endoscopic cranial base surgery will augment and supplement current microsurgical techniques. Intraorbital lesions may be approached by frontal craniotomy or subcranial approaches, often combined with transfacial approaches.[18]

For middle cranial base lesions, access is most often provided by combining temporal or frontotemporal craniotomy with infratemporal fossa dissection, transfacial exposure, or transtemporal techniques. In addition, endoscope-assisted and image-guided navigational approaches are increasingly being applied (see Chapter 177). In anterior and middle cranial base approaches, craniofacial disassembly techniques have been widely used.

Implicit in the term *craniofacial disassembly* is the concept of the systematic, stepwise dissection of cranial and facial soft tissues on the basis of the knowledge of regional vascular territories and functional anatomy, followed by osteotomies and dismantling of the craniofacial skeleton. Some of these techniques, which were developed originally by plastic and reconstructive surgeons for the correction of congenital craniofacial deformities, are of major importance in cranial base surgery, because they allow wide exposure of the skull base through temporary displacement of the viscerocranium.[19,20] The enhanced exposure of the skull base from below the neuraxis significantly reduces the need for brain retraction and therefore helps minimize postoperative neurologic dysfunction. It also allows the surgeon greater oncologic precision during the extirpative phase, with preservation of the functional and aesthetic units of the face for reconstruction.[58]

Box 174-3

Goals of Cranial Base Surgery

1. Extirpation of disease
2. Protection of vital structures
3. Restoration of critical anatomic barriers
4. Functional and aesthetic reconstruction

Planning the Operative Approach

Whether the surgery is being performed for a benign tumor, a malignancy, or other indications (e.g., inflammatory or vascular lesions, CSF fistula), the approach should be planned and executed to accomplish the four specific goals that are applicable to all cranial base operations, summarized in Box 174-3.

GOAL 1. The approach should provide adequate exposure to allow extirpation of the disease process. To a large extent, the degree of needed exposure is based on information obtained from the physical examination and imaging studies.

GOAL 2. The approach should be designed to protect critical structures near the lesion. Traditionally, the safest way to protect critical structures has been to achieve surgical access beyond the boundaries of the lesion itself to allow for direct visualization and control over the structures of interest. For example, surgical exposure around a tumor would be broadened to identify, dissect, and perhaps displace nearby cranial nerves or the carotid artery. Although obtaining this additional exposure may increase the operative time, it can be a major factor in the reduction of postoperative morbidity.

More recently, the introduction and increased application of two major technical advances have given the surgeon additional options for the protection of critical structures, often without the need for increased surgical exposure: image-guided computer-assisted surgery and endoscopic surgery.

Image-guided (stereotactic) computer-assisted surgery has become a very useful alternative—or adjunct—to wide surgical exposure in selected cases.[21-26] Such "navigational surgery" employs one of a variety of referencing systems that can assimilate preoperative imaging studies into a computer-based algorithm that allows image reformatting in three dimensions (The preoperative reference images may be CT- or magnetic resonance imaging [MRI]-based, or they may be a "fusion study" that takes advantage of both types of studies). The reformatted images then serve as the basis for intraoperative navigation, which involves the use of an interactive probe that transmits spatial-orientation information back to the computer via transmitters; these can be either electromagnetic or optical. The computer screen then displays the appropriate preoperative images with the location of the probe superimposed, thus "targeting" the area of interest (Figure 174-11). With navigational systems, structures that are anatomically fixed (i.e., orbital walls, carotid canal, optic canal) can be precisely located, and the risk of injury can be minimized.

Reported uses of image-guided surgery include primary and revision endoscopic sinus surgery, osteoplastic frontal sinusotomy, transsphenoidal hypophysectomy, endoscopic cerebrospinal fluid leak and encephalocele or meningocele repair, endoscopic skull base tumor resection, orbital surgery, and endoscopic pterygomaxillary fossa biopsy.[27,28]

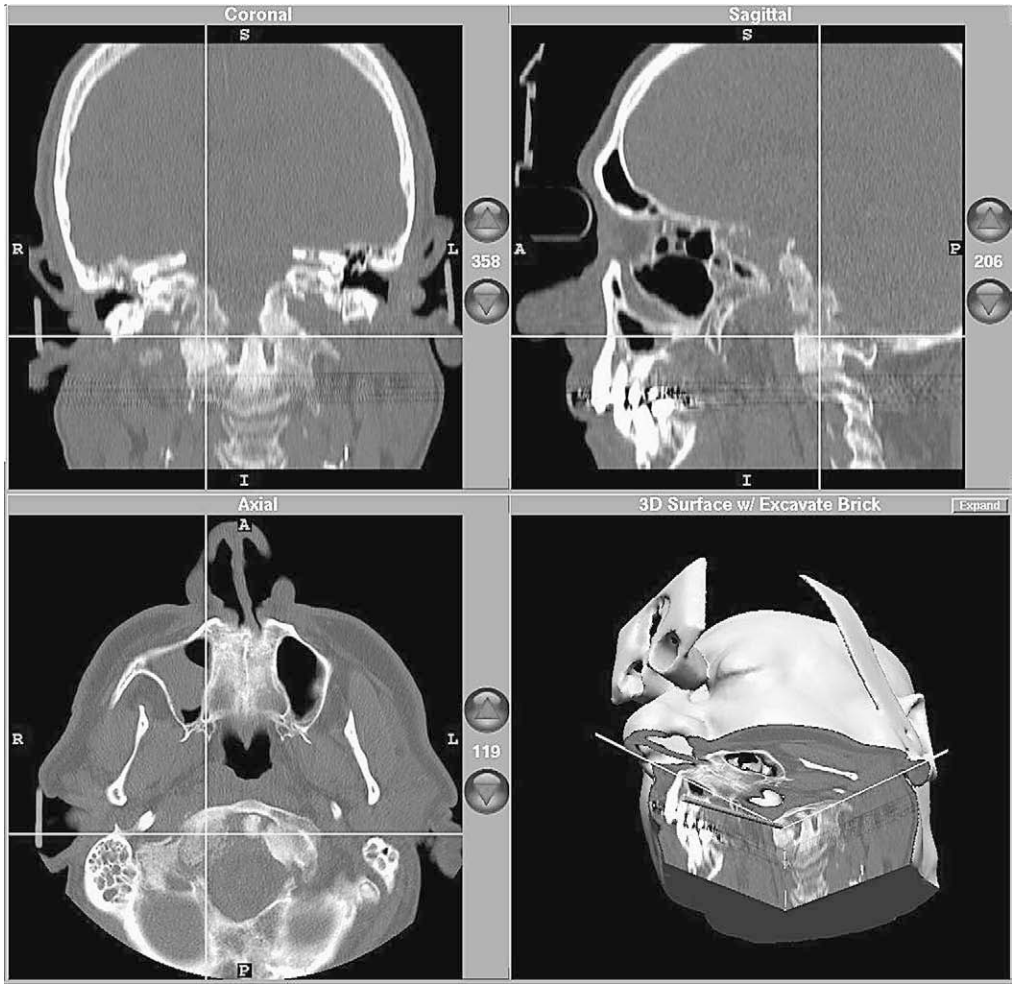

Figure 174-11. Navigational images as seen on intraoperative computer display. The patient's computed tomography images are displayed in the coronal *(top left)*, axial *(bottom left)*, and sagittal *(top right)* planes, and a three-dimensional cutaway view *(bottom right)* also is shown. On each image, the intersection of the crosshairs indicates the position of the navigational probe. As the probe is moved within the operative field, the images change to reflect the probe's precise location. In this case, a lesion that was both osteoblastic and osteolytic and that involved the occipital condyle was approached endoscopically through the nasal cavity without the need for an extensive disassembly approach. The lesion turned out to be a metastasis from a previous renal cell carcinoma.

The American Academy of Otolaryngology–Head and Neck Surgery endorses use of computer-aided surgery for the following specific procedures or conditions[29]:

- Revision sinus surgery
- Distorted sinus anatomy of development, postoperative, or traumatic origin
- Extensive sinonasal polyposis
- Pathology involving the frontal, posterior ethmoid, and sphenoid sinuses
- Disease abutting the skull base, orbit, optic nerve, or carotid artery
- CSF rhinorrhea or conditions that feature a skull base defect
- Benign and malignant sinonasal neoplasms

Intraoperative MRI or CT also has been proposed as a useful adjunct in skull base surgery. Proponents advocate the improved ability to detect residual tumor and evaluate for intraoperative complications, however, limitations of time and cost have prevented its widespread use outside of certain academic centers.[30]

Although large, multi-institutional prospective studies are yet to be accomplished, smaller studies and anecdotal reports demonstrate the efficacy of endoscope-assisted approaches for the treatment of selected skull base problems, most notably sinonasal neoplasms, pituitary tumors, and CSF leaks.[31-37]

Stamm[38] classifies endoscopic skull base approaches as follows:

1. Transnasal direct
2. Transethmoidal
3. Transseptal
4. Transplanum
5. Transsphenoidal-transpterygoid
6. Transsphenoidal-transclival
7. Transnasal-transpharyngeal (cranial-cervical junction)
8. Combined

The location and suspected pathology dictate the selection of approach.

Endoscopy-based approaches to the nasal cavity, olfactory groove, nasopharynx, ethmoid roof (anterior skull base), orbit and orbital apex, sphenoid sinus and sellar and parasellar areas, clivus, cavernous sinus, optic chiasm, pterygopalatine and infratemporal fossae, parapharyngeal space, craniocervical junction, petrous apex, and jugular foramen all have been described. In short, access to the central skull base from the frontal sinus to C2 and from the sella to the jugular foramen is now possible using the expanded endonasal approach.[39-43]

The endoscopic approach to the orbital apex and optic canal for orbital decompression in fibrous dysplasia, Graves' orbitopathy, compressive or traumatic optic neuropathy has been described. Of note, decompression is indicated only in patients with fibrous dysplasia with continuous deterioration of vision or undergoing removal of neighboring bone, but not as a prophylactic procedure.[44,45] This approach also is used in the management of clival lesions, anterior skull base tumors, and vascular malformations of the skull base.[46,47]

Kassam and associates described an approach to identify the petrous portion of the carotid artery following identification and retrograde dissection of the vidian artery. They found this to be a consistent landmark radiographically and intraoperatively.[48]

Endoscopic approaches to pituitary surgery offer benefits of improved cosmesis, decreased recovery time, and fewer complications. Three approaches exist: transnasal-transethmoid, transnasal-transseptal, and direct transnasal. The direct transnasal approach has been touted because of the advantages of avoiding the ethmoid complex, decreased operative time, and improved visualization.[2] Although endoscopic skull base surgery has been more extensively described for the anterior cranial base, endoscopic-assisted approaches to the middle cranial base also have been described.[49]

The protection of critical structures at the cranial base also is enhanced by the appropriate use of electrophysiologic monitoring, including intraoperative somatosensory evoked potentials, auditory brainstem evoked response, and EMG.[14] The injection of low-dose intrathecal fluorescein has been shown to be a useful adjunct intraoperatively to decrease the CSF leak rate and, when appropriate medication is provided, has been proven safe and without significant adverse effects.[50]

GOAL 3. The approach should be designed so that, at the completion of the extirpative phase, critical barriers between the neurocranium and viscerocranium can be reliably restored. These barriers, particularly the dura and subjacent soft tissues, normally serve to effectively insulate the intracranial contents and the ICA from exposure to the aerodigestive tract below, including the nasal cavity, sinuses, eustachian tube, and pneumatic spaces within the temporal bone. After they have been disturbed, the barriers should be restored to reduce the potential for such consequences as CSF fistula, meningitis, and septic carotid artery rupture. Also, an approach should respect the vascular territories of local tissues (i.e., the temporalis muscle, galea, and pericranium), which can then be used for the reconstruction.

Such vascularized local flaps are preferable to free flaps or nonvascularized grafts when available, however others have displayed excellent closure rates with materials ranging from acellular dermis to free microvascular transfers.[51,52] In general, smaller defects (less than 2 cm) are less likely to require vascularized tissue to achieve closure.[53,54]

Robotic endoscopic skull base surgery and transoral robotic surgery have been advocated by some researchers for the advantages of improved visualization, access, precise technique, and improved watertight closure following endoscopic skull base surgery. Although promising, more clinical investigation is needed before widespread acceptance of these techniques.[55,56]

GOAL 4. The choice of operative approach should reflect consideration for functional and aesthetic reconstruction, and it should include the placement of incisions within natural skin lines that respect aesthetic units of the face. The soft tissue closure should follow plastic surgery principles. Excellent skull base exposure usually can be achieved by elective osteotomies and the temporary removal of craniofacial bone segments, which are subsequently replaced, thereby preserving facial contour.[17,51,57-59] Even in cases in which aesthetically important segments should be removed for oncologic reasons, acceptable cosmesis can usually be accomplished through the judicious use of bone grafts and soft tissue flaps or through surgical closures designed to support alloplastic or prosthetic materials.

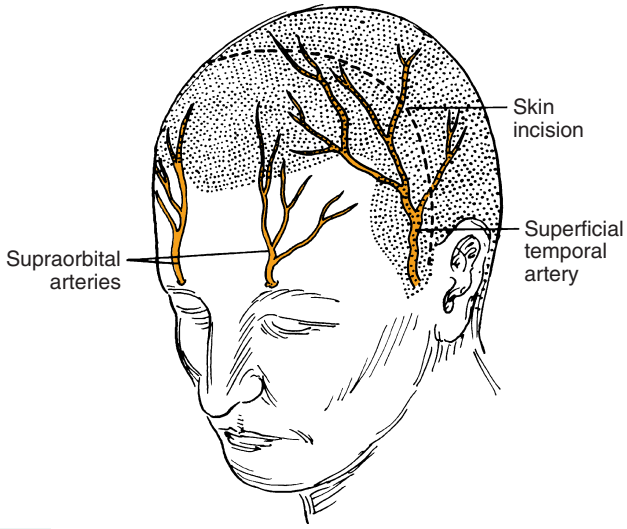

Figure 174-12. Bicoronal incision shown from the patient's left and demonstrating proper placement to allow for preservation of anterior branches of the superficial temporal artery. This incision design permits the use of a long pericranial or galeal flap (based on supraorbital vessels), which is important for the reconstruction of anterior cranial base defects.

Anterior Cranial Base Approaches

Surgical approaches to the anterior cranial base include methods that are purely extracranial and those that use combined extra- and intracranial exposures. The extracranial techniques—external ethmoidectomy, frontal sinusotomy, and intranasal ethmoidectomy—are suitable only for the management of discrete, well-localized lesions, such as CSF fistulas and some very limited benign anterior cranial base tumors. These procedures are well described elsewhere.[60,61]

Most of the remaining anterior cranial base lesions are best managed using the combined intracranial and extracranial techniques, of which there are basically two types: the classic anterior craniofacial resection and the basal subfrontal approach. Both of these approaches require bifrontal craniotomy for obtaining intracranial exposure. Except in special circumstances (e.g., in the presence of scars from previous surgery or trauma), the most utilitarian incision for surgery of the anterior cranial base is the bicoronal incision.

Technical Note: The Bicoronal Incision

The bicoronal incision should be in the true coronal plane at the level of the top of the helix of the ear or slightly anterior to it (Fig. 174-12). A short, forward-directed, preauricular extension can be made on both sides to enhance scalp flap rotation. This coronal placement of the incision preserves the anterior branches of the superficial temporal artery, enhancing viability of the scalp flap. In addition, it substantially increases the length of vascularized galea and pericranium available for reconstruction as compared with incisions along the anterior hairline, the midforehead crease, or the brow. Additional length can be gained by back-elevating the scalp flap before division and elevation of the pericranial flap.

The central portion of the anterior scalp flap (i.e., the portion between the two superior temporal lines) is elevated in the subgaleal plane if a pericranial flap may be used and in the subperiosteal (subpericranial) plane if not. Lateral to the two superior temporal lines, it is elevated in the plane just above the deep temporal fascia. Therefore, at the temporal lines, the pericranium should be sharply incised to separate it from the origin of the deep temporal fascia (see Fig. 174-15). The pericranium is divided far enough posteriorly to provide sufficient

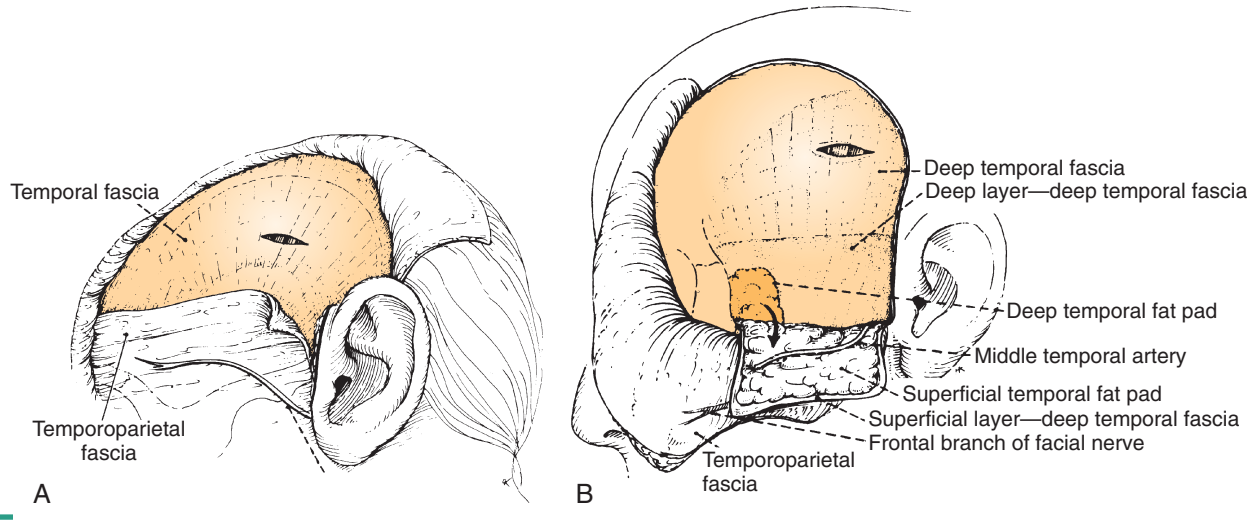

Figure 174-13. Relationship of the frontal branch of the facial nerve to layers of the temporal fascia. **A,** Anatomic dissection showing superficial temporal fascia (temporoparietal fascia), through which the nerve courses; attempts at surgery to elevate this relatively thin fascial layer alone may injure the nerve. **B,** Surgical dissection showing a deeper plane of fascial elevation that is less likely to cause injury to the frontal branch of the facial nerve. *(From Stuzin JM, Wagstrom L, Kawamoto HK, Wolfe SA. Anatomy of the frontal branch of the facial nerve: the significance of the temporal fat pad.* Plast Reconstr Surg. *1989;83:265-271.)*

length to the flap; then the dissection is carried forward in the subperiosteal plane as described earlier.

This deep temporal fascia begins to split into superficial and deep layers, beginning at approximately the level of the superior orbital rim.[62] These fascial layers diverge to envelop the lateral and medial surfaces of the zygomatic arch inferiorly; between the layers is the temporal fat pad. The frontal (temporal) branches of the facial nerve course just superficial to the zygoma along the superficial temporal fascia (temporoparietal fascia) and are prone to injury if the dissection is done at that level (Fig. 174-13A). Often these injuries can be avoided by maintaining the plane of dissection at the level of the deep layer of the deep temporal fascia (i.e., at the surface of the temporalis muscle itself). This deep plane of exposure essentially elevates the fat pad along with the superficial fascia and the superficial layer of the deep temporal fascia, thereby protecting the facial nerve branches (see Fig. 174-13B).[63,64] After the dissection reaches the level of the zygomatic arch, the arch is palpated, and its superior surface is directly exposed by sharply incising the fat pad and periosteum.

Further medially, flap elevation proceeds down the frontal area toward the supraorbital rims. Care should be taken to preserve the supraorbital supply of the galea and pericranium. This is best performed with elevation of the supraorbital rim periosteum that begins laterally and proceeds medially. A fine elevator is used first to palpate the supraorbital foramen (or notch) and then to expose its margins. If the pedicle is completely surrounded by bone, a 3-mm osteotome is used to fracture the inferior margin of the foramen, thereby liberating the pedicle and allowing it to be elevated intact, along with the remaining pericranium and underlying periorbita (Fig. 174-14). If the entire scalp flap is difficult to rotate inferiorly, the preauricular parts of the incision can be extended to as low as the tragus (without danger to the facial nerve trunk) or anteriorly (as far as the temporal hairline) to further enhance flap rotation.

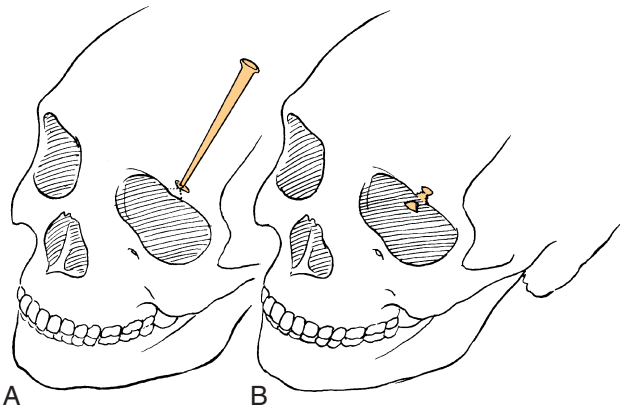

Figure 174-14. Technique for preserving the supraorbital neurovascular pedicle. **A,** After the foramen has been identified, a 3-mm osteotome is inserted along its lower border. **B,** A small segment of bone along the inferior rim of the foramen is fractured to liberate the nerve and vessels, which are reflected downward, along with soft tissues of the bicoronal flap.

Anterior Craniofacial Resection

Anterior craniofacial resection (Fig. 174-15) combines bifrontal craniotomy with transfacial exposure of the nasal cavity, ethmoid, maxillary, and orbital areas, usually by modifications of lateral rhinotomy, midfacial degloving, or other transfacial approaches.[65-67] Anterior craniofacial resection most often is used for removal of neoplasms that originate in the sinonasal tract and invade the anterior cranial fossa floor, such as squamous cell carcinoma, esthesioneuroblastoma, and adenocarcinoma. For cases in which tumor frankly invades the soft tissues of the orbit, the approach is extended to include orbital exenteration.[68]

The operation begins with transfacial exposure, which is followed by bifrontal craniotomy performed by the neurosurgeon. If the patient has a large frontal sinus, an osteoplastic flap may be elevated to avoid burr holes in the forehead area, which could later become aesthetically unsatisfactory. In such cases, the thin posterior table of the frontal sinus is opened with a diamond burr to expose the dura and then removed. If the frontal sinus is small, a frontal bone flap is developed using a guarded craniotome introduced through burr holes placed above the hairline or in the temporal areas. Near the midline, care is taken to separate the dural fold containing the sagittal sinus away from the bone to protect it before the craniotome is allowed to cross the sagittal plane. The lower horizontal bone cut should be kept low (within 1 cm of the superior orbital rims) to lessen the need for subsequent brain retraction. Withdrawing 25 to 50 mL of CSF from the lumbar subarachnoid catheter, lowering P_{CO_2} through controlled hyperventilation, and occasionally administering mannitol or corticosteroids will further reduce the need for mechanical frontal lobe retraction.

Next, the frontal lobes are elevated from the anterior cranial fossa floor by incising the dura and severing the olfactory nerves at the cribri-

form plate. This always results in some leakage of CSF, which is controlled by direct dural suture or a dural patch (from temporal fascia, fascia lata, or pericranium). The dural closure should be as watertight as possible. Dura is further elevated to expose the orbital roofs and planum sphenoidale and finally the base of the anterior clinoid processes.

If disease extirpation mandates the removal of the planum, the intracranial portions of the optic nerves should be exposed through the unroofing of the optic canal to protect them from injury at the time of sphenoid osteotomy.[14] If the disease is confined to the cribriform area, however, the planum may be entered with a cutting burr or osteotome[66] to establish the posterior bony margin without optic nerve decompression. This completes the intracranial portion of the exposure for anterior craniofacial resection.

The transfacial exposure often involves modifications of a lateral rhinotomy incision, which may transect the upper lip; this depends on whether a total maxillectomy will be done in conjunction with the resection. The periosteum is elevated from the nasal bone and from the medial and inferior surfaces of the orbit, and the nasolacrimal duct is identified and transected distally. The anterior and posterior ethmoid arteries are identified and cauterized or clipped. In most cases, it is necessary to perform a complete en bloc ethmoidectomy. For this purpose, a contralateral Lynch incision is made to elevate the contralateral periorbita, cauterize the anterior and posterior ethmoid vessels, and make the appropriate osteotomies using a sagittal saw. If preoperative imaging studies or intraoperative observations confirm the presence of tumor within the soft tissues of the orbit, then orbital exenteration may be performed after extending the skin incision laterally to include a portion of the eyelids. Depending on the nature and extent of the tumor, osteotomies also may be made to include part or all of the maxilla.

At this point, a reciprocating saw or cutting drill bit is used to create the osteotomies of the cranial floor. The frontal lobes are retracted or protected from the cutting instrument by inserting an appropriate malleable retractor. The reciprocating saw or cutting drill bit is introduced through the nasal and ethmoid exposures, and, under direct

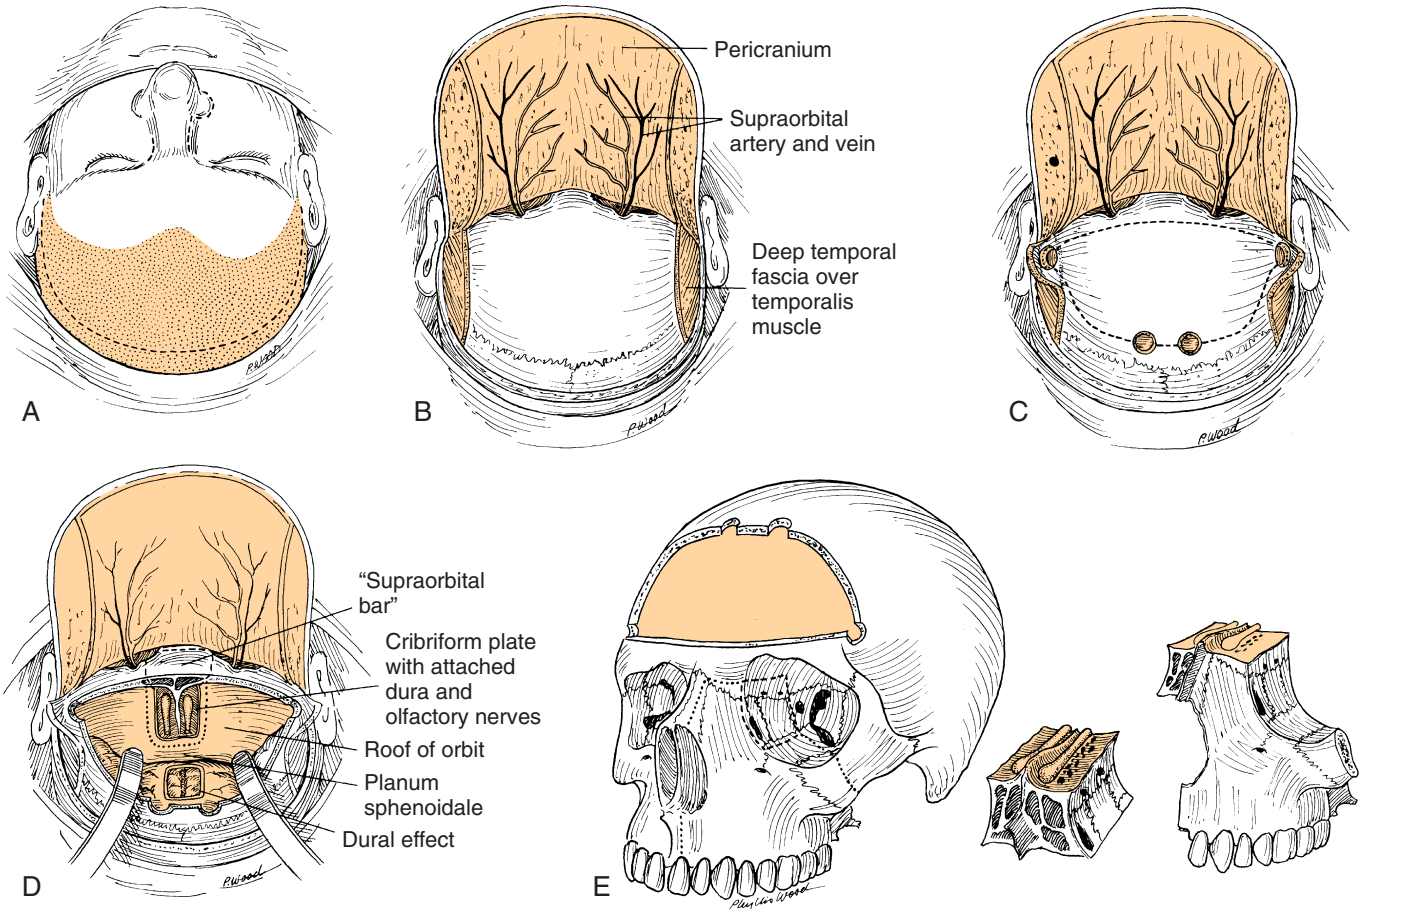

Figure 174-15. Anterior craniofacial resection. **A,** Incisions. High bicoronal incision preserves the optimal length of the galea and the pericranium for use as a reconstructive flap. Facial incisions usually include lateral rhinotomy and contralateral Lynch incisions, but these may be modified to suit the clinical situation. **B,** Elevation of the bicoronal scalp flap. The pericranium has been incised bilaterally at the superior temporal lines to separate it from the deep temporal fascia. Supraorbital vessels have been released from the supraorbital foramina to allow for the exposure of the superior orbital rims (zygomatic arches may be exposed using bicoronal incision by dissecting further laterally, as may be required for extended anterolateral craniofacial resections). **C,** Bifrontal craniotomy. *Dashed lines* represent the outline of the planned craniotomy. Temporalis muscles have been partially elevated so that burr holes may be placed below the temporal lines; superior burr holes are placed above the level of the frontal hairline. Such placement helps minimize postoperative cosmetic deformity. Paramedian positioning of superior burr holes aids in protection of superior sagittal (venous) sinus while the bone flap is being cut. **D,** Intracranial exposure. The frontal lobes have been retracted, and the dura has been incised, thereby leaving olfactory nerves and the margin of the dura to be resected en bloc, along with the cribriform plate and the ethmoid labyrinth *(dotted line)*. The amount of dura and anterior cranial fossa floor resected will depend on the extent of tumor. To enhance exposure and direct visualization, the supraorbital bar *(dashed lines)* may be included in the resected specimen; after resection margins have been verified, this portion of bone is detached from the tumor-bearing part of the specimen and replaced. **E,** Osteotomies as seen from transfacial exposure. *Dashed lines* illustrate bone cuts used for en bloc ethmoidectomy, which result in the obtaining of a specimen *(left)*. *Dotted lines* indicate additional osteotomies to be used when total maxillectomy (with or without orbital exenteration) also is performed, thereby resulting in the obtaining of a specimen *(right)*. In both cases, resection encompasses part of the anterior cranial fossa floor. The extent of anterior fossa floor resection varies and should be modified as required by the extent of tumor.

