Maxillary sinus pneumatization is evaluated with respect to the presence of any infraorbital ethmoid cells, and the medial wall is evaluated for the presence of any accessory ostia that might have been missed during nasal endoscopy. The presence of a medially retracted posterior fontanelle in conjunction with an atelectatic infundibulum suggests that gaining entry into the maxillary sinus will be challenging.

Should surgery be necessary in the region of the sphenoid sinus, this structure is best evaluated in both the axial and the coronal planes. The axial plane demonstrates the relation of the intersinus septum to the carotid arteries and the relative size of the two sphenoid sinuses, and the coronal view demonstrates the relation of the optic canal with the sinus.

The frontal recess requires triplanar views (axial, coronal, and sagittal) to achieve understanding of the three-dimensional anatomy of the area. The ability to scroll through the anatomy in multiple planes is even more preferable. If significant trauma is to be avoided in this critical region, it is essential that the surgeon have a complete understanding of the anatomic relationships, particularly with regard to the anteroposterior diameter of the frontal sinus, as well as the relationship to adjacent agger nasi and supraorbital ethmoid cells.

Magnetic Resonance Imaging

Although CT is clearly the primary diagnostic modality for sinus disease, MRI is adjunctive and required in certain situations. MRI is essential when CT reveals disease adjacent to skull base erosion. In this situation, MRI identifies whether the erosion is caused by sinus disease or secondary to a prior skull base erosion or trauma with resultant meningoencephalocele. The evaluation of dehiscent areas becomes even more important when there are sphenoid erosions and the possibility of a carotid artery aneurysm. MRI also enables differentiation of sinus from intranasal soft tissue masses as well as of tumor from retained secretions (Table 52-2).

Concepts of Antrostomy

Several theoretic considerations need to be kept in mind when one is considering the most appropriate size for antrostomy in FESS. In rabbits, experimental exposure of the maxillary sinus to airflow results in dramatic slowing or cessation of mucosal clearance. Therefore, the maxillary sinus ostium and the maxillary sinus mucosa should ideally remain protected from airflow. It also has been demonstrated that nitric oxide is actively liberated from the sinus mucosa at levels that may reach bacteriostatic concentrations, theoretically creating another advantage for keeping the surgically created ostium small. Conversely, a significant part of the medial wall of the maxillary sinus is composed of the uncinate process, a bone that frequently displays osteitic changes. When the uncinate process is diseased and is not completed resected, persistence of disease and scarring are typically seen at this site. Therefore, if disease is very mild, a minimal opening of the ostium is preferable. However, in the presence of long-standing diffuse chronic sinusitis, especially with evidence of osteitis, or when there is a strong likelihood that significant local care of the maxillary sinus may be required after surgery, a wide middle meatal antrostomy is preferred. The wide middle meatal antrostomy would include careful and complete removal of the uncinate process both anteriorly and inferiorly. If the maxillary sinus extends medially into the nasal cavity so that the medial wall posterior to the antrostomy is displaced into the nasal airflow, this medially displaced wall creates an "air scoop" that will preferentially dry the mucosa of the posterior maxillary sinus wall. In this instance it is better

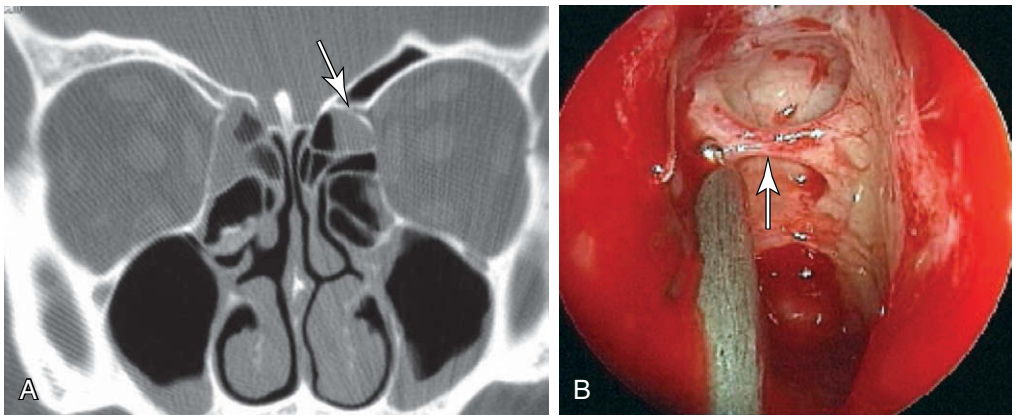

Figure 52-6. Paired coronal computed tomography scan **(A)** and endoscopic view **(B)** of the anterior ethmoidal artery (*arrow*). Note that the artery comes through a foramen that is demarcated by the convergence of the medial rectus and superior oblique muscles.

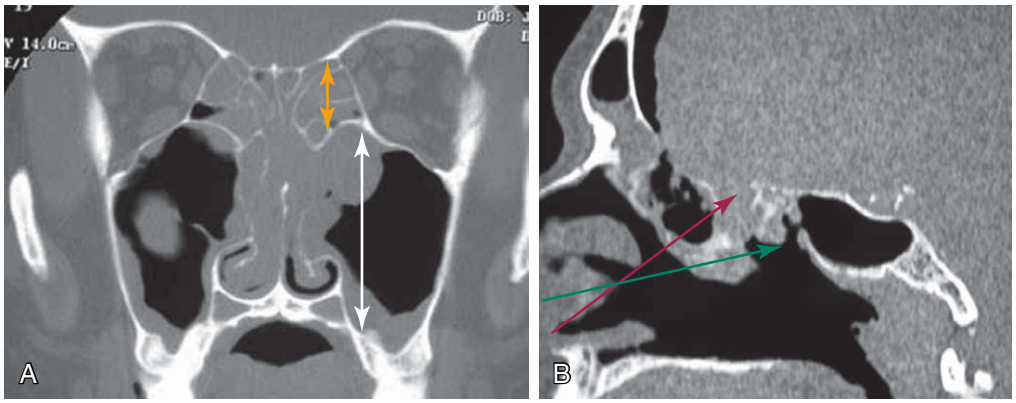

Figure 52-7. **A** and **B,** Paired coronal and sagittal computed tomography scans demonstrating the importance of the ratio of maxillary height (*white arrow*) to ethmoid height (*orange arrow*). When the maxillary sinus is larger, the ethmoid height is relatively shorter, and vice versa. The larger the maxillary sinus, the more superior the basal lamella attachment—therefore, the higher the "angle of attack" through a 0-degree scope into the posterior ethmoid, and the higher the risk of skull base penetration in the posterior ethmoid. In **B,** the *red arrow* indicates a larger maxillary sinus; the *green arrow* indicates a smaller maxillary sinus.

Table 52-2

Appearances of Sinus Lesions on Magnetic Resonance Imaging (Simplified)

Image	Tumor	Mucocele	Fungus Ball	Meningocele	Encephalocele
T1-weighted	Low	Variable (brighter as protein rises)	Variable	Low	Low
T2-weighted	Low-intermediate	Variable (brighter in high-water, low-protein fluids)	Variable; often drops out	High	Low
T1-weighted with contrast enhancement	Solid, central bright	Peripheral enhancement	Peripheral bright	Rim enhancement	Low

to extend the antrostomy in the posterior direction to the pterygoid plate.

Whatever the size of antrostomy created, it is important that the opening communicates with the natural ostium to prevent failure of surgery. One of the more common causes of persistent maxillary sinus disease after surgery is the presence of a middle meatal antrostomy that does not connect with the natural ostium anteriorly.[19] If the natural ostium is not opened, persistent disease may remain in the periostial area, with pooling of secretions and continued recurrent and persistent disease. Additionally, if the natural ostium does reopen and a noncontiguous middle meatal antrostomy is present, recirculation of mucus frequently occurs, with the mucus re-entering the maxillary sinus through the iatrogenic ostium. Such recirculating mucus will, almost of necessity, become more acutely infected from time to time. Confirming that a middle meatal antrostomy communicates with the natural ostium may not be easy. The bone of the uncinate process may become thickened after infection, and the ostium may become tightly closed and difficult to reopen. Additionally, there are no easy landmarks for the extent to which an antrostomy should be brought anteriorly. Inspection with a 45-degree or 70-degree telescope frequently is helpful

in this regard and is definitely required to exclude with certainty the presence of a noncontiguous antrostomy (Figs. 52-8 and Fig. 52-9). Another anatomic abnormality that bears mention is the diseased infraorbital (Haller) cell, which even when opened may have residual osteitic partitions, creating persistent localized mucosal hypertrophy. Use of angled telescopes is important to evaluate the drainage pathways. Occasionally, when such bony partitions are clearly a cause of localized persistent disease and they are inaccessible from the intranasal route, a limited sublabial approach may be indicated for their removal (Fig. 52-10). Other long-term causes of antrostomy failure are osteoneogenesis from stripped mucosa, retained foreign body, and mucus draining into the sinus from persistent frontal recess inflammation.

Ethmoidectomy

The surgeon must work from "known" to "unknown." Once the middle turbinate is medialized and the uncinate removed in its entirety, the maxillary sinus may be addressed, and antrostomy performed as discussed. If the sinus is opened, the posterior and superior walls of the sinus can be used as landmarks for subsequent dissection. The medial orbital wall is identified and is the first critical ethmoid landmark. Failure to identify the medial orbital wall early can lead to dissection in the medial part of the ethmoid cavity, where the skull base is both thin and downsloping, at a point in the surgery at which adequate visualization of the anatomy has not been achieved. The ethmoid sinus is in close proximity to the other three paranasal sinuses, and often FESS includes a complete ethmoidectomy to allow access to each diseased sinus. In primary CRS, surgery is focused to areas of disease, and when complete ethmoidectomy is performed, the goal is to create a marsupialized cavity lined by healthy, intact mucosa. Ethmoidectomy is most safely performed with a 0-degree telescope and Microdebrider or straight and 45-degree through-cutting forceps. After positive identification is made of the medial orbital wall, the skull base provides the second critical landmark so it must be identified carefully. We advocate dissection low in an anterior-to-posterior direction, across the basal lamella to the sphenoid face, and then identification of the skull base in the posterior ethmoid or sphenoid sinus, followed by completion of the dissection from posterior to anterior.

Some of the more common postoperative results of failure of correct complete ethmoidectomy are lateralized middle turbinate, retained uncinate process, failure of removal of the uncinate superiorly (persistent recessus terminalis), and residual agger nasi cells. Careful attention to bony lamellar remnants, the use of through-cutting forceps,

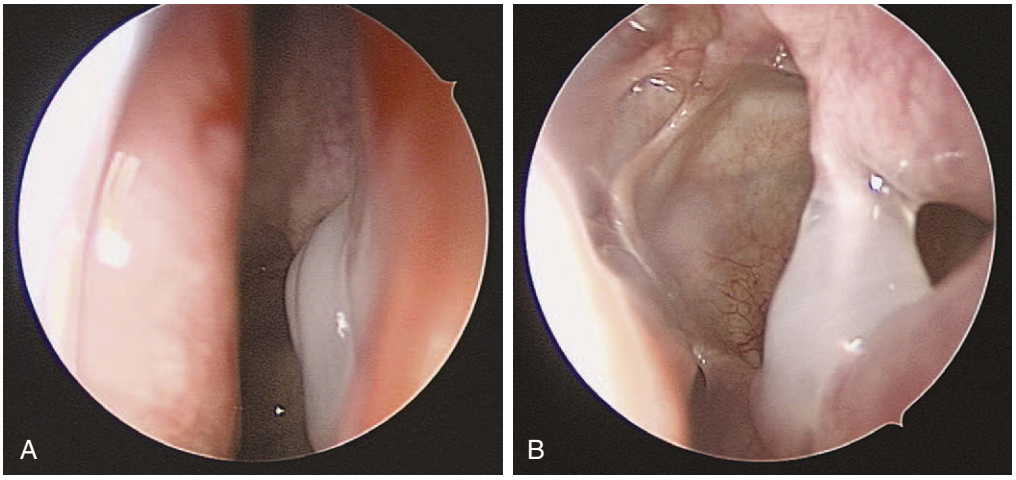

Figure 52-8. Paired images from 0-degree **(A)** and 70-degree **(B)** endoscopes. It is easy to imagine that if the surgeon were to use only a 0-degree endoscope in this patient, the adhesion that is allowing recirculation of mucus in the maxillary sinus would not be identified and subsequently addressed.

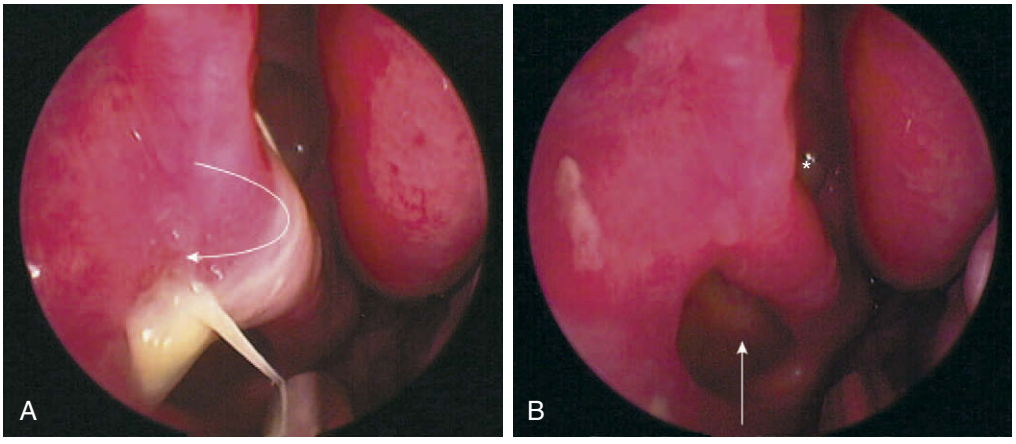

Figure 52-9. **A** and **B,** Endoscopic views of the right middle meatus through a 0-degree telescope demonstrating recirculation of infected secretions. Normal mucociliary flow sweeps contents from the maxillary sinus out the surgically enlarged maxillary sinus ostium. **A,** In this case, secretions re-enter the maxillary sinus through a patent antral nasal window. As these secretions continue to recirculate, they are prone to becoming infected. **B,** Structures shown immediately after suctioning. The *star* denotes the surgically enlarged maxillary sinus ostium, and the *arrow* the nasal antral window. Secretions are rotating around a previously amputated inferior turbinate.

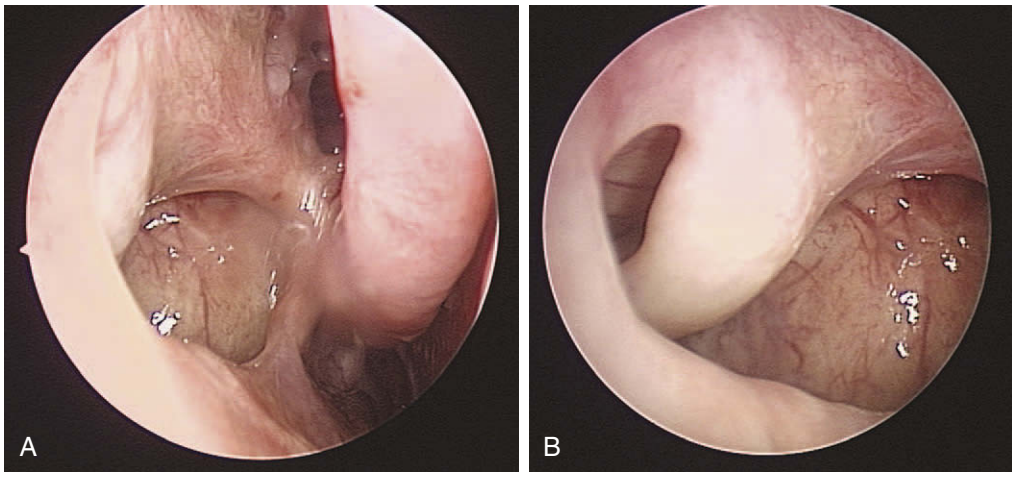

Figure 52-10. Paired images from 0-degree **(A)** and 70-degree **(B)** endoscopes. It is easy to imagine that if the surgeon were to use only a 0-degree endoscope in this patient, any disease in the left infraorbital (Haller) cell would not be addressed.

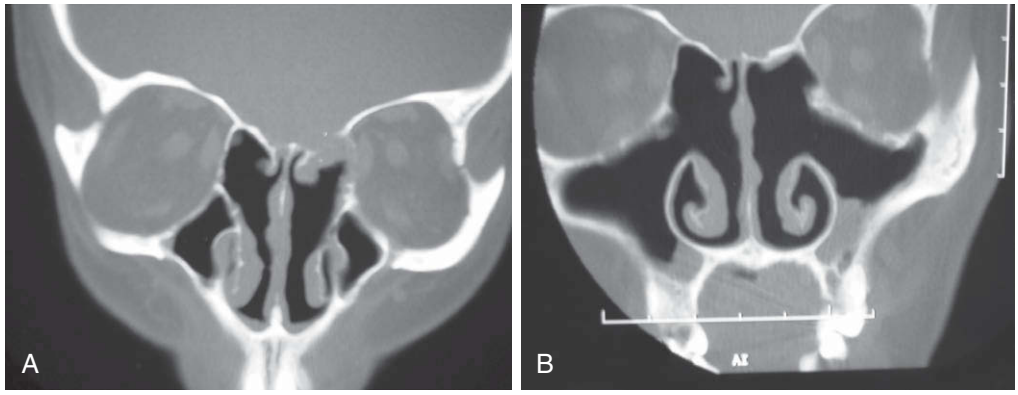

Figure 52-11. Patient who had undergone endoscopic ethmoidectomy presented with an encephalocele that had not been diagnosed because the endoscopic appearance was similar to that of nasal polyposis. **A,** Preoperative computed tomography scan. **B,** Scan obtained 6 months after endoscopic repair with a bone graft.

and the use of a Microdebrider helps achieve resection of disease while leaving a mucosa-lined cavity. Unresected bony partitions trap mucosa and mucosal secretions and will frequently thicken and become difficult to remove after surgery, so it is important to remove them at the first operation. On occasion, particularly in revision surgery, a drill may be needed to remove osteitic bone if it cannot be removed with forceps.

Iatrogenic disease can also include a meningocele or encephalocele. In a case in which a skull base dehiscence is identified and a meningocele is suspected, intrathecal injection of fluorescein before the surgery (0.1 mL of 10% fluorescein injected slowly in 10 mL of the patient's own cerebrospinal fluid) can be considered, to help distinguish encephalocele from surrounding mucosa (Fig. 52-11).[20]

Sphenoidotomy

Before entry of the sphenoid sinus, it is advisable to re-review the radiographic anatomy in both the coronal and axial planes. In addition, the surgeon should review the course of the optic nerve and the carotid artery, especially if a sphenoethmoidal (Onodi) cell is present. The surgeon should also remember that the carotid artery is "clinically dehiscent" in 23% of sphenoid sinuses, making the potential for serious complication in this region significant (Table 52-3). The importance of preoperative diagnosis through radiologic studies must be emphasized (Fig. 52-12). Once the diagnosis is more firmly established and risk to surrounding structures is evaluated, multiple approaches to the sphenoid can be considered.

The transethmoid/transnasal approach is ideal when sphenoidotomy is combined with ethmoidectomy or when wide unilateral sphenoid exposure is required. Following complete ethmoidectomy, the sphenoid face, skull base, and superior turbinate are identified. In cases in which the last structure may be difficult to identify in the presence of severe disease, a ball-tipped seeker may be helpful in locating the superior meatus medially within the cavity. It can also be helpful to resect the posterior portion of the middle turbinate with a backbiter to further expose both the superior meatus and the turbinate. Once the appropriate structures are identified, the inferior third of the superior turbinate is sharply resected; then the natural ostium of the sinus is identified medial to it and is widened. It is important to create a very wide opening that extends to both the skull base and medial orbital wall to avoid the risk of postoperative stenosis (Figs. 52-13 and 52-14).

The other two approaches used for isolated sphenoid sinus disease are the transseptal and the endoscopic transnasal approaches. Before the endoscopic era, a transseptal approach to the sphenoid was frequently used because it provided the advantage of keeping the surgery in the midline of the nasal cavity. The endoscopic transnasal approach provides an excellent approach in isolated sphenoid disease. The advantage is that is quick and avoids disruption of ethmoid sinus anatomy. However, it offers the smallest total exposure to the sinus of any approach.

The most common local causes of failure leading to persistent sphenoid disease are missed or inadequate entry and stenosis, the latter occurring either as a result of inadequate sinusotomy or because of limited postoperative care and scarring of the lateral superior turbinate.

Table 52-3

Possible Complications of Sphenoid Sinus Surgery

Complication	Associated Structure(s)
Vascular hemorrhage	Posterior ethmoidal artery, internal carotid artery, cavernous sinus, sphenopalatine artery
Hematoma	Retrobulbar
Intracerebral injury	Cerebrospinal fluid leak, meningitis, cerebritis, abscess, brain injury, pituitary trauma
Fistula	Cavernous sinus: carotid artery
Cranial nerve (CN) injury	Optic nerve: blindness, pupillary defects Oculomotor nerve (CN III): diplopia, pupillary defects Trochlear nerve (CN IV): diplopia, pupillary defects Abducens nerve (CN VI): diplopia, pupillary defects Trigeminal nerve (CN V_1 to V_x): facial numbness

Frontal Sinusotomy

The frontal sinus continues to present the surgeon with the most challenge, in terms of both the surgical procedure and the potential for persistent and recurrent disease. At minimum, exploration of the frontal recess commits both the patient and the surgeon to a prolonged period of postoperative care and endoscopic observation. At worst, unnecessary exploration of the frontal sinus or inadvertent stripping of mucosa in this area can result in prolonged morbidity and multiple surgical procedures. Therefore, the most difficult decision in FESS is whether the frontal recess should be explored. In some cases of frontal sinus involvement, it is clearly better to perform just an ethmoid dissection and then monitor the patient to see whether the frontal recess disease resolves. The decision should depend, in addition to the pathology present, on the surgeon's experience and ability to preserve mucosa, the regional anatomy as seen on CT, and the availability of through-cutting mucosal-sparing instrumentation.

Preoperative evaluation of the frontal sinus and frontal recess anatomy requires careful evaluation of coronal and axial CT views. A reconstructed sagittal view, as provided in computer-assisted stereotactic navigation, is also of benefit, particularly in cases of complicated frontal recess pneumatization. In evaluation of the frontal recess for potential surgical intervention, attention is paid to its size in both the anteroposterior and lateral diameters, the presence of neo-osteogenesis, and an evaluation of the underlying disease process. Additionally, attention should be paid to the extent of the pneumatization of the frontal sinus itself, because a hypoplastic frontal sinus appears to be significantly more likely to lead to frontal recess stenosis than a sinus that is well pneumatized, irrespective of the anatomy of the frontal recess. One possible explanation for this phenomenon is that mucociliary clearance from a well-pneumatized sinus is greater than

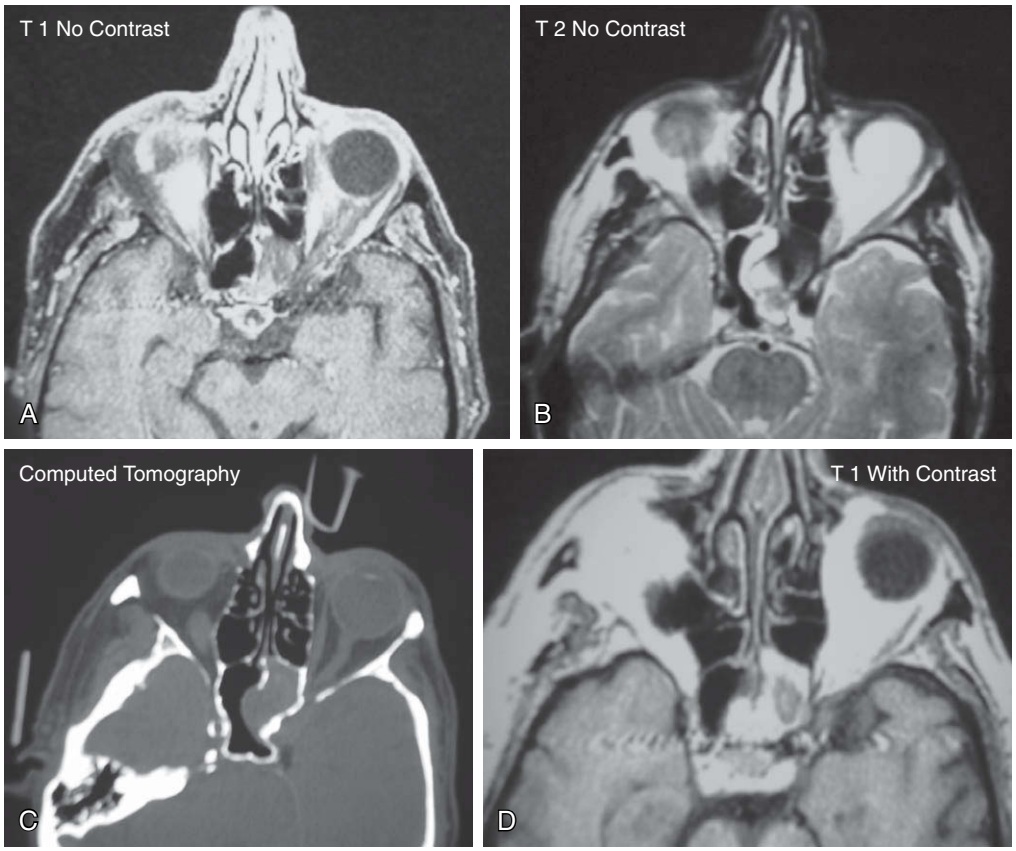

Figure 52-12. Imaging of a patient with a fungus ball in the sphenoid sinus. The heterogeneous mass in the left sphenoid shown on the T1-weighted magnetic resonance image **(A)** drops out on the T2-weighted image **(B)**. The bright areas around the fungus ball are from associated inflammation. **C,** Computed tomography scan. **D,** On a T1-weighted gadolinium-enhanced magnetic resonance image, contrast agent lights up the associated mucosal inflammation around the fungus ball.

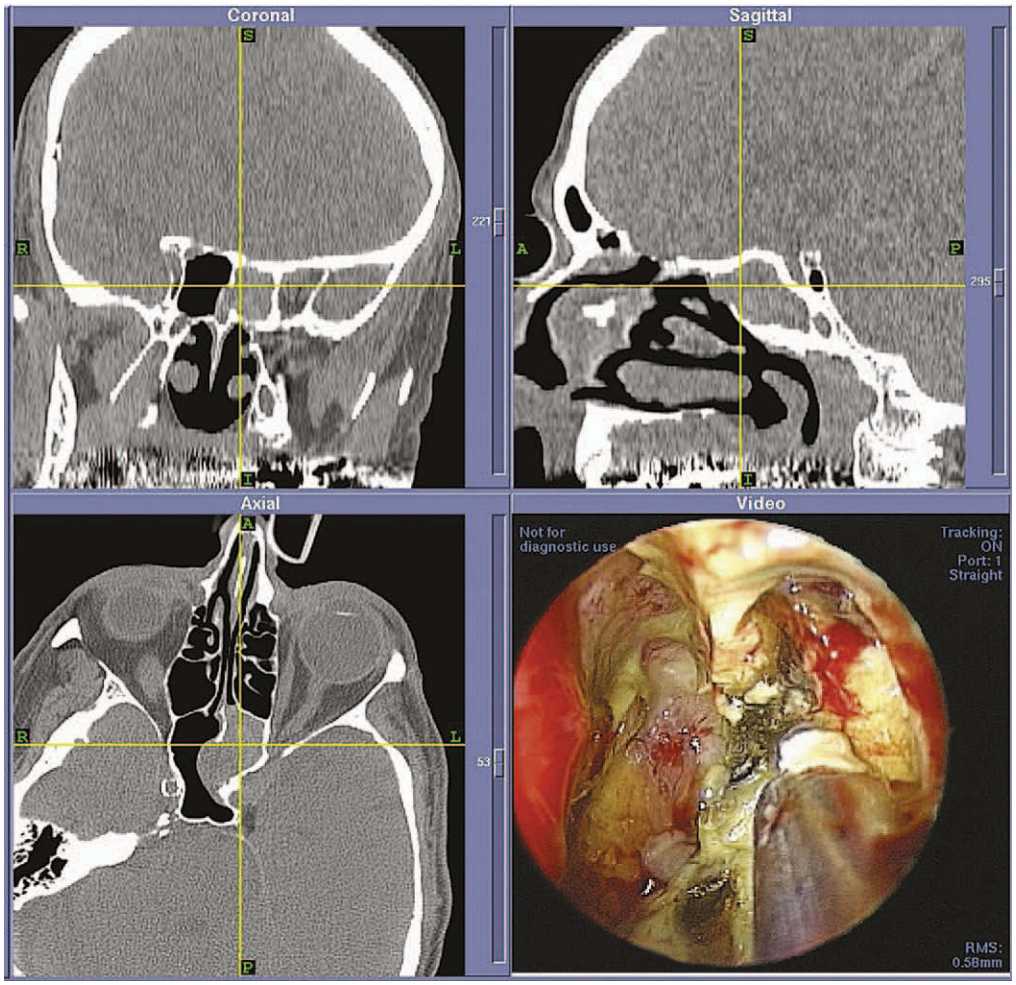

Figure 52-13. Intraoperative images from endoscopic sphenoethmoidectomy using an image-guided navigation system performed in the patient from Fig. 52-12. The cross hairs on the reformatted three-dimensional computed tomography scans (*top, bottom left*) denote placement of the probe as seen in the endoscopic view (*bottom right*). The remains of the fungal ball as well as the associated inflammation can be seen in the endoscopic view. After its removal, the patient had complete relief of symptoms with an uneventful postoperative period.

from a hypoplastic sinus, and mucociliary flow may aid in maintaining patency.

In our clinical experience, the most common immediate cause of frontal sinus disease is the presence of infundibular disease displacing the uncinate process medially, thereby obstructing a frontal sinus. Indeed, in some cases, the medially displaced uncinate process may undergo fusion to the middle turbinate. The second most common cause of frontal sinus disease appears to be mucosal disease and expansion of an agger nasi cell, with resultant posterior displacement of the frontal sinus ostium.

The concept therefore in FESS with respect to the frontal sinus is to work in a stepwise progression to remove all bony septae from cells present, in a procedure termed a *frontal recess dissection*. The initial step in frontal recess dissection involves identification of the appropriate boundaries and the drainage pathway of the frontal recess on CT scan, as well as correlation of this anatomy with the endoscopic view through a 45- or 70-degree telescope (Box 52-1 and Table 52-4). A fine malleable probe can be very helpful in locating the access to the frontal sinus. Once the inferior wall of the agger nasi cell is identified, the surgeon can resect it by sliding a 90-degree frontal sinus curette between the skull base and the posterior agger nasi cell wall and fracturing wall in an anterior and inferior direction (Fig. 52-15). Stammberger has very aptly described this gently performed maneuver as "uncapping the egg." The remaining medial agger nasi cell wall is then removed. After the bone is fractured, the loose bony fragments can be teased out with a fine malleable hook and removed with giraffe forceps with preservation of the mucosa. Mucosal preservation is critically important during frontal recess dissection, but redundant mucosa can be removed with through-cutting forceps or gentle application of curved, powered dissection blades. In general, frontal sinus stents are less satisfactory in maintaining patency than meticulous postoperative care. However, if a stent is used, it should be made of a soft, conformable material.

Frontal cells originate as anterior ethmoid cells that pneumatize into the frontal recess, creating the potential for compromise of the frontal sinus outflow tract and thus serving as a significant potential cause of persistent disease.[21] Because these are the second most anterior of the ethmoid cells, the origins of the frontal cells are located posterior to the agger nasi cell. Each frontal cell then pneumatizes superior to the agger nasi cell into the frontal recess and up into the frontal sinus, where it can cause frontal recess obstruction. A classification of four types of frontal sinus cells has been described, and the nomenclature for them expresses the distance they pneumatize into the frontal sinus, from a type I cell, which is just above the agger nasi cell, to a type IV cell, which pneumatizes completely into the frontal sinus itself. However, for a surgeon performing ESS, the relationship of the cell to the opening of the frontal sinus outflow tract is typically more important than the extent of the cell within the frontal sinus. The surgeon best determines this relationship by using triplanar CT reconstructions or, even better, by scrolling through the triplanar "cuts" on an image guidance system screen until he or she has developed a true three-dimensional conceptualization of the anatomy and how it will appear endoscopically. Frontal recess obstruction by frontal cells occurs in a

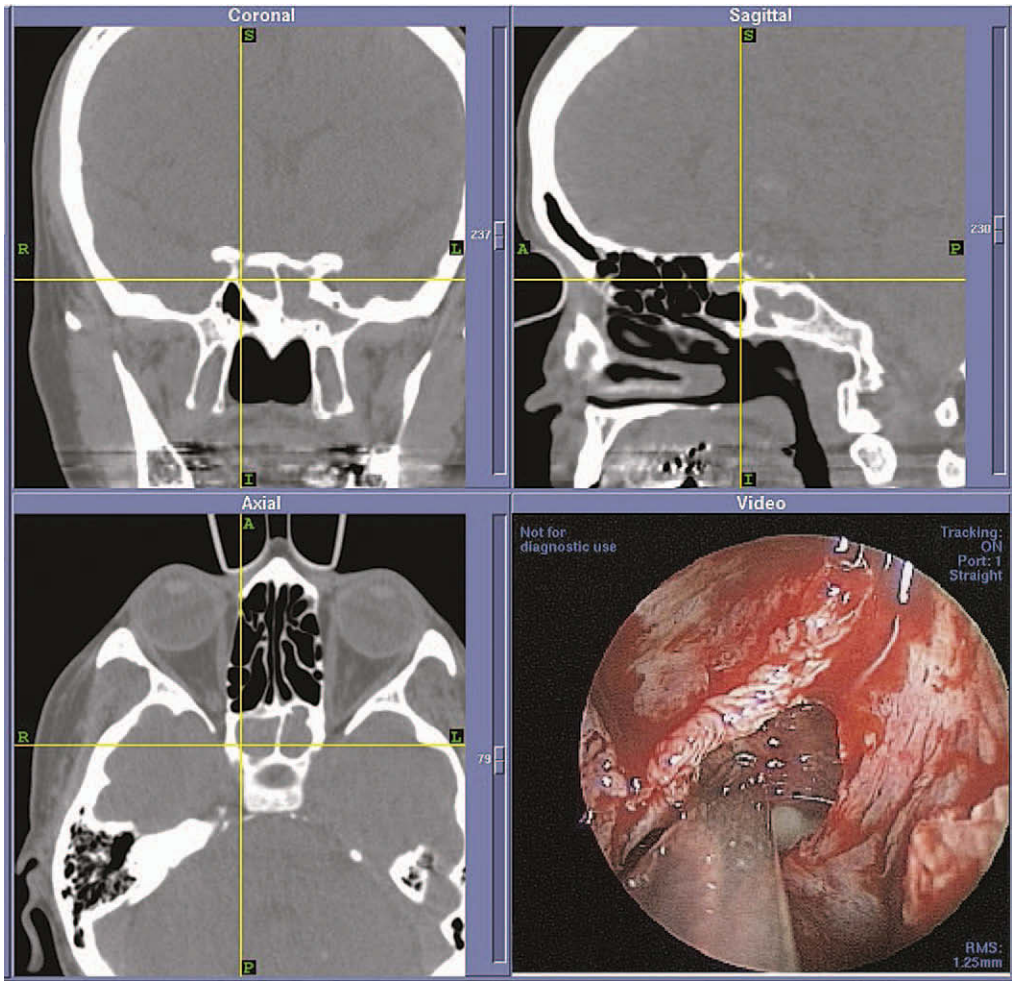

Figure 52-14. Intraoperative images from endoscopic surgery using an image-guided navigation system for chronic sphenoid sinusitis. The cross hairs on the reformatted three-dimensional computed tomography scans (*top, bottom left*) denote placement of the probe as seen in the endoscopic view (*bottom right*). A drill was required to open the sphenoid on account of the extreme neo-osteogenesis.

Box 52-1

Cells and Structures Important in Frontal Recess Disease

Agger nasi cell
Supraorbital ethmoid cell
Frontal cells of types I through IV
Interfrontal sinus septal cell
Suprabullar cell
Frontal bullar cell
Recessus terminalis

Table 52-4

Boundaries of the Frontal Recess

Medial	Superior attachment of the middle turbinate
Lateral	Lamina papyracea
Superior	Internal os of the frontal sinus
Anterior	Posterior buttress nasal spine—nasofrontal "beak"
Posterior	Superior extension of the ethmoid bulla to the skull base
Inferior	Nasal communication of the frontal recess

similar fashion to that of obstruction of an agger nasi cell; that is, edema in very small, tight pathways or in an iatrogenic scar after surgery can close off the frontal recess.

The supraorbital ethmoid cell or cells develop posterior to the frontal sinus, and either failure to address disease within these cells or subsequent scarring is another potential reason for persistent frontal sinus disease. The important feature of these cells is that they pneumatize laterally out over the orbit, and they also may pneumatize forward from their lateral position and appear to be part of a septated frontal sinus. Understanding the spatial relationship of a supraorbital ethmoid cell with the frontal sinus, orbit, and skull base is key to performing frontal recess dissection. As with the other cells in this region, triplanar CT reconstructions are helpful in identifying the exact anatomic relationships. Typically, one or two supraorbital ethmoid cells, with variable degrees of pneumatization, lie posterior to the opening of the frontal sinus. Because of its proximity to the frontal sinus, a well-pneumatized supraorbital ethmoid cell can be easily confused with entrance into the frontal sinus ostium. Once the individual cells have been identified, it is important to remove the common wall between the supraorbital ethmoid cell and the

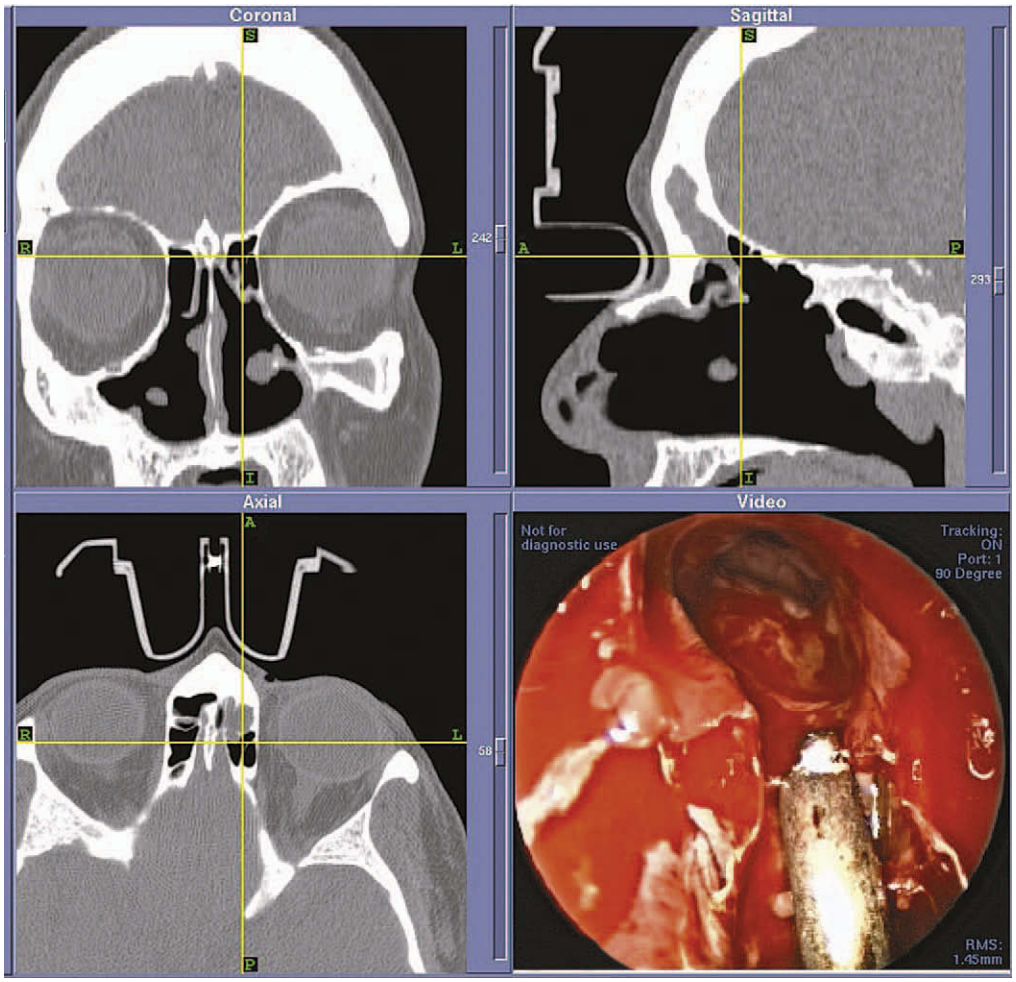

Figure 52-15. Intraoperative images from endoscopic surgery using an image-guided navigation system. The cross hairs on the reformatted three-dimensional computed tomography scans (*top, bottom left*) denote placement of the probe as seen in the endoscopic view (*bottom right*). The patient underwent surgery for recurrent frontal sinusitis from residual agger nasi cell cap adherent to the superior attachment of the ethmoid bulla, which was causing stasis and mucocele. The endoscopic view depicts appropriate findings after frontal recess dissection. The mucosa of the frontal recess is intact. Note the excellent view afforded by the 70-degree telescope.

frontal sinus as far superiorly as possible, preferably to the level of the skull base.

The interfrontal sinus septal cell appears less frequently than the agger nasi or supraorbital ethmoid cell and develops in the septum between the two frontal sinuses. The cell may pneumatize to different extents, varying from just the lower septum all the way to the frontal sinus apex or into a pneumatized crista galli. This cell empties into one frontal recess, usually medial and anterior to the internal frontal ostium and, in some situations, into the frontal sinus. With the endoscopic approach, it should be opened inferiorly, and then as much of the common wall as possible should be removed.

If the uncinate process inserts on the medial orbit wall, the ethmoid infundibulum will end in a blind pocket called a *recessus terminalis*. This common anatomic variation (occurring in up to 50% of people) forces the frontal sinus drainage pathway down the medial surface of the uncinate process and thereby directly into the middle meatus. Because of the proximity of the downsloping skull base, dissection of this variant can be tricky, and failure to identify and meticulously dissect this structure is a common cause of surgical failure (Fig. 52-16).[22]

In all instances of frontal recess dissection, external approaches ranging from frontal sinus trephine to osteoplastic flap can be used as an adjunct to allow access to disease and completion of a thorough frontal recess dissection. The extended frontal sinus approaches, Draf IIB (Fig. 52-17) and Draf III (or transseptal frontal sinusotomy or modified Lothrop approach), have also offered new possibilities for the management of frontal sinus disease.[23-25] In particular, the combination of a Draf III approach with an osteoplastic procedure enables the management of frontal sinus lesions such as tumors without the necessity of frontal sinus obliteration. This combination of endoscopic and external approach means that the big disadvantage of obliteration, the loss of subsequent accurate imaging, is eliminated and the frontal sinus can be monitored directly via endoscope, with either angled rigid scopes or a flexible endoscope, during routine follow-up.

Turbinate Management

At the end of the procedure, attention should be directed toward the middle turbinate to help ensure a good postoperative result. Any exposed bone should be removed. A floppy middle turbinate should be stabilized; frequently this is done via a controlled scar to the nasal septum. At 1 month or more in the postoperative period, the adhesions between the septum and middle turbinate may be lysed to return the middle turbinate to its normal profile.[26] Another option to stabilize the middle turbinate and prevent a lateralized one is to suture the turbinate to the septum with an absorbable suture. Routine amputation or resection of the middle turbinate is not recommended because it alters whatever is left of normal physiologic actions of the turbinate and because the stump often lateralizes anyway, causing iatrogenic frontal sinus disease.

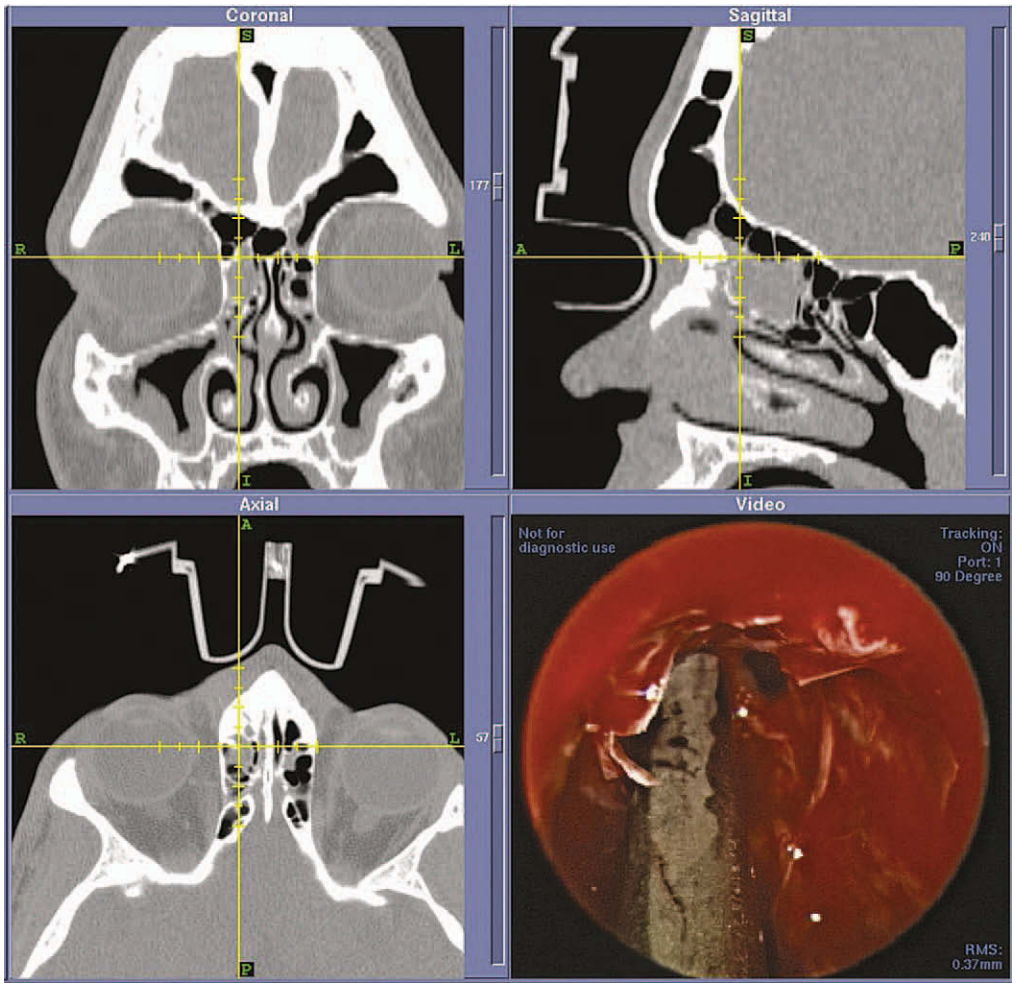

Figure 52-16. Intraoperative images from endoscopic surgery using an image-guided navigation system. The cross hairs on the reformatted three-dimensional computed tomography (CT) scans (*top, bottom left*) denote placement of the probe as seen in the endoscopic view (*bottom right*).The sagittal CT image (*top right*) demonstrates both a frontal bullar cell and a suprabullar cell, whereas the axial image (*bottom left*) shows an interfrontal sinus septal cell, a supraorbital ethmoid cell, an agger nasi cell, and a type I frontal cell. The endoscopic view shows the image-guided probe at the top of an agger nasi cell cap.

Computer-Assisted Navigation and Intraoperative Imaging

One of us (JNP) has used computer-assisted navigation devices during selected ESS procedures for the past 18 years. However, the early devices were based on rigid arms, had software that was not user-friendly, and required that the patient undergo general anesthesia and rigid head fixation. Additionally, a repeat CT was required the day before surgery with fiducial markers in place, so as to allow accurate registration of the patient's head during surgery.

Significantly more user-friendly devices based on either electromagnetic or infrared tracking have become available in the past decade. These newer devices allow head movement and yet provide reasonable accuracy (generally within 2 mm) for ESS. No devices have yet been demonstrated to clearly reduce complications during surgery, but they do provide the surgeon with additional information and probably also permit more complete surgery to be performed. The technology is changing, but at the time of writing, it appears that all devices have relative advantages and disadvantages.

The ability to check the anatomy with computer-assisted imaging may have an advantage in any given case, but computer-assisted navigation is particularly important during a transseptal frontal sinusotomy (Draf III) procedure and is almost essential for removal of a large fibro-osseous tumor that is based in a critical area. Similarly, computer-assisted imaging is helpful during transnasal endoscopic pituitary surgery to help ensure that the pituitary dissection is performed in the midline despite a slightly oblique transethmoid approach.

Because computer-assisted surgery is based on computer storage and manipulation of the preoperative CT data, the limitation of this technology is that it does not record any changes in the relative anatomy that occur intraoperatively. Unlike intracranial surgery, however, endoscopic sinus surgery is generally performed within a stable space delimited by boundaries of bone, so the limits of the dissection are generally fixed, and this is not generally a critical issue. Nevertheless, it becomes an issue when surgery is performed within the sella turcica or intracranially or where there is marked loss of bone. These problems can be overcome with the use of intraoperative MRI or intraoperative CT, both of which provide a real-time image. Unfortunately, intraoperative MRI currently is prohibitively expensive for use in routine sinus surgery, in terms of both the cost of the magnet and the special nonferromagnetic instrumentation required for the surgery. Intraoperative CT involves additional radiation exposure for both patient and surgeon. The newest intraoperative CT scanners have the advantage of using a volumetric protocol rather than helical slices. This change in protocol allows the radiation exposure to the patient to be $\frac{1}{7}$ to $\frac{1}{10}$ that of a standard head CT scan, and therefore worth the added radiation when one considers the clinical information garnered, which can then be uploaded to the image guidance system. We suspect the future will combine the advantages of intraoperative CT scanning with computer-assisted surgery in one machine.

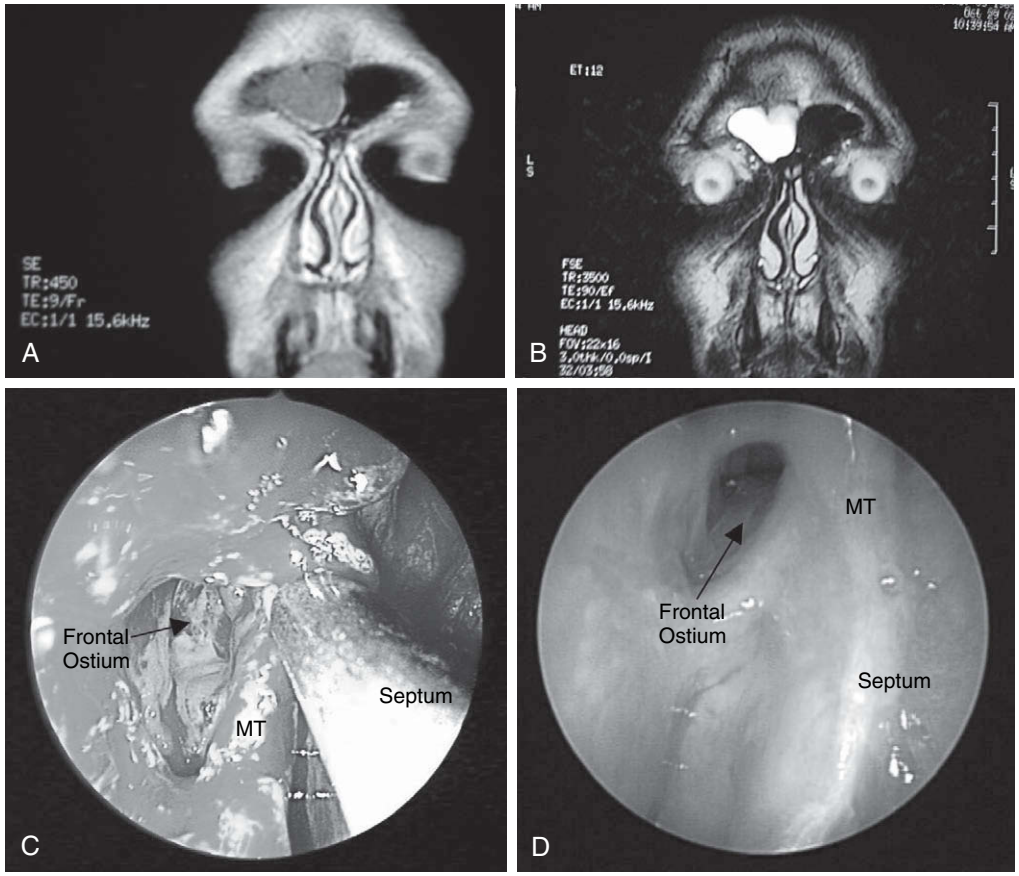

Figure 52-17. A patient with recurrent frontal sinusitis after endoscopic sinus surgery that included amputation of the middle turbinate (MT). Appearances on T1-weighted **(A)** and T2-weighted **(B)** magnetic resonance images are consistent with mucocele. **C,** Intraoperative photograph of the mucoperiosteal flap advancement onto the skull base medially. **D,** Endoscopic view (with 70-degree telescope) demonstrates a patent ostium 1.5 years after surgery; the patient had no symptoms.

Postoperative Medical Management and Débridement

Medical therapy in the postoperative period includes antibiotic coverage instituted in the operating room and, when possible, adjusted postoperatively according to results of culture of intraoperatively collected specimens. Long-term antibiotic therapy may be indicated in a patient with evidence of significant bone inflammation. In many patients undergoing revision procedures in which there is significant bony change but *Pseudomonas* is not present, a combination of clindamycin and trimethoprim-sulfamethoxazole is a consideration for treatment. At any point in the postoperative period, if the inflammation increases and pus is seen, the cavity is resampled for culture, and appropriate antibiotics are instituted.

All patients are given long-term topical steroid sprays to minimize postoperative edema, to reduce the need for oral steroid use, and to decrease the potential for late recurrence. The most common site for disease persistence and recurrence remains the frontal recess. Therefore, multiple ways have been described to increase topical steroid deposition in this area. The Moffat head-down position and the Mygind head-hanging in hyperextension are two positions in common use. The following alternative approach may allow the patient to maintain the position and hold the spray in the nose for a longer period: The patient is instructed to place a couple of large pillows on the bed, to spray the nose while sitting on the bed, and then to roll over, lying prone with the head alongside the pillows with the neck flexed and the forehead dependent. This relatively comfortable position (Kennedy position) can be maintained for at least 5 minutes. The dosage of any oral steroid administration begun in the preoperative setting is slowly tapered on the basis of the endoscopic appearance of the mucosa over days to weeks, but in severe disease the course may need to be prolonged or the dosage even slowly reduced to an alternate-day, low-dose maintenance regimen.

Patients are instructed to use saline spray frequently in the postoperative period and may be instructed to irrigate the nose with a saline solution using either a bulb syringe or Waterpik. However, meticulous attention must be paid to cleaning and aseptic technique to prevent the introduction of gram-negative organisms. An antibiotic may be added to the saline solution, either in Wilson's solution (80 mg gentamicin in 1 L normal saline) or mupirocin (7.5 mg mupirocin in 1 L normal saline). Multiple topical preparations of antifungal medications have been tried, including nystatin, amphotericin B, and itraconazole. The administration of topical antifungal medications seems rational in the patient with fungal sinusitis, but the data on their efficacy are difficult to interpret.

Débridement begins at postoperative day 1, when the polyvinyl acetal (Merocel) sponges are removed, and the cavity is suctioned. We believe that this ability to suction mucus postoperatively from the dependent sinuses, before it becomes heavily contaminated with bacteria and mold, is a significant advantage of a removable rather than an absorbable spacer in the middle meatus. Débridement is then initially performed weekly and continued as necessary until the entire cavity is healed, all exposed bone is mucosalized, and the mucosa itself has stabilized. The frequency and the amount of débridement are determined primarily by the amount of inflammation present, because greater inflammation increases the tendency for scarring. In severe disease, débridement can be a labor-intensive process that requires both topical analgesia and, frequently, an oral narcotic/analgesic. Any persistent exposed bone is removed, crusts are cleaned, and any pools of blood clots or mucus are suctioned from the cavity. Any cells not removed at

surgery and discovered in the postoperative period can be removed at this time. Areas of possible stenosis, scarring, or synechiae are lysed and removed with through-cutting forceps. Such visits may take as long as 30 minutes, and it might seem as if the surgeon is "doing the surgery again." The tendency to form scarring slowly decreases as the inflammation decreases with continued medical management. In the office setting, local anesthesia can be achieved using 1% lidocaine (Xylocaine) with 1:100,000 adrenaline administered with a long, 27-gauge needle attached to a tuberculin syringe. The needle can be bent to allow infiltration directly at the site. For more posterior access, an angled tonsil needle or spinal needle can be used.

Long-term follow-up and medical management are required for patients who undergo revision surgery. Because patients who have had surgery are at risk for persistence of disease, and because persistent disease is frequently asymptomatic in the early postoperative period, the critical factor guiding care is the appearance of the cavity on nasal endoscopy rather than symptoms. The postoperative care for a patient who has had revision surgery can easily last at least a year with a decreasing frequency of visits, but in severe disease it is commonly even longer.[27] Over this period, while the inflammation is settling down, multiple courses of oral steroids and culture-directed antibiotics may be required. The occurrence of a viral upper respiratory infection during this period may need additional attention, with either prophylactic antibiotic coverage or a short course of oral steroids to manage the hyperreactive mucosa. However, over time, the mucosa typically stabilizes and returns to more normal function. Symptoms should be monitored closely. Pain and pressure in the postoperative period are uncommon and should prompt further investigation, because they are frequently signs of persistent inflammation. Postnasal discharge is common, resolving slowly and sometimes incompletely. Loss of olfaction is a sensitive sign of return of disease and also an indication for repeat endoscopic evaluation and, possibly, additional medical management.