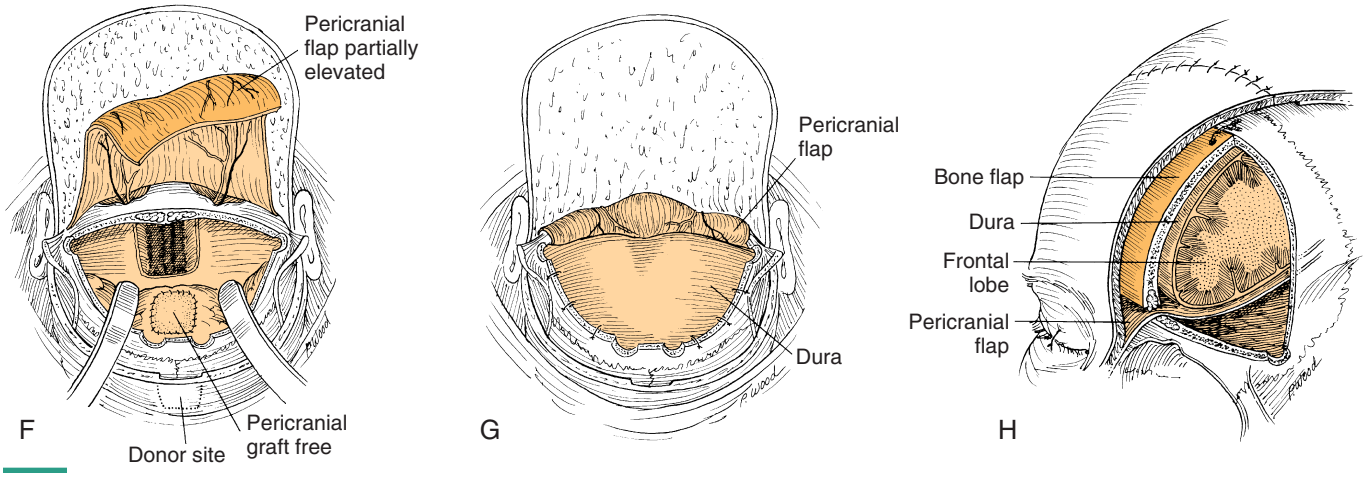

Figure 174-15, cont'd. **F,** Operative defect and preparation for closure. Large communication between the anterior cranial fossa and nasal cavity is closed by an inset of vascularized pericranial flap (shown here partially elevated from the galea). A dural defect created by resection of the olfactory nerves and surrounding dura has been closed with free graft of the pericranium taken from the posterior scalp *(dotted lines)*. Frontal sinuses have been stripped of mucosa and filled with autogenous fat after obliterating the frontonasal ducts. **G,** Cranial base defect repaired. A pericranial flap has been turned intracranially to line the anterior cranial fossa floor. Release of the frontal lobe retraction and clamping of the spinal drain have allowed for reexpansion of the brain and obliteration of the epidural dead space. The frontal bone flap is replaced and secured, with care taken to avoid compression of the pericranial flap. **H,** Cutaway view of final closure, showing the position of the pericranial flap relative to the brain and the cranial base. *(**A** to **G,** Adapted from Schramm VL. Craniofacial resection. In: Sasaki CT, McCabe BF, Kirchner JA, eds.* Surgery of the Skull Base. *Philadelphia: JB Lippincott; 1984.)*

vision, osteotomies are created from the planum sphenoidale, along the ethmoid roof, and forward to the front of the cribriform plate. These osteotomies may or may not include the supraorbital bar of bone, which is a portion of the frontal bone between the supraorbital rims (see Fig. 174-15D). If the tumor extends anteriorly to a significant degree, this supraorbital bar is removed with it as a single specimen, which can be closely inspected. If the supraorbital bar is not actually involved by tumor, it may be detached from the specimen and replaced for reconstruction at the completion of the operation.

After the resection margins have been verified by frozen section and are negative, reconstruction begins. As mentioned, it is critical that the dura be closed in a watertight fashion. This usually involves the placement of a patch of pericranium, temporal fascia, or fascia lata, followed by the placement of a vascularized pericranial flap over the defect in the floor of the anterior cranial fossa. The pericranial flap is developed by sharp dissection from the previously reflected scalp flap (see Fig. 174-15F).[69] Elevation of this flap of pericranium is continued down to the level of the glabella, with care taken to not injure its vascular pedicles. It is then rotated intracranially and positioned to form a bridge of soft tissue across the orbital roofs and back to the planum sphenoidale. If necessary, the distal end of the pericranial flap may be sutured to the dura over the planum for security; this provides a vascularized tissue barrier between the dura above and the nasal cavity below (see Fig. 174-15G and H). Unless a large amount of anterior cranial fossa bone has been resected and concern for brain herniation exists, it is usually not necessary to place a bone graft across the bony defect. Also, it is not necessary to place a skin graft on the undersurface of the pericranium (facing the nasal cavity), because this tissue mucosalizes readily on its nasal surface. After the pericranial flap is in place, the spinal drain is clamped so that no further intraoperative CSF decompression will take place. This will allow the gradual reexpansion of the brain to make contact with the pericranial flap, thereby obliterating any residual dead space. Because the pericranial flap traverses the frontal sinus, it is necessary to obliterate the frontonasal ducts and to remove all mucosa from within the sinus. A small amount of fat or free muscle may be packed into the ducts to obliterate any dead space inferiorly. The flap covers the frontonasal duct orifices and sinus floor. If the sinus is small, it may be obliterated by packing it with abdominal fat. If the sinus is large, however, removing the posterior table completely and allowing the brain and dura to expand and fill the space (cranialization of the frontal sinus) may be advisable.

In closing the facial incision, the medial canthal ligament is identified and secured to the remaining medial orbital wall. The upper and lower lid canaliculi may be intubated with a canalicular stent to prevent dacryostenosis. Before further closure, several tacking sutures are placed to secure the frontal dura to the margins of the craniotomy site; this will help in the prevention of postoperative epidural fluid and blood collections. The bifrontal craniotomy bone flap is then replaced and secured according to the surgeon's preference; this may be done with wires, plates, or sutures.

Basal Subfrontal Approach

The basal subfrontal approach or transbasal approach (Fig. 174-16)[14,70] is in many ways similar to the anterior craniofacial resection operation, except that the transfacial exposure is less extensive. Because the target area in this approach is more posterior (sphenoid and clivus) than that in the anterior craniofacial resection (ethmoids and cribriform), the craniotomy bone flap generally is somewhat larger and the orbital bone cuts are broader. This approach is used for lesions that primarily or secondarily involve the bony cranial base in the regions of the sphenoid body and upper clivus (e.g., meningiomas, fibrous dysplasia, chordomas, chondrosarcomas, ossifying fibromas).[63]

This approach also begins with a bicoronal incision. After exposing the orbital rims, periorbita is elevated from beneath the orbital roofs and medial walls in preparation for osteotomy. The anterior and posterior ethmoid arteries are identified bilaterally as landmarks, but they need not be divided because the axial ethmoid osteotomy can be made just above this level. Bifrontal craniotomy is then performed, and dura is elevated from above the orbital roofs and cribriform areas, as described. Using malleable retractors to protect the orbital contents and the brain, the reciprocating saw is used to create osteotomies that result in the temporary removal of both orbital roofs and the supraorbital bar (see Fig. 174-16A).

The coronal osteotomies along the posterior orbital roof should be made as far posteriorly as possible to simplify reconstruction, to conserve orbital contour, and to prevent postoperative pulsatile exophthalmos. These orbital cuts can be made as far back as the posterior ethmoid foramen but should be made only under direct vision from intra- and extracranial perspectives. With the use of these osteotomies, a very broad and basal exposure of the entire anterior cranial base is achieved (see Fig. 174-16B).

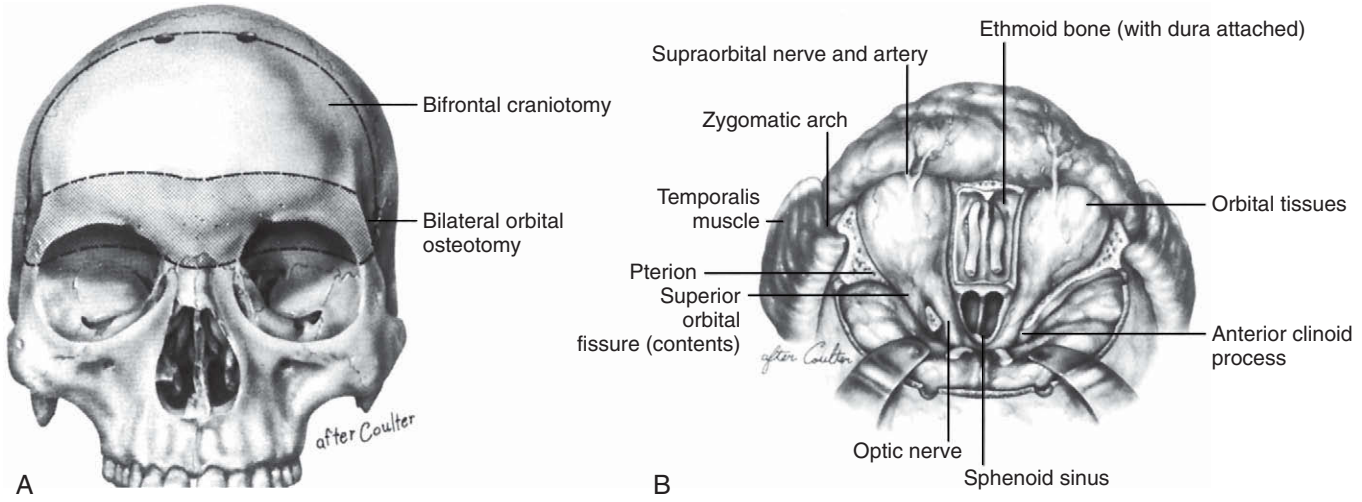

Figure 174-16. Basal subfrontal approach to the cranial base. **A,** Outlines of bifrontal craniotomy and bilateral orbital osteotomies. **B,** Surgeon's view from above after the removal of cranial and orbital bone segments. Olfactory nerves have been transected to allow sufficient brain retraction for exposure of the anterior fossa floor and decompression of the optic nerves. The sphenoid sinus has been widely opened. *(From Sekhar LN, Janecka IP. Intracranial extension of cranial base tumors and combined resection: the neurosurgical perspective. In: Jackson CG, ed.* Surgery of Skull Base Tumors. *New York: Churchill Livingstone; 1991.)*

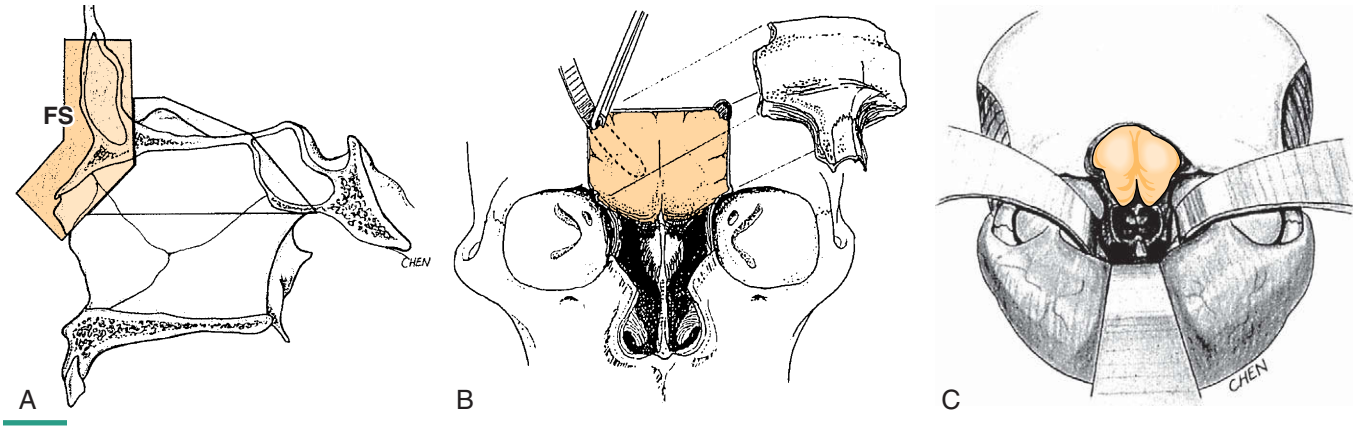

Figure 174-17. Subcranial approach to the anterior cranial base as described by Raveh.[71-73] **A,** Sagittal schematic showing the osteotomized frontonasal segment (FS), which is removed to allow access to deeper structures and then later replaced. **B,** Initial exposure afforded by the removal of the frontonasal bony segment; note the protection of the dura by a malleable retractor. **C,** Extent of exposure after lesion extirpation, with sphenoid sinus, sella, and orbital apices visible at the depth of the wound. Note that the bicoronal scalp flap has been elevated quite extensively along the lateral and medial orbital rims and nose to permt the frontonasal osteotomies and to compensate for the very low plane of access to the anterior cranial base while avoiding facial incisions *(see text)*. *(From Raveh J, Laedrach K, Ilzuka T, et al. Subcranial extended anterior approach for skull base tumors: surgical procedure and reconstruction. In: Donald PJ, ed.* Surgery of the Skull Base. *Philadelphia: Lippincott-Raven; 1998. With permission.)*

Working with the aid of the microscope, the approach is completed by rongeuring or drilling a small amount of bone remaining posteriorly to unroof the optic nerves, the superior orbital fissures, and the sphenoid sinus. Extirpation proceeds as required by the tumor and is followed by reconstruction, which is similar to that done for anterior craniofacial resection.

Raveh and colleagues[71-73] have described and refined an approach, now generally referred to as the subcranial approach, that offers significant advantages over the traditional anterior craniofacial resection and the basal subfrontal approach while combining elements of each. In the subcranial approach, facial incisions are not used; instead, the bicoronal scalp flap is reflected much further inferiorly to more completely expose both orbits and the nasomaxillary bony framework (Fig. 174-17). Extensive access along the entire anterior cranial base is possible as far back as the sella, the orbital apices, and the upper clivus. Advantages of the subcranial approach include minimal brain retraction, wide exposure, and the absence of facial scars.

Middle Cranial Base Approaches

In contrast with the anterior cranial base, surgical approaches to the middle cranial base are numerous and varied. This reflects the anatomic complexity of the region and the diversity of lesions found there. This discussion reviews several approaches and presents examples of those that have been found to be most useful.

Division into Central and Lateral Compartments

When considering surgical approaches to the middle cranial base, it is helpful to subdivide the region into a single central compartment and paired lateral compartments (Fig. 174-18).[74] When viewing the skull from the inferior perspective, the central compartment may be defined as that area between two parasagittal lines drawn from the medial pterygoid plate to the occipital condyle on each side. These lines correspond approximately to the pathways of the ICAs through the skull base. Thus, the central compartment consists of the pituitary fossa, the sphenoid rostrum and lower sphenoid sinus, the nasopharynx, the pterygopalatine fossa, and the lower portion of the clivus. (The lower

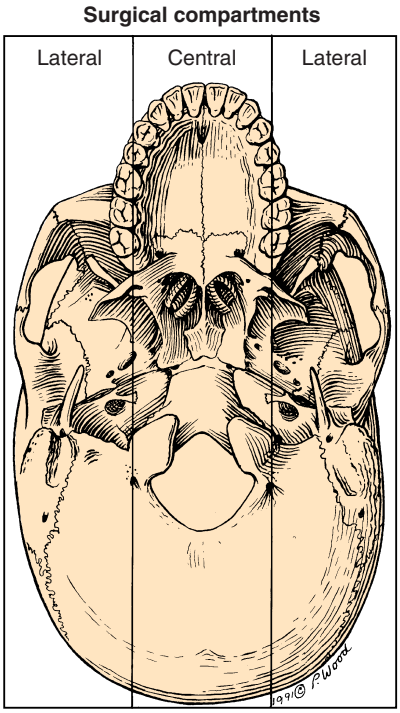

Figure 174-18. Compartments of the middle cranial base. The pathways of the internal carotid arteries as they traverse the middle cranial base region divide the region into one central and two lateral compartments. *(From Krespi YP, Sisson GA. Transmandibular exposure of the skull base.* Am J Surg. *1984;148:534-538.)*

clivus actually is part of the occipital bone and not technically part of the middle cranial base. However, the surgical approaches to this area and also to the craniovertebral junction and upper cervical spine are essentially extensions of the approaches to the central compartment.)

The lateral compartment includes the entire infratemporal fossa, the parapharyngeal space, and the petrous portion of the temporal bone. This area is important because of the high density of neural and vascular structures within, including, extratemporally, the ICA; the internal jugular vein; the maxillary nerve (V2); the mandibular nerve (V3); the facial nerve (VII); cranial nerves IX, X, XI, and XII; the sympathetic nerves; and major branches of the external carotid artery, and, intratemporally, the cochlea, the vestibule, and cranial nerve VIII.

These distinctions between central and lateral compartments are valid in the sense that limited lesions within their respective boundaries will clearly be more amenable to resection using one type of approach vs another. However, it is not unusual for advanced lesions to extend beyond the line that separates the central from the lateral compartment; therefore, the surgical approach should be tailored to suit each clinical situation.

Approaches to the Central Compartment

The major surgical approaches to the central compartment of the middle cranial base are listed in Table 174-1, along with the anatomic areas for which they provide useful exposure. Except for pituitary surgery, these approaches are used primarily for the management of extradural lesions along the skull base.

Although most central compartment approaches in the literature can give access to the sphenoid sinus, not all are suitable for pituitary or parasellar surgery because of indirect exposure or oblique angle of entry into the sinus, which increases the risk of injury to adjacent neurovascular structures. When lesions are limited to the sphenoid sinus or the pituitary fossa, the transethmoidal sphenoidotomy (Fig. 174-19)[75,76] and the transseptal sphenoidotomy (Fig. 174-20)[77,78] are

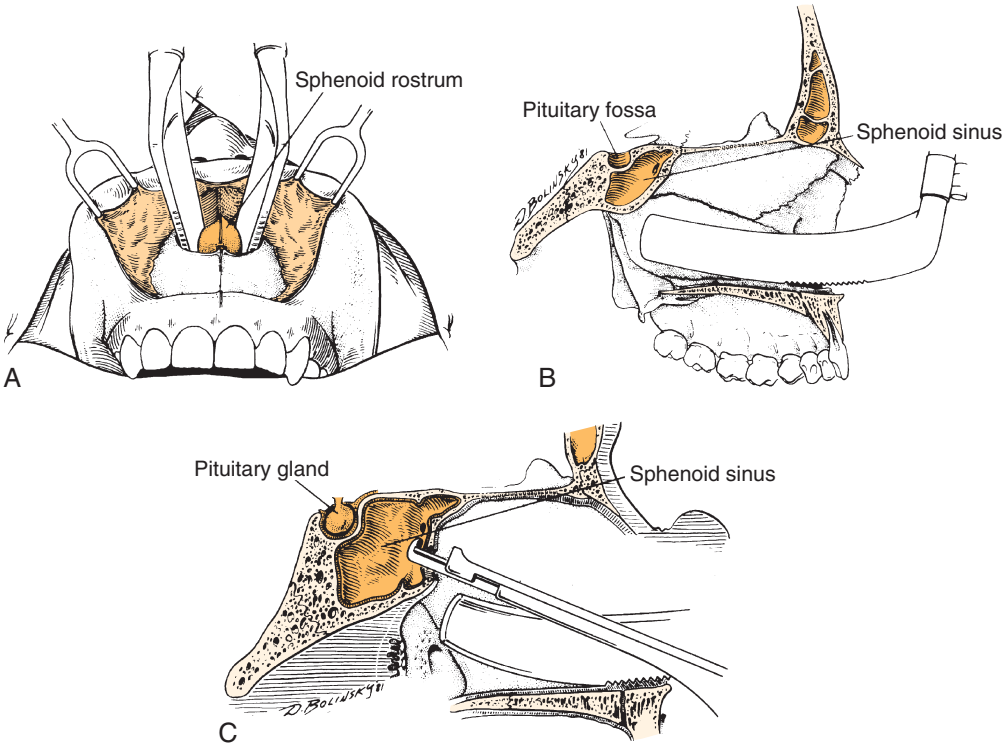

Figure 174-20. Transseptal-transsphenoidal approach to the cranial base. **A,** A sublabial incision is used to gain access to the premaxilla and to the nasal septum, which is exposed from the anterior nasal spine to the sphenoid rostrum in the subperichondrial-superiosteal plane. **B,** Lateral view of exposed area, showing a self-retaining speculum in position at the sphenoid rostrum. **C,** Sphenoid sinus is opened. A transseptal-transsphenoidal approach may be used for pituitary fossa surgery, for the removal of limited lesions of sphenoid region, or for the biopsy of tumors that involve the area. *(From Sasaki CT. Transseptal-transsphenoidal approach to the sella. In: Sasaki CT, McCabe BF, Kirchner JA, eds.* Surgery of the Skull Base. *Philadelphia: JB Lippincott; 1984.)*

usually satisfactory, safe, and effective. These approaches are useful for obtaining biopsy specimens of more extensive lesions that involve that region. For larger lesions that involve adjacent areas, however, the exposure is inadequate, because the operative field is deep and narrow, thus requiring the use of the operating microscope in most cases.

With trends toward less invasive surgical techniques, endoscopic procedures are gaining popularity as primary or adjuvant approaches in cranial base surgery. For tumors of the pituitary gland, endoscopic transnasal-transsphenoidal resection is another valuable option. Proponents of endoscopic pituitary surgery report fewer complications of facial swelling, septal perforations, nasal septal deviation or synechia formation, and numbness of the upper incisors; they also report a shorter hospital stay.[79,80] The surgery is performed with the patient under general anesthesia in the supine position with the head elevated 10 degrees. In most cases, the operation can be performed through one nostril, the choice of which depends on the width of the nasal cavity and the laterality of the pituitary tumor. The nose is decongested topically, and further vasoconstriction is achieved by infiltrating the mucosa over the rostrum of the sphenoid, the middle turbinate, and the posterior septum with lidocaine hydrochloride 1% with epinephrine 1 : 100,000.