Patients undergoing revision surgery may require endoscopic follow-up for years if a stable cavity is not obtained. In terms of the goal of disease resolution, it is much more effective to intervene earlier in the disease process with débridement, steroids, and antibiotics than to wait until the patient requires another revision procedure for removal of hyperplastic or polypoid disease. In the setting of well-performed surgery, the appearance of mucosal hypertrophy or inflammation or any return of symptoms, especially loss of olfaction or nasal congestion, requires aggressive medical treatment. However, in all situations, the goal is to minimize oral steroid therapy and replace it with a combination of topical and mechanical treatments whenever possible. In addition to environmental and allergy management, adjunctive therapy with antihistamines, antileukotrienes, and anti–immunoglobulin E monoclonal antibody may be considered. Imaging with another CT scan is not typically required as long as a nicely patent cavity is achieved. However, postoperative CT can be help evaluate whether any cells were missed in the original procedure or whether frontal stenosis has reccurred.[28-30]

Conclusion

The concept of functional endoscopic sinus surgery is to surgically remove inflamed tissue and bone from critical points in the mucociliary clearance pathways. In inflammatory disease, it is one tool of an armamentarium of therapies utilized in an overall management aimed at the inflammation and the inciting factors causing that inflammation in the nose and sinus cavities. However, the same surgical techniques have been extended to manage a variety of neoplastic and other lesions of the nose and skull base, and continued refinements in technique and instrumentation will further expand the opportunities for these techniques in the years ahead.[31]

CHAPTER FIFTY-THREE

Management of the Frontal Sinuses

Nick S. Jones

Key Points

- Use instruments in the frontal recess only with good reason.
- In most circumstances it is desirable to establish drainage.
- Preserve mucosa around the frontal recess.
- Maintain bony support around the frontal recess.
- Avoid pressure necrosis of mucosa if a stent is used (rarely necessary).
- If obliteration of the sinus is required, remove all mucosa.

Acute Frontal Sinusitis

Acute bacterial frontal sinusitis is relatively uncommon and it normally follows a viral upper respiratory tract infection. Typically the patient with frontal rhinosinusitis presents with a low-grade fever, malaise, and a frontal headache often accompanied by marked tenderness of the medial aspect of the infraorbital margin. The infection usually responds to antibiotics with the correct antibacterial spectrum, which varies from area to area depending on the prevalence of resistance to amoxicillin. The most common organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, anaerobic streptococci, *Bacteroides*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus milleri*, and microaerophilic *Streptococcus*. Culture results–directed prescription is desirable for severe infections or for the complications of sinusitis.

Occasionally the infection does not respond and needs to be drained. It is worth placing a topical decongestant via endoscopy high in the middle meatus, because doing so sometimes allows spontaneous drainage through the frontal recess. If this maneuver does not work, the options are to trephine the frontal recess through an incision in the medial aspect of the eyebrow or to open the frontal sinus endoscopically by removing the ethmoid air cells surrounding the frontal recess while trying to preserve the mucosal lining of the recess.

Acute frontal sinusitis is normally a single infection, and the patient is unlikely to go on to have a further sinus infection. An argument can be made, particularly in children, for trephining the frontal sinus in order to reduce the chance of physician-induced stenosis of the frontal recess. Endoscopic drainage of the frontal sinus can be difficult in these circumstances because the hyperemia associated with infection can result in a lot of bleeding. Damage to mucosa in the area of the recess may result in adhesions or stenosis, leading to further problems.

Frontal sinusitis can be complicated by periorbital cellulitis or the formation of a periorbital abscess. The indications for an urgent computed tomography (CT) scan are the presence of signs of central nervous system involvement, inability to assess vision accurately, gross proptosis, ophthalmoplegia, deteriorating visual acuity or color vision, bilateral edema, no improvement or deterioration after 24 hours, and a spiking pyrexia not resolving within 36 hours.[1] Intracranial complications include a subdural empyema, intracerebral abscess, extradural abscess, meningitis, and, more rarely, cavernous and superior sagittal sinus thrombosis. It is important to be aware that almost 50% of patients with intracranial complications present with a periorbital cellulitis or frontal swelling. Therefore it does not follow that a collection of infection that spreads around the orbit excludes any intracranial involvement.[2] It is important to look for the symptoms or signs of intracranial involvement—namely, an altered mental state, headache, vomiting, seizure, neck stiffness, papilledema, unilateral weakness, and signs of cranial nerve involvement. If there is intracranial involvement, sinus surgery has a role in obtaining pus for culture as well as draining the collection if the sinus is in continuity with the intracranial collection.

Chronic Frontal Sinus Disease

Before a discussion of the specific management of this condition, it is worth considering the history of frontal sinus surgery.

In the pre-endoscopy era, the principles of surgical treatment of the frontal sinus were essentially the same as they are now; namely, when antibiotics failed, drainage of the frontal sinus was the primary goal.

Jurasz was the first surgeon to describe an intranasal approach to the frontal sinus. Ogston[3] in the late 1880s and Luc[4] in the next decade described trephination and widening of frontonasal duct through the anterior ethmoid sinuses. Brieger[5] first described the osteoplastic operation in the 1890s. Riedel[6] described a technique in 1889 wherein he removed its anterior and inferior walls. This technique resulted in a cosmetic deformity that would require a second operation if an improvement in cosmesis was sought. In 1908 Knapp[7] advocated an extensive ethmoidectomy through the medial orbital wall, leaving the anterior wall of frontal sinus intact but removing the diseased mucosa and enlarging the frontonasal duct. Lothrop[8] in 1912 resected the frontal floor between the frontal recesses and the intersinus septum along with the upper aspect of nasal septum after an ethmoidectomy

via an external approach as described by Lynch. By 1921 Lynch[9] and Howarth[10] had surgically entered the frontal sinus through an external approach via the medial orbital wall and, like Knapp, removed sinus mucosa and left a stent in position to try to maintain a patent duct. The osteoplastic flap with fat obliteration then became popular for the treatment for persistent frontal sinus disease. Macbeth[11] and Bosley[12] later postulated that fat obliteration is not necessary, as they claimed that the cavity is filled by osteoneogenesis. However, I and others have found that, unless the frontal sinus is obliterated in this procedure, loculated areas within the sinuses are more likely to form, which may become infected or form mucoceles.

With the introduction of CT and endoscopes, it became possible to open the frontal recess to a greater or lesser extent, with mucosal preservation dependent on the extent of disease and the skill of the operator.

The bacteriology of chronic rhinosinusitis differs from that of acute rhinosinusitis, in that there is a higher prevalence of anaerobic organisms with the chronic form. Typical infections include *S. pneumoniae*, *H. influenzae*, *Moraxella catarrhalis*, and, when there has been previous surgery, methicillin-resistant *S. aureus*, *Pseudomonas aeruginosa*, and *Enterobacter*. Obtaining a culture and determining antibiotic sensitivities of the organisms grown is vital in the treatment of purulent disease, and care in the taking and culture of specimens is important in culturing anaerobic organisms.

In the medical treatment of bilateral chronic rhinosinusitis without purulent secretions, there is growing evidence that some antibiotics work not only through their antibacterial action but also by down-regulating inflammation.[13] Long-term (12 weeks to 6 months), low-dose therapy with erythromycin, clarithromycin, and other macrolides along with douching has been shown to be beneficial.[14] The efficiency with which an antibiotic disperses biofilms may also be of importance.

Indications for Surgery in Chronic Frontal Sinusitis

Disease in many patients with chronic frontal sinus disease appears to have been initiated by unnecessary instrumentation of the frontal recess. In order to make a diagnosis of chronic frontal sinusitis, the clinician must find out whether the periodicity of symptoms correlates with upper respiratory tract infections or changes in barometric pressure or are associated with a purulent discharge, because many patients with frontal symptoms have tension-type headache. Opacification of the frontal recess alone is not a reason to use instruments in the frontal recess, because the opacification is often due to retained secretions that will clear if the ostiomeatal complex is opened and medical treatment is given.

The primary indication for instrumentation of the frontal recess is when maximum medical treatment has failed to help frontal sinus symptoms, and a partial anterior ethmoidectomy and medical treatment have not succeeded.

There are few other reasons for operating on the frontal recess before trying a partial anterior ethmoidectomy along with medical treatment; these reasons include the presence of fungal disease in the frontal sinus, barotrauma, mucocele (Figs. 53-1 to 53-3), an osteoma causing obstruction with evidence of mucosal disease, and other pathology, such as osteomyelitis (Fig. 53-4) and tumors.

The normal frontal recess is narrow, raising a question as to the role of anatomic variations in the pathogenesis of rhinitis. The frequency of such "variations" and anatomic "restrictions" appears to be no higher in a control population than in a patient with proven rhinosinusitis.[15] It seems likely that the primary problem is the mucosal pathology or a patient's immunity—the reason why one individual experiences chronic rhinosinusitis and another does not.

The variability of the anterior ethmoid air cells makes them a fascinating subject on their own. In more than 94% of people there are anterior ethmoid air cells over the lacrimal bone or adjacent to the anterior aspect of the middle turbinate; these are called *agger nasi cells*. A high anterior ethmoidal cell that has pneumatized into the frontal bone, known as the *bulla frontalis,* can displace the frontal recess posteriorly and medially. The bulla frontalis can be so large that it can mimic the frontal sinus, almost forming a sinus within a sinus. Not infrequently a *supraorbital cell*—that is, a posterior cell in the anterior ethmoid complex that is well pneumatized—can extend laterally into the frontal bone over the orbit and also can narrow the frontal recess by pushing it forward. Occasionally air cells exist within the frontal sinus itself, the ostia of these cells draining within the frontal sinus.[16] Another variation is the intersinus septal cell that may extend into the crista galli; this cell often drains into the frontal recess. The prevalence of these variations does not appear to correlate with the presence or absence of frontal sinus disease.

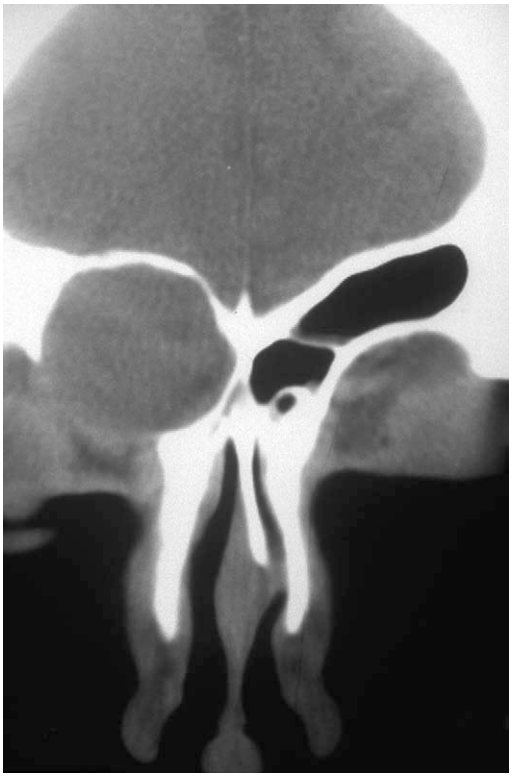

Figure 53-2. Computed tomography scan of the right frontoethmoid mucocele shown in Figure 53-1.

Endoscopic Frontal Sinusotomy

There are two main approaches to opening the frontal recess, each with the aim of "deflating" the cells or "balloons" of the ethmoid air cells and preserving the mucosa around the recess as much as possible. To this end a submucosal dissection, removing the thin walls of the agger

Figure 53-3. Postoperative view of patient in Figure 53-1 after endoscopic marsupialization of the right frontoethmoid mucocele.

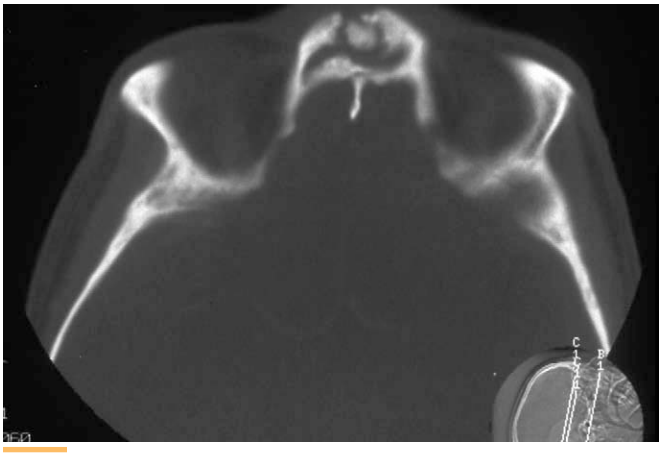

Figure 53-4. Osteomyelitis of frontal bone with bony sequestra.

nasi cells and using through-cutting instruments to remove excessive mucosa, leaves a mucosa-lined recess that is far less likely to stenose.

One method of accessing the frontal recess involves removing the superior remnant of the uncinate process with a 45-degree through-cutting forceps or a punch. A 45- or 70-degree endoscope is then used to examine the area. Careful palpation, not prodding, with a ball probe next to the middle turbinate reveals a crevice between the middle turbinate and the agger nasi cells. The aim is to open this crevice, which will turn out to be the pathway to the frontal recess and the frontal sinus, by "deflating" the cells. This is best done by passing the ball probe well above them and gently fracturing them to one side. The shaft of a Kuhn curette works well for this maneuver (Figs. 53-5 and 53-6). If visibility is good, it may be possible to do this by submucosal dissection. Fragments of bone are removed, with care taken not to grab the mucosa, because doing so might leave bone exposed and predispose to scar tissue and stenosis.

When they are opened, agger nasi cells, the terminal recess, and the ethmoid bulla can all form concave domes of a variable size and give the appearance of the frontal sinus, but the sinus itself has a convex posterior surface that is distinctive. It is possible to confirm that an instrument is actually in the frontal sinus by using a ball probe, a Kuhn curette, or a curved sucker as a sound, passing it into the area in question and then registering the angle and length of this ball probe in relation to the maxillary spine. To ensure that the instrument is within the frontal sinus, the surgeon can grip the shaft of the ball probe between the thumb and the index finger next to the nasal spine, noting the angle of the instrument at the same time. The surgeon then withdraws the instrument and places it alongside the outside of the nose,

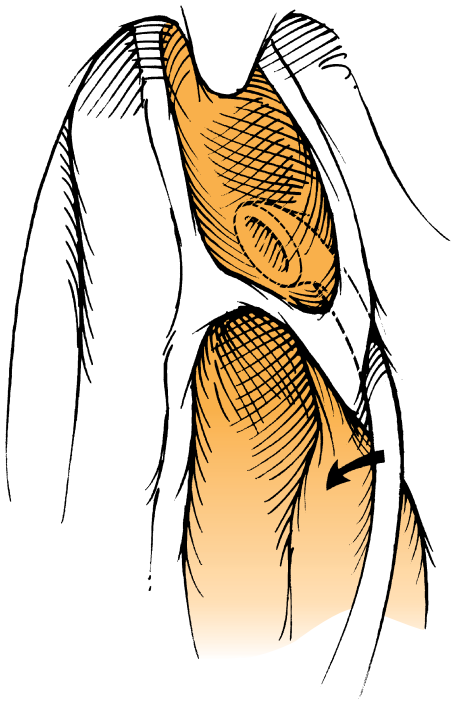

Figure 53-5. A Kuhn curette is used, submucosally if possible, to pull down and remove the roof of an ethmoid air cell. Fragments of bone from the agger nasi cell are removed, but the mucosa is preserved. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

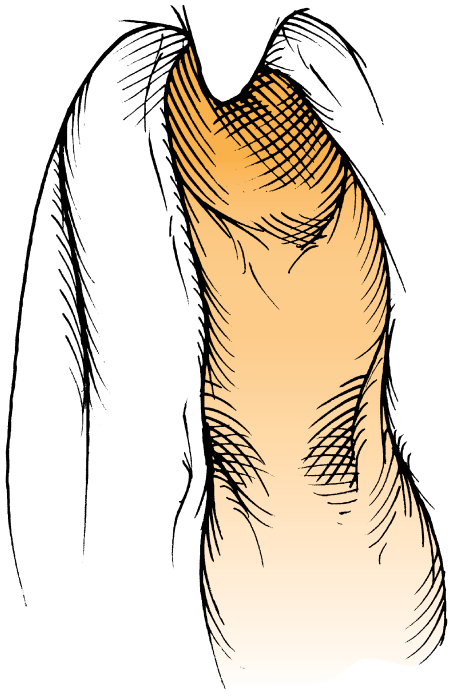

Figure 53-6. The right frontal recess after removal of the ethmoid air cells. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

at the same angle it had in the sinus and with the pinch grip placed alongside the nasal spine (Figs. 53-7 and 53-8). If the end of the ball probe is then higher than the eyebrow line, the instrument was probably in the frontal sinus. If the instrument is around or just above the medial canthus, then the ball probe is likely not within the frontal recess

Figure 53-7. Confirming location of instrument in the frontal sinus. The surgeon "pinches" the instrument against the maxillary spine, noting the angle of the instrument. (See Figure 53-8.)

Figure 53-8. Confirming location of instrument in the frontal sinus (see Figure 53-7). The surgeon then aligns the instrument outside the nasal airway at the same angle, keeping the fingers at the same place on the instrument against the nasal spine. If the end of the probe is well above the medial canthus, it is likely to be within the frontal sinus when reinserted. (The exception is a large bulla frontalis, presence of which can be checked for on the computed tomography scan.)

but is within an agger nasi cell. If the handle of the ball probe is noted to have been turned laterally when it passes up through what is thought to be the frontal recess, it may have been channeled in this direction by a bulla frontalis or a supraorbital cell, and the surgeon should correlate this possibility with the CT scan.

It is vital not to prod with any instrument medially as it is passed toward the frontal recess, because the lateral lamella is usually the thinnest part of the skull base and it would be easy to cause a cerebrospinal fluid leak in this area. To avoid entering the orbit, the surgeon should not push in any way laterally. Instead the surgeon should check the proximity of the orbit and the pattern of air cells on CT and ask the assistant to ballotte the eye while this area is being examined to make sure the orbit has not been entered.

An alternative method is to approach the frontal recess anteriorly with a 0-degree scope if there is a large agger nasi cell. An anteriorly based mucosal flap on the lateral nasal wall is raised over the prominence of agger nasi cells. A punch is used to remove the "armpit" of the area where the middle turbinate attaches to the lateral nasal wall, the agger nasi cells are removed submucosally, and the lateral flap is placed over any raw bone to further reduce the chance of stenosis.

Figure 53-9. Ten previous external ethmoidectomy procedures have resulted in a loss of lateral bony support and scar tissue around the frontal recess. Small mucoceles have also formed.

If previous surgery has caused stenosis and there are few landmarks, access to the frontal recess can be difficult. In such cases it is safest to palpate anteriorly, where the bone is very thick, and any probe must be angled vertically to reduce the risk of a cerebrospinal leak or of entering the orbit. A "mini-trephine" can help define the site of the frontal recess. An incision is made within the medial aspect of the eyebrow, and a small bur hole is made into the sinus. Fluorescein dye can then be placed into the frontal sinus and then sought endoscopically within the nose to see where it comes out.

Lynch-Howarth External Ethmoidectomy

The Lynch-Howarth external ethmoidectomy has largely been replaced by endoscopic techniques because stenosis developed in approximately a third of patients who underwent the procedure.[17,18] An external scar, the necessary loss of bone lateral to the frontal recess, and loss of mucosa often result in scar tissue and stenosis of the frontal recess.

A curved incision is made from the inferomedial aspect of the eyebrow and extended along the upper third of the nose, with a break in it shaped like the silhouette of a seagull (to produce less webbing). If the area of the trochlea—the sling of the superior oblique muscle attached to the superior-anterior-medial aspect of the orbit—is involved, it must be cut cleanly away from the periosteum, not torn, to avoid damaging it and causing diplopia. The anterior ethmoidal artery may have to be clipped or ligated. The thin medial wall of the orbit is perforated, and the opening is enlarged with a punch. The ethmoid air cells are removed, and the frontal recess is opened. As much medial bony support to the recess is retained as possible. Historically, as large a stent was placed in the frontal sinus as it would accept. It is now recognized, however, that the stent causes pressure necrosis of the mucosa, leading to medium- and long-term stenosis. Local mucosal flaps have been advocated but are rarely possible, and a free mucosal or composite graft can be used with a loose stent.

It is possible to support and reconstruct the lateral wall of the frontal recess to prevent its collapsing or to deal with collapse of that area. The problematic circumstances affecting this area are large mucoceles and previous surgery in the area, particularly when an external ethmoidectomy has led to a loss of bone lateral to the frontal recess (Fig. 53-9). There is often a great deal of fibrosis in the area of the frontal recess if it has stenosed after an external ethmoidectomy. It is rarely possible to reflect a septal flap that can extend into this area and provide the lining for a new channel; a free turbinate graft is the main option. A free cartilage graft from the septum or conchal bowl is sutured in position with mucosa over it, and a loose stent is placed to hold it open (Figs. 53-10 and 53-11). The stent is loose in order to avoid any pressure necrosis on the graft. Its placement provides lateral support and reduces the chance of further stenosis. Two weeks after the proce-

Figure 53-13. Paget's disease of the frontal bone, an indication for an external approach.

dure, endoscopy shows that the stent is loose and surrounded by healthy mucosa in the frontal recess.

Median Frontal Sinus Drainage Procedure

In the median frontal sinus drainage procedure, the frontal recesses are opened to create a central drainage channel by removal of the top of the septum, the frontal intersinus septum, and the anterior beak of the frontal bone (Fig. 53-12).[19] The procedure is indicated when the lateral support has been removed in an external procedure, allowing medial collapse of the orbital contents or as a method to address stenosis of the frontonasal recess.

The nasal process of the frontal bone is thick posteriorly, forming a "beak" that can be removed to help create a large central drainage channel. The frontal intersinus septum varies greatly in its position. The main concern with this procedure is that the cribriform plate is positioned behind the posterior limit of the coronal plane that connects the frontal recesses. Laterally, the bone of the lamina papyracea is preserved to avoid prolapse of the orbital contents, which might impair drainage.

Both frontal recesses are identified, and then the bone anterior to and between them is removed. Image-guided equipment can help *confirm* the position of instruments, but the definition is not reliable enough to operate by. Unlike with other procedures in the frontal recess, it is not possible to preserve mucosa around more than a minority of its circumference.[20]

Obliteration of the Frontal Sinuses

Obliteration of the frontal sinuses is a more invasive procedure, particularly if the sinuses are well pneumatized, as is often the case. The surgeon should beware if the patient has Paget's disease of the bone, because the bleeding can be torrential (Fig. 53-13). A coronal flap using a zigzag incision disguises the scar well in patients with male-pattern baldness. Alternatively, the sinus can be approached through an eyebrow incision (Figs. 53-14 and 53-15). A sterilized template of the frontal sinus can be constructed either from a preoperative Caldwell's view radiograph of the frontal sinus or from a three-dimensional model based on digital CT data. A plain radiograph fails to account for some pneumatization, so if a template alone is used to remove the anterior plate, it will leave some overhang because areas of pneumatization often occur superiorly and laterally, even extending to the zygomatic process. An alternative is for the extent of the sinus to be gauged by image-guided surgery. It is worth dissecting the periosteum off the frontal

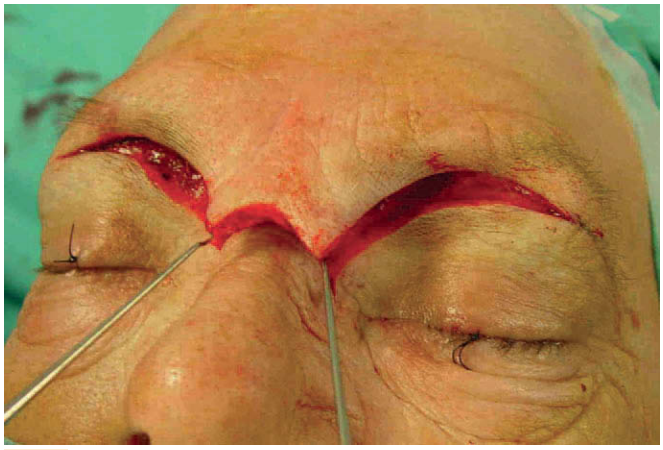

Figure 53-14. An eyebrow incision.

Figure 53-15. Postoperative appearance 9 months after an eyebrow incision.

bone down to the supraorbital margins. This description differs from conventional descriptions, in which the anterior wall is hinged on a flap of periosteum inferiorly. Such a hinge arrangement is rarely possible without putting the periosteum in tatters between the areas where bone has been divided along its inferior margin. Past descriptions of retaining intact periosteum on the frontal bone are misleading. It is important to remove all the mucosa from the whole of the frontal sinus, because if any is left, a mucocele forms. The mucosa is removed not only from the posterior wall but also from the anterior flap, and this removal is difficult to perform thoroughly while the flap is still attached to the periosteum.

The outline of the frontal sinus is estimated with the use of a template, image-guided surgery, or shining an endoscope transnasally into the frontal recess, and an initial hole is made into the sinus in its medial third. A blunt-ended hook can be used to check the outline of the extent of the frontal sinus,[21] and by rotating the hook to where its end reaches the limit of the frontal sinus, the surgeon can follow the outline around with a fissure bur (Fig. 53-16). This maneuver reduces the amount of overhang left after the anterior wall is removed and makes removal of the mucosa easier. It is unwise to make an entry hole high in the midline, where the venous sinuses are large, because entry there can cause torrential bleeding. Before the whole anterior plate is removed, it is worthwhile to fix miniplates onto its anterior wall (to be removed subsequently) and to make bur holes into the cranium to match them; this step makes replacement of the plate at the end of the procedure not only more accurate but quicker.

It is vital to remove all the mucosa of the frontal sinuses before they are obliterated, to avoid formation of a mucocele; a Mitchell's trimmer is an ideal shape for this maneuver. Donald[22] has shown that mucosa follows the veins of Breschet into the posterior wall of the frontal sinus, so these structures must be cleared by drilling of the posterior wall a fraction of a millimeter. The remaining bony walls, including the back wall of the anterior frontal plate, should be drilled with a diamond bur to ensure that all the mucosa has been removed. Care must be taken not to enter the orbit. The floor of the frontal sinus can be very thin, and if it is entered, orbital fat can prolapse upwards, making it difficult to remove the mucosa around this area. If fat does prolapse into the orbit, it can be ablated with bipolar diathermy, but it should not be pulled or pushed. Entering the orbit causes a periorbital ecchymosis, and the vision and orbital pressure must be checked postoperatively to ensure that the vasculature of the optic nerve is not compromised by any bleeding into the posterior-septal compartment of the orbit.

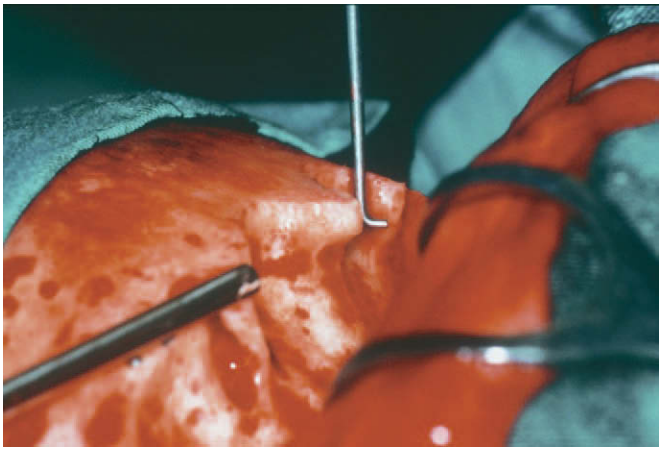

Figure 53-16. A blunt-ended hook can be used to palpate the limit of the frontal sinus and help reduce the amount of overhang. Here the hook is shown after the anterior wall has been removed to better illustrate how it is used.

Once all of the mucosa has been removed, the frontal recess is separated from the nasal airway with a sheet of fascia lata, and fat is used to obliterate the sinuses. The bony plate with its attached mini-plates is then secured, and the pericranium and coronal flap are closed with 2-0 polyglactin 910 (Vicryl) sutures and skin staples. The anterior bone flap is susceptible to infection, so prophylactic antibiotic coverage should be prescribed. A relatively tight cotton elastic bandage is placed to ensure that no hematoma develops between the flap and the bony plate; the bandage is kept in place for at least 3 days.

Various materials have been used to obliterate the sinuses, ranging from muscle to bone to synthetic materials. All have their proponents, but infection of foreign material and bone implants poses a particular challenge because infected materials have to be removed.[23] Fat is readily obtained and gives results as good as, if not better than, any other material. It is important to close the frontonasal duct and to remove the mucosa along with the inner bony cortex of the frontal bone. If the anterior bony wall is also infected, Riedel's procedure is required to rescue the situation.

Postoperative monitoring of the sinuses can be a problem with this obliterative procedure, because when persistent symptoms occur it can be difficult to distinguish recurrent disease from neuropathic pain. The most helpful form of imaging appears to be magnetic resonance imaging, which although the most accurate still has its limitations. The detection of a small recurrent mucocele and the differentiation of vital adipose tissue from fat necrosis in the form of oil cysts prove to be the main difficulties. The most disastrous complication of frontal sinus surgery is infection, because the anterior plate of bone is inevitably involved and because of the incidence of resistant organisms. Even in the 1970s infection was a major concern, with reputable surgeons reporting a complication rate of 18%.[24] If infection occurs in this situ-

Figure 53-17. A laterally placed mucocele.

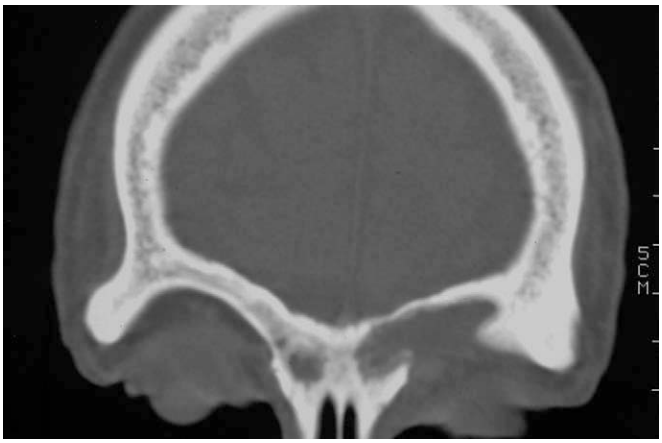

Figure 53-18. New bone formation just weeks after an infection, a contraindication to an endoscopic approach.

ation, it is best to remove the anterior wall and the remains of any sinus content with Riedel's procedure.

Indications for an External Approach

Situations in which removal of pathology and/or drainage is difficult to achieve endoscopically are as follows:

- Laterally placed mucocele
- Lateral loculation within the frontal sinus (Fig. 53-17)
- Fibrosis or new bone around the frontal recess (Fig. 53-18)
- Marked loss of bony support of frontal recess and floor of frontal sinus (previous external surgery or large mucocele)
- Coexisting malignancy
- Other pathology, such as Paget's disease of the frontal bone (see Fig. 53-13), large osteoma, osteomyelitis (see Fig. 53-4), verrucous carcinoma, squamous cell carcinoma, and inverted papilloma
- Gross prolapse of the orbital contents with a small medial anteroposterior diameter of frontal sinus preventing a wide median drainage procedure
- Narrow anteroposterior diameter of frontal sinus (even allowing for removal of the "beak" of the frontal bone)

Surgical options when there is a lack of lateral bony support and frontal recess stenosis is present are as follows:

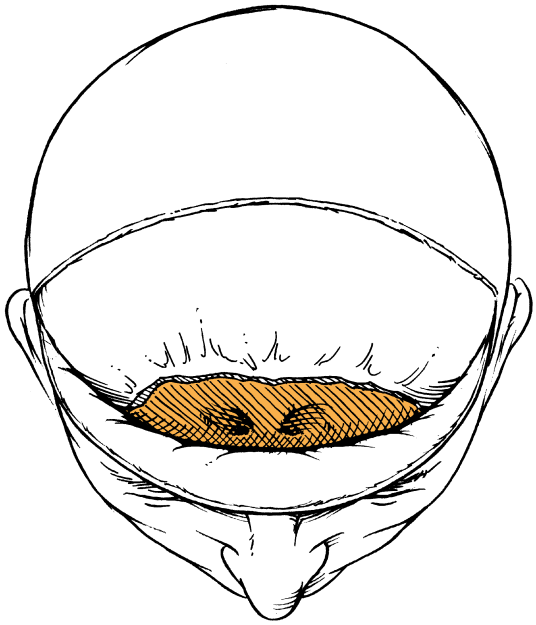

Figure 53-19. Preoperative appearance. The anterior wall of the frontal sinus has been removed.

- Median drainage procedure
- Reconstruction of bony support and mucosal lining of the frontal recess
- Obliteration

Options when endoscopic drainage is unlikely to work are as follows:

- Frontal sinus obliteration
- Riedel's procedure

Riedel's Procedure

Riedel's procedure is used for the following situations:

- Osteomyelitis of the anterior wall of the frontal sinus
- Failure of frontal sinus obliteration
- Some tumors of the frontal sinus

Most large studies of patients undergoing sinus obliteration have reported recurrent disease, yet the management of patients with recurrence is rarely discussed. The larger series reporting obliterative procedures have found a 3% recurrence rate for infection[24,25]; Weber and colleagues[26] reported a 10% chance of recurrent infection. Riedel's procedure has an important role in the management of patients with recurrent infection. Riedel's procedure can help eradicate frontal sinus disease and symptoms when drainage and obliteration have failed and there is persistent disease involving the anterior wall of the frontal sinus or the sinus itself. Although cranialization has a role in removing the mucosa or contents of the frontal sinus in craniofacial resection, the morbidity associated with it make an extradural Riedel's procedure preferable in dealing with chronic infection or locally invasive disease. Riedel's procedure maintains a barrier in the form of the posterior wall of the frontal sinus and the intracranial contents. Postoperative disfigurement, the main criticism of this procedure, can be reduced to some extent by chamfering the margins of the frontal sinus along with the supraorbital rims (Figs. 53-19 to 53-21).[27] Reconstruction of the anterior wall can be performed at a later date if necessary.

Figure 53-20. Postoperative appearance after the mucosa of the frontal sinus has been removed and the edges of the frontal sinus have been drilled down to make a smooth contour.

Figure 53-21. The bony shoulders of the cranial part of the frontal bone are removed and the supraorbital rims are reduced.

If there is a tumor in the frontal sinus, radical clearance is required. In this situation Riedel's procedure is useful. It involves removing the anterior wall and floor of the frontal sinus and all its mucosal lining.

Riedel's procedure has a useful role in the management of a small proportion of patients in whom drainage of the frontal sinus cannot be established, in whom frontal sinus obliteration has failed, or who have osteomyelitis of the anterior wall of the frontal sinus. Because the frontal sinus mucosa is completely removed, the chance of recurrent complications are few, and if recurrence happens, it can easily be recognized.

Cranialization

Cranialization of the frontal sinuses is performed in the following situations:

- When resection of the posterior wall of the frontal sinus is indicated
- For anterior skull base tumors
- In severe comminution of the posterior wall of the frontal sinus

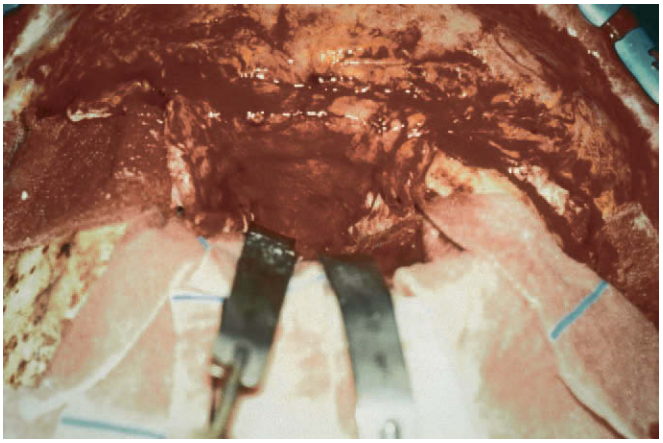

Figure 53-22. A pericranial flap is folded over the anterior skull base to separate the remaining sinuses from the intracranial contents.

In the majority of patients with either an infective or a neoplastic condition within the frontal sinus, cranialization is not desirable because it removes the barrier between the frontal sinus process and the brain. Cranialization does have a role, however, in removal of the potential problems of infection and mucocele formation that can occur after craniofacial surgery that involves the frontal sinus, as well as in trauma in which the posterior wall and, inevitably, the anterior wall of the frontal sinus have been significantly disrupted. All of the posterior wall of the sinus is removed, along with the mucosa attached to the anterior wall, which is then reconstructed. The anterior intracranial contents are separated from the paranasal sinuses and nasal airway by either a fascia lata or pericranial flap (Fig. 53-22).

Balloon Catheter Sinusotomy

The concept of using a balloon to dilate sinus ostia was introduced in 2006.[28] The idea that the balloon can dilate ostia to aid aeration and mucociliary clearance of sinuses and to minimize the risk of causing stenosis because mucosa is preserved around the ostia is attractive. Initial studies have been encouraging.[29] There are technical problems with dilatation of the maxillary sinus ostia because the uncinate process limits the introduction of the balloon; even if this problem is overcome, the narrow crevice between the uncinate process and the mucosa of the medial wall of the maxilla remains.[30] More long-term data are required before the role of this technique can be substantiated.[31] The current evidence is based on a 24-week follow-up, and a longer period of monitoring outcome is needed to eliminate the placebo effect and the cognitive dissonance as well as to ensure that the sinus ostia remain patent.

A key question is, What are the indications for balloon catheter sinusotomy? Acute frontal sinusitis usually resolves with antimicrobial treatment and is an isolated event. The immune status should be checked in patients who have more than two episodes of acute bacterial sinusitis a year,[32] because an immune problem is more likely than an anatomic irregularity to be the primary problem. Chronic bacterial infective frontal sinusitis is uncommon. The majority of patients with pain or pressure over the forehead have tension-type headache or migraine and do not require surgery, which would exacerbate the symptoms in a third of patients.[33-36] The majority of patients with rhinosinusitis and involvement of the frontal sinus have nasal polyposis, which is not amenable to balloon catheter sinusotomy—nor is osteomyelitis, mucoceles, or neoplasia. Similarly, infective sphenoid sinusitis that is unresponsive to medical treatment is uncommon. The majority of patients with symmetric facial symptoms of pressure have a version of tension-type headache that affects the midface.[37]

When balloon catheter sinusotomy was introduced, a guidewire was placed into the sinus under fluoroscopic control, but in one cadaveric study the balloon was introduced into the frontal recess on its own.[38] Researchers were unable to dilate the maxillary ostia with balloon catheter sinusotomy.[38] Is this a technique looking for a patho-

Figure 53-23. A superior view of a patient with pneumosinus dilatans of the frontal sinuses; it is more marked on the left side.

logic process to treat?[30] Its use should be studied with well-defined entry criteria, good outcome measures, and a follow-up period that would negate the effect of cognitive dissonance.

Specific Pathologic Conditions

Pneumosinus Dilatans

Pneumosinus dilatans is a rare condition characterized by the benign expansion of an aerated sinus beyond the normal margin of the frontal bone. The precise etiology and pathogenesis of pneumosinus dilatans are unknown, although a large number of mechanisms have been proposed. A *hypersinus* is an enlarged sinus with normal walls that do not extend beyond the normal boundaries of the frontal bone. A *pneumocele*, unlike pneumosinus dilatans, has walls with either generalized or focal thinning and total or partial loss of its integrity within the contours of the frontal bone.

Pneumosinus dilatans has a fluctuating course: It may be slowly progressive or may develop suddenly following a refractory period. Most cases are asymptomatic and are diagnosed only when a deformity is noticed, such as frontal bossing, or when the mass effect due to involvement of surrounding structures leads to symptoms (Fig. 53-23). Depending on the site and rate of expansion and the vulnerability of the surrounding structures, this deformity may result in diplopia, reduced visual acuity, headache, and other local pressure symptoms. Pneumosinus dilatans has been associated with pathologic conditions such as planum meningiomas and other brain tumors, arachnoid cysts, fibrous dysplasia, prolonged cerebrospinal fluid shunting and cerebral hemiatrophy infantile meningoencephalitis, von Recklinghausen's disease, and acromegaly. It can also be idiopathic. Six different hypotheses have been advanced to explain the etiology of these cases of pneumosinus dilatans; they are the presence of a gas-forming microorganism, spontaneous drainage of a mucocele, the presence of a one-way valve, congenital origin, programming of osteoblastic and osteoclastic activity, and hormonal origin.

Chronic inflammatory changes are occasionally noted histologically, although the surrounding "nonaffected" paranasal sinuses have rarely been examined; in paranasal sinuses that have been evaluated, minor chronic inflammation of the other paranasal sinus has been seen. It has been proposed that inflammation of the surrounding sinuses stimulates the pneumatization power of the subepithelial layers of the sinus mucosa, causing pneumosinus dilatans.[39,40]

The most commonly proposed pathogenic mechanism, and the one that has acquired the most credibility, is a local process involving obstruction of the sinus ostium with a one-way valve mechanism.[41] In this hypothesis, the one-way valve results in long-term air trapping in the affected sinus, by which air entering under positive pressure after events such as nose blowing is subsequently prevented by the valve from escaping. The best experimental evidence for a one-way valve mechanism comes from antral pressure studies showing the absence of patent ostia together with a loss of normal antral pressure variation with the respiratory cycle and increased sinus pressure for several minutes after Valsalva's maneuver. Other evidence for a one-way valve comes from the pain experienced in the affected sinus by some patients during changes in atmospheric pressure, such as flying or diving, or with nose blowing.

Evidence against this "trapdoor" theory includes the normal drainage of sinus secretions in the affected sinus; one would expect mucus to be trapped by the partial obstruction of the valve. In addition, none of the involved sinuses has notable mucoperiosteal thickening or other evidence of infection, which would be expected with ostial obstruction. Complete occlusion of the sinus would be expected to lead to negative antral pressures and effusion but not sinus expansion. Furthermore, the highly vascularized nature of the mucosal lining would be expected to reduce the pressure of the gases by diffusion in a relatively short time, preventing any long-term effects; in fact the pressures demonstrated after Valsalva's maneuver have been shown to be normal in some patients with pneumosinus dilatans. For there to be a trophic effect on bone, a sustained pressure would probably be required. This theory would not explain the focal cases of pneumosinus dilatans.

The congenital conditions associated with pneumosinus dilatans, such as the finding of an association with polyostotic fibrous dysplasia (McCune-Albright syndrome) may help support the theory that a genetically altered sinus becomes enlarged after it is acted upon by a programmed alteration in the balance between osteoclastic and osteoblastic activities—hence the association of pneumosinus dilatans with conditions such as acromegaly. This theory is as yet unsubstantiated.

A variety of surgical options for treating this condition, based on a presumed etiology of occlusion of the sinus ostium by a one-way valve, have been proposed. In the majority of cases, opening the sinus ostium has been shown to arrest expansion of the sinus. In patients who have a functioning ostium, the cosmetic deformity is of primary importance and can be corrected by resection and a bone graft from the cranial vault.

Mucoceles

A paranasal sinus mucocele is an epithelium-lined sac containing inspissated mucus.[42] Obstruction of a sinus ostium has been suggested as the primary etiologic factor. The obstruction may be due to a mass lesion or secondary to fibrosis, inflammation, osteoma, fibrous dysplasia, Paget's disease, or, rarely, malignancy, trauma, or previous surgery. Local production of bone resorption factors such as prostaglandins, interleukin-1, and tumor necrosis factor have been identified at the interface between the mucocele and bone.[43,44] Other researchers suggest that expansion occurs through the direct effect of positive pressure within the mucocele.[45] Irrespective of the method by which expansion arises, subsequent intraorbital or intracranial extension can occur.

Prior to surgery, assessment of the size and location of the lesion on CT is important. The accepted, preferred method of managing paranasal sinus mucoceles is endoscopic marsupialization, if possible. The significant early, medium-term, and long-term recurrence rate, between 9% and 15%, should be explained to the patient as part of the consent process.

Osteoma

Osteomas rarely cause symptoms except when they are large enough to cause a cosmetic deformity (Fig. 53-24) or a mucocele.[46] The presence of other symptoms, such as pain, should prompt clinical suspicion of another cause, because an osteoma rarely causes such symptoms. Osteomas are so common that they are likely to be a coincidental finding; approximately 3% of people have an osteoma in the paranasal sinuses. Often, the lesions are blamed for causing headaches or excision is recommended before they do cause symptoms. Actually, however, osteomas rarely cause any problems other than cosmetic. If an osteoma does cause symptoms by obstructing the frontal recess, the history should include symptoms that are worse after upper respiratory tract infections and there should be endoscopic and CT findings of mucosal disease. All too often tension-type headaches are blamed on an osteoma that is coincidental.

Figure 53-24. An axial view of a right frontoethmoid osteoma that is causing marked proptosis.

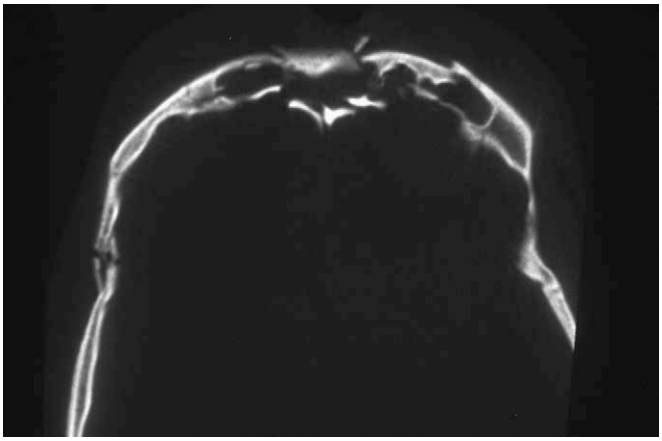

Figure 53-25. A fracture of the anterior and posterior walls of the frontal sinuses, which is best managed by cranialization and reconstruction of the anterior wall.

The removal of an osteoma depends on how accessible it is. The endoscope can be used to shell out the osteoma, and then its walls can be removed or fractured inwards. Because the most symptomatic lesions are in the frontal recess, it is important to establish drainage, which usually requires removal of the osteoma combined with a median drainage procedure.

Fractures of the Frontal Sinus

Frontal sinus fractures that are restricted to the anterior wall do not require exploration unless there is a significant cosmetic defect. The exception to this rule is when a fracture affects the frontonasal duct—these are often overlooked. Undisplaced posterior wall fractures without any complications such as cerebrospinal fluid leak can be managed conservatively. In a patient with a compound comminuted fracture affecting the posterior wall (Fig. 53-25) or near the frontonasal duct, cranialization of the frontal sinus by removal of the posterior wall along with all the mucosa and obliteration of the frontonasal recess is the best treatment.[47,48]

Split calvarial and corticocancellous grafts are best for reconstructing the anterior wall if there is a large defect. When initial débridement is undertaken, any fragments of bone can be cleaned and left in the wound for later use if needed.

CHAPTER FIFTY-FOUR

Cerebrospinal Fluid Rhinorrhea

Martin J. Citardi

Samer Fakhri

Key Points

- Cerebrospinal fluid rhinorrhea may be classified as traumatic (>90%) or nontraumatic (<10%). Approximately 80% of all traumatic leaks occur in the setting of accidental trauma, and the remaining traumatic leaks occur after neurosurgical and rhinologic procedures. Nontraumatic etiologies include neoplasms and hydrocephalus.
- Idiopathic nontraumatic cerebrospinal fluid rhinorrhea has been linked with elevated intracranial pressure. Numerous studies have confirmed an association of this entity with both benign intracranial hypertension and empty sella syndrome.
- Clinical presentation includes unilateral watery drainage with a characteristic metallic or salty taste, often in the clinical setting of possible etiologic factors.
- The differential diagnosis for watery rhinorrhea includes allergic rhinitis, vasomotor rhinitis, and retained nasal saline irrigation fluid as well as cerebrospinal fluid otorrhea that is draining through the eustachian tube.
- Confirmation of a cerebrospinal fluid leak can be achieved through detection of β_2-transferrin or β-trace protein in nasal secretions.
- Cisternogram studies provide diagnosis confirmation and localization information. Both CT cisternography and radionuclide cisternography require lumbar puncture for the administration of tracer agent, whereas MRI cisternography can be achieved solely through specific imaging protocols. Radionuclide cisternography has poor sensitivity and poor spatial resolution. Both CT cisternography and MRI cisternography offer much greater spatial resolution but still require the presence of a relatively large, active leak for reliable detection.
- Endoscopic examination after the administration of intrathecal fluorescein can confirm the diagnosis of a cerebrospinal fluid leak and indicate its location. Dilute fluorescein must be used; serious neurologic sequelae have been reported after higher intrathecal doses of this agent.
- Endoscopic repair has emerged as the preferred modality for most cases of cerebrospinal fluid rhinorrhea requiring operative repair. During endoscopic repair, the leak site is identified and then closed with autogenous graft materials (fascia, free bone graft, fat), allograft (acellular dermal allograft), and xenogeneic collagen dural substitutes, or a combination. A free mucosal graft is typically placed over these materials, and the reconstruction is secured with surgical sealant and resorbable and nonresorbable packing material.
- The role of prophylactic antibiotics remains controversial. Some data suggest that antibiotics should be administered after detection of a cerebrospinal fluid leak, but the data are far from conclusive. Certainly, in the presence of active infection adjacent to the leak site, antibiotics are prudent.
- Traumatic cerebrospinal fluid leaks are likely to resolve with conservative measures (lumbar drainage and bed rest); operative repair is reserved for those cases in which these measures fail or in which massive injury requires urgent formal operative exploration and repair.
- Cerebrospinal fluid leak that is recognized at the time of surgery should be repaired during that procedure. Cerebrospinal fluid rhinorrhea that develops after surgery may be managed conservatively at first, but most cases require operative repair.
- Nontraumatic cerebrospinal fluid rhinorrhea is unlikely to resolve spontaneously. After potential etiologic factors (brain tumor) have been excluded, operative repair is warranted.

Cerebrospinal fluid (CSF) rhinorrhea results from a direct communication between the CSF-containing subarachnoid space and the mucosalized space of the paranasal sinuses. Because it may serve as a path for the spread of bacterial pathogens and other microorganisms, CSF rhinorrhea may lead to meningitis and intracranial infections, which carry significant morbidity even today. In addition, the skull base defect through which CSF drains may provide a route for the development of pneumocephalus and secondary brain compression. Although CSF rhinorrhea is a simple concept, its diagnosis and localization may be problematic; fortunately, contemporary strategies now provide a more direct means of diagnosis and localization. Over the past two decades, the optimal treatment strategy has undergone significant evolution as minimally invasive, endoscopic techniques have gained acceptance and supplanted more traditional techniques requiring external incisions or craniotomy.

Historical Perspective

CSF rhinorrhea was first reported in the 17th century.[1] In the early 20th century, Dandy[2] reported the first successful repair, which used a bifrontal craniotomy for placement of a fascia lata graft. Although this surgical strategy provided direct access for the repair, reported failure rates were quite high and the procedure entailed the morbidity of craniotomy. In fact, reported recurrent rates were as high as 27%,[3] and in one series only 60% of leaks were successfully repaired.[4]

Extracranial approaches were introduced in the mid-20th century. In 1948, Dohlman[5] presented a patient whose CSF leak was repaired through a standard naso-orbital incision. Several years later, Hirsch[6] reported the successful closure of two sphenoid sinus CSF leaks through a pure endonasal approach. In 1964, Vrabec and Hallberg[7] described the repair of a cribriform defect through an endonasal route. All of these endonasal procedures were performed before the advent of surgical nasal endoscopy.

Endoscopic approaches were introduced and popularized in the 1980s and early 1990s. Both Wigand[8] and Stankiewicz[9] described closure of incidental CSF leaks during endoscopic sinus surgery. In 1989, Papay and colleagues[10] introduced rigid transnasal endoscopy for the endonasal repair of CSF rhinorrhea, and in 1990, Mattox and Kennedy[11] presented another series of cases in which the CSF rhinorrhea was addressed with use of endoscopic visualization. Since then, numerous series have been published,[12-14] and endoscopic repair has emerged as a mainstay of surgical management.[15]

Classification

Box 54-1 summarizes a classification system for all cases of CSF rhinorrhea. This approach, which is based on the established pathophysiology of CSF rhinorrhea, has important clinical implications for the selection of treatment strategies as well as patient counseling about prognosis.

Box 54-1

Classification of Cerebrospinal Fluid Rhinorrhea

Traumatic

Accidental

Immediate

Delayed

Surgical

Complication of neurosurgical procedures:

- Transsphenoidal hypophysectomy
- Frontal craniotomy
- Other skull base procedures

Complication of rhinologic procedures:

- Sinus surgery
- Septoplasty
- Other combined skull base procedures

Nontraumatic

Elevated Intracranial Pressure

Intracranial neoplasm

Hydrocephalus:

- Noncommunicating
- Obstructive

Benign intracranial hypertension

Normal Intracranial Pressure

Congenital anomaly

Skull base neoplasm:

- Nasopharyngeal carcinoma
- Sinonasal malignancy

Skull base erosive process:

- Sinus mucocele
- Osteomyelitis
- Idiopathic

The importance of accurate classification was first recognized by Ommaya and associates,[16] who proposed dividing CSF rhinorrhea into traumatic and nontraumatic forms. These researchers believed that the application of the term "spontaneous" to cases of CSF rhinorrhea was inappropriate because comprehensive investigations of all cases of CSF rhinorrhea should reveal the true proximate cause. Most cases of so-called spontaneous rhinorrhea have a specific etiology, so the term "spontaneous" is probably best reserved for cases of true idiopathic CSF rhinorrhea, in which various investigations cannot determine a specific cause.

Data about the incidence of CSF rhinorrhea are sparse. Only 4% of all CSF leaks are nontraumatic, and 16% occur as a direct result of intracranial and extracranial procedures.[17] The vast majority result from accidental or surgical trauma. Approximately 80% of all cases of CSF rhinorrhea occur in the setting of accidental trauma, mostly in the form of closed-head injury. Conversely, CSF rhinorrhea is noted in only 2% to 3% of cases of serious head trauma.[17] The presence of a skull base fracture is associated with a CSF fistula in 12% to 30% of cases.[18] More than 50% of CSF fistulas resulting from accidental head trauma are located at the anterior cranial base, most of them involving the cribriform plate.[19,20] The majority of traumatic CSF leaks become clinically evident within 2 days, and almost all manifest within 3 months after the traumatic event.[21] Most CSF fistulas resulting from accidental head trauma resolve spontaneously or with conservative management, including lumbar drainage and bed rest.

Pathophysiology

CSF is produced by the choroid plexus in the ventricles at a rate of 20 mL per hour in adults. The CSF circulates from the ventricles through the foramina of Luschka and Magendie to the subarachnoid spaces around the cerebral hemispheres, cerebellum, and spine. Total CSF volume is 140 mL, consisting of 20 mL in the ventricles, 50 mL in the intracranial subarachnoid space, and 70 mL in the paraspinal subarachnoid space. The typical upper limit of normal CSF pressure ranges from 40 mm H_2O in infants to 140 mm H_2O in adults. CSF pressure fluctuates with respirations and arterial pulse pressures as well as with changes in head position. CSF pressure is maintained by a relative balance between CSF secretion (from the choroid plexus) and CSF resorption (by the arachnoid villi). Because CSF secretion occurs at a steady rate, the rate of CSF resorption plays the major role in determining CSF pressure.[22] Processes that disrupt CSF resorption tend to lead to increased intracranial pressure (ICP).

The presence of active CSF rhinorrhea requires a disruption of the barriers that normally separate the contents of the subarachnoid space from the nose and paranasal sinuses; that is, the leak incorporates defects of the arachnoid and dura mater, paranasal sinus mucosa, and the intervening bone. Furthermore, a pressure gradient is also required to produce flow of CSF.

From these apparent observations, the possible etiologies for CSF leaks may be inferred. Various surgical interventions, including routine sinus surgery, can lead to inadvertent disruption of the skull base. Complex intracranial and skull base procedures often directly violate the normally sturdy barrier; however, reconstitution of that barrier may be incomplete. Severe head trauma can lead to skull base fractures with dural laceration. Direct erosion of the skull base by neoplasm or infection can also create a CSF fistula.

The other major factor in the pathogenesis of CSF rhinorrhea is increased ICP. Both an intracranial mass and hydrocephalus are associated with elevated ICP. Strong coughing and the Valsalva maneuver both serve to transiently increase ICP. Elevated ICP is also an important factor in cases of apparent idiopathic CSF rhinorrhea. In a series of publications, Schlosser and coworkers[23,24] have noted that all patients who underwent clinically indicated lumbar puncture or drainage after successful endoscopic repair of nontraumatic CSF rhinorrhea had elevated ICP (mean 26.5 cm H_2O in the first report[23] and 32.5 cm H_2O, in the second report[24]), suggesting that occult elevation of ICP may be an etiologic factor in even so-called idiopathic or spontaneous CSF rhinorrhea. It could be postulated that in patients with occult elevated

CSF pressure, the CSF leak may serve as a release valve that decompresses the elevated pressure. (If the patient has an active leak at the time of lumbar puncture, the opening pressure may be normal—because the leak has decompressed the ICP. Thus, the increased pressure may be apparent only after a site of leakage has been surgically repaired.)

In at least certain instances, nontraumatic CSF rhinorrhea seems to result from abnormally elevated ICP. Given that elevated ICP is a primary characteristic of benign intracranial hypertension (BIH), the pathophysiology of nontraumatic CSF rhinorrhea and that of BIH may be similar. *Benign intracranial hypertension,* also known as *idiopathic intracranial hypertension* and *pseudotumor cerebri,* is a syndrome of increased ICP in the absence of specific causes such as intracranial masses, hydrocephalus, and dural sinus thrombosis. Clinical manifestations of BIH include headache, pulsatile tinnitus, papilledema, and visual disturbances including abducens nerve palsy. Most patients with BIH are obese, middle-aged women. In fact, the demographics of the population with spontaneous CSF leak are quite similar to those of the average population of patients with BIH.[25] Thus the diagnosis of BIH must be examined in the setting of spontaneous CSF rhinorrhea. In fact, Schlosser and coworkers[26] demonstrated that 8 of 11 patients (72%) with apparent idiopathic CSF rhinorrhea strictly fulfilled the modified Dandy criteria used by neuro-ophthalmologists to make the diagnosis of BIH.[26] The other 3 patients fulfilled most but not all the criteria.

In a separate publication, Schlosser and Bolger[27] assessed the incidence of an empty sella in 15 patients with apparently spontaneous CSF rhinorrhea and in 9 patients with nonspontaneous CSF rhinorrhea and noted a statistically significant ($P = .01$) greater incidence of empty sella in the nontraumatic CSF leak group (100% vs. 11%, respectively). An empty sella may therefore serve as a marker of elevated ICP.[28] Normally, the pituitary gland fills the entire sella turcica; however, if arachnoid and CSF herniate through the sellar diaphragm, this CSF-filled sac may partially or completely compress the pituitary gland. When this compression occurs, an "empty sella" results. The clinical manifestations and demographic profile of patients with empty sella syndrome (ESS) are highly similar to those for patients with BIH and patients with nontraumatic CSF leaks. The clinical presentation of ESS includes headache, memory losses, cerebellar ataxia, papilledema, and visual field defects. In addition, many patients with ESS are obese, middle-aged women with elevated body mass index (BMI). In a later report, Silver and colleagues[29] demonstrated that the radiographic signs displayed in 14 patients with nontraumatic, apparently idiopathic, CSF rhinorrhea were largely similar to those seen in patients with ICP and BIH. The signs included arachnoid pits in 79% of patients, empty sella in 50% of patients, meningoencephaloceles in 50% of patients, and dural ectasias in 35% of patients. Because ESS is associated with altered CSF circulation dynamics,[30] treatment of nontraumatic CSF rhinorrhea, which has a demonstrated association with ESS, should include consideration of the concomitant diagnosis of ESS as well as the potential clinical impact of ESS.

These associations among nontraumatic CSF rhinorrhea, BIH, and ESS have important clinical implications, because these three entities may all be manifestations of the same underlying pathophysiologic derangement that leads to elevations in intracranial and CSF pressures. Persistent headache after successful surgical repair may indicate occult ICP hypertension. Similarly, recurrent or persistent CSF rhinorrhea often represents decompression of abnormally high ICP. Thus, the issue of abnormal CSF dynamics should be considered in instances of apparently idiopathic CSF rhinorrhea.

The bony architecture of the skull base plays a role in the development of CSF rhinorrhea. Certainly bony dehiscences or even partial thinning weakens the normal barrier that separates the subarachnoid space from the paranasal sinus space. Alternatively, these weaknesses can be considered congenital anomalies. In addition, specific areas of the skull base are normally quite thin. In particular, the lateral lamella of the cribriform plate (LLCP) has been well recognized as an area of potential weakness (Fig. 54-1). The length of the LLCP shows considerable variation; if the LLCP is especially long, this anatomic variation weakens a significant portion of the skull. Congenital dehiscences in the lateral sphenoid roof, occurring from persistence of the lateral craniopharyngeal canal (Sternberg's canal), have also been implicated in the pathogenesis of sphenoid CSF leaks and meningoencephaloceles.[31,32] In all instances of thinning of the bony skull base, the pressure from the overlying intracranial contents coupled with constant dural pulsations may further erode the weakened area with the resultant development of CSF rhinorrhea.

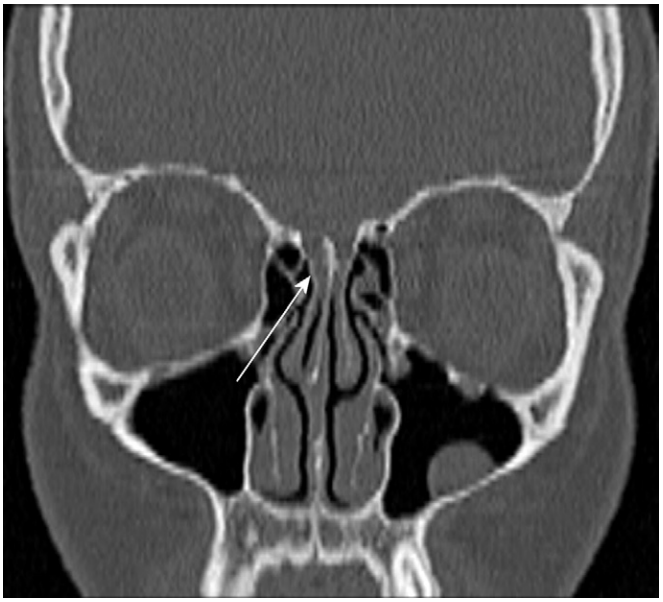

Figure 54-1. The lateral lamella of the cribriform plate (indicated by an *arrow* in this coronal sinus computed tomography scan) forms the weakest part of the skull base. The length of the lateral lamella is quite variable. In this example, it is quite long; hence, the skull base is at increased risk of inadvertent injury.

Although skull base trauma leading to CSF rhinorrhea during or after routine endoscopic sinus surgery is a rare event, the frequency of this procedure makes this complication an important cause of CSF rhinorrhea today.[9,33,34] Inadvertent pressure along the thin skull base may fracture the skull base and lacerate the dura. Because the LLCP is the weakest part of the skull base, even minor trauma in this region may cause CSF rhinorrhea. Aggressive middle turbinate retraction or resection (Fig. 54-2) may be associated with LLCP injury. The mechanism of injury during the procedure should also be considered. It is likely that powered instrumentation produces a greater skull base injury than the standard sinus forceps and through-cutting forceps. Powered instrumentation is invariably associated with greater removal of tissue; as a result, the resultant skull base defect may be quite extensive. Later generations of powered instrumentation may increase the risk of this complication, because they can remove tissue more quickly and easily. CSF rhinorrhea may occur both intraoperatively and postoperatively. When patients report symptoms that are consistent with CSF rhinorrhea after sinus surgery, the diagnosis of CSF rhinorrhea should be considered, even if the procedure itself was seemingly uneventful.

A meningocele or meningoencephalocele may occur in association with CSF rhinorrhea, although each of these lesions may occur independently. Meningoceles and meningoencephaloceles develop from the constant pressure exerted by the dura over a weakened portion of the skull base. Over time, a portion of dura may protrude through the bony defect into the paranasal sinuses and nose. If the defect is large enough and sufficient time has elapsed, meningoencephalocele may eventually develop. Often CSF rhinorrhea is the presenting symptom of a meningocele or meningoencephalocele, but not universally so.

In many patients, it is difficult to determine a precise etiology. Conceivably, multiple factors may play a role in the pathogenesis. A long LLCP increases the risk of a spontaneous leak, although most

Figure 54-2. Intraoperative images from endoscopic surgery using an image-guided navigation system for repair of bilateral cerebrospinal (CSF) leaks. The cross hairs on the reformatted three-dimensional computed tomography scans (*top, bottom left*) denote placement of the probe as seen in the endoscopic view (*bottom right*). Middle turbinate resection may result in inadvertent skull base trauma and CSF leak. The instrument tip rests on the anterior skull base defect. The coronal sinus CT shows bony loss of the skull base and middle turbinate on both the left and right sides.

individuals with this skull base feature do not have such a leak. However, the combination of a long LLCP and elevated ICP—perhaps owing to a variant of ESS and/or BIH—may lead to CSF rhinorrhea. It is important to remember this multifactorial etiology, especially in patients with recurrent or persistent CSF rhinorrhea after surgical repair. Of course, surgical failure may result from other unrecognized factors.

Diagnosis

Intuitively, the diagnosis of CSF rhinorrhea may seem simple; in practice, however, it may be problematic. In selected instances, the presence of CSF rhinorrhea may be obvious. For instance, the development of unilateral watery rhinorrhea after head trauma with resultant anterior skull base fracture warrants little effort for diagnosis confirmation. However, the establishment of the diagnosis of a CSF leak as well as its precise localization often represents a major clinical challenge for a number of reasons. First, CSF rhinorrhea is relatively rare, but other rhinopathies, including seasonal allergic rhinitis, perennial nonallergic rhinitis, and vasomotor rhinitis, are relatively common. These more innocuous conditions may mimic some of the signs and symptoms of CSF rhinorrhea or may occur simultaneously with CSF rhinorrhea. Second, CSF rhinorrhea is often intermittent. As a result, a diagnostic test performed at a time when the CSF rhinorrhea is quiescent may lead to a false-negative result. Finally, the CSF drains from a low-pressure system; therefore, the quantity and duration of drainage may be quite low, because the pressure gradient that drives the CSF flow is intrinsically low, even in the presence of relative increases in CSF rhinorrhea.

The diagnosis of CSF rhinorrhea is typically a two-step process: First, the presence of a CSF leak must be confirmed through the documentation of objective evidence of extracranial CSF. Second, the position of the skull base defect or defects through which the CSF is draining must be determined.

Differential Diagnosis

Occasionally, CSF otorrhea may manifest as CSF rhinorrhea. In this circumstance, a skull base defect communicates between the intracranial space and pneumatized spaces of the middle ear and mastoid behind an intact tympanic membrane. The CSF collects in the middle ear space and then drains down the eustachian tube to the nose, where it appears as watery nasal drainage.

Patients who perform sinonasal saline irrigations may note watery nasal drainage that occurs even hours after they have completed the irrigation. Retained irrigation fluids may be more problematic when the surgically opened sinuses hold the saline until the patient tips the head. When this situation occurs in the immediate postoperative period, distinguishing between a true CSF leak and the release of retained saline irrigation fluid can be somewhat challenging; however, discontinuing the irrigations quickly eliminates any problems caused by them, but will not diminish a true CSF leak.

A large number of sinonasal inflammatory conditions, including both seasonal and perennial allergic rhinitis, and noninflammatory conditions, including vasomotor rhinitis, may produce watery rhinorrhea. Associated features typically serve to separate these conditions from true CSF rhinorrhea.

History

The patient's clinical history provides important cues about CSF rhinorrhea. A patient with active CSF rhinorrhea reports unilateral watery nasal discharge that occurs on the side of the presumed CSF leak. Often, the rhinorrhea is associated with a salty taste, but this may not necessarily be so. Of course, the patient with a septal perforation is not able to reliably localize the side of the skull base defect, and the patient with bilateral defects describes bilateral watery rhinorrhea. Rhinorrhea caused by a CSF leak has a typical characteristic of positional variation; that is, the rhinorrhea occurs only when the patient lowers the head. For instance, such a patient indicates that the watery drainage occurs when he or she bends over to tie his or her shoelaces.

In the situation of a traumatic CSF leak, the history of the antecedent event provides obvious cues about the presence of a skull base defect. Unilateral watery drainage that develops after a head injury from a motor vehicle accident or fall or unilateral drainage that is first noted after sinus surgery or skull base surgery must be regarded as possible CSF leak.

CSF leaks that are seemingly idiopathic may be preceded by transient increases in ICP. Clinical anecdotes suggest that some patients experience CSF rhinorrhea after strong nose blowing. In this situation, the CSF leak may best be classified as a traumatic leak.

If the skull base defect involves the cribriform plate, the patient may report hyposmia, anosmia, parosmia, or a combination of these disorders. A skull base neoplasm, causing a skull base defect, may produce remarkably minimal symptoms, aside from those associated with skull base defect, until the lesion is relatively massive and encroaches upon and destroys adjacent cranial nerves and other structures.

A detailed history of nasal and sinus health is also warranted in patients with suspected CSF rhinorrhea. First, the presence of inflammatory paranasal sinus disease may influence the treatment strategy if a true CSF leak is present. Second, inflammatory conditions may mimic the symptoms of a CSF leak, and fluctuating nasal symptoms due to varying inflammation may complicate the clinical history. Finally, many patients with suspected CSF leak may have undergone surgery, although not recently. In such cases, unrecognized skull base injury may manifest as CSF rhinorrhea years or decades after the initial procedure.

A history of headache must be explored in detail. Some patients with idiopathic, nontraumatic CSF rhinorrhea report severe diffuse headache that improves when the rhinorrhea occurs and worsens when the rhinorrhea stops. The pathophysiology of these headaches probably reflects variations in ICP. When the ICP is elevated, the headache occurs; however, when the CSF leak, appearing as watery rhinorrhea, releases the ICP elevation, the headache improves. Chronic headache may also result from other causes of elevated ICP, including BIH and ESS, which have been associated with CSF rhinorrhea (as described previously). Rarely, a chronic headache may result from an unrecognized intracranial neoplasm. Severe chronic headache may also occur from low ICP caused by chronic depletion of CSF through a persistent CSF leak.

A history of bacterial meningitis, especially of multiple episodes of bacterial meningitis, may suggest a possible skull base defect that provides a route for the intracranial extension of bacterial pathogens from the paranasal sinuses.

Physical Examination

During the physical examination of a patient with a suspected CSF leak, the physician should attempt to demonstrate the unilateral watery rhinorrhea by having the patient lean forward. Failure of such a maneuver to produce the watery drainage should not be considered definitive proof that a CSF leak is not present, especially if the clinical history supports the diagnosis of a CSF leak.

Traditionally, the so-called halo sign has been considered an important marker of CSF rhinorrhea after head trauma. The halo sign is considered present when a clear ring surrounds a central bloody spot after bloody nasal discharge is dropped upon a handkerchief or paper towel. However, the presence of either tears or saliva is likely to yield a falsely positive halo sign.

Results of the nasal examination, including traditional anterior rhinoscopy and nasal endoscopy, are often nonspecific. Glistening, moist nasal mucosa may be identified on the side of the CSF leak. A stream of clear fluid may herald an active CSF leak. Nasal examination may demonstrate the mass of a meningoencephalocele and also provides important cues about other nasal conditions that may mimic a CSF leak.

In patients with elevated ICP, papilledema may be present. Elevated ICP associated with BIH may also be associated with abducens nerve palsy. Stigmata of maxillofacial trauma may be present in patients with traumatic CSF rhinorrhea.

Diagnostic Testing

Strategies for diagnostic testing for CSF rhinorrhea may be divided into two groups. The first group focuses on the identification of a substance that can serve as a chemical marker of CSF. The second group relies upon the administration of agents that can document the presence of communication between the intradural space and extradural space.

Chemical Markers

For many decades, glucose was considered a sensitive and specific marker of CSF. Proponents of this marker applied nasal discharge to glucose oxidase test strips; the presence of glucose—indicated by a color change—was believed to represent CSF mixed with the nasal secretions. Numerous reports describe a very high false-positive rate for glucose oxidase strips as a test for CSF rhinorrhea,[35,36] because reducing substances in tears and nasal mucus react with these glucose oxidase strips.[37] In addition, false-negative results may occur in the presence of active bacterial meningitis, which typically reduces CSF glucose levels.

β_2-transferrin has now emerged as the preferred biochemical marker of CSF. In 1979, Meurman and colleagues[38] performed protein electrophoresis of CSF, tears, nasal secretions, and serum and noted a β_2-transferrin fraction only in the CSF samples. Several years later, Oberascher and Arrer[39] further described the technique for this marker and noted no false-positive results in a series of 42 tests performed. The techniques used in these reports were not overly sensitive (although they were quite specific); technical improvements have enhanced sensitivity and even simplified the technique.[40] Because β_2-transferrin is a reliable marker of CSF, it has been proposed that a negative β_2-transferrin test result in a patient with a suspected CSF leak may be sufficient justification for not performing additional invasive procedures.[41]

Important caveats about the β_2-transferrin test must be stated, however. First, a reliable test result requires that the laboratory receives an adequate sample. Because the test is not commonly available, transportation time may degrade the sample. Furthermore, a patient may be unable to obtain a sufficient volume of nasal drainage if he or she has a very slow or intermittent CSF leak. In addition, some elderly, disabled, or uncooperative patients may be unable to collect the nasal drainage because of difficulties in the actual collection process. Finally, although β_2-transferrin seems quite specific for CSF, it has been detected in aqueous humor[42] and in the serum of patients with alcohol-related chronic liver disease.[43]

Beta-trace protein (βTP) is another chemical marker that could be used for the detection of CSF. The second most common protein found in CSF after albumin, βTP has been identified as a prostaglandin D_2 synthase. It is produced by the meninges and choroid plexus and released into CSF. This protein is also present in other body fluids, including serum, but at much lower concentrations than in CSF. Detection of βTP has 100% sensitivity and specificity in cases of confirmed CSF rhinorrhea.[44] It is important to mention that the βTP test cannot be reliably used in patients with renal insufficiency or bacterial meningitis, because serum and CSF levels of βTP have been shown to substantially increase with reduced glomerular filtration rate and to decrease with bacterial meningitis.[45] βTP testing is a rapid and cost-effective procedure that should be included in the diagnostic battery for CSF rhinorrhea.

A novel strategy for the detection of CSF is the "electronic nose," a system that uses organic semiconductors for identification of volatile gases; Thaler and colleagues[46] reported that the electronic nose was able to distinguish between CSF and serum in 18 of 19 instances.

Cerebrospinal Fluid Tracers

Intrathecal agent tests provide information that can confirm the presence of a CSF leak; these tests also may provide information about the location of the skull base defect associated with the leak. All of these tests require a lumbar puncture for the introduction of a tracer agent into the subarachnoid space. Complications of the use of the intrathecal agent can be quite severe, and intrinsic properties of the agent may limit the specificity and sensitivity of the test. Agents may be categorized as visible dyes, radionuclide markers, and radiopaque dyes. Any of these tests are considered to have a positive result if the agent is visualized within the nose and paranasal sinuses.

Intrathecal fluorescein is probably the most popular visible agent. Kirchner and Proud[47] introduced the technique in 1960, and Messerklinger[48] later refined and popularized it. In brief, a lumbar puncture is performed for the introduction of fluorescein into the intrathecal space, the patient is kept in the head down-position, and nasal endoscopy is performed to identify fluorescein within the nose and sinuses. Because the fluorescein has a characteristic green color, it is quite easy to identify even in minute quantities. Specific blue-light filters may be used to enhance visual detection of fluorescein, but typically they are not necessary. Intrathecal fluorescein has been associated with various but isolated catastrophic complications, including grand mal seizures and even death. However, in most of those instances, the complication either was nonconclusively linked to the administration of fluorescein or resulted from the injection of an unusually high dose. In a large study of 420 administrations of intrathecal fluorescein in Europe and the United States, Keerl and associates[49] concluded that fluorescein is very useful in localizing CSF fistulas and that low-dose fluorescein (50 mg or less) is unlikely to be associated with adverse events because most complications seem to be dose-related. The recommended dilution of fluorescein is 0.1 mL of 10% fluorescein (the intravenous preparation, not the ophthalmic preparation) in 10 mL of the patient's own CSF[12]; this dilution should be infused slowly over 30 minutes. Patients should be counseled about the risks of intrathecal fluorescein, because this use of fluorescein is clearly not approved by the U.S. Food and Drug Administration.

Radioactive iodine (I^{131})–labeled serum albumen (RISA), technetium Tc 99m–labeled serum albumen or diethylenetriamine/pentaacetic acid (DTPA), and radioactive indium (In^{111})–labeled DTPA have all been used for radionuclide cisternography, which involves the intrathecal administration of a radionuclide tracer via a lumbar puncture and subsequent monitoring of the distribution of tracer with a scintillation camera. Typically, intranasal pledgets are also placed in close proximity to the suspected skull base defect and assayed for tracer 12 to 24 hours later with a gamma counter. Pledget counts should be determined per unit mass of dry pledget, and a radionuclide ratio that compares tracer counts in the pledget with counts in a unit volume of peripheral blood should be calculated.[50] An elevated ratio suggests the presence of a CSF fistula; the distribution of counts across the pledgets may suggest the location of the defect. Because radionuclide cisternography requires active CSF flow for the documentation of a CSF leak, the technique of overpressure radionuclide cisternography (ORNC), which incorporates a constant tracer infusion to increase the intrathecal pressure and thereby enhance flow, may improve the sensitivity of radionuclide cisternography.[51] In practice, the utility of radionuclide cisternography has been limited by the poor spatial resolution of the scintillation cameras. Despite its apparent advantages, this modality has an unacceptable rate of false-positive or indeterminate results, and thus, it cannot be the sole test to confirm CSF leak.

Computed tomography (CT) cisternography, which incorporates CT scanning after the intrathecal administration of radiopaque contrast (metrizamide), may also be used to document the presence of a CSF leak (Fig. 54-3).[52,53] Approximately 80% of CSF leaks can be confirmed through CT cisternography.[54]

Magnetic resonance (MR) cisternography is a noninvasive method for assessing the presence of intranasal or intrasinus CSF (Fig. 54-4).[55] In this technique, a heavily T2-weighted image with fat suppression

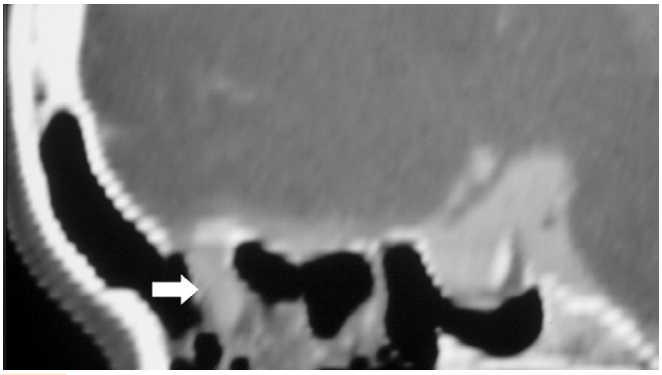

Figure 54-3. A cerebrospinal fluid leak on computed tomography (CT) cisternography is characterized by the presence of contrast material within the pneumatized paranasal sinuses. The contrast material should be in direct continuity, so that a precise site of communication can be reliably demonstrated, as shown in this sagittal CT reconstruction from a positive CT cisternogram. The *arrow* points to the area of the contrast material within the ethmoid sinuses.

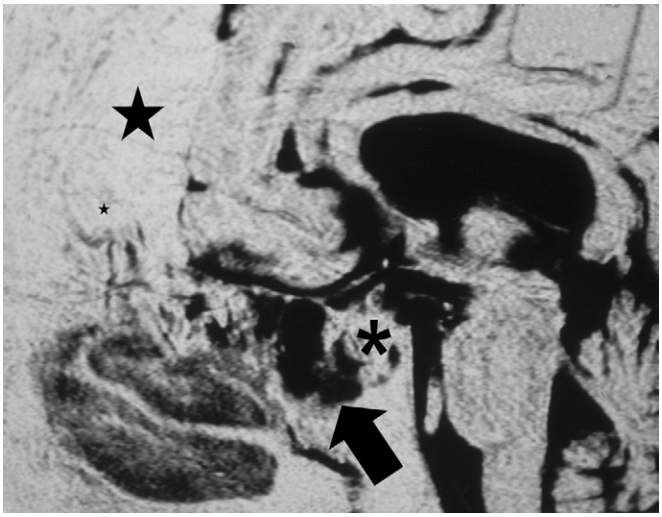

Figure 54-4. Magnetic resonance (MR) cisternography provides a noninvasive way to confirm and localize cerebrospinal fluid (CSF) leaks. In this sagittal image, obtained during a positive MR cisternogram in a patient with a CSF leak after transsphenoidal hypophysectomy, the CSF signal, which appears black, is present in the sphenoid sinus (*arrow*). The *asterisk* shows the position of the sella. The anterior cranial fossa shows minimal signal because of a pneumocephalus (indicated by the *star*).

and video reversal provides a means to image CSF; extension of the characteristic signal from the intracranial space to the paranasal sinuses represents a CSF leak. Reported sensitivity, specificity, and accuracy of MR cisternography are 0.87, 0.57, and 0.78, respectively.[56]

Localization Studies

The diagnostic tests that rely on CSF tracers also provide information about localization of the skull base defect through which the CSF is draining. Such information is critical for the development of a strategy for the surgical repair of CSF leaks. The extent to which these studies can provide anatomic information varies. For instance, even under the best of circumstances radionuclide cisternography has notoriously poor spatial resolution. Even when results of such a study are positive, they may only suggest a general region (i.e., cribriform plate) or even just a side. MR cisternography provides greater anatomic information, but the long image acquisition times required by contemporary MR imagers produce relatively thick image slices that are not thin enough to show small skull base defects. Even metrizamide CT cisternography may be difficult to reliably interpret, although scan slices may be as thin as 1 mm. It is important to remember that all of these studies assume the presence of active CSF flow; if the leak is intermittent or very small, any of these studies may yield a false-negative result.

Nasal endoscopy after intrathecal administration of fluorescein provides a means for direct confirmation of the presence and location of a CSF leak. This study, too, requires active CSF flow to identify a leak. Typically it plays a role in two circumstances. First, intrathecal fluorescein may be administered at the beginning of a procedure aimed at repairing a CSF leak confirmed by other means (typically β_2-transferrin testing). Second, intrathecal fluorescein with nasal endoscopy may be employed for diagnosis alone; this procedure should be performed with use of anesthesia in the operating room to enhance patient safety and comfort.

The specificity of β_2-transferrin testing has significantly altered the role of the various cisternography tests. Because β_2-transferrin testing is both reliably specific and noninvasive, it has relegated these other imaging-based studies to use in selected cases only. After the diagnosis of a CSF leak has been confirmed through β_2-transferrin testing, high-resolution CT (either 1-mm direct coronal images or coronal images reformatted from 1-mm axial data through a robust software algorithm) and MR imaging (MRI) of the skull base may provide adequate anatomic information about the integrity of the skull base. Endoscopic exploration for identification and repair of the defect site (described later) may be performed with attention directed at the area or areas of suspected skull base dehiscence. In fact, Zapalac and associates[57] recommended β_2-transferrin testing for diagnosis and high-resolution CT for localization. In this strategy, CT and MRI are complementary; that is, CT provides detail about the bony anatomy, including bony skull base dehiscences (Fig. 54-5), and MRI provides detail about soft tissues, including coincident meningoencephaloceles and incidental intracranial masses (Fig. 54-6). CT scans also provide information about meningoencephaloceles but often lack the soft tissue detail present in MRI studies (Fig. 54-7). Improvement in imaging software and computer-aided surgery (CAS) technology has enabled the application of CT-MRI fusion. In this modality, high-resolution CT scans are fused with MR images to create a hybrid image with excellence of both bony detail and soft tissue and fluid signal. Using this application, Mostafa and Khafaqi[58] were able to accurately localize the site of CSF leakage in 17 of 19 cases with a sensitivity of 89.5%.

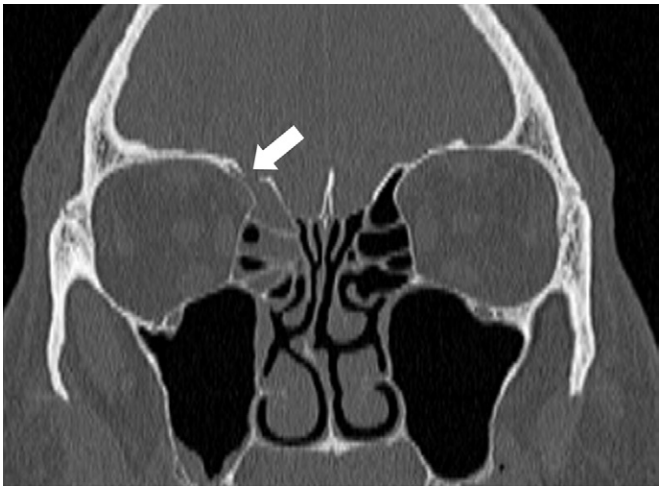

Figure 54-5. High-resolution sinus computed tomography (CT) may be used to image even small bony defects of the skull base. This coronal CT scan was reconstructed from 1-mm direct axial CT image data using a robust image processing software system. It should be noted that not all reformatted coronal images are of sufficient quality to permit this precise examination of the skull base. A bony dehiscence (indicated by the *arrow*), together with a positive β_2-transferrin study result, represents a likely site for an active CSF leak; however, in the absence of a positive β_2-transferrin study result, the presence of a CSF leak should not be assumed from the presence of such a finding.

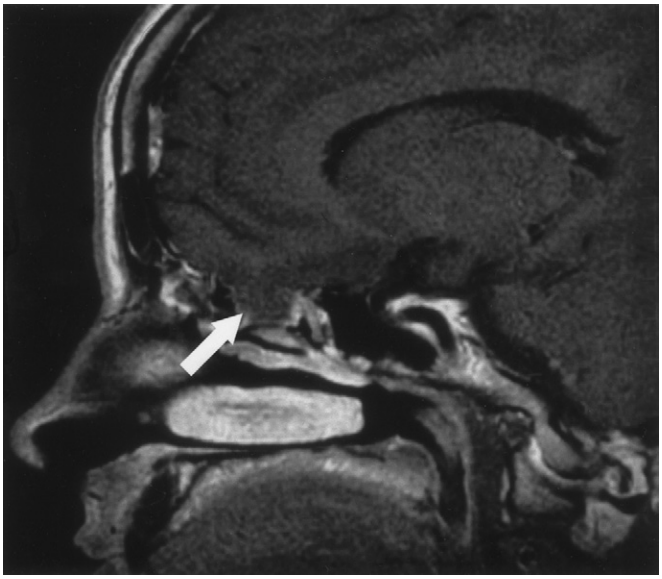

Figure 54-6. Magnetic resonance (MR) imaging provides excellent visualization of anterior skull base meningoencephaloceles. The *arrow* shows the characteristic appearance of such a finding on this sagittal MR image.

Management

After confirmation of the presence of a CSF leak and localization of the skull base defect, optimal management of CSF rhinorrhea focuses on the selection of an appropriate treatment strategy. That decision-making process should include consideration of the leak's etiology and probable natural history.

Optimal treatment requires cooperation among various disciplines, including otorhinolaryngology, neurosurgery, and neuroradiology. Even if the otorhinolaryngologist will manage the CSF rhinorrhea primarily, he or she should seek the input of neurosurgery colleagues. In addition, consultation with infectious disease specialists may be helpful for the selection of appropriate antibiotics in the situation of suspected meningitis.

Conservative Treatment

Conservative treatment of CSF rhinorrhea includes a 1- to 2-week period of strict bed rest with head elevation as well as several days of continuous subarachnoid drainage through a lumbar catheter (or intermittent drainage through serial spinal taps) (Box 54-2). In addition, patients are advised to avoid coughing, sneezing, nose blowing, and

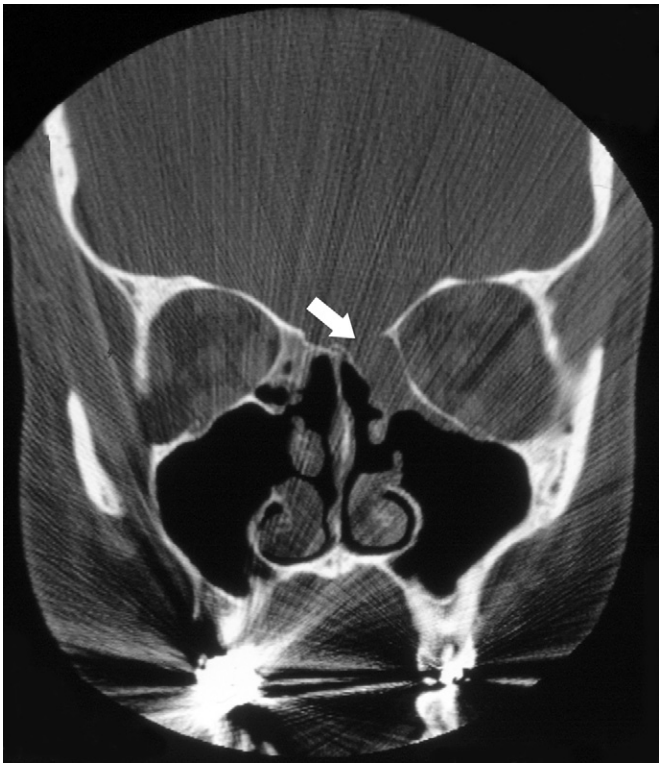

Figure 54-7. Computed tomography (CT) may be used to visualize the bony structures of the skull base, but it cannot reliably distinguish between a meningoencephalocele and a mucocele with bony resorption. This coronal CT scan shows a bony skull base dehiscence (*arrow*) and an adjacent area of opacification. In this case, a meningoencephalocele was confirmed by magnetic resonance imaging.

Box 54-2

Conservative Treatment of Cerebrospinal Fluid Rhinorrhea

Subarachnoid drainage through a lumbar catheter
Strict bed rest
Head elevation
Stool softeners
Advising patient to avoid coughing, sneezing, nose blowing, and straining
Prophylactic antibiotics (possible)*

*Routine administration of prophylactic antibiotics is controversial. The best data support the use of antibiotics after a traumatic leak, but even these data are far from conclusive. Data for the use of antibiotics for other etiologies are sparse.

straining. Stool softeners are often recommended. The goal of these measures is to reduce the CSF leak flow by decompressing the ICP; in this way, healing at the defect site may seal the leak without surgical intervention.

Although lumbar drains are passive devices, they require active management. CSF specimens for cell count, protein and glucose measurements, and culture should be collected daily. An hourly drainage rate of 10 mL is desirable. Of course, higher rates produce a greater decompression of ICP; however, higher rates may lead to abnormally low ICP, which can produce severe headache. Low ICP also may cause pneumocephalus as air is drawn through the skull base defect. If low ICP is suspected, the rate of drainage should be decreased or the drain should be clamped until the ICP equilibrates at a higher level.

Complications of lumbar drainage are significant, so this technique should be used cautiously.[59] In the scenario of markedly elevated ICP, it should be avoided. In addition, lumbar drainage carries a risk of meningitis. Despite that risk, routine antibiotic therapy for prophylaxis of meningitis is not warranted, because it is probably ineffective and may even induce resistance in likely pathogens.[17,60] Nonetheless, a first-generation cephalosporin (or similar agent) for coverage of skin flora may minimize the risk of cellulitis at the puncture site with secondary ascending meningitis. In addition, it is reasonable to administer antibiotics in those patients with a history of suppurative bacterial rhinosinusitis.

Transcranial Techniques

The concept of transcranial repair of CSF rhinorrhea is quite simple: After craniotomy, the defect site is identified, and then a tissue graft is placed to close the defect. Fascia lata grafts, muscle plugs, and pedicled galeal flaps may be used. A tissue sealant, such as fibrin glue, may be used to hold the grafts in position. Access to the cribriform plate region and roof of the ethmoid requires a frontal craniotomy; extended craniotomy and skull base techniques with even greater brain compression provide access to the sphenoid sinus defects.

The well-recognized and potential morbidities of these techniques include brain compression, hematoma, seizures, and anosmia. Despite direct access to the skull base defect, failure rates are quite high; in fact, reported failure rates may exceed 25%.[3] For these reasons, extracranial techniques are now preferred in most circumstances.

Extracranial Techniques

Early extracranial techniques required an external incision for transsinus access to the skull base defect., Endoscopic techniques, which rely upon transnasal, trans-sinus access to the defect, have supplanted the older techniques. Both extracranial techniques attempt to seal the defect by the placement of graft at the defect site, although endoscopic techniques provide superior visualization. Since the initial descriptions of the endoscopic repair of CSF rhinorrhea in the 1980s, endoscopic management has emerged as the primary technique for the surgical management of skull base defects.[15]

The initial steps for endoscopic repair of CSF rhinorrhea consist of the standard endoscopic dissection so that the defect site is adequately visualized. Intrathecal fluorescein (discussed previously) may be administered to facilitate identification of the defect. The defect site must be prepared for grafting. Bipolar cautery or potassium-titanyl-phosphate (KTP) laser may be used to fulgurate a concomitant meningoencephalocele, which must never be reduced by simply being pushed intracranially. Bipolar cautery and KTP laser may also be used to remove sinus mucosa that is adherent to dura. Mucosa within 5 mm of the margins of the skull base defect must also be removed to facilitate mucosal grafting. Middle and superior turbinate resection is not routinely necessary for access.

The specific details of graft selection have generated considerable controversy. Potential grafts include temporalis fascia, fascia lata, muscle plugs, pedicled middle turbinate flaps (mucosa alone or mucosa and bone), autogenous fat, free cartilage grafts (from the nasal septum or the cartilaginous auricle), and free bone grafts (from the nasal septum or calvarium as well as other sites). Acellular dermal allograft may also serve as a graft.[61] Although pedicled intranasal grafts may be used, they have been associated with a relatively high failure rate; as a result, free grafts seem preferable for most circumstances.[62] In a meta-analysis of 289 CSF fistulas, Hegazy and colleagues[63] found that the choice of the grafting material did not seem to alter the outcome of the repair.

The selection of grafting material largely depends on the availability of the material and the experience and preference of the surgeon. Interest in the use of xenogeneic collagen dural substitutes—for example, Durepair Dural Regeneration Matrix (Medtronic Inc., Minneapolis, MN), DuraGen Dermal Graft Matrix (Integra, Plainsboro, NJ), and Dura-Guard Dural Repair Patch (Synovis Surgical Innovations, St. Paul, MN)—for closure of skull base defects has increased. This increase is partly due to advances in the endoscopic management of complex skull base pathology, which results in relatively large skull base defects. The collagen implant provides a scaffold for the native

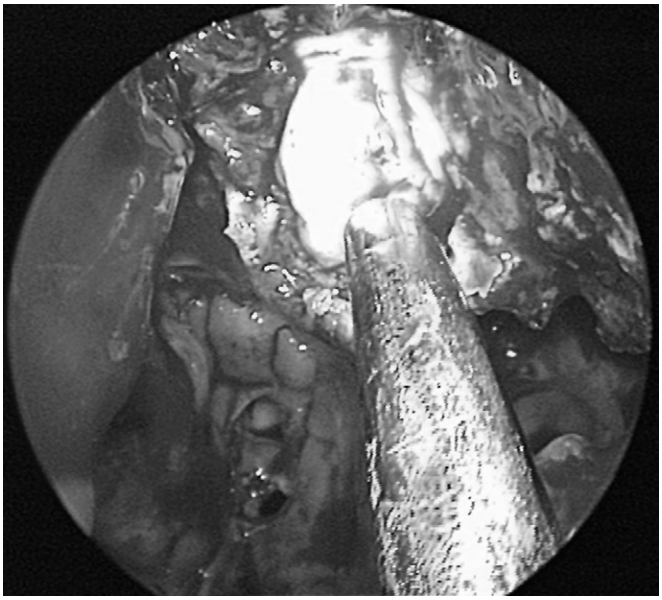

Figure 54-8. Appropriate graft placement is critical to successful repair of cerebrospinal fluid leak. In this endoscopic image, the instrument tip rests on an acellular dermal allograft, which has been tucked beneath the edges of an anterior skull base defect.

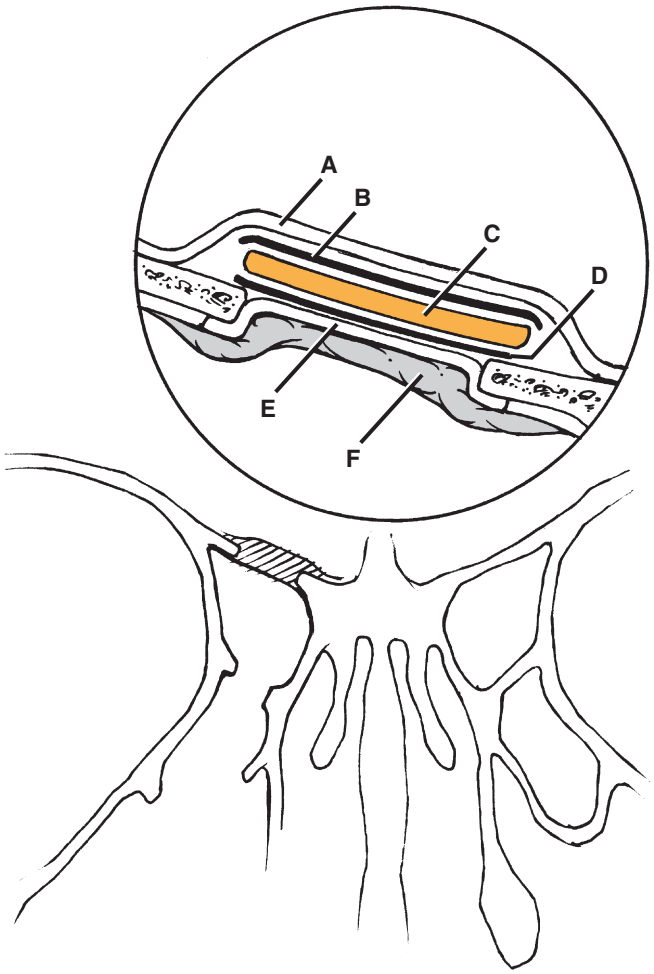

Figure 54-9. Layered skull base reconstruction provides a stronger barrier. In this illustration of a repair of a defect of the roof of the left ethmoid, representative layers are depicted as follows: *A,* dura; *B,* fascial autograft (or acellular dermal allograft); *C,* bone or cartilage autograft; *D,* fascial autograft (or acellular dermal allograft); *E,* mucosal free autograft; *F,* surgical sealant. *(Redrawn with permission from Lorenz RR, Dean RL, Hurley DB, Chuang J, Citardi MJ. Endoscopic reconstruction of anterior and middle cranial fossa defects using acellular dermal allograft.* Laryngoscope. *2003;113:496-501.)*

fibroblasts to produce a collagen layer that blends and eventually replaces the implant. In an animal study comparing the three dural substitutes listed previously, all three implants were found to be safe and effective in healing surgically created defects in the dura mater.[64]

Appropriate graft placement is critical for successful endoscopic repair (Fig. 54-8). Ideally, grafts of fascia (or similar materials) should be placed on the intracranial side of the defect with use of an underlay technique. Ambient ICP serves to hold the graft in position. Wormald and McDonogh[65] have described the "bath-plug" technique, which incorporates an intracranial fat graft; the patient's ICP helps to hold the graft in the desired position.[65] Larger defects may require a layered reconstruction including solid support such as cartilage or bone grafts placed in the epidural space (Figs. 54-9 and 54-10). In fact, this layered reconstruction offers a more robust boundary and may reduce the risk of delayed recurrence and/or meningoencephalocele formation, especially in patients at risk for elevated ICP (namely patients with suspected BIH or ESS). It should be mentioned, however, that data in the literature do not show better outcomes for use of rigid support or multilayered reconstruction of larger defects.[66] In addition to defect size and location, the CSF pressure gradient across the skull base defect is an important factor in the choice of surgical technique (underlay vs. overlay) and graft material.

Mucosal grafts should never be placed intracranially, and care should be taken to ensure the correct placement, which avoids inadvertent intracranial placement. Intracranial mucocele after endoscopic CSF leak repair has been reported; this complication probably resulted from incorrect placement of mucosal grafts.[67]

After the grafts are placed, a surgical sealant (such as fibrin glue) may be used to help hold them in place. Typically, absorbable nasal packing is placed adjacent to the grafts, and traditional nonabsorbable packing is used to support the absorbable packing. The nasal packing supports the grafts and provides some hemostasis.

Pure endoscopic approaches provide excellent access to the ethmoid roof, cribriform plate, and most of the sphenoid sinus. Lateral sphenoid leaks may require an extended approach, which incorporates endoscopic dissection of the medial pterygomaxillary space.[68,69] An osteoplastic flap or a simple trephine may be required for repair of defects through the posterior table of the frontal sinus (Fig. 54-11).

Postoperative care includes strict bed rest for several days as well as antistaphylococcal antibiotics (for prophylaxis against complications from the nasal packing). In the immediate postoperative period, patients must be monitored for potential intracranial complications (such as hematoma); observation in the intensive care unit is appropriate for the first 24 hours (or longer if necessary). If a lumbar drain was placed intraoperatively, CSF drainage, which decompresses the pressure on the repair site, should be continued for 4 or 5 days, and standard lumbar drain management principles should be closely followed (as discussed previously). Nasal packing is removed several days after surgery, and the operative site may be checked through serial nasal endoscopy sessions. Patients should be advised to avoid strenuous activity, sneezing, coughing, and so on, for approximately 6 weeks after surgical repair. The long-term postoperative management of patients with increased ICP and apparent spontaneous CSF rhinorrhea should be aimed at lowering the ICP. The reduction may be achieved with diuretic therapy, such as acetazolamide,[70] or less commonly through a CSF diversion procedure, such as ventriculoperitoneal shunting or lumbar peritoneal drain.

Endoscopic techniques offer several advantages. The excellent visualization afforded by nasal endoscopy facilitates identification of the defect and placement of the grafts. Endoscopic repair is also well toler-

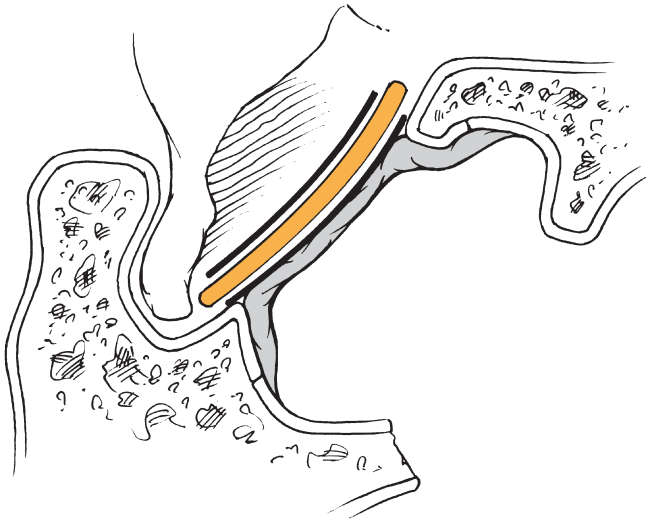

Figure 54-10. Layered reconstruction also provides an optimal barrier for sphenoid cerebrospinal fluid leaks, as shown in this illustration of such a repair of a midline sphenoid defect (after transsphenoidal hypophysectomy). Layers are as indicated in Figure 54-9. *(Redrawn with permission from Lorenz RR, Dean RL, Hurley DB, Chuang J, Citardi MJ. Endoscopic reconstruction of anterior and middle cranial fossa defects using acellular dermal allograft.* Laryngoscope. *2003;113:496-501.)*

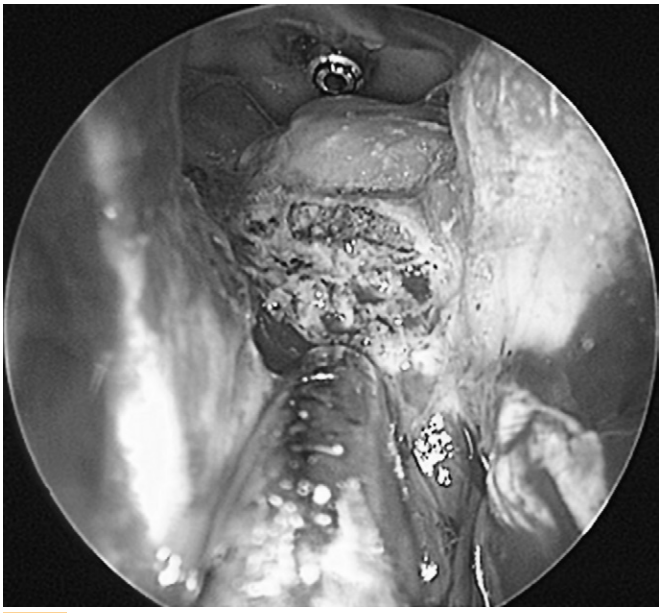

Figure 54-11. Endoscopic repair of a frontal sinus posterior table defect may require an anterior table trephination. In this endoscopic image of the left frontal recess (obtained through a 70-degree telescope), the inferior suction rests on the inferior edge of a small meningocele, and the superior bipolar suction cautery, which was passed through the trephine, rests on the superior edge of the meningocele.

ated, especially in comparison with intracranial techniques. Reported outcomes are excellent.[12-14,57] Successful repair may be anticipated in more than 85% to 90% of primary procedures; secondary endoscopic repair is also associated with a high likelihood of success.

Precautions for CSF Rhinorrhea

Patients who have confirmed CSF leak and are awaiting definitive management as well as patients who have suspected CSF leak should be counseled about the pathophysiology of CSF rhinorrhea. For many patients, watery rhinorrhea may seem trivial, but aggressive patient education is warranted to correct that potentially fatal misconception. In particular, patients must understand the early symptoms of meningitis, so that they can seek appropriate medical care quickly if such symptoms start to develop. In addition, these patients should be advised to minimize actions that can increase ICP and exacerbate a CSF leak.

Bacterial meningitis is the major cause of mortality and morbidity in patients with CSF fistulas. Considering the contaminated surgical field during the endoscopic repair of CSF fistulae, most surgeons elect to use perioperative antibiotics. Typically an agent with good CSF penetration, such as ceftriaxone, is administered. The efficacy of long-term prophylactic antibiotics for the prevention of meningitis in patients with active CSF rhinorrhea, however, remains a very controversial issue. The primary concern about unwarranted use of antibiotics is the potential for selection of resistant organisms. The reported incidence of meningitis in patients with posttraumatic CSF fistulas varies greatly (2% to 50%).[71-73] Multiple factors, including the duration of CSF leakage, delayed onset of CSF leakage, site of the fistula, and concomitant infections, seem to affect the occurrence of meningitis. Patients with posttraumatic CSF leaks lasting more than 7 days have at least 8- to10-fold increase in risk of meningitis.[71,72] Strong consideration should therefore be given for surgical repair of posttraumatic CSF leaks persisting more than 7 days despite appropriate conservative management.

MacGee and associates[74] reported one of the main studies frequently cited in arguments against the use of prophylactic antibiotics in posttraumatic CSF fistulas. They described a series of 58 patients and reviewed data on 344 patients from the literature, for a total of 402 patients with posttraumatic CSF leaks. There was a 14% incidence of meningitis in the group who received prophylactic antibiotics, compared with 5% in the group treated without antibiotics. However, the difference in incidence of meningitis between the two groups did not reach statistical significance. In a meta-analysis of six studies involving 324 patients with posttraumatic CSF leaks, Brodie[73] found a 2.5% incidence of meningitis in patients who received prophylactic antibiotics and a 10% incidence in those who did not receive antibiotics. The difference was statistically significant ($P = .006$). Individually, however, none of the studies included in this analysis demonstrated a significant difference in incidence of meningitis with prophylactic antibiotic therapy. It is important to mention that there is a paucity of studies examining the incidence of meningitis in nontraumatic, idiopathic CSF leaks.

For patients with persistent leaks, immunization against *Streptococcus pneumoniae*, *Haemophilus influenzae,* and *Neisseria meningitidis* may be considered.

Comprehensive Management Strategy

Indications for operative CSF leak repair include failure of conservative management, intraoperative recognition of a leak (during sinus surgery, skull base surgery, or craniotomy), large defects or leaks (especially in association with pneumocephalus), idiopathic leaks, so-called spontaneous leaks, and open traumatic head wounds with CSF leakage.

A single management strategy cannot be utilized for the treatment of all CSF leaks. Instead, selection of the appropriate treatment should reflect the natural history of CSF rhinorrhea as well as potential morbidity. Therefore, treatment should be targeted to the underlying etiology of the CSF leak. It is practical to consider management options in the following four scenarios: traumatic (nonsurgical) etiology, intraoperative injury with immediate recognition or onset, operative injury with delayed recognition or onset, and nontraumatic ("spontaneous") leaks.

Traumatic (Nonsurgical) Etiology

CSF rhinorrhea due to head injury should be managed initially with conservative measures that reduce ICP and promote spontaneous closure of the CSF leak. If the rhinorrhea does not resolve within several days, operative exploration and repair is necessary. Often, extracranial endoscopic techniques are applicable; however, open transcranial procedures may be warranted. An important exception to the use of con-

servative measures is the situation of massive head injury requiring urgent operative exploration; in this scenario, direct closure of the skull base defect should be performed.

Massive skull base trauma is often associated with intracranial and maxillofacial injuries. Such cases are typically managed in an interdisciplinary fashion with immediate attention given to address life-threatening neurologic injuries. Pneumocephalus should be treated promptly because rapid air accumulation may lead to a catastrophic outcome. Most cases of massive head and skull base trauma are initially handled by a trauma neurosurgeon in conjunction with an otorhinolaryngologist, a maxillofacial surgeon, and an ophthalmologist, depending on the extent and location of injuries.

The vast majority of cases of CSF rhinorrhea due to head trauma do not require operative intervention, because the leaks tend to resolve with conservative measures only.

The administration of prophylactic antibiotics for CSF rhinorrhea due to trauma is controversial, as discussed previously. Certainly, in instances of contaminated, open wounds, most surgeons would employ intravenous antibiotics, but in most circumstances, the decision to administer intravenous antibiotics should be made on a case-by-case basis.

Intraoperative Injury with Immediate Recognition or Onset

CSF leaks that are noted intraoperatively should be repaired at the time that they are recognized. If a CSF leak is suspected during routine endoscopic sinus surgery, the surgeon should attempt to confirm its presence. If a leak is confirmed, endoscopic repair should be performed. Deliberate breach or resection of the dura in operations on the anterior skull base should be closed to provide a watertight seal at the end of the procedure.

Operative Injury with Delayed Recognition or Onset

In some instances, the presence of CSF rhinorrhea may not be confirmed until days, weeks, months, or even years after a surgical procedure. A trial of conservative therapy for a few days is warranted in most instances, because at least some of these leaks close with use of simple measures. However, it is reasonable to pursue operative intervention for massive leaks early. In addition, if there has been a significant delay (i.e., more than several weeks at most) between the time of the surgery and the time of CSF leak diagnosis, conservative measures are less likely to be successful, and early surgical intervention is warranted. Of course, when conservative measures fail, surgical repair is the next step.

Nontraumatic Leaks

In general, nontraumatic CSF leaks are likely to require surgical repair, but in selected instances, a trial of conservative measures may be attempted. Treatment of nontraumatic CSF rhinorrhea due to neoplasm, hydrocephalus, and so on, should involve treatment of the specific etiologic factors. Commonly, nontraumatic leaks occur "spontaneously"—that is, there is an absence of obvious antecedent factors. In this scenario, consideration of unrecognized elevation of ICP due to BIH or ESS must be considered. Regardless, operative repair will likely be necessary.

Conclusions

CSF rhinorrhea occurs when a skull base defect permits the drainage of CSF from the intracranial space to the nose and paranasal sinuses. CSF leaks are best categorized as traumatic or nontraumatic. Accurate diagnosis has been problematic, although the β_2-transferrin test now provides a relatively specific testing modality. Several CSF tracer studies are available; however, all of these studies suffer from suboptimal precision, specificity, and sensitivity. High-resolution CT provides detailed information about the bony skull base anatomy, and MRI assesses soft tissue issues, including unrecognized tumors and coincidental meningoencephaloceles. Many CSF leaks respond to conservative management (observation plus measures to minimize ICP); in particular, traumatic CSF rhinorrhea tends to resolve with conservative measures alone. In contrast, nontraumatic CSF rhinorrhea is especially likely to require direct operative repair. Although transcranial techniques for CSF leak closure have been present for many decades, they are often second-line choices in the contemporary management of CSF rhinorrhea. Extracranial techniques were developed in the middle of the 20th century, but the incorporation of endoscopic visualization and instrumentation over the past 20 years has made endoscopic repair the preferred surgical modality for those instances in which operative repair is warranted.

CHAPTER FIFTY-FIVE

Endoscopic Dacryocystorhinostomy

Erik Kent Weitzel

Peter-John Wormald

Key Points

- Chronic epiphora should be investigated with a dacryocystogram and possibly a scintillogram prior to surgery to localize the site of obstruction to ensure that it is amenable to dacryocystorhinostomy.
- Although anatomic obstructions of the lacrimal system are associated with excellent surgical outcomes, functional obstructions have less impressive responses to surgery. It is important to differentiate between these two types of obstruction to determine a patient's prognosis.
- The superior edge of the lacrimal sac is located well above the insertion of the middle turbinate. Surgical outcomes are improved when the entire sac is marsupialized.
- The primary surgical goal is to lay the marsupialized lacrimal sac flat without tension in direct contact with surrounding mucosa for primary intention healing. This concept allows outcomes of endonasal dacryocystorhinostomy to equal those of the external procedure.
- Advantages of endonasal over external dacryocystorhinostomy include the lack of an incision and no disruption of the lacrimal pump mechanism.

Endoscopic dacryocystorhinostomy (DCR) was first described in the otolaryngology literature by McDonogh[1] in 1989. Over the ensuing years, there has been a steady improvement in outcomes owing to advances in surgical technique, instrumentation, and comprehension of the anatomy. Specifically, once the superior extent of the lacrimal sac was recognized to extend significantly above the middle turbinate, surgical outcomes improved.[2] Today's endoscopic DCR is a reliable and effective technique that is comparable to external DCR in outcome measures.[3-6] In 2007, endoscopic DCR was reported to be economically superior to the external technique.[7]

Pathophysiology

Obstructions of the lacrimal apparatus can occur anywhere along its course. DCR surgically bypasses the most distal portion of the lacrimal apparatus, creating a new outflow in the lateral wall of the nasal cavity instead of below the inferior turbinate. Thus, DCR is specifically designed to manage obstructions of the lacrimal sac and duct. It is important to note that DCR is not capable of reliably managing obstructions within the lacrimal apparatus proximal to and including the common canaliculus (Fig. 55-1). In selected cases, a stenosis of the common canaliculus immediately proximal to its entry into the lacrimal sac can be managed by temporary stenting with O'Donoghue tubes.