Using a rigid zero-degree endoscope, the sphenoid ostium is identified, and its position may be confirmed by the use of C-arm fluoroscopy or image-guided navigation. The middle turbinate can be outfractured or removed to provide increased exposure to the sphenoid rostrum. The sphenoid ostia are identified and fractured inferomedially. Kerrison rongeurs or Hardy punches are used to widen the sphenoidotomy and to remove the sphenoid rostrum. The posterior septum may be rongeured to provide wide visualization, including that of the contralateral sphenoid sinus cavity. The 30-degree endoscope is inserted into both sides of the sphenoid sinus for identification of the optic and carotid protuberance, the opticocarotid recess, the clival indentation, and the anterior wall of the sella[81] (Fig. 174-21). After removal of the intersinus septum, the sella and dura are exposed and entered in the standard fashion. For resection of macroadenomas, insertion of the 30-degree endoscope allows the surgeon to follow intrasellar and extrasellar extension of the tumor and to identify and preserve the arachnoid membrane[81] (Fig. 174-22). The ability to directly visualize tumor and healthy pituitary gland through the endoscope is a major advantage over the operating microscope. This increased visualization may allow

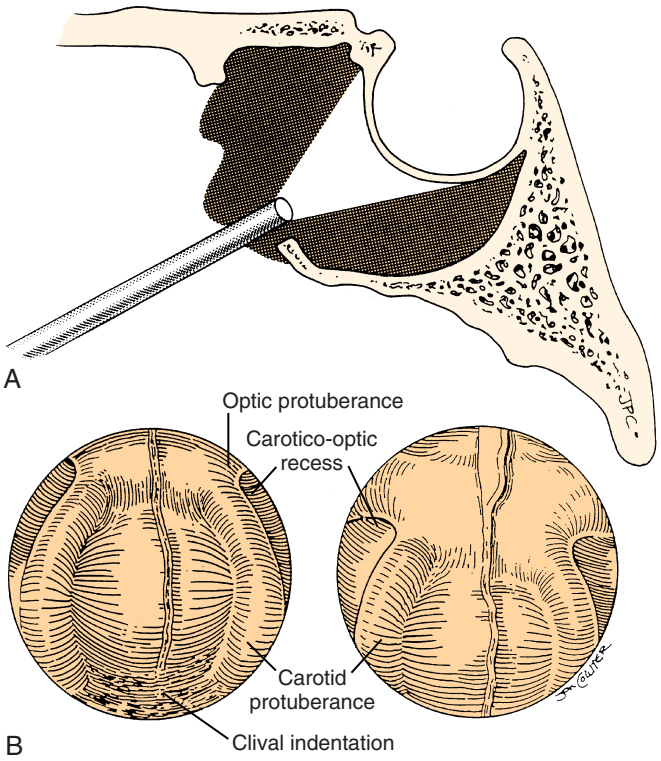

Figure 174-21. **A,** Endoscopic view of the sphenoid sinus after the completion of anterior sphenoidotomy and resection of the sphenoidal septum. **B,** *Left*: View with a zero-degree endoscope reveals the carotico-optic recesses, carotid protuberances, and clival indentation to the anterior wall of the sella. *Right*: A 30-degree endoscope provides a better panoramic view of the optic protuberances, the carotico-optic recesses, the carotid protuberances, and the upper portion of the anterior wall of the sella. *(From Jho HD, Carrau RL, Ko Y. Endoscopic pituitary surgery. In: Rengachary SS, Wilkins RH, eds.* Neurosurgical Operative Atlas. *Vol 5. Park Ridge, Ill: AANS; 1996. Copyright by the American Association of Neurological Surgeons.)*

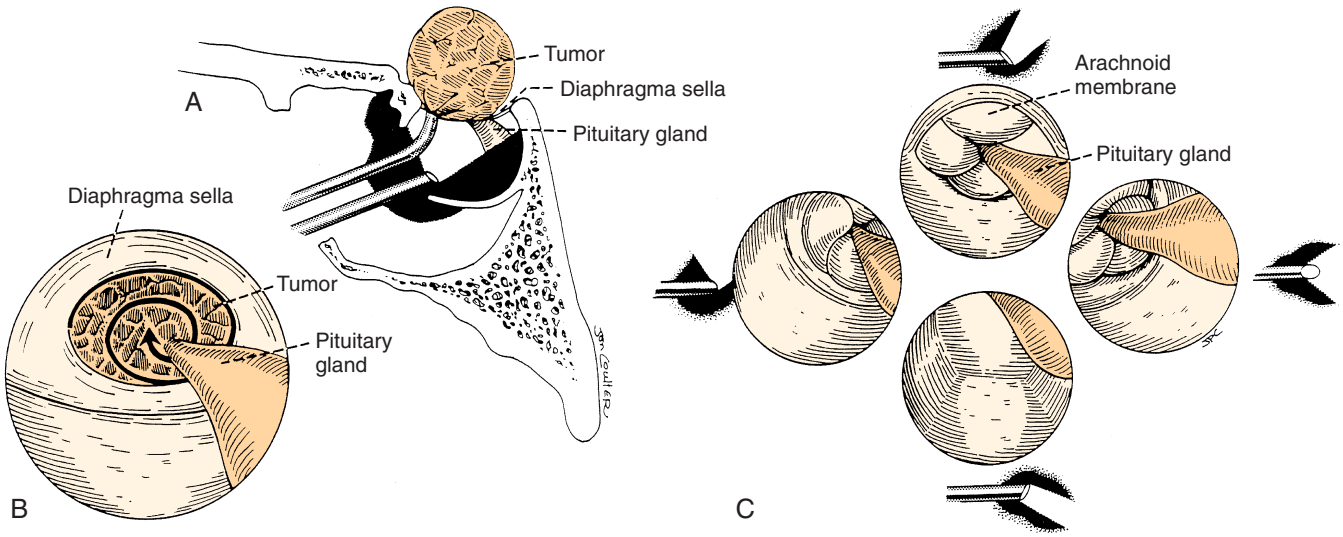

Figure 174-22. **A,** Sagittal view of the sella. **B,** 30-Degree endoscopic view of the suprasellar tumor. The suprasellar portion of the tumor is removed with a curved suction cannula beginning around the edge of the diaphragma sella circumferentially and heading toward the center of the tumor gradually. The healthy pituitary gland tissue is preserved, if possible. **C,** The arachnoid membrane will herniate down gradually when the suprasellar portion of the tumor has been completely removed. The center of the flower-shaped arachnoid membrane will be the pituitary stalk. Any healthy-looking pituitary gland tissue is preserved. When the 30-degree–angled endoscope placed inside the sella is rotated, it will reveal the suprasellar region superiorly, the lateral wall of the sella laterally, and the floor of the sella inferiorly. Residual tumor is removed from all corners by rotating the 30-degree endoscope. *(From Jho HD, Carrau RL, Ko Y. Endoscopic pituitary surgery. In: Rengachary SS, Wilkins RH, eds.* Neurosurgical Operative Atlas. *Vol 5. Park Ridge, Ill: AANS; 1996. Copyright by the American Association of Neurological Surgeons.)*

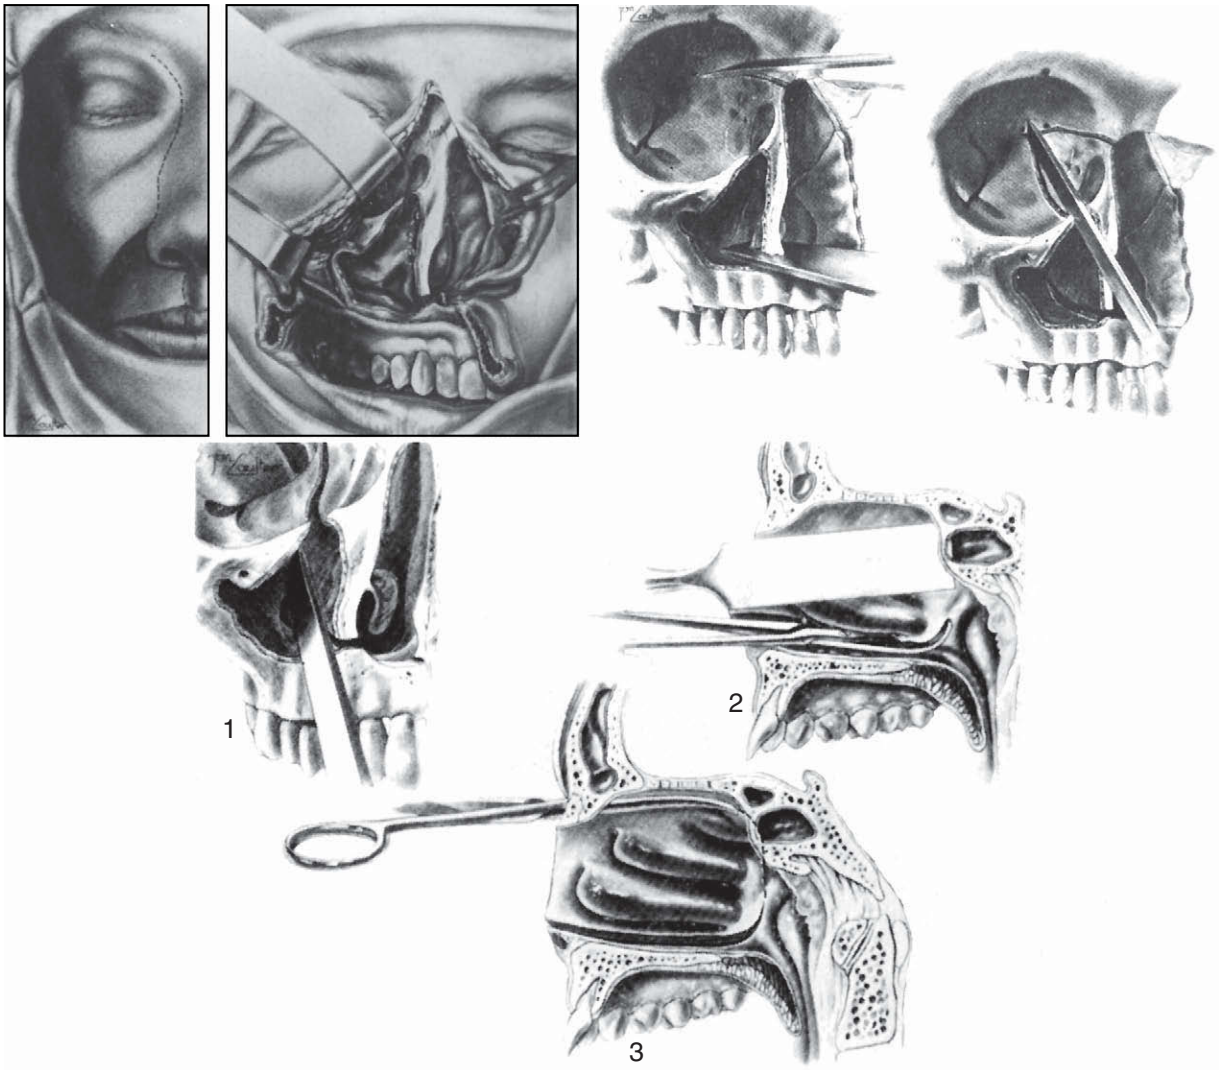

Figure 174-23. Lateral rhinotomy. *Top left,* Incision and soft tissue exposure followed by maxillary antrostomy. *Top right,* Osteotomies of the orbit and maxilla. *Bottom,* Anterior (1) and sagittal (2 and 3) views of posterior osteotomies and soft tissue cuts to remove medial portions of the orbit and maxilla. Such exposure can provide access to the face of the sphenoid, nasopharynx, pterygopalatine fossa, and ethmoid regions. *(From Schramm VL, Myers EN. "How I do it"—head and neck. A targeted problem and its solution. Lateral rhinotomy.* Laryngoscope. *1978;88:1042-1045.)*

for more complete tumor resection, while limiting the potential complications associated with blind curettage of the superior and lateral sella contents.

The lateral rhinotomy (Fig. 174-23)[82] and transantral (Fig. 174-24)[83] procedures afford wider access to the anterior sphenoid and adjacent nasopharynx, the pterygopalatine fossa, the maxilla, and the ethmoid regions. However, they generally are unsatisfactory for extirpation of any but the smallest lesions situated in the sphenoidal-clival area. The midfacial degloving approach (Fig. 174-25)[84] is more suitable for dealing with larger central compartment lesions, because it allows for improved midline access through the nose and both maxillary sinuses. Medial maxillectomy and resection of the ascending process of the palatine bone are included, if necessary, giving the surgeon good visualization of the nasopharynx and the adjacent skull base. The Le Fort I osteotomy (Fig. 174-26)[85,86] can be an alternative method for reaching these areas from a slightly more inferior angle, or it may be used as an adjunct to midface degloving, offering additional access to the oronasopharynx and clivus by displacing the hard and soft palate inferiorly.

For lesions of the clivus that also involve the upper cervical vertebrae (the craniovertebral junction), mandibulotomy (Fig. 174-27)[74,87,88] will afford a paramedian route to reach the lower areas of extension. The transpalatal (Fig. 174-28)[89,90] and transoral (Fig. 174-29)[91,92] approaches are also used for the management of lesions at the craniovertebral junction and may be used concomitantly with mandibulotomy, if necessary. A significant benefit of such a combined approach is that, with mandibulotomy, it is also possible to expose the parapharyngeal space and therefore to safely dissect along the ICA from the neck up to its entrance into the temporal bone.[74,87,88] This advantage is important when removing tumors that arise primarily in the central compartment but that have extended laterally. Conversely, for lesions that originate in the lateral compartment and extend centrally, the infratemporal fossa approach or one of its modifications can be used.[93] These approaches and the facial translocation approach,[17] which is suitable for lesions in both compartments, will be discussed in the following section.

An alternative approach for the removal of extensive lesions of the clivus and craniovertebral junction is the extended maxillotomy operation or its modification, the subtotal maxillectomy (Fig. 174-30).[94] In general, these innovative techniques combine the advantages of many approaches. They afford wide exposure of the central compartment by unilaterally displacing or resecting the hemimaxilla.

For very extensive clival and craniovertebral junction tumors, when bilateral transmaxillary access is needed, the midfacial split approach (Fig. 174-31) can be used.[51,57] This approach provides access to the entire central skull base in a unified surgical field that can extend

Figure 174-24. vertically from the anterior fossa floor to the level of the second cervical vertebra (and lower, if combined with mandibulotomy) and horizontally from jugular fossa to jugular fossa. This exposure is achieved using craniofacial disassembly to completely displace the midfacial skeleton, including both maxillae, the orbital floors, and the palate. It is especially useful for the management of large tumors that originate in the central compartment and that have also involved the adjacent anterior cranial base, the craniovertebral junction, or the lateral compartment.

Approaches to the Lateral Compartment

Numerous approaches have been developed and advocated for obtaining surgical access to the lateral compartment of the cranial base. Despite this apparent diversity of techniques and the sometimes confusing terminology by which they are described, considerable overlap exists. Most of the currently used approaches arrive at the cranial base through one (or more) of four main avenues: transtemporal, infratemporal, transfacial, or intracranial. These avenues refer to the primary direction or orientation from which the surgical exposure is ultimately achieved. In most cases, this orientation will influence the usefulness and morbidity of the operation. The cranial base surgeon should be familiar with the advantages and limitations of each of these four routes. For extensive lesions, it often becomes necessary to combine approaches.

Transtemporal Approaches

The transtemporal routes include the transcochlear,[95] translabyrinthine,[15,96] presigmoid, retrolabyrinthine,[2] and combined[97] approaches. These are lateral, primarily extradural techniques that traverse the mastoid and petrous portions of the temporal bone to provide exposure of lesions of the petrous apex, the clivus, and the cerebellopontine angle. The anterior limit of purely transtemporal approaches is the intrapetrous course of the ICA, and these approaches therefore give only limited access to the middle cranial base. Accordingly, they more often are used for the management of tumors of the posterior cranial base (e.g., acoustic neuromas, petroclival meningiomas, aggressive cholesteatomas), and they will therefore be discussed in more detail in Chapter 177. With respect to the middle cranial base, the transtemporal approaches are useful mainly as adjunctive techniques in combination with craniotomy, infratemporal, or transfacial approaches. They can be used to enhance exposure of advanced lesions of the middle cranial base that have secondarily extended into or beyond the petroclival region and posterior to the course of the ICA. Postoperative consequences include permanent unilateral deafness with or without disequilibrium caused by functional loss of the middle or inner ear structures and facial paralysis of variable degree and duration caused by seventh nerve decompression or transposition.

Infratemporal Approaches

The infratemporal routes to the lateral compartment include the infratemporal fossa, lateral transparotid, extended rhytidectomy, lateral transtemporal-sphenoid, lateral facial, and subtemporal-infratemporal approaches.

The infratemporal fossa approach of Fisch and colleagues[93,98,99] encompasses three variations for use in specific clinical situations (Fig. 174-32). The type A approach provides exposure between the sigmoid sinus and the condylar fossa, and it is designed to reach to the petrous apex and infralabyrinthine areas. It is most useful for the management of cholesteatomas, meningiomas, and glomus tumors of those regions. The type B approach allows access from the sigmoid sinus to the petrous tip (including exposure of the horizontal ICA and foramen ovale) to reach lesions of the clivus, such as chordomas, meningiomas, and extensive apex cholesteatomas. The type C approach expands this access to include the parasellar region, the cavernous sinus, the foramen

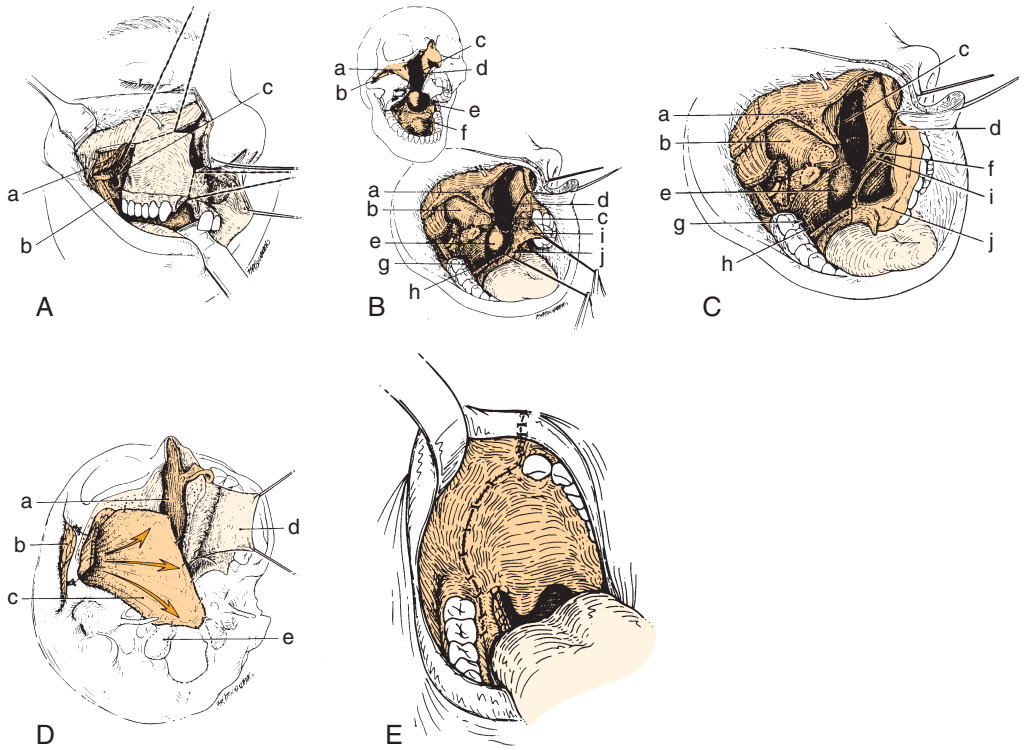

Figure 174-30. Extended maxillotomy; subtotal maxillectomy approach to the cranial base. **A,** Maxillectomy variation. Modified Weber-Fergusson incision followed by osteotomies to remove the hemimaxilla: a, masseter muscle divided; b, coronoidectomy defect; c, lateral pterygoid plate. **B,** Maxillectomy; defects: a, maxillary roof; b, infratemporal fossa; c, sinonasal defect; d, nasal septum; e, clivus tumor; f, C1 vertebra; g, lateral pharyngeal wall; h, pharyngeal wall incision; i, mucoperiosteum of hard palate; j, soft palate. **C,** Maxillotomy variation in which the hemimaxilla (j) is preserved but temporarily translocated, based on mucoperiosteum of the hard palate. See key in **B** for other lettered structures. Exposure is otherwise similar to that shown for maxillectomy. **D,** Temporalis muscle transferred into operative defect for reconstruction: a, sinonasal defect; b, fat graft; c, temporalis muscle flap; d, mucoperiosteum of hard palate; e, occipital condyle. **E,** Closure of the oral cavity and lip after subtotal maxillectomy. *(From Cocke EW Jr, Robertson JH, Robertson JT, Crook JP Jr. The extended maxillotomy and subtotal maxillectomy for excision of skull base tumors.* Arch Otolaryngol Head Neck Surg. *1992;116:92-104.)*

rotundum, and the foramen lacerum. Removal of the pterygoid plates in this approach also facilitates access to the nasopharynx. This approach is used in the resection of small nasopharyngeal carcinomas, adenoid cystic carcinomas, and angiofibromas. All three variations of the infratemporal fossa approach involve mastoidectomy, facial nerve dissection (and transposition), and obliteration of the eustachian tube, middle ear, and external auditory canal with resultant permanent conductive hearing deficit. Thus, types A, B, and C infratemporal fossa approaches share some features of the basic transtemporal approaches and yet extend the field of access anteriorly to reach the middle cranial base by virtue of exposing and controlling the petrous ICA (see Chapter 176).

For lesions of the middle cranial base that involve the infratemporal fossa, the upper pterygomaxillary space, the lateral orbit, and the orbital apex, the lateral facial approach[100] (Fig. 174-33) and the lateral transtemporal sphenoid approach[101] (Fig. 174-34) have been described. These procedures reach the infratemporal fossa from a slightly more superior direction by displacing the zygomatic arch inferiorly and reflecting the temporalis muscle. The greater wing of the sphenoid is followed to the lateral pterygoid plate, which is used as a surgical landmark, as outlined earlier. These approaches also incorporate partial removal of the greater wing of the sphenoid, which means that they include subtemporal craniectomy and extradural dissection. The advantages of these procedures are that they require no facial nerve dissection (the temporal branch of cranial nerve VII is retracted inferiorly with the skin flap), and they allow some access to the cranial base from both intracranial and extracranial perspectives.

The lateral facial approach is useful as a straightforward approach to a limited area of the middle cranial base that is technically simple to perform (after the anatomy is well understood) and that incurs relatively little morbidity. It is applicable in the management of small- to medium-sized benign tumors with limited intracranial extension, such as that which occurs with some angiofibromas. The similarly oriented lateral transtemporal sphenoid approach can be extended so that it is significantly more complex than the lateral facial approach but affords additional exposure, thus making it useful for the management of lesions in the clivus, the parasellar region, the nasopharynx, the petrous apex, and the infratemporal fossa. As the name implies, the lateral transtemporal sphenoid approach is a combination of techniques. It is similar to the infratemporal fossa approaches of Fisch except that it does not usually result in permanent conductive hearing loss, and it does not require rerouting of the facial nerve.

The subtemporal-preauricular infratemporal approach (Fig. 174-35)[14,102] is a combination of the transparotid and lateral transtemporal sphenoid procedures in addition to temporal craniotomy. It provides excellent exposure of much of the middle cranial base and allows for improved access for intracranial dissection when necessary. The orientation of the exposure begins laterally and progresses medially so that it is useful for the management of lesions of the greater sphenoid wing, the petrous apex, and the middle and lower clivus. This approach is used extensively for the resection of tumors such as meningiomas, chondrosarcomas, chordomas, and petrous apex cholesteatomas. It illustrates many important techniques used in surgery of the middle cranial base.

A hemicoronal or curved temporal incision is extended into the preauricular and cervical regions to expose the temporalis muscle, the zygomatic arch, the parotid gland, and the upper neck. (As discussed in the description of the bicoronal incision, the temporal fascia and fat

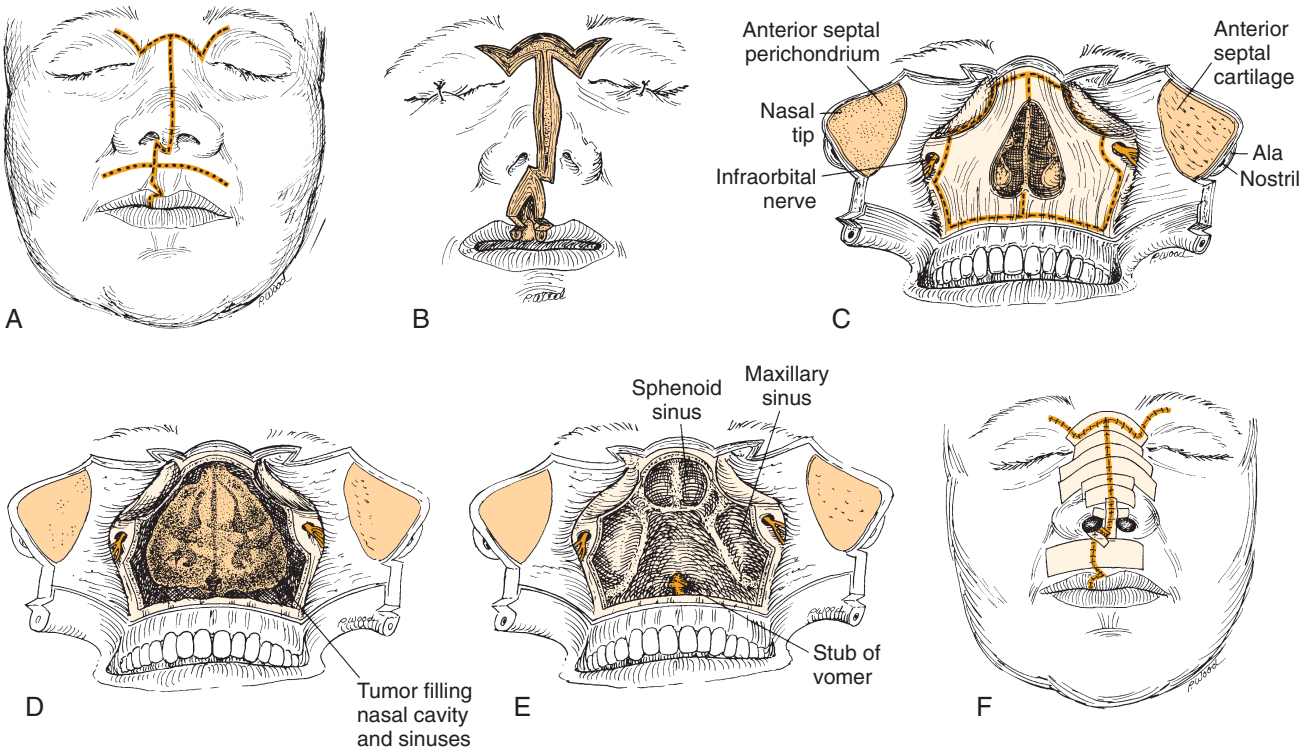

Figure 174-31. Midfacial split approach to the cranial base. **A,** Incisions. Horizontal incision across the nasion allows access to the upper orbits. Midline nasal incision divides skin and separates upper and lower lateral cartilage to expose septum; it is carried inferiorly along one side of the philtrum, splitting the upper lip. Gingivolabial incision *(dotted line)* facilitates exposure of the maxilla bilaterally. **B,** Partially developed facial soft tissue flaps, with attached nasal cartilages. **C,** Soft tissue flaps fully developed and reflected laterally to expose the orbitonasomaxillary skeleton. Proposed osteotomy sites are indicated by *dotted lines*. **D,** Midfacial exposure after osteotomies and temporary removal of bone segments, including portions of the medial and inferior orbital walls, the anterior maxilla, and the nasal bones. When necessary, osteotomies also may include the hard palate, which gives additional access to the oropharynx, the nasopharynx, and the clivus. In this example, tumor fills the posterior nasal cavity and nasopharynx and extends into the sphenoid sinus. **E,** After removal of the tumor, which included the nasal septum, the medial maxillae, and the sphenoid rostrum. **F,** Final closure. Orbitonasomaxillary bone segments are replaced and secured using microplates, and soft tissues are primarily repaired. Adhesive strips are applied, and silicone nasal stents are used for 1 week postoperatively.

pad are elevated with the skin flap, thereby protecting the frontal branch of the facial nerve). The cervical extension is used to gain access to the ICA, the internal jugular vein, and cranial nerves IX through XII, and to help identify the facial nerve extratemporally. The parotid gland is mobilized away from the sternocleidomastoid muscle, and the underlying styloid complex is divided, revealing the high cervical ICA, the internal jugular vein, and cranial nerves IX to XII. Next, the zygomatic arch is osteotomized with a reciprocating saw and removed temporarily, thereby allowing the temporalis muscle to be reflected inferiorly to expose the greater wing of the sphenoid and the underlying infratemporal fossa. In cases in which the lesion also involves the orbit (e.g., sphenoid wing meningiomas), the lateral orbital wall and rim may also be osteotomized and removed along with the zygoma. The condyle of the mandible may be retracted or resected to expose the spine of the sphenoid and its nearby structures, including the middle meningeal artery, cranial nerve division V3, and the ICA at its entrance into the carotid canal. More medially, V2 can be identified just anterior to the lateral pterygoid plate.

A low temporal craniotomy is performed, and, by extradural dissection, the temporal lobe is elevated off of the middle fossa floor, thereby revealing the intracranial landmarks: the GSPN, the middle meningeal artery, and cranial nerve divisions V2 and V3.

By progressive removal of the greater wing of the sphenoid, cranial nerve divisions V3 and V2 may be completely unroofed. If necessary, the sphenoid sinus may be opened by removing the bone between V2 and V3 and the base of the pterygoid plates. The superior orbital fissure may be unroofed in the same way.

The intrapetrous course of the ICA may be exposed, beginning at the infratemporal opening of the carotid canal and extending to just above the foramen lacerum (where the ICA enters the cavernous sinus). This is accomplished with a high-speed drill and a diamond burr using a technique analogous to that used for facial nerve decompression. To facilitate this exposure, the middle meningeal artery and the GSPN should first be divided, and the high cervical ICA with its fibrous periosteal sheath should be rendered accessible by removal of the styloid process and the surrounding bone. The ICA may be displaced forward out of its bony canal; this is useful whenever the lesion involves the clivus medial to the ICA or the petrous part of the temporal bone posterior to the ICA. The inferior aspect of the cavernous sinus may also be approached from this exposure.[7]

The sequence and extent of exposure at the skull base depend on the nature of the lesion to be extirpated. Certain steps in the procedure may be eliminated or modified to suit the needs of the particular case. For example, it is only necessary to dissect the neck if the procedure will benefit from proximal control of the ICA or from low exposure of the internal jugular vein or cranial nerves IX through XII. Otherwise, the cervical extension may be avoided.