E. Weitzel has no financial interest/arrangement or affiliation with one or more organizations that could be perceived as a real or apparent conflict of interest in the subject of this paper. P-J. Wormald has a financial interest/arrangement with Medtronic Xomed for royalties received from design of surgical instruments.

There are two principal categories of lacrimal obstruction, anatomic and functional. Anatomic obstructions are more common than functional obstructions, the approximate rates being 70% and 30% respectively.[5] Anatomic obstructions are complete blockages most commonly noted between the lacrimal sac and nasal cavity. Functional obstructions are caused by either critical narrowings within the lacrimal system that delay normal lacrimal flow or a failure of the proximal pumping mechanism. Both anatomic and functional obstructions may be managed with endoscopic DCR; however, surgery of anatomic obstructions is noted to have superior outcome.

Evaluation

The clinical evaluation of the patient presenting for DCR excludes other causes of epiphora, including entropion, ectropion, lid malposition, punctal abnormalities, and blepharitis. The discovery of reflux of purulent material from the lacrimal puncta during medial canthal palpation indicates obstruction of the nasolacrimal system that is amenable to DCR. Probing of the lacrimal system with a Bowman's lacrimal probe adds a more detailed clinical picture to the level of blockage. A "hard stop" implies that the probe has impacted against the lacrimal bone, suggesting a patent lacrimal system up to the lacrimal sac. A "soft stop" implies that distal progress of the probe is impeded by soft tissue, suggesting either stenosis of the common canaliculus or a tight common canaliculus-sac junction. Further information is gleaned by syringing of the lacrimal apparatus. A 25-gauge blunt lacrimal needle is inserted into the inferior puncta, and saline is gently flushed. The taste of saline confirms a patent system, although the test is not diagnostic because the pressures developed during the test are much higher than normal

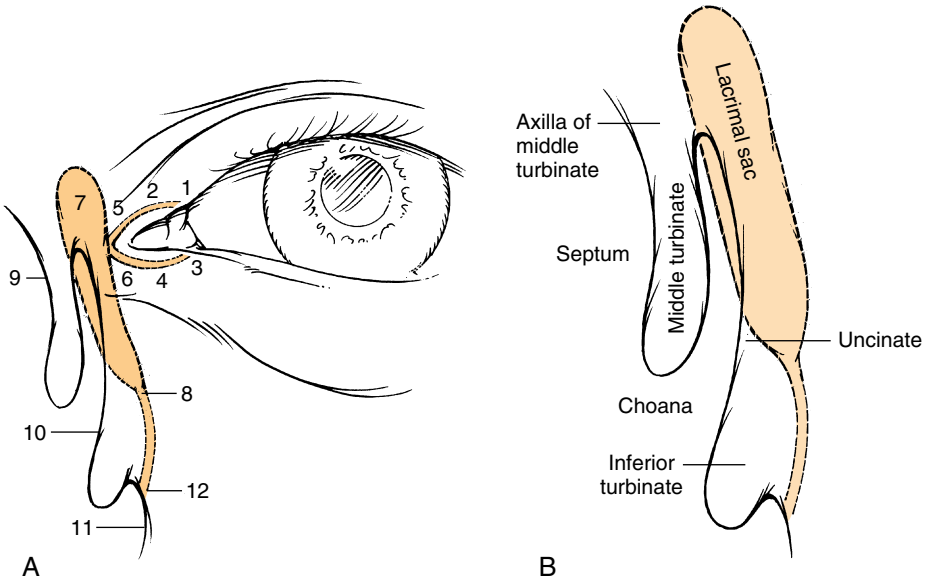

Figure 55-1. **A,** Anatomy of the left lacrimal apparatus: 1, superior punctum; 2, superior canaliculus; 3, inferior punctum; 4, inferior canaliculus; 5, medial canthal ligament; 6, common canaliculus; 7, lacrimal sac; 8, lacrimal duct; 9, middle turbinate; 10, lacrimal bone; 11, inferior turbinate; 12, Hasner's valve. **B,** Position of lacrimal sac as seen during endonasal visualization. Figure 55-2. Anatomic obstruction. This left-sided dacryocystogram shows dye failing to penetrate past the lacrimal sac/duct junction.

and thus cannot identify functional constrictions within the system. An anatomically blocked system causes reflux through the superior punctum during irrigation. More proximal canalicular obstructions can cause reflux out of the punctum being injected.

Radiologic evaluation of lacrimal obstructions begins with the dacryocystogram (DCG). Because it, like saline irrigation, causes elevated pressures within the lacrimal system, this study is capable of diagnosing only anatomic obstructions (Fig. 55-2). Failure of DCG to identify a blockage in a symptomatic patient necessitates lacrimal scintilligraphy. Unlike DCG, scintilligraphy is a physiologic test of the lacrimal system; thus functional obstructions cause delays in the flow of radioisotopes from the conjunctiva into the nasal cavity over the 30-minute duration of the test. If isotope delay is detected in the lacrimal sac during the test, a narrowed segment is more likely than a failure of the lacrimal pump mechanism (Fig. 55-3). However, if the isotope does not penetrate the lacrimal system, a pump failure is then more likely. Studies have shown that outcome of DCR performed for anatomic obstructions is superior to that of DCR done for functional obstructions.[5] The ability to confirm an obstruction with scintilligraphy and to differentiate anatomic from functional obstruction with DCG allows the surgeon to better prepare the patient for the prognosis of the procedure.

Surgical Technique

(Video clip available on website.)

Nasal preparation is performed with both pledget-applied vasoconstrictor and lateral nasal wall injection of 2% lidocaine with 1:80,000 adrenaline. The injection is performed in two places: superior to the axilla and well anterior to the uncinate process. If a septoplasty must be performed, the septum is likewise injected. Endoscopic septoplasty is performed in 48% of cases,[8,9] because any narrowing of the anterior nasal cavity increases the complexity of the procedure dramatically. Generally, the septoplasty is very limited and specifically addresses the most anterior and superior portion of the bony septum. This area is checked for adequacy by gentle medialization of the septal mucosa to ascertain mobility in the region medial and anterior to the axilla (Fig. 55-4).

A 30-degree scope angled superolaterally is used during the entire procedure to improve visualization around the frontal process of the maxilla. The posteriorly based DCR flap is created with the underlying lacrimal sac in mind. Because approximately half of the sac extends above and posterior to the insertion of the middle turbinate, the superior incision for the flap is created 5 mm posterior and 10 mm superior to the axilla (Fig. 55-5). The flap is brought 10 mm anterior to the middle turbinate, because a shorter flap would limit the ability to marsupialize the lacrimal sac fully. The inferior incision is created at the insertion of the inferior turbinate about two thirds of the way down the middle turbinate.

A suction Freer elevator is used to establish a subperiosteal plane along the incisions onto the frontal process of the maxilla. The flap should be developed over the broadest possible area and mobilized over the frontal process of the maxilla until the lacrimal bone is identified. The easiest place to identify the lacrimal bone is in the region directly adjacent to the inferior horizontal incision just above the inferior turbinate. The junction of the hard bone of the frontal process of the maxilla and the soft thin lacrimal bone is a critical landmark and must be identified in all cases. Posteriorly, the flap is elevated past the lacrimal bone and just onto the uncinate process. Superiorly the flap elevation is carried well on to the insertion of the middle turbinate (Fig. 55-6).

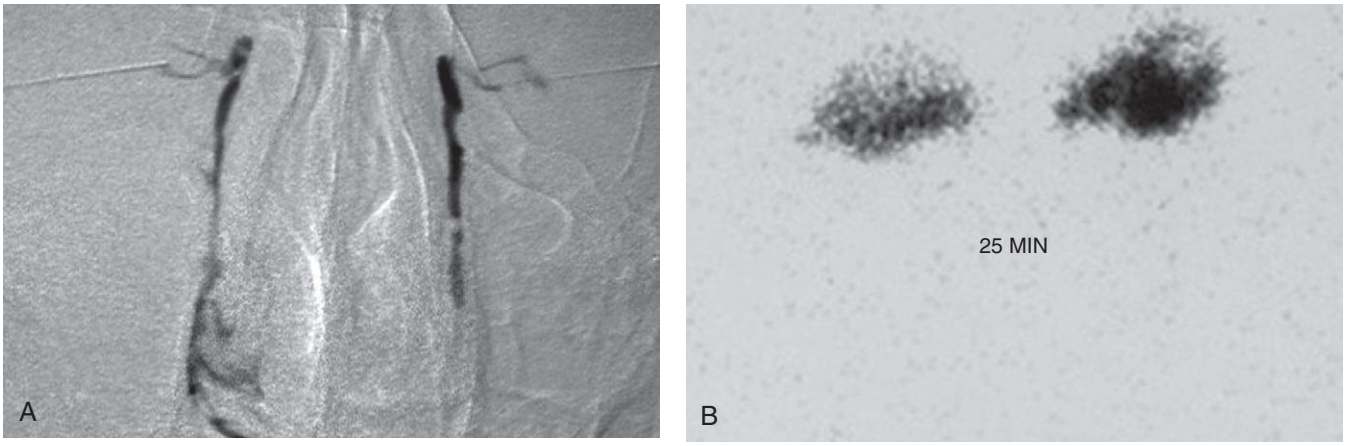

Figure 55-3. Functional obstruction. Dye penetrates the nasal cavity on the right-sided dacryocystogram (**A**), but after 25 minutes, scintilligraphy fails to show any penetration (**B**).

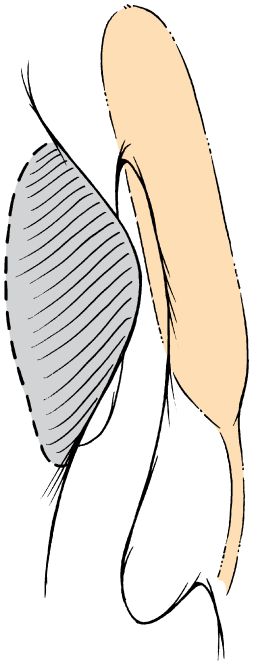

Figure 55-4. High endoscopic septoplasty. Ideal area of bone removal for dacryocystorhinostomy (DCR) is indicated by the *dashed line*. This subsequently pliable region of septum will be a potential space to give additional freedom of endoscope movement. All endonasal DCRs require a septoplasty if the axilla is not completely visualized. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

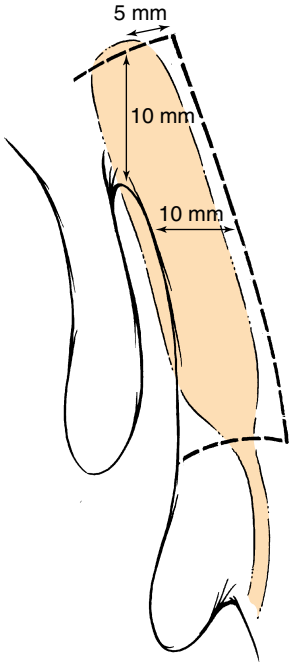

Figure 55-5. Detail of dacryocystorhinostomy flap with measurements. Superior margin of the flap is 5 mm posterior to the insertion of the middle turbinate and 10 mm above the axilla. The inferior limit of the flap is 10 mm anterior to the uncinate and just at the superior margin of the inferior turbinate. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

When completed, the posteriorly based DCR flap is pedicled inferiorly off the superior aspect of the inferior turbinate and insertion of the uncinate. In the midportion of the flap, the pedicle is rather weakly attached to the uncinate bone, and tears in this portion of the flap may occur.

A round knife (from the ear instrument set) is used to identify the frontal process–lacrimal bone junction and to flake off the lacrimal bone. This region is difficult to see if a 0-degree scope is used; this maneuver exposes the posteroinferior aspect of the lacrimal sac and adjacent nasolacrimal duct. Next, a forward-biting Hajek-Koffler punch is used to remove the frontal process of the maxilla overlying the anteroinferior aspect of the lacrimal sac. After each bite the surgeon opens the punch to release the bone before closing the punch and carefully removing the bone; this maneuver prevents the lacrimal sac that may be adherent to the medial side of this bone from being torn, as it would if the punch were simply closed and the bone removed. As this bone removal continues superiorly, the bone thickens and it becomes increasingly difficult for the Hajek-Koffler punch to grip the bone. The completion of this task requires drilling, for example with a 25-degree angled DCR diamond bur (Medtronics ENT, Jacksonville, FL). The bur is used to thin the remaining visible bone within the limits of the DCR flap, avoiding the bone-sac junction. Once this bone is thin, the bone-sac junction is addressed, with care taken to ensure that the bur does not slip under the junction and thereby place excessive pressure on the sac wall.

As the bone removal continues to the edges of the mucosal flap incisions, the lacrimal sac begins to "stand proud" of the lateral nasal wall, so that when it is opened it will lie flat on the lateral nasal wall. Effectively the sac is marsupialized into the lateral nasal wall. As the bone is removed over the posterolateral region of the lacrimal sac, the

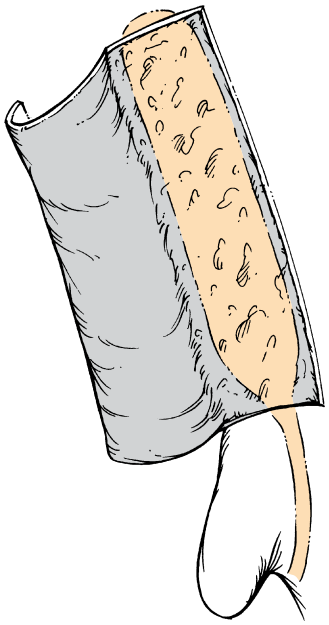

Figure 55-6. Mucosal flap elevated off the frontal process of the maxilla and rolled over the middle turbinate. The flap must be aggressively mobilized off the axilla of the middle turbinate to allow adequate superior and posterior bony removal. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

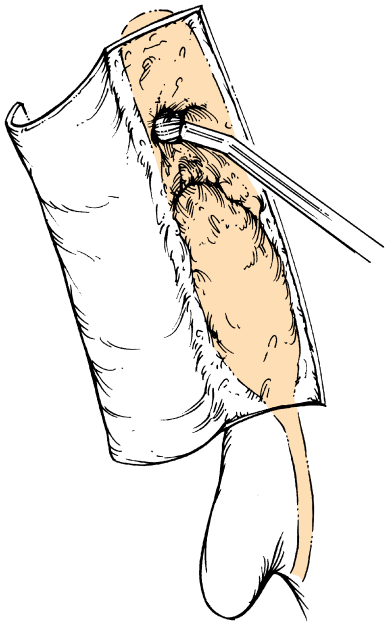

Figure 55-7. Bony work. A bone punch is used to remove frontal process of maxilla off the lacrimal sac. Next a diamond bur is used to saucerize remaining visible bone to the margins of the dacryocystorhinostomy flap. Finally, the bone overlying the agger nasi cell is removed until the cell's mucosa can be marsupialized. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

mucosa of the agger nasi cell is exposed. The bone between the anterior aspect of the agger nasi cell and the lacrimal sac forms an inverted pyramid and must be carefully removed to establish complete exposure of the lacrimal sac. A sickle knife is used to open the agger nasi mucosa, thus creating the posterior mucosa to which the lacrimal sac will approximate (Fig. 55-7).

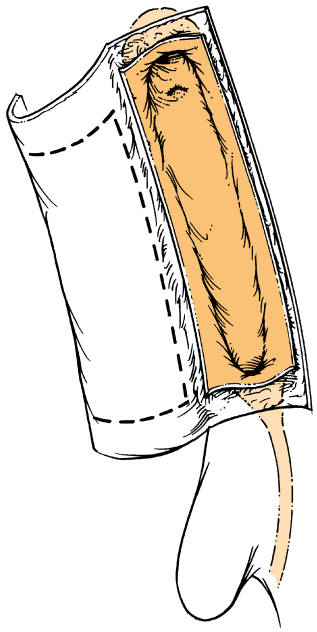

Figure 55-8. The lacrimal sac is open and laid out flat on the lateral wall of the nose. The dacryocystorhinostomy flap is then cut (indicated by *dashed lines*) to cover any exposed bone. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

When bony work is completed, the lacrimal puncta are inspected and are dilated if too small to accommodate a lacrimal probe. The sinus endoscope provides adequate lighting and magnification to assist with this part of the procedure. An assistant holds the endoscope while the primary surgeon passes a Bowman's lacrimal probe along the inferior canaliculus and into the lacrimal sac. Passing the lacrimal probe to the assistant, the surgeon then identifies the metal of the lacrimal probe visible within the translucent sac wall. If the probe is not creating a sharp-pointed projection, but instead is causing a more generalized movement of the sac, the probe has not yet emerged from the common canaliculus and requires further manipulation until its point is clearly seen within the sac. A spear knife (Medtronics ENT) is then used to cut down on the lacrimal probe and open the sac superiorly and inferiorly with a rotating cutting movement. A lacrimal mini-sickle knife (Medtronics ENT) is used to make the superior and inferior flap cuts in the anterior lacrimal sac. These cuts allow the anterior lacrimal sac to be rolled out over the frontal process of the maxilla, approaching the anterior vertical mucosal incision. The posterior cuts are made with a microscissors in the most superior and inferior aspects of the sac again, allowing the posterior sac to be rolled posteriorly, resulting in a complete marsupialization.

The mucosal flap is then positioned to evaluate where it needs to be cut to create flaps to ensure that approximation of the nasal mucosa to the lacrimal mucosal occurs. Usually a superior flap is required to cover the exposed bone above the lacrimal sac, and occasionally an inferior flap is required to cover bone. The middle portion of the flap is removed until the posterior aspect of the flap approximates the posterior edge of the lacrimal sac. The flaps are then positioned with a ball probe (Fig. 55-8).

The common canaliculus should be visible in the lateral sac wall in every case and is easily located by placement of a lacrimal probe back through the inferior canaliculus. Stenting the system during recovery is now considered. Lacrimal tubes do not have to be placed if the passage of the lacrimal probe was without resistance through the canaliculus and the common canaliculus valve of Rosenmüller. However, if there is any doubt about the possibility of common canaliculus tightness, then stents such as O'Donoghue tubes (BD Visitec, Bidford-Upon-Avon, UK) are placed through the superior and inferior canaliculi and brought out of the common canaliculus. This is done in order to

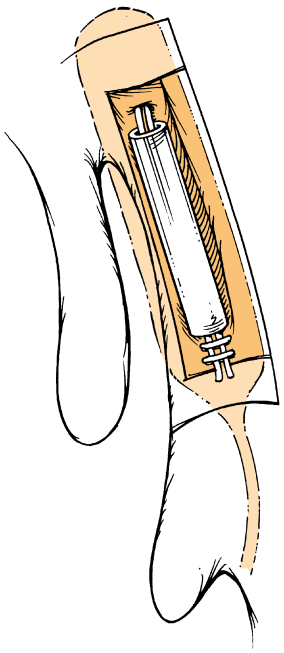

Figure 55-9. Close-up view of completed dacryocystorhinostomy (DCR). O'Donoghue tubes stent open the common canaliculus. The marsupialized lacrimal sac is in direct approximation to the cut margins of the DCR flap. No bone is left exposed, and no force is required to keep the sac in an open position. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

dilate the common canaliculus and treat any functional obstruction of the proximal lacrimal system. The tubes are not placed to keep the sac open; the sac should lie open without the stenting action of the tubes. A 1.5-cm circular piece of gelatin sponge (Gelfoam) is loaded on the O'Donoghue tubes, followed by a 1-cm segment of 4-mm silicone tubing. The tubing is used to push the gelatin sponge into the lacrimal sac. A loop of tubing is pulled in the medial canthus to prevent "cheese-wiring" of the puncta. Two titanium Liga clips are crimped below the silicone tubing, and the tubes are cut just below these clips (Fig. 55-9). The gelatin sponge is raised out of the lacrimal sac to allow inspection of the flaps to ensure that they remain fully rolled out and that the nasal mucosal flaps do not cover any part of the lacrimal sac.

Outcomes

A number of series have shown that 90% to 95% of patients are asymptomatic after a DCR regardless of the type of approach (endonasal or external).[3-5,10-14] Subgroup analyses in these studies have shown that success with DCR is related to the type of obstruction. When Tsirbas and Wormald[6] evaluated outcomes with endonasal DCR, regardless of obstruction type, they noted a 95% rate of lacrimal sac patency, as indicated by clear flow of fluorescein placed in the conjunctiva. However, in terms of symptom control, 95% of anatomic obstructions became asymptomatic, whereas only 81% of patients with functional obstructions had complete relief of symptoms. The higher rate of symptomatic failures in the functional obstruction group was thought to be due to tear collection by the eyelids off the globe, which is not addressed by DCR. It is important to note that despite the diminished number of asymptomatic patients within the functional obstruction group, the patients who did not meet the criteria for success (asymptomatic) still enjoyed an appreciable amount of improvement.[8,9]

Revision Endoscopic Dacryocystorhinostomy

The principles of revision DCR are similar to those of primary DCR. The most important factor that determines the success of revision surgery is the size of the lacrimal sac. Preoperative DCG should be obtained for all patients who have undergone prior DCR (either external or endoscopic) to evaluate the size of the lacrimal sac. If the sac is of normal size, then the success rate of the procedure is similar to that of a primary procedure. However, if there is scarring and cicatrization of the sac, the success rate is lower, because even with full sac exposure only a small amount of lacrimal mucosa can be marsupialized. This leads to a higher risk of repeated scarring and stenosis. Analysis of outcomes shows that revision surgery has very acceptable rates of success (89% success with multiple attempts).[8,9] In cases in which there is significant scarring and stenosis of the lacrimal sac, the agger nasi mucosa has been used as a free graft to create functional mucosa surrounding the common canaliculus–sac junction.

Complications

Theoretical complications of endonasal DCR are similar to those for endoscopic sinus surgery. The most common complication is epistaxis, occurring in 2% of cases. All cases of epistaxis in a large series were managed solely with nasal packing.[8,9] Other possible complications are postoperative frontal or maxillary sinusitis from damage to the drainage pathways, orbital penetration with damage of the ocular muscles, and skull base penetration with subsequent cerebrospinal fluid leak. All significant complications occurring as a result of an endonasal approach are due to a surgeon's inexperience with the endoscopic surgical anatomy of the nose and have been reported only in series not involving otolaryngologists.[6,15-19] It is for this reason that an oculoplastic surgeon and an endoscopic otolaryngologist should work together as a team so that all aspects of this technique are mastered quickly with minimal associated learning morbidity.

Conclusions

Endonasal DCR is a highly evolved surgical technique with outcomes comparable to those of traditional techniques. Advantages of endonasal DCR include a lack of skin incisions, preservation of the lacrimal pump, cost-effectiveness, and the safety profile. The technique remains useful in revision situations despite multiple previous operations.

Evaluation and Management of Laryngeal and Pharyngeal Disorders

CHAPTER FIFTY-SIX

Laryngeal and Pharyngeal Function

Gayle Ellen Woodson

Key Points

- The upper aerodigestive tract serves the competing functions of respiration and swallowing.
- The anterior ends or the vocal folds are fixed at the anterior commissure.
- All motion of the vocal folds is caused by muscles that move the arytenoid cartilage.
- The posterior cricoarytenoid muscle is the only muscle that actively opens the larynx.
- The recurrent laryngeal nerve supplies all intrinsic laryngeal muscles except for the cricothyroid muscle.
- The cricothyroid muscle is supplied by the motor branch of the superior laryngeal nerve.
- The internal branch of the superior laryngeal nerve carries sensory information from the larynx.
- Vocal sound is produced by passive vibration of the vocal folds, powered by exhaled air.

The upper aerodigestive tract serves the competing functions of respiration and swallowing. The nose is the primary respiratory orifice, and the mouth is the portal for ingestion of food. Both open into a common cavity, the pharynx. The patency of the upper airway must be actively supported during breathing, yet total and forceful collapse is required to propel food into the esophagus during swallowing. The airway must be protected during a swallow so that ingested food or water does not spill into the trachea. Aspiration of food or foreign material can lead to serious consequences, such as asphyxia or lung infection. In humans, the function of the upper aerodigestive is considerably more complex, owing to the demands of speech as well as to a significant structural difference. In infants and in all nonhuman mammals, the pharynx is functionally compartmentalized into separate passages for breathing and alimentation. The epiglottis interdigitates with the uvula to form a respiratory channel from the nose into the larynx and two lateral pathways from the mouth to the esophagus through the pyriform sinuses.[1] During postnatal development in humans, enlargement of the cranium with flexion of the base of the skull results in a downward displacement of the larynx. This displacement elongates the pharynx and distracts the uvula and epiglottis so that they are no longer in contact. The result is a common pharyngeal cavity for breathing and swallowing (Fig. 56-1).[2,3] The larynx begins its descent at the age of about 18 to 24 months. There are two positive outcomes. Vocal power is greater because of increased resonance, and articulatory diversity is expanded.[4]

This complicated and potentially hazardous configuration of the upper airway results from embryology and reflects evolution. The lower respiratory tract has evolved as an offshoot of the digestive tract, first appearing in the lungfish as a simple muscle sphincter to protect the lungs from water.[5] Consequently, during embryologic development, the foregut is the common origin of the larynx, trachea, and esophagus.

Normal function of the larynx and pharynx requires precise timing and coordination of competing functions of this system. Thus, function is easily disrupted by structural or neurologic pathology. Further, the treatment of any disease or disorder of this region may have an impact on more than one function. For example, surgery to improve the glottic airway can impair the voice or lead to aspiration during swallowing. It is therefore imperative for otolaryngologists to understand the function of the upper aerodigestive tract. This chapter focuses on the functions of breathing and speech; swallowing is addressed in another chapter of this book.

Laryngeal Motion

Applied Anatomy

In the illustrations of many textbooks, the membranous vocal folds are depicted as moving solely in the axial plane, with rotational motion similar to that of a windshield washer. Details of motion of the posterior, cartilaginous portions of the larynx have been largely ignored. The reason is that early concepts of motion were based on observing laryngeal motion with a mirror, and then recording the observations with two-dimensional freehand drawings. However, with the advent of flexible endoscopy, stroboscopy, videorecording, and computerized imaging, it has become clear that laryngeal motion is more complex than previously recognized. Vocal folds move in three dimensions and undergo conformational changes in length, shape, and volume (Fig. 56-2).[6] The terms *cadaveric* and *paramedian* have been commonly used to describe the position of paralyzed vocal folds. These terms are inadequate to describe the three-dimensional changes in configuration of the glottis in paralysis.[7] Motion of the larynx is best understood as the net result of the interaction of its component parts.

The laryngeal skeleton consists of the hyoid bone and a series of cartilages. The hyoid bone is a U-shaped structure, open posteriorly, which is suspended from the base of the skull and mandible by muscles and ligaments. The thyroid cartilage, the largest cartilage in the larynx, is suspended from the hyoid bone. The word thyroid means "shield"

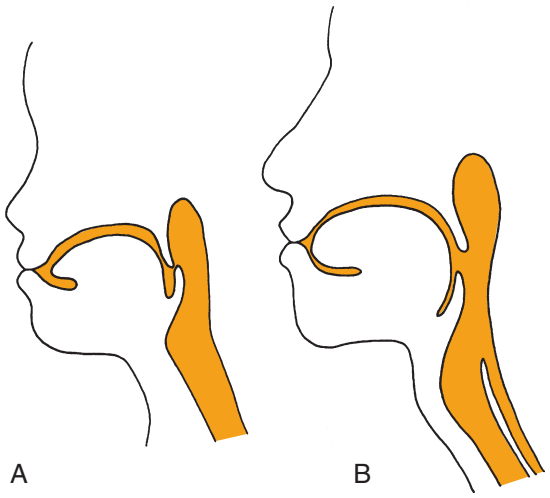

Figure 56-1. Postnatal descent of the larynx. Migration of epiglottis away from the uvula results in loss of pharyngeal compartmentalization for breathing and feeding. **A,** Sagittal view through the head and neck of a neonate. **B,** Sagittal view through an adult head and neck.

and this name is appropriate, because the structure is not only shaped like a shield but also provides support and protection for the vocal folds. In the axial plane, the thyroid cartilage is shaped like a V, with two wings that project posteriorly. Like the hyoid bone, the thyroid cartilage is open posteriorly. The vocal folds attach to the anterior inner surface of the thyroid cartilage. The posterior ends of the vocal folds are anchored to the arytenoid cartilages, which are the chief moving parts of the larynx. The arytenoid cartilages sit atop the posterior rim of the cricoid cartilage and articulate via shallow ball-and-socket joints. The cricoid cartilage is the only complete rigid ring within the airway. It is shaped like a signet ring and is broadest posteriorly. Inferiorly, and just lateral to the cricoid joints, the inferior cornua of the thyroid cartilage articulates with the cricoid in two hingelike joints, creating a visor-like, or "bucket handle" structure, with motion that controls the space between the anterior rims of the thyroid and cricoid cartilages.[8]

The epiglottic cartilage is a leaf-shaped structure that is attached inferiorly to the anterior interior surface of the thyroid cartilage. The upper margin is free and projects into the hypopharynx above the glottic opening. The mucosa covering the epiglottis spreads laterally on both sides and is continuous with the mucosa over the arytenoid, to create the aryepiglottic folds, the lateral borders of the supraglottis. There are some muscle fibers within each aryepiglottic fold that contribute to constriction of the supraglottis. Two small sesamoid cartilages, the corniculate and cuneiform cartilages, sit just above each arytenoid within the aryepiglottic fold.

Most intrinsic laryngeal muscles connect the arytenoid cartilages to either the cricoid or thyroid cartilages. These include the thyroarytenoid muscle, the lateral cricothyroid muscle, the interarytenoid muscle, which act to adduct the vocal folds, and the posterior cricoarytenoid muscle, which is the only active abductor of the larynx. As mentioned above, the arytenoid cartilages are the chief moving parts of the larynx. The membranous vocal folds are suspended between the thyroid cartilage and the arytenoids, and the position of each membranous vocal fold is determined by the motion of the arytenoid cartilage. The arytenoid rotates upward and outward to open the larynx, and rotates inward to close it. Contraction of the posterior cricoarytenoid muscle pulls the muscular process of the arytenoid posteriorly and caudally. The structure of the cricoarytenoid joint prevents the entire arytenoid from being pulled along this vector. Instead, the arytenoid rotates, displacing the vocal process upward and laterally, abducting the vocal fold (Fig. 56-3).[9] Conversely, the lateral cricoarytenoid muscle pulls the muscular process of the arytenoid anteriorly and caudally, which rotates the arytenoid, moving the vocal process medially and adducting the vocal fold. The interarytenoid muscles pull the arytenoid cartilages together. The thyroarytenoid muscles exert some adductor force, but their major action is to shorten or tense the vocal fold and increase its cross-sectional area (Fig. 56-4).

In addition to the diverse force vectors of individual laryngeal muscles, there is also segmental compartmentalization within muscles, increasing the possibilities for fine control. For example, the human posterior cricoarytenoid muscle is divided into two compartments. These are supplied by separate nerve branches, differ in fiber type, and

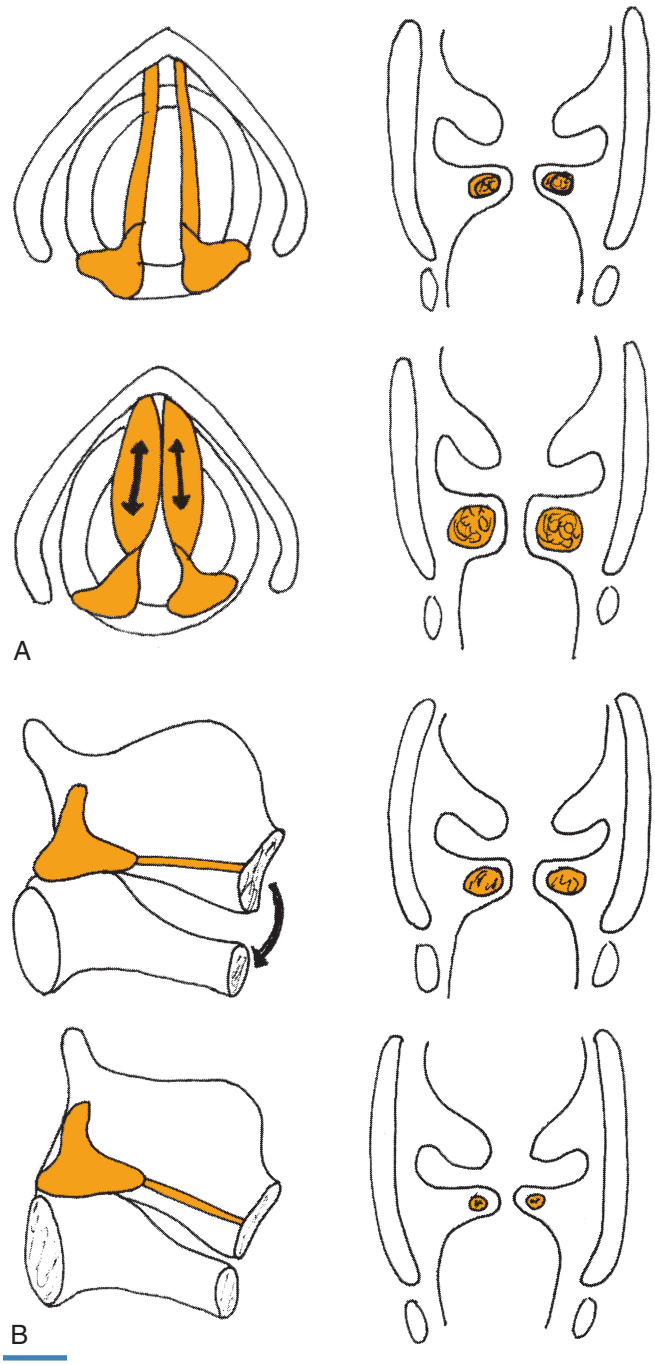

Figure 56-4. Effects of **(A)** thyroarytenoid and **(B)** cricothyroid muscle contraction on the thickness of the vocal fold.

insert on opposing sides of the muscular process (Fig. 56-5).[9,10,11] The human thyroarytenoid muscle is also compartmentalized: It has long been regarded to have a separate medial compartment, the "vocalis."

In contrast to other intrinsic laryngeal muscles, the cricothyroid muscle does not insert on the arytenoid cartilage and therefore has no direct action on arytenoid motion. Instead, the cricothyroid muscle connects the anterior edges of the thyroid and cricoid cartilages. Contraction of this muscle pulls the two cartilages closer together, which increases the distance between the anterior commissure and the cricoid. The result is stretching of the vocal fold, increasing its length and tension. Because both vocal folds insert on the anterior commissure, contraction of either cricothyroid muscle affects both ipsilateral and contralateral vocal folds. Contraction of both right and left cricothyroid muscles results in maximal anterior traction.[8]

Figure 56-5. Compartmentalization of the human posterior cricoarytenoid muscle. Posterior view of a cadaver larynx.

Muscles that are extrinsic to, but connect with, the larynx can also affect glottic function by exerting traction on the laryngeal cartilages. The sternohyoid, thyrohyoid, and omohyoid muscles, innervated by the ansa cervicalis, exert caudal traction on the larynx. This action, as well as downward traction on the trachea during inspiration, causes abduction of the vocal folds.[12,13] Muscles that exert a cephalad force include the geniohyoid, anterior belly of the digastric, mylohyoid, and stylohyoid muscles. In patients with hyperfunctional dysphonia, excess activity can usually be palpated in the extrinsic laryngeal muscles.

The nerve supply to the larynx is via the superior laryngeal nerves and the recurrent laryngeal nerves, both of which are branches of the vagus nerves. The superior laryngeal nerve leaves the vagus nerve high in the neck, at the nodose ganglion. Its internal branch exits the lateral thyrohyoid membrane and carries sensory afferent fiber from the supraglottis and vocal folds, whereas the external branch of the superior laryngeal nerve supplies motor fibers to the cricothyroid muscle. All other intrinsic laryngeal muscles are supplied by the recurrent laryngeal nerves, which leave the vagus nerve in the chest and then travel back up to enter the larynx near the cricothyroid joint. The course of the recurrent laryngeal nerve is much longer on the left side, because it runs under the ligamentum arteriosum, a vestigial remnant of embryonic connection between the aorta and pulmonary artery. On the right side, the recurrent nerve travels only as far caudally as the subclavian artery before returning cephalad.

The laryngeal mucosa is richly supplied with sensory receptors. In fact, there are many more sensory receptors in the larynx than in the lungs, which have a vastly larger area of surface mucosa. Laryngeal sensory receptors respond to a variety of stimuli, including mechanical, thermal, chemical, and taste. These receptors provide important input for protection of the larynx and also information on the movement of air in and out of the lungs. The receptors provide the afferent limbs of a variety of reflexes.

Laryngeal Function in Breathing

The primary and most primitive function of the larynx is to protect the lower airway. In evolution, the larynx first appeared as a sphincter to prevent the ingress of water into the airway of the lungfish.[5] Subsequently, dilator muscles evolved to permit active opening of the larynx. In more evolved animals, the larynx is not just an open or shut valve but, rather, a variable resistor, capable of regulating airflow. Other laryngeal functions are the Valsalva maneuver and coughing. The larynx

is also a sensory organ, providing information about airway function and the purity of inhaled air and serving in the afferent limb of many reflexes.

Protection

When the larynx is mechanically stimulated, it closes abruptly, and respiration ceases. Apnea can also occur in response to such diverse chemical agents as ammonia, phenyl diguanide, and cigarette smoke. These are appropriate and beneficial responses that prevent the entry of foreign matter into the lower airway, although strong laryngeal stimulation may result in responses that appear to be maladaptive, such as laryngospasm and prolonged bronchoconstriction.[14] These reflexes may be produced in experimental animals by electrical stimulation of the superior laryngeal nerve and probably represent an oversaturation of pathways that serve a useful function at lower levels of input.

The larynx occupies a protected position in the body, and it is rarely subject to direct stimulation. Therefore, laryngospasm and apnea are not everyday occurrences. Severe laryngeal reflexes are most often encountered in patients in the operating room in response to direct stimulation during intubation, endoscopy, or extubation. These reflexes most likely occur in patients during light anesthesia and in those who are well oxygenated.

Recurrent paroxysmal laryngospasm is occasionally encountered in clinical practice. In some patients, it is caused by gastroesophageal reflux, which responds to acid-suppressing medication. In other patients, the pathophysiology appears to be a hypersensitive laryngeal closure reflex, because such patients report some triggering event such as eating or inhaling steam or odors. The onset frequently occurs during an upper respiratory infection, but it also can occur after surgical trauma to the recurrent laryngeal nerve. Most often the condition resolves spontaneously within a few months, but it may become a permanent and debilitating problem. The laryngeal closure reflex is particularly sensitive in infants and can be elicited by a stimulus as weak as water. During early infancy, the strength of this reflex increases, then decreases, along a time course similar to that of the incidence of sudden infant death syndrome, suggesting that laryngeal reflexes may play a role in its cause.[15]

Cough

Another important protective reflex involving the larynx is the cough, which ejects mucus and foreign material from the lungs.[16] Cough can be a voluntary action or a reflexive response to stimulation of the larynx or receptors in the lungs. The cough reflex is suppressed during sleep, so that a greater stimulus is required with progressive stages of sleep. During deep sleep, a cough cannot be elicited unless the stimulus first results in arousal to a lighter level of sleep.

The first phase of a cough is inspiratory. The larynx opens widely to permit rapid and deep inhalation. In voluntary cough, the extent of inspiratory effort is varied according to the intended strength of the cough. The second phase is compressive, involving tight closure of the glottis and strong activation of expiratory muscles. The effectiveness of the cough is impaired by glottic incompetence. Finally, the larynx suddenly opens widely, resulting in a sudden and rapid outflow of air, at speeds of as much as 10 L/second. Cough plays an important role in cleaning the tracheobronchial tree and in maintaining patency of the lower airways. Abnormal cough can be a serious clinical problem that interferes with normal daily function and impairs quality of life.

Control of Ventilation

The role of the larynx as an active organ of respiration is not widely recognized. Abduction and adduction of the larynx in phase with respiration has been acknowledged for many years.[17,18] It has been postulated that all respiratory motion of the larynx is passive, resulting from biomechanical coupling of the larynx to the tracheobronchial tree.[12,19] There is some evidence that downward traction on the larynx dilates the glottis.[13] But clinical observations and experimental evidence indicate that the larynx moves actively in respiration and, in fact, plays an important role regulating respiration. The larynx is located at the entrance into the trachea and is capable not only of rapid opening and closure but also of sudden alterations in resistance. Hence, the larynx is better adapted than any other portion of the respiratory tract for regulating airflow. The resistance changes resulting from laryngeal responses to respiratory stimuli, such as negative airway pressure and blood gas changes, have a beneficial effect on ventilation.[20]

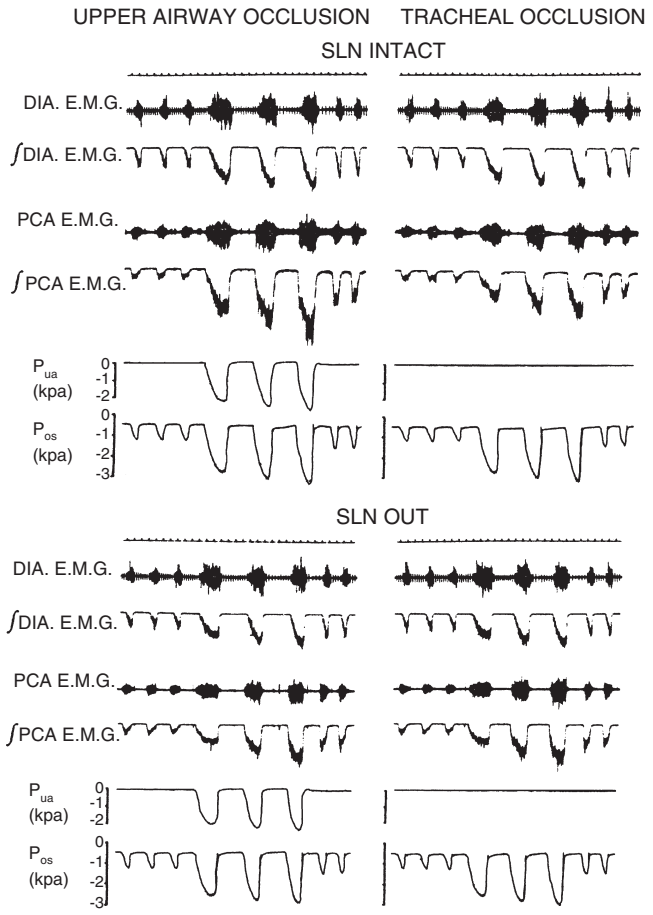

Figure 56-6. Effects of upper airway and tracheal occlusions in an anesthetized dog, before and after a section of the superior laryngeal nerve (SLN). In each panel, the top trace is time in seconds, and the second and third traces are integrated electromyographic activity of the diaphragm (DIA E.M.G.) and posterior cricoarytenoid muscle (PCA E.M.G.). The lower two traces in each panel are pressure in the upper airway (P_{ua}) and esophagus (P_{os}) (intrathoracic pressure). Tracheal occlusion affects only intrathoracic pressure, whereas upper airway occlusion also affects upper airway pressure, which is sensed by the SLN. *(From Sant'Ambrogio FB, Mathew OP, Clark WD, Sant'Ambrogio G. Laryngeal influences on breathing pattern and posterior cricoarytenoid muscle activity.* J Appl Physiol. *1985;58:1298.)*

Widening of the glottis during inspiration is a primary action of ventilation that ceases only during deep anesthesia or sleep. The posterior cricoarytenoid muscle (PCA), the only active dilator of the larynx, begins to contract with each inspiration before activation of the diaphragm.[5,21,22]

The level of PCA activity, and hence laryngeal movement with breathing, varies. Laryngeal motion may be imperceptible during unlabored, quiet breathing. With increasing respiratory drive, peak inspiratory PCA activity increases proportionately with diaphragmatic activity. There are important differences between PCA activity and diaphragmatic behavior (Fig. 56-6). When the upper airway is partially occluded, inspiration generates negative airway pressure, which is a potent stimulus to the PCA and the several other upper airway muscles that dilate the upper airway.[20,23] In contrast, the diaphragm responds by actually decreasing inspiratory force and by increasing the duration of inspiration.[14] This response occurs because, during partial airway obstruction, the PCA and the diaphragm have opposing effects on

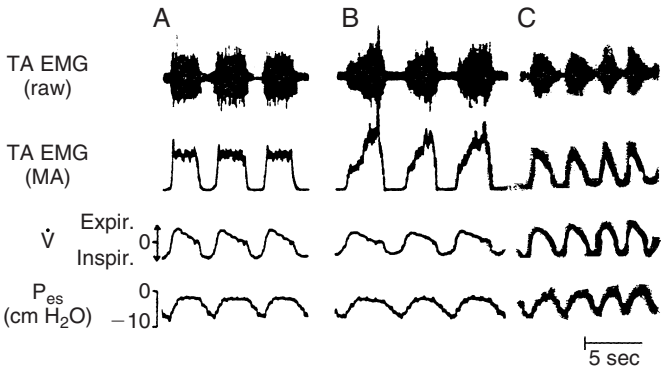

Figure 56-7. Laryngeal adductor activity during breathing as shown on electromyography. **A,** Plateau in thyroarytenoid muscle activity (TA EMG) correlates with decreasing flow. **B,** Progressive increase in TA activity correlates with flattened airflow trace and longer exhalation. **C,** Decreasing activity during expiration correlates with shorter exhalation. Expir., expiration; Inspir., inspiration; MA, averaged; P_{es}, esophageal (intrathoracic) pressure; $\dot{V}$, airflow. *(From Kuna ST, Insalaco G, Woodson GE. Thyroarytenoid muscle activity during wakefulness and sleep in normal adults. J Appl Physiol. 1988;63:1332.)*

patency of the lumen. Increasing diaphragmatic force raises the negative pressure, favoring airway collapse. To inspire the same volume, the diaphragm extends the duration of inspiration. PCA contraction dilates the airway, opposing the effects of the diaphragm. During strong respiratory demand, the PCA continues contracting during expiration after the diaphragm has relaxed, thus delaying expiratory adduction and facilitating the outflow of air. During panting, the glottis sustains an abducted posture, ensuring maximal airflow. Because of these physiologic differences, the phrenic nerve is not an ideal choice for reinnervation of the PCA in patients with laryngeal paralysis.

There has been some controversy in the literature as to whether laryngeal adduction during expiration is an active or passive process. Some electromyographic studies have not confirmed any expiratory activity of laryngeal adductor muscles, suggesting that expiratory narrowing of the glottis is passive, a result of relaxation of the PCA.[24,25] Other researchers have documented phasic expiratory activity of laryngeal adductors.[26,27] These conflicting observations have been reconciled by the finding that respiratory activity of laryngeal adductor muscles is much less consistent than that of the PCA. Expiratory adduction of the larynx is either active or passive, depending on breathing strategy. During baseline conditions, such as sleep, laryngeal adductor muscles are silent. During consciousness, expiratory activation of laryngeal adductor muscles is frequently detected, but at highly variable levels. Correlations of laryngeal adductor muscle activity with expiratory airflow, ventilatory pattern, and transglottal resistance suggest that this is an important mechanism for controlling the rate of breathing (Fig. 56-7).[28] Glottic adduction increases expiratory resistance to airflow, prolonging exhalation. During normal breathing conditions, respiratory rate is primarily controlled by variation in the rate of exhalation.[29] Exhalation is slowed by partial contraction of the diaphragm during expiration. Abdominal muscle pushing increases the rate of exhalation, although during tidal breathing under baseline conditions, the larynx appears to be the primary mechanism for controlling the ventilatory pattern.

Laryngeal regulation of breathing is not essential for life, as evidenced by the fact that patients ventilate satisfactorily through a tracheotomy, although the inability to breathe and speak normally through natural orifices has a devastating impact on quality of life. Optimal function of the upper aerodigestive tract requires normal laryngeal function.

Sensory Receptors

The larynx is not only a motor organ. It also is the location of a variety of sensory receptors that exert influences on breathing and cardiovascular function. The larynx is densely supplied with sensory receptors; sensory fibers from the larynx are several times more numerous than those from the lungs. This finding is remarkable when one considers that the internal surface area of the lungs is several square meters, whereas the larynx is a small orifice. Single nerve fiber recordings from the superior laryngeal nerve have identified three major types of laryngeal respiratory receptors: negative pressure, airflow, and "drive."[30] These receptors are activated by the process of breathing and influence the central control of breathing. Airflow receptors actually respond to a decrease in temperature because the larynx is cooled by inspired air. Thus, flow receptors do not respond to air that has been warmed and humidified by the nose. They are activated by air that comes in through the mouth, particularly in cold and dry weather. "Drive" receptors are probably proprioceptors that respond to the respiratory motion of the larynx. Laryngeal sensations of touch and chemical stimuli are not activated during normal breathing conditions, but stimulation can profoundly affect ventilation.

Circulatory Reflexes

Stimulation of the larynx can alter heart rate and blood pressure. During induction of general anesthesia, endotracheal intubation can result in bradycardia. The direct result of experimental laryngeal stimulation on blood pressure is hypertension,[31] although in the clinical situation, the effects of bradycardia or ectopy usually prevail, resulting in hypotension. In patients with obstructive sleep apnea, negative airway pressure may stimulate receptors in the larynx so strongly that cardiac arrhythmias occur. Animal experiments show that the afferent limb is the superior laryngeal nerve because transection of this nerve abolishes cardiovascular responses (Fig. 56-8). The efferent limb for bradycardia is the vagus nerve, and the efferent limb for blood pressure elevation is via sympathetic nerve fibers, but intervening central connections have not been identified.[32]

Pharyngeal Function in Breathing

The upper airway is a conduit with several points wherein the shape and cross-sectional area can be dynamically altered. The pharynx is the largest but most compliant region, and it is susceptible to passive collapse. Maintenance of patency requires the action of striated upper airway muscles in coordination with the activity of respiratory pump muscles.[33] Upper airway muscles also determine whether air is inspired through the nose or the mouth. The anatomy and intrinsic properties of upper airway muscles indicate that they are primarily adapted for nonrespiratory functions but can be used in respiratory tasks. Most of the muscles acting on the pharynx show no respiratory activity during awake, tidal breathing, but they are recruited by increased respiratory drive or upper airway obstruction (Fig. 56-9).[34]

In healthy patients, the nose is the preferred route of breathing, because the relaxed position of the mandible closes the mouth and the relaxed palate occludes the oropharyngeal inlet. Furthermore, the nose warms, humidifies, and filters inspired air. The selection of oral or nasal breathing is performed primarily by the soft palate, a band of moveable soft tissue suspended from the posterior bony palate. Oral breathing requires activation of the levator veli palatine to elevate the soft palate as well as activation of the musculus uvula. Nasal breathing is favored by constriction of the oropharyngeal passage, which is accomplished primarily through activation of the palatoglossal muscles, medialization of the faucial arches, and elevation of the base of tongue. This activity is highest during forced nasal breathing with the mouth open.[35]

Little objective information is available regarding the respiratory function of the pharyngeal constrictors. It is widely assumed that some active tone in these muscles increases the stiffness of these muscles, thereby decreasing the tendency of the pharynx to collapse with the negative pressure generated during inspiration. Conversely, flaccidity of the constrictors is considered to destabilize the airway, promoting collapse, although there are no physical data to support this concept.[5] On the contrary, contraction of the constrictor muscles actively collapses the pharyngeal lumen. Spontaneous activity in the respiratory cycle has been detected in the superior constrictor muscle, but this activity occurs during the expiratory phase and disappears with bronchoconstriction, suggesting that it plays a role in modulating expiratory airflow resistance.[36]

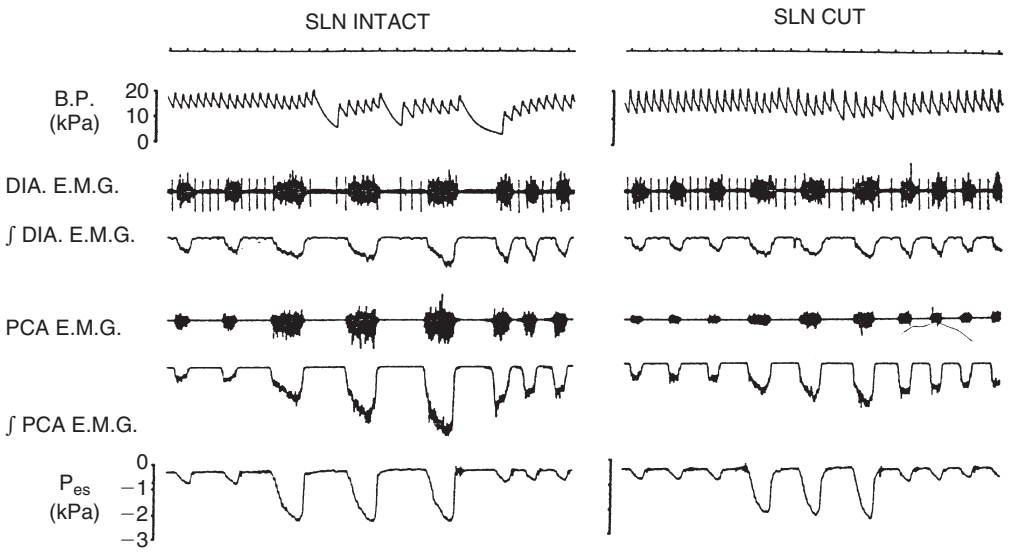

Figure 56-8. The effects of upper airway occlusion on arterial blood (B.P.) pressure in an anesthetized dog before and after transection of the superior laryngeal nerve (SLN). In each panel the top trace marks time in seconds. The third and fifth traces are raw and integrated electromyographic activity of the diaphragm (DIA) and posterior cricoarytenoid muscle (PCA). The bottom trace is intraesophageal pressure (P_{es}) as an indicator of respiratory effort. *(From Sant'Ambrogio FB, Mathew OP, Clark WD, Sant'Ambrogio G. Laryngeal influences on breathing pattern and posterior cricoarytenoid muscle activity.* J Appl Physiol. *1985;58:1298.)*

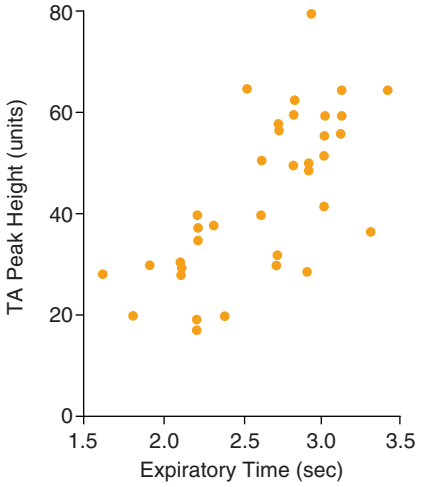

Figure 56-9. The peak electromyography activity of the thyroarytenoid muscle (TA peak height) as a function of expiratory time in an awake human. Correlation coefficient = 0.680. *(From Kuna ST, Insalaco G, Woodson GE. Thyroarytenoid muscle activity during wakefulness and sleep in normal adults.* J Appl Physiol. *1988;63:1332.)*

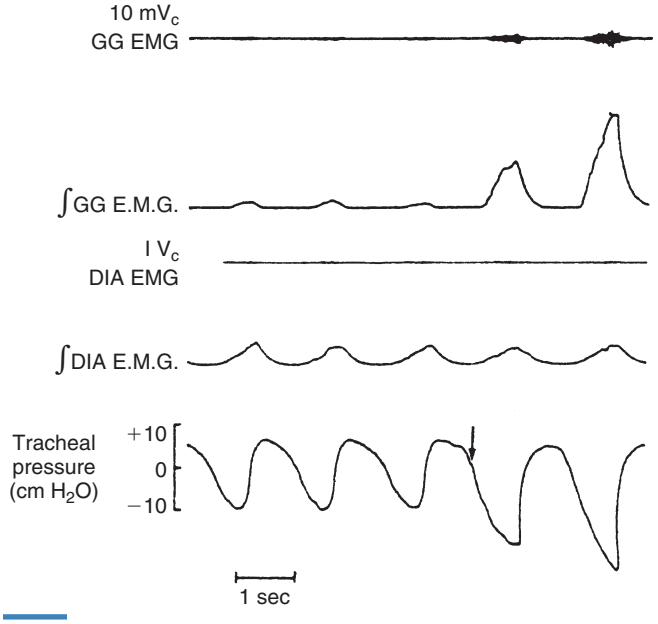

Figure 56-10. The diaphragm (DIA) and genioglossus (GG) muscle responses to nasal occlusion (beginning at *arrow*) in an anesthetized vagotomized rabbit. The upper trace is raw electromyographic activity (EMG) of the genioglossus muscle (GG) in millivolts, and the second trace is integrated GG activity in volts. The third and fourth traces are raw and integrated EMG of the diaphragm (DIA). *(From Mathew OP, Abu-Osba YK, Thach BT. Influence of upper airway pressure changes in respiratory frequency.* J Appl Physiol. *1982;52:483.)*

The dilator muscles of the pharynx are located anteriorly and laterally. The best-studied and probably most important pharyngeal dilator is the genioglossus (GG), a fan-shaped muscle that originates from the anterior mandible and spreads out to insert into the tongue. Although no studies have conclusively established what muscles are responsible for pulling the base of the tongue forward to dilate the airway, evidence strongly supports the role of the GG. In animal experiments, increased electromyographic activity of the GG is associated with a greater capacity of the pharynx to withstand negative collapsing pressure.[37] GG electromyographic activity increases reflexively in response to negative upper airway pressure (Fig. 56-10).[14,23] In humans with obstructive sleep apnea, decreased GG electromyographic activity has been noted during obstructive events, whereas obstruction is relieved with recovery of GG activity.[38]

The hyoid bone supports the hypopharynx. In humans, as in other primates, the hyoid does not articulate with any other skeletal element; rather, it is suspended by muscles and ligaments. Contraction of muscles attached to the hyoid has been shown in animal experiments to increase the size and stability of the upper airway.[39] Muscles attached to the hyoid are also believed to resist the downward traction exerted on the airway by the trachea during inspiration.[35,40]

Function in Speech

Human speech requires coordinated interaction of the mouth, pharynx, larynx, lungs, diaphragm, and abdominal and neck muscles. The three

Box 56-1

Requirements for Phonation

Adequate breath support
Approximation of vocal folds
Favorable vibratory properties
Favorable vocal fold shape
Control of length and tension

fundamental components in the processes are phonation, resonance, and articulation. *Phonation* is the generation of sound by vibration of the vocal folds. *Resonance* is the induction of vibration in the rest of the vocal tract to modulate laryngeal output. *Articulation* is the shaping of the voice into words.

Phonation

The role of the larynx in sound production has been recognized for centuries,[41] although the mechanism of how the larynx generates sound from exhaled air was not clear until the mid-20th century. In 1950, Husson[42] presented the neurochronaxic hypothesis, which held that glottic vibrations were caused by rhythmic impulses in the nerves to the larynx, synchronous with the frequency of the sound produced, so that each vibratory cycle was caused by a separate neural impulse. This hypothesis is physiologically impossible.

In the 1950s von Leden used high-speed motion pictures to document the motion of the vocal folds during vibration and subsequently reported his theory of the mechanism of phonation; now widely accepted, the theory holds that the interaction of aerodynamic forces and the mechanical properties of the laryngeal tissues are responsible for inducing vocal fold vibration and generating vocal sound.[43]

Normal phonation requires that five conditions be satisfied, as listed in Box 56-1. There should be adequate breath support to provide power, and the vibratory edges of the vocal folds should be aligned and separated by an appropriately small gap. The physical properties of the vocal fold should be conducive to vibration, and its three-dimensional contour should be favorable. Finally, a normal voice requires volitional control of glottic length, tension, and shape.

The process of phonation begins with the inhalation of air, and then glottic closure, to position the vocal folds near the midline. A simplified explanation of phonation is that exhalation causes subglottic pressure to increase until the vocal folds are displaced laterally, producing a sudden decrease in subglottic pressure. The forces that contribute to the return of the vocal folds to the midline include this pressure decrease, elastic forces in the vocal fold, and the Bernoulli effect of airflow. When the vocal folds return to the midline, pressure in the trachea builds again, and the cycle is repeated. Vocal fold structure determines whether the resulting vibration is periodic or chaotic.

Actual phonation is more complex than the previous model because the vocal fold is not a homogeneous structure and also because it vibrates in three dimensions.[44] Moreover, the pattern of vibration varies with pitch and vocal register. The "body-cover" concept of phonation is that vibration of the mucosa does not correspond directly to that of the rest of the vocal fold.[45] Instead, the "body" of the vocal fold is relatively static, whereas the wave is propagated in the mucosal "cover." This mucosal wave begins on the inferomedial aspect of the vocal fold and moves rostrally (Fig. 56-11). As the superior edges of the vocal fold begin to separate, the lower edges close, and this temporal relationship is accounted for by the two-mass model proposed by Ishizaka and Flanagan.[46] As the superior edges of the vocal folds separate, airflow through the divergent glottis generates greater negative pressure at the lower edge of the vocal folds, accelerating closure of the inferior glottis. The body-cover theory and the two-mass model are consistent with most of the observed motion during modal phonation (e.g., chest register, in the middle range of pitch), although the mucosal wave decreases at higher pitches and is not visible during falsetto, suggesting that the motions of the mucosa and the underlying tissue become coupled. In this mode, elastic recoil, rather than the Bernoulli effect, is the primary force driving the closing phase of phonation. The closing phase is much shorter, and only the superior edges of the vocal folds make contact. The vibratory characteristics of falsetto have been attributed to increased tension and decreased thickness of the vocal fold. During phonation at low pitches, the vocalis muscle is relaxed so that the "body" of the fold participates in oscillation.

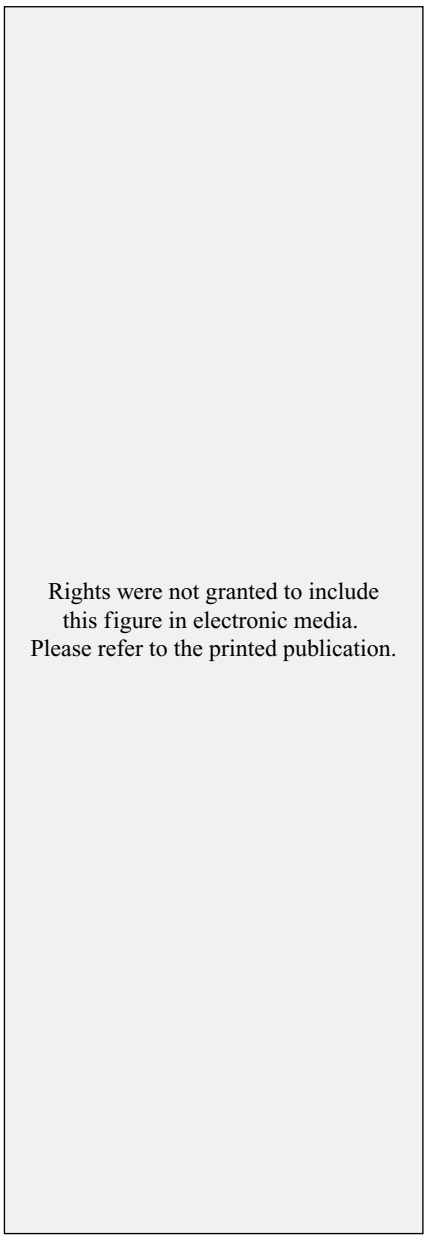

Figure 56-11. Movements of different portions of vocal folds during one cycle of vibration shown schematically in coronal plane (*left*) and from above (*right*). Mucosal upheaval begins caudally (1) and then moves rostrally. The lower portion is closing as the upper margin is opening (5). (*From Hirano M.* Clinical Examination of Voice. *New York: Springer-Verlag; 1981.*)

Expiratory Force

The force available to drive phonation depends on the volume of air in the lungs, the elastic recoil in the chest wall and diaphragm, and the strength in abdominal and intercostal muscles. Normally, passive expiration is sufficient to power conversational speech. Shouting and singing require deeper prephonatory inspiration for larger lung volume and for active expiratory effort. Because the amount of breath support required for normal voice use is small compared with lung capacity, voice loss generally is not a presenting complaint of pulmonary disorders. Breath support available for phonation becomes a clinical issue in

two situations: First, in patients with functional dysphonia, there is insufficient prephonatory inspiration, so excessive glottic pressure is required to produce an acceptable volume, which may lead to stress-induced injury of the vocal folds. Second, in a patient with an organic voice disorder and impaired pulmonary function, the capacity to compensate for the glottic defect is limited. For example, a patient with laryngeal paralysis is more symptomatic when there is coexisting emphysema. An important component of vocal training is instruction on control of breathing to maximize the power of vocal output.

Vocal Fold Positioning

Phonation requires a critical relationship between the gap between the medial surface edges of the vocal folds and the expiratory airflow. The folds should be close enough together so that airflow entrains oscillations. If the gap is too wide, the voice is breathy, or aphonic, with only turbulent airflow noise and no periodic sound. The gap may be wider if airflow is greater; conversely, low airflow requires a narrower gap. If the vocal folds are too tightly apposed, excessive pressure is required, and phonation sounds strained or might not even be possible. An analogy to phonation is the sound generated by air released from a toy balloon. The pitch and volume may be varied by adjustments in the tension across the neck of the balloon. The sound is louder with more air in the balloon. If pressure on the neck is sufficient to interrupt airflow, then sound ceases. With decreasing closing pressure, the sound becomes increasingly turbulent.

Vibratory Capacity of the Vocal Folds

The physical properties of the vocal folds are crucial in determining vocal function. During normal modal phonation, the mucosa undulates freely over the underlying vocal ligament and vocalis muscle. Hirano's[47] important histologic studies showed that this undulation is possible because the mucosa and muscle are separated by a specialized layer of connective tissue that serves as a shock absorber. This highly specialized tissue is characterized by stratified concentrations of elastin and collagen. The most superficial layer is made up of loosely connected fibers of collagen and elastin. This layer also is known as Reinke's space. The intermediate layer is composed predominantly of elastic fibers, and the deep layer is constructed of densely arranged collagen fibers. Together, the intermediate and deep layers form the vocal ligament.

Vocal Fold Shape

In falsetto mode, only the superior edges of the vocal folds contact during the closing phase, although during modal phonation, which is more efficient, the mucosal wave begins on the inferior surface of the vocal fold. This requires a favorable configuration of the glottis in the coronal plane, with the medial surfaces of the vocal folds nearly parallel. If the vocalis muscle is atrophic or paralyzed, then the medial surface of the vocal fold is convex, and the glottal tract is too convergent for optimal phonation. A divergent glottis is also unfavorable.

Pitch Control

Changes in vocal fold length and tension are used to control the fundamental frequency of vocal fold vibration to produce dynamic inflections of the voice. Such adjustments involve fine motor control. In the lower vocal range, contraction of the thyroarytenoid results in a lowering of pitch because it decreases tension in the vocal cover. During contraction of the cricothyroid muscle, which increases length and tension, strengthening thyroarytenoid muscle contraction results in rising pitch. Contraction of the cricothyroid muscle in the absence of thyroarytenoid muscle activity is generally accepted to be the mechanism of falsetto.

The size and physical properties of a larynx determine the range of pitch that can be produced. A child has a smaller larynx and a higher pitch range than an adult. During puberty in boys, the rapid increase in size of the larynx results in unstable pitch control until adaptation to the new anatomy occurs. Size is not the only determinate of pitch range, because age-related loss of elasticity and increasing ossification of the thyroid lamina result in an elevation of pitch. The lowest pitches are produced by young men, whose vocal folds are longer and heavier than those of women and more compliant than those of older men.

Resonance

The raw sound produced by the glottis in isolation from the rest of the vocal tract does not sound like human voice but is harsh and sounds something like a goose call. Phonated sound acquires the characteristics of a human voice through the resonance of the chest, upper airway, and skull. Resonance is the prolongation, amplification, and filtering of sound by the induction of sympathetic vibration. The vocal frequencies that are enhanced by resonance are termed *formants*. The pharynx itself does not resonate because its walls are too compliant to support sympathetic vibration. The primary resonating structure is actually the air column contained in the pharynx. The length of the vocal tract and the locations of constricted segments confer characteristic resonant frequencies, which are excited by any sound fed into the tract, whether from the glottis or from an artificial larynx. These resonant frequencies are called formants. A speaker controls resonance of the voice by altering the shape and volume of the pharynx, by raising or lowering the larynx, by moving tongue or jaw position, or by varying the amount of sound transmission through the nasopharynx and nose. Vocal training for singing, acting, or public speaking concentrates heavily on refining and maximizing resonance. The goal is to produce the loudest and most pleasing sound possible with minimal strain or pressure on the larynx.

Articulation

The source-filter hypothesis of speech states that the larynx is the source of a constant sound, which is shaped into words by the upper vocal tract. In this generally accepted model, consonants and vowels are formed by the action of the lips, tongue, palate, and pharynx. Participation of the larynx during articulation is generally considered to be limited to the onset and offset of phonation, coordinating with upper articulators to produce voiced and unvoiced sounds. In computerized simulation, this model seems to account for speech fairly well, although evidence now suggests that the position and shape of the glottis may actually vary with production of different vowels, so that the contribution of the larynx to phonation may be more complex than previously recognized.[48]

Sensory Input to Speech Control

One obvious mechanism for controlling phonatory output during speech is auditory feedback. This sensory input is most important while one is learning speech and is not essential for everyday use. Prelingually deaf persons never develop completely normal-sounding speech, although those who become deaf after language acquisition are able to maintain fairly normal speech patterns, in part because of ballistic speech production but also probably because of the use of nonauditory cues for feedback. An example of the importance of nonauditory cues in voice control is the ability of well-trained singers to perform with good control of pitch and loudness even when they cannot hear their own voices. Tactile sensations of induced vibration in the face, throat, and chest are important cues. There are many sensory receptors in the larynx, responding to such cues as air pressure and flow and joint motion, but the degree to which laryngeal sensation influences vocal control is not known.

CHAPTER FIFTY-SEVEN

Visualization of the Larynx

Robin A. Samlan

Jackie Gartner-Schmidt

Melda Kunduk

Key Points

- Laryngeal endoscopy, using flexible or rigid endoscopes, is used to examine vocal fold structure and gross function.
- Videostroboscopy is used to examine vocal fold vibration patterns and the relationship between the body and the cover.
- High-speed digital imaging complements endoscopy and stroboscopy, showing details of short and aperiodic vibration as well as quantifying vibration parameters.
- Narrow-band imaging is a newer visualization technique that uses the tissue's light absorption characteristics to show vascular detail.
- Each vocal fold visualization tool makes a unique contribution to the assessment puzzle.

In this chapter, we describe several tools for laryngeal visualization and how to analyze and interpret the images. Laryngeal videoendoscopy and stroboscopy (LVES), high-speed digital imaging (HSDI), and narrow-band imaging (NBI) are discussed.

Laryngeal videoendoscopy is a clinical tool that is used to examine vocal fold structure and gross function. It is used to diagnose and document voice and laryngeal disorders, plan treatment, make longitudinal comparisons, educate patients, provide biofeedback for voice and breathing therapy, and provide a record for medicolegal proceedings. Both rigid and flexible endoscopes can be used for endoscopy.

Stroboscopy is a lighting technique that helps clinicians examine vibration patterns and the relationship between the vocal fold body and cover. It is valuable for describing mucosal disease and its effect on vocal fold vibration. Stroboscopy is necessary to determine glottic closure and mucosal pliability, to make inferences about tension, and, sometimes, to identify or differentiate lesions. The decisions to use continuous or strobe light and rigid or flexible endoscope are largely based on whether the examiner is more interested in gross structure and function or mucosal health and vibration patterns. Often, both rigid and flexible examinations are used as part of a dynamic assessment to thoroughly evaluate laryngeal function during a variety of voicing conditions and therapy probes.

Examination with *high-speed digital imaging systems* complements endoscopy and stroboscopy; details of short and aperiodic vibration can be observed, and the image analysis allows quantification of vibratory details that is not otherwise possible.

Narrow-band imaging is a new endoscopic imaging technique that uses the absorption characteristics of light to enable a detailed analysis of mucosal and vascular structures. The technique holds promise for becoming a powerful tool to screen for malignancies by identifying high-yield areas to sample for biopsy.

In most states, LVES, HSDI, and NBI can be performed by either an otolaryngologist or a qualified speech-language pathologist.[1] Each professional brings a different perspective and training to the process, and the most thorough examinations are typically conducted in a team setting. The otolaryngologist is responsible for assessing mucosal health and diagnosing laryngeal pathology; the speech-language pathologist is interested in the vibratory patterns during various voicing conditions, the behavior of the laryngeal and supralaryngeal structures during phonation, and how treatment probes alter phonatory physiology. As team members work together over time, they often learn from each other and develop common skill sets.[2]

The advantages and disadvantages of rigid and flexible endoscopes are described in the first section of this chapter, with recommendations for technique and troubleshooting. The second section details the assessment process for endoscopy and stroboscopy. The third section discusses HSDI, its advantages and limitations, and how images are processed and analyzed. The final section is an introduction to the emerging technology of NBI.

Endoscopes

Rigid Endoscopes

Advantages

Rigid endoscopes used with LVES are usually 70- or 90-degree scopes. Rigid scopes have the advantage of high resolution with bright, clear pictures. Contrast is excellent, there is a large selection of viewing angles, and the image is more accurately magnified than with a flexible endoscope. The examination is simple and does not usually require topical anesthesia.[2-4]

Disadvantages

The primary limitation of the rigid endoscope is that phonation is limited to sustained vowels, most commonly "ee." Because visualization with a 70-degree rigid endoscope usually requires an extended neck and protruded tongue, the size of a glottic gap might appear exaggerated with the rigid endoscope.[5] To counteract this problem, Rammage and

colleagues[2] suggest a lateral approach to the larynx to decrease neck extension during the examination. Alternatively, a 90-degree endoscope does not require the same amount of neck extension as the 70-degree endoscope does. A second limitation is that the mobility of the arytenoids might not be accurately assessed via rigid endoscopy; often, it appears as if there is a vocal fold paresis when the perceived lack of motion is, in actuality, an artifact of the tongue protrusion and neck extension. Lastly, disorders more evident in connected speech than in sustained vowels (e.g., muscle tension dysphonia and spasmodic dysphonia) are not as well documented with rigid endoscopy as they are with flexible endoscopy.

Technique

The laryngeal examination with a 70-degree rigid endoscope is conducted with the patient bending slightly forward from the hips while maintaining a straight back. The neck and chin are extended, and the tongue is protruded. The examiner wraps the tongue in gauze and holds it gently during the examination. The endoscope is advanced just under the uvula or between the uvula and faucial pillars until the epiglottis is visualized. Turning the endoscope tip to face the cheek during insertion, to prevent tongue residue from coating the lens, might keep the lens cleaner. Having the patient vocalize a sustained "hey" lowers the tongue base, facilitating placement. The patient is then instructed to sustain "ee," which moves the epiglottis anteriorly for a better view of the vocal folds. The examiner might need to flex the wrist to tilt the endoscope tip inferiorly. The angle can be varied for differing levels of magnification and differing fields of view. The patient is then guided through the examination tasks listed in the following "Assessment" section. Examination with the 90-degree endoscope is similar, but the patient does not need to bend forward or extend the neck. Another difference is the angle; the tip of the 90-degree scope is positioned with minimal tilt so that the light is parallel to the surface of the vocal folds. This type of endoscope is often preferable for viewing the larynx when a wider viewing angle is desired. A longer lens or a zoom lens might be necessary for adequate visualization of vocal fold details.

Defogging the endoscopes can be a challenge, because sterilizing beads can cause damage to both the lens and the patient. Alternatives include liquid defogger, hot (not boiling) water, soap film, surgical wax, and holding the endoscope lens briefly against the patient's cheek or the side of the tongue. The examination is generally tolerated without topical anesthesia, but a small amount of benzocaine topical spray or a similar product is sometimes useful and does not appear to affect examination results.[6]

Troubleshooting

A good-quality examination means that the image is in focus, that it is large enough to show small mucosal irregularities, and that it is bright enough to show details (but not so bright as to obscure them). Contrasting color is important for differentiating subtle lesions and vascular changes. Ideally, an examination includes both a wide-angle view of the larynx and a close-up view of the vocal folds. The stroboscopic portion of the examination should include several complete stroboscopic cycles at the patient's most comfortable pitch and loudness (MCPL) in addition to the rest of the protocol (see "Assessment"). Common imaging problems and solutions are listed in Table 57-1.

Flexible Endoscopes

Advantages

The primary advantage of the flexible endoscope is the ability to view the larynx dynamically—that is, during natural functions such as speech and singing. Arytenoid mobility and the glottic gap can be more accurately described with flexible than with rigid endoscopy because of the neutral tongue and neck positions.[5] Flexible endoscopy also allows the clinician to assess the nasal cavity and velopharyngeal port during the same examination. Flexible endoscopy is preferred when the question is one of movement rather than structure or mucosal health. It is particularly useful for disorders such as spasmodic dysphonia and muscle tension dysphonia, in which the voice problem is more obvious during speech than in sustained vowels, and vocal fold motion impairment, where having the patient sniff through the nose allows the examiner to assess subtle motion.

Disadvantages

The primary limitation of flexible endoscopy is that light transport and magnification of the image are inferior to those of rigid endoscopy. There is also a distortion of the periphery of the image and a trade-off between adequate focus and light fiber mismatch, so that when the image is in focus, there is a moiré or honeycomb effect that is enhanced by the edge-detection software of digital imaging systems. The honeycomb effect is not a concern with the newer-technology flexible endoscope with a charged-coupled device (CCD) camera in the tip. These "chip-tip" endoscopes eliminate the fiberoptic bundle and provide superior optics. Although the chip-tip endoscope represents a significant improvement, the new technology comes at a significant cost increase, and the quality of resultant examinations is not equal to that achieved with rigid endoscopy. In addition, many patients find the flexible examination to be more invasive than the rigid examination, and the flexible technique carries the risks of nosebleed, adverse reactions to the anesthetic, and vasovagal reaction.

Technique

The flexible endoscope is typically inserted after the application of a topical anesthetic and a vasoconstrictor. It can be passed through the inferior or middle meatus of the nose. The higher path is preferred for examination of the velopharyngeal port, but the paths are equivalent for visualizing the larynx. The examiner should raise the endoscope slightly as the patient swallows to avoid triggering a cough or laryngeal closure reflex, which can occur if the endoscope touches the rising larynx during a swallow.

Troubleshooting

As with the rigid endoscope, a good-quality flexible examination means that the image is in focus, large enough to show small lesions, bright enough to show details, and not so bright that details are obscured. Varying the field of view of the flexible endoscope is easy, but it is sometimes challenging to bring the endoscope close enough to the vocal folds for optimal light and vibratory detail. Patients generally allow a more complete examination when they are fully informed about the procedure, have some feeling of control (e.g., they know the examiner will respond if they say they have had enough), and have received adequate anesthetic.

Videoendoscopy and Stroboscopy

Endoscopy: Assessment Using Continuous Light

Protocol

Endoscopic parameters that require only continuous light (as opposed to the xenon light of stroboscopy) include laryngeal structure, arytenoid and vocal-fold motion, color and quantity of mucus, vascularity, supraglottic activity or compression, and deformation of vocal fold edges. The tasks during this portion of the examination include rest breathing, deep breathing, easy cough or throat clear, and laryngeal diadochokinesis, which consists of rapid repetitions of "ee" with glottal stops between productions. Laryngeal diadochokinesis is a useful measure, and production rates of four to six syllables per second are considered normal.[7] Difficulty with accurately and rhythmically producing the voice onset/offset gesture has been found in patients with neurologic impairment.[8,9] If a flexible endoscope is used, several other parameters can be assessed, including repetitions of a short "ee" followed by a quick sniff through the nose, a standard set of phrases or sentences, and conversational speech if voice quality during the endoscopic examination is not consistent with what was heard before it. Examination of velopharyngeal function is indicated if nasal emission or hypernasality is heard. At a minimum, soft palate and lateral pharyngeal wall motion should be assessed during a sustained vowel and a voiceless fricative, as well as during words or phrases with nasal-oral consonant transitions. A sample protocol is outlined in Box 57-1.

Table 57-1

Common Problems and Solutions for Laryngeal Endoscopy and Stroboscopy

Problem	Solution(s)
Foggy image	Warm the endoscope. Apply defogger. Clean the endoscope lens; mucus or dried disinfectant might be obscuring the image. Turn the endoscope so that the lens is facing the cheek during insertion, to prevent tongue residue from coating the lens.
Fuzzy image	Check or adjust the focus. Whenever possible, set the focus on the endoscope (if there is one) prior to connecting it to the camera, and then leave it alone. Clean the endoscope lens.
Dark image	Clean the lens of the endoscope, the eyepiece, or the camera. Increase light. Different techniques are used for different light sources and cameras. For some systems, decreasing the shutter speed or turning the electronic light control (ELC) on/off can increase brightness. Change the position of the endoscope; the light might not be directly over the vocal folds or area of interest. If it is the xenon light that is too dark, check the number of hours on the bulb. The brightness of the xenon light fades with use, whereas the halogen bulb burns out all at once.
Grainy image	Decrease the gain. Slightly defocus the endoscope. Consider a shorter camera lens.
Image is tilted or the vocal folds appear to have different widths	Modify the alignment of the endoscope and camera. Be sure your arm and wrist are straight, not tilted, when approaching the patient. Have a third party hold the laryngeal microphone to the patient's neck or attach it to a hook-and-loop strap.
Image is mostly of the valleculae and epiglottis or anterior commissure cannot be seen	Insert the endoscope farther into the oropharynx. Tilt the tip of the endoscope. Ask the patient to "smile down" around the endoscope (decreases mouth opening). Check the patient's position: legs uncrossed, back straight, neck slightly extended, jaw jutted. Ask the patient to produce a high-pitched "ee" to lengthen the vocal folds.
Mostly arytenoids and posterior vocal folds are seen	Withdraw the endoscope slightly from the oropharynx. Tilt the tip of the endoscope. Have the patient phonate in a high pitch. Request that the sound be more "ee-like."
The base of tongue is high	Ask the patient to produce sustained "hey" or "ā." Ask the patient to allow the back of the tongue and jaw to release and be "floppy." Have the patient hold his/her own tongue.
Uvula is "in the way"	Direct the endoscope around the uvula. Have the patient breathe through the mouth, not the nose. Ask for the sound to be more "ee-like." Have the patient plug the nose or use nose clips.
Abnormal color	Solution depends on the particular system; color can often be adjusted by controls on the monitor, camera, or videoprinter. Check the brightness settings. Check the focus; slight defocusing might be needed.
Omega-shaped epiglottis	Use a 90-degree endoscope. Have the patient (1) bend farther forward so that the elbows rest on the knees and (2) extend the neck as much as possible. Try a lateral approach.

Continued

Table 57-1

Common Problems and Solutions for Laryngeal Endoscopy and Stroboscopy—cont'd

Problem	Solution(s)
Strobe is "not tracking"	Modify placement of the laryngeal microphone or electroglottograph electrodes. They should be placed flat on the neck over the thyroid laminae. Have the patient phonate louder. Try the other fundamental frequency extractor (i.e., use the laryngeal microphone if fundamental frequency is not tracking with the electroglottograph). Vibration might be aperiodic; try other vocalization tasks, such as high pitch, low pitch, quiet voice, phonation on inhalation, instruction to take a better breath, and relaxing the shoulders. Some systems allow the examiner to select an approximate fundamental frequency as an override. If the system does not have the override feature, a third party can phonate at the approximate fundamental frequency to trigger the strobe light.
"Plica ventricularis": ventricular folds closed so the true vocal folds cannot be seen	Ask the patient to produce a soft, gentle, breathy "hhheee," almost like a sigh. Model such a production. Ask the patient to laugh "hee hee hee." Have the patient phonate on inhalation. Perform voice therapy and then repeat the evaluation.
Gagging	Reduce anticipation by educating the patient about the exam. It is sometimes helpful to use a model to show that the vocal folds are in view with the endoscope placed far above them. Talk the patient through the exam in a calming voice, reminding him/her to breathe slowly through the mouth and start phonating in a relaxed, breathy voice. Distract the patient by having him/her focus on a certain spot, think the alphabet backwards, or try not to blink (attenuation of the blink reflex can suppress the gag reflex). Ask the patient to keep the tongue protruded and to pant when breathing in. Have the patient hold his/her own tongue. Alter the approach (e.g., lateral versus anterior; elevate or lower the endoscope tip). Apply topical anesthetic. Use a flexible endoscope.

Box 57-1

Protocol for Laryngeal Videoendoscopy (Continuous Light)

Rigid Endoscopy

Rest breathing
Deep breathing
Easy cough or throat clear
Laryngeal diadochokinesis "ee"
Laryngeal diadochokinesis "hee"

Flexible Endoscopy

All components of rigid exam
"ee" followed by a quick sniff (×3)
Whistling
Sentences and/or conversation as needed
Observation of velopharyngeal function during sustained sounds such as "ee" and "s"
Observation of velopharyngeal function during sentences loaded with nasal-oral contrasts

Laryngeal Structure

The valleculae, pyriform sinuses, epiglottis, aryepiglottic folds, ventricular folds, and posterior glottic rim should be examined. Lowered pitch during sustained "ee" widens the angle, allowing better visualization of the valleculae. Abnormalities and asymmetries of laryngeal structure are noted. An omega-shaped epiglottis is a common variant in men, but it is rare in women.[7,10] Signs of laryngeal irritation or possible laryngopharyngeal reflux are noted; these primarily include edema, erythema, surface irregularities, and lesions of the posterior larynx.[11-14] The specificity of signs for reflux is still being evaluated. In particular, interarytenoid bar, arytenoid medial wall erythema, and posterior pharyngeal wall cobblestoning have been found in a substantial number of "normal" volunteers.[13]

Arytenoid and Vocal Fold Motion

Movement and position of the arytenoids inform the examiner about the integrity of the cricoarytenoid joint and the recurrent laryngeal nerve. Arytenoids are typically described as mobile or immobile, symmetric or asymmetric, and upright or rotated. Immobility is further described by position: median, paramedian, intermediate, or lateral. Motion of the arytenoid should be described separately from movement of the posterior third of the vocal fold because sometimes the arytenoid is mobile when the vocal fold is fixed. Mobility is rated when patients phonate then breathe, and during laryngeal diadochokinesis, cough, whistling, and sniff. The etiology of the motion impairment, along with particular characteristics such as arytenoid position, gap size, shape, and vocal-fold plane difference, can influence management strategy as described in Chapters 66 through 68.

Mucus

Thickened mucus often adheres to the vocal fold edges or superior surface. The presence of thick mucus generally relates to a lack of hydration or to chronic irritation from sources such as mechanical trauma, smoking, or laryngopharyngeal reflux. Mucus pooling in the pyriform sinuses can indicate poor laryngeal sensation, weak lateral pharyngeal walls, or inefficient swallow. Thickened mucus adhering to the vocal folds can masquerade as a lesion or mask an abnormality. To

allow differentiation of mucus from underlying structures or lesions, patients should be instructed to try to clear the mucus by swallowing or gentle cough.

Vascularity

The vocal folds are generally pearly white. A blush throughout the tissue is considered erythema or hyperemia. If capillaries are visible, they are generally aligned parallel with the free edge; horizontal vascularity is cause for concern. Abnormally dilated and tortuous vessels, called *capillary ectasias* or *microvarices*, might represent areas of stiffness or risk for hemorrhage. Hemorrhage occurs when enough blood cells have escaped from a vessel to lend a diffuse coloring to the vocal fold. Post-hemorrhage vocal folds often appear yellow-brown, similar to healing bruises in other areas.

Supraglottic Activity

Supraglottic activity refers to any abnormal motion above the true vocal folds. Examples are tremor of the larynx or pharynx, other involuntary contractions (e.g., myoclonic movements), and compression of the supraglottic structures. Supraglottic movements help tease apart neurologic voice disorders from disorders caused by abnormal muscle tension; tremor and myoclonic movement are evidence of a neurologic disorder, whereas sustained constriction is more typically found in muscle tension disorders. Constriction is often categorized by direction (anteroposterior or lateromedial) and frequency (constant or intermittent). Anteroposterior constriction during phonation is shown in Figure 57-1, and lateromedial constriction in Figure 57-2. The Stroboscopy Evaluation Rating Form proposed by Poburka[15] displays a superior view diagram of the vocal folds with superimposed concentric circles on which raters estimate the extent of constriction. Aryepiglottic narrowing or dilation and pharyngeal shape for different vowels can alter vocal-fold vibratory characteristics.[2,16,17]

The frequency and severity of supraglottic constriction in subjects without voice disorders is still somewhat uncertain, although it is clear that both anteroposterior and lateromedial constrictions are sometimes normal variants.[18-20] Stager and associates[20] found that supraglottic movements were present at the initiation of phonation in normal controls. Behrman and colleagues[18] showed a greater severity of anteroposterior constriction in dysphonic subjects than in normal controls.

Ventricular fold closure with or without vibration is not considered a normal variant. It can be the primary disorder[2] or compensation for another problem, such as incomplete glottic closure or a lesion.[21,22] In other words, the patient can have a primary muscle tension dysphonia, in which the muscle tension causes the voice disorder, or can present with a secondary muscle tension dysphonia, in which a vocal-fold abnormality is causing the muscle tension. To tease apart the etiology, voice therapy maneuvers should be used to reduce the amount of constriction, and then visualization should be repeated.

Other supraglottic activity occurs in people with normal voices. Lateral wall constriction, for example, is frequently observed with increasing pitch. Anteroposterior narrowing of the epilaryngeal space during singing might be a desired pattern that helps create the singer's formant.[23]

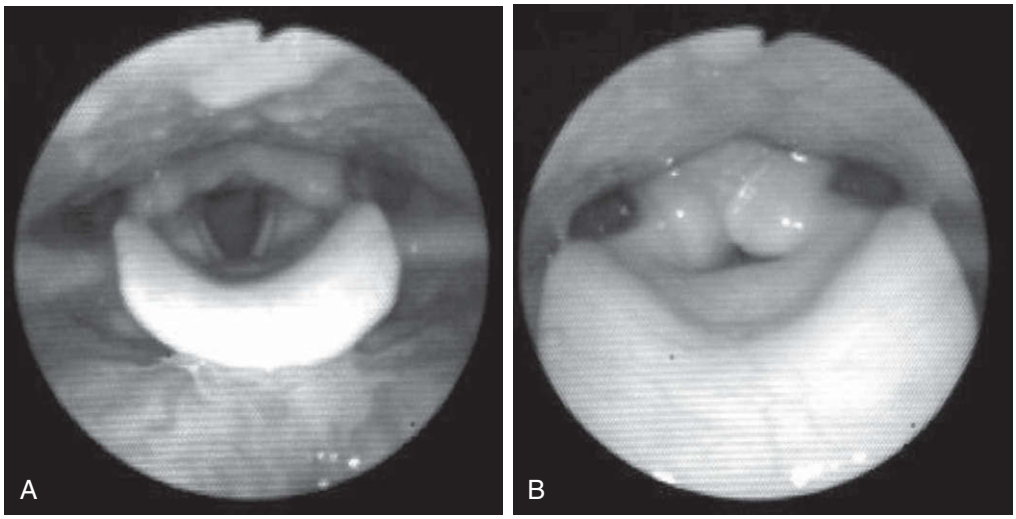

Figure 57-1. **A,** Vocal folds during respiration. **B,** Vocal folds with anteroposterior constriction during phonation.

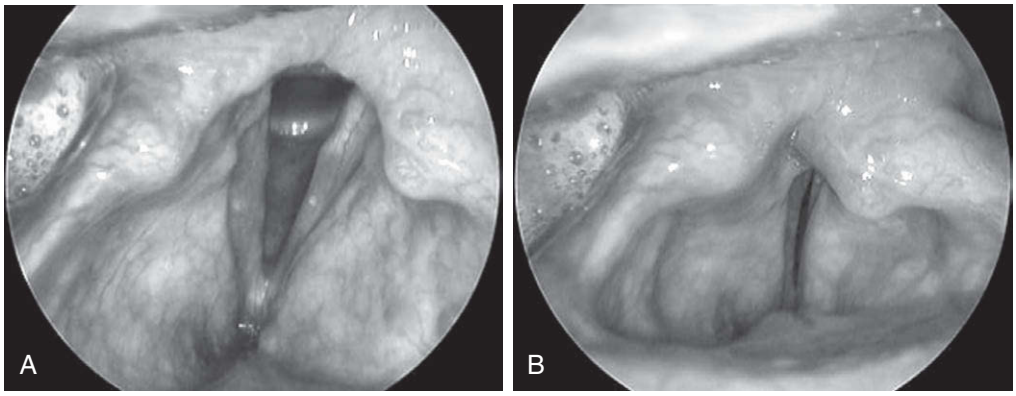

Figure 57-2. **A,** Vocal folds during respiration. **B,** Vocal folds with lateromedial constriction during phonation.

Vocal Fold Edges

Vocal fold edge shape can be rated on two scales, straight to smooth and rough to irregular.[15] Along the straight-smooth continuum, abnormalities should be further described as convex or concave ("bowed"), along with the degree of deviation. Bowing is not a pathognomonic symptom; rather, it is a symptom of several underlying disorders.

Assessment Using Stroboscopy

A *stroboscope* is defined as "an instrument for determining the speed of cyclic motion (as rotation or vibration) that causes the motion to appear slowed or stopped."[24] Videostroboscopy is not slow-motion photography; it is an illusion of slow motion. The illusion is possible because images linger on the retina for 0.2 second, and only five distinct images can be viewed per second. If more than five per second are presented, the viewer perceives the images as connected and sees the result as a smooth motion; this phenomenon is referred to as *Talbot's law*.[3] For videostroboscopy to be used for the analysis of vocal fold vibration, the light must flash at specific points in the glottic cycle, or the illusion of slow motion vibration will crumble. Extraction of the vocal fold fundamental frequency (rate of vibration) facilitates the process. The strobe light can be used to create two effects, the running phase (often called strobe) and the stop or locked phase. In the running phase (the more frequently used mode), the light flashes slightly faster or slower than a rate matched to the frequency of vibration, thereby creating the illusion that the vocal folds are vibrating in slow motion. Because each image is from a different glottal cycle, the cycles must be fairly regular to show a smooth stroboscopic cycle during the running phase. If the vocal fold vibration is aperiodic, the illusion of slow motion will not occur; rather, the vocal folds will appear to "flutter." In the stop phase, the light flashes at a rate that is matched with the frequency of the vocal fold vibration, thereby creating the illusion that the vocal folds are not moving at all.

Videostroboscopy is used to assess vocal fold vibration patterns, mucosal pliability, the underlying layered structure of the vocal folds, and the undersurface of the vocal fold edges. It is particularly valuable for assessing stiffness, scar, or submucosal injury; detecting small vocal fold lesions; estimating the depth of invasion of a tumor; identifying asymmetric mass or tension; or determining the resumption of phonation after phonosurgery.

Understanding normal vocal fold physiology for different modes of phonation is essential to interpreting stroboscopic examinations, although a thorough review is beyond the scope of this chapter. Detailed descriptions of vibratory physiology can be found in several sources cited.[2,3,16,17] In brief, it is helpful to think of the vocal folds as having three functional divisions; cover, transition, and body. The cover is composed of the epithelium and the superficial layer of the lamina propria. The transition consists of the intermediate and deep layers of the lamina propria (i.e., vocal ligament), and stiffness increases from the superficial to the deep layers of the lamina propria as the proportion of dense collagen fibers increases and that of elastin fibers decreases. The body of the vocal fold is the thyroarytenoid muscle, which is even less pliable.[3,25,26]

The vocal folds are set into vibration through a combination of aerodynamic, muscular, and elastic forces. As they vibrate, each vocal fold moves away from the midline and back. In spite of simplified explanations to patients, the vocal folds do not move like French doors; rather, the inferior vocal fold edges separate before the superior edges, and they return to midline in the same order (a vertical phase difference). Additionally, the folds separate at the anterior aspect before the posterior aspect, and they close in the same order (a horizontal phase difference). The ability of the vocal folds to move with these phase differences is critical to the initiation and sustenance of vibration. Furthermore, the inertia of the supraglottal air column, particularly the portion just superior to the vocal folds, aids in initiating and sustaining vibration. Alterations to vocal fold structure, occurring with disorders or postoperatively, can significantly affect the vibratory patterns; in the extreme, such perturbations may prevent vibration from occurring at all.

As the vocal folds move back and forth in whatever pattern their particular structure allows, they cyclically open and close the airspace between them, which is called the *glottis*. This time-varying glottal area transforms the steady tracheal airflow into a series of air pulses called the *glottal flow*. A particular pattern of vocal-fold vibration and the influence of the supraglottal air column determine the temporal characteristics of each glottal flow pulse. For example, a rapid movement of the vocal folds toward the midline creates a sharp cutoff of the pulse (rapid declination of flow). The shape of the glottal flow pulses determines the amount of acoustic energy available at the fundamental frequency and all of its harmonics.

Normally, vibration patterns are different for high and low pitch as well as loud and quiet phonation. For example, the vocal folds are stretched during high-pitch phonation, thereby increasing stiffness of the cover. During low-pitch phonation, they are shortened, and the cover is lax. Stiffness and mass are intricately linked with fundamental frequency, in that a decrease in stiffness or increase in mass can cause frequency to decrease, and vice versa.[16] Most stroboscopic parameters are rated at most comfortable pitch and loudness (MCPL), and then their variation with pitch and loudness changes is described.

Stroboscopic parameters include closure pattern, phase closure, amplitude of vibration, mucosal wave, adynamic segments, vertical closure level, symmetry, and regularity. Of these, closure and mucosal wave are often considered key indicators of function. Although it is tempting to consider judgments of these parameters as objective data, they are visual perceptual ratings and subject to reliability and validity errors.

Protocol

The protocol for stroboscopy includes several productions of sustained "ee" at MCPL; phonation on inhalation; pitch glide from midrange to high, sustaining the high note; pitch glide from midrange to low, sustaining the low note; quiet "ee," loud "ee"; "ee" at MCPL with locked phase; and, possibly, physical manipulation of the larynx or trial therapy. These tasks are listed in Box 57-2.

During the examination, it is important to monitor the patient's voice so that all of the necessary information is recorded. For example, the patient may initially sustain phonation quietly and at a high pitch

Box 57-2

Protocol for Laryngeal Videostroboscopy (Xenon Light)

Rigid Endoscope

Sustained "ee" at patient's most comfortable pitch and loudness (MCPL) (several)
"ee" on inhalation
Glide midrange to high, sustaining the high note
Glide midrange to low, sustaining the low note
Quiet "ee"
Loud "ee"
Sustained "ee" at MCPL using locked mode
Trial therapy or laryngeal manipulation as needed

Flexible Endoscope

All components of rigid exam
Consensus Auditory Perceptual Evaluation for Voice (CAPE-V)[27] sentences:
- "The blue spot is on the key again."
- "How hard did he hit him?"
- "We were away a year ago."
- "We eat eggs every Easter."
- "My mama makes lemon muffins."
- "Peter will keep at the peak."

Singing tasks as necessary
Conversation as necessary
Humming or other trial therapy tasks as needed

rather than at MCPL. Most vibratory parameters are rated from "ee" at MCPL, and the examiner should attempt to elicit several of these productions so that the vibration patterns can be accurately analyzed. Monitoring the voice quality is also important; sometimes the patient complains of roughness when talking, but the sustained vowel during stroboscopy is clear and normal. In this case, the examination would be most useful if the examiner can also elicit some productions that are similar to the patient's typical patterns or symptoms. Sometimes stroboscopic assessment is not possible when the patient uses a typical voice (e.g., the vocal folds do not vibrate quasiperiodically or are not visible). When this is the case, the examiner should indicate in the report that the stroboscopic examination was not congruent with the auditory perceptual findings before and after it.

Several components of the protocol just described might not be intuitive or might be left out at a busy clinic. Each task, however, contributes unique data to the assessment puzzle. Phonation on inhalation, for example, is useful when supraglottic constriction interferes with visualization of the vocal folds.[2] It also highlights edema or lesions of the inferior compartment of the vocal fold edge.

The patient should produce a variety of pitches during the examination. Bilateral and symmetric lengthening of the folds during ascending pitch glides confirms that gross cricothyroid muscle function is intact. High-pitch phonation is useful for highlighting midmembranous edema and stiff or scarred segments along the edge.

The locked phase is useful for assessing the regularity of vibration, which is the extent to which one vibration cycle is similar in duration to the next. It is also useful for highlighting lesions of the vocal fold edge. Most stroboscopy systems have foot-pedal control of the phase so that the examiner can select the point in the cycle that best shows the lesion. Vocal-fold plane differences are sometimes more easily seen in the locked mode.

When the flexible endoscope is used, connected speech should be an examination task. The sentences included in the Consensus Auditory Perceptual Evaluation for Voice (CAPE-V)[27] are a good standard sample, because each sentence has different characteristics:

"The blue spot is on the key again" contains many English vowel sounds.

"How hard did he hit him?" emphasizes easy onset.

"We were away a year ago" is all-voiced.

"We eat eggs every Easter" elicits glottal onsets.

"My mama makes lemon muffins" uses nasal sounds.

"Peter will keep at the peak" is loaded with voiceless plosive sounds.

If the patient's concern is related to the singing voice, that should also be assessed with the use of glides, vocalizes, and songs. If the patient's voice is different during the examination and typical conversation, engaging the patient in a dialogue might uncover habitual maladaptive laryngeal and supraglottic posturing.

Trial (probe) therapy techniques are often used during a flexible examination to "unload" the larynx or change vibration patterns for a more accurate diagnosis; they are also helpful to assess potential for change and to guide therapy. There are many such techniques, and some of the most useful are listed here. Pitch and loudness changes and phonation on inhalation were described earlier. Humming can alter glottic closure, symmetry, and regularity or decrease supraglottic activity. Twang, sighs, or descending glides with high airflow can alter supraglottic postures or the closure pattern. Trills, breathy voice, flow phonation, coughing, pushing, abdominodiaphragmatic onsets, and visual feedback are also useful probes. Leonard and Kendall[22] describe the combination of a traditional voice evaluation and flexible endoscopy as a "phonoscopic" evaluation. In their retrospective study of 100 cases, the findings from the phonoscopic evaluation differed from the findings of the referring physician in 42 cases. In an additional 32 cases, the findings were consistent with the referral diagnosis, but the phonoscopic examination provided additional detail (e.g., there was indeed hyperfunction, but it appeared as a result of an underlying pathology, such as atrophy or a lesion).

Closure Pattern

Closure pattern indicates how well the vocal folds come together at midline during the closed phase of the vibratory cycle. There are two principal options: Is the glottis completely closed (Fig. 57-3A) or not completely closed? If the vocal folds are not completely apposed, it is helpful to characterize the shape of closure. Patterns of incomplete closure are posterior gap (Fig. 57-3B), anterior gap (Fig. 57-3C), spindle-shaped gap (Fig. 57-3D), hourglass-shaped gap (Fig. 57-3E), irregular, and variable. With complete closure, there is no space between the folds; complete closure is the most common pattern for men,[28] and it occurs in some women at MCPL or with increased loudness.[5,28,29]

An *incomplete closure pattern* occurs when the gap extends for the entire length of the folds. Incomplete closure most often occurs with vocal fold motion impairment, scar, and the muscle tension dysphonia/aphonia variant in which the patient does not fully adduct the folds for phonation.

A *posterior glottic gap* can vary from small to large, and the extent of the gap should be indicated. Posterior glottic gap is one of the most common closure patterns for women,[28,30,31] and it might be a normal variant for men.[28] The gap is typically limited to the space between the cartilaginous folds during MCPL, but it can extend into the membranous folds during quiet productions.[28] Rammage and colleagues[2] categorize extended glottic gap as a laryngeal isometric pattern of muscle tension dysphonia.

An *anterior gap* is a condition in which there is closure of the arytenoids and cartilaginous folds but a gap between part or all of the membranous folds. Anterior gaps occur as a normal variant in men of any age and in older women.[7,30] They are also present in patients with disordered voices and can occur with tissue deficit of the membranous folds as a result of scarring, prior surgery, atrophy, superior laryngeal nerve deficit, or sulcus vocalis; at other times, they appear because of edematous posterior folds.

Spindle-shaped gap refers to a condition in which there is closure of the arytenoids but otherwise a gap that extends the length of the folds. Spindle-shaped gaps occur as normal variants in men of all ages and in older women[7]; they also occur with bowing as a result of vocal fold motion impairment, superior laryngeal nerve injury, sulcus vocalis, or tissue deficit due to aging or prior surgery.

Hourglass closure refers to a pattern of an anterior gap and a posterior gap with a point of closure in between. This pattern is typical for bilateral lesions (e.g., nodules) or a cyst or polyp and a contralateral reactive lesion; it can also occur with large unilateral lesions.

Irregular closure is a pattern that involves multiple gaps or that does not quite classify as another pattern. Irregular closure is most common with multilobular lesions or irregular vocal fold edges, which often occur with malignant lesions.

Sometimes the closure alternates between two or more patterns; it is then called *variable*, with the multiple patterns delineated. The closure pattern is rated at MCPL. For most people, vocal fold vibration patterns change as pitch and loudness change. With increasing pitch, the vocal folds lengthen, and only the medial edge is involved in vibration. Closure pattern can become incomplete, and the amplitude of vibration and mucosal wave can decrease. In the description of glottic closure, it is often helpful to describe it in multiple conditions. For example, the closure pattern for a patient with bilateral lesions may be described as follows: "Closure pattern is variable at MCPL; it is sometimes hourglass shaped, and, at other times, a posterior gap extends to the midmembranous folds. At higher pitch, closure is always hourglass. At low pitch and loud voice, glottic closure becomes complete."

Phase Closure

Although "*closure pattern*" describes the extent of closure, "*phase closure*" describes the duration of closure. During vibration at MCPL, the glottis is typically open (opening, fully open, or closing) for approximately two thirds of one vibratory cycle and maximally closed for the remaining third. This parameter is typically rated by counting of "frames" with

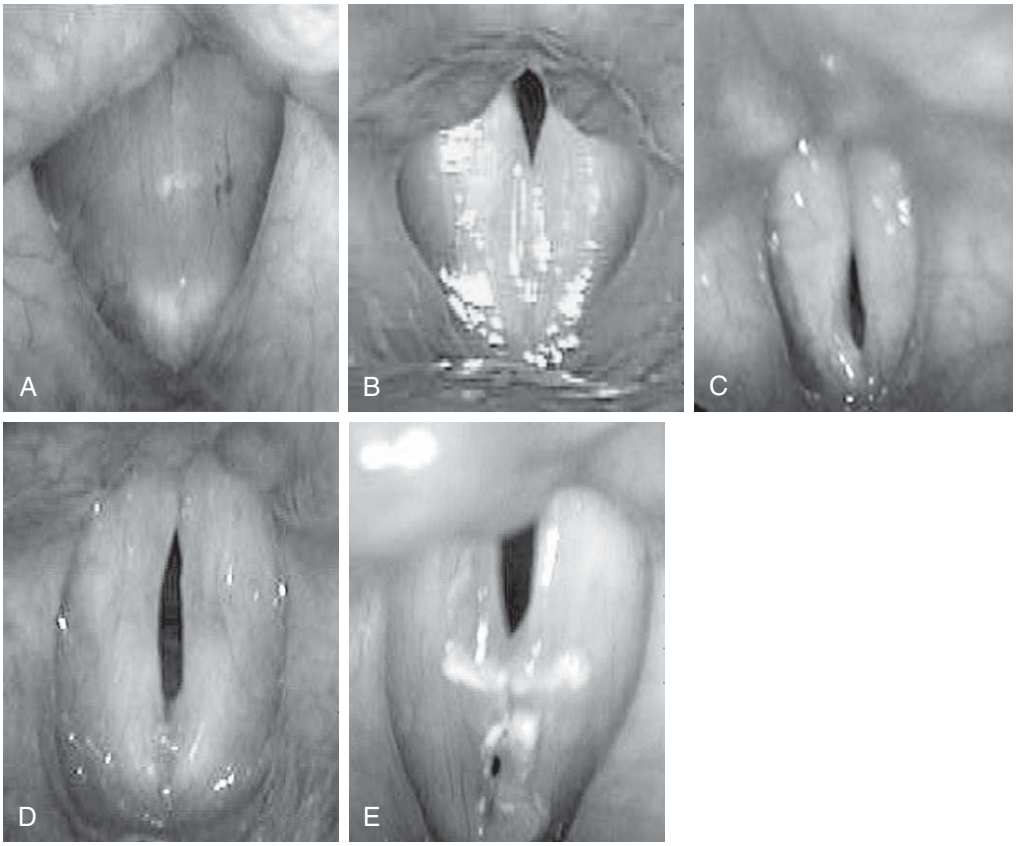

Figure 57-3. Glottal closure and gap patterns. **A,** Complete closure; **B,** posterior glottic gap; **C,** anterior glottic gap; **D,** spindle-shaped gap; **E,** hourglass-shaped gap.

the use of clicks of a computer mouse. Closed time generally decreases with higher pitches and in older women; it increases in older men.[10] Phase closure is a useful measurement in a patient who sounds breathy but achieves complete closure or during hyperfunctional patterns when the vocal folds open only briefly.

Amplitude of Vibration

Amplitude of vibration refers to the fold's horizontal excursion from midline. Normal is defined as approximately one third of the width of the fold (Fig. 57-4).[3] In normal conditions, the vocal folds are symmetric in amplitude; that is, the maximum amplitude of the left fold is similar to the maximum amplitude of the right fold. Amplitude can be rated as a percentage of the width of the fold[15] or on a five- or seven-point equal-appearing interval scale from normal to reduced.[3] Amplitude of vibration is typically smaller in women than men, it generally covaries with loudness, and it varies inversely with pitch.[10] Decreased amplitude of vibration can be the result of glottic incompetence, tight glottic closure, or increased vocal-fold mass or stiffness. Decreased amplitude is common in lesions such as firm polyps, cysts, papilloma, carcinoma, Reinke's edema, scarring, and hyperfunction.[3] Increased amplitude may be a sign of decreased tonicity, as observed in vocal-fold paresis or atrophy.

Mucosal Wave

Mucosal wave is the vertical upheaval of the cover over the body. It occurs because of the vertical phase shift (the timing difference between the upper and lower margins of the vocal folds) that is vital to the self-oscillation of the folds.[16,17,32] The wave is propagated from the infraglottic lip of the vocal fold, then travels up the medial edge and across the superior surface of the fold. The velocity of the mucosal wave is linked to the amount of pressure that is needed to establish phonation,[33,34] and we judge mucosal wave as the distance it travels across the superior surface of the fold. Normally, this wave moves approximately half the width of the vocal fold during phonation at MCPL.[41] Increased mucosal wave (i.e., it moves farther across the fold) is observed when mucosa is abnormally pliable, such as in polypoid degeneration or when there is increased subglottal air pressure. As such, it is normally greater than half of the width of the fold for loud phonation, when subglottal air pressure is increased. Mucosal wave is decreased or even absent when the mucosa is stiff or there is minimal differentiation of the vocal fold layered structure; this occurs normally with increasing pitch[3] and with aging.[30] In pathologic conditions, decrease or absence of mucosal wave is seen with some lesions, scarring, or sulcus vocalis. Incomplete glottic closure resulting from aging, atrophy, or motion impairment can also lead to decrease or absence of mucosal wave.[30,35,36]

Adynamic Segments

Adynamic segments refers to nonvibrating areas of the vocal fold (i.e., areas that have no mucosal wave and poor amplitude of vibration). They are described by location and by the percentage of the vocal-fold surface that they cover. These stiff areas are generally related to a lesion or to a scarred segment.

Symmetry

Symmetry is a timing parameter. It refers to the extent to which the vocal folds appear as mirror images of each other during vibration. The vocal folds should depart from midline at the same time and arrive back at midline at the same time. The asymmetry should be described whenever possible; for example, "the excursion of the right fold lags behind that of the left," or "the folds are asymmetric at the end of tasks." Depending on the rating scale, the parameter can be rated as either the percentage of the examination during which vibration was asymmetric or the extent of asymmetry. Asymmetric vibration raises questions about differences in mechanical properties or neurologic status between the folds.[3] Differences between the vocal folds in position, mass, tension, elasticity, or viscosity should be further assessed.

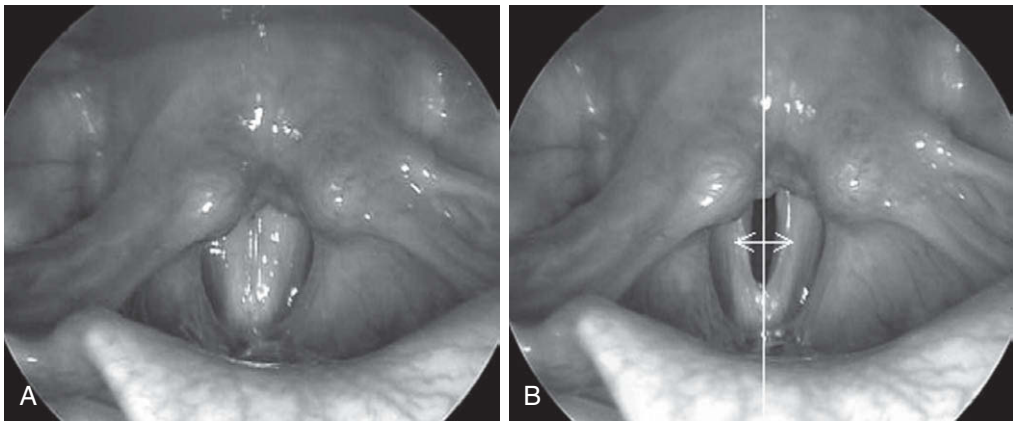

Figure 57-4. **A,** Complete glottic closure. **B,** Maximum amplitude of vibration/excursion.

Regularity

Regularity (or periodicity) describes the degree to which one phonatory cycle is similar in both amplitude and time to the next phonatory cycle.[3] The goal is to answer the question "Do the vocal folds vibrate in a regular, rhythmic pattern?" Regularity is best assessed in the locked or stop mode, but it can be estimated from the running phase as well. In the stop mode, the image appears static if the vibration is regular and appears to quiver or shake if the vibration is irregular. In running mode, the strobe light cannot adequately track fundamental frequency and adjust the illumination rate if vibration is irregular, and so quiver or shimmer appears. Vibratory regularity is rated just like symmetry, either by describing the percentage of time that the vibration was regular or irregular or by describing occurrences of irregularity. It is difficult to assess the amount of aperiodicity from stroboscopy; this would require acoustic analysis.