After the lesion has been extirpated, the wound is irrigated with antibiotic solution and carefully inspected. Any dural openings are meticulously repaired primarily or by using grafts of pericranium, temporalis fascia, or fascia lata. In addition to repairing dura, every effort is made to reconstitute a functional barrier between the intracranial compartment and the visceral spaces of the head and neck. Usually this does not include any attempt to rebuild the bony basicranium. Instead,

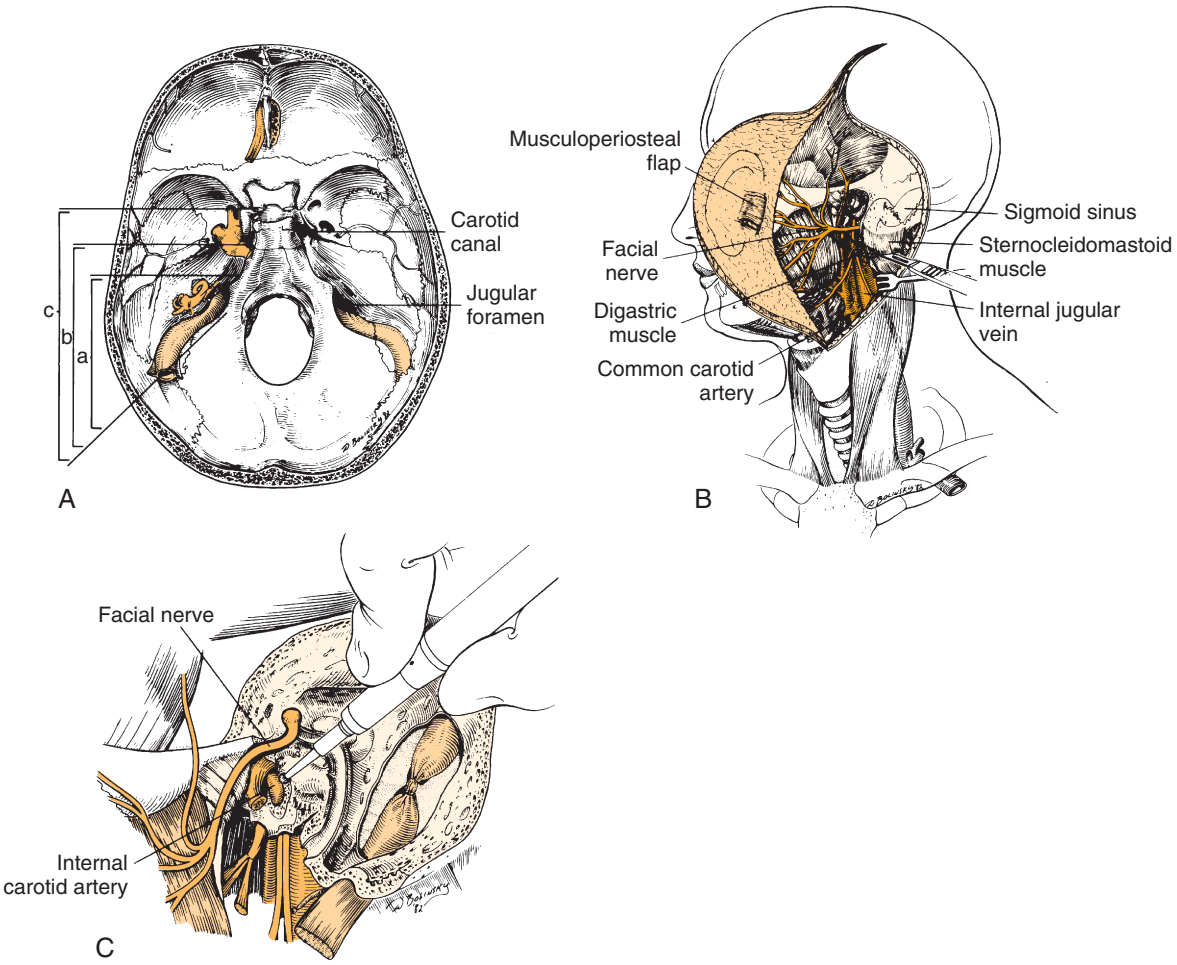

Figure 174-32. Infratemporal approach to the cranial base. **A,** Areas of the skull base accessible by each of the variations of the infratemporal approach: a, jugular foramen and petrous apex; b, clivus; c, parasellar and parasphenoid compartments. **B,** Postauricular incision with extensions into the scalp and neck. Sternocleidomastoid and digastric muscles have been divided at the mastoid tip, thereby allowing access to the carotid artery and the internal jugular vein. The facial nerve has been identified extratemporally. The external auditory canal has been closed by turning the musculoperiosteal flap. **C,** Radical mastoidectomy has exposed the sigmoid sinus (which has been ligated) and the middle fossa dura. The tympanic membrane and ossicles have been removed. The facial nerve has been unroofed and transposed anteriorly. By progressive drilling, the internal carotid artery can be traced distally through its petrous course to reach the cavernous sinus. Similarly, additional bone removal anteriorly will allow access to the parasellar region and the nasopharynx. *(From Fisch U, Pillsbury HC, Sasaki CT. Infratemporal approach to the skull base. In: Sasaki CT, McCabe BF, Kirchner JA, eds.* Surgery of the Skull Base. *Philadelphia: JB Lippincott; 1984.)*

efforts are focused on the interposition of reconstructive soft tissues—vascularized tissues, whenever possible—into the surgical defect.

Any communications with the aerodigestive tract are identified. These most often include the sphenoid sinus, the nasopharynx, and the eustachian tube. If the sphenoid sinus has been opened, its mucosa is removed, and it is obliterated with autogenous fat or by the transfer of vascularized temporalis muscle medially. If the eustachian tube has been entered, it is denuded of mucosa, packed with fat or muscle, sutured closed, and covered with vascularized temporalis muscle. If the nasopharynx has been violated, the opening is filled with a temporalis muscle flap or a free microvascular flap (e.g., rectus abdominis), depending on the size of the defect. Special care is taken to ensure that the ICA is covered with vascularized tissue throughout its course, particularly in cases in which the nasopharynx has been entered. Failure to protect the ICA in this way may result in continued exposure of the artery to bacterial contamination from the upper aerodigestive tract, with subsequent carotid rupture.

Finally, the zygomatic and craniotomy bone segments, which were previously displaced by osteotomy, are returned to their anatomic positions and secured appropriately. If the temporalis muscle has not been used as a reconstructive flap, it is returned to the temporal fossa. If a temporalis flap has been used, the temporal fossa may be filled with autologous fat from the abdomen or thigh to minimize the temporal fossa depression. Soft tissue closure then follows.

Transfacial Approaches

Transfacial exposure of the cranial base, particularly of the lateral compartment (middle cranial base region), is not a new concept. Operative procedures for the removal of neoplasms from this region were described by several authors in the 1960s.[103,104] These early procedures, which were used initially for the radical resection of malignant tumors, resulted in unacceptably high morbidity and mortality rates and considerable deformity, largely because methods to adequately reconstruct major cranial base defects were not yet available. With the introduction of craniofacial disassembly techniques and vascularized reconstructive flaps, it has become possible to dismantle the facial skeleton, to extirpate deep-seated lesions, and to perform functional reconstruction to a greater extent than ever. Accordingly, lesions of the lateral and central compartments are more amenable to surgery.

A transfacial approach to this region is desirable because it eliminates the viscerocranial skeleton as an obstacle to exposure, thereby opening up the entire infratemporal fossa and the nasal cavity, the

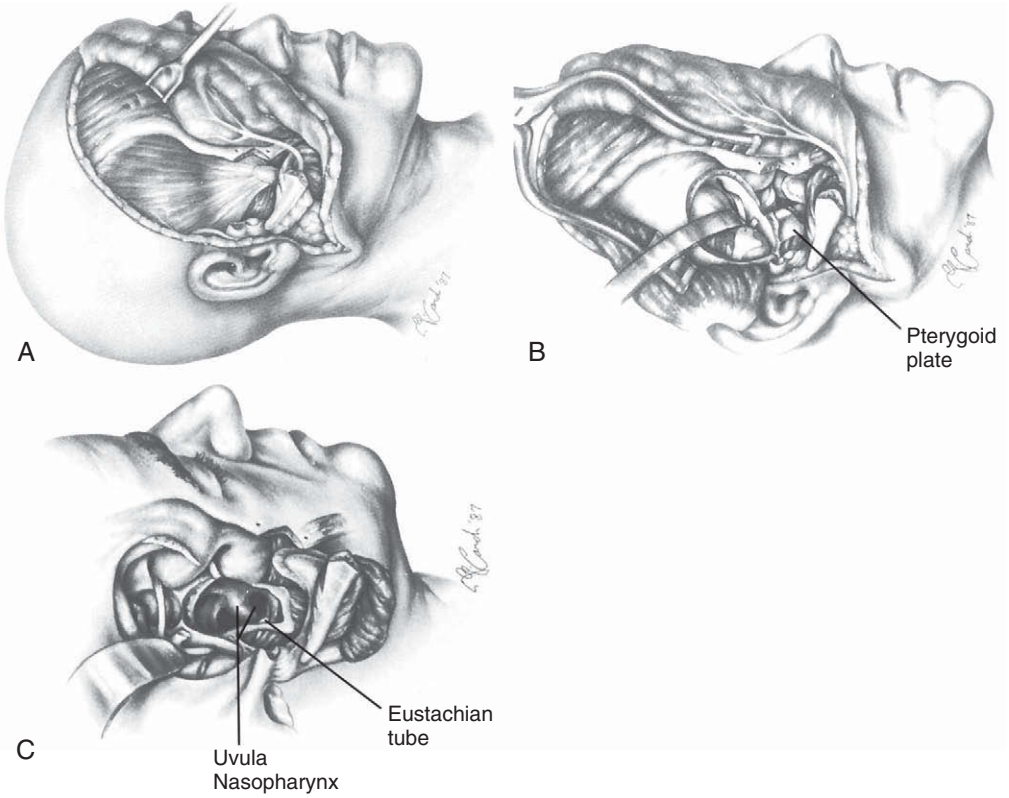

Figure 174-33. Lateral facial approach to the cranial base. **A,** A temporal and preauricular incision is used to expose the temporalis muscle and the zygomatic arch. The zygoma is sectioned to allow access to the insertion of the temporalis at the coronoid process. The frontal branch of the facial nerve is preserved within the skin flap. **B,** With the temporalis muscle retracted, the greater wing of the sphenoid is partially removed (subtemporal craniectomy). Retraction of the temporal lobe dura reveals branches of the trigeminal nerve and attachment of the pterygoid plate at the base of the sphenoid bone. **C,** Division of the maxillary nerve (V2) and resection of the pterygoid plate expose the nasopharynx. *(From Gates GA. The lateral facial approach to the nasopharynx and infratemporal fossa.* Otolaryngol Head Neck Surg. *1988;99:321-325.)*

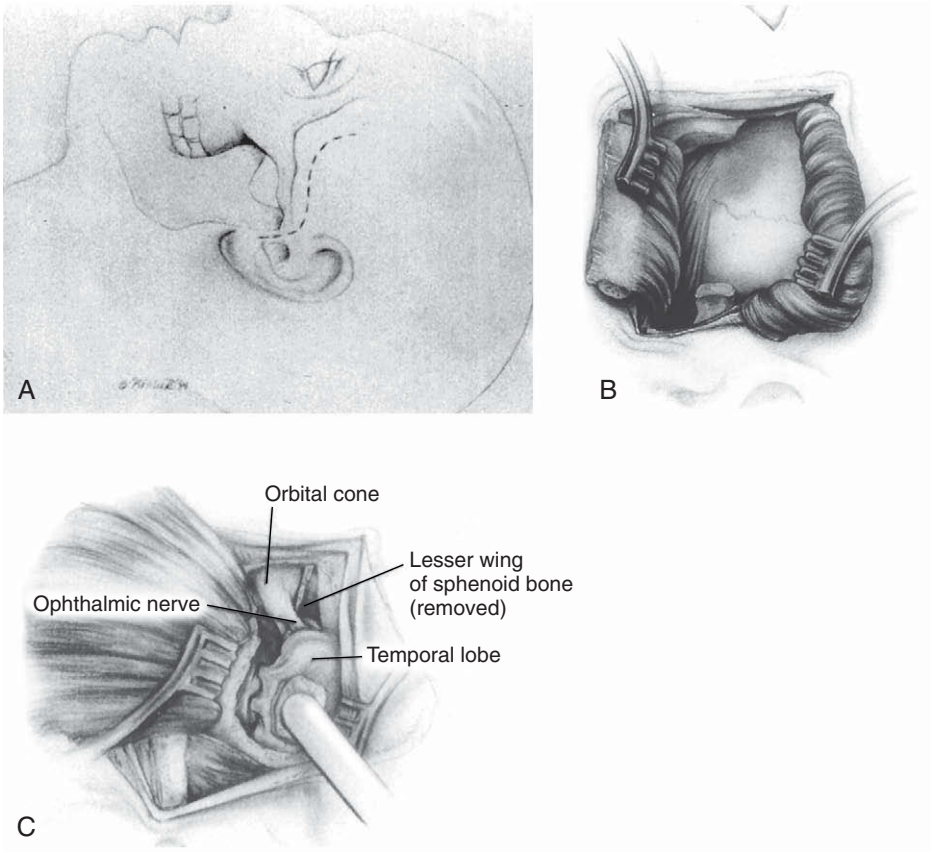

Figure 174-34. Lateral transtemporal sphenoid approach to the cranial base. **A,** Incision. **B,** Retraction of the temporalis muscle to expose the greater wing of the sphenoid. This muscle should be preserved intact and reflected inferiorly if muscle flap reconstruction of a skull base defect is anticipated. The zygomatic arch has been temporarily removed. **C,** Subtemporal craniectomy exposes the orbital apex and the floor of the middle cranial fossa. *(From Holliday MJ. Lateral transtemporal-sphenoid approach to the skull base.* Ear Nose Throat J. *1986;65:153-162.)*

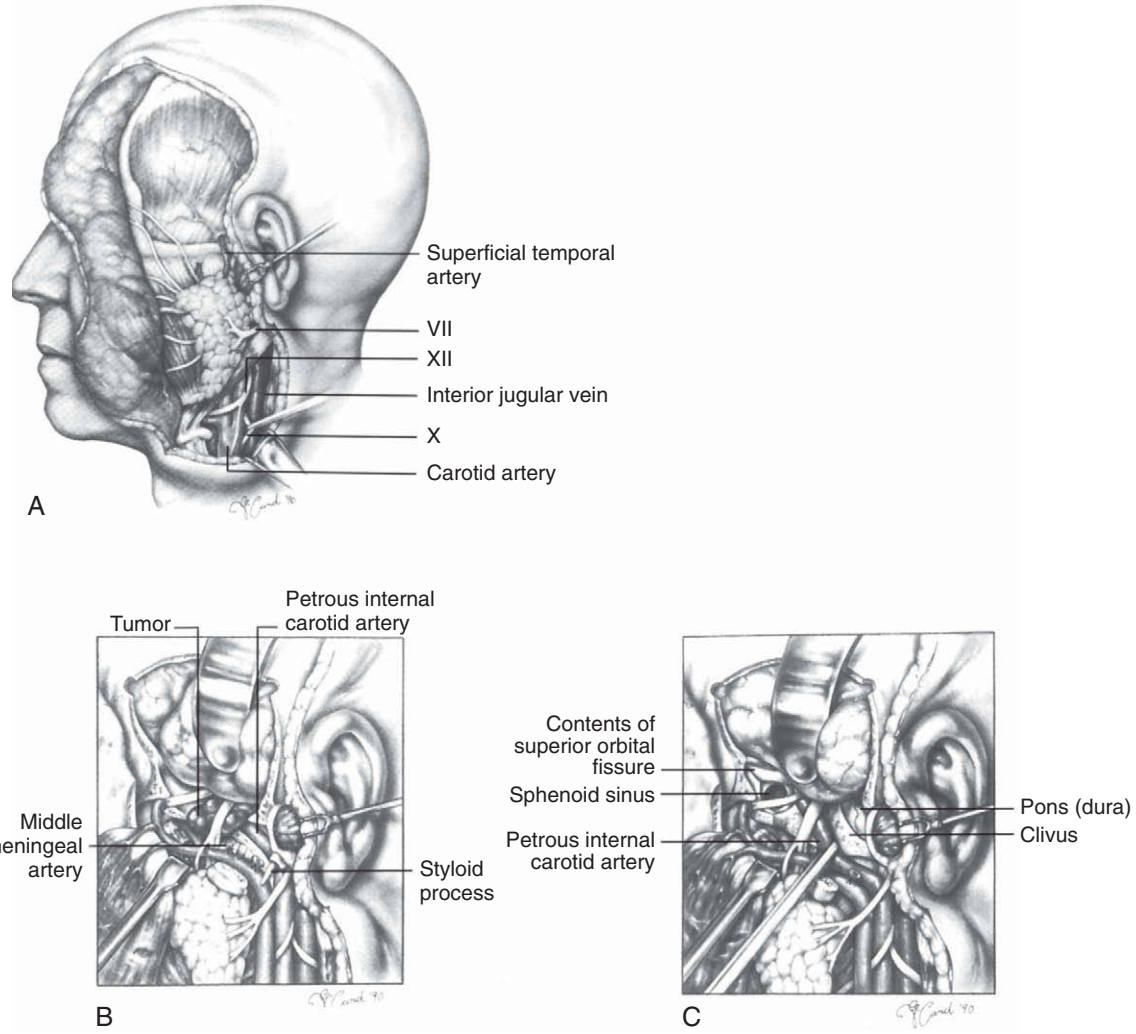

Figure 174-35. Subtemporal-preauricular and infratemporal approach to the cranial base. **A,** Initial exposure. Distal branches of the facial nerve are for demonstration only; in most cases they are not dissected. The frontal branch is included with the skin flap and retracted inferiorly. **B,** The temporalis muscle has been reflected inferiorly *(bottom left)* after temporarily removing the zygomatic arch, the mandibular condyle has been resected, and a subtemporal craniectomy has been performed. After dividing the styloid complex, the carotid artery is traced distally through part of its course within the temporal bone to separate it from the tumor. The facial nerve need not be transposed, and the conducting mechanism of the middle ear remains undisturbed in this approach. **C,** Progressive dissection exposes the clivus, the sphenoid sinus, the superior orbital fissure, and the adjacent neural and vascular structures. *(From Sekhar LN, Janecka IP. Intracranial extension of cranial base tumors and combined resection: the neurosurgical perspective. In: Jackson CG, ed.* Surgery of Skull Base Tumors. *New York: Churchill Livingstone; 1991.)*

nasopharynx, the pterygopalatine fossa, and the sphenoid region to direct access all at once. The facial translocation approach (Fig. 174-36)[17] is such a procedure.

Incisions are made in the face and scalp as shown in Figure 174-36A. The horizontal incision connects a lateral rhinotomy with a hemicoronal incision to create superior and inferior soft tissue flaps. (At this stage, the frontal branches of the facial nerve are identified using evoked EMG, tagged, and divided to be reconnected later on during the procedure. This horizontal incision is a key element in the exposure because it allows a single, unified surgical field that is unhampered by the need to work alternatively from separate cranial and facial incisions that limit the surgeon's ability to develop three-dimensional exposure at the cranial base.) The soft tissue flaps are then elevated in the subperiosteal plane from the zygoma and maxilla. Periorbita is likewise elevated from the lateral, inferior, and medial orbital rims and walls. A reciprocating saw is used to create osteotomies, and the orbitozygomaticomaxillary skeletal segment is temporarily removed.

After the temporalis muscle is reflected inferiorly, the subtemporal skull base is fully exposed, and further dissection proceeds as dictated by the lesion, using the same skull base landmarks as for other approaches. Intracranial exposure is readily obtained, if needed, by subtemporal craniectomy or by frontal or temporal craniotomy. Similarly, the pterygoid plates and muscles may be removed, thus revealing the nasopharynx, the sphenoid sinus, and the clivus. As mentioned previously, facial translocation may therefore be used as an approach to the central compartment of the middle cranial base; it provides a unified surgical field with access to both compartments.

At the completion of the extirpation, reconstruction follows the same principles as discussed. After dural repair, the temporalis muscle is used to fill the skull base defect. Because of its appreciable soft tissue bulk, the muscle also is useful for obliterating the maxillary sinus space. There it serves as a vascularized tissue bed for the orbitozygomaticomaxillary bone segment, which is replaced and secured as a free bone graft. Bony stabilization is achieved with sutures or miniplates. If it has not been resected for oncologic reasons, the infraorbital nerve (which was transected during the development of the lower facial soft tissue flap) is rerouted through its maxillary canal and reconnected to its distal trunk by suture neurorrhaphy. The frontal branches of the facial nerve also are repaired. The nasolacrimal system is stented to prevent dacryostenosis, and the medial canthal ligament is secured to the lacrimal

The lip-splitting portion may be omitted in many cases in which low maxillary exposure is not needed. **B,** Facial soft tissue flaps fully developed and reflected to expose the craniofacial skeleton. **C,** Outline of osteotomies of the orbitozygomaticomaxillary skeleton. **D,** Exposure after temporary removal (translocation) of the orbitozygomaticomaxillary segment. **E,** Inferior reflection of the temporalis muscle—enhanced by outfracture of the coronoid process—gives access to the pterygoid region and the nasopharynx. **F,** Subtemporal craniectomy allows exposure of the middle fossa floor, the sphenoid sinus, and the adjacent neural and vascular structures. ICA, internal carotid artery. *(From Janecka IP, Sen CN, Sekhar LN, Arriaga M. Facial translocation: new approach to cranial base.* Otolaryngol Head Neck Surg. *1990;103:413-419.)*

crest. Temporary tarsorrhaphy helps support this repair during the early postoperative period. Closure of skin incisions completes the procedure.

Postoperatively, tarsorrhaphy sutures may be removed within 1 week; nasolacrimal stents remain in place for 6 to 8 weeks. In most patients, infraorbital sensation returns within 3 to 6 months, and frontalis muscle function resumes in 6 to 9 months.

The facial translocation technique is valuable for obtaining the broad exposure needed when managing large or advanced lesions of the lateral and central compartments of the middle cranial base, especially those in which much of the lesion is extracranial. Because of its modular nature, it also can be applied in various scaled-down versions that are tailored for dealing with smaller cranial base lesions.

Intracranial Approaches

Temporal craniotomy is the traditional, standard neurosurgical method for gaining access to the middle cranial fossa. For intradural lesions within the temporal lobe or for extradural lesions along the lateral convexity of the middle fossa, it is the most direct approach.[105] For lesions at the cranial base, however, temporal craniotomy alone is often less than ideal, because it requires (by virtue of its superolateral-to-inferomedial orientation) significant retraction or, in some cases, resection of the brain to reach a target area. Such brain manipulation can result in intraoperative and postoperative cerebral edema; temporal encephalomalacia; deficits of speech, memory, and cognition; and long-term risk of seizure disorder. These risks increase as the location of the lesion becomes more medial and more temporal lobe retraction is required.

Still, temporal craniotomy alone is useful for some limited lesions of the lateral compartment–middle cranial base region, such as meningiomas of the sphenoid wings. Risks of intracranial complications can be minimized by designing the craniotomy bone flap as low as possible, thereby giving a more basal and direct access to the skull base, with less need for brain retraction. The limiting factors are the petrous ridge of the temporal bone and the zygomatic arch. When preoperative imaging suggests that these structures will impede adequate exposure, a wider approach should be chosen, such as the subtemporal-infratemporal, lateral facial, or transtemporal sphenoid approach.

The middle fossa approach of House[106] involves the use of temporal craniotomy as a preliminary step to reach the IAC by the removal of bone from the superior surface of the petrous portion of the temporal bone. Because most lesions in these areas originate in relation to the seventh and eighth cranial nerves, this approach is considered in more detail in Chapters 171, 176, and 177.

When the skull base is involved only to a minimal extent and the lesion is mostly infracranial, a subtemporal craniectomy may be performed (see Figs. 174-33 and 174-36). In this procedure, only a limited area of cranial bone is removed, generally as a safe means of establishing a superior margin in resecting, for example, the base of the pterygoid plates and surrounding soft tissue. Subtemporal craniectomy may be performed by inserting a Kerrison or a similar rongeur extradurally inside the foramen ovale and gradually removing bone in the direction of the foramen rotundum. The resulting bone window allows for the protection of the middle fossa dura under direct vision while the subjacent lesion is removed.

For many lesions of the lateral compartment of the middle cranial base, temporal craniotomy and subtemporal craniectomy are used in combination with transtemporal, infratemporal, or transfacial exposure. These intracranial approaches provide added control over the neural and vascular structures in the region. As is true for all transcranial operations for cranial base lesions, close cooperation between the otolaryngologist and the neurosurgeon is essential.[107]

Reconstruction

As stated previously, use of locoregional vascularized flaps is the primary reconstructive method for skull base defects; however, support is growing for microvascular reconstruction of these defects, especially

large ones, or in revision surgery, when locoregional flaps may be unavailable.[53,54,108]

In a retrospective study, Newman and associates found a 95% success rate in reconstructing anterior and middle skull base defects. Despite a 30% overall complication rate, no cases of intracranial complication or CSF leak or deaths were associated with this reconstruction.[109] Other authors have experienced higher rates of complications including flap failure and intracranial problems (cerebrovascular accident [CVA], syndrome of inappropriate antidiuretic hormone [SIADH], meningitis, seizure, pneumocephalus, CSF leak), although most reported series have been smaller with a retrospective study design.[110]

The progression of expanded endoscopic approaches has also necessitated the development of nonvascularized materials to repair skull base defects. Acellular dermis, hydroxyapatite cement, free abdominal fat, autologous cartilage and bone grafts may be used to match each defect. Of importance, hydroxyapatite cement must not be allowed to contact the sinonasal mucosa, to avoid infection and failure.[2,111]

Postoperative Concerns

Initial Postoperative Care

All patients initially are admitted to an intensive care unit that is staffed by nurses who are experienced in neurosurgical and head-and-neck surgical care. Consultants in critical care medicine, internal medicine, and other specialties actively participate in management, when appropriate. Typically, patients will have a continuous recording of the electrocardiogram, oxygenation status (monitored by pulse oximetry), and systemic blood pressure (monitored by arterial catheter). In specific circumstances, Swan-Ganz catheters or central venous lines are used to assess cardiovascular status and fluid balance. These parameters are crucial for maintaining optimal intravascular volume, cardiac output, and cerebral blood flow.

Given the complexity of intraoperative fluid and electrolyte management, close monitoring of hematologic and chemical parameters is essential (i.e., hemoglobin; hematocrit; platelets; prothrombin and partial thromboplastin times; sodium, potassium, calcium, magnesium, and phosphorus concentrations; and serum osmolality). The appropriate replacement of blood components maintains oxygen delivery (erythrocytes) and prevents coagulopathy (platelets, plasma). Electrolyte balance is especially important, because deviation from physiologic norms can lead to confusion, agitation, stupor, or seizure activity, which may be otherwise mistaken for surgery-related neurologic insults.

Pharmacologic therapy plays an important role in the prevention of complications. Antibiotics are routinely given, beginning just before surgery and for a duration of 24 to 48 hours afterward. Inhibitors of gastric acid secretion are given postoperatively to reduce the chance of stress ulceration and gastrointestinal bleeding, and they are continued until the patient is tolerating adequate enteral nutrition. Anticonvulsants are used to prevent seizures whenever significant frontal or temporal lobe manipulation is necessary. Once instituted, anticonvulsant therapy should be periodically monitored using serum drug levels and should be continued for at least 6 to 12 months after surgery. Analgesic therapy is limited in most cases to the judicious use of intramuscular codeine, which has a mild, predictable (and reversible) effect on mental status and respiratory drive. Stronger narcotics and benzodiazepines and related sedatives generally are avoided because of their more profound and less predictable influences on these functions, potentially confounding accurate neurologic assessment.

For most procedures in which the cranial vault has been opened, a CT scan is obtained on postoperative day 1. This scan serves as a baseline study for comparison with any subsequent studies performed to investigate neurologic complications if they arise.

Prophylaxis against deep vein thrombosis and pulmonary embolism includes the intraoperative and postoperative use of dynamic compression stockings. In addition, patients are mobilized as soon as feasible after surgery.

Complications

Many of the most serious complications of cranial base surgery are related to the brain,[14] and their prevention and management demand neurosurgical expertise. First, brain manipulation, especially by excessive retraction, can lead to cerebral edema, subdural hematoma, and acute brain dysfunction specific to the anatomic site involved. In the long term, it may cause encephalomalacia and deficits of speech, memory, and cognitive and intellectual functions. Brain injury (by contusion) also may predispose the patient to seizures, especially when the temporal lobe is affected. These problems are best prevented by obtaining adequate surgical exposure through basal bone removal and craniofacial disassembly (thereby limiting the need for significant brain manipulation) and by intraoperative brain relaxation through the use of subarachnoid CSF drainage, hyperventilation, and corticosteroids.