Incidence of aperiodicity rises with age. Biever and Bless[30] found that 85% of geriatric women demonstrated aperiodicity, compared with 30% of young women. Regular vibration depends on a steady balance between pulmonary pressure and the vocal folds. Irregular vibration can be caused by asymmetry of the mechanical properties of the vocal folds, interference with the homogeneity of the vocal folds, flaccidity, unsteady tonus, or inconsistent force. Examples are paralysis (asymmetry); a small cyst or carcinoma (homogeneity); paralysis, atrophy, or edematous lesion (flaccidity); spasmodic dysphonia or another neuromuscular disease (tonus); and functional pulmonary disease (inconsistent force).[3] Aperiodic vibration gives rise to acoustic noise, which can be perceived as roughness or hoarseness.

Vertical Closure Level

Whether the vocal folds meet on the same plane is typically rated as on-plane or off-plane. Closure is off-plane typically because of either neuromuscular differences between the folds (paralysis or paresis) or laryngeal trauma or surgery.

High-Speed Digital Imaging

Even though videostroboscopy is one of the most frequently used visualization techniques of vocal-fold vibration and is a powerful tool to examine symmetric and regular vibration,[3,35,38,39] stroboscopic analysis of irregular vibration, which is frequently observed in disordered voice production, is limited. Videostroboscopy requires a long enough phonatory segment to trigger the strobe light and cannot provide information about the phonation onset and offset, because they are very short and irregular. Currently, only HSDI[37,40,42-44] and high-speed kymography[45-47] allow the examiner to see the patterns of vocal-fold vibration regardless of their length, in most voice disorders, and during voicing initiation and termination phases. Both techniques capture images much faster than the vibration rate of the vocal folds; therefore, they allow the examiner to view vocal-fold vibration without the pitch-tracking requirement that exists for LVES. Kymography and HSDI are capable of demonstrating actual, real-time vibratory characteristics of the vocal folds. Video kymography allows the observation of movements at a single horizontal line from a laryngeal image, added together in real time to represent the vibratory pattern. It can be considered a one-dimensional version of HSDI. In contrast, HSDI allows the observation of the full length of vocal folds (Figs. 57-5 and 57-6).

Since the first recordings of vocal fold vibrations were made with high-speed photography,[48-50] high-speed recordings have shown promise for clinical applications. These recordings provided the foundation upon which much of our subsequent knowledge of vocal-fold vibration is based. Technologic advances in cameras, image resolution, and computers have resulted in development of HSDI, which permits recording of 2000 to 4000 (and higher) frames per second (fps) as opposed to the 25 or 30 fps available in videostroboscopy. This technique holds great promise for overcoming the limitations of currently available techniques for direct observation of laryngeal function. Images of stroboscopy and HSDI for a person with normal voice and a patient with a history of laryngeal cancer can be viewed in online video segments.

Equipment

Two HSDI systems are commercially available at present: the KayPENTAX Color High Speed Video system 9710 (KayPENTAX, Lincoln Park, NJ), which has spatial resolution of 160 × 140 pixels, and the Wolf High Speed Endocam 5562 (Richard Wolf Medical Instruments Corporation, Vernon Hills, IL), which has spatial resolution of 256 × 256 pixels. As a frame of reference, a typical LVES system has spacial resolution of 750 × 500 pixels. Both HSDI systems use the conventional 70- or 90-degree endoscopes to visualize the vocal folds, as in the LVES system. The flexible endoscopes have been used only in limited research settings with very few subjects because the image is generally not bright or clear enough. With a rigid endoscope, each of these systems requires a 300-watt cold light source to achieve sufficient clarity and the brightness of HSDI images. The recording time and capturing rate of the Wolf system are 2 seconds and 4000 fps, respectively, and the system stores color images as in an LVES system. The KayPENTAX HSDI system captures 2000 fps for 4 seconds. Faster capture rates are possible for less time and with smaller image size. Images using a capture rate of 4000 fps will still be color and 10,000 fps will be black and white. Both HSDI systems allow the examiner to play back the captured images at different playback rates. Even though synchronized audio playback is not available with either system, both systems allow simultaneous recordings of the endoscopic and acoustic signals and later analysis and comparisons of endoscopic and acoustic data.

Deliyski[51] reported in 2007 on the ongoing development of another HSDI system, which is equipped with temporal resolution of 10,000 fps, spatial resolution of 640 × 480, and sample duration of 32 seconds. At present, powerful HSDI systems like the one Deliyski's group is developing are impractical for clinical use owing to the equipment size, the magnitude of the data acquired, the lengthy duration of reviewing the captured data, and the image processing.

Assessment

Some of the parameters used in high-speed image analysis are the same as those for LVES: closure pattern, phase symmetry, amplitude of vibration, mucosal wave, pliability of tissue, adynamic segments, symmetry, regularity, vertical closure level, and vocal-fold edges. In addition, HSDI allows the observation of phonation onset and offset,[52,53] vibration in the surrounding structures such as ventricular folds,[54] intermittent vibration breaks, asymmetry between right and left vocal fold vibration, and the differences in frequency of vibration along different portions of the same vocal fold.[55] The primary challenge in analyzing high-speed images has always been managing the vast amount of data generated (a 2-second recording requires ~90 MB of digital storage).[48-50] The analysis was previously subjective, and reviewing the whole captured phonation segment took a very long time. This problem has been eliminated by higher computer processing speed, storage capacity, and newer image-processing techniques.[56-58] Current image-processing techniques allow rapid and objective data analysis and introduce easily recognizable visual representations of vocal-fold vibratory patterns in normal and disordered voice production. The Wolf system includes an automated image-processing system that provides quantitative informa-

tion regarding right and left vocal-fold asymmetry and the glottal perturbation measures (e.g., open quotient, speed quotient, jitter, and shimmer). The other image-processing systems used to process HSDI data are not commercially available at this time.

Limitations

Many challenges prevent HSDI from replacing LVES as a clinical tool: short duration of the recording, prolonged saving time of the captured images (which will lengthen the examination session if the tester wishes to obtain several phonation tasks in one session), cost, lack of synchronized audio playback, decreased spatial resolution, and no medical insurance billing code for the procedure.

In addition, information about normal and disordered vibratory characteristics is still being collected and reported. The parameters used to rate vocal-fold vibration are still being refined. Research showing firm evidence for the clinical relevance of HSDI is in its infancy. Only when standard parameters and normative data are identified will the added benefit of observing real-time vocal-fold vibration be realized in a clinical setting.

Image distortion secondary to the distance between the endoscope and the vocal folds, endoscope angle, or movement of the endoscope during the image-capturing process are inherent to any endoscopic procedure and make comparison of images taken from different visits difficult. The calibration issue has been addressed by the development of a laser projection system,[59] but laser projection is not available with the current HSDI systems. Each of the image-processing systems[57,58] can compensate for some of the endoscope movement during the imaging. The examiner's endoscopic skills, training in, and understanding of the HSDI technique further improve the quality of the data collection and analysis.

Applications

Results of studies using HSDI have already improved our understanding of normal and pathologic voice production. Kiritani and colleagues[40,60] found that, during diplophonia, the left and right vocal folds vibrate at different frequencies and the phase difference between the movements of vocal folds varies with time. Lindestad and associates[54] used HSDI techniques to study the relationship between ventricular fold vibration, vocal-fold vibration, and voice quality. High-speed analysis might be useful in quantifying the effects of neurologic diseases such as spasmodic dysphonia and vocal tremor[61] on vocal-fold vibration, possibly helping with differential diagnosis. HSDI has also been used to investigate different singing styles and their effects on laryngeal configuration.[62,63]

It appears that HSDI techniques will further our understanding of the voice source and biomechanics of vocal-fold vibration. With continued improvement of spatial and temporal resolution and image-processing systems, HSDI has the potential to become an excellent tool to show the efficacy of medical, surgical, and behavioral interventions for voice disorders.

Narrow-Band Imaging

Narrow-band imaging (NBI) is a new endoscopic imaging technique that employs the absorption characteristics of light for the detailed analysis of mucosal and vascular structures. This technique was initially developed to improve the recognition of Barrett's esophagus at the squamocolumnar junction of the lower esophageal sphincter.[64,65] NBI takes advantage of the differential absorption characteristics of tissues. Blue light with its shorter wavelength is better absorbed by hemoglobin. With the use of mechanical light-filtering technology to pass only the blue subset of the white light spectrum, structures with high hemoglobin concentration become more apparent with increased visualization of tissue's vascular pattern.[66] This creates a sharper contrast for better visualization of fine mucosal detail and helps to better identify subtle abnormalities (Figs. 57-7 and 57-8).

The applicability of this new technology to identify mucosal pathology in the aerodigestive tract is under investigation. To date, the technique has been shown to improve identification of abnormalities at the gastroesophageal junction, stomach, and colon.[65-71] NBI shows promise for improving the yield of biopsies by directing the examiner to the more "suspicious" areas, a type of optical biopsy. It is currently available for gastroscopes including transnasal esophagoscopes and flexible laryngoscopes. Clinicians are beginning to explore the utility of NBI in laryngeal[72] and hypopharyngeal[73] lesions. The real benefits and

limitations of NBI will emerge with future studies employing this technique.

CHAPTER FIFTY-EIGHT

Voice Evaluation

Robin A. Samlan

Julie Barkmeier-Kraemer

Key Points

- The voice is multidimensional, so voice assessment should be.
- The patient's perception of the problem is an important component of the evaluation. Several published scales can be used to report various aspects of handicap or quality of life.
- Perceptual assessment is notoriously unreliable yet remains important. Auditory, visual, and tactile perceptual examinations are key components of a voice evaluation.
- Vocal function measurements are less "objective" than they sound; standardization of tasks, instructions, and recording situations helps make them more useful.
- Specific measurement techniques contribute different information to the process, and the constellation of results is more useful than any one component.

Voice is produced by interactions among the respiratory, laryngeal, and resonance systems. The speech-language pathologist's voice evaluation is multifactorial, assessing each system in addition to the speech output. The purpose of this chapter is to describe the typical components of a voice evaluation and how to interpret the results. The focus of this chapter is on the perceptual, physical, and physiologic evaluation; the patient history and videostroboscopy are detailed in other chapters.

Both clinical and research requirements factor into decisions on how to measure voice. In the clinical arena, vocal function measures are used in both the diagnosis and treatment of voice disorders. Vocal function testing helps clinicians document the status of the voice source and the supraglottic vocal tract, characterize the type and severity of the voice disorder, and explain discrepancies between voice quality and stroboscopic evaluation by providing cycle-to-cycle information that is not available with stroboscopy. Vocal function measures can help the voice care team determine treatment goals and can be used as visual feedback during behavioral treatment. Repeated testing over time allows clinicians to monitor and document changes that result from treatment and also to monitor disease progression or recurrence. From a research perspective, voice measurements can improve our understanding of voice production, help identify links between laryngeal disease and voice production, and document change with interventions.

Many of the instrument-based tests yield numbers that lead some clinicians to view the results as "objective"; however, examiners influence results through their specific instructions to the individual as well as the selection of stimulus, token, measure, and equipment. In addition, the testing environment, time of day, day of week, and the number and type of prior tests conducted on the same individual can affect measurements. Results of vocal function testing should, therefore, be interpreted with these considerations in mind. To be considered reliable, measures must be made with the use of standard protocols, recording procedures, patient instructions, and test environments. Because of the multidimensional nature of the voice, one measure cannot adequately characterize an individual's voice. Thus, a group of measures is frequently selected to capture the primary elements of the voice, such as pitch, loudness, and quality.

The following discussion describes a typical voice evaluation, with a focus on how to interpret the results. The evaluation is divided into the following categories: patient scales, perceptual evaluation, measures, and diagnostic therapy. Within each category, measures can reflect typical voice use or maximum performance capabilities. The particular measures performed vary from one speech-language pathologist to the next, depending on equipment available as well as on the examiner's education and philosophy.

Patient Scales

Individuals have different requirements and expectations of their voices; thus, the same level of dysphonia can differentially limit participation in typical daily activities. As part of a complete voice evaluation, the effect of the voice problem on each individual's life should be assessed. Patient measures are scales completed by the patient and sometimes a caregiver or significant other. These scales typically measure patient satisfaction, quality of life, general health, handicap or loss as a result of the voice disorder, or some aspect of voice production (e.g., ease of phonation, effort, quality). Several scales specific to voice have been published in the last decade. The scales vary in length, construction, and what they assess.

Each published scale measures a different aspect of the voice. Some scales were constructed more carefully than others, so reliability and validity characteristics differ. Scale selection should be made according to variables of interest and reliability requirements. In general, patient scales are a wonderful addition to a voice evaluation and provide novel information about the patient's point of view. A patient scale can guide discussion between health care providers and patients and help the team determine treatment goals.

Two commonly used scales, the Voice Handicap Index (VHI)[1] and Voice-Related Quality of Life (V-RQOL),[2] are described here. Details and information about scale construction can be found in the

Table 58-1

Patient Scales

Scale	Abbreviation	Total No. Items	Domains
Voice Handicap Index[1]	VHI	30	Function, physical, and emotional
Voice-Related Quality of Life[2]	V-RQOL	10	Physical and social-emotional functioning
Voice Activity and Participation Profile[7]	VAPP	28	Severity, effect on: job, daily communication, social communication, and emotion
Voice Symptom Scale[4,6]	VoiSS	30	Impairment, emotional response, physical symptoms
Reflux Symptom Index[9]	RSI	9	Symptoms associated with laryngopharyngeal reflux
Patient Questionnaire of Vocal Performance[10,11]	VPQ	12	Physical, social, and emotional
Voice Outcome Survey[12]	VOS	5	Symptoms associated with unilateral vocal fold paralysis

reference articles, and a synopsis of current scales can be found in Table 58-1.

Voice Handicap Index

The Voice Handicap Index was designed to assess handicap, "a social, economic, or environmental disadvantage resulting from an impairment or disability."[3] The instrument consists of 30 statements that patients rate on a 5-point equal-appearing interval scale that reflects the frequency of occurrence. The total possible score is 120, with higher scores reflecting greater handicap. Although the initial publication suggests division into functional, physical, and emotional subscales,[1] other writers have questioned the subscale structure,[4,5] suggesting that total score appears more meaningful. Since its publication in 1997, the Voice Handicap Index has been widely used to show voice handicap in specific groups of patients, comparisons between handicap and vocal function measures, and change with treatment.

Voice-Related Quality of Life

The Voice-Related Quality of Life comprises 10 items divided into physical functioning and social-emotional functioning subscales. Each item is scored on a 5-point interval scale that reflects the severity of the problem. For the subscales and the total score, 100 is the highest possible score and reflects the highest quality of life.

Other Patient Scales

The Voice Symptom Scale (VoiSS)[4,6] is a psychometrically sound 30-item scale representing physical impairment, emotional response, and related physical symptoms. The Voice Activity and Participation Profile (VAPP)[7] follows the terminology and framework of the World Health Organization's 1997 revision[8] of the International Classification of Functioning, Disability, and Health. Patients indicate their extent of limitation in daily activities and restriction of participation in corresponding activities.

The Reflux Symptom Index (RSI), the Patient Questionnaire of Vocal Performance (VPQ), and the Voice Outcome Survey (VOS) are more limited in scope. The Reflux Symptom Index, made up of 9 items, is designed to document patient symptoms of laryngopharyngeal reflux.[9] The Patient Questionnaire of Vocal Performance is a 12-item scale designed to assess the physical, social, and emotional impacts of a nonorganic voice disorder.[10,11] The Voice Outcome Survey is a 5-item survey designed for patients with unilateral vocal fold paralysis.[12]

Perceptual Evaluation

Auditory Perceptual Assessment

Several formal measures and scales have been proposed to rate voice quality; two of the most commonly used scales are described here. Auditory perceptual ratings are appealing because the ultimate goal of voice treatment is to improve perceived voice quality. Unfortunately, such measures are fraught with definition, rating, and interpretation difficulties. Voice quality is difficult to define, leading to many, often circular, definitions of each term. Raters have different internal representations of the parameters and severity. It is difficult to differentiate between related qualities, and univariate ratings do not often correlate well with global ratings or measurements (for a detailed discussion, see Kreiman and Gerratt[13]). Although auditory perceptual assessment often results in a number, the number represents a perceptual judgment rather than a measurement and should be treated accordingly.

GRBAS

GRBAS is a well-known standard scale that was developed by the Committee for Phonatory Function of the Japanese Society of Logopedics and Phoniatrics. As described by Hirano,[14] the *G* represents grade or overall quality. The other four letters represent dimensions of voice quality, as follows: *R* for roughness, *B* for breathiness, *A* for asthenia, and *S* for strain. Descriptions of each parameter are given in Table 58-2. Each parameter is rated on a 4-point scale: 0 means that there is no deficit in this parameter, 1 is a mild deficit, 2 is a moderate deficit, and 3 indicates a severe deficit. There is no standard recommendation for the type of utterance(s) to use with GRBAS, so specific information about testing conditions should be documented in the report.

CAPE-V

The Consensus Auditory-Perceptual Evaluation–Voice (CAPE-V) was developed at a 2003 consensus conference sponsored by the American Speech-Language-Hearing Association Special Interest Division 3, Voice and Voice Disorders.[15] Six core and additional examiner-selected parameters are rated on a visual analog scale. The clinician uses a tick mark to rate function on a 100-mm line and then measures the distance from the left end of the line to establish a score; higher scores reflect a more severe deviation from normal quality. Core parameters are overall severity, roughness, breathiness, strain, pitch, and loudness. The judged parameters are identified as consistent or intermittent, and resonance differences can be noted. The CAPE-V is to be scored from two sustained vowels, six standard sentences, and at least 20 seconds of natural running speech. Recommendations about testing and recording environments are included.

Other Aspects of Speech Production

The speech-language pathologist might comment on other aspects of speech production that can indicate structural or neurologic disorders that affect voice production. Examples are imprecise articulation, resonance, and prosody disturbances. *Resonance* is described as hypernasal,

Table 58-2

Parameter	Hirano Definition*	National Center for Voice and Speech Definition†
Grade (G)	Overall severity	
Roughness (R)	Psychoacoustic impression of irregular vocal-fold vibration	An uneven, bumpy quality that appears to be unsteady in the short term but stationary in the long term; acoustically, the waveform is often aperiodic, with the modes of vibration lacking synchrony, but voices with subharmonics can also be perceived as rough.
Breathiness (B)	Psychoacoustic impression of air leakage through the glottis	Containing the sound of breathing (expiration) during phonation; acoustically, breathy voice, like falsetto, has most of its energy in the fundamental, but a significant component of noise is present owing to turbulence in the glottis. In hyperfunctional breathiness, air leakage may occur in various places along the glottis, whereas in normal voice, air leakage is usually at the vocal processes.
Asthenia (A)	Weakness or lack of power in the voice	A voice that appears too low in effort, weak; hypofunction of laryngeal muscles is apparent.
Strain (S)	Psychoacoustic impression of a hyperfunctional state of phonation	A voice that appears effortful; visually, hyperfunction of the neck muscles is apparent; the entire larynx seems compressed.

†From Titze IR. *Workshop on Acoustic Voice Analysis: Summary Statement*. Iowa City, IA: National Center for Voice and Speech; 1995.

hyponasal, or cul-de-sac. *Prosody* refers to rate, repeated or prolonged syllables, rushes of speech, intonation (i.e., monopitch or monoloudness), and stress patterns.

Auditory perceptual correlates of speech breathing are often assessed. Breath group length, average loudness, loudness variability, and inspiratory duration provide important information about lung volume expended, adequacy and consistency of alveolar pressure, and shape of rib cage and abdominal walls during talking.

Visual Perceptual Examination

The *visual perceptual examination* refers to visible and physical aspects of voice production related to etiology, maintenance, or effect of dysphonia. Koschkee and Rammage[16] have divided the visual perceptual examination into the following five categories: (1) general appearance; (2) posture, breathing, and musculoskeletal tension; (3) neurologic dysfunction; (4) physical dysmorphology; and (5) clinical manifestations of disease. Several components of the visual perceptual evaluation are described in more detail here.

General appearance factors, such as apparent age, height and weight, facial expression, skin, hair, and nails, personal hygiene and dress, and head and neck observations, can be indicative of underlying systemic disease, previous treatment, or emotional disorder. One example is the masked face of parkinsonism.

Posture, breathing, and musculoskeletal tension are key components of a voice evaluation because they frequently affect pitch, loudness, and quality. Postural assessment likely involves information about the alignment of the head, neck, torso, pelvis, and legs. Visual assessment of breathing includes observations of neck, shoulder, chest, and abdominal movement. Reports of musculoskeletal tension contain information about extent of jaw motion, chin jut, neck extension, bulging of the neck muscles while talking, or raised shoulders.

Neurologic dysfunction is indicated by observations such as unsteadiness, asymmetry, rigidity, hesitation, slowness, weakness, incoordination, inconsistency, and extraneous movements. Weakness, asymmetry, and incoordination of the tongue, jaw, lips, or soft palate are especially noteworthy. The presence of focal dystonias, such as writer's cramp, blepharospasm, torticollis, and oromandibular dysphonia, usually leads the examiner to consider a neurologically based voice disorder, such as spasmodic dysphonia.

Tactile Perceptual Evaluation

The manual examination of laryngeal musculoskeletal tension includes palpation of the suprahyoid muscles, the major horns of the hyoid bone, the superior cornu and the lateral aspects of the thyroid cartilage, the thyrohyoid space, and the anterior border of the sternocleidomastoid muscle. It is useful to assess suprahyoid tension and thyrohyoid space both at rest and during phonation. The examiner should also attempt to move the thyroid cartilage from side to side.[17-19] Figure 58-1 depicts this evaluation. Some authors recommend palpating the thyrohyoid, cricothyroid, and pharyngolaryngeal (inferior constrictor and posterior cricoarytenoid) muscles as well.[20,21] Normal findings include palpable space between the hyoid bone and the superior border of the thyroid cartilage and mobility of the laryngeal complex. Findings indicative of excessive musculoskeletal tension include pain with palpation (frequently more severe on one side), decrease or absence of thyrohyoid space at rest or with phonation, muscle "knots," high carriage of the hyoid bone and thyroid cartilage, and difficulty rotating the larynx.[17-21]

A drawback of the examination is that it is subjective, and examiner's skill and experience likely affect ratings. In addition, there are currently no intra- or inter-examiner reliability data for the technique, and the sensitivity and specificity of abnormal findings are unknown. Even given these limitations, tactile perceptual evaluation is a powerful technique to rapidly assess the contribution of muscle tension to the observed voice quality. Teasing apart the muscle tension and other components of the dysphonia can help ensure proper diagnosis and management; the tactile examination is one tool used in this endeavor.

Measures

Many different types of measurements can be used in the voice evaluation to describe pitch, loudness, and quality. Most speech-language pathologists use a subset of these measures, depending on their particular philosophy, education, and the equipment available to them. The measures described here are grouped into several categories based on measurement technique: chest wall displacement, aerodynamic assessment, and acoustic analysis. A fourth category, vocal fold measures, includes noninvasive evaluation techniques designed to assess vocal fold vibration patterns.

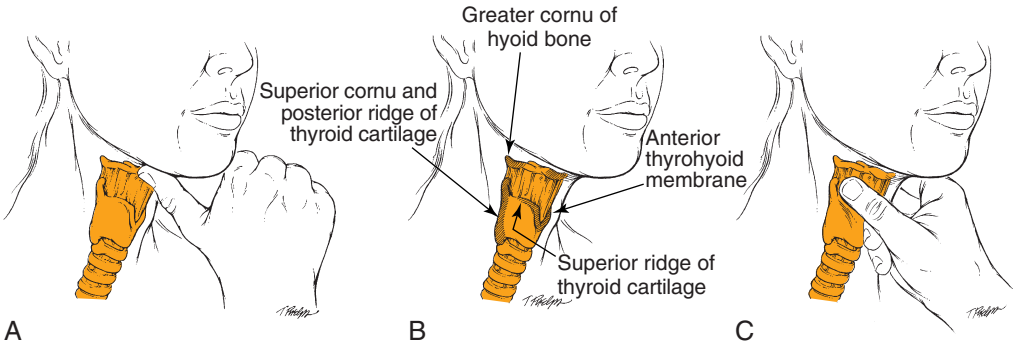

Figure 58-1. Manual musculoskeletal tension evaluation. **A,** Palpation of suprahyoid musculature. **B,** Palpation of greater cornu of the hyoid bone, superior cornu of the thyroid cartilage, and lateral aspects of the thyroid cartilage. **C,** Palpation of the thyrohyoid space.

Table 58-3

Perceptual Correlates of Aerodynamic Measures

Measure	Perceptual Correlate
Subglottal air pressure (Ps)	Phonatory effort
Phonation threshold pressure (PTP)	Effort to initiate phonation
Airflow	Breathiness
Laryngeal airway resistance (R_{law})	Phonatory effort, vocal strength, strain
Velopharyngeal measures	Nasal emission, strength of pressure consonants

Chest Wall Displacement

Measurements of chest wall movement can be used to estimate volume changes during voice production. Reports typically include information about the lung volumes used and chest wall shape during phonation. Lung volume variables of interest are the volumes at which the patient initiates and terminates speech. In general, people tend to initiate phonation around 20% of vital capacity above resting tidal end-expiratory level and to terminate phonation around resting tidal end-expiratory level.[22] Shape is usually described in terms of rib cage wall and abdominal wall movement. Because some shapes are more mechanically advantageous to phonation, the patient's typical shape and ability to change shape might be reported.

Aerodynamic Assessment

Aerodynamic evaluation involves measuring air pressures and airflows. Many calculations from these measures appear to be useful for vocal function analysis. Equipment can range from "low-tech" to "high-tech." Measurements are listed, along with their perceptual correlates, in Table 58-3.

MAXIMUM PHONATION TIME. *Maximum phonation time* (MPT) has long been used to describe both breath support and phonatory efficiency. The maximum length of time a patient can sustain phonation, however, is not fully explained by either vital capacity or laryngeal function.[23] Respiratory capacity and function, phonatory function, resonance, practice, frequency, intensity, instructions, and vowel choice all influence maximum phonation time.[23-29] Because of the variety of influences and because maximum phonation time is so dissimilar to conversational speech, the measure is neither accurate nor meaningful, especially when it is the sole measure reported.[23] When maximum phonation time is used, the longest of three trials should be reported. The normative range is quite large; for healthy young adults, the normal range is 6.6 to 69.5 seconds.[30]

SUBGLOTTAL AIR PRESSURE. *Air pressure* is defined as the force per unit area. The airway pressures important to voice production are tracheal pressure (*subglottal pressure*, or P_s), intraglottal air pressure (P_g), vocal tract input pressure (supraglottal pressure), and intraoral pressure (P_o). Relatively constant P_s and variable P_g are required to sustain vocal fold vibration. Measuring tracheal pressure (P_t) requires a tracheal puncture; thus, the intraoral air pressure (P_o) during a voiceless consonant (when the glottis is open) is typically used clinically for noninvasive estimation of P_t.[31] The magnitude of a normal pressure peak varies with loudness, age, gender, consonant, and speech context.[30] Normative values of 6.43 cm H_2O (standard deviation, 1.07) in men and 7.52 cm H_2O (standard deviation, 2.17) in women are reported.[32] Abnormal values can indicate a lack of driving pressure, an incompetent or insufficient velopharyngeal or laryngeal valve, or increased vocal fold mass or stiffness. Intraoral air pressure is useful to document clinician perceptions of weak pressure consonants, such as with velopharyngeal incompetence or dysarthria.

The minimum P_s needed for vocal fold vibration is called *phonation threshold pressure* (PTP),[33] and it is often measured at different pitches. At high pitches, phonation threshold pressure is sensitive to increased viscoelasticity of the vocal folds and has been useful in demonstrating subtle changes after dehydration, vocal fatigue, and vocal warm-up.[34-40] The measure is useful for documenting a patient's perception of increased effort to phonate, a common symptom of patients with vocal fold lesions, muscle tension dysphonia, and adductor spasmodic dysphonia.

AIRFLOW. *Airflow,* a change in volume of air over a specific time, is measured as volume (mL or L) per time (second or minute). Mean airflow is commonly assessed during sustained phonation, although it is sometimes measured during connected speech. Airflow measures are influenced by gender, age, fundamental frequency, and intensity. Normal values for women range from 91 to 156 mL/second, with a standard deviation range of 16 to 71 mL/second. Mean values for normal men range from 101 to 183 mL/second, with a standard deviation range of 16 to 77 mL/second.[30] Mean airflow is typically increased when there is poor vocal fold closure, such as for vocal fold motion impairment.[14,41] The shape of the airflow trace can also be useful; it is common with motion impairment to see a burst of air at the beginning of phonation and low airflow by the end. With hyperfunction, mean airflow might be reduced owing to over-closure of the vocal folds during phonation.[24]

LARYNGEAL AIRWAY RESISTANCE. *Laryngeal airway resistance* (R_{law}) is the ratio of translaryngeal air pressure to translaryngeal airflow.[30] Smitheran and Hixon[31] demonstrated that it can be estimated using P_o and mean airflow from repetitions of the syllable /pi/ at a rate of 1.5 syllables per second. Average values range from 24 to 45 centimeters of water per liter per second (cm H_2O/LPS) for adult men and 27 to 51 cm H_2O/LPS for adult women.[30] Higher R_{law} can occur with increased intensity, a long closed phase, or a higher force of closure.[24] Because it is a ratio, the R_{law} might be normal when the P_o

Table 58-4

Acoustic Measures and Their Perceptual Correlates

Measure	Perceptual Correlate
Frequency (Fo)	Pitch
Intensity (sound pressure level [SPL])	Loudness
Voice range profile (VRP)	Interaction of pitch and loudness ranges
Variability measures	Quality (e.g., roughness, breathiness, timbre)
Spectral displays	Quality
Fast Fourier transform (FFT)	Quality
Linear predictive coding (LPC)	Quality
Long-term average spectrum (LTAS)	Quality
Cepstral peak prominence (CPP)	Quality
Nasalance	Hypernasality, hyponasality

and airflow values are not. It is therefore a good idea to know the individual values used in the calculation.

AERODYNAMIC ASSESSMENT OF VELOPHARYNGEAL FUNCTION. The *velopharyngeal system* can be assessed aerodynamically with the use of P_o and nasal airflow (V_n) during stop consonants (usually /p/). Comparing the V_n and P_o traces during a transition between nasal and stop consonants (e.g., "mp" in the word "pamper") shows the timing of the velopharyngeal closure. If nasal cavity pressure is also measured, velopharyngeal orifice area can be calculated.[42,43]

Acoustic Analysis

The acoustic speech signal is the system's output and is rich in information about pitch, loudness, and quality. The signal is quite complex and is therefore broken down for analysis into the dimensions of frequency, amplitude (intensity), and time. Acoustic measurements are best made from signals recorded on high-quality equipment in a quiet environment and with the use of standard instructions. Data should be interpreted in light of subject age and gender, interactions between parameters, speech sample selected for analysis, and number of tokens. It is also important to know whether the samples were consistent with typical voice use or maximum/best performance. Commonly used acoustic analysis measurements are described here and are listed, along with their perceptual correlates, in Table 58-4.

FREQUENCY. *Frequency* is the number of repeating cycles in the acoustic waveform each second. Pitch is the perceptual correlate of frequency. In truth, many additional factors contribute to perception of pitch, but frequency is the most salient one. Lower pitches are associated with a longer glottal cycle as reflected by fewer cycles per second and a lower fundamental frequency. Higher pitches are associated with shorter glottal cycles, as reflected by more cycles measured per second and a higher fundamental frequency. Altered pitch and restricted pitch range are common symptoms of voice disorders and can represent a significant concern for patients. Average speaking fundamental frequency and maximum phonational frequency range (MPFR) are the most common clinical parameters used to examine frequency. Normative values are influenced by intensity, speech sample, vowel type, age, and gender.[30,44] Average speaking fundamental frequency ranges from approximately 100 to 125 Hz for normal adult men into their 70s and from 190 to 225 Hz for normal adult women.[30] The maximum

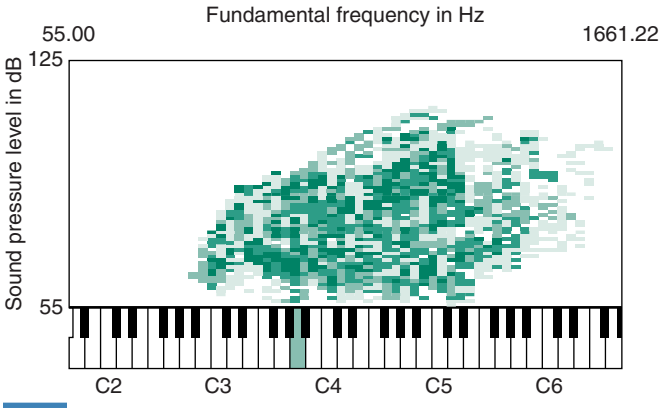

Figure 58-2. Sample Voice Range Profile (VRP).

phonational frequency range is frequently reported through the use of a semitone scale, whereby perceived changes in pitch are equalized across the frequency range. The semitone scale corresponds with the musical scale, with 12 semitones in an octave. Maximum range for men and women is typically two-and-a-half to three octaves, or approximately 29 to 36 semitones.[30]

INTENSITY. Sound pressure level (SPL), often referred to as *intensity*, is the acoustic correlate of loudness. Many factors influence the perception of loudness, but intensity is the primary one. Sound pressure level is measured in decibels (dB) and is influenced by frequency, vowel, speech sample, equipment, distance from the sound source, and ambient noise.[44] The most common measures are average speaking, minimum, and maximum sound pressure levels. On average, men and women speak at approximately 70 dB,[30] although there can be large variability in conversational speech. Maximum range is typically less than 60 dB to at least 110 dB.[24,45] Intensity measures are useful to document concerns about decreased loudness levels, which are common for patients with Parkinson's disease or impairment of vocal fold motion, and they help identify patients who have difficulty speaking quietly, such as people with vocal fold scarring or lesions.

COMBINED FREQUENCY AND INTENSITY. A frequency-by-intensity plot for an individual's total range is called a *phonetogram* or a *voice range profile* (VRP). The minimum and maximum intensities an individual can produce are plotted for every frequency in that person's range. There is a typical shape to the plot, which is demonstrated in Figure 58-2. Visual inspection of the voice range profile highlights the interaction between frequency and intensity, with the highest frequencies generally produced at greater intensities than the lowest frequencies. The middle of the frequency range is usually the location of the individual's maximum intensity range.[33] There is no standard for analyzing the voice range profile, but several writers have proposed methods of quantifying the plot.[46-51] Even though it is difficult to describe a voice range profile with one number, the profile is very useful for tracking changes and for documenting difficulty with specific pitch and loudness combinations (e.g., trouble singing particular notes quietly).

VARIABILITY MEASURES. Acoustic measurement of voice quality remains elusive. Theoretically, measures that document variability in the sound wave or noise in the spectrum should correspond well with roughness, breathiness, and strain. Unfortunately, how well the measures relate to voice quality ratings remains uncertain,[44,52-59] and no particular measure or group of measures has emerged as indispensable for the diagnosis of voice disorders. The best-known short-term perturbation measures are jitter and shimmer, which are the most likely to be included in a report because normative values are reported in the literature. *Jitter* is cycle-to-cycle variation in frequency, and *shimmer* is cycle-to-cycle variation in amplitude. Various measures of harmonics or signal to noise have also been proposed. An excellent review of acoustic measures and algorithms can be found in a chapter by Buder.[60] One important limitation to perturbation analysis is that it can be reliably performed only for nearly periodic signals. If the signal has no

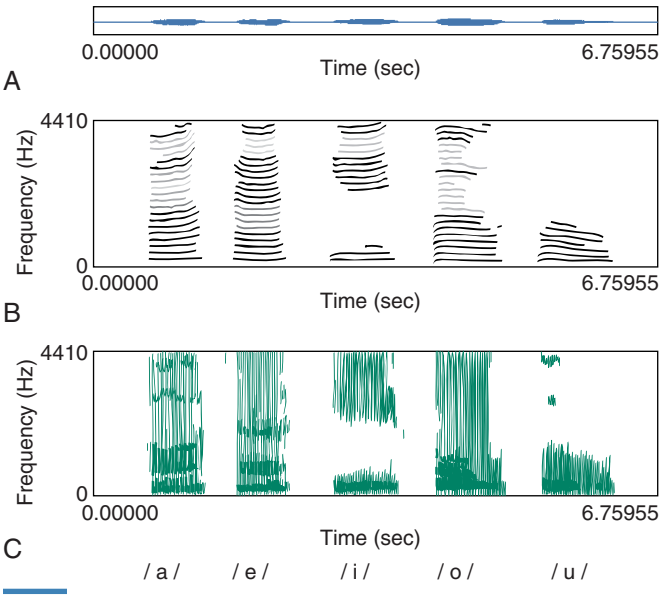

Figure 58-3. **A,** Audio signal; **B,** narrow-band spectrogram; **C,** wide-band spectrogram for /a/ /e/ /i/ /o/ /u/.

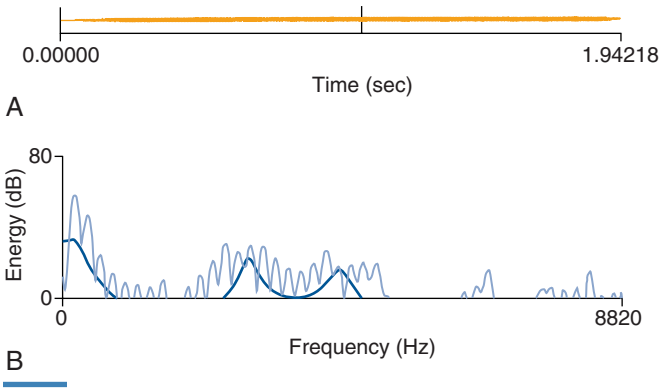

Figure 58-4. **A,** Audio signal of sustained /i/; **B,** Fast Fourier Transform (*light blue*) and linear predictive coding (*dark blue*) spectra from the marked portion of the /i/.

single fundamental frequency or has qualitative changes (common for patients with disordered voices), perturbation analysis is not appropriate.[61]

SPECTRAL DISPLAYS. Vocal fold vibration produces a (source) signal that has a fundamental frequency and multiples of that frequency, called *harmonics*.[62] This source signal is modified as it passes through the supraglottic vocal tract, called the *filter*. The vocal tract structures change position for different vowels, changing the location of resonant peaks, called *formants*.[30] Because the voice that people hear is a combination of source and filter characteristics, the harmonics and the formants each tell part of the story of voice production.

A *spectrogram* is the most common visual depiction of an acoustic wave. It displays time on the x-axis, frequency on the y-axis, and amplitude on a gray scale. Changing the bandwidth of the analysis window allows us to view details of either the source or the filter. A narrow-band spectrogram, with its greater frequency resolution, emphasizes the fundamental frequency and the harmonics. A wide-band spectrogram, with its greater time resolution, highlights the formants.[30] Figure 58-3 shows both a narrow-band spectrogram and a wide-band spectrogram of /a/ /e/ /i/ /o/ /u/. Spectrograms clearly show noise versus harmonic structure, tremor, phonation breaks, and pitch breaks. The relative amplitude of the first harmonic has been shown to correlate with ratings of breathiness,[63,64] as have increased noise in the higher harmonics and increased bandwidth of the first formant.[65] Spectrograms are useful for tracking change and can be used in real time during voice therapy for visual feedback.

ADDITIONAL ACOUSTIC MEASURES. A *Fast Fourier Transform (FFT) analysis* converts the signal so that the individual frequencies from a narrow time band can be identified. The display shows frequency on the x-axis and intensity on the y-axis. *A linear predictive coding (LPC) spectrum* shows a smoothed line that highlights the formant structure but that again reveals the amplitude of frequencies for a narrow band of time. Figure 58-4 shows the Fast Fourier Transform and linear predictive coding spectra for the marked location in the audio signal of a sustained /i/.

Long-term average spectra (LTAS) show the amount of energy at each frequency over a long period (e.g., a standard reading). Because the measure is averaged over such a long sample, the effects of speech context are minimized. Measurements of the long-term average spectra typically compare the amount of energy in different frequency bands. The resultant values, which are often referred to as *spectral tilt*, indicate whether low or high frequencies dominate the spectrum.[66] Increased spectral tilt is linked with breathy voice.[65]

Cepstral peak prominence (CPP) is a measure of signal periodicity that does not rely on fundamental frequency extraction, but instead corresponds to the regularity of harmonic peaks. The measure has been found to correlate with breathiness and overall dysphonia ratings.[63,64,67] A lower cepstral peak performance reflects less periodic vibration.

Acoustic assessment of velopharyngeal function: Oronasal resonance balance can be assessed acoustically using a commercial program such as the Nasometer (KayPENTAX, Lincoln Park, NJ). This instrument computes *nasalance*, a ratio of nasal sound energy to total (oral plus nasal) sound energy. There has been some debate about the validity of nasalance because of inconsistent correlation between nasalance and the perceptual evaluation of hypernasality. Proposed hypernasality cutoff scores have varied according to testing centers and raters but appear to range from 25% to 33% for a standard passage without nasal consonants (zoo passage). That is, mean nasalance scores of 25% to 33% or greater are generally associated with perceived hypernasality; hyponasality is generally perceived when mean nasalance falls below 50% for nasal sentences.[68-71] There is evidence to suggest that regional normative data should be collected, because resonance patterns vary according to dialect.[68] Documenting hypernasality due to velopharyngeal dysfunction can be an important factor in narrowing potential sites of lesions.

Measures of Vocal Fold Vibration

ELECTROGLOTTOGRAPHY. Electroglottography (EGG) measures the conductance of a low-frequency electric signal across the neck between two surface electrodes.[24,30,72] The conductance of the signal varies with the vibration of the vocal folds; when the vocal folds contact each other, conductance increases, and the resultant EGG trace has a positive slope. As vocal folds separate, conductance decreases, and the trace has a negative slope. Because the traces display the extent of contact relative to the rest of the signal, maximum contact does not necessarily indicate complete vocal fold closure. The waveform's shape is potentially meaningful for describing the pattern of vocal fold vibration. Baken and Orlikoff[30] summarize a variety of EGG shapes and the corresponding glottic cycles. Specific measures of increasing contact, decreasing contact, and speed quotients have been proposed over the years, but some researchers question their validity.[73]

In EGG, abnormalities in the signal are not always the result of abnormalities in vocal fold motion; the signal can be affected by the placement of electrodes, movement of the larynx during phonation, irregularities of neck tissue, and mucous bridges. Even given its limitations, EGG is an excellent measure of fundamental frequency and offers a unique opportunity to study the vocal fold vibration without any influence of supraglottic structures or shaping. It is noninvasive, relatively inexpensive, and can be used at the same time as other measures (e.g., airflow, videostroboscopy).

INVERSE FILTERED FLOW. In inverse filtered flow, the effects of the vocal tract (resonances) are filtered out of either the acoustic or the

aerodynamic waveform, and the glottic source signal is left. From this trace, several measures can be made, including *skewing quotient* (the ratio of the positive slope to the negative slope) and *open quotient* (the ratio of the time open to the period of the waveform).[33] Inverse filtered flow is quite useful because it allows us to study the glottal flow signal, yet it is technically complicated and therefore challenging to incorporate into clinical assessment protocols.

Diagnostic Therapy

Diagnostic therapy (i.e., probe therapy) is used to determine whether voice quality can be modified and in what situations. Response to therapeutic probes can guide intervention decisions and even help determine the diagnosis. Therapy probes often include modification of extrinsic laryngeal muscle tension or posture. They also include techniques to modify the breath, phonation, and resonance subsystems.

Summary

Voice evaluation and measurement should be multidimensional, reflecting the complexity of the voice. Evaluation includes patient scales, perceptual evaluation, vocal function measures, and diagnostic therapy. Individual measures are influenced by many factors that must be considered by the clinician or researcher interpreting the data. Each of the measures addresses a piece of the puzzle, and none stands alone as the perfect answer to all questions. A set of measures should be selected that documents the patient's particular concerns or that parallels the questions that are of interest to the examiner. The development of standard protocols and testing conditions among centers will improve the ability of clinicians and researchers to communicate and hasten further understanding of the human voice.

CHAPTER FIFTY-NINE

Neurologic Evaluation of the Larynx and Pharynx

Gayle Ellen Woodson

Andrew Blitzer

Ronda E. Alexander

Nazaneen N. Grant

Key Points

- Evaluation of the larynx and pharynx is a multidisciplinary endeavor and may involve otolaryngologists, neurologists, speech-language pathologists, and radiologists.
- Normal functions of the larynx include regulation of respiratory mechanics, airway protection during deglutition, and phonation.
- Normal function of the pharynx includes maintenance of patency for respiration and effective constriction for swallowing with prevention of reflux into the nose or mouth.
- Neurologic evaluation begins with observation of voluntary and involuntary movements and having the patient perform various phonatory tasks.
- Flexible laryngoscopy and stroboscopy give information on vocal cord movement, compensatory mechanisms, laryngeal sensation, mucosal wave and pliability, and velopharyngeal competence.
- Video recording of physical examinations facilitates later review and consultation with colleagues.
- Acoustic analysis gives objective measures of fundamental frequency, perturbation, and spectral analysis.
- Electromyography can be used to assess the integrity of a neural pathway. It is useful to prognosticate the potential for recovery of motion in a patient with a fully immobile vocal fold.
- Sensory testing quantifies sensory loss and can give information for evaluating the site of a neurologic deficiency.

The upper aerodigestive tract serves the diverse purposes of breathing, eating, and communicating. These activities require some orthogonal functions. For example, pharyngeal patency should be maintained during respiration, but the pharynx should be forcibly constricted during swallowing. In addition, the anatomic structure of the upper aerodigestive tract is precarious, with ingested food and inspired air traversing the same space. Precise coordination of motor activity and appropriate response to sensory feedback are essential for normal function. Neurologic disorders may impair upper aerodigestive tract function by diverse mechanisms, including motor weakness, incoordination, and impairment of sensation.[1,2]

The diagnosis of disorders in patients with neurologically impaired function of the upper aerodigestive tract is often elusive, particularly when the problem is isolated to that region. The reason is that the ability of the throat and larynx to function cannot be directly observed. Patients with complaints of hoarseness, dysarthria, dysphagia, aspiration, or airway obstruction are often seen by otolaryngologists, whose training emphasized morphologic rather than functional evaluation. Neurologists, whose forte is functional assessment, generally confine their evaluations to structures that are more accessible, such as limbs. If the anatomy is normal and if no functional deficit is noted on a traditional neurologic examination, a patient who actually has a neurologic impairment is often incorrectly assumed to have a functional or psychiatric disorder. Thus, the diagnosis of a generalized neurologic disorder, such as myasthenia gravis or amyotrophic lateral sclerosis (ALS), may be delayed until the disease process is more widespread and apparent. As a result, patients may receive well-intentioned but ineffective therapy instead of potentially effective treatment.[3-5]

In patients whose neurologic diagnosis has been established, assessment of laryngeal and pharyngeal function is an important component and may be lifesaving. Optimal treatment and rehabilitation of patients with swallowing, speech, or phonation disorders require identification of the precise pathophysiology of the problem so that appropriate therapy may be designed.

The diagnosis of neurologic impairment of the upper airway requires an awareness of the possibility of neural dysfunction, familiarity with the signs and symptoms of neural dysfunction, and a systematic approach to the examination of the throat and pharynx. Box 59-1 lists some symptoms that suggest neurologic impairment. The patient's interests are best served by the collaborative efforts of the otolaryngologist, who is highly skilled in visualizing the throat and larynx, and the neurologist, who is knowledgeable in the pathophysiologic processes. This chapter reviews normal physiology and salient features of specific neurologic diseases that affect function, outlines the approach

Box 59-1

Laryngeal and Pharyngeal Symptoms Suggesting Neuropathology

Speech Problems
Lack of volume
Breathiness
Instability of pitch or volume
Lack of voice inflection
Abnormal resonance
Dysarthria

Swallowing Problems
Oral incompetence
Velopharyngeal incompetence
Inability to initiate a swallow
Aspiration

Breathing Abnormalities
Fluctuating inspiratory stridor
Weak breathy cough
"Gurgly" breathing noises

to the history and physical examination of patients in whom such diseases are suspected, and discusses how ancillary tests may be useful.

Normal Function

Phylogenetically, the most important function of the larynx is protective; the larynx prevents ingested food and drink from entering the lungs. To fulfill this role in humans, the larynx should be open during breathing and tightly closed during swallowing. Phonation is a more advanced evolutionary function. Glottic closure during forced exhalation results in an effective cough to clean the lungs and prevent atelectasis. Laryngeal closure is required to generate positive intrathoracic pressure for defecation, childbirth, and lifting heavy objects and for the stabilization of the thorax. The larynx also seems to play a sophisticated role in controlling airflow and pressure during breathing. The vocal folds open just before respiration and then close gradually during exhalation, braking expiratory airflow and thereby influencing the rate of breathing. The sensory feedback loops that control these respiratory functions of the larynx are not well understood, but it is clear that feedback from a variety of receptors is involved.[1,2,6]

Swallowing is a deceptively simple function. Food prepared in the mouth is ejected into the pharynx and then rapidly propelled downward around the glottis, through the pyriform sinus, and into the esophagus. During the swallow, the same pharynx that remains patent during breathing is responsible for constricting tightly in an organized sequence from top to bottom. Regurgitation into the nose or reflux into the mouth is prevented by actions of the soft palate, tonsillar pillars, and base of the tongue. The larynx is pulled upward and forward, away from the flow of the bolus. This action also decompresses the sphincter between the pharynx and esophagus. Flexion of the epiglottis and closure of the glottis prevent the entry of any errant material into the airway. After this complex and coordinated activity, the cricopharyngeal muscle should be relaxed when the bolus reaches the caudal end of the pharynx to permit passage into the esophagus. If pharyngeal peristalsis is inadequate or if the upper esophageal sphincter is insufficiently opened, residual material in the pharynx could penetrate the airway during the next inhalation. The unique anatomic configuration in humans after infancy renders swallowing more difficult. In all other mammals, the feeding and breathing channels are offered a degree of separation by interdigitation of the epiglottis and uvula. In humans, these structures are separated during early development by the descent of the larynx relative to the palate.[7-9]

Speech is audible communication that results from phonation, resonance, and articulation. The production of sound *(phonation)* requires several conditions. Expired airflow and pressure should be sufficient to induce oscillation of the vocal folds. The vocal folds should be appropriately approximated. If they are closed tightly, excessive expiratory force is required, resulting in a strained, harsh voice or complete aphonia. If the vocal folds are too far apart, increased expiratory airflow volume is required, so that the voice becomes weaker and breathier or even fades to a whisper. The three-dimensional shape of the vocal fold is also important in imparting favorable aerodynamic features to the glottis. Atrophy of the vocal fold causes concavity in the axial and coronal planes. The former results in incomplete glottal closure even during tight approximation of the vocal processes. Concavity in the coronal plane results in a convergent airflow tract. Control of length and tension is required to produce normal inflections in pitch and tone. In the absence of such control, the voice may be flat and expressionless, or it may be distorted by uncontrolled pitch breaks. The mucosa of the vocal folds should be supple to permit free vibration. All but the last of these requirements for phonation are susceptible to derangement by neurologic dysfunction.[10,11]

Resonance is the modification of phonation to produce voice. Pure phonated sound as produced by the vocal folds does not sound like a human voice; it is a strident and unpleasant noise. This sound is modified by resonance of the head, neck, and chest so that component frequencies are selectively amplified or dampened. Vocal resonance is largely determined by anatomy, but it also is significantly modulated by motor activity of the pharynx, soft palate, and oral cavity. This principle may be used in speech therapy to achieve stronger voices in patients with impaired function. Certain neurologic disorders, such as ALS, stroke, and Guillain-Barré syndrome, result in altered vocal resonance. The characteristic sound of the voice in patients with these disorders may be a valuable physical sign to aid in early diagnosis.[10,11]

Articulation is the shaping of voice into words by actions of the lips, tongue, palate, pharynx, and larynx and is highly susceptible to neurologic impairment. Whereas dysarthria in children is caused most often by a hearing deficit, acquired dysarthria in adults usually indicates neurologic impairment. Dysarthria may be a result of impaired motor output, such as weakness, paralysis, or incoordination, but may also result from cognitive or language defects or from apraxia of speech.[10,11]

Neurologic Examination of the Mouth, Larynx, and Pharynx

Listening to the patient is the first step of the examination in the patient with a voice complaint. Often, it is possible within minutes to make a working diagnosis on the basis of the sound of the voice and the patient's description of the problem. The patient should be questioned carefully about vocal fatigue, pain with speaking, increased effort required for speech, glottal tightness, pitch breaks, and tremor.

The standard neurologic examination does not address the relatively inaccessible regions that are familiar to the otolaryngologist. The following protocol is suggested as a systematic approach to detecting neurologic dysfunction. The objectives are to assess the integrity of the lower cranial nerves and to seek signs of central nervous system disorders.[10]

Oral Cavity

Observe the lips, palate, and tongue for abnormal spontaneous movement. Involuntary, slow, athetoid movements of the tongue occur in patients with tardive dyskinesia, which is usually a reaction to a major tranquilizer. A quivering, "bag of worms" appearance indicates fasciculations, a characteristic sign of ALS. Spasmodic motions, in particular excessive blinking and jaw thrusting, are characteristic of Meige's syndrome. Assess range of motion, strength, and symmetry of the mouth and palate muscles as usual. Ask the patient to purse the lips, to protrude the tongue and move it from side to side, and to open the mouth and say the traditional /ah/ to test for palate motion and symmetry. The best way to assess tongue strength is to have the patient push the tongue against the buccal mucosa while the physician palpates the cheek externally.[10]

It is important to test not only the strength but also the central control of lip and tongue muscles. Rapid repetition of the syllable /Pa/

shows lip function. A healthy person is able to maintain a regular rhythm at a rapid rate. A lower motor neuron lesion decreases the strength of this action. Upper motor neuron involvement reduces the rate at which the patient can repeat the syllable, but regular rhythm should be preserved. In patients with cerebellar dysfunction, the rhythm is erratic. Myasthenia gravis involvement results in fatigue with repetitive motion. Other syllables address other muscle groups. /Ta/ tests the tip of the tongue, and /Ga/ tests the posterior tongue.[10]

Flexible Laryngoscopy

Neurologic function of the larynx is difficult to assess without the use of flexible laryngoscopy. This technique permits observation during both quiet breathing and a variety of tasks. The addition of a video camera is invaluable, because it produces an enlarged image on the monitor that may be recorded for detailed evaluation and saved for comparison with future evaluations.[12,13]

Attention is first directed to the soft palate. With the scope in the posterior choana, the soft palate is observed for any tremor or spasmodic movement at rest. The patient is instructed to swallow and say "kitty cat." These tasks show the symmetry and competence of velopharyngeal closure.[12,13]

The scope then is advanced to visualize the base of the tongue. Alternating phonation of /ee/ and /ah/ should result in first anterior and then posterior movement of the tongue. Assessment of the pharynx is more difficult, because during a normal swallow, the view through the flexible scope is totally obscured. In those with pharyngeal paralysis or paresis, closure is impaired, and impairment of motion on the involved side may often be detected. Pooling of secretions in the hypopharynx is indicative of poor swallowing function, which could be attributed to either sensory or motor impairment.[12,13]

The most detailed assessment is focused on the larynx. During quiet breathing, the vocal folds may appear motionless and partially abducted, but abduction usually occurs just before inspiration, and gradual adduction during exhalation. The degree of motion varies with the respiratory effort and with the level of upstream resistance. With deep inspiration, the vocal folds abduct widely. During panting, the vocal folds remain fixed in an abducted position. Nasal breathing in most patients offers more resistance than mouth breathing, so the range of vocal fold movement is usually greater with the mouth closed.[12,13]

Having the patient perform a vigorous voluntary cough is a good way to assess the strength and range of motion of the larynx. The vocal folds abduct during the inspiratory phase, close tightly for the compressive phase, and then suddenly open widely. The cough is a useful way to differentiate psychogenic stridor from true bilateral laryngeal paralysis.[12] Aphonic malingering patients may not adduct their vocal folds completely when asked to phonate but adduct them normally with cough. During phonation, the vocal folds should adduct smoothly and symmetrically. Recurrent laryngeal nerve paralysis can usually be diagnosed through observation of the vocal folds during breathing and phonation, although paresis may become evident only if the patient performs repetitive brief phonations. Asking the patient to sniff and then say /eee/ repetitively may elucidate a paresis. Repetitive phonations also reveal fatigue in patients with myasthenia gravis. For assessment of the cricothyroid muscle, which is innervated by the superior laryngeal nerve, the patient is asked to perform a pitch glide, phonating from a low pitch to a high pitch and back down. The pitch should rise as the vocal folds become longer and thinner.[12,13]

It is sometimes difficult to differentiate a functional or psychiatric voice problem from a neurologic disorder. It is helpful if the physician is familiar with characteristic distortions of the larynx in hyperfunctional dysphonia. Some common distortions are compression of the glottis in the anteroposterior dimension, contraction of the aryepiglottic folds, and false vocal fold adduction, which may be severe enough to totally obscure the true vocal folds. Patients with hyperfunctional dysphonia also characteristically elevate the larynx and speak with a low lung volume. Such dysfunction is usually amenable to voice therapy. It is important to remember that neurologic and functional conditions commonly coexist and that some patients may use hyperfunction to compensate for a neurologic defect.

Video recording of the endoscopy may enhance the examination, because the record can be reviewed repeatedly or viewed by other consultants. An objective record is also provided for monitoring the progress of the disorder or the patient's response to therapy. Transoral telescopic laryngoscopy with a rigid-rod quartz lens system provides a clear, magnified view of the larynx. This is the best technique for demonstrating laryngeal morphology and documenting even minute laryngeal lesions. The use of the telescope has limitations. The patient's mouth should be open with anterior traction on the tongue, although this position prevents examination of the larynx during speech or swallowing. The examination also requires topical anesthesia in many patients.[12,13]

The stroboscope provides a flashing light to simulate a slowed vocal cord vibration. The stroboscope has a microphone to sense the fundamental frequency of the vibrations and to coordinate the flashing light to the same frequency. If the light flashes at the fundamental frequency, the stroboscope freezes one image in the vibratory cycle. The slowed motion allows the most accurate assessment of the mucosal wave, which may be impaired by scarring, edema, or subtle defects in the mucosa. Lesions such as subtle edema, vocal cord cysts, and early carcinoma may be best seen as an adynamic segment of the vocal cord on stroboscopy. Stroboscopy also allows accurate evaluation of the closing and opening pattern of the larynx and may be able to indicate the probable underlying cause of a faulty closure. Probable causes that can be detected with a stroboscope include vocalis muscle atrophy, posterior laryngeal edema, and faulty vocal technique. The stroboscope has limitation in patients in whom an unstable voice does not allow for a steady frequency of slow motion. This occurs in patients with vocal cord paralysis or vocal cord scarring and in some patients with spasmodic dysphonia.[14]

Ancillary Tests

Rating Scales

In the past, assessment of voice disorders has focused on objective measures of voice quality and aerodynamic tests. These measurements, however, do not account for global voice function and its effect on quality of life, which is the ultimate goal of therapy and surgical intervention. Several rating scales have thus been validated to quantify the degree of disability attributable to a voice disorder. The Voice Handicap Index (VHI) is a patient-based self-assessment tool consisting of 30 items equally distributed over three domains—functional, physical, and emotional aspects of voice disorders. A modified, 10-item rating scale known as the VHI-10 was subsequently developed and validated. Other measures have been developed as well, including the voice-related quality of life (V-RQOL) instrument, a 10-item outcome instrument with a social-emotional domain and a physical-functional domain.[15] In interpreting the scores from such scales, the physician must keep in mind that the output is ordinal ranking only, rather than rational number values.

Acoustic Analysis

The sound of a voice can be assessed quantitatively by mathematical processing of the recorded sound. Voice is not a simple sine wave; rather it is a complex group of waves of varying frequency. In a pure periodic waveform, all frequencies above the fundamental frequency are multiples of f_0 called *harmonics*. Lack of periodicity is perceived as noise and is described as frequencies between the harmonics. A Fournier analysis is a computational method of simplifying complex waveforms into component parts. Transmission of sound through the vocal tract with its characteristic resonant properties alters the sound by enhancing the resonant frequencies. Most commercial packages for acoustic analysis provide measures of f_0 (a correlate of pitch) as well as perturbation measures that track variations in loudness (shimmer) and pitch (jitter). Acoustic measures have only limited clinical relevance. Although they can be used to document severity and to track changes over time and with treatment, they provide little diagnostic information. For neurogenic disorders, acoustic parameters do not differentiate voices of patients with neurologic disorders such as Parkinson's disease, ALS, and Huntington's disease.[16] Furthermore, validity diminishes with the

severity of hoarseness, and it is impossible to analyze a severely dysphonic voice sample. The one acoustic measure that is very useful in neurologic voice disorders is the documentation of breaks in the acoustic signal. These events are quite characteristic of spasmodic dysphonia but rare in subjects with habitual or psychogenic hyperfunctional dysphonia.[17] Thus, detection and measurement of voice breaks can be very useful in diagnosing spasmodic dysphonia.

Performance Measures

Performance measures evaluate the capacity of the patient to produce vocal sound. Maximum phonation time is a clinically valuable parameter that is very simple to measure. It is the maximum duration that a subject can sustain phonation of a vowel. It can be measured by a computerized program or just with an ear and a stopwatch. If the glottis is incompetent, excess air escapes during phonation and the duration of maximum phonation time decreases; in some cases of excessive glottic closure, it increases. Maximum phonation time can also be decreased by poor respiratory function or inadequate patient effort, and these factors should be considered in interpretation of results.

A more complex assessment of vocal capacity can be acquired by the phonetogram, which tracks the minimum and maximum loudness that the subject can produce across a spectrum of pitch. This technique, which is not widely used in the United States, is time and effort intensive.

Aerodynamic Assessment

Whereas acoustic measures address the sound of the voice, measurements of airflow and air pressure provide important information about the mechanics of vocal production. Phonatory and respiratory airflow can be easily measured directly and are useful in monitoring the effects of therapy. Accurate interpretation of airflow data requires concurrent measurement of subglottic pressure—the driving force for phonation. Direct measurement of subglottic pressure requires invasive procedures, such as transglottic placement of a transducer or tracheal puncture. More commonly, phonatory subglottic pressure is estimated from measures of intraoral pressure during repetitions of the syllable /pi/. This technique was developed in normal subjects and has not been validated in pathologic conditions.

Other means of assessing aerodynamic ability are body plethysmography (measurements of chest wall movement), spirometry, and airflow measurement with a hot wire anemometer (to determine rapid changes in airflow).[7,18]

Glottography

Photoglottography and electroglottography are tools that track motion of the edges of the glottis during phonation. Photoglottography is performed by shining a light on the larynx. The amount of light that passes through the glottis is proportional to the size of the glottic opening. The light transmission may be measured by a photosensor overlying the subglottic neck skin. Electroglottography is a technique based on a change in electrical resistance and is related to movement of the vocal cords. Low-voltage electrical current is applied through surface electrodes that have been placed on the skin over the thyroid alae. The electrodes then measure a change in electrical resistance that is representative of the surface area of contact of the vocal folds. Changes in the electroglottography amplitude and duration of the opening-and-closing phase may characterize abnormal function. The electroglottography results suggest an abnormal condition through variance from normal rather than with a pathognomonic sign.[7,19]

Electromyography

Electromyography (EMG) can be used to assess spontaneous and voluntary activity of laryngeal muscles. Its chief value is in assessing nerve integrity, and it can be used to assess the prognosis of recovery from a nerve injury. It is occasionally useful in the diagnosis of myasthenia, motor neuron disease, and myopathy.

Laryngeal EMG makes use of standard equipment. Topical anesthetic is not used because it has been shown to affect the electrical signal.[20] The thyroarytenoid muscle, supplied by the recurrent laryngeal nerve, is most commonly sampled. The needle is introduced between the thyroid and cricothyroid cartilages and directed superiorly. One approach is to enter the subglottic airspace in the midline and then to divert the needle into the right or left vocal fold. This step frequently stimulates coughing, because sensory receptors in the vocal fold mucosa are activated. An alternative approach is to enter the cricothyroid space off the midline so the muscle may be entered without violating mucosa. To verify needle location, the examiner asks the patient to phonate. The cricothyroid muscle is commonly tested by insertion of the needle in the midline, down to the superior edge of the cricoid cartilage. The tip of the needle is then "walked" over the cartilage superiorly and laterally to avoid the strap muscles. There usually is a palpable pop as the needle enters the cricothyroid muscle. To verify needle placement, the examiner asks the patient to begin phonating at a comfortable pitch and then to glide to a higher, falsetto pitch. The cricothyroid muscle may be active or silent at the comfortable pitch, but it is activated at higher pitches.[21]

One important clinical use of the laryngeal EMG is for needle guidance in injecting botulinum toxin for treatment of spasmodic dysphonia. It is helpful to confirm needle placement into thyroarytenoid muscle for adductor spasmodic dysphonia and into the posterior cricoarytenoid muscle in the less common abductor spasmodic dysphonia.

The most common application of laryngeal EMG is the assessment of laryngeal nerve integrity in vocal fold immobility. If abnormalities are detected on EMG, the diagnosis of a neural lesion is confirmed. A normal EMG supports, but does not confirm, mechanical fixation of the vocal fold. It does not necessarily rule out a nerve lesion, because spontaneous reinnervation is quite common after nerve injury and neuropathic signs can be subtle and difficult to detect. EMG can be used to differentiate between a vagus nerve and recurrent laryngeal nerve (RLN) injury, because cricothyroid function should be intact after RLN injury. EMG is often used to counsel the patient about the prognosis for recovery of function. When a nerve is completely severed, voluntary activation of the muscle is abolished. After 3 weeks, fibrillation potentials may appear and indicate denervation. In such patients, recovery is extremely unlikely, and early surgical intervention is prudent. Most patients with RLN paralysis do not have electrical silence, because either the lesion was not complete or reinnervation has occurred. Polyphasic action potentials, which can also be detected on laryngeal EMG, are discoordinate nerve signals that indicate reinnervation. Although there is a potential for recovery in a patient with polyphasic action potentials, the rate of that potential is unclear. If the nerve regenerates synkinetically so that nerve fibers do not connect with the functionally appropriate muscles, the vocal fold may remain immobile despite recovery of a vigorous interference pattern. EMG is also used to assess severity of vocal fold paresis; however quantification of reinnervation on the basis of EMG is controversial, because the amplitude and activity pattern can vary greatly with many factors, including electrode impedance, position in muscle, and volitional activity.

The clinical utility of laryngeal EMG is currently limited by the lack of standards for electrodes and testing protocols as well as the lack of normative data.

Edrophonium Test

The edrophonium test is important in the diagnosis of myasthenia gravis. When symptoms are confined to the larynx or pharynx, this test may require observation of laryngeal and pharyngeal function before and after edrophonium is administered. To accomplish this, an intravenous line is established, and the nose is topically anesthetized. The patient is asked to perform repetitive tasks to produce fatigue, and a baseline endoscopic video recording is made. A small test dose of edrophonium is administered, and if there is no adverse reaction, the full test dose is given. The patient is instructed to perform the same tasks, and another recording is made.

Cineradiography

Cineradiography uses a modified barium swallow, and it is useful in assessing pharyngeal function and in planning therapy for patients with swallowing problems. The technique is most commonly performed with the collaboration of a radiologist and a speech pathologist. It is important in planning swallowing therapy and diet modification, for

identification of surgically correctable problems, and for detection of aspiration.

Sensory Assessment

Laryngopharyngeal sensory testing is a method of evaluating the causes of aspiration. The sensory apparatus may be tested with a pressure-controlled and duration-controlled puff of air delivered to the anterior wall of the pyriform sinus and arytenoid (the area innervated by the superior laryngeal nerve). The air puff is delivered from the internal port of a flexible fiberoptic laryngoscope made especially for this purpose (Pentax Precision Instrument Corporation, Orangeburg, NY) or a port that is part of a disposable sheath. To determine a patient's sensory pressure threshold, air pressure is varied according to the psychophysical method of limits, whereas the duration of the air puff is held constant at 50 msec. Thus, the severity of sensory loss can be recorded. The right and left sides of the pharynx and supraglottic larynx are studied to reveal any asymmetry that can indicate the side of the lesion.[22]

Summary

During the past decade, a greater understanding of neurologic disorders of the larynx has led to earlier diagnosis and treatment of these disorders. New technology and the collaboration of neurologists and laryngologists have created a better understanding of the neuromuscular physiologic abnormalities found in patients with motion disorders of the larynx. Because new treatment modalities are available, it is imperative to make accurate neurolaryngologic diagnoses.

CHAPTER SIXTY

Neurologic Disorders of the Larynx

Andrew Blitzer

Ronda E. Alexander

Nazaneen N. Grant

Key Points

- Neurologic disorders of the larynx may be focal diseases or local manifestations of systemic disorders. Characteristic deficiencies found on clinical examination may aid in ascertaining the site of a lesion.
- Hyperfunctional disorders include dystonia, myoclonus, essential tremor, stuttering, and muscle tension dysphonia.
- Hypofunctional disorders include focal disorders such as vocal fold paresis, and central causes such as Parkinson's disease, multiple sclerosis, neuromuscular junction disorders, poliomyelitis, myopathies, medullary disorders, and psychogenic disorders.
- Spasmodic dysphonia is an idiopathic focal laryngeal dystonia characterized by either breathy or halting speech breaks.
- Botulinum toxin is an important treatment for spasmodic dysphonia and other dystonias.
- Vocal fold paresis can result from trauma, tumor, neurologic, idiopathic, or other medical diseases. Vocal fold positioning can vary on presentation.

Neurologic conditions that affect the larynx span a wide spectrum. They may be focal diseases or local manifestations of systemic disorders. These lesions can produce stereotyped patterns of abnormal function that the otolaryngologist should strive to recognize. Evaluation should include a complete head and neck examination, neurologic examination, and visual recording of the functional disability for documentation. For systemic disorders, consultation with a neurologist is useful for diagnosis and for optimizing medical management. In general, neurologic dysfunction results from one or more insults within the central or peripheral nervous system.

A few important generalized neurologic disorders are characterized by specific patterns of involvement of the larynx and pharynx. In early stages of involvement, patients with these disorders may consult otolaryngologists because symptoms are located in the head and neck region. At any stage of these disease processes, otolaryngologic consultation may be vital to differentiate manifestations of the disease from problems caused by other concurrent disorders and to ensure appropriate management. The neurologic disorders affecting the larynx are best understood when characterized as hypofunctional disorders. Although this is a general categorization, often both types can exist concurrently, particularly when hyperfunctional activity, such as muscle tension dysphonia, works to overcome a hypofunctional deficit.

Laryngologic Manifestations of Neurologic Diseases

Cortical lesions may result from strokes, tumors, or trauma and may impair memory as well as the planning and execution of actions. Because of the diffuse and bilateral representation of laryngeal structures in the cortex, cortical lesions, such as those caused by tumors or strokes, do not produce classic flaccid or spastic paralysis. Inappropriate vocal fold adduction with inspiration may have the symptom inspiratory stridor.[1,2] Extrapyramidal system defects are characterized by abnormal motor control, which may manifest as inappropriate or excessive muscle tension, tremor, and involuntary spasmodic muscle contractions. Vocally, it translates into strain, arrests, pitch breaks, and pitch instability. The dysfunction may be focal, regional, or generalized. In addition to problems caused by tumors or trauma, the extrapyramidal system is disrupted by conditions of uncertain etiology such as Parkinson's disease, tremor, and dystonia.[3] Cerebellar lesions impair coordination of motor activities. Patients' problems are generalized rather than focal. "Scanning speech" is regarded as characteristic of cerebellar involvement. Diagnosis is based on the presence of attendant physical signs, such as intention tremors, dysdiadochokinesia, dysmetria, ataxia, and nystagmus.[4] Brainstem lesions result in flaccid paralysis. Because the cranial motor nuclei are densely packed within the brainstem, lesions at this level affect multiple outputs. Strokes and tumors of the brainstem produce severe dysfunction related to paralysis of the larynx, pharynx, or tongue and are associated with sensory deficits.[2] The site of lesion is best identified from the type of motor disruption, because observable clinical signs are predominantly disruptions of motor acts (Table 60-1).[5,6] Diffuse central nervous system (CNS) lesions result from specific neurologic disorders, such as multiple sclerosis and amyotrophic lateral sclerosis (ALS), and have a myriad of signs and symptoms. Patients with movement disorders have a paucity of movement (akinesia or bradykinesia), excessive or hyperfunctional movement (hyperkinesia), or a combination of the two. The hyperkinetic motor programming errors can produce spasms, tremors, jerks,

Table 60-1

Signs Indicating Site of Lesion in Neurologic Disorders of the Larynx

Site of Lesion	Signs
Cortex	Aphasia Aphonia Dysarthria Dysphonia Stridor
Extrapyramidal system	Vocal strain and pitch breaks Tremor Spasmodic movements Focal, regional, or generalized dystonia
Cerebellum	Ataxia Dysmetria Tremor Incoordination
Brainstem	Flaccid paralysis Never isolated

or tics as well as symptoms related to the body part involved. For those with laryngeal manifestations, a multidisciplinary approach that includes the involvement of an otolaryngologist, a neurologist, and a speech pathologist is key to successful diagnosis and management of hyperfunctional disorders of the larynx.[7,8]

Hyperfunctional Disorders

Dystonia

Dystonia is a syndrome dominated by sustained muscle contractions of skeletal muscles that frequently causes twisting and repetitive movements or abnormal postures that may be sustained or intermittent. Because the condition is rare and the movements and resulting postures are often unusual, dystonia is among the most commonly misdiagnosed neurologic conditions.[9] The prevalence is unknown, but there are an estimated 50,000 to 100,000 cases of idiopathic dystonia in the United States. Classification is important because it can inform prognosis and the approach to management. The classification scheme is outlined in Box 60-1.

Dystonia can begin at nearly any age. Presenting signs have occurred as early as 9 months and as late as 85 years. In general, onset has a bimodal distribution, with peaks at ages 8 and 42 years. Early-onset dystonia begins to manifest before age 26 years, whereas in the late-onset form, the signs appear at older ages. Patients are also categorized according to symptom distribution. Focal dystonia involves one small group of muscles in one body part, segmental disease involves a contiguous group of muscles, and generalized dystonia is widespread. The more common examples of focal dystonia are listed in Box 60-2.[7]

History, physical examination, and laboratory studies may not identify the cause of a patient's dystonic symptoms (idiopathic dystonia). Therefore, there should be a normal perinatal and early developmental history; no history of neurologic illness or exposure to drugs known to cause acquired dystonia (e.g., phenothiazines); normal intellectual, pyramidal, cerebellar, and sensory examination findings; and normal diagnostic study results. The clinical phenomenology is often a clue to the cause. Primary dystonia is typically action induced and normal at rest, but secondary dystonia frequently results in fixed dystonic postures. The presence of extensive dystonia limited to one side of the body (hemidystonia) also suggests a secondary cause.[7,9]

Box 60-1

Classification of Dystonia

Primary

Without hereditary pattern
With hereditary pattern
Autosomal dominant
Autosomal recessive
X-linked recessive
Undefined

Secondary

Associated with other hereditary neurologic disorders (e.g., Wilson's disease, Huntington's disease, ceroid lipofuscinosis, progressive supranuclear palsy, Hallervorden-Spatz disease, olivopontocerebellar atrophy, acquired hepatocerebral degeneration, Tourette's syndrome)
Environmental
Posttraumatic
Postinfectious
Vascular
Neoplastic
Toxic
After antipsychotic drug therapy (phenothiazines, piperazines, butyrophenones, molindone, thioxanthenes)
Antiemetics (prochlorperazine, promethazine, metoclopramide)
Antiparkinsonian drugs (levodopa, bromocriptine, lisuride, pergolide)
Associated with parkinsonism
Hysterical

Box 60-2

Distribution of Dystonia

Focal:
- Blepharospasm (forced, involuntary eye-closure)
- Oromandibular dystonia (face, jaw, or tongue)
- Torticollis (neck)
- Writer's cramp (action-induced dystonic contraction of hand muscles)
- Spasmodic dysphonia (vocal cords)

Segmental (cranial, axial, or crural)
Multifocal
Generalized (ambulatory, nonambulatory)

Because up to 16% of patients with dystonia and primary laryngeal involvement experience spread of the disease to another body part, patients should be advised of this potential and should be reexamined on a regular basis for signs of other dystonic involvement. Approximately 10% of patients with primary laryngeal dystonias have a family history of dystonia.[10]

In most cases of childhood-onset idiopathic dystonia, family studies show an autosomal dominant inheritance with reduced penetrance. A marker for some cases of childhood-onset dystonia has been found on chromosome 9.[11] There are heterogeneous genetic patterns among patients with idiopathic dystonic symptomatology, including a linkage to the X chromosome and parkinsonism,[12-14] a dopamine-responsive form.[15]

Family and linkage studies have identified several subtypes with different genetic bases, including the autosomal dominant dopamine-responsive dystonia already mentioned,[15] X-linked Filipino torsion dystonia,[12-14] and an autosomal dominant (non–dopamine-responsive)

idiopathic torsion dystonia related to the DTY1 gene mapped to chromosome 9q34. Both dopamine-responsive dystonia and X-linked torsion dystonia are rare forms of idiopathic torsion dystonia associated with parkinsonism.[6,11,16,17]

Clinically, spasmodic dysphonia is an idiopathic focal dystonia of the larynx.[17a] Although the disease was initially described by Traube[18] in 1871, Fraenkel[19] and Gowers[20] later recognized the relationship with other dystonias, such as writer's cramp. The vast majority of cases of laryngeal dystonia cause spasmodic adduction of the vocal folds during speech, which results in a strained and strangled voice. Fewer patients have abductor dysphonia, with intermittent or sustained opening of the larynx during speech[21] that leads to breathy voice breaks or a whispering voice. Some patients display a combination of adductor and abductor signs and have been classified as having "mixed laryngeal dystonia."[7,22] Patients with spasmodic dysphonia have reported that symptoms momentarily improve when he or she pinches the nares, presses the hand against the back of the head, presses the hand into the abdomen, pulls on an ear, or touches the clavicular notch (personal experience). Many patients observe that they speak better after a yawn or sneeze or when they sing or yell; these sensory tricks are also common for patients with other craniocervical dystonias.[9,23] Systemic pharmacotherapy provides little relief of symptoms. Dedo and Izdebski[24] described dramatic relief of symptoms with sectioning of the recurrent laryngeal nerve. The initial favorable reports were temporized by a review of 33 patients by Aronson and De Santo[3,25] that addressed surgical management. Three years later, only 36% of patients had some persistent improvement, and only 3% achieved a persistent normal voice. At present, the symptoms are most effectively managed with use of an individualized regimen of chemodenervation with botulinum toxin.

Another rare form of laryngeal dystonia is adductor breathing dystonia, in which patients adduct their vocal cords while inspiring. The adduction causes stridor and dyspnea, but these patients do not become hypoxic and do not need tracheostomy. Localized injection of botulinum toxin into involved muscles is an effective way to diminish the symptoms of patients with dystonia, particularly those with adductor spasmodic dysphonia.[26-30] Patients with more generalized dystonia that also involves the larynx have vocal dysfunction, which is clinically indistinguishable from idiopathic spasmodic dysphonia. Meige's syndrome, a regional dystonia of the head and neck, may be evident in those with blepharospasm, oromandibular dystonia, torticollis, or spasmodic dysphonia.

Botulinum Toxin Therapy

The bacterium *Clostridium botulinum* produces eight immunologically distinct toxins that are potent neuroparalytic agents: A, B, C_1, C_2, D, E, F, and G.[31,32-36] Botulinum toxin exerts its effect at the neuromuscular junction by inhibiting the release of acetylcholine, causing a flaccid paralysis.[4,37-39] Botulinum toxin type A (Botox; Allergan, Inc., Irvine, CA) is most commonly used, and type B (Myobloc; Elan Pharmaceuticals, Inc, San Francisco) is also available for clinical application.

Although botulinum toxin has been used therapeutically in humans since the mid-1970s without evidence of a direct effect on uninjected muscles, the later consequences of long-term injections are unknown. Weakness and routine electromyography (EMG) changes in muscles distal to the site of injection have not been reported. However, there are detectable abnormalities on single-fiber EMG.[40] It is not known how long these abnormalities persist or whether they have any clinical significance. There is a paucity of data regarding use of botulinum toxin during pregnancy. Currently, injection should be avoided in pregnant or lactating patients. Caution is warranted for the management of patients with conditions such as myasthenia gravis, Eaton-Lambert syndrome, and motor neuron disease, particularly when large doses are required (e.g., in the management of cervical dystonia). However, the amount of toxin entering the circulation after injection is thought to be minute, and this theoretic concern should be balanced against the severity of the hyperkinetic symptoms.[40]

In patients with adductor spasmodic dysphonia, botulinum toxin injection has been demonstrated to improve speaking to 60% to 100% of normal function,[41] with a mean of 90%; the duration of effect was between 3 and 4 months. Adverse effects include a mild breathy dysphonia for less than 2 weeks (45%), mild choking on fluids for the first several days (22%), hyperventilation and dizziness when trying to speak while hypophonic, a sore throat or coughing up blood-tinged sputum, and itching (without rash).[42-45,81] In patients with abductor laryngeal dystonia, injection of botulinum toxin into the posterior cricoarytenoid muscle produces marked improvement, with a return to mean maximal functional performance of 70% of normal. Adverse effects include mild dysphagia without aspiration and mild stridor on exertion.

The effective treatment dose is variable for each patient and for each muscle injected; therefore, injections are individualized.[46] The dose range for adductor spasmodic dysphonia is 0.05 to 20 units of Botox, with an average dose of less than 1 unit per vocal fold.[24,29,30,47,48] In general, a starting dose of 1.0 units in 0.1 mL of saline is used for bilateral thyroarytenoid injections. Subsequent doses are varied according to clinical response and adverse effects. A trend toward lower doses has been observed and may be useful in reducing adverse effects.[49] Injections are given by means of a tuberculin syringe with a 27-gauge monopolar polytef-coated hollow EMG recording needle. Adductor laryngeal injections are performed percutaneously through the cricothyroid membrane and into the thyroarytenoid-vocalis muscle complex, with use of EMG guidance for optimum placement (Fig. 60-1). Injections for abductor spasmodic dysphonia are administered to the posterior cricoarytenoid muscle. The physician reaches muscle by manually rotating the larynx, placing the EMG needle behind the posterior edge of the thyroid lamina, and advancing the needle to the cricoid cartilage to arrive at the posterior cricoarytenoid muscle. Alternatively, a transcricoid injection can be made. When the patient is instructed to sniff, which maximally uses the posterior cricoarytenoid muscle, there is a burst of activity on the EMG, and the toxin is administered.[42,43,47,50]

After an injection, the patient typically reports improvement in voice within 24 hours followed by a breathy, hypophonic period lasting 1 to 2 weeks (45%), occasionally causing hyperventilation and dizziness when trying to speak. Mild choking on fluids for the first several days (22%) is also common; in addition, sore throat or coughing up blood-tinged sputum may occur in the first 1 to 2 days after injection.[42-44]

Patients with abductor spasmodic dystonia are also managed with an EMG-guided percutaneous injection. The larynx is manually rotated away from the side of intended injection, and the hollow EMG needle with syringe is placed posterior to the posterior edge of the thyroid lamina (Fig. 60-2).

For treatment of adductor spasmodic dysphonia, Ford and colleagues[51] reported an indirect laryngoscopic approach for injecting the toxin into the vocal fold. They reported that the technique has the advantage of being "familiar to the otolaryngologist and requires no special EMG equipment or training." The onset of response to toxin appears delayed (mean, 9.1 days), but the level of benefit and duration of efficacy appear comparable with those of EMG techniques. Nevertheless, at initial management, the muscle appears to be electrically active at multiple sites throughout the course of the muscle. On follow-up, the electrical recruitment pattern, an index of muscle contraction, may be patchy. EMG guidance has the advantage of controlled administration into the more actively contracting regions of the muscle.[7,44]

Regardless of technique, botulinum toxin injections have several advantages over surgical therapy in the management of intractable disease. The patient is awake for the procedure, and there is no risk of the complications that would be involved with anesthesia. Graded degrees of weakening can be achieved by varying of the dose. Most adverse effects are transient and are caused by an extension of the pharmacology of the toxin. If the patient has a strong response to therapy and too much weakness occurs, strength gradually returns. Follow-up therapy is carefully individualized. The response to therapy should be meticulously documented.[40]

Pseudobulbar Palsy

Pseudobulbar palsy (PBP) results from bilateral lesions of the corticobulbar tracts. Patients have muscle spasticity and hyperreflexia of the pharynx, palate, lips, tongue, and larynx. The voice in the patient with PBP is harsh, strained, and strangled, and it sounds somewhat like that of a patient with spasmodic dysphonia. Patients with PBP are easily distinguishable clinically, because they have associated signs of

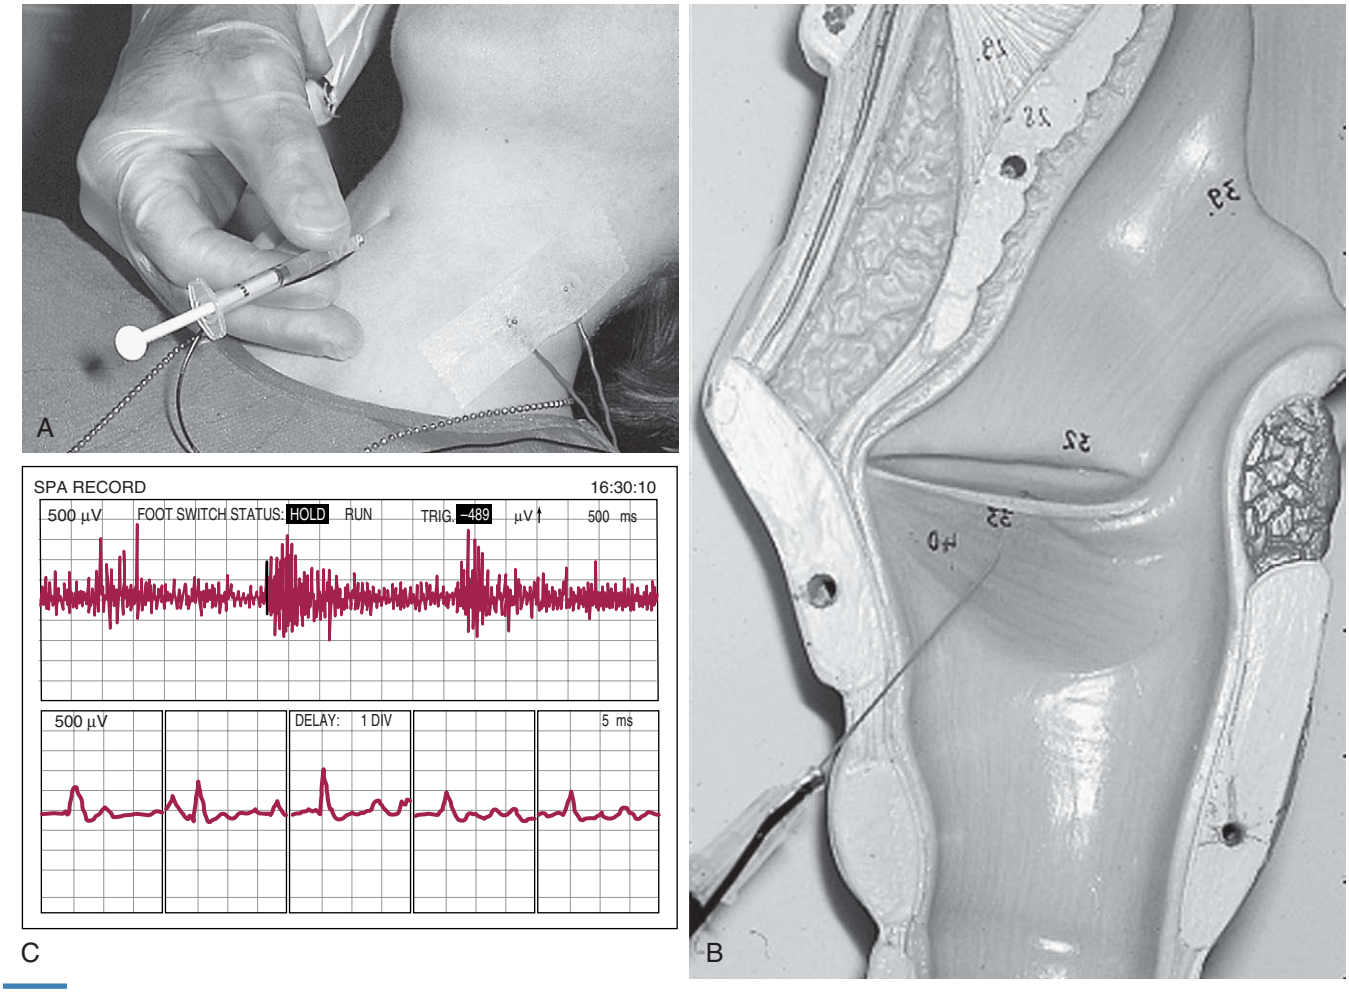

Figure 60-1. **A,** Anterior approach to the thyroarytenoid muscle through the cricothyroid membrane. The injection needle is passed into the airway and directed laterally and superiorly into the thyroarytenoid muscle. **B,** Model depicting placement of 27-gauge injection needle into the thyroarytenoid-vocalis muscle. An acute angle places the injection into the anterior belly of the thyroarytenoid muscle. **C,** Electromyogram obtained during injection of the thyroarytenoid muscle. The patient is asked to say "ee," resulting in recruitment and increased motor unit activation and confirming accurate placement of the electrode before injection.

hypernasality as well as slow, labored articulation, emotional lability, and subcortical cognitive impairments.[2]

Myoclonus

Oculopalatolaryngopharyngeal myoclonus is an uncommon disorder consisting of rhythmic contractions of the soft palate, pharynx, and larynx at a rate of one or two contractions per second. This condition may affect only the palate, all of the laryngopharynx, and even the eyes, and is caused by a lesion in the central tegmental tract. It may result in a speech that sounds like a choppy voice with intermittent hypernasality. The palate and vocal folds may be treated with injections of botulinum toxin to decrease the severity of the contractions and thereby reduce the symptom. A patient complaint of clicking in the ears, thought to be caused by involvement of the eustachian tube and tensor veli palatini muscles, was first noted in the 19th century by Muller and then Politzer.[52] The clicking can often be heard by family and examiners. Laryngeal involvement may produce a broken speech pattern, simulating that heard in laryngeal dystonia or tremor (personal observation). Examination of the vocal cords often shows slow rhythmic adduction and abduction of the vocal cords at the same timing and frequency as the palatal, pharyngeal, and occasional diaphragmatic contractions. This causes the broken speech pattern and a respiratory dysrhythmia. Although oculopalatolaryngopharyngeal myoclonus is usually unresponsive to pharmacotherapy, isolated cases have reportedly responded to serotonin,[27,53] carbamazepine,[54] clonazepam,[55,56] tetrabenazine,[56] and trihexyphenidyl.[57,58] Several patients whose symptoms were unresponsive to drug therapy have been managed with local injection of botulinum toxin into the thyroarytenoid muscles.

Essential Tremor

Tremor is an involuntary, purposeless rhythmic movement of a part of the body. It causes a 6- to 8-Hz shaking of the hands, head titubation, and a tremulous voice. The proposed underlying neural bases for tremor include a central mechanism[59-61] and a peripheral mechanism.[62] Tremors have been classified according to cause or clinical appearance and are characterized by their frequency, amplitude, distribution over the body, and exacerbating and relieving factors.[63] Of patients with essential tremor, 60% have a family history of tremor, and 30% of these had voice involvement.[64]

The involuntary, rhythmic, oscillatory movements that affect the distal musculature in patients with tremulous diseases can also affect the muscles of speech production and generate rhythmic alterations in pitch and loudness, termed *vocal tremor*. Vocal tremor can result in either rapid decreases and increases in loudness and pitch or complete phonation stoppages. Intelligibility and rate of speech may be decreased. Vocal tremor has been described perceptually as "tremulous voice,"[30,65] "wavy voice,"[66] or "tremulous, quavering speech"[66] and has been associated with neurologic disorders such as essential tremor, Parkinson's disease, cerebellar ataxia, and flaccid dysarthria.[21,67]

Essential tremor is typically absent at rest, maximal during maintenance of a posture, attenuated during movement, and often accentuated at the termination of movement.[7,68,69] Vocal tremor occurs in

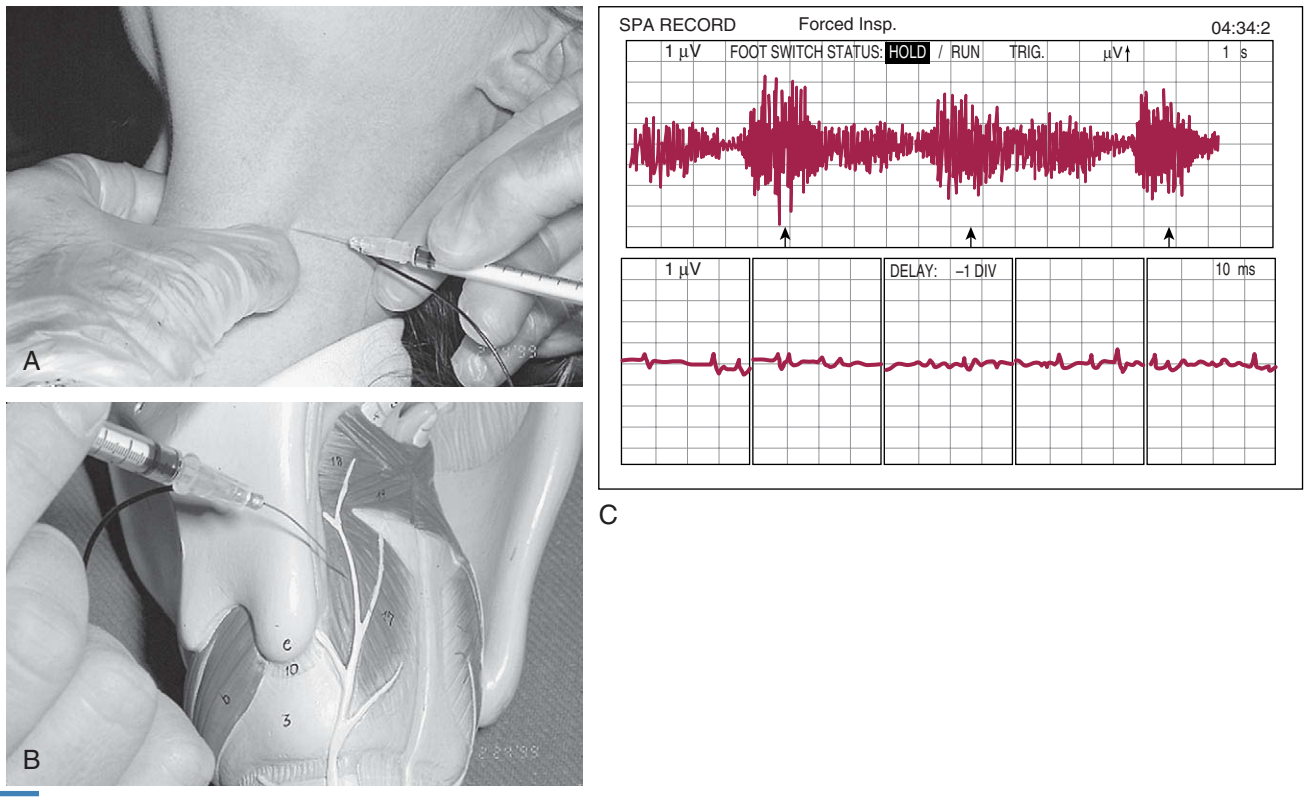

Figure 60-2. **A,** Lateral approach to the posterior cricoarytenoid (PCA) muscle. The thyroid cartilage is rotated laterally with simultaneous anterior displacement, exposing the posterior lateral border of the thyroid cartilage. The 27-gauge injection needle is inserted into the posterior lateral aspect of the cricoid cartilage. **B,** Model depicting placement of the injection needle into the PCA muscle using a posterior lateral approach. **C,** Electromyogram obtained during injection of the PCA muscle. *Vertical arrows* indicate volitional "sniff" maneuvers with recruitment of PCA motor units.

approximately 10% to 20% of patients with essential tremor.[70] It may be the first[65] or only sign of the disease,[38] or it may accompany tremors in other body parts.[71] Vocal tremor may parallel the onset of other symptoms or may have a sudden onset and cause rapid deterioration in speech intelligibility.[65,71] Vocal tremor has been reported to be greater with emotional stress or fatigue.[27] Pitch breaks (octave breaks to a lower frequency) and phonation arrests have been reported in some cases of essential tremor[70,72] and have been associated with visible vertical oscillations of the larynx.[73]

The effect of medication on reducing vocal tremor is equivocal. Certain researchers have reported reductions in vocal tremor with administration of propranolol,[70,72] primidone,[27,74] and a combination of clonazepam, propranolol, and diazepam.[54] Limited, clinically significant changes in vocal tremor have been found with administration of propranolol[66,75] and primidone.[55] One report describes a better than 70% improvement of vocal tremor with thalamotomies.[76] Preliminary studies have also shown reduction of tremor with long-term electric stimulation of the thalamic nucleus through surgically implanted neuropacers.[77] Local injection of botulinum toxin in the management of essential vocal tremor has shown a dramatic benefit in preliminary studies. The injections are given into the muscles that seem to be most tremulous. In many cases, the most active muscles are the sternohyoid and sternothyroid muscles, which rhythmically elevate and lower the larynx in the airway (resonator), causing oscillations and producing a tremulous voice quality. In these cases, injecting botulinum toxin into the strap muscles diminishes the up-and-down motion of the larynx, thereby diminishing the amplitude of the tremor and making speech more fluent. Generally, 5 units in 2.5-unit aliquots are injected on each side. If the vocal folds are tremulous, they are injected at a second session. Although the toxin does not eliminate the tremor, it decreases the amplitude, thereby reducing the severity of the symptom. Tremor commonly accompanies spasmodic dysphonia and other focal dystonias.[3]

Stuttering

Stuttering might best be considered a movement disorder because it characteristically includes abnormal, involuntary, and inappropriate use of the muscles of speech production resulting in dysfluency. The abnormal movements are task specific and may be repetitive and stereotyped. Stuttering occurs in three subsystems of speech: respiratory, phonatory, and articulatory. Stuttering is a result of increased muscle tension in these three subsystems, which causes the muscles to move too quickly and too far.[78] This increased muscle tension results in postures that are sustained for longer than expected or in quick repetitive movements of the same posture. In addition, other cranial musculature may inappropriately contract, including the eyelids and other muscles of facial expression.[79-81] One report describes stuttering followed by the development of jaw-opening dystonia.[82]

As in other movement disorders, competing stimuli, such as emotional arousal, sensory stimuli, motor actions (e.g., walking), and the use of rhythmic patterns (e.g., a metronome), increase fluency. Communicative pressures such as audience size, listener reactions, concern about social approval, time pressure, and the extent to which the stutterer is responsible for conveying a meaningful message to a listener are found to increase stuttering.[83]

The use of antidepressants does not improve fluency.[84] Most persons with a stuttering disorder respond to traditional speech therapy and training. For cases resistant to traditional therapy, chemodenervation of the thyroarytenoid muscles may be considered; in a group of patients with stuttering and glottal block, this maneuver initially achieved promising results.[82] Small doses of botulinum toxin (1 unit or less, given bilaterally) has produced improvement in 50% of patients. The number of glottal blocks and the duration of the glottal blocks significantly diminish with management. The most significant advances in treatment of stuttering have been achieved with altered auditory feedback in-the-ear devices.[74,85,86] With the use of both delayed and frequency-altered auditory feedback, significant improvement in

fluency and normalcy of speech has been demonstrated. Improvement was demonstrated for both young and adult subjects, and these devices are currently marketed under the trademark SpeechEasy (Janus Development Group, Inc, Greenville, NC).

Muscle Tension Dysphonia

In muscle tension dysphonia, which is functional, a patient postures the vocal folds. This hyperfunction causes tightness and dysphonia, with harshness, breathiness, choppy vocal production, or tremor. Patients are best treated with speech therapy to learn to use their voices in a less strained manner.

Hypofunctional Disorders

Central Causes of Vocal Fold Paresis

Central nervous system disorders that may produce vocal fold paralysis/paresis are syringobulbia, Arnold-Chiari malformations, stroke (including Wallenberg's lateral postmedullary syndrome, posterior, inferior cerebellar artery occlusion) and other lower motor neuron disorders. Vocal fold paresis as a result of peripheral nerve injury or compression is discussed separately later in the chapter.

Neuromuscular Junction Disorders

Neuromuscular junction disorders include myasthenia gravis and the less common Eaton-Lambert disease. In such disorders, muscles fatigue quickly with use.

The incidence of myasthenia gravis is less than 10 per 100,000 people. Specific patient complaints may vary, depending on the distribution of muscles involved. Many patients have ptosis or double vision, because ocular muscles are most commonly affected. General fatigue is also a common complaint. Sometimes the disease is localized to the throat, and patients have difficulty speaking, breathing, or swallowing. Careful examination of the larynx and palate in such patients may reveal fatigue as a result of repetitive movements. For example, asking the patient to repeat "ee-ee-ee" can elicit laryngeal fatigue. Electromyography and an edrophonium test are used for rapid diagnosis and treatment of myasthenia gravis. Blood testing is used to detect antibodies against acetylcholine. Early detection of this disorder is invaluable, because medical treatment is effective and may be lifesaving.[16,87]

Poliomyelitis

Poliomyelitis (polio) is essentially nonexistent today, thanks to vaccination programs. However, there are survivors of polio who experienced postpolio syndrome with a recurrence of motor weakness. The exact cause of postpolio syndrome is unknown, but it is thought that the syndrome is derived from the natural loss of motor neurons during the aging process. Patients who have recovered from polio function by virtue of a small pool of surviving neurons that sprout to supply expanded numbers of muscle fibers. Thus, these patients are particularly susceptible to the loss of even a small number of neurons. Acute bulbar polio causes pharyngeal and laryngeal paresis but spares the cricopharyngeus muscle. The resulting symptoms are hoarseness, dysphagia, and aspiration. Because the cricopharyngeus muscle retains tone, cricopharyngeal myotomy often is helpful in the patient with recent onset of polio; however, in those with postpolio syndrome, the effectiveness of myotomy has not been established.[87]

Myopathies

Examples of myopathies are dermatomyositis, muscular dystrophy, and metabolic myopathies. Dermatomyositis manifests as dermatitis in conjunction with muscle weakness. This disorder may be associated with lung cancer, systemic lupus erythematosus, or poliomyelitis. The muscular dystrophies vary in age at onset and anatomic distribution of involvement. The infantile variety often presents with oculopharyngeal weakness. Metabolic myopathies may result from abnormalities in acid maltase, glycogen brancher enzyme, and cytochrome c-oxidase. Also, some episodic myopathies with periodic paralysis are drug induced.

Medullary Disorders

Medullary disorders that affect motor neurons include ALS, primary lateral sclerosis, postpolio syndrome, Arnold-Chiari malformations, and medullary strokes. ALS (also known as Lou Gehrig's disease) is an idiopathic and progressive degeneration of upper and lower motor neurons that results in muscle wasting, fasciculations, and weakness. Incidence in the United States has been estimated at 1 to 2 per 100,000 people. As many as 25% of patients with ALS initially have complaints related to speech and swallowing. In many patients, limb symptoms predominate. The clinical course varies in its rate of progression and is inevitably "downhill." Approximately 25% of patients survive from 5 to 10 years after the onset of the disease. Death is most often related to respiratory insufficiency due to weak breathing muscles and aspiration pneumonia. Therefore, prognosis for a more rapid demise is higher in patients with throat involvement.[25]

When ALS involves the upper airway, the voice is monotonous and raspy with abnormal hypernasal resonance. Speech is commonly dysarthric and labored and has velopharyngeal incompetence. The dysarthria is related to tongue involvement. Patients have slurred speech as a result of weakness and slowed activity of the tongue. The tongue often has visible fasciculations. There also is weakness in the palate, pharynx, and larynx, along with an inability to make rapid muscle adjustments or repetitive motions. Secretions pool in the hypopharynx, and aspiration often occurs during swallowing. Certain characteristics distinguish ALS from myasthenia gravis. Symmetric facial weakness is common in patients with ALS, although extraocular motion is preserved; this characteristic contrasts with the proclivity of myasthenia to involve the eyelids and extraocular muscles. ALS results in muscle wasting and fasciculations that are most easily observed in the tongue and the intrinsic muscles of the hand. Tongue fasciculations have a classic "bag of worms" appearance.[25,30]

Therapeutic options for patients with ALS are essentially limited to supportive care. In some patients, a palatal lift prosthesis may improve speech intelligibility and reduce nasal regurgitation during speech. In most patients, nothing can be done to improve speech. Eventually, the only options for avoiding aspiration are nasogastric feeding and gastrostomy. Tracheostomy often is necessary for airway protection and assisted ventilation.[25,49]

The lower motor neuron disorders that affect the laryngopharynx include progressive spinal muscular atrophy (PSMA) and progressive or pseudobulbar palsy (PBP). PBP results from bilateral lesions of the corticobulbar tracts. Patients have muscle spasticity and hyperreflexia of the pharynx, palate, lips, tongue, and larynx. The voices of these patients are harsh, strained, and strangled, like those of patients with spasmodic dysphonia. Patients with PBP are easily distinguished clinically, however, because they have associated signs of hypernasality, slow labored articulation, emotional lability, and subcortical cognitive impairments.

Parkinson's Disease

The criteria for diagnosis of Parkinson's disease require at least two of the following findings: a resting tremor, rigidity, bradykinesis, and a loss of postural reflexes. Parkinson's disease is an extrapyramidal syndrome caused by cell death in the substantia nigra. It may be idiopathic or secondary and may be caused by drugs, encephalitis, stroke, toxins, tumors, or head trauma. Affected patients typically have a flat facial expression and abnormal posture. Tremor is often present in the distal parts of the extremities and the lips when patients are at rest. "Pill-rolling" tremor of the hands is typical. Speech abnormalities in Parkinson's disease are nearly universal, manifesting as defects in articulation and voicing. The patients have a hypokinetic dysarthria (45% of patients) with a reduced range of articulation for linguals and labials. They also have decreased loudness, monopitch, and prosodic insufficiency because of poor air presentation to the vocal apparatus (sound generator), which is due to decreased airflow from a bradykinetic bellows mechanism. The vocal folds may be adynamic and/or bowed. On testing, patients with Parkinson's disease show an increased shimmer and jitter, a decreased harmonic/noise ratio, and a tremor. Less commonly, these patients experience a predominant effect of rigidity of the larynx and produce a strained voice with frequent breaks that

are similar to the voice of a patient with spasmodic dysphonia. Swallowing usually is not noticeably impaired in patients with this syndrome, but patients may drool because of the inability to voluntarily swallow.[3,37,40,47]

Parkinson's disease may also be accompanied by autonomic nervous system dysfunction or failure of supranuclear functions. The Parkinson's-plus syndromes include progressive supranuclear palsy (PSP) and multiple system atrophy. In the latter, there is an autonomic nervous system failure with orthostatic hypotension, impotence, sphincter dysfunction, and anhidrosis. One form of multiple system atrophy is known as Shy-Drager syndrome. Patients with this disorder have failure of vocal fold abduction with inspiration that is worse during sleep. Many require tracheotomy for maintenance of the airway. The progression of multiple system atrophy may be rapid and may lead to death.[3]

Multiple Sclerosis

Multiple sclerosis is a diffuse demyelination process with an incidence of approximately 3 per 100,000 people in the United States. The signs and symptoms are protean but basically consist of relapsing and remitting sensory and motor deficits. Visual problems, numbness, and limb weakness are common. As many as 50% of patients with multiple sclerosis have problems that lie within the domain of the otolaryngologist. These problems include vertigo, tremor, scanning speech, and dysphagia. The clinical course in some patients is intermittent and slowly progressive, whereas others experience a rapid and inexorable decline. There have been some promising developments in experimental drug therapy for this disorder.[87]

Psychogenic, Malingering, and Mixed Causes

Psychiatric voice disorders can mimic all of the preceding disorders and hence are very difficult to distinguish from neurogenic voice disorders. Complete aphonia is most often due to a conversion disorder.

Vocal Fold Paresis

Vocal fold paresis is most commonly due to injury of the recurrent laryngeal nerve resulting in vocal fold immobility. It may or may not involve the superior laryngeal nerve, and thus, sensation of the larynx is variably affected. The term *paralysis* implies a complete denervation of the vocal fold with no motor activity, as proven by EMG. *Paresis* implies that there is some residual nerve function, as is most often the case. *Vocal fold immobility* as a broad term encompasses impaired motion from either a neurogenic or a rare mechanical cause, such as arytenoid dislocation, joint fixation, or web formation.

The causes of vocal fold paresis can be divided into the broad categories of trauma, idiopathic, tumor, and neurologic or other medical diseases. Trauma can be surgical, such as from thyroidectomy, anterior cervical spine surgery, or thoracic procedures, or from endotracheal intubation. Skull base tumors, mediastinal lymphadenopathy, and esophageal cancers are examples of tumors that can impinge at various points on the vagal nerve or its recurrent branch; for this reason, neck and chest imaging is obtained in the evaluation of vocal fold paresis. Systemic neurologic diseases that can cause vocal fold paresis are discussed earlier in the chapter; it can also manifest as a peripheral neuropathy in disorders like Charcot-Marie-Tooth disease, sarcoidosis, and Lyme disease. Up to a third of cases of vocal fold paresis are diagnosed by exclusion as idiopathic.

Clinically, the patient with vocal fold paresis presents with an effortful, weak, breathy, and hoarse voice. Vocal fatigue is common, because lack of proper vocal fold closure (glottic insufficiency) due to paresis requires greater effort to create subglottic pressure against a leaking laryngeal valve. This is especially apparent when a patient makes unfruitful attempts to yell. Increased subglottic pressure pushes the flaccid and paretic vocal cord even further away. Dysphagia can also be present from glottic insufficiency and sensory deficits. Maximum phonation time, measured as the length of time that the patient can phonate a sustained vowel, is often decreased.

Vocal fold positioning can vary on examination. Despite prior characterizations, it is now clear that the traditional terms for vocal fold position (e.g., intermediate, paramedian, and cadaveric) do not adequately characterize glottic configuration and that the distance of the vocal fold from the midline is not a reliable indicator of lesion site.[23] The effect of an isolated superior laryngeal nerve lesion on the level of the vocal fold and rotation of the glottis also is controversial. Some writers report rotation of the glottis to the side of the lesion in patients with unilateral cricothyroid muscle paralysis, although the preponderance of the evidence indicates that the cricothyroid muscle does not appreciably influence the spatial orientation of either the vocal fold or the glottis as a whole. Clinically observed variations in glottal configuration are chiefly determined by the extent of the nerve lesion (complete or incomplete) and the extent and accuracy of nerve regeneration. Information on the cricothyroid joint structure now indicates that the two cartilages interact in a visor fashion, similar to a bucket handle, with little translational movement. Thus, a unilateral cricothyroid muscle paralysis may decrease the strength of motion along the arc of rotation but has no differential effect on one vocal fold.[25]

When the cause of vocal fold paresis is not obvious from history, such as recent surgery, further workup, including a detailed medical history and imaging, is needed to rule out other causes. Computed tomography of the neck and chest to examine the full course of the recurrent laryngeal nerve is usually indicated. Magnetic resonance imaging can be considered when skull base lesions are suspected. Blood tests, such as rheumatoid factor and antinuclear antibody tests, Lyme titer, and measurement of erythrocyte sedimentation rate, are not typically performed unless prompted by clinical history.[88] Electromyography can assist in estimating potential for recovery, particularly if the paresis is less than a year old, and is discussed in another chapter. Surgical management of vocal fold paresis is also discussed in other chapters.

CHAPTER SIXTY-ONE

The Professional Voice

Mark S. Courey

Gregory N. Postma

Robert H. Ossoff

Key Points

- Management of patients with voice disorders is most effectively performed by a multidisciplinary team that includes a laryngologist, a speech language pathologist, and a vocal pedagogue; and current standard of care mandates that all patients with voice disorders receive the same level of care regardless of their level of voice use.
- Voice and speech are produced according to the source-filter theory of voice production. In this theory, the vocal folds provide a harmonic sound source that is filtered by the vocal tract. During filtering of the sound source, the vocal tract attenuates and amplifies certain frequencies of the harmonic sound source to create sounds characteristic of speech.
- Regardless of vocal style, patients all use the same basic mechanism to produce voice. The intrinsic laryngeal musculature contracts to bring the vocal folds into a nearly closed position appropriate to allowing vocal fold vibration to occur, while the abdominal, thoracic, and/or pelvic musculature is used to control the rate and volume of air intake and egress to drive the vocal folds into vibration. The patient uses the extrinsic laryngeal muscles to position the larynx within the neck. This positioning controls the length of the vocal tract. The patient uses the tongue, lips, and teeth to control the shape of the vocal tract. The length and shape of the vocal tract determine which frequencies of the harmonic sound source are attenuated and which resonated.
- Vocal efficiency is achieved when the patients are able to produce their desired vocal output with minimal input.
- Laryngeal stroboscopy is currently the best method for evaluating patterns of vocal fold vibration. To be used most effectively, laryngeal stroboscopy should be performed at multiple vocal pitches and intensities to enable study of the vocal fold vibratory patterns under different requirements.
- Voice analysis with acoustic and aerodynamic measures may be helpful to quantify or measure voice disorders; however, perceptual analysis of the voice by a trained observer remains the most sensitive test to semi-objectify vocal changes.
- Often, vocal professionals complain of a change in vocal effort or slight change in voice quality before other people and trained clinicians can identify a change. “Hoarseness,” a term often used to describe voice changes, is therefore inadequate. Clinicians must strive to describe the voice changes in terms of the specific alterations in effort of production and in vocal quality (roughness, breathiness, weakness, and strain) as well as which portion of the vocal range is most disturbed.
- Physical examination of patients with voice disorders should include palpation of the anterior cervical structures in the region of the larynx and tongue base for tension and tenderness at rest and during phonation. Excess tension or tenderness indicates excessive extralaryngeal muscular effort for voice production. Findings of tension or tenderness may be secondary to habitual inefficient vocal mechanisms or to compensation for suboptimal laryngeal vibration from loss of mucosal pliability or loss of laryngeal closure.
- Benign, nonneoplastic vocal fold lesions are most commonly a response to injury. The most common source of injury is the use of excessive, loud, and abusive voice production methods.
- Even if distinct anatomic abnormalities are identified within the larynx, the patient with a voice complaint should be evaluated by a speech language pathologist and/or a vocal pedagogue, to assess the efficiency of voice production and ability to improve the voice through behavioral changes.
- *Voice rest* means complete vocal silence. It is useful primarily as a diagnostic tool. By eliminating vocal behaviors, it allows the clinician to assess what portion of the acute vocal changes are due to the patient’s abusive vocalization patterns. The period of voice rest rarely needs to exceed 1 week. Voice rest may also be useful in patients with acute injuries or illness, to allow quicker recovery.
- Speech-language pathologists and vocal pedagogues help patients modify their voice use techniques through vocal hygiene techniques and techniques of direct voice therapy.
- Surgical intervention is appropriate if malignancy is suspected or if the patient has been compliant with speech therapy recommendations but the voice has not improved.