Pneumocephalus may occur as a sudden event during the early postoperative period, after a patient attempts (against advice to the contrary) to blow his or her nose, thereby inadvertently insufflating air through the dural closure. This rapid-onset pneumocephalus may cause intracranial mass effect (tension pneumocephalus), with confusion, obtundation, and progressive neurologic deterioration. Pneumocephalus also may develop more slowly as a result of the overdrainage of CSF from a lumbar spinal drain, which can cause a siphon effect, drawing air upward from the nasal cavity. Preventive measures therefore include the following: (1) keeping patients intubated or tracheotomized until they are alert enough to follow instructions; and (2) judiciously using spinal drainage at a conservative rate and for a short duration. In most patients after cranial base surgery, the lumbar catheter is allowed to drain 25 to 50 mL every 8 hours and is removed after 24 to 72 hours. When pneumocephalus is suspected, prompt CT assessment is necessary. Small collections of air may be observed, whereas larger ones may require decompression by needle aspiration (through an osteotomy site or burr hole) or by reexploration and reinforcement of the reconstruction. In cases of acute-onset pneumocephalus, the administration of 100% oxygen is a useful adjunctive measure to enhance resorption of the intracranial air. Lumbar subarachnoid CSF drainage should be discontinued in the presence of any significant pneumocephalus.

CSF fistula is another brain-related complication that is important because of its association with meningitis. It usually manifests as rhinorrhea, but it also may cause the patient to experience a salty taste in the throat. If the nature of nasal discharge is doubtful, the β_2-transferrin assay may be used to confirm or rule out the presence of CSF.[112] For small-volume leaks, which are the most common, observation and continued spinal drainage (or serial lumbar spinal taps) usually suffice. For high-volume leaks (grossly apparent rhinorrhea) or those that are persistent, careful sinonasal endoscopy or CT cisternography can be used to localize the fistula site (i.e., frontal, ethmoid, sphenoid, eustachian tube, temporal bone), after which operative repair frequently is needed. A CSF fistula may manifest as otorrhea or as wound discharge; the management principles are similar in either case. In some situations, the original repair simply needs to be revised; in others, additional vascularized tissue may be needed to obliterate the fistula site. Such tissues may include temporalis muscle, galeal, or free microvascular flaps (e.g., rectus abdominis, omentum). In selected cases, the closure may be augmented by the judicious use of free autogenous fat grafts or fibrin glue. The risk of reconstructive failure is substantially decreased if the original repair is performed using vascularized local tissue.[69]

CNS infections, including meningitis and brain abscess, also may occur. These complications can lead to extreme neurologic morbidity or death. Preventive measures include the use of perioperative antibiotics, strict adherence to sterile technique, the minimization of dural exposure to the aerodigestive tract, and meticulous attention to reconstruction, as outlined earlier. Management consists of antimicrobial drugs (given intravenously and sometimes intrathecally) and surgical exploration when necessary to drain abscesses or to obliterate sources of continued bacterial contamination.

Cerebrovascular complications are of major concern during the perioperative period. These events may have several causes. Carotid rupture may occur as a result of infection (and pseudoaneurysm) or excessive adventitial dissection. This complication is often sudden and fatal, but it may sometimes be preceded by a sentinel bleed, which, if recognized as such, can provide time for prompt intervention (i.e., reexploration and bypass or permanent ICA occlusion). Thrombotic

ICA occlusion or embolism into distal vessels can cause stroke and death. The strict maintenance of systemic blood pressure intraoperatively and postoperatively avoids hypotension, which can precipitate ICA thrombosis. Careful surgical technique when working in the vicinity of the ICA and cautious postoperative anticoagulation in high-risk patients may decrease embolic phenomena. Although the incidence of stroke in cranial base surgery is low, stroke is a source of considerable morbidity when it does occur; this morbidity can usually be lessened when the cranial base team adopts a vigorous approach to intervention and rehabilitation. Intervention after stroke should include the tight control of the hemodynamic factors that affect cerebral blood flow to prevent extension of the infarct. It also should include measures to ensure optimal homeostasis, such as control of the airway and oxygenation, maintenance of fluid and electrolyte balance, and nutritional support. Rehabilitation of stroke patients (and of patients with neurologic deficits from other causes) is greatly facilitated by input from professionals in rehabilitation medicine, physical and occupational therapy, and speech therapy.

Cranial nerve deficits deserve special consideration because of their profound impact on postoperative recovery and quality of life. The sacrifice of olfactory nerves (cranial nerve I) often is regarded as a minor disability, but it can contribute to significant malnutrition in some patients who, because of anosmia, no longer enjoy eating. Deficits of cranial nerves II, III, IV, and VI lead to visual disability of variable degree, depending on the extent of surgical trauma and nerve involvement by the disease process itself. Dense palsies of the extraocular muscles seldom recover completely. Patients in whom such deficits are predictable should therefore be prepared for the loss of binocular vision before surgery is undertaken. Extraocular muscle surgery by the ophthalmologist can sometimes help to compensate for such deficits. The loss of visual acuity is a potential complication of anterior cranial base surgery, but it is unusual unless the optic nerves are compromised preoperatively. In these patients, recovery of optic nerve function is difficult to predict.[63]

Deficits of the fifth and seventh nerves are dangerous, mainly because of loss of sensation (V1) or protection (VII) of the cornea. Tarsorrhaphy and careful attention to ocular lubrication are important means of preventing keratitis and visual loss in these cases. Fifth nerve dysfunction, in addition to the obvious sensory deficits, may also cause significant problems with mastication (and with nutrition) because of the loss of motor innervation to the pterygoid, temporalis, and masseter muscles (V3). Seventh nerve paralysis can be a tremendous social and emotional handicap and should be rehabilitated aggressively whenever possible. Eighth nerve deficits, although rarely reversible, usually can be compensated for (when unilateral) by audiologic and vestibular training.

Deficits of cranial nerves IX, X, and XII are potentially life-threatening, especially when they occur together, because of aspiration and dysphagia with subsequent pneumonia and malnutrition. Management of patients in whom these deficits are present preoperatively or expected postoperatively should include tracheostomy and gastrostomy at the time of the cranial base surgery or very soon thereafter, before complications compromise the patient's recovery. Laryngoplasty or injection of collagen or fat into the unilaterally paralyzed larynx also may be beneficial. Patients who have multiple bilateral deficits of cranial nerves IX, X, and XII are extremely difficult to rehabilitate. Management of these cases nearly always involves permanent tracheostomy and gastrostomy and, sometimes, laryngotracheal separation.

Many complications of cranial base surgery are not brain related (Table 174-2) and can affect any physiologic system. Despite the relatively less invasive appearance of endoscopic skull base surgery, these procedures carry many of the same risks of more traditional open skull base procedures. CSF leaks remain the most common complication, and additional serious complications including damage to cranial nerves, meninges, blood vessels, and venous sinuses can present in the immediate postoperative period. Delayed complications include meningitis, brain abscess, and tension pneumocephalus, anosmia, and synechia formation. Visual loss or changes may result from damage to the optic nerve or chiasm or orbital contents, including extraocular musculature. Damage to the pituitary stalk also may result with transsphenoidal approaches.[38] Postoperative diabetes insipidus rates are reported to be as much as 50% lower in endoscopic cases.[113]

Table 174-2

Non-neurologic Complications in Cranial Base Surgery

Type of Complication	Examples
Cardiovascular	Myocardial infarction Hypotension Congestive heart failure
Respiratory	Pulmonary embolism Pneumonia Aspiration Respiratory distress syndrome Pulmonary edema
Hematologic	Post-transfusion coagulopathy Anemia Deep venous thrombosis
Renal	Acute tubular necrosis Drug-induced nephropathies
Infectious	Pneumonia Sepsis Thrombophlebitis Wound infections Viral hepatitis Urinary tract infections
Gastrointestinal	Malnutrition Stress ulcer Gastrointestinal bleeding
Metabolic	Derangements of serum sodium, potassium, calcium, phosphorus, magnesium, and other minerals
Endocrine	Diabetes insipidus Syndrome of inappropriate antidiuretic hormone Hypopituitarism
Hepatic	Drug-induced hepatitis Cholestasis

Outcomes

Although the many technical advances and multispecialty approaches in cranial base surgery have expanded the ability to achieve complete and safe tumor resection, the question remains regarding the extent that patients benefit from these invasive procedures. A 1995 review of 40 years of cranial base surgery for carcinomas and sarcomas provided some insight into the answer to this question.[114] Three general eras of major advancement in the field were analyzed for survival outcomes and trends in morbidity.

From the 1960s to the 1970s, surgical pioneers achieved 3- and 5-year survival rates of 52% and 49%, respectively. The application of skull base approaches was limited, and tumors were designated as inoperable if they extended intracranially or into the pterygopalatine fossa. Morbidity rates were significant, with overall infection rates of 54% and CSF leaks occurring in 31% of cases. From the 1970s to the 1980s, the number of cranial base cases and the number of surgeons

performing these cases increased. The major advancement was that patients with tumors previously designated as inoperable underwent attempts at complete tumor resection. Reports included tumors that extended intracranially and intracerebrally and into the pterygopalatine fossa. The 3-year survival rates rose slightly from 57% to 59%, with only limited reports of 5-year survival rates in the range of 49%. Infection rates ranged from 4% to 48%, but the incidence of CSF leaks dropped from 3% to 19%. From the 1980s to the 1990s, a multispecialty approach to cranial base surgery was introduced. Complications dropped significantly, with infection rates ranging from zero to 28% and CSF leaks diminishing from 2% to 4%. Another significant factor is that local disease control improved greatly. The 3-year survival rate increased from 67% to 74%, and the 5-year survival rate increased from 56% to 70%.[114] A recent multi-institutional study of patients undergoing craniofacial resection revealed 5-year overall, disease-specific, and recurrence-free survival rates of 48%, 53%, and 45%, respectively. Poor prognostic indicators included positive surgical margins and intracranial and orbital involvement. Melanoma and undifferentiated carcinoma carried the worst outcomes and esthesioneuroblastoma and low-grade sarcoma the best.[115]

In a large multi-institutional study of craniofacial resection patients, postoperative complications occurred in 36%. Increased risk of postoperative complications was found with the following factors; comorbid illness, previous radiation therapy, and tumor extension. Overall wound complication rates were less than 20%.[116]

Although reports in the literature are encouraging,[117-119] a need for controlled investigations and prospective clinical trials remains. This undertaking will prove to be very difficult. Unlike head and neck cancer, in which most cases are squamous cell carcinoma, cranial base tumors are less common and more varied in histologic type. Compounding the problem of broad histologic variation is the lack of uniformity of location and patterns of invasion of tumors in this complex anatomic region. When these factors are taken into consideration, investigations with adequate patient numbers to yield an accurate reflection of outcomes become nearly impossible. Multi-institutional studies may be required to circumvent these difficulties and to provide important information about the value of cranial base surgery. Such collaborative efforts may help establish the consistent use of primary and adjuvant therapies for tumors of the cranial base.

CHAPTER ONE HUNDRED AND SEVENTY-FIVE

Transnasal Endoscopic-Assisted Surgery of the Anterior Skull Base

Aldo Cassol Stamm

Shirley S. N. Pignatari

Key Points

- Effective and safe treatment of lesions involving the anterior skull base and brain depends on several factors, including a careful clinical history, preoperative evaluation and imaging studies, familiarity with regional anatomy and cerebrovascular physiology, and refined surgical technique.
- Technologic advances such as image-guided systems and enhanced endoscopic surgical techniques and equipment have facilitated approaches to the anterior skull base and brain, optimizing the surgical exposure and reducing the risk of complications while avoiding extensive brain retraction and nerve damage.
- Use of a multidisciplinary team approach has increased survival and decreased complication rates from skull base surgery, and this type of surgery is contraindicated without such a team. The multidisciplinary team should include neurosurgery, otolaryngology, anesthesiology, pathology, endocrinology intensive care, and paramedical staff, familiar with the care of patients at risk for significant neurologic sequelae.
- The development of new reconstruction techniques for closing dural defects has been assisted by the use of pedicled nasal septal flaps and has enabled more extensive resections and reduced complication rates. However, infection, cerebrospinal fluid leakage, and difficulty controlling intradural bleeding still present a challenge, and a frank discussion of the risk of these problems is essential for the patient to give informed consent.

The past decade has brought about technologies and insights that have revolutionized our strategy in treating patients with lesions involving the skull base, orbit, and optic nerve. Our work developed from microscopic anterior skull base approaches that aimed to avoid nerve and brain retraction and were developed along two basic anterior midline routes, the transoral and the transnasal.[1-3] We have expanded the scope of the surgery we perform through these approaches and have expanded our armamentarium in achieving postresection reconstruction. Effective and safe treatment of lesions involving the skull base still presents significant challenges, however, because although we have improved postresection reconstruction, the expanded scope of surgery has added risks to the procedures.

Surgical Anatomy

Anterior Cranial Fossa

The anterior cranial fossa is composed of the orbital portion of the frontal bone anteriorly, the cribriform plate of the ethmoid bone centrally, and the lesser wing and body of the sphenoid bone posteriorly (Fig. 175-1A). The cribriform plate is located in a midline depression between the orbital roofs and separates the anterior cranial fossa from the nasal cavity. It has 15 to 20 small foramina that transmit the olfactory nerves from the superior nasal mucosa to the olfactory bulb. The crista galli projects upward at the median anterior portion of the cribriform plate and serves as the site of attachment of the falx cerebri. Between the crista galli and the frontal crest, the foramen cecum in the frontoethmoidal suture transmits an emissary vein to the superior sagittal sinus. The anterior and posterior ethmoidal branches of the ophthalmic artery exit the orbit by passing through the ethmoidal foramina to enter the cranium at the anterolateral and posterolateral edges of the cribriform plate, respectively (see Fig. 175-1B). Posteriorly, the cribriform plate articulates with the sphenoid body, which from anterior to posterior is the site of the planum sphenoidale, limbus sphenoidale, chiasmatic sulcus, tuberculum sella, pituitary fossa, and the dorsum sella. The planum sphenoidale forms the roof of the posterior ethmoid sinus and the anterior part of the sphenoid sinus and borders on the optic canals posterolaterally.[4]

Nasal Cavity

The nasal cavity is wider below than above and is bounded superiorly by the anterior cranial fossa, laterally by the orbits and the maxillary sinus, and inferiorly by the hard palate. This cavity is divided sagittally

by the nasal septum, which is formed anteriorly and superiorly by the perpendicular plate of the ethmoid bone, posteriorly and inferiorly by the vomer, and anteroinferiorly by septal cartilage (Fig. 175-2). The nasal cavity opens anteriorly onto the face through the pyriform anterior nasal aperture and is continuous posteriorly with the nasopharynx at the posterior nasal apertures.

Each posterior nasal aperture measures approximately 25 mm vertically and 13 mm transversely and is bordered above by the anterior aspect of the sphenoid body that contains the sphenoid sinus, below by the posterior margin of the hard palate (horizontal plate of the palatine bone), medially by the nasal septum (vomer), and laterally by the medial pterygoid plate of the sphenoid.

The lateral nasal wall usually has three medially directed projections: the superior, middle, and inferior nasal turbinates or conchae (Fig. 175-3). The airway passages below these turbinates are termed the superior, middle, and inferior nasal meatuses, respectively. The paired sphenoethmoidal recesses are located above and behind the superior turbinate and in front of the upper anterior aspect of the sphenoid body. They are the sites of the paired sphenoid ostia that form the communication between the nasal cavity and the sphenoid sinus (Fig. 175-4). The upper half of the lateral nasal wall corresponds to the medial orbital wall. From anterior to posterior, it is composed of the frontal process of the maxilla, the lacrimal bone, and the orbital plate of the ethmoid bone (lamina papyracea), each separated from the next by a vertical suture. The extremely thin lacrimal and ethmoid bones contain the ethmoid air cells that separate the nasal cavity from the orbit. The nasolacrimal groove and canal (the site of the lacrimal sac and nasolacrimal duct, respectively) pass downward in front of the anterior end of the middle turbinate and open into the inferior nasal meatus. The frontoethmoidal suture is located at the level of the roof of the nasal cavity and the cribriform plate.

The anterior and posterior ethmoidal foramina transmit the anterior and posterior ethmoidal arteries and nerves and are located in, or just above, the frontal ethmoidal suture. These arteries and nerves exit the ethmoidal foramina and enter the anterior cranial fossa at the lateral

edge of the cribriform plate. The anterior ethmoidal artery is a terminal branch of the ophthalmic artery and supplies the mucosa of the anterior and middle ethmoid air cells and the dura covering the cribriform plate and the planum sphenoidale. The posterior ethmoidal artery usually is smaller than the anterior and is absent in nearly 30% of persons.[5] It supplies the mucosa of the posterior ethmoid cells and the dura of the planum sphenoidale. The distance from the anterior lacrimal crest of the maxilla's frontal process to the anterior ethmoidal foramen is 22 to 24 mm; the distance between the anterior and posterior ethmoidal foramina is 12 to 15 mm, and that between the posterior ethmoidal foramina and the optic canal usually is 3 to 7 mm. In the midline transfacial procedures, these ethmoidal arteries can be divided in a subperiorbital plane along the medial orbital wall. Care should be taken to prevent damaging the optic nerve, which sometimes is located immediately behind the posterior ethmoidal foramen (see Fig. 175-1B).

The inferior half of the lateral nasal wall comprises part of the medial wall of the maxillary sinus. It is formed anteriorly by the maxilla and posteriorly by the perpendicular plate of the palatine bone. The base of the middle turbinate attaches to the lateral nasal wall near the junction of the orbit and the maxillary sinus. Thus, the medial wall of the maxillary sinus is made up of the lateral wall of the middle and inferior nasal meati and the inferior turbinate. The maxillary sinus communicates with the middle nasal meatus through an opening located in the medial wall just below the roof of the sinus.[4]

The pterygopalatine fossa is situated between the posterior wall of the maxillary sinus anteriorly and the pterygoid process of the sphenoid posteriorly. The pterygopalatine fossa contains the pterygopalatine ganglion, which receives the nerve of the pterygoid canal (vidian nerve), the maxillary nerve just as it leaves the foramen rotundum, the internal maxillary artery (one of the two terminal branches of the external carotid artery), and the maxillary artery's two terminal branches, the posterior lateral nasal artery and the septal artery. Both of these terminal branches enter the nasal cavity through the sphenopalatine foramen just above the caudal aspect of the bony end (not the soft tissue end) of the middle turbinate. The septal artery courses along the roof of the nasal cavity toward the sphenoid rostrum and divides into a number of vessels that extend to the septum and the superior nasal walls. In the lateral wall of the nasal cavity, the posterior lateral nasal artery divides and provides nourishment to the turbinates and meatal spaces[6] (Fig. 175-5).

Paranasal Sinuses

The paranasal sinuses are the frontal, ethmoid, sphenoid, and maxillary. The frontal sinus consists of two large cells separated by an intersinus septum. The anatomic relationships of the sinus are mainly with the roof of the orbit, agger nasi cells, and the anterior cranial fossa. It drains

Figure 175-6. I. Inoue and A. Rhoton.)*

through the frontal recess into the middle meatus. The ethmoid sinus is composed of two groups of air cells: The anterior air cells drain into the middle meatus and the posterior group into the superior meatus.

Posterior ethmoid cells can become pneumatized far laterally and to some degree superiorly to the sphenoid sinus, in which case they are called *sphenoethmoid cells* (Onodi cells). The optic nerve and carotid artery may project into these cells, where they can be damaged during a surgical procedure. The ethmoid sinus is in intimate relation with the medial orbital wall and the floor of the anterior skull base.

The sphenoid sinus varies in shape and size and is asymmetrically divided into two parts by an irregular septum. When the sphenoid sinus is well developed, its thin lateral wall is the medial wall of the cavernous sinus. The intracavernous portion of the internal carotid artery is the most medial structure within the cavernous sinus, and in well-developed sphenoid sinuses it produces a serpiginous bony elevation in the lateral wall of the sinus called the *carotid prominence*. The carotid prominence is divided into presellar, infrasellar, and retrosellar segments.[11] The presellar segment corresponds to the anterior vertical segment and the anterior bend of the intracavernous portion of the internal carotid artery. The infrasellar segment corresponds to the short horizontal portion of the carotid, and the retrosellar segment reflects the posterior bend and posterior vertical segment (Fig. 175-6).

The optic canal often is partially encircled by the sphenoid sinus and creates a bony bulge in the superoanterior portion of its lateral wall.

The bony depression between the optic canal and the presellar segment of the carotid prominence is called the *opticocarotid recess*; it extends a variable distance into the optic strut. The bony lateral sphenoid sinus wall over the internal carotid artery and the optic nerve usually is very thin and may be absent in some areas. Although Lang[7] observed that the canal of the optic nerve was dehiscent in 6% of cases, Seibert[8] found that 57% of the optic nerves bulged into the sphenoid sinus and 1% had no bony canal. Seibert[8] also noted that the horizontal portion of the intracavernous carotid artery extended prominently into the sphenoid sinus in 67% of cases and that its bony covering was dehiscent in 6%. In his series, the maxillary nerve was prominent in the sphenoid sinus in 48% of specimens and dehiscent in 5%, and the pterygoid nerve (vidian nerve) was prominent 18% of the time.

Just below the tuberculum sellae, where they are closest to each other, the average distance between the left and right internal carotid arteries is 13.9 mm (range, 10 to 17 mm). At the anterior wall of the sella, the carotid arteries are separated by 20 mm (range, 13 to 26.5 mm), and at the level of the clivus, the distance between them is 17.4 mm (range, 10.5 to 26.5 mm).[9]

The maxillary sinus has thin walls that face the lower nasal cavity medially, the orbit superiorly, the infratemporal fossa posterolaterally, the pterygopalatine fossa posteromedially, and the soft tissue of the cheek anterolaterally. The maxillary sinus provides a transantral avenue for extending a midline surgical approach for more extensive lateral exposures of the cavernous sinus and the infratemporal fossa.[4]

Nasopharynx

The nasopharynx is situated behind the posterior nasal apertures where the septum and the inferior turbinate end. It is partially separated from the oropharynx below by the soft palate. The roof of the nasopharynx is formed by the mucoperiosteum of the upper clivus. The posterior nasopharyngeal wall is formed in successive layers by the mucosa, the superior pharyngeal constrictor muscle, the prevertebral fascia, and the longus capitis muscle. It abuts the mid- to lower clivus, the anterior aspect of the foramen magnum, and the anterior arch of the atlas (see Fig. 175-3). The pharyngeal tubercle is a small bony elevation located in the midline at the junction of the middle and lower clivus approximately 1 cm above the foramen magnum and serves as the site of attachment of the pharyngeal raphe of the superior pharyngeal constrictor muscle. The longus capitis muscles are attached to the clivus lateral to the pharyngeal tubercle on each side.

The eustachian tube, also termed the pharyngotympanic or auditory tube, opens into the lateral wall of the nasopharynx immediately posterior to the medial pterygoid plate. The fossa of Rosenmüller (pharyngeal recess) is located at the junction of the lateral and the posterior walls of the nasopharynx and projects laterally just behind the orifice of the eustachian tube. At the posterolateral depths of the fossa of Rosenmüller, only a thin layer of fibroconnective tissue separates the mucosa from the cervical internal carotid artery. The horizontal segment of the internal carotid artery in the petrous portion of the temporal bone is located immediately medial and posterior to the eustachian tube.[4]

Clivus

The clivus separates the nasopharynx from the posterior cranial fossa. It is composed of the posterior portion of the sphenoid body (basisphenoid) and the basilar part of the occipital bone (basiocciput), and it is further subdivided into upper, middle, and lower thirds. The upper third of the clivus is at the level of the sphenoid sinus and is formed by the basisphenoid bone including the dorsum sella. The middle clivus corresponds to the rostral part of the basiocciput and is located above a line connecting the caudal ends of the petroclival fissures. The lower third of the clivus is formed by the caudal part of the basiocciput. The intracranial surface of the upper two thirds of the clivus faces the pons and is concave from side to side.

The extracranial surface of the clivus gives rise to the pharyngeal tubercle at the junction of the middle and lower clivus. The upper clivus faces the roof of the nasopharynx, which extends downward in the midline to the level of the pharyngeal tubercle (Fig. 175-7).

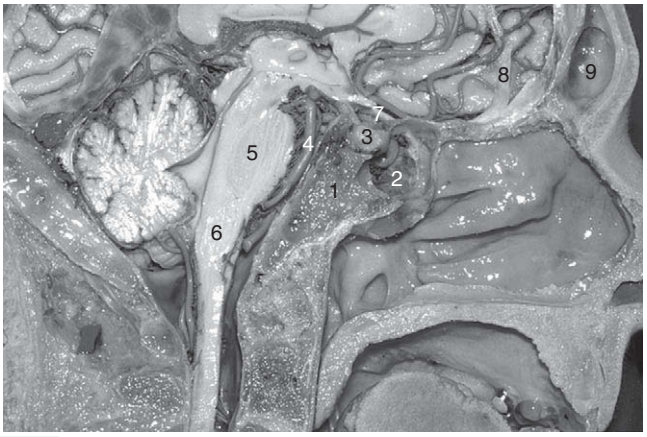

Figure 175-7. Midline sagittal section of the cranium: 1, clivus; 2, sphenoid sinus; 3, pituitary gland; 4, basilar artery; 5, pons; 6, medulla; 7, optic nerve; 8, frontal lobe; 9, frontal sinus.

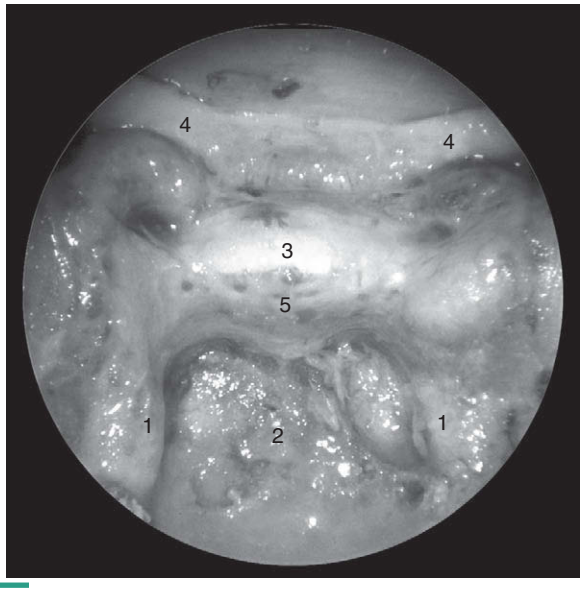

Figure 175-8. Endoscopic view of the posterior wall of the sphenoid sinus: 1, prominence of the internal carotid arteries; 2, clivus; 3, anterior sellar wall; 4, optic nerves; 5, intercavernous sinus.

The upper and middle clivus are separated from the petrous portion of the temporal bone on each side by the petroclival fissure. The basilar venous plexus is situated between the two layers of the dura of the upper clivus and is related to the dorsum sella and the posterior wall of the sphenoid sinus. It forms interconnecting venous channels between the inferior petrosal sinuses laterally, the cavernous sinuses superiorly, and the marginal sinus and epidural venous plexus inferiorly. The basilar sinus is the largest communicating channel between the paired cavernous sinuses.

Retroclival Region

When all the bone of the posterior and lateral walls of the sphenoid sinus has been removed, only periosteum covers the underlying anatomy (Fig. 175-8). The tectorial membrane protects the clival dura in the middle and lower clivus. When the external layer of the dura is opened, the basilar venous plexus and cranial nerve VI (the aducens nerve) on each side can be seen. The average distance between the two abducens nerves at the dural emergence is 19.8 mm.[10]

On opening the inner layer of the clival dura, the view through the 0-degree endoscope reveals the vertebral arteries, basilar artery and its branches (superior cerebellar arteries, anterior inferior cerebellar

Figure 175-9. Endoscopic view of the posterior fossa after the removal of the posterior wall of sphenoid sinus and upper clivus: 1, basilar artery; 2, internal carotid arteries; 3, optic nerves and chiasm; 4, pituitary gland and pituitary stalk; 5, brainstem.

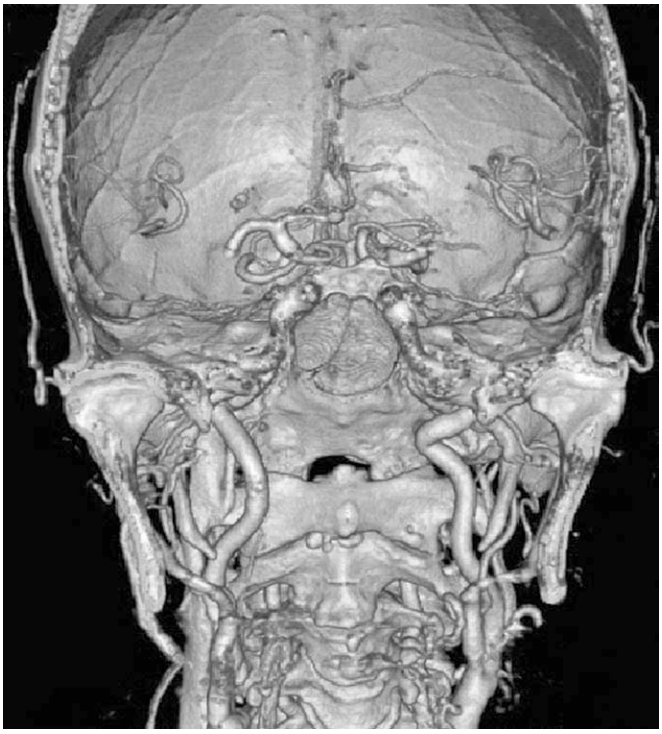

Figure 175-10. Coronal projection, computed tomographic angiography of the head and neck, showing the main vessels of the skull base region. Note the course of the internal carotid arteries and its division.

arteries), posterior cerebral arteries, brainstem, mammillary bodies, and the intradural pathway of cranial nerves III, IV, V, and VI. Just above the pituitary gland, the pituitary stalk, optic nerves, and optic chiasm can be seen. By introducing a 30-degree or 45-degree angled endoscope, it also is possible to view the cerebellopontine angle and cranial nerves VII and VIII, as well as the lower cranial nerves and the retrosellar region (Fig. 175-9).

Preoperative Assessment

The success of any skull base procedure depends on several factors, including a thorough clinical history, a careful preoperative evaluation, a well-developed surgical plan, and physician-patient conversations that include a frank discussion of the diagnosis, surgical plan, possible complications, and the roles of both the physician and the patient in the anticipated postoperative care plan.

Physical examination includes endoscopic assessment of the nasal cavity performed with the patient in a semisitting position. The nasal cavity is prepared with a topical anesthetic solution containing a vasoconstrictor. The examination is performed with rigid 4.0-mm 0-degree, 30-degree, and 70-degree endoscopes. In children, the flexible 3.2-mm endoscope is preferable, and occasionally a straight 2.7-mm endoscope is used.

Appropriate radiographic imaging studies always include diagnostic computed tomography (CT) and are essential in the assessment of all skull base lesions. CT permits assessment of critical anatomic information important during surgery including the presence and extent of erosions of the skull base; integrity of the medial orbital wall; position of the anterior skull base vessels; integrity and degree of aeration of the paranasal sinuses (particularly the sphenoid sinus); location and presence of intersinus septa; position of the internal carotid arteries, optic nerves, and cavernous sinuses; relationships between the ethmoid sinuses and the orbits and optic nerves; relationship between the roof of the ethmoid sinuses and the cribriform plate; and the presence of an Onodi cell. In assessing the frontal sinus, it is important to verify the presence of the intersinus septum and the relationship between the frontal sinus and the supraorbital ethmoid cells, the distance between the anterior and posterior sinus walls, and any bony erosions of the orbit, anterior wall, or posterior wall (anterior cranial fossa).

If the image-guided system is to be used, a multislice helical CT study is mandatory and should be performed as close as possible to the day of surgery. The images are stored on a compact disc and are used at surgery to provide a three-dimensional reconstruction of the patient's skull base region.

CT angiography is a robust technology that allows simultaneous visualization of bony and vascular structures. Venous and arterial structures can be visualized separately in the venous and arterial phases, or seen together. "Angio-CT" is especially useful in assessing the internal carotid and vertebrobasilar systems. Venous structures of particular interest include the cavernous sinus, the inferior aspect of the superior intercavernous sinuses, and the basilar venous plexus. This technology allows us to better plan surgical procedures[11] (Fig. 175-10).

Magnetic resonance imaging (MRI) is important to demonstrate the morphology of the soft tissues and the presence of liquid, but it is not helpful in assessing bony architecture. It helps to differentiate between neoplastic or inflammatory tissue and retained secretions, and to assist in clarifying the diagnosis of skull base malformations when meningoencephalocele, meningocele, or nasal glioma is suspected. MRI also is valuable to demonstrate erosion of the lateral sphenoid wall.

Magnetic resonance angiography (MRA) assesses the structure of medium-sized to large arteries and should be considered in patients with erosion of the lateral and posterior sphenoid walls to visualize the relationship between the basilar and internal carotid arteries.

Although conventional angiography is not routinely performed, it can provide essential information in some specific situations. If a lesion is suspected to involve, impinge on, or displace the internal carotid artery, the surgeon must have accurate preoperative knowledge of the position of the internal carotid artery and its relationship with the lesion, especially when the transnasal-transsphenoidal approach is contemplated (accessing the skull base through the posterior and lateral walls of the sphenoid sinus). Angiography also is helpful to verify the functional integrity of the circle of Willis and the extent of any carotid artery narrowing or occlusion, and to differentiate an aneurysm from tumor.

Operative Technique

The patient is prepared in the usual fashion for transnasal endoscopic-assisted surgery. The patient lies in a supine position on the operating

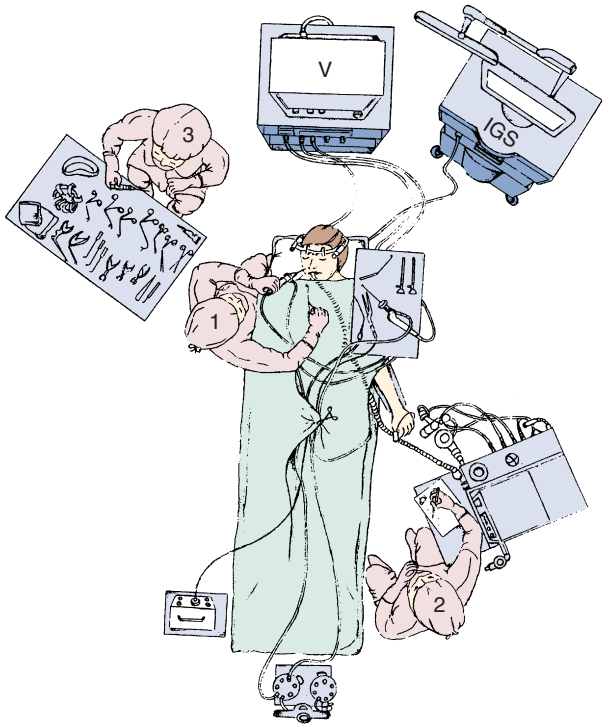

Figure 175-11. Surgical team setup in the operating room: 1, surgeon; 2, anesthesiologist; 3, nurse. IGS, image-guided system; V, video system.

table with the dorsum elevated 30 degrees, and with the head slightly extended and turned toward the surgeon. Head fixation is used when the navigation guidance system is required.

Transnasal endoscopic-assisted surgery of the skull base is performed with the patient under general controlled hypotensive anesthesia (Fig. 175-11). Compressed-rayon surgical sponges (Cottonoids) containing epinephrine, 1:2000 concentration, are placed in the nasal cavity, especially over the areas of surgical access. These Cottonoids are left in place for approximately 10 minutes before the surgical procedure is begun. If the surgical access is through the nasal septum, the septum is infiltrated with lidocaine and epinephrine, 1:100,000. When the surgery includes the pterygopalatine and zygomatic fossae and the sphenoid, the region of the sphenopalatine foramen is infiltrated with approximately 2.0 mL of the same concentration solution with an angulated 25-gauge spinal needle after first aspirating. If necessary, epinephrine-soaked Cottonoids are used for hemostasis during the surgery. If a CSF fistula is suspected, intrathecal fluorescein can be introduced at the beginning of the surgical procedure to facilitate its precise location.[12] If the use of the image-guided system is contemplated, the head frame is set up for calibration.

Instrumentation

Most skull base surgical procedures are performed with the endoscope attached to an endocamera and a video monitoring system. Endoscopes angled 0 degrees, 45 degrees, and 70 degrees can be used. In conjunction with KARL STORZ Endoscopy-America, Inc. (Culver City, California), we are developing a 5-mm wide-angle 0-degree telescope for these procedures to increase the field of view and illumination.

Although conventional surgical instrumentation also can be used, most of the microendoscopic surgical instruments for these cases are slightly longer and thinner, but just as strong or stronger. Most have an articulation located at the edge, allowing adequate visualization of the operative field. Extra-long handpieces for the surgical drill are essential and are used almost exclusively with diamond burrs of various sizes. Suction cannulas should have a blunted edge to avoid unnecessary trauma and mucosal bleeding. We recommend a micro-Kerrison punch to remove thin delicate bony plates such as those of the ethmoid air cells near the medial wall of the orbit and the bony canal of the optic nerve.

Monopolar and bipolar electrocautery can be used to control bleeding intraoperatively. Bleeding originating from branches of the anterior and posterior ethmoid arteries is more safely controlled by bipolar coagulation. Bleeding from the basilar venous plexus is not coagulated. Compression with oxidized cellulose (Surgicel) packing and obliteration of involved bony channels by diamond burrs are helpful measures.

Powered instrumentation was developed initially for soft tissue shaving and represents a major advance in transnasal endoscopic-assisted surgery. These instruments—microsurgical débriders, or "microdébriders"—have multiple functions, including suction, cutting, and irrigation. At present, newer instruments with curved blades and burrs are able to remove bone such as ethmoidal cells, drill out the frontal sinus, and debulk some tumors. The newer microsurgical débriders also produce a more precise cut of the diseased tissue, avoiding mucosal stripping, and are provided with continuous irrigation, which improves visualization and diminishes blood loss.

The new-generation image-guided systems are precise and have been very helpful in some cases of skull base surgery. These three-dimensional navigation systems provide important information about the location of anatomic structures in the operative field and create an individual anatomic map generated from a preoperative helical CT study. The advantage of this system lies in diminishing the chances of surgical complications, because it delineates the exact anatomic location of an instrument. On the basis of our experience in skull base surgery with such image-guided systems (Evolution computerized image-guided tracking system, Medtronic-Xomed, Jacksonville, Florida), we believe that they are very safe and precise and can be particularly helpful for surgery in patients who have unusual or high-risk anatomic variations, who have diseases involving the frontal sinus recess or sphenoid sinus that put the carotid artery and the optic nerves at risk, or who have recurrent or extensive disease.[13] The navigation system currently in use in our practice allows visualization of CT or magnetic resonance images or both simultaneously. This greatly improves the surgeon's ability to identify the extradural and intradural extent of the various lesions.

Transnasal Surgical Approaches to the Skull Base

Several transnasal approaches to the skull base have been described. The choice of the appropriate transnasal technique for each patient depends on the nature, location, and extent of the lesion. We currently are using the following extended transnasal surgical approaches:

- Transsphenoidal: transsellar and parasellar, transclival, and petrous apex
- Transcribriform
- Transtuberculum-transplanum
- Transmaxillary/transpterygoid/infratemporal
- Craniocervical junction

The transsphenoidal approaches (transsellar and parasellar, transclival, and petrous apex) require previous sphenoidectomy, which can be accomplished by several ways as briefly described below: direct transnasal access, transseptal access, transseptal transnasal access, and transethmoidal access. Regardless of the chosen expanded approach, the first step of the surgical procedure is the creation of a large pedicled septal flap originating at and based on the vascular pedicle of the sphenopalatine foramen. The extent of this flap is determined by the chosen approach. A vertical incision is made approximately 1 to 2 cm from the caudal edge of the nasal septum, followed by two horizontal incisions, one parallel to and just above the floor of the nasal cavity and the other approximately 0.8 cm to 1.0 cm beneath the upper limit of

the nasal septum. The inferior incision borders the superior edge of the choana toward to the sphenopalatine foramen. The flap should be subperichondrial and subperiosteal, preserving the vascular pedicle. During the procedure, the flap can be safely placed into the maxillary sinus cavity through a large middle meatus antrostomy. This maneuver avoids any obstruction of the surgical field by the flap.[14]

Transsphenoidal Approach

The great majority of the transnasal endoscopic skull base operations directly involve the sphenoid sinus, which is the focal point for several of the surgical approaches. Although the operative lesion may involve the sella or parasellar region, the clival region, or the petrous apex, the specific nature and location of the lesion will determine the technique to access the sphenoid sinus. Choices include the direct transnasal, transseptal (anterior incision, posterior incision), transseptal-transnasal (binostril approach), and transnasal plus transethmoidal (middle turbinate removal) approaches. The direct transnasal approach is used for removal of lesions involving the roof of the nasal cavity without involvement of the ethmoid sinus, lesions of the nasopharynx, and some lesions involving the sphenoid sinus. The transseptal approach is used primarily for removal of lesions involving the sphenoid sinus and sella such as pituitary adenomas.[15] The transethmoidal approach is useful for disease localized to the ethmoid sinus, the roof of the ethmoid sinus, the orbits, or lesions involving both the ethmoid and sphenoid sinuses.

Direct Transnasal Access

With direct transnasal access, the procedure is carried out through one nostril. If the nasal cavity is very narrow and the passage of the endoscope and operating instruments is limited because of a septal deviation, septoplasty is done first. After identification of the middle and superior turbinates, the posterior region of the nasal septum, and the choanal arch, the ostium of the sphenoid sinus is probed with the seeker-palpator. If diseased tissue such as polyps obstructs the access to the sphenoid recess, a microsurgical débrider can be helpful. To improve access, the superior turbinate is identified and removed with a through-cutting forceps. When the surgical access is very narrow, the posterior portion of the middle turbinate also can be removed by means of microscissors.

The initial opening of the sphenoid sinus is made with a micro-Kerrison punch, beginning at the ostium. The sphenoidotomy is enlarged inferiorly, with care taken to avoid damaging or cauterizing the septal artery that crosses the anterior wall of the sphenoid sinus in that region. If both sphenoid sinuses are to be surgically exposed, the mucoperiosteum of the anterior wall and the sphenoid rostrun are displaced laterally. The anterior wall, rostrum, and all intersinus septa are resected by semicutting or diamond burrs, giving wide exposure of the sinus (Figs. 175-12 and 175-13).

Transseptal Access

Thetransseptal approach was conceived to provide a midline access to the sphenoid sinus region through the nasal septum, avoiding damage to the structures in the nasal cavity and avoiding the lateral wall of the sphenoid sinus and the nearby carotid artery and optic nerve. This approach has been particularly useful for obtaining access to the clivus, sella, and parasellar regions, because they are midline structures.

The surgeon first performs a submucoperichondrial and submucoperiosteal infiltration with lidocaine (2%) and epinephrine (1:100,000), producing a hydraulic dissection that facilitates surgical elevation. A vertical hemitransfixion incision is made at the caudal edge of the septal cartilage, and septal flaps are elevated as in performing a septoplasty. Disarticulation of the osseocartilaginous junction (septal cartilage, ethmoid plate, and vomer) is performed with the suction elevator, with preservation of the uppermost part of the osseocartilaginous junction to avoid postoperative dorsal nasal saddling. The posterior attachment of the septum to the perpendicular lamina of the ethmoid is fractured. The posterior part of the septal bone, which obstructs access to the sphenoid rostrum, is resected with a Jansen-Middleton forceps. The mucoperiosteum of the anterior wall of the sphenoid sinus is elevated until the sinus ostia on both sides are visualized. At this point, a self-retaining speculum is introduced between the two leaves of septal mucosa, and the anterior wall of the sphenoid sinus is entirely exposed. The anterior wall is then opened with a chisel and is enlarged with a micro-Kerrison punch (Fig. 175-14). The sphenoidotomy is made large enough to allow easy simultaneous introduction of a 4-mm endoscope and a surgical instrument. Once the septum is

resected and the two septal flaps are displaced, the self-retaining speculum can be removed, and the surgeon can work exclusively with an endoscope and the instruments (Fig. 175-15).

Transseptal-Transnasal Access

For the transseptal-transnasal (binostril) approach (Fig. 175-16), a classic anterior septoplasty incision is made. A submucoperichondrial-mucoperiosteal dissection is performed on both sides. The posterior portion of the nasal septum is removed, with preservation of the inferior portion as a landmark for the midline. The sphenoid rostrum and anterior wall of the sphenoid sinus are exposed. The next step is the creation of a nasal septal mucosal flap on one side. Three incisions are made: vertical, superior horizontal, and inferior horizontal. These incisions can be completed with scissors or other sharp instruments as necessary, creating a mucosal flap that is displaced onto the nasal floor. This nasal septal flap preserves a posterolateral pedicle containing the sphenopalatine neurovascular bundle. Multiple modifications in length and width are possible, and the flap should be designed in accordance with the size and shape of the anticipated skull base defect. This approach has several advantages: It allows two surgeons to simultaneously manipulate surgical instruments using both nostrils; it has a very robust tissue pedicle to help in the closure of skull base defects; and it preserves the nasal septal mucosa on one side, avoiding nasal septal perforation (see Fig. 175-16).[16]

Transethmoidal Access

Transethmoidal surgical access usually is indicated for cases in which lesions extend into or involve the ethmoid and sphenoid sinuses. The most common of these lesions are hemangiopericytoma, inverted papilloma, schwannoma, meningoencephalocele, meningocele, and malignant tumors. CSF fistulas also commonly affect this area.[17]

First, an ethmoidectomy is performed beginning with the resection of the uncinate process and followed by resection of the ethmoid bulla and the remaining ethmoid cells. During the resection of the posterior ethmoid cells, the surgeon must correlate direct observation and intraoperative review of the CT scan to determine whether an Onodi cell is present, and, if so, to recognize its relationship to the optic nerve canal and the internal carotid artery.[18,19]

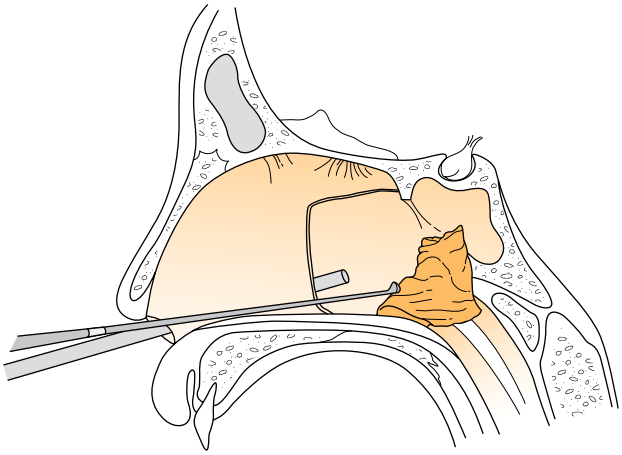

Figure 175-16. Nasal septum mucosal flap. Surgical instrument enters through one nostril and the endoscope through the septum; contralateral septal mucosa is intact and preserved.

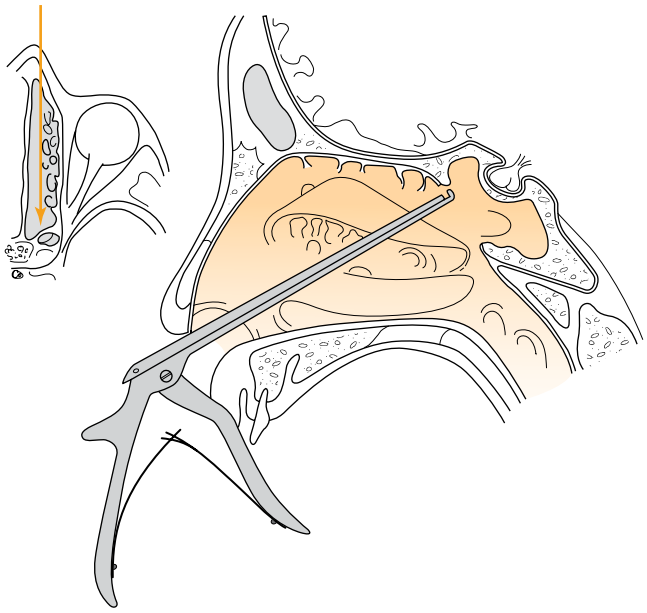

Figure 175-17. Transethmoidal approach (*arrow* on *inset*) to the sphenoid sinus.

Next, the posterior ethmoid artery is identified anterior to the front wall of the sphenoid sinus, which makes an angle of approximately 90 degrees with the roof of the ethmoid sinus. The initial opening of the sphenoid sinus is made with a delicate curette or with an atraumatic aspirator medially and inferiorly. The sphenoidotomy is then enlarged with a micro-Kerrison punch, incorporating the natural ostium into the opening (Fig. 175-17). Figure 175-18 shows a fracture of the optic nerve canals. Removal of the middle turbinate may be necessary when the lesion is located in the roof of the ethmoid sinus or the cribriform plate, as occurs in some cases of inverted papilloma, osteoma, or schwannoma. When the middle turbinate is removed, its mucoperiosteum can be used as a free graft to repair dural defects that were created by the lesion or its removal. Figure 175-19 shows removal of a schwannoma by this technique.

Transsellar and Parasellar Approaches

After the opening of the sphenoid sinus, the next step consists of opening the pituitary fossa. The anterior wall of the sphenoid sinus must be largely exposed, to facilitate the identification of the principal anatomic structures of this region, such as the prominence of the internal carotid artery canals, optic nerve canals, clivus, planum sphenoidale, and also the floor of the sella. Any intersinus and or intrasinus septa are resected by means of a strong through-cutting forceps. The mucoperiosteum of the sphenoid sinus covering the floor of the sella is displaced laterally and preserved for use in reconstruction. The next step consists of wide resection of the sellar bone, exposing the dura from one internal carotid artery to the opposite internal carotid artery and from the planum sphenoidale to the clivus. This usually is performed with a diamond burr and a micro-Kerrison punch. Thereafter, a quadrangular dural incision is made very carefully, with an attempt to visualize the precise localization of the cavernous sinus and the superior and inferior intercavernous sinuses, and of both internal carotid arteries through the exposed dura (Fig. 175-20).

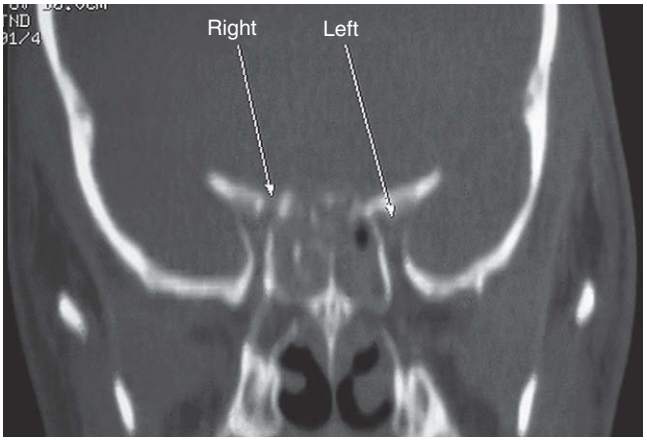

Figure 175-18. Coronal computed tomography scan showing bilateral fracture of the optic nerve canals.

These structures represent the anatomic limits of the dural opening. The dura mater, along with any attached fragments of tumor, is removed and sent for histopathologic examination. Resection of the tumor begins laterally with a 45-degree angled endoscope and curved suction tube, first identifying the angle between the arachnoid and the ICA. The arachnoid is the limit of the superior and posterior dissection (classically known as the diaphragma sella). When a complete removal is accomplished, the arachnoid frequently descends to fill the space occupied by the tumor. This can partially obstruct the surgical field of view and is one factor in incomplete tumor removal. In pituitary adenoma surgery, disection is more important than the use of the curette. Occasional bleeding is carefully controlled by application of warm saline solution, Surgicel packing, and other measures as appropriate.

If no fistula is present, the mucoperiosteum of the sphenoid sinus is replaced and secured with fibrin glue. In the presence of a CSF leak, the defect is sealed with fascia lata, fat, and mucoperiosteum of the sphenoid sinus. Fibrin glue completes the sealing process. In larger defects with high fluid flow, in addition to the previous steps, we use a pedicled flap originating from the mucoperiosteum of the posterior nasal septum to cover the region of the sella. Packing of the sphenoid sinus and nasal cavity for 5 to 7 days is recommended.

Transclival Approach

Approach to the Clivus and Cavernous Sinus

The transsphenoidal-transclival approach is used for lesions involving the clivus or retroclival region. Anterior approaches to the craniovertebral junction and clivus originally were proposed in the 1960s for the treatment of neoplasms and vertebrobasilar aneurysms.[20-23] Anterior procedures include the transseptal, transsphenoidal,[24,25] transmaxillary,[26,27] transpalatal and transoral-transpalatal,[28,29] transmandibular,[30] transmaxillary-transnasal,[31] and facial translocation approaches.[32]

Despite the fact that anterior approaches offer a more direct anatomic approach to the structures beyond the clivus, the risks of CSF leakage and infection limit most of the aforementioned approaches to extradural lesions, especially those approaches that traverse a nonsterile

Figure 175-19. Figure 175-20. Quadrangular incision area in sellar dura.

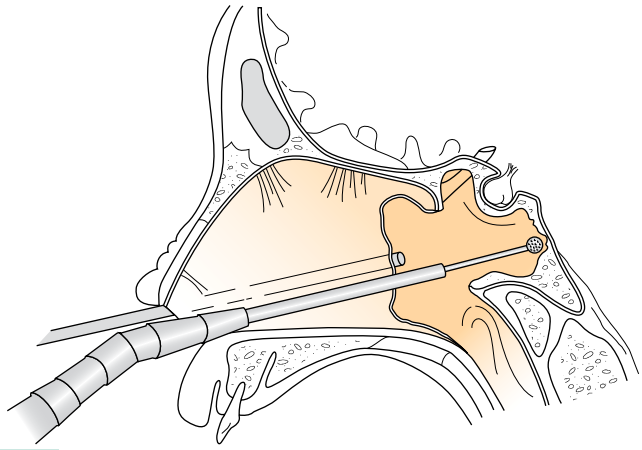

Figure 175-21. Schematic drawing showing a modified transseptal approach to the posterior sphenoid sinus wall (clivus). A surgical drill with a long handpiece and a diamond burr is used to remove the bone of the upper clivus.

operative field.[10] The major advantage of the midline transfacial approaches is the direct anterior surgical access through the large spaces of the nasal cavity, nasopharynx, oral cavity, and paranasal sinuses. However, these midline routes are restricted by critical neurovascular structures such as the internal carotid artery, optic nerve, cavernous sinus, cranial nerves, and the orbital contents.[4]

The transnasal endoscopic-assisted surgical technique begins with one of the surgical approaches to the sphenoid sinus (transnasal direct, transethmoidal, or transseptal). A wide opening of the anterior sphenoid sinus wall is obtained with a micro-Kerrison punch. The floor of the sella, the two carotid protuberances, the medial aspect of the optic canals, and the upper clivus are visualized. The sinus mucosa that lines the clival area is reflected carefully, exposing the clival bone. The bone removal initially is done with a drill system that uses a diamond burr and continued carefully with a micro-Kerrison punch if necessary (Fig. 175-21). The limits of clival bone removal are the floor of the sella superiorly, the foramen magnum inferiorly, and the bony canals of the sixth cranial nerves, the internal carotid arteries, and the occipital condyles laterally. To obtain an intradural exposure, the external layer of the dura is first incised, and the basilar venous plexus and cranial nerve VI are encountered. Bleeding in the plexus cannot be cauterized safely but usually can be controlled with small pieces of Surgicel. Large lesions

Figure 175-22. Surgical endoscopic view during a transseptal transclival approach: 1, basilar artery and branches; 2, anterior inferior cerebellar artery; 3, vertebral artery; 4, superior cerebellar artery; 5, posterior cerebral arteries; 6, intradural course of cranial nerve III; 7, brainstem; 8, mammillary bodies.

often encroach on and obliterate much of the plexus, but if the lesion is not large or if the plexus is not completely compressed, profuse and intense venous bleeding can occur. Judicious packing, time, patience, and experience are required to control such bleeding.

The opening of the internal layer of the dura at the level of the middle and superior clivus must be accomplished with great care to avoid injury to the underlying basilar artery. Once the dura is opened, minor bleeding is stopped with bipolar coagulation, and it is finally possible to introduce the endoscope carefully into the intradural space and to identify the major vessels of the posterior fossa (basilar artery and branches, anterior inferior cerebellar arteries, vertebral arteries, superior cerebellar arteries, and posterior cerebral arteries); the intradural course of cranial nerves III, IV, V, and VI; the brainstem; and the mammillary bodies. The cerebellopontine angle, cranial nerves VII through XII, and the retrosellar regions are best visualized by use of endoscopes angled 30 degrees, 45 degrees, or 70 degrees (Fig. 175-22).

Dural repair at the clivus region is difficult. If the defect is large, we occlude it with abdominal fat first and then cover the defect with grafts of fascia lata or synthetic dura (Duraform, Duragen). These grafts are covered by a large pedicled nasal septal flap, as described previously, secured in position with fibrin glue and pieces of surgical gel (Gelfoam). For small defects, the nasal cavity is packed with Merocel for 5 to 7 days, whereas for larger ones, the packing is made with gauze embedded in antibiotics for 10 to 14 days. Broad-spectrum antibiotics are given for 10 to 14 days.

The main advantages of the transsphenoidal-transclival approach with removal of the posterior nasal septum are the avoidance of cerebral retraction and a decreased incidence of injury to the lower cranial nerves. In addition, the approach is direct without external incisions, is relatively quick, and best preserves the anatomic structures. Even though endoscopes do not allow a three-dimensional perspective, they do provide a close view of the operative field from different angles. However, this technique requires working in a narrow operative field limited by critical neurovascular structures, such as internal carotid arteries, optic nerves, cavernous and basilar sinuses, and the pituitary gland. The risks of major intradural bleeding, CSF leakage, and meningitis are not to be taken lightly. Figure 175-23 illustrates this approach in a patient with a clivus chordoma.

Petrous Apex Access

This type of surgical access can be useful for biopsy and drainage purposes. It can be particularly helpful in selected cases of cholesterol granuloma of the petrous apex because complete excision is unnecessary (see Fig. 175-14). Although surgical drainage is usually accomplished through the temporal bone, the transsphenoidal endoscopic approach may be indicated when the lesion abuts against the posterior and lateral wall of the sphenoid sinus. In these cases, the use of an image-guided system can be very helpful, especially to precisely identify the internal carotid artery, optic nerve, and the lesion.

The clival region is completely exposed, and both carotid canals are identified. When the anatomy is clearly apparent, these canals are easily recognized. If the canals are difficult to identify, use of diamond burrs with suction-irrigation can help identify the vertical segment, particularly at the junction of the cavernous and petrous portions of the internal carotid artery.

The transmaxillary-transpterygoid access also permits approaching the petrous apex by exposing completely the pterygopalatine and infratemporal fossae. First, the vidian nerve canal, foramen rotundum and superior orbital fissure, and V_2 are dissected along their entire extradural extent. The early identification of the vidian canal is very important, because this can be an excellent guide to the identification of the canal of the internal carotid artery between its petrous and paraclival portions.[34] After exposure of the lateral recess of the sphenoid sinus and the lateral portion of the cavernous sinus, a diamond burr is used laterally and inferiorly, exposing the petrous apex. The petrous part of the internal carotid artery must be identified after careful dissection and resection of its bony canal. By mobilizing the artery laterally, a complete exposure of the petrous apex can be accomplished.

Transcribriform Approach

The transcribriform approach is indicated to remove lesions involving the olfactory groove, hypophysis, or crista galli; it can be performed unilaterally or bilaterally. Among the most common lesions treated using the transcribriform surgical approach are CSF leaks, meningoencephaloceles, encephaloceles, meningiomas, esthesioneuroblastomas, and malignancies.

Transcribriform Unilateral Access

The unilateral transcribriform approach is designed to remove the cribriform area and to preserve the crista galli, with or without resection of the dura mater. The procedure begins with a wide middle meatal antrostomy. The middle turbinate is removed to the level of the skull base and a complete sphenoethmoidectomy is performed, including removal of the lateral wall of the orbit, exposing the periorbita. Next, the frontal recess and frontal sinus are exposed. The anterior and posterior ethmoid arteries are then identified, coagulated, and divided. The bone of the roof of the ethmoid sinus is removed, completely exposing the dura. The medial dissection is accomplished by removing the posterior and superior portions of the ipsilateral nasal septum. Perichondrium and periosteum of the contralateral side are preserved to be used in the reconstruction.

Especially in cases of malignancy in which the lesion presents intradural extension, the dura is then removed. Reconstruction of the dural defect is achieved with one or two layers of fascia lata, covered by the contralateral septal flap. These layers are kept in place with fibrin glue and nasal packing. Lumbar drainage usually is not necessary. This endoscopic-assisted unilateral transnasal approach preserves the olfactory area on one side, which represents a great advantage over the classic craniofacial approach.

Transcribriform Bilateral Access

In cases with bilateral involvement, intradural extension of the lesion is very commom. The procedure is performed in the same way on both sides as decribed above. In such cases however, it is necessary to make a large aperture of the frontal sinus through a Draf III surgical access. Depending on the extent of the lesion, and especially in malignant tumors, the upper part of the nasal septum is also removed.

The limits of the dissection are as follows: laterally, the medial wall of the orbit; anteriorly, the frontal sinuses, and posteriorly, the sphenoid sinuses. The anterior and posterior ethmoid arteries of both sides are identified and coagulated with a bipolar cautery.

Next, complete removal of the skull base bone in this region is performed with a drill system and suction irrigation. The dura mater within the aforementioned limits is then resected. The opening of the dura is initiated with a surgical knife with a No. 11 blade after bipolar cauterization and is completed with microscissors on both sides of the falx. The falx is coagulated and the sagittal sinus packed with Surgicel, if necessary. The falx is transected and detached from the crista galli. When the lesion has a subpial extension, the dissection must be performed extremely carefully, with special attention directed at possible bleeding from branches of the anterior cerebral artery, such as the frontopolar artery. The dural defect may be large, necessitating meticulous reconstruction using two layers of fascia lata (one intradurally and another between the dura and the bone). The nasal flap, including mucoperiosteum-mucoperichondrium, is used to cover the grafts. If this flap is not available because the tissues are involved by a malignant lesion, a mucoperichondrial flap from the floor of the nasal cavity can be used (Fig. 175-24).

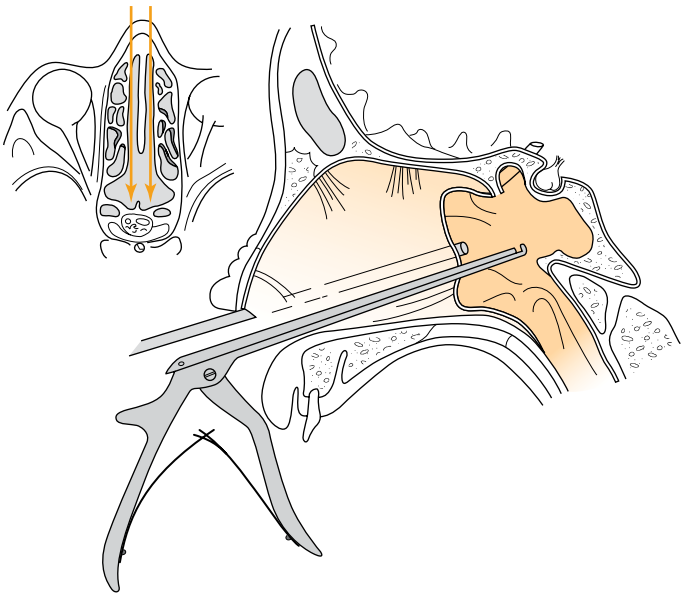

Figure 175-24. Schmatic drawing of a modified transseptal approach (*arrows* on *inset*) to the sphenoid and parasphenoid sinus regions.

Transtuberculum-Transplanum Approach

We use the transtuberculum-transplanum approach for removal of lesions involving the planum sphenoidale and tuberculum sella, most typically meningiomas. It also is useful to remove lesions that compromise the suprasellar cistern region and pre– and post–optic chiasma lesions such as pituitary microadenomas, craniopharyngiomas, Rathke's pouch cysts, and even optic nerve gliomas.

The first step in the procedure is the development of a nasal mucoperichondrial flap pedicled on the sphenopalatine foramen to be used for reconstruction at the end of the procedure. The surgical access portion of the procedure consists of a wide sphenoidotomy with resection of the posterior part of the nasal septum and the intersinus septum. To obtain adequate exposure, it also is necessary to perform bilateral posterior ethmoidectomies and to resect both middle turbinates.

The ethmoidectomies remove all cells laterally to both medial walls of the orbits and anteriorly to the level of the posterior ethmoid arteries, in order to avoid damaging the neuroepithelium. All bone in the region of the planum sphenoidale is exposed by using a high-speed drill with irrigation, continuing until the bone is as thin as an egg shell. The final layer is removed carefully with a micro-Kerrison punch.

We are especially careful not to damage the optic nerves by excessive heat generated by the use of the drill, and use shorter periods of drilling and copious irrigation. The eggshell bone over the internal carotid arteries in the parasellar region also is removed with a micro-Kerrison punch.

After the dura mater from the sellar region to the anterior portion of the planum and laterally to the lamina papyracea is exposed completely, the superior intercavernous sinus is cauterized using a bipolar system and transsected. The posterior ethmoidal arteries are coagulated and sectioned. Then the dura mater is opened carefully avoiding any damage to the attached vessels.

The intradural dissection is critical, and it is imperative to identify the internal carotid arteries in the paraclinoid region, the anterior cerebral arteries (A_1 and A_2), the anterior communicating artery, and the recurrent artery of Heubner. The optic nerve and chiasm must be identified more superiorly and also the pituitary stalk. Dissection in the arachnoidal plane is highly recommended whenever possible, as is the avoidance of excessive coagulation and traction, in order to reduce the possibility of minor surgical trauma to neurovascular structures.

Reconstruction is begun with a double layer of fascia lata, which is then covered with the pedicled nasal septal mucosal flap. We secure these with fibrin glue and place nasal packing, to remain for 7 to 10 days. We do not use external lumbar drainage.

Transmaxillary-Transpterygoidal-Infratemporal Approach

The transmaxillary approach is excellent for removing lesions that involve the medial portion of the maxillary sinus, and for larger lesions in the pterygopalatine, zygomatic, or infratemporal fossa such as angiofibromas. This approach also can be extended to gain exposure to the cavernous sinus.

The procedure begins with an anterior ethmoidectomy and continues with a wide middle meatus antrostomy to give maximal exposure

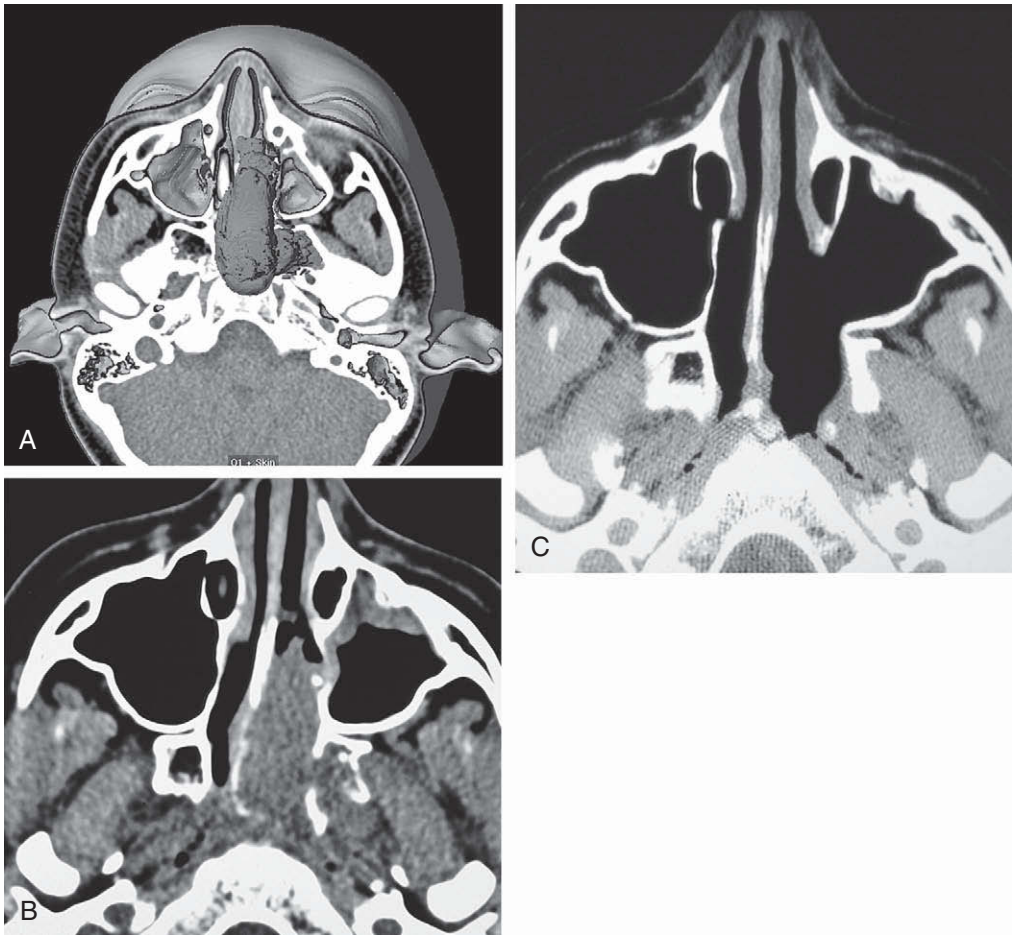

Figure 175-25. Angiofibroma in a 13-year-old boy. **A,** Axial three-dimensional computed tomography (CT) reconstruction. **B,** Preoperative axial CT scan. **C,** Postoperative axial CT scan.

of the posterior maxillary sinus wall. Sometimes it is necessary to remove the inferior turbinate, entirely resecting the medial wall of the maxillary sinus to obtain adequate exposure of the posterior and posterolateral portions of the wall of the sinus. During removal of the inferior turbinate, special care must be taken to avoid injuring the terminal branches of the maxillary artery at the sphenopalatine foramen and the second division of the trigeminal nerve.

The amount of posterior wall bone to be removed depends on the location and extent of the lesion as determined by preoperative image studies or by information from the image-guided system at the time of surgery. The posterior wall of the maxillary sinus can be opened by enlarging the sphenopalatine foramen with a micro-Kerrison punch and exposing the periosteum of the pterygopalatine, zygomatic, and infratemporal fossae. It is important to try to preserve the integrity of the periosteum and avoid fat protrusion into the operative field. If fat does protrude into the sinus, it is reduced by bipolar electrocoagulation, which also is used to control any bleeding. This technique is particularly useful in removing angiofibroma, when early identification of the feeding vessels is essential. Figure 175-25 illustrates removal of an angiofibroma using this technique.

The transpterygoid and infratemporal approaches are extensions of the transmaxillary access. In the transpterygoid approach, lateral extensions of the sphenoid sinus (pterygoid recess) and lesions involving the pterygopalatine fossa and zygomatic fossa can be accessed. This may require removal of the medial and sometimes lateral pterygoid processes in order to achieve access to the lateral and pterygoid regions of the sphenoid sinus. A wide sphenoidotomy is performed at the beginning or during the surgical operation. This access allows treatment of lesions involving the cavernous sinus that are lateral to the paraclival internal carotid artery.

The infratemporal access adds a medial endoscopic maxillectomy, including section of the nasolacrimal duct (a dacryocistorhinostomy is needed afterward). In this surgical access, we resect the posterior wall and sometimes the lateral wall of the maxillary sinus, particularly in situations with lateral expansion of the lesion.

Craniocervical Junction–Odontoid Approach

The most common indication for craniocervical junction–odontoid access is an extradural compressive lesion, the basilar invagination, which may be secondary to rheumatoid arthritis, exostosis, osteotoma, or other disorders (Fig. 175-26). Foramen magnum meningiomas, clivus chordomas with inferior extension, metastasis (especially in the odontoid process) also can be approached in this manner.

The procedure consists of the following sequence: general exposure, osseous exposure, removal of the lesion, and reconstruction. The otolaryngologic surgeon is responsible for the exposure of and access to the lesions. The surgery procedure usually is accomplished through both nostrils (four-hand technique), to permit use of multiple surgical instruments such as suction tubes, drills, and navigation system devices. The drill system must be thin, delicate, and long enough to allow its passage through the nose but without interfering with endoscopic vision. The image guide system is very helpful in these cases.

A panclival exposure creates a single cavity that extends from the sphenoid sinus to the level of the fossa of Rosenmüller. To expose the odontoid and the foramen magnum, additional soft tissue removal is required. The nasopharyngeal mucosa is cautherized with monopolar eletrocautery and then resected from the sphenoclival junction to the level of the soft palate. The longus capitis and longus colli muscles are exposed and partially resected to expose the ring of C1. Care should be taken to stay medial to the eustachian tube, especially during use of

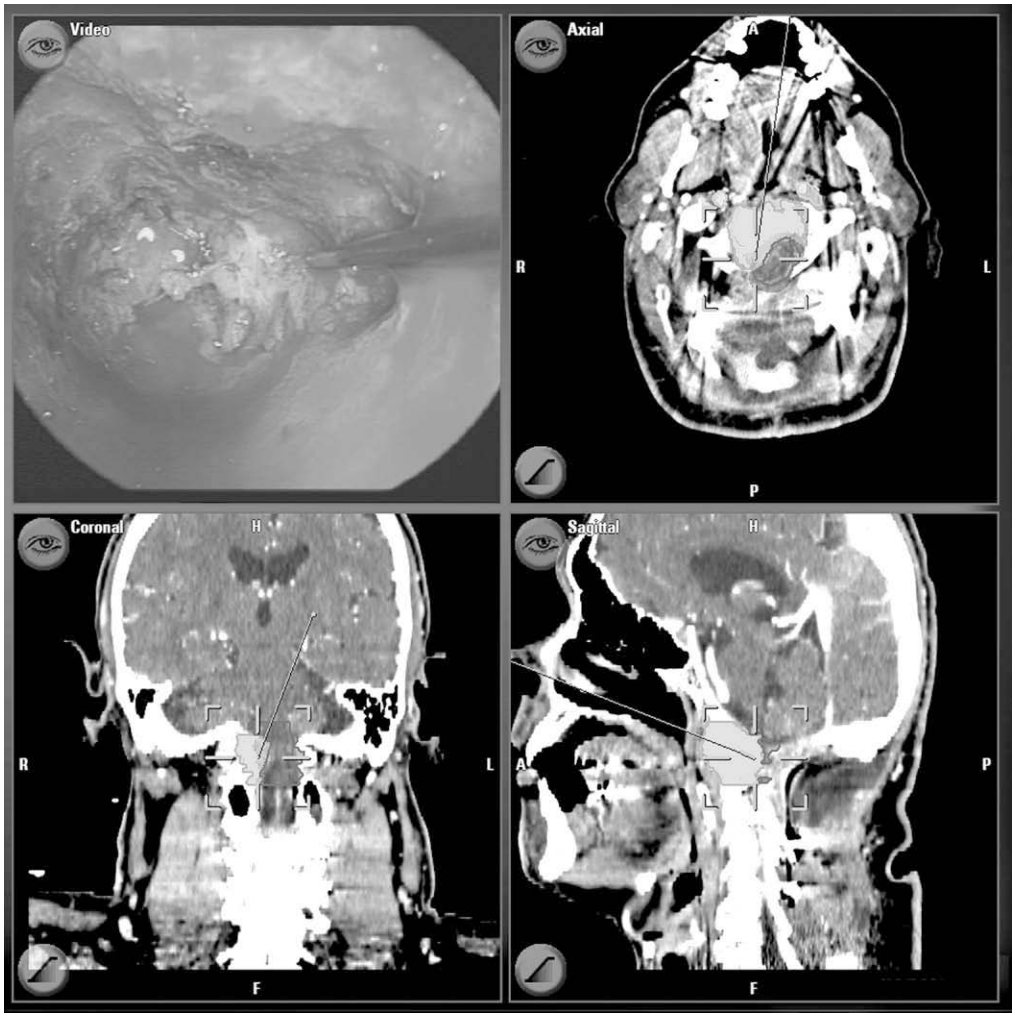

Figure 175-26. A surgical image-guided system was used to identify an osteoma located at the craniocervical junction.

electrocautery, because the parapharyngeal internal carotid artery is directly posterolateral to the eustachian tube. At the completion of the procedure, the nasopharyngeal tissues do not need reapproximation, and the surgical defect is covered with fibrin glue. The nasal passages are cleared of blood, and Silastic septal splints are inserted to minimize the risk of postoperative synechia formation.

Combined Approaches

Unfortunately, many lesions do not respect the anatomic boundaries for which the previously outlined approaches are ideal. In many instances, it is necessary to combine some of the previous approaches—for example, the transnasal direct with the transethmoidal or the transmaxillary with the transethmoidal.

Reconstruction

Reconstruction of the skull base after transnasal endoscopic surgery remains a major challenge, particularly when the dural defects are large and located at the posterior fossa.

The basic principle in sealing the dural defect is based on the use of several layers of tissue for the closure. We use fascia lata and free mucoperiosteum grafts from the floor of the nasal cavity or the middle or inferior turbinates. More recently we have used a septal flap pedicled at the region of the sphenopalatine foramen arteries. All of these layers are kept in position with fibrin glue.

If a large free space remains between the cerebral tissue and the dura, it is filled with fat (abdominal or from the thigh where the fascia was previously removed) before the first layer of fascia lata. The first layer of fascia lata is placed in a circumferential fashion, as an underlay graft between the dura and the nervous tissue. The second layer is then positioned between the dura and the bony skull base margins. The fascia lata can be substituted by artificial dura such as the collagen matrix graft (Duragen, Duraform). The third layer consists of vascularized mucoperiosteum-perichondrial flap pedicled at the region of the sphenopalatine foramen arteries. Fibrin glue is used to give support to these layers. When the septal flap is not large enough or is unavailable because of previous surgery, free mucosal grafts from the nasal floor, septum, and turbinates constitute an option. In this situation, they are ultimately covered by pieces of Gelfoam and supported by sponge packings (Merocel). When the dural defect is very large, gauze soaked in antibiotics is preferable to Merocel; over the gauze, a Foley catheter balloon is inflated to keep the tissues in position and to avoid displacement of the nasal packing into the nasopharynx. The balloon must be positioned under direct vision and inflated with no more than 10 mL of saline solution. It is left for approximately 5 days; the packing can remain for 10 to 14 days, depending on the extent of the reconstruction.

Postoperative Care

The goal of surgical treatment is to ensure the complete removal of the disease and the best possible functional result. A satisfactory postoperative result depends on both appropriate operative technique and meticulous postoperative care.

Wide-spectrum antibiotics are given during the operation and for 10 days postoperatively or until the nasal packing is removed. Adequate postoperative care of the operative site requires appropriate instrumentation, including 4-mm 0-degree, 45-degree, and 70-degree angled

endoscopes, straight and curved atraumatic aspirators, and straight and curved microforceps.

For extended endoscopic skull base and brain surgery, the nasal cavity packing can remain in place as long as 2 weeks, depending on the type of procedure and dural reconstruction grade. The operative cavity is carefully suctioned, and any residual bone fragments are removed. The patient is instucted to peform frequent nasal irrigations with 0.9% or 3% saline solution. Nasal vasoconstriction with oxymetazoline is peformed by the patient until postoperative day 5. If the procedure includes repair of a dural defect, the patient is instructed to refrain from moderate or intense physical activity, straining, nose blowing, and sneezing for approximately 30 days. To prevent constipation, a high-fiber soft diet and laxatives are recommended.

The patient returns for postoperative visits every 2 weeks. At each visit, the operated nasal cavity is cleaned of crusts, granulation tissue, clots, and secretions. Imaging exams are performed when the cavity is well healed; the timing varies with the clinical course.

Complications

Every skull base surgical procedure has potential to cause complications. For example, a U.S. survey conducted in 1997 addressed complications of transsphenoidal surgery for pituitary gland lesions and documented carotid artery injury in 1.1% of cases, central nervous system injury in 1.3%, loss of vision in 1.8%, CSF fistula in 3.9%, and meningitis in 1.5%. The estimated mortality rate was 0.9%. These data were derived from several centers that used different transnasal approaches for only one surgical site but illustrate that serious complications do occur.[33] In the experience of Kassan and colleagues,[34] the incidence of neurovascular complications in 700 patients who underwent an expanded endonasal endoscopic approach was approximately 1.0%.

Prevention of the complications of transnasal endoscopic-assisted surgery of the skull base begins with an adequate preoperative evaluation of the patient, including history of the use of medications and previous operations. High-resolution CT in coronal and axial projections with sagittal reconstruction, MRI, and sometimes angiography are essential to plan the procedure and to execute it safely with the lowest possibility of complications.[35]

Complications can be classified by severity as minor or major and by time of appearance as immediate or delayed. Minor complications are associated with little morbidity and do not compromise the life of the patient, although they may be annoying and troublesome. Most resolve with time and conservative treatment. However, major complications are the cause of significant morbidity and increased risk of death. Most orbital complications stem from direct injury to the optic nerve or the extraocular muscles or from arterial or venous bleeding within the rigid bony orbit. These injuries can result in diplopia, hematoma, proptosis, and decreased visual acuity or blindness (which can be temporary or permanent). Blindness secondary to orbital hematoma can be reversible, mandating prompt hematoma evacuation to relieve the increased pressure compromising the blood supply to the retina or the optic nerve. Direct or indirect damage to the optic nerve usually occurs at the superolateral sphenoid sinus wall or in the posterior ethmoid cells.

Intracranial complications can result from direct injury to brain, cranial nerves, meninges, blood vessels, or venous sinuses. The resulting deficits reflect the loss of function of the damaged structures in the case of brain and cranial nerves, or the effects of loss of vascular supply to critical areas (stroke), or the mass effects of a resulting hematoma. Also, CSF leakage can cause symptoms directly, as well as predisposing the patient to the development of meningitis, and air entering the brain (pneumocephalus) can cause mass effect symptoms.

Bleeding is a risk in any surgical procedure, but seldom are so many important vessels susceptible to injury. The transnasal approaches outlined previously visualize and put at risk the anterior and posterior ethmoid arteries; the sphenopalatine and maxillary arteries and their branches; the internal carotid, anterior cerebral, basilar, and vertebral arteries and their branches; and the venous sinuses of the skull base: the cavernous sinus, basilar venous plexus, and the anterior intercavernous sinus.[36]

Immediate complications occur during surgery. The most frequent of these are CSF leakage, intraoperative bleeding, orbital hematoma, brain injury, and intrasellar complications, which can include injuries of the diaphragma sella, arachnoid membrane, pituitary stalk, intra-arachnoid vascular structures, and the hypothalamus, optic nerve, and chiasm and the vessels surrounding them. Injuries to cranial nerves III and VI are uncommon except in transsphenoidal-transclival approaches.

Delayed complications include progressive loss of vision or smell, meningitis, bleeding, synechia, and infection. The surgeon also must be aware of the possibility of transitory or permanent endocrinologic complications that can result from manipulation, compression, or traction of the pituitary stalk. The surgeon must be able to diagnose acute anterior pituitary insufficiency and be able to manage the condition or have available appropriate consultants who can do so.

Summary

Dramatic improvements in technology have made it possible to extend endoscopic surgical procedures well beyond the sinuses to all three cranial fossae, as well as to the orbit and pterygopalatine, zygomatic, and infratemporal fossae. Visualization is superior, morbidity is lower, and complications of endoscopic skull base and brain surgery, particularly vascular and neurologic lesions, CSF leak, and infection, are the same as after open procedures.

Despite all of the technologic and surgical advances, extensive dural defect repair remains a considerable challenge. Even with the dazzling technical advances, surgical success depends more on other factors: The surgeon must have a perfect knowledge of the involved anatomy, extensive endoscopic surgical training and experience, good surgical skills and judgment, and a highly skilled neurosurgical colleague. Only then can transnasal endoscopic-assisted surgery of the skull base reach its full potential.

CHAPTER ONE HUNDRED AND SEVENTY-SIX

Temporal Bone Neoplasms and Lateral Cranial Base Surgery

Michael Marsh

Herman A. Jenkins

Key Points

- Patients with encasement of the internal carotid artery by tumor, contour irregularity on angiography, or anticipated internal carotid artery resection should undergo preoperative temporary balloon test occlusion (BTO) with neurologic monitoring with or without quantitative cerebral blood flow (CBF) assessment. When preoperative BTO reveals neurologic deficit or CBF is less than 30 mL/100 g per minute, definitive resection is not an option, unless extracranial-intracranial bypass can be accomplished beforehand. The decision regarding revascularization versus permanent balloon occlusion optimally is made preoperatively.
- The minimal procedure for treatment of carcinoma of the external auditory canal usually is a lateral temporal bone (LTB) resection. If radiation therapy is anticipated postoperatively, the cavity should be obliterated, in view of the high risk of osteoradionecrosis in irradiated open cavities.
- Carcinomas of the external auditory canal extending to the mesotympanum are optimally treated with a subtotal temporal bone resection and postoperative radiation therapy.
- High-grade malignancies of the temporal bone with extension outside the petrous bone to the petrous apex, extensive dural involvement, frank parenchymal involvement, gasserian ganglion involvement, or invasion along the skull base portend a poor outcome in nearly all cases. Palliation should be strongly considered.
- Aneurysms of the upper cervical and petrous internal carotid artery can be managed by endovascular stenting, balloon trapping, or surgical resection with or without revascularization or extracranial-intracranial bypass, as indicated by angiography and BTO assessment findings.
- Glomus tympanicum tumors whose borders are clearly seen through the tympanic membrane can be removed transtympanically; otherwise, an extended facial recess approach is indicated.
- Glomus jugulare tumors are best removed through a Fisch type A infratemporal approach. Staging may be necessary with significant intracranial extension. Preoperative embolization may greatly lessen intraoperative blood loss.
- Radiotherapy for glomus jugulare tumors may be indicated for recurrences or unresectable lesions, or in the presence of a medical contraindication to surgery.
- Jugular foramen schwannomas that are primarily intracranial are most easily approached suboccipitally. Jugular foramen schwannomas that are intraforaminal or combination tumors are removed in the safest manner using an infratemporal fossa approach with (Fisch type A) or without facial nerve transposition.
- The classic history of facial nerve schwannomas is one of a slowly progressive facial paralysis over months to years, not days to weeks, although sudden onset of paralysis, fluctuating paresis, and facial tic may occur. It is recommended to wait for facial function to deteriorate to House-Brackmann grade IV before surgical resection, because this may be the best expected outcome with facial nerve resection and reanastomosis.
- Drainage of cholesterol granulomas can be performed through the perilabyrinthine pathways or transsphenoidally using endoscopic image guidance techniques.
- Surgical management of a congenital cholesteatoma involving the petrous apex requires either complete removal of the cholesteatoma matrix or permanent exteriorization.
- Chordomas of the clivus can be resected using postauricular (Fisch type B) or preauricular lateral temporal bone techniques. Transnasal endoscopically assisted approaches also may result in complete extirpation, with greatly reduced morbidity compared with lateral skull base or facial translocation anterior techniques.

Lateral approaches to the skull base require numerous manipulations of intervening structures to gain access to the various regions of the skull in and around the posterior and middle cranial fossae. Advances in preoperative assessment, surgical techniques, and perioperative care have permitted removal of tumors previously regarded as unresectable. Concomitantly, the morbidity and mortality rates associated with these procedures have decreased significantly. A cohesive skull base team affords the patient the best possible preoperative assessment, planning, and surgical execution. The team requires the expertise of an otolaryngologist or neurotologist working with the neurosurgeon, neuroradiologist, interventional arteriographer, and anesthesiologist. The reconstructive surgeon may play a major role, especially if free flaps are required. This chapter reviews pertinent anatomy, various approaches to the lateral skull base, and selected pathologic entities.

Benign and malignant lesions (Box 176-1) involving the middle ear and temporal bone are located in one of the most inaccessible areas of the body. Although a variety of histologic types of tumor are found in these areas, each is uncommon, and clinical experience in their diagnosis and management is not easily acquired. Surgical approaches to the skull base are difficult, and the risks of neurologic deficit are significant. The major arteries and veins supplying the brain, intracranial structures, and all of the cranial nerves either exit through or are contiguous with the temporal bone. Modern surgical technique strongly stresses the minimization of cosmetic or neurologic loss in the management of benign and malignant lesions of the temporal bone. Through the years, collaborative approaches to the temporal bone have been developed for treatment of benign lesions and are being expanded to encompass malignant lesions as well. Nevertheless, considerable knowledge of temporal bone anatomy and adequate temporal bone-drilling laboratory experience are essential in adapting these approaches for each patient. Many histologic types are encountered only rarely, accounting for isolated case reports in the literature. Dividing tumors into benign and malignant categories, in combination with knowledge of the particular tumor biology and meticulous preoperative planning, greatly facilitates selection of the appropriate surgical approach and successful outcome.

Skull Base Anatomy

An overview of skull base anatomy may be found in Chapters 127 and 173. With lateral approaches to the skull base, anatomic structures are approached from a vantage point different from that presented in classic anatomic texts in terms of the course of dissection, in that such approaches are designed to enhance exposure while preserving neurovascular structures. The superior boundary of the infratemporal fossa as described by Grant[1] consists of the greater wing of the sphenoid the temporal fossa containing the temporalis muscle. The medial limit is

Box 176-1

Temporal Bone Neoplasms

Primary Benign Tumors
- Paraganglioma
- Neurofibroma/schwannoma
- Meningioma
- Adenomas
  - Ceruminous adenoma
  - Eccrine cylindroma
  - Pleomorphic adenoma
- Mesenchymal
  - Chondroma
  - Chondroblastoma
  - Chondromyxoid fibroma
  - Hemangiomas
  - Lipoma
  - Myxoma
  - Fibro-osseous tumors
    - Ossifying fibroma
    - Fibrous dysplasia
  - Giant cell granuloma
  - Aneurysmal bone cysts
  - Osteoblastoma
  - Osteoma/exostosis
  - Unicameral bone cyst
  - Teratoma
- Dysontogenic tissue
- Choristoma
- Glioma

Metastatic Tumors
- Prostate
- Breast
- Gastrointestinal
- Renal cell
- Lung
- Multiple myeloma
- Lymphoma
- Leukemia (chloroma)

Primary Malignant Tumors
- Epidermal carcinomas
  - Squamous cell carcinoma
  - Verrucous carcinoma
  - Basal cell carcinoma
  - Melanoma
- Adenocarcinomas
  - Ceruminous adenocarcinoma (low-grade and high-grade)
  - Adenoid cystic
  - Mucoepidermoid
  - Sebaceous cell
  - Papillary cystadenocarcinoma
- Mesenchymal
  - Rhabdomyosarcoma
  - Fibrosarcoma
  - Chondrosarcoma
  - Osteosarcoma
  - Liposarcoma
  - Dermatofibrosarcoma protuberans

- Craniopharyngioma
- Chordoma
- Scalp tumors
- Nasopharyngeal carcinoma

the lateral pterygoid plate, and the lateral limit is the mandibular ramus and condyle. The posterior wall of the maxillary sinus marks the anterior limit, and posteriorly and inferiorly, the infratemporal fossa opens into the parapharyngeal space, where fascial bands and ligaments subdivide the enclosed spaces.[2-4]

The facial nerve exits the stylomastoid foramen to enter the parotid gland and then emerges from the gland distally encased in the superficial muscular aponeurotic system fascia.[5] The glenoid fossa may limit superior exposure in lateral approaches.

As low-pressure, valveless channels, the venous system in the skull base is pivotal in lateral approaches. The torcular Herophili is the confluence of the transverse sinus (lateral sinus), superior longitudinal sinus, straight sinus, and occipital sinus. Bisaria[6] found that this confluence of sinuses was missing in 24.5% of 110 cadaver dissections. Ligation of the transverse sinus may lead to massive cerebral edema if the torcular Herophili is absent.[7] The vein of Labbé, or inferior anastomotic vein, connects the superficial middle cerebral vein with the transverse sinus, draining the superficial posterior temporal and inferior parietal lobes. It occurs on the right 66% of the time and on the left 77% of the time.[8] When present, it empties into the transverse sinus just proximal to the sigmoid sinus. Interruption of the vein of Labbé may lead to temporal lobe edema and infarction, unless good collateral drainage is present.[7,8] The superior petrosal sinus runs along the posterosuperior edge of the petrous bone from the cavernous sinus to the junction of transverse and sigmoid sinuses, receiving tributaries from the tympanic cavity and from the cerebellar and inferior cerebral veins.[9] The jugular bulb, averaging 15 mm in width, usually is separated from the tympanic cavity by bone but has been reported to be dehiscent in 6% of temporal bones.[10] The inferior petrosal sinus courses between the jugular bulb and cavernous sinus in the petrooccipital fissure, receiving tributaries from the internal auditory canal, pons, medulla, and inferior cerebellum.[9] The inferior petrosal sinus, occasionally the vein of the cochlear aqueduct, and the occipital sinus drain into the jugular bulb. Cranial nerves IX, X, and XI pass through the anterior medial portion of the jugular foramen and may be compressed during maneuvers to obtain hemostasis of the inferior petrosal sinus.[11]

The internal carotid artery ascends deep to the digastric and styloid muscles to enter the carotid siphon medial to the styloid process, ascending through vertical and horizontal segments. In the vertical segment near the genu, the artery is just deep to the eustachian tube orifice, posteromedial to the glenoid fossa. The osseous eustachian tube orifice is separated from the internal carotid by, on average, 1.5 mm of bone and may have dehiscences.[12,13] The midportion of the vertical arterial segment is anteromedial to the basal turn of the cochlea. The distance to the cochlea averages approximately 1.34 mm.[14] The average length of the vertical segment is approximately 10 mm (range, 5 to 15 mm).[12,15] The horizontal segment travels obliquely in a lateral to medial direction from the genu to the intracranial entry of this vessel at the superior aspect of the foramen lacerum. Its average length is 20 mm (range, 14.5 to 26 mm).[12,15] Relevant lymphatic anatomy includes the preauricular and parotid lymphatics that drain the external ear, with more medial aspects of the external auditory canal draining into deep jugular and postauricular nodes. The mucosa of the middle ear and mastoid drains into channels surrounding the eustachian tube, which then drains into the deep superior jugular and retropharyngeal nodes.[16]

Evaluation of Skull Base Lesions

Accurate diagnosis and evaluation of tumor extent of the middle ear space and temporal bone require appropriate physical examination and audiologic, vestibular, and radiologic assessment. Tumors of the middle ear space frequently can be seen on physical examination. The combination of the frequency of certain lesions and their classic presentations often suggest the tumor type. Tumors of the lateral skull base often manifest with cranial nerve deficits, including hearing loss, pulsatile tinnitus, and eustachian tube dysfunction. A thorough history and physical examination with special attention to the cranial nerves should be undertaken. Audiometry is useful in surgical planning, particularly when removal of the labyrinth will be necessary. Radiographic evaluation provides information regarding location, extensions, surrounding structural relationships, and probable histologic findings.[17-25]

Computed Tomography and Magnetic Resonance Imaging

Preoperative computed tomography (CT) and magnetic resonance imaging (MRI) are indispensable to modern skull base surgery (see Chapter 135). Hirsch and Curtin[26] noted that MRI and CT are "complementary and not competitive in the initial evaluation of skull base lesions." Modern CT affords exquisite bony detail and fairly good soft tissue information. The strength of CT lies in delineating the effect of the tumor on the bone of the skull base. Soft tissue–soft tissue discrimination is still limited because of the narrow range of electron densities in soft tissues of interest. More soft tissue discrimination is available with CT if iodinated contrast material is administered intravenously. The advent of MRI with its superb soft tissue sensitivity has resulted in fewer indications for use of iodinated contrast CT techniques. Although MRI is able to evaluate alterations in bony structure, it does so only indirectly, because cortical bone has few mobile water protons and hence nearly no intrinsic signal. For this reason, MRI is inferior to CT in the evaluation of subtle bony changes. Such features are important findings in temporal bone masses. The fine soft tissue discrimination of MRI is improved by the intravenous infusion of the MRI contrast medium gadolinium. Another advantage of MRI is its ability to display numerous imaging planes without repositioning the patient, which makes it easier to acquire coronal, sagittal, and even off-axis oblique images. For these reasons, MRI is superior to CT in defining brain or meningeal effects from temporal bone lesions. Because of potentially dangerous magnetic effects, MRI cannot be used in patients with certain cardiac pacemakers or valves, ferromagnetic cerebral aneurysm clips, some vena cava filters, and ferromagnetic intraocular foreign bodies.

The usual evaluation of a potential temporal bone mass begins with noncontrast temporal bone CT. This study will immediately show large lesions and usually suggests the presence of smaller lesions. Even though results of temporal bone CT may be negative, follow-up MRI may be indicated if clinical findings strongly suggest a mass. Like CT, MRI is focused to the region of interest instead of just providing thick-slice imaging of the entire head. Temporal bone MRI almost always is performed without and with gadolinium. Many practitioners choose to bypass CT if they believe the disease is retrocochlear. CT then can be added after the MRI study if precise bone detail is required.

Both CT and MRI are computerized imaging techniques. For this reason, either can be reformatted in any desired digital display. A popular type of reformatted display is a three-dimensional image. Three-dimensional displays may assist the surgeon by making it easier to understand the extent of the lesion, but they almost never provide diagnostic information that was not available on the standard axial or coronal slices. Moreover, three-dimensional displays are heavily post-processed. Significant image information can be lost in such processing. At present, three-dimensional images are used almost exclusively as supplemental displays, as dictated by the preference of the practitioner.

Preoperative Carotid Artery Assessment

In extirpation of skull base tumors, appropriate management of the internal carotid artery remains paramount (Fig. 176-1). The morbidity associated with carotid artery occlusion is well known. The first documented carotid ligation, for a sword injury, performed in 1585 by Paré, resulted in stroke.[27] Literature review reveals that unselected abrupt sacrifice of this vessel resulted in 26% (65 of 254) cerebral infarctions, with a 46% fatality rate (30 of 65).[28] Gradual occlusion, as with a Silverstone clamp, does not seem to alter morbidity. Berenstein and associates[29] noted that a significant reduction of blood flow or pressure does not occur until a cross-sectional area less than 2 mm^2 is attained, regardless of the diameter of the vessel. Late-onset complications from cervical internal carotid artery ligation may result after several hours, as a result of stasis with distal thrombosis and embolic phenomena.

Four-Vessel Arteriography

All patients considered for extensive lateral skull base surgery should undergo a four-vessel carotid angiogram with venous phase (see

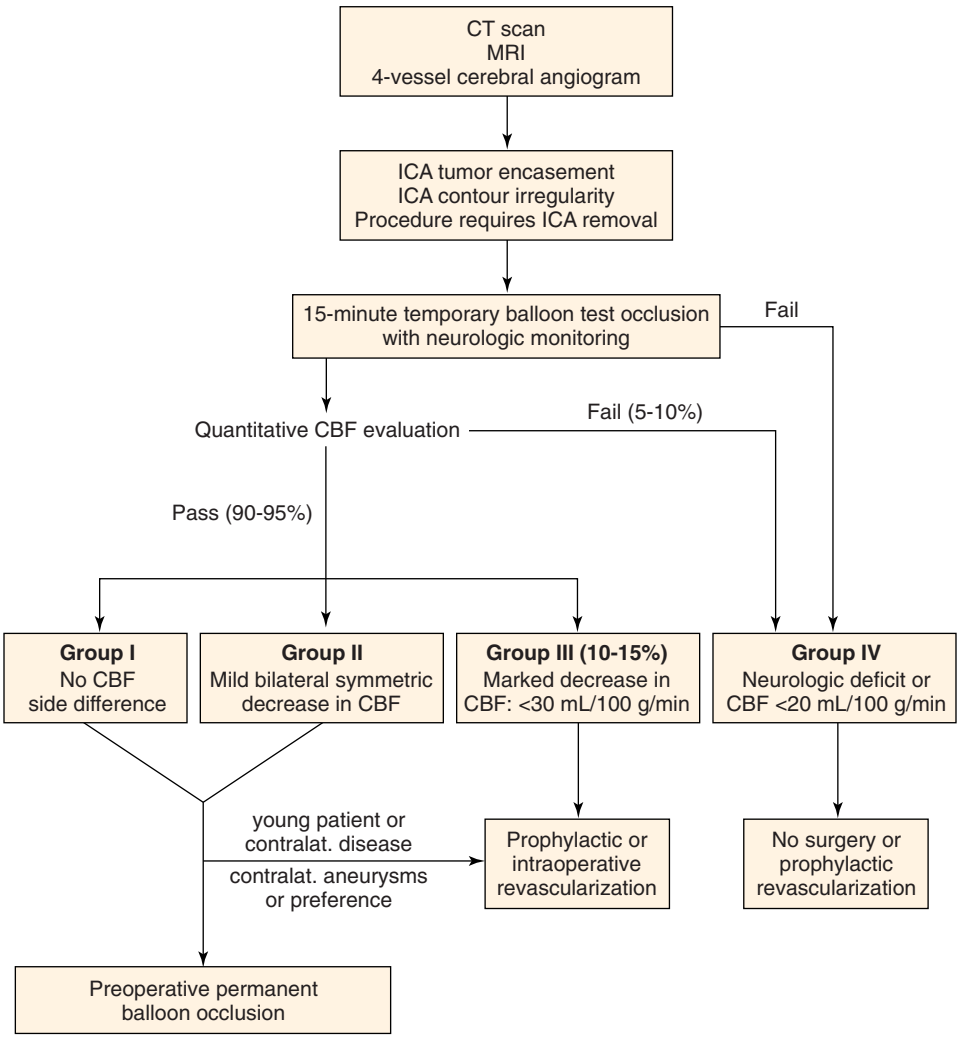

Figure 176-1. Algorithm for preoperative internal carotid artery (ICA)/cerebral blood flow (CBF) evaluation. CT, computed tomography; MRI, magnetic resonance imaging.

Chapters 135 and 136). Angiography is only qualitative but may provide critical information (Fig. 176-2).

According to Fisch and colleagues, angiographic evidence of ICA contour irregularity or stenosis at the level of lesion should prompt consideration of elective preoperative ipsilateral carotid balloon occlusion.[30] Intraoperative carotid occlusion is associated with a higher rate of permanent neurologic sequelae.

The venous phase provides critical information regarding collateral venous drainage, should ligation of the transverse sinus or the vein of Labbé be required.

Cerebral Blood Flow Assessment

Some understanding of cerebral blood flow (CBF) is essential to carotid artery management. Normal CBF approximates 50 mL/100 g per minute.[31] In alert humans, CBF less than 20 mL/100 g per minute produces failure of brain function, resulting in at least temporary hemiparesis or hemiplegia.[32] At this point, electroencephalography (EEG) usually reveals changes reflecting synaptic transmission failure.[31] As CBF decreases below 15 mL/100 g per minute, electrical activity is lost.[33] Jones and coworkers[34] found that long-lasting ischemia in monkeys from local CBF less than 17 to 18 mL/100 g per minute resulted in infarction. The time course of irreversible neuronal damage at various CBF levels in humans is unknown.

Functional assessment of CBF is required in the following clinical circumstances:

1. En bloc resection of a malignant tumor necessitating resection of the internal carotid artery
2. Tumor encasement of the internal carotid artery as seen on MRI or CT
3. Angiographic contour irregularity or stenosis at the level of the tumor

Qualitative Cerebral Blood Flow Evaluation

Various methods have been proposed to assess functional collateral circulation in the circle of Willis. Simplest is the Matas test, in which the ipsilateral carotid artery is compressed against a vertebral transverse process while the examiner observes for deterioration of neurologic function.[35] Cross-compression carotid arteriography will give a qualitative feel for ipsilateral CBF.[36] Direct intraoperative carotid stump pressures can estimate collateral circulation. A back-pressure of 50 mm Hg has been considered to be indicative of adequate CBF,[37] but stump pressures have been shown to be unreliable.[38,39] Ocular plethysmography and transcranial Doppler velocitometry of the middle cerebral artery[40] have similar theoretic limitations. In a series of patients undergoing carotid surgery, intraoperative EEG revealed no change in 18% to 56% of those with CBF levels less than 20 to 24 mL/100 g per minute, depending on the anesthetic used.[41] EEG, therefore, may be too insensitive for detection of CBF abnormality in patients who experience prolonged occlusions of the internal carotid artery.

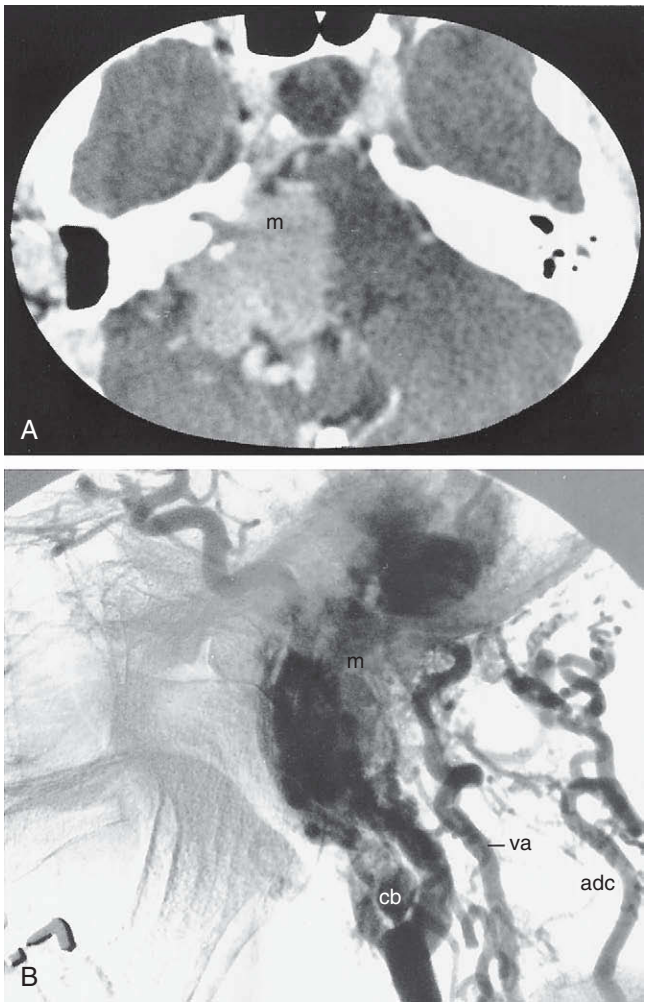

Figure 176-2. Two right-sided paragangliomas in a 61-year-old woman. **A,** Axial view, computed tomography after administration of intravenous contrast. A dense, pathologically contrast-enhancing mass (m) with tortuous dilated vessels is demonstrated. This lesion has ascended from the glomus jugulare up into the cerebellopontine angle cistern. It covers the internal auditory canal. **B,** Innominate artery angiogram, lateral subtraction view centered at the craniocervical junction. The wildly hypervascular nature of the paraganglioma is demonstrated. The tumor has parasitized the vertebral artery (va) and is ascending the deep cervical arteries (adc). These vessels have dilated and become tortuous because of the increased flow demanded from them. Besides the large glomus jugulare paraganglioma (m), the patient has a small carotid body paraganglioma (cb).

Generally accepted evaluations of CBF all involve the interventional radiologic technique of balloon test occlusion (BTO). The assessment of CBF will be either qualitative or quantitative with BTO with neurologic monitoring. Fisch uses qualitative BTO as the sole method to assess collateral CBF, with the neuroradiologist making an experienced, qualitative judgment regarding which patients should undergo permanent occlusion.[30] The collateral circulation may be stressed during BTO with pharmacologically induced hypotension or acetazolamide. Other qualitative techniques for CBF evaluation, such as single photon emission computed tomography (SPECT) and magnetoencephalography, attempt to "quantify" CBF.[42-45]

Quantitative Cerebral Blood Flow Evaluation

The impetus for quantitative evaluation of CBF is to identify the 10% to 25% subset of patients who "pass" BTO (as described next under "Carotid Management Algorithms") but are still at moderate to high risk of irreversible neurologic damage in the event of internal carotid artery occlusion. Quantitative methods of CBF evaluation during BTO include (1) positron emission tomography (PET), (2) MRI techniques, (3) cerebral perfusion CT, and (4) xenon CT or xenon 133 nuclear studies.

PET has the advantage of measuring CBF and metabolic parameters simultaneously.[46] Of the tests mentioned, PET provides the most accurate knowledge regarding cerebral hemodynamics, although it requires expensive infrastructure, is not widely available, and is time consuming.

New advances show that functional MRI (fMRI) has the potential to supplant xenon flow studies.[47-51] Such MRI studies have been used to evaluate CBF preoperatively and postoperatively for extracranial-intracranial bypass procedures.[52] The potential advantage of fMRI lies in that it requires only software upgrades to current MRI scanners. Disadvantages include the need for transport away from the vascular suite and for special equipment tolerant of the highly magnetic field.

Cerebral perfusion CT with or without acetazolamide challenge can be performed quickly on any standard helical (spiral) CT scanner with perfusion maps generated by software.[53,54] Further studies are needed to validate perfusion CT as a quantitative technique comparable to xenon CT.

Xenon 133 scintillation shows excellent correlation with quantitative assessments of CBF in a defined region with a scintillation counter on the scalp[41] and also may be used intraoperatively.

Xenon CT blood flow mapping is the best studied clinical, quantitative measure of CBF.[28,42,55-58] Inhaled xenon acts as a contrast agent, whose uptake and diffusion from cerebral tissue is proportional to blood flow. CBF distribution is estimated with specialized computer software before and after BTO of the internal carotid artery during serial CT scans and from which a blood flow map is calculated. An algorithm for carotid artery management has been proposed on the basis of preoperative xenon CT blood flow mapping with temporary carotid balloon occlusion (see Fig. 176-1). Group 3 patients (see Fig. 176-1), although "passing" BTO, have CBF values between 20 and 30 mL/100 g per minute and are thought to be in hemodynamic decompensation without neurologic deficit but entirely dependent on systemic blood pressure.[56] As is well recognized, intraoperative or postoperative blood pressure fluctuations after ICA occlusion may send these patients over the precipice. It is estimated that 90% of group 3 patients will have a major stroke after permanent occlusion of the internal carotid artery.[59]

Carotid Management Algorithms

A decision regarding management of the internal carotid artery is best made preoperatively. Intraoperative carotid occlusion usually is performed to control massive bleeding under suboptimal circumstances, resulting in a higher neurologic complication rate. Intraoperative balloon occlusion or intra-arterial shunt placement may be required if the carotid is lacerated and control is difficult.[60-62]

After preoperative functional evaluation of the internal carotid artery, either qualitative or quantitative, decisions about management of the carotid are dependent on the following factors:

- Results of the functional evaluation
- Young age
- Contralateral skull base tumor or vascular disease

Vein graft reconstruction, instead of sacrifice of the artery, may be a consideration regardless of the BTO result, especially in young patients and in cases in which contralateral involvement is a possibility, to restore physiologic circulation and reduce risk of late intracranial aneurysms.[33,42] The rationale for preservation of an ICA encased by benign tumor when this is possible, or revascularization when preservation is not possible, is valid.[63]

Opinion differs further regarding algorithms for management of the internal carotid artery based on functional evaluations, just as opinion differs regarding what constitutes an adequate evaluation in

the first place. The results of temporary BTO can be classified as either "pass" or "fail," as follows:

Pass: no neurologic deficit and CBF greater than 30 mL/100 g per minute (if quantitative evaluation has been performed)

Fail: neurologic deficit or CBF less than 30 mL/100 g per minute (if quantitative evaluation has been performed), or both

For patients with BTO results in the "fail" category, definitive resection may not be possible; alternatively, extracranial-intracranial bypass antecedent to the resection procedure should be considered.[42,64-66]

Patients who "pass" are further subclassified depending on whether qualitative or quantitative testing has been done. Fisch[30] using qualitative BTO, recommends permanent occlusion of the internal carotid artery preoperatively if the neuroradiologist confirms adequate cross-circulation and no neurologic deterioration occurs during the test. In a series reported by Zane and colleagues, only 5% (2 of 46 patients, 1 preoperatively and 1 postoperatively) had permanent neurologic sequelae after occlusion when this algorithm was used.[30] If quantitative testing has been performed, transarterial permanent balloon occlusion may be considered for operative candidates in groups 1 and 2 (CBF greater than 30 mL/100 g per minute) (see Fig. 176-1) for the same indications as those that occasioned functional CBF testing. If the decision for occlusion of the internal carotid artery is reached preoperatively, permanent balloon occlusion should be performed 1 to 4 weeks before the resection to lessen thromboembolic sequelae. Placement proximally at the level of the carotid bifurcation and distally just before the ophthalmic artery minimizes late thromboembolic sequelae.[67] The long-term sequelae of carotid occlusion are unknown, although xenon CT blood flow mapping after BTO correlates well with medium-term neurologic outcome.[28] Direct vein graft reconstruction is indicated to allow complete tumor resection (see Fig. 176-1) in patients assigned to group 3 by quantitative CBF assessment (CBF less than 30 mL/100 g per minute), those with bilateral lesions, and young patients with benign tumors, according to Sen and Sekhar.[64] Intraoperative revascularization is associated with increased operative time, graft occlusion, need for transfusion, and potential for postoperative blowout.[30] Risk of graft occlusion is especially high among patients with long grafts.

Disregarding the surgeon's preference for revascularization or permanent balloon occlusion, the decision optimally is made under controlled circumstances preoperatively.

Surgical Approaches