Care of patients who use their voices professionally requires knowledge and skills not easily mastered within the field of otolaryngology alone. It is part of the discipline of performing arts medicine. The laryngologist enlists the expertise of speech language pathologists and vocal pedagogue retrain and rehabilitate the professional voice patient. A team approach is mandatory and has been strengthened over the past decade by the establishment of several multidisciplinary voice centers.

Professional voice patients are a diverse group. Limiting the definition to singers and actors is too narrow. All people who depend on speaking or singing skills for employment (e.g., salesmen, receptionists, telephone operators, lawyers, clergy, teachers, politicians, public speakers, and most physicians) should be considered professional voice users, because all of them place diverse yet significant demands on their voices.

Singers and actors (*performing* vocal professionals) put the greatest demand on the vocal apparatus. The extraordinary amount of practice and performance stress they are under exceeds that of any other type of vocal professional. They are often highly trained and push their voices to their physical limits. No other patients are as sensitive to subtle changes in their vocal abilities. Singers and actors with voice disorders often challenge the most experienced laryngologist. The knowledge and expertise gained from managing such patients can and should be generalized to care for other professional and nonprofessional voice users with voice disorders. It is no longer appropriate to treat voice problems in nonprofessional voice users differently from those in professional voice users.

Anatomic Considerations

Voice and voice use patterns can be affected by emotional status and general health. Therefore, in the evaluation of the patient with a voice disorder, the entire body and psyche should be considered. The body itself is the vocal instrument, and the larynx is its most sensitive part. Altered function in nearly any area of the vocal professional's body can result in vocal changes. The larynx, therefore, should not be evaluated as an isolated entity.

Sound generation of any type requires a power source, a vibrator, and a resonator. The lungs are the power supply, the larynx is the vibratory source, and the supraglottal vocal tract (supraglottic larynx, pharynx, oral cavity, and, potentially, the nasal cavity) is the resonator, which shapes the sound into words and song. The sound of the voice is affected by changes in any of these three systems, which should be regarded as a unit during evaluation of the professional voice patient.

Laryngeal function depends on extrinsic and intrinsic laryngeal musculature. The extrinsic laryngeal muscles alter the position of the larynx, which in turn can affect the length of the vocal tract resonator. Classically trained singers use the extrinsic musculature to stabilize the larynx within the neck when singing.[1] The intrinsic laryngeal muscles allow delicate control of adduction, abduction, and tension of the vocal folds.

Within the larynx, the human vocal folds are unique structures with no correlates in another animal species. Hirano,[2,3] who contributed greatly to the understanding of the laminar structure of the human vocal fold, described the *cover-body theory* of vocal fold vibration. The vocal fold is covered by a layer of stratified squamous epithelium. The subepithelial tissue, the lamina propria, is divided into superficial, intermediate, and deep layers. The superficial layer, often called Reinke's space, is composed of fibroblasts, which produce proteins and glycoproteins to form an extracellular matrix of loose connective tissue. The intermediate layer is composed chiefly of elastin fibers, and the deep layer is composed primarily of collagen fibers. Collagen fibers from the deep layer blend into the underlying thyroarytenoid muscle, which forms the main bulk of the vocal fold (Figs. 61-1 and 61-2).

According to the cover-body theory of vocal fold vibration, the cover is composed of the overlying epithelium combined with the superficial layer of the lamina propria. The intermediate and deep layers of the lamina propria, known as the vocal ligament, form a transition zone, and the body is composed primarily of the thyroarytenoid muscle. The contrasting masses and physical properties of the vocal fold cover and the body causes them to move at different rates as air passes between the vocal folds. This movement, or vibration, creates sound at the level of the vocal folds by disturbing the local pressure equilibrium within the area of the glottis. The sound, a buzzing-like tone, is modulated and radiated by the supraglottal vocal tract into audible speech or song.

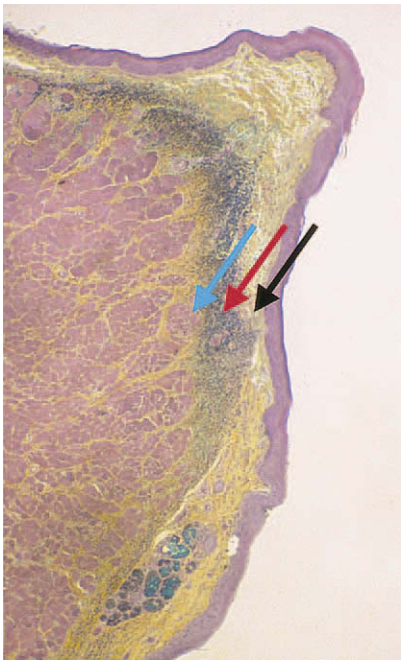

Figure 61-1. Cross section of a true vocal fold stained for elastin (*black*) and collagen (*yellow*). The trilaminar arrangement to the lamina propria is shown. Nonkeratinized squamous epithelium forms the mucosal layer over the superficial portion of the lamina propria. The *black arrow* indicates the superficial portion, the *red arrow* indicates the intermediate layer, which is rich in elastin, and the *blue arrow* is pointing to the deep layer, which is rich in collagen (Movat stain, ×40).

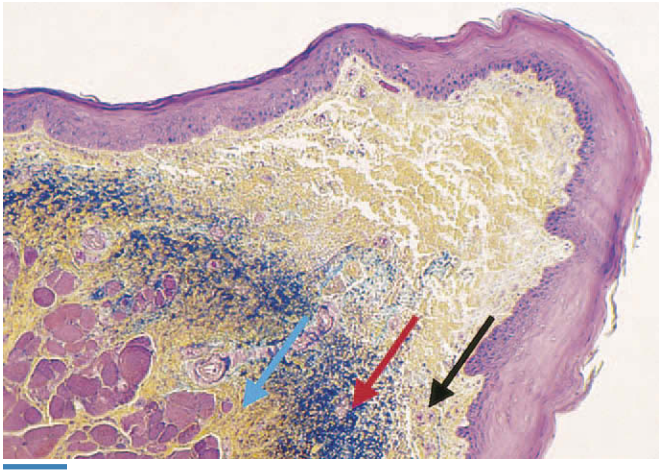

Figure 61-2. Cross section of a true vocal fold under higher magnification. Collagen with increased cross-linking appears deeper yellow (*blue arrow*) compared with less cross-linked collagen in the superficial portion of the lamina propria (*black arrow*) (Movat stain, ×100). The *red arrow* indicates the intermediate layer, which has a high concentration of elastin. In this Movat stain elastin fibers are black.

Blood vessels enter the vocal fold anteriorly and posteriorly. Vessels run parallel to the longitudinal axis of the fold. This arrangement allows the cover to vibrate over the body without placing excessive stretch or shearing forces on the vessels. Electron microscopy has shown that several arteriovenous shunts are present in the vocal fold microcir-

culation. These shunts may allow autoregulation of blood flow to this area.[4]

Gray and colleagues[5] began to identify the contents of the basement membrane zone and the lamina propria. The basement membrane zone is a complex area anchoring the epidermis to the superficial layer of the lamina propria (Fig. 61-3). It is the site of tremendous shearing forces in the human vocal fold that occur during vocal fold vibration. Excessive shear forces can lead to disruption of the basement membrane zone and the development of infiltrates in this area.[6] This process is important in the formation of vocal fold lesions. In the superficial layer of the lamina propria, collagen type III and VII fibers intertwine. This arrangement fixates the basement membrane zone to the superficial layer of the lamina propria yet allows passive stretch during vibration (Fig. 61-4).[5,7-9]

Immunohistochemical analysis has also been used to study the basement membrane zone and extracellular matrix of the lamina propria. In diseased states, which correlate clinically with vocal fold nodules, the basement membrane zone is widened significantly. In lesions that are clinically labeled polyps, collagen type IV within the basement membrane zone appears less pronounced than in the healthy state. Perhaps this relative weakness predisposes patients to polyp formation under phonotraumatic stress.[10,11]

Morphologic ultrastructure of anchoring fibers in normal vocal fold basement membrane zone.* J Voice. *1994;8:48.)*

Voice Production

Vocalization begins with the air or power supply. The lungs supply the essential energy for sound production by presenting the larynx (oscillator) with a stream of air. The diaphragm, the intercostal, back, and abdominal musculature, and the elastic recoil of the chest wall work in concert during inspiration and expiration to control the release of air.[12,13] Classically trained singers use the abdominal and thoracic musculature to regulate exhalation; they tend to use a greater percentage of total lung capacity than non–classically trained singers to produce sound in a more efficient manner.[14,15] This enhanced efficiency of air propulsion to the larynx is a key difference between trained and untrained voice users.

As the diaphragm relaxes and the chest wall recoils to a resting state, air is pushed through the nearly closed vocal folds. Because the air passage at the glottal level is smaller than the air passage of the trachea and subglottis, pressure in the region of the glottis drops as the velocity of the air column increases. The relative vacuum created by this drop in pressure draws the pliable rima glottal tissues of the membranous vocal fold region together; this phenomenon is known as the *Bernoulli effect*. After closure at the membranous vocal fold at the glottal level, the air column from the lungs and trachea continues to flow into the subglottal region. The rising subglottal air pressure forces the vocal folds back open. The vocal folds, or rima glottal tissues, open from inferiorly to superiorly (inferior to superior lip), forming an alternating convergent and divergent glottal configuration. The aerodynamic forces of the air column and the inherent myoelastic properties of the vocal folds, particularly in the region of the vocal fold cover, are responsible for the repeated opening and closing of the rima glottal tissues that pulses the air column as it flows out of the glottis. These disruptions in the steady state of the tracheal air pressure by glottal activity result in sound production. The sound produced by the vibratory source has a buzzlike quality. In professional voice production, glottal sound production can be further complicated by voluntary muscular activity that can influence the intensity and frequency characteristics of the glottal sound before its presentation to the supraglottal vocal tract.

The intensity of the sound source is related directly to subglottic pressure—that is, as subglottal pressure increases, sound intensity also increases. Humans can alter subglottal pressure, and therefore sound intensity, by two methods. The first and probably more efficient method is to modify the force of the expelled air from the trachea. This is accomplished through activation of the abdominal and thoracic musculature to increase the amount of air inspired and then, partially through elastic recoil properties of the thoracic cavity and partially through voluntary muscular activity, controlling the rate of air egress. The varied regional schools of classical singing all emphasize different areas of muscular control to accomplish this phenomenon.[16] However, the effect is the same in that the percentage of air used during singing is greater.[17] The second method used to control subglottal pressure is to modify the force of vocal fold adduction. This method is somewhat less efficient. Increasing the force of laryngeal closure through activity of the thyroarytenoid, lateral cricoarytenoid, and interarytenoid muscles achieves greater resistance to the glottal opening. This in turn raises subglottal pressure, which increases sound intensity. However, frequency of vocal fold vibration is directly related to tension within the vibratory system. Therefore, if sound intensity is controlled by the addition of tension in the vibrating system, the frequency of vibration can be inadvertently affected.

Well-trained vocal professionals can independently modulate the frequency characteristic of the source signal from vocal fold vibration through voluntary behaviors. They do so through adjustments in cricothyroid, thyroarytenoid, lateral cricoarytenoid, and interarytenoid muscle activity. The cricothyroid muscle, when activated, elongates the vocal fold, thus tensing the cover and elevating the frequency of vibration. Fine control of the amount of tension is accomplished by balancing these cricothyroid contraction forces against thyroarytenoid, lateral cricoarytenoid, and interarytenoid muscle forces to keep the vocal folds in an appropriate position for phonation. Unopposed cricothyroid muscle contraction leads to increases in the glottal width, which negatively affect the vibratory cycle. In addition, fine control of this mechanism allows the blending of the registers of the singing voice for a smoother transition between what singers term the "chest" and "head"

voice regions. Inappropriate or unbalanced changes lead to what is perceived as voice breaks. Although these breaks may be unappealing in a classically trained singer, they can be used for stylistic effects in commercial singing voice production. The yodel is probably the most commonly appreciated stylistic technique using the break in registers to produce a desired sound.

The sound source signal produced by vocal fold oscillation has a fundamental vibratory rate termed the *fundamental frequency*. Owing to the characteristics of the larynx as a natural vibrator, the sound that is produced has harmonic qualities—that is, as the vocal fold tissue vibrates to disturb the local air pressure, the pressure waves created are refracted. Refracted pressure waves that are out of phase with the fundamental frequency cancel each other out. Waves that are in phase with the fundamental frequency, on the other hand, are also radiated. These in-phase waves may be faster or slower by a whole-number multiple of the fundamental frequency. They create the harmonic or subharmonic frequencies produced by the laryngeal sound source. Again, each harmonic is a whole-number multiple of the fundamental frequency. This harmonic sound source is presented to the supraglottal vocal tract. In turn, the supraglottal vocal tract, on the basis of its physical characteristics (length, shape, and size of the opening at the distal end), amplifies or attenuates particular regions in the source harmonic spectrum.

The harmonic frequencies that are amplified are referred to as *formant regions*. They shape the output from the sound source into sounds appreciated as vocal communication. Through spectral analysis of the voiced signal, we can measure four or five formant regions significant in vocal sound production. The first two of these regions are primarily responsible for vowel determination, whereas the third, fourth, and fifth formant regions color the sound or provide timbre. Vocal professionals, particularly classically trained singers, are able to alter the characteristics of the vocal tract to modulate or shift these formant regions. When the third through fifth formant regions are brought closer together by the voluntary changes in characteristics of the vocal tract, they amplify one another and a ring, termed the *singer's formant*, is produced. This formant region, in the range of 2300 to 3200 cycles/second, is detected by the human auditory system preferentially over other frequencies, allowing the singer to be heard and understood above the sound of an orchestra or other instruments.[18-20] Appropriate use of these principles may give a professional voice user greater vocal efficiency, that is, greater radiated output with less physical effort. A trained vocal professional provides an aesthetically pleasing sound quality for the listener by modulating the formant regions of the sound produced in the following ways: (1) altering the length of the vocal tract through actions of the abdominal, thoracic, and cervical musculature, (2) altering the shape of the vocal tract through the action of the pharynx, tongue, jaw, and lips, and (3) altering the size of the distal opening primarily through the actions of the jaw and lips. The purpose of all vocal training, either commercial or classical, is to teach the performer to control these vocal subsystems to produce the desired, and hopefully aesthetically pleasing, sound.

From this simplified discussion of voice science and the source-filter theory of voice production, the reader should understand that voice and speech production for complex human communication involves the interplay of several subsystems of the human body. These subsystems are:

- The respiratory tract
- The abdominal cavity and abdominal wall musculature
- Perhaps the pelvic cavity and pelvic musculature, depending on the patient's respiratory technique
- The anterior cervical musculature
- The paraspinous musculature
- The pharyngeal musculature
- The laryngeal musculature

Changes in any one of these subsystems can affect the vocal output. Therefore, coordination of these subsystems, for complex vocalization, is not an innate activity. Like any complex activity or sporting skill, such as a golf swing or tennis swing, people have a natural ability that is affected by their muscular set pattern, which in turn is determined in part by their genetics and epigenetics.

Laryngeal Stroboscopy

Although first reported by Oertel[21,22] in 1878, stroboscopic examination of the larynx has only recently become popular in the United States. Stroboscopy is necessary to evaluate the vibratory patterns of the vocal folds that occur too rapidly to be visualized by the unaided human eye.[23-25] According to Talbot's law, the retina is able to resolve only five images per second. Therefore, images presented to the retina for less than 0.2 seconds (5 images/sec) persist and are fused together by the ocular cortex to produce apparent motion. Because the vocal folds vibrate at rates of 75 to 1000 cycles/second, even the slowest vibratory patterns cannot be visualized without assistance. During stroboscopy the larynx is visualized with a xenon light source. Characteristics of xenon light allow rapid on-and-off bursts. In this manner, the larynx is visualized for only brief periods in the range of $\frac{1}{1000}$ second. These brief images, sampled from various points across many vibratory cycles, are then fused together to provide apparent slow motion of the laryngeal vibratory tissue. In modern stroboscopic equipment, the rate of laryngeal vibration is sensed by a microphone and used to control the rate of xenon light firing. When the rate of visual sampling of the laryngeal image is out of phase with the rate of vibration, the laryngeal tissue appears to move. When the sampling rate is in phase with the vibratory rate, the laryngeal tissue appears to stand still.

Stroboscopy permits observation of the vibratory action of the vocal folds, which is not possible with still-light examination (Fig. 61-5). As previously described, this vibratory action is responsible for sound production. Therefore, by using stroboscopy, the examiner can observe how small lesions alter the normal laryngeal vibratory pattern and glottal closure. The significance of a given lesion can then be determined.

In addition to providing information about vibratory status, examinations captured in video format can be reviewed for comparison with previous examinations and for consultation. This information improves accuracy in the diagnosis of vocal problems. Ideally, a baseline laryngeal stroboscopic examination should be performed in each professional voice patient while the health and voice are good. The findings can be compared with the vocal fold appearance during dysphonic states, and conclusions regarding the effects of vibration patterns on the cause of dysphonia can be made.

Recorded laryngeal stroboscopic examinations can be used to follow changes in the glottal vibratory pattern over days, weeks, and years. This process, known as *interval examination*, helps determine the effects of behavioral, medical, and surgical interventions on the larynx. Changes in laryngeal stroboscopy findings can be shown and documented on videotape, computerized formats, and still prints.

Interpretation of laryngeal stroboscopy requires knowledge of the stroboscopic appearance of the healthy larynx phonating at various frequencies and intensities. A regular format for evaluation also enables a more objective interpretation of this subjective test. Standardized checklists for laryngeal stroboscopy interpretation are available.[2,25-27] Evaluation criteria include symmetry, amplitude, periodicity, mucosal wave propagation, and glottal closure (Table 61-1). These vibratory characteristics are evaluated at a comfortable loudness level and modal speech frequency. In professional voice patients, it is beneficial to perform laryngeal stroboscopy during high and low pitch and loud and soft phonation. This approach provides additional data about the vibratory characteristics. If a professional voice patient is having difficulty at a particular point in the vocal range, stroboscopy and laryngoscopy should be performed while the patient phonates within the troubled range. With this approach, the clinician may observe subtle vibratory changes that may be the source of the patient's vocal difficulties.

Symmetry refers to the paired appearance of the vocal folds, which are mirror images of each other during glottal vibration. Any difference in the mechanical properties of the vocal folds—mass, tension, pliabil-

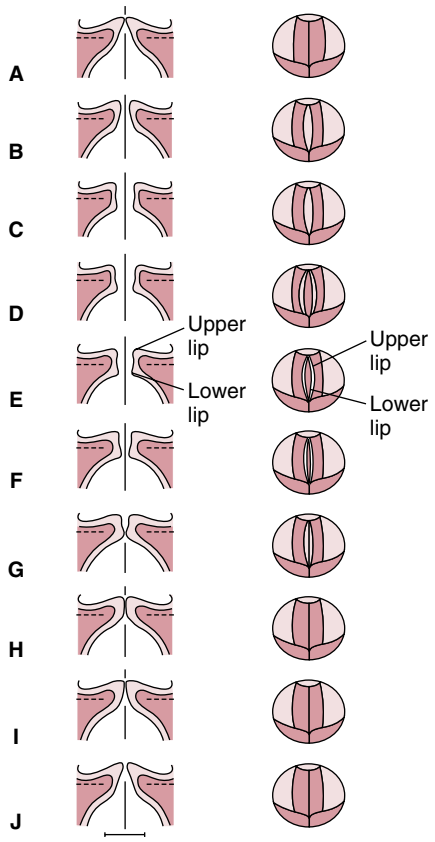

Figure 61-5. Vocal fold vibration. The frontal section (*left column*) and the view from above (*right column*). *(From Hirano M, Bless DM.* Videostroboscopic Examination of the Larynx. *San Diego: Singular Publishing Group; 1993.)*

ity of the superficial layer of the lamina propria or mucosa, elasticity, position, or inflammation—can alter symmetry. Asymmetry of vibration can result in dysphonia.

Amplitude of vibration refers to the lateral excursion of the midmembranous portion of the vocal fold during vibration. This movement is normally one third to one half of the width of the visible fold. As with symmetry, lesions that affect the mass, tension, or pliability of the vocal fold alter amplitude. Vocal pitch and vocal intensity or loudness also alter vibratory amplitude. Vocal folds vibrating at high pitch are stiffer and thinner, so their vibratory amplitude is reduced both in total and in relative relation to the visible size of the vocal fold. On the other hand, when volume is increased, particularly by increases in the force of expelled air, the vibratory amplitude increases as well. This phenomenon occurs at all pitches of phonation.

Periodicity, or the regularity of successive glottal cycles, is ascertained by synchronizing the stroboscopic flash with the frequency of vocal fold vibration. The vocal folds are visualized at approximately the same point in each cycle. This maneuver "freezes" the image or makes the vocal folds appear to be standing still. Any perceived motion of the folds indicates aperiodicity. Any alteration in the balance of the vocal folds and the lungs can result in aperiodic vibrations. During a single phonation, vibratory cycles can range from periodic to aperiodic. Therefore, it may be helpful to determine whether the vibratory pattern is completely periodic, mostly periodic, mostly aperiodic, or completely aperiodic.[28,29]

Mucosal wave propagation has both vertical and horizontal components. The vertical component, known as the *vertical phase*, is visualized during stroboscopic examination along the medial surface of the vocal fold. During vocal fold vibration, owing to characteristics of the mucosa and the vocalis muscle, two distinct ridges appear to form. These ridges are referred to as the upper and lower masses or lips of the vocal fold. The position of the *upper lip* is determined by the reflection of the vocal fold mucosa as it turns from horizontal to vertical over the superior surface of the vocal fold. The position of the upper lip is relatively fixed by the physical characteristics of the vocal fold. The *lower lip* is determined by the change in the physical properties of the mucosa covering the vocal folds from those of the mucosa covering the respiratory tract. Mucosa is technically defined as epithelium and submucosal tissue. Respiratory mucosa consists of a columnar epithelial layer supported by a relatively thin submucosal layer with occasional mucus-producing cells and minor salivary glands. Vocal fold mucosa, however, consists of a stratified nonkeratinized epithelium supported by a relatively thickened and specialized submucosa (see the section on vocal fold anatomy and physiology). The transition between the two types of epithelia is known as the *inferior arcuate line* or the *conus elasticus*. As the air pushes through the glottis, the specialized submucosa of the vocal fold separates from the underlying structure. This is the point of mucosal upheaval. As the vocal fold mucosa is tensed

through the action of the cricothyroid muscle, the submucosal tissue is thinned three-dimensionally in the same manner that a rubber band thins as it is stretched. This thinning causes the lower lip to move in a cephalad direction relative to the upper lip. In this manner, the tension in the vocal fold is increased and the mass of vocal fold tissue available for vibration is reduced to allow pitch elevation. Because the lower lip moves closer to the upper lip, the vertical phase and the time difference between closure of the lower lip and upper lip regions, known as the *vertical phase difference*, is also reduced.

In short, with tensing of the vocal fold for elevation of pitch, the vocal fold cover thins in three dimensions and the time difference between closings of the lower lip of the vocal fold and upper lip (the vertical phase difference) is reduced. This action, which can be witnessed under stroboscopic light examination, is a critical feature in professional voice patients. Often a small lesion or stiffness along the medial surface of the vocal fold will become noticeable only as the vocal fold is stiffened by elevation pitch. The action of elevating pitch limits the vibratory motions of the vocal fold to the superficial region of the cover. This is one of the first areas injured by prolonged or excessive phonation.[11] It is visualized as a reduction in the distinctness of the upper and lower mass formation from one vocal fold to the other.

The *horizontal phase* of vocal fold vibration has been described as a "ripple of light across the superior surface" of the vocal fold.[30] It is a reflection of light either from the upper lip of the vocal fold as it travels from medial to lateral or from motion of the mucosa created by a shock wave as the two upper lips meet during closure. This wave is similar to the wave moving across the surface of a pond after disturbance of the water by a pebble. Lesions that stiffen the mucosa and reduce its pliability lead to loss of this light reflex. This is an important characteristic when visualized under stroboscopic light examination, particularly when the vocal folds are compared with each other at various pitches of phonation. Lesions that fill the superficial layer of the lamina propria and abut or infiltrate the vocal ligament tend to restrict or eliminate both components of the mucosal wave. In contrast, small to moderate-sized lesions limited to the superficial portion of the superficial layer of the lamina propria usually allow propagation of the wave, although it may be decreased and asymmetric.[31,32] Finally, large and exophytic lesions may disrupt the mucosal vibratory characteristic even if they do not infiltrate deeply into the lamina propria, by altering the glottal shape and impairing glottal closure.

Closure of the membranous glottis is vital to laryngeal efficiency. Men usually have complete glottal closure, whereas up to 70% of women normally show a small posterior glottal chink.[33] This glottal chink, however, is considered normal only when it extends from the vocal process of the arytenoid posteriorly. This region from the vocal process to the posterior commissure, referred to as the *cartilaginous glottis,* is not typically important in phonation unless the closure deficiency is large enough to create alterations in closure of the membranous portions of the rima glottic tissue. Berry and colleagues[34] determined that the most efficient glottal output occurred when the vocal folds were approximately 1 mm apart at the region of the vocal process. Glottic closure patterns can be described as complete, long or short, small or large posterior chink, slit, elliptic, and hourglass or asymmetric hourglass. Closure can be altered by a mass lesion, scarring, muscular tension, and neurologic abnormalities, which become clinically significant when they involve deficiencies of closure at the membranous vocal fold level.

High-speed digital video is currently a research instrument but holds great promise for the evaluation of the vibrational function of the vocal folds, especially in patients with severe aperiodic dysphonia, in whom stroboscopy is of limited value.

Voice Analysis

Several methods can be used to quantify voice or measure vocal vibration. No single test is considered the gold standard for documenting vocal fold function. All tests have significant limitations. In addition, intrapatient and interpatient variability exists. Therefore, in professional voice patients, perceptual analysis by a trained observer and patient satisfaction with vocal outcome are often the most useful indicators of a successful intervention. Most laryngologists consider objective and semiobjective voice analysis to be important, particularly regarding preoperative and postoperative voice documentation. Little agreement exists as to the optimal tests and their performance, relative importance, or interpretation.

Acoustic Measures

Acoustic analysis has been used to objectively document voice and to compare preoperative and postoperative surgical results. Acoustic measures include fundamental frequency, perturbation or cycle-to-cycle variation in frequency and amplitude, and maximal phonation range. Comparison of interval examinations requires a high-quality microphone and recording system with strict, standardized recording techniques and patient tasks. Although several computer-integrated acoustic analysis systems are available, they are of limited benefit for the average patient. The reliability of acoustic measures, secondary to variation in patient effort, is limited. In addition, the validity of acoustic measures designed to evaluate periodic vibration is questionable in dysphonic voices because dysphonia results from aperiodic vibration.

Spectrometry

Spectrometry provides a visual display of vocal harmonics and noise. In spectral analysis of sound, time is plotted on the vertical axis against frequency and intensity. This display shows the impact of resonance (formant structure) and articulation on the laryngeal buzz. Spectral analysis can evaluate and compare resonance changes and may be useful in documenting vocal alterations after surgical procedures on the pharynx. Some laryngologists have found it to be valuable in singers and other professional voice patients.[35,36]

Electroglottography

Electroglottography measures the efficiency of glottal closure by graphically recording the contact time of the vocal folds. It shows the opening and closing rates of the vocal folds, which are not well visualized by stroboscopy. Electroglottography is performed by the passage of a low-voltage, high-frequency current between two electrodes placed on either side of the patient's neck. It measures the electrical impedance, which varies with opening and closing of the glottis. Some clinicians consider this measure objective and reproducible. Electroglottography may provide clinically useful information when combined with laryngeal stroboscopy or other measurements of layrngeal function.[37-39]

Aerodynamic Measures

Aerodynamic studies are based on the fluid mechanics of airflow and involve the measure of airflow, volume, and pressure. Some are related to Ohm's law ($R = P \div F$, in which R is laryngeal resistance, P is subglottal pressure, and F is airflow).

Normative aerodynamic data are very broad, making comparisons among patients almost useless. However, changes in measures after intervention in individual patients are quite useful, particularly in the evaluation of changes in laryngeal closure.

Standard pulmonary function testing may be used to objectively evaluate the lungs. Mild obstructive or restrictive pulmonary disorders may be the basis of a patient's vocal fatigue or dysphonia. Bronchodilator trials and methacholine challenge may rule out cough-variant asthma and other types of reactive airway disease.

Subglottal pressure is usually measured indirectly rather than by tracheal puncture or esophageal balloon. It is measured via oral pressure when the glottis is open. The oral pressure achieves equilibration with the subglottal pressure across the open vocal folds for voiceless stop consonants, such as /p/ and /t/.[40]

Maximum phonation time is an average of the (1) phonation length in one breath voicing the vowel /a/ at a comfortable pitch and (2) loudness after deep inspiration. It is highly variable but can reasonably estimate laryngeal competence and glottal closure.

Mean airflow rate (airflow volume ÷ phonation time) of a sustained vowel /a/ is occasionally tested. In general, low flow rates suggest laryngeal hyperfunction, obstruction, or primary pulmonary disorders. Higher values imply abnormalities in glottal competence that allow air loss.

Perceptual Analysis

For evaluation of the professional voice, the "trained" ear remains the most discerning instrument.[41-43] Perceptual improvement or degradation of the professional voice to the performer, manager, other performers, the laryngologist, the speech language pathologist, and the vocal pedagogue is critical. To make perceptual vocal analysis more objective, vocal characteristics can be evaluated independently in a systematic manner. In addition, judges are trained in vocal evaluation to decrease subjective bias. However, agreement on the terminology of vocal characteristics is not universal. Hirano[44] proposed the GRBAS (grade, rough, breathy, asthenic, strained) scale, which is widely used. However, Sundberg[45] and Kreiman and associates,[46] who performed research in this area, concluded that the clinical application of perceptual analysis was difficult, and it remains so even today.[45,46]

Voice Outcomes

Because of daily variation in vocal measures, vocal quality is frequently best judged by measures of patient satisfaction or direct comparisons of voice at different times. Patient satisfaction can be assessed through direct questioning or specially designed questionnaires for rating perceived vocal problems. Voice can be directly compared with the use of taped samples. By eliminating dates and other identifying factors, blinded analysis of vocal changes can be determined. A panel of judges can thus evaluate objective qualitative changes in a blinded manner over time. This approach is useful to determine the effect of a specific therapeutic intervention.

Outcomes research for judging patient satisfaction with voice and treatment is a valuable tool for studying vocal disorders. A voice handicap index has been developed to quantify a patient's perception of his or her voice and its change in response to therapy.[47] Cohen and associates[48] have validated a voice handicap index specifically designed to measure self-perceived vocal handicaps among patients who sing.[48] Both of these self-rating questionnaires are useful for measuring patients' self-perceptions about voice and the changes in voice after medical, behavioral, or surgical intervention.

Evaluation

Medical History

A complete history of the present illness and past medical problems is necessary. Several laryngologists have developed patient questionnaires to obtain the most complete history possible and to streamline the evaluation process.[49]

Salient points regarding a patient's past medical history and general health include diseases that affect pulmonary status, posture, and hydration as well as any of the other body systems involved in voice production, as described in the introductory portion of this chapter. Any underlying chronic or acute pulmonary condition can significantly affect a singer's voice. Asthma, emphysema, or chronic bronchitis, all of which impair pulmonary function, decreases a singer's power supply to the voice. Musculoskeletal injuries alter posture and impair a patient's ability to position the larynx within the neck, leading to vocal dysfunction. Prescription and nonprescription drugs change the voice through direct effects on the autonomic nervous system and indirect effects on the larynx and vocal tract.[50,51] Drugs that alter a patient's emotional status affect the manner in which the patient approaches the vocal task. Drug-induced changes in hydration lead to poor laryngeal lubrication, which affects vocal fold vibration. History taking in a female singer should include questions about oral contraceptives and hormonal drugs (e.g., danazol), which may adversely affect the voice.[52-54]

A singer's personal habits should also be reviewed. Moderate use or abuse of alcohol is detrimental to the voice through dehydration and effects on judgment. Caffeine (a diuretic) and high-fat dairy products affect the voice by thickening mucous secretions, thereby decreasing the efficiency of vocal fold vibration. Certain foods and alcohol exacerbate gastroesophageal and extraesophageal reflux.[50] Finally, tobacco use should be evaluated. Inhaled smoke is particularly irritating to the mucosa acutely and may induce esophageal reflux, which reduces vibratory efficiency. In addition, exposure to carcinogens can lead to neoplastic changes.

A history of any surgery is important to learn in patients with vocal dysfunction. In addition to questions concerning head- and neck-related procedures, any history of endotracheal intubation should be identified because it may adversely affect the larynx. Procedures in the neck can alter a patient's ability to stabilize the larynx during voice production either through injury to the muscles and nerves controlling the extrinsic musculature or through pain from the surgical intervention itself. Recent abdominal or thoracic surgery could also greatly restrict a singer's capacity for inspiration or expiration for many weeks or months after the operation.

The identification of endocrine dysfunction is often useful. The laryngeal manifestations of hypothyroidism may create subtle changes in Reinke's space, leading to alterations in the voice.[55] Even mild hypothyroidism can cause a muffling of the voice, decreased range, and vocal fatigue.

Less well understood are the vocal changes caused by hormonal fluctuations in women just before and during menstruation. Flach and coworkers[56] reported that 75% of female singers show a premenstrual change in their voices, manifested as decreased range and vocal fatigue. Using cytologic smears, Abitbol and colleagues[57] objectively showed cyclical changes in vocal fold epithelial cells corresponding to the menstrual cycle; these changes have been called *laryngopathia praemenstrualis*.[58] The common increases in size of vocal fold varices before and during menstruation have been associated with a higher incidence of submucosal vocal fold hemorrhage.[59,60] Vocal fold varices are most commonly found in female professional voice patients.[59,61-63]

Finally, the history must also address what type of professional voice use the patient requires as well as the amount and type of formal vocal training the patient has received. Professional voice users who primarily speak have different vocal demands from those who primarily sing. Speakers often lower the pitch of the voice to sound more authoritative. This practice is particularly common among female newscasters and physicians. Prolonged artificial pitch lowering often leads to muscular strain and early vocal fatigue. Such patients can lose flexibility in the speaking voice over time, a loss that is often perceived as an increased sense of roughness.

In patients who sing, the clinician must ascertain the style of singing. Those who sing commercial rock music have different demands from those of country and western or bluegrass musicians. Classically trained vocalists in opera and those in legitimate Broadway performance have completely different sets of demands from each other as well as from the other types of performers previously mentioned. It is helpful for the clinician to become familiar with the demands and requirements for each type of performer. If the otolaryngologist caring for the voice patient does not have an interest in obtaining this knowledge, he or she must work jointly with someone who does. The clinician should determine whether the patient has a current voice coach or they have worked with one in the past. It is helpful to determine the level of vocal performance education as well. What are the patient's long-term goals? A trained vocalist may be able to correct the vocal technique more easily than an untrained vocalist.

History of Present Illness

The exact nature of a singer's complaint should be reviewed with care. A vocal professional may simply complain of "hoarseness." This common term is used to describe most vocal abnormalities, including loss of upper register, roughness, pitch instability, difficulty in transition between singing registers, and early vocal fatigue. These are frequently symptoms of laryngeal edema, muscle tension dysphonia, extraesophageal reflux, upper respiratory infections, nonneoplastic lesions, or poor vocal technique. Patients, therefore, should be questioned specifically about range, pitch breaks, anterior cervical discomfort, esophageal reflux, and stamina. An understanding of the required type of voice use is helpful in evaluating these complaints and their effect on vocal production. Professional speakers usually speak in and around their most common vocal pitch; in speech language pathology this is referred to as the *modal register* of voice production. If professional patients attempt to artificially lower the pitch to slightly below the natural speaking pitch, they often complain of vocal fatigue and/or increased effort. After prolonged inefficient use patterns, the speakers

may also complain of increased vocal roughness even though examination does not reveal any discernible lesions.

Singers, on the other hand, divide their modal voice register into chest voice, head voice, and a transition register between head and chest voice. *Chest voice* is the lower portion of the modal register in which the singer feels the sensation that the voice is resonating from the chest. *Head voice* production includes the upper portion of the modal register in which the singer has the sensation that the voice is coming from the head. The area between head voice and chest voice is referred to as the *transition voice* or *transition register* by most singers. In this register the classically trained performer attempts to blend the chest voice into the head voice so that the register shift is not apparent. These register shifts are most likely secondary to physical vocal fold mass and absolute laryngeal size. As the singer attempts to elevate pitch, cricothyroid muscle activation elongates the vocal fold and tenses the vocal fold cover. In addition, cricothyroid activity slightly abducts the vocal folds. To maintain the vocal folds in an efficient posture for vibration, the singer must delicately adjust vocal fold adduction by increasing activity in the thyroarytenoid, lateral cricoarytenoid, and/or interarytenoid muscles. The abductory force on the vocal fold from the cricothyroid muscle pull is most likely responsible for the break between the chest voice and the head voice. The "break" region is termed the *passagio*. The specific notes are called the *primo passagio* for the lower break point and the *secundum passagio* for the upper break point. These points vary for different singers but can be broken down into expected regions according to a singer's overall pitch range. These break points or regions, along with the singer's overall range, help determine whether the singer is a bass, baritone, tenor, contralto, or soprano. There are also many divisions among classically trained singers within each one of these categories. A more complete discussion of this topic can be found in Miller.[16] Commercial or pop performers may not be aware of their vocal range classification. It may be unimportant to them because they may often sing in a different vocal register termed the *falsetto*, *flagelette*, or *whistletone* register. These terms essentially imply voice production with light or incomplete vocal closure and are often used somewhat interchangeably by both speech language pathologists and vocal pedagogue.

The onset and offset of the vocal difficulty can often provide clues about the cause. Specifically, time of the difficulty throughout the day, situations that aggravate the dysphonia, events that immediately precede the onset of the difficulty, and the association between dysphonia and voice use are significant in determining the cause and may aid in management.

Professional activities that can contribute to these problems include air travel, performing on older indoor stages with poor acoustics, exposure to chemicals and fumes, required excessive use of the speaking voice for promotion, and overscheduling of performances. Air travel remains a problem for the serious voice user because the air on planes is very dry (5%-10% relative humidity) and affects the larynx; also, the high background noise tempts the patient to speak more loudly.[8] Performing on older stages, which may be dusty, and traveling in areas with a large amount of allergens can degrade a patient's voice. Exposure to other types of irritants, including tobacco smoke at parties or at performances in smoke-filled rooms, also affects the voice. Vocal professionals required to give multiple interviews often experience dysphonia of various degrees. A singer's schedule may make it difficult for the singer to drink large quantities of water to lubricate the vocal cords, and although a singer may complain of singing problems, the main difficulty may be voice abuse caused by excessive speaking. Significant abuse of the speaking voice leads to eventual singing difficulties.

Often, a younger vocal professional does not seek help until the problem becomes significant or the performer is about to go on tour or has a performance in the near future. Management of the problem may vary according to when the next performance is to take place. This should be considered in the development of a management plan.

Physical Examination

Every voice patient presenting to the otolaryngologist or laryngologist should undergo complete examination of the head and neck. The physical evaluation of the vocal professional begins with observation of gait and posture as the patient walks into the physician's office. Does the patient stand comfortably erect with shoulders slightly back or slouched? Does the patient appear tense and anxious?

While taking the history, the physician should evaluate the quality of the patient's speaking voice. The frequency or pitch should be appropriate for the performer's age, gender, and body habitus. Volume or vocal intensity should be appropriate for conversational speech. The timing of voice onset should be studied, including speech breaks and the overall rhythm. Finally, vocal quality is evaluated for roughness, breathiness, asthenia, and strain.

Neck palpation, specifically of the anterior cervical musculature, cricothyroid space, thyrohyoid space, and tongue base above the hyoid bone, is performed with the patient at rest and while phonating. These areas should be nontender. They should remain supple and should tense or move only minimally during phonation if the patient is producing voice efficiently. Excessive tenderness indicates excessive extralaryngeal muscular tension or effort. Excessive tensing during voice production indicates excessive effort to produce glottal closure. This is common in patients with inefficient patterns of voice production, often termed *functional dysphonia*. Tension during phonation without tenderness at rest may indicate that a patient needs to use extralaryngeal muscular effort to compensate for impairment of laryngeal closure from paresis, paralysis, or a large mucosal lesion

Certain areas of the nonlaryngeal examination are also significant. Jaw range of motion should be checked, and the temporomandibular joint should be palpated. Temporomandibular joint dysfunction can create significant muscular tension difficulties in a professional voice patient. The ears should be examined for any abnormalities, and an audiogram should be obtained. Hearing loss, particularly if sensorineural, can cause a singer to sing too loudly, resulting in excessive trauma to the vocal folds.

The nasal examination can provide information about mucous membrane disease. Pale and edematous nasal mucosa suggests the presence of significant allergies. Evidence of a chronic infection with purulent discharge or crusting should be sought. Nasal obstruction can lead to chronic mouth breathing. The subsequent exposure of the larynx to unfiltered dry air can cause significant dysphonia by thickening the secretions and therefore raising the phonation threshold pressure. In addition, the physician can determine the nature of the patient's secretions by noting their consistency in the nose and oral cavity. Cough resulting from chronic postnasal drip can also lead to vocal fold edema.

Laryngeal and pharyngeal examination can be performed by various methods. There are three ways to examine the larynx: with a laryngeal mirror, with a rigid telescope, or with a flexible transnasal laryngoscope. The first and classic method is with a laryngeal mirror. It gives the most natural color to the tissues being examined and potentially allows a panoramic view of the entire larynx.

Vocal professionals may be evaluated with the rigid telescope and/or a flexible transnasal laryngoscope. Single-point light sources, however, can distort color, and this fact should be considered in the evaluation. Rigid indirect endoscopy and flexible laryngoscopy are complementary; each has certain advantages. Using both methods in the professional voice patient enables a full evaluation.. Use of the rigid telescope requires that the examiner gently grasp the patient's tongue and draw it forward. This maneuver alters the patient's normal use of the supraglottal vocal tract and articulators, making glottal closure and laryngeal hyperfunction difficult to interpret. Most efficient voice users can compensate for these changes and actually use the larynx relatively efficiently while being able to sing scales on vowel sounds. The rigid rod lens endoscope provides the best illumination and magnification, allowing an unparalleled view of the larynx during vibration and inspection of the laryngeal mucosa for disease. Small lesions or areas of vascular abnormality in the larynx, which may be missed with the mirror or flexible laryngoscopy, can be identified with a 70- or 90-degree telescope. In addition, laryngovideostroboscopy is performed better through the rigid telescope than with the flexible device. The picture is clearer, larger, and brighter and therefore allows the examiner to better evaluate the laryngeal vibratory pattern.

Flexible laryngoscopy with either a distal chip camera or older fiberoptic technology allows examination of a vocal professional without

traction on the tongue. Although the presence of the flexible endoscope may induce some discomfort and therefore alter laryngeal behavior, most patients can use connected speech or can sing during evaluation of the supraglottal vocal tract and larynx. This provides an opportunity to evaluate laryngeal biomechanics, particularly in a hyperfunctioning larynx, but does not give the examiner the opportunity to directly palpate tongue tension. Drawbacks of fiberoptic systems include the well-known fish-eye distortion of the peripheral image, decreased resolution, linear color stripe distortion on video imagery (moiré effect), and decreased illumination, which makes stroboscopy findings more difficult to interpret (Table 61-2).[64] These problems are reduced or eliminated by flexible endoscopes, which use a distal chip camera to transmit the image rather than the older standard fiberoptic technology. The presence of a large mucosal lesion or paralysis of the vocal folds may be apparent to the examiner using an endoscope. Subtle laryngeal findings may be less apparent. The presence of thick, tenacious mucous secretions should be noted and compared with the usually seen watery lubrication, which is preferable. Evidence of vocal fold swelling, ventricular effacement, and erythema, swelling, or granular tissue in the posterior glottis may indicate recurrent trauma due to chronic coughing or extraesophageal reflux. Areas of vocal fold edema, particularly in the middle third of the fold, may be present in a vocal professional who complains of slight dysphonia. Evidence of hyperfunction should be sought; it can manifest in its most subtle form as widening of the posterior glottis. More severe hyperfunction could cause closure of the false vocal folds (plica ventricularis) as well as anterior-to-posterior contraction of the supraglottis. If these findings are present, subtle vocal fold paresis should be considered.

The vocalist should be evaluated by a vocal pedagogue even if an obvious laryngeal problem is identified. The singer's posture and general stance should be noted. The "singer's stance" is a fully upright position with the feet about shoulder-width apart and the weight slightly forward on the balls of the feet. Frequently, commercial performers are required to play instruments while singing. In this instance, the patient should be observed while holding the instrument. Facial, shoulder, or cervical tension should be noted if present when the patient is singing. Is the singer using the abdominal muscles appropriately to support the singing voice or breathing only with the use of chest and shoulders? The presence or absence of laryngeal elevation with rising pitch should be noted; this is considered poor technique in a classically trained singer and can lead to vocal fatigue due to excessive muscular tension. In commercial singing, however, laryngeal elevation can often be used to achieve a desirable sound, and elimination of elevation causes an uncharacteristic vocal quality for many styles of commercial music.

Problems in Singers

Professional singers have the same maladies that affect the general population. However, because of the tremendous demands placed on their voices, these vocalists are highly sensitive to problems affecting the larynx and the associated areas involved in voice production.

Extraesophageal Reflux

Gastroesophageal reflux is a common problem often manifested as heartburn, belching, or an acidic taste on waking. Patients may have significant reflux with no abdominal or chest complaints; this type is called extraesophageal or laryngopharyngeal reflux.[50,65-69] The symptoms are often frequent throat clearing, mild dysphonia, cough, a sensation of phlegm or a foreign body sensation in the throat (globus), vocal fatigue, cervical dysphagia, and decreased singing range.[70,71] Singers and other vocal professionals with extraesophageal reflux often have hoarseness in the morning and require longer vocal warm-up. Signs of reflux laryngitis should always be sought during the physical examination.[72,73] If signs or symptoms suggest extraesophageal reflux, conservative management directed at diet and general lifestyle is initiated. Adhering to these measures might be difficult for performers with a demanding travel schedule. Extraesophageal reflux is partially managed with proton pump inhibitor. This agent is taken 30 minutes to an hour before a meal and, for extraesophageal reflux, is often used twice daily. It is uncertain whether the addition of drugs to enhance gastric emptying makes any definite contribution in the management of extraesophageal reflux. Patients with a confusing clinical picture or those who do not show a good response to maximal-dose proton pump inhibitors undergo 24-hour pH monitoring. Some cases of reflux may be resistant to proton pump inhibitors.[74-77]

Laryngeal Hygiene

Laryngeal hygiene can be problematic in professional singers. The key to good laryngeal hygiene is adequate hydration. Poor hydration causes an increase in mucus viscosity, resulting in less efficient vocal fold vibration.[78-80] Singers should drink larger amounts of water. The noted otolaryngologist and voice specialist Van Lawrence is quoted as stating that singers should "pee pale" (ingest so much water that they exhibit lightly colored urine), and vocal professionals should not drink a set amount of water but allow their kidneys to "tell" them how much to drink. At least eight glasses (64 ounces) of water per day appears to be needed, and the amount should be increased if the voice user is traveling by air, is ill, or has a demanding or excessive performance schedule. The use of caffeine is discouraged because of its diuretic effect. Dairy products also appear to increase the viscosity of secretions and hinder the healthy smooth vibratory function of the vocal folds. Guaifenesin

can thin the secretions in some patients. The use of tobacco by the professional voice patient also contributes to poor laryngeal hygiene.

Vocal Abuse and Misuse

Vocal abuse refers to phonation that is excessive in length or is produced in an overly loud manner. Loud phonation and excessive phonation lead to increased trauma in the mucosal membrane during voicing. After periods of vocal abuse, patients complain of a sense of vocal fatigue and tightness in the larynx. If voice abuse is long-term, patients can experience a response to the trauma, with lesions appearing on the vibratory surface of the vocal folds. Common forms of voice abuse in professional voice users are: (1) over-rehearsing, (2) spending too much time working in the studio, (3) singing too loudly, and (4) singing outside the singer's capable range. In addition, commercial singing frequently incorporates artificial roughness to render "validity" to the performance.

Vocal abuse behaviors can also occur if performers give too many interviews or shout and talk excessively in areas of loud background noise (e.g., restaurants, airplanes). The vocal professional should conserve the voice by limiting unnecessary speaking, exercising what is called *modified voice use*. This is particularly important if the vocalist is having vocal difficulties or is ill. Punt[81] advises singers "not to say an unnecessary word unless they are paid for it," especially if they are ill or have an excessively demanding performance schedule.

Vocal misuse refers to dysphonia caused by inefficient methods of voice production. Inefficient vocal patterns occur when voice is produced with inappropriate laryngeal tension and/or poor respiratory support. This often leads to early vocal fatigue, increased vocal roughness, or pain with phonation. Most of the time, patients who misuse their voices have a relatively normal vocal fold appearance; this condition is often referred to as *muscular tension dysphonia*. Long-term misuse coupled with loud and excessive phonation (abuse) can eventually lead to organic changes in the vocal folds. These changes most commonly appear as vocal nodules and disrupt the normal laryngeal vibratory pattern, causing dysphonia. Elimination of the inefficient/inappropriate vocal behaviors lessens or eliminates the dysphonia. With time, the organic changes may reverse, and healthy vibratory patterns may return.

Voice misuse or muscular tension dysphonia is not limited to vocal professionals, and voice misuse can be the primary or secondary cause of dysphonia. Singers are not immune from voice misuse despite misconceptions that vocal training should eliminate such difficulties. This problem is common, particularly as a maladaptive, compensatory behavior after an upper respiratory infection. The singer attempts to maintain a normal voice while the vocal folds or pharynx are swollen from illness or too much use and develops inappropriate vocal behaviors. Such a patient often complains of hoarseness, vocal fatigue, loss of range, and neck or ear discomfort.

Koufman and Blalock[82,83] formulated a grading or classification system for muscular tension dysphonia. Class I muscular tension dysphonia is defined as an increase in muscular tension manifested as an enlarged posterior glottal chink, an elevated larynx, and palpable neck tension or tenderness. It may produce a breathy or strident voice and commonly occurs in patients with vocal nodules. Class II muscular tension dysphonia is a lateral to medial constriction of the larynx with the false vocal folds adducted. This problem causes greater vocal fatigue. In its most severe form, the false folds are used for phonation, so-called *plica ventricularis*. It is often seen as a compensatory maneuver after laryngitis or laryngeal surgery. Class III muscular tension dysphonia is an anterior-to-posterior constriction of the supraglottis when the epiglottis and the arytenoids obscure at least 50% of the laryngeal aditus. Class IV muscular tension dysphonia is present when the epiglottis and arytenoids contact one another, and lateral constriction is often seen.

Koufman[84] reviewed laryngeal biomechanics during singing. In this study, 100 singers of various singing styles were evaluated with fiberoptic laryngoscopy. Koufman found that vocal training, warming up before singing, and singing classical musical styles decrease muscular tension. This finding supports the belief that vocal training increases vocal efficiency and decreases muscular tension. Koufman also found that singers with asymptomatic vocal nodules had significantly higher levels of laryngeal muscular tension than those without nodules. The management of muscular tension dysphonia is directed by the speech language pathologist and the vocal pedagogue. It aims to retrain the patient to improve speaking and singing efficiency, thereby decreasing laryngeal tension and vocal fold trauma.

An interesting type of vocal misuse in professional voice patients is an inappropriately low-pitched speaking voice. This deepening of the voice gives it a more authoritative quality. It requires a significant amount of muscular tension to maintain.[85]

Laryngitis

Acute laryngitis (inflammation of the laryngeal mucosa) is common in adults and can be devastating to a professional voice patient. Inflammation of the vocal folds causes irritation and edema and hinders the pliable motion of the mucosa, leading to dysphonia. To compensate, singers may exert extra effort to maintain the normal voice. Singers may correctly compensate by decreasing the volume, increasing the amplification, altering the repertoire, and other measures.

A very mild case of laryngitis can be managed conservatively with voice rest. Some singers may, however, elect to continue to perform. A singer who elects to perform while the vocal folds are inflamed should be aware of the risk of permanent damage to the vocal folds and the greater risk for submucosal hemorrhage. Preferred management of laryngitis involves an increase in fluid intake and humidification of the room. If cough is present, an antitussive agent may be of benefit. Conservative voice use is key. The singer should speak little, if at all, to allow the vocal folds to heal.. Before the performance, the singer should warm up in a normal fashion and should be told not to force the voice to produce the usual or normal sound. The performer should be instructed to sing by feel and not by sound. This technique may avoid exacerbating the injury. The singer should speak in a normal, unforced voice without whispering. If a bacterial infection is suspected, antibiotics should be prescribed. The use of corticosteroids, although not empirically tested, is clinically beneficial in most patients with acute laryngitis.

Severe laryngitis should be managed like acute laryngitis, but in the case of severe laryngitis, every possible effort must be made to persuade the vocalist to agree to vocal rest. Serial examinations enable the physician to advise the vocal professional when it is safe to return to vocal activity.

Anxiety

Apprehension before a performance is normal. A few professional voice patients may have dramatic stage fright. Professional vocalists should learn to cope with this anxiety by working with a vocal coach and laryngologist. Several medications have been used, but all have potential adverse effects, and none replaces good training and the confidence that comes with repeated performance under such stress.

The use of β-blockers to decrease the tachycardia that often accompanies the anxiety is common, but this medication has adverse effects. Gates and coworkers[86] stated that β-blockers decrease anxiety but also take some of the dramatic edge and excitement away from the singer. These agents should be used only on rare occasions (e.g., when a crisis occurs before a performance) and never on a regular basis.

Pulmonary Disease

Any respiratory ailment alters the amount of power available for singing or phonation and limits the vocalist's ability to modulate it. Pulmonary health and good conditioning are important for proper voice support.[87,88]

An uncommon but reported type of exercise-induced asthma exists in some singers when they have been singing for a lengthy period. This airway reactivity–induced asthma in singers[89,90] can be diagnosed with pulmonary function testing performed before and after prolonged singing.

Vocal Fold Varices

A true *vocal fold varix* is a dilated, tortuous, or elongated blood vessel stemming from the microcirculation of the vocal fold; it occurs mainly in female professional vocalists. The cause of this relatively uncommon lesion is uncertain, but its preponderance in female singers suggests that hormones and vocal trauma are major factors.[59,91,92] The laryngologist

should determine whether the patient's symptoms correlate with the menstrual cycle. Varices may enlarge premenstrually and menstrually and can increase a singer's dysphonia.

If a vascular lesion is found, its functional significance should be determined. This determination is best made with serial laryngovideostroboscopy. The lesion's effect on the laryngeal vibratory pattern can be accurately determined, including whether the vascular lesion is the cause of the singer's problems. The lesion should be examined periodically throughout the menstrual cycle for changes in size or leakage of blood. Nonsurgical management of vascular lesions involves improvement in vocal hygiene, particularly with increased water intake and the avoidance of caffeine. In addition, working with a speech pathologist and vocal pedagogue to improve vocal efficiency is important. Hormonal manipulation has been advocated by some writers but has not been proven to be beneficial. Indications for surgery include recurrent hemorrhage, an enlarging varix, and continued dysphonia despite maximum medical and behavioral management.

Performance Cancellation

Possible cancellation of a performance can be very stressful for a professional singer and the laryngologist. The performer and the manager have many concerns beyond the singer's health—for example, the singer's professional image, perceived reliability, and financial obligations. The musical style and the importance of the performance are also important variables; slight vocal roughness would be acceptable in a contemporary rock or country performer but unacceptable in an opera singer.

The physician's recommendations for performing are categorized by (1) conditions in which damage to the larynx will not be significant and (2) conditions that place the performer at significant risk for development of chronic vocal difficulties (Box 61-1). However, the decision to perform ultimately belongs to the performer. Singing will still be problematic during and after the performance. Examples of conditions that pose a mild risk to the performer are a mild viral upper respiratory infection and mild to moderate vocal fold edema. In an upper respiratory infection, the postnasal drip and generalized congestion can be managed, but the supraglottal vocal tract is altered and the singing voice will not be normal. To produce the usual perceived sound, the vocalist can exert significant extra effort, possibly leading to the development of maladaptive singing behaviors that could take time for the vocal pedagogue and speech language pathologist to correct. The singer and manager should also decide whether a decrease in vocal quality would alter the performer's image or reputation.

Conditions that are likely to cause permanent vocal changes include submucosal vocal fold hemorrhage, enlarging varix, and a vocal fold mucosal break (see Box 61-1). In the presence of any of these conditions, absolute voice rest is essential. The usual conservative care of the larynx should also be undertaken. Aggressive antireflux therapy should be initiated in patients with laryngeal mucosal breaks. These individuals should be followed closely for the development of submucosal scarring, granulation tissue, or polyps.

Management

Medical Therapy

The mainstay of medical therapy for a singer is appropriate lifestyle change. This begins with maintenance of adequate hydration. In addition, for many problems, a period of conservative voice use is the best remedy. A humidifier should be used when the singer is traveling or sleeping in rooms with inadequate humidity. Altering the diet to avoid reflux-inducing foods and avoiding irritants are always important, particularly when the singer is ill. In general, these interventions improve laryngeal hygiene primarily through their effect on lubrication and avoidance of further vocal trauma.

The special needs of vocal professionals require the avoidance of certain commonly used medications, including inhaled corticosteroids, antihistamines, decongestants, aspirin, topical analgesics, and mentholated preparations.

The application of topical corticosteroids on the larynx should be avoided. They directly irritate the laryngeal mucosa and are associated with a higher incidence of fungal infections of the larynx.

Systemic corticosteroids are indicated for conditions in which there is little chance of permanent laryngeal damage (Box 61-2). They can be used when a patient with vocal fold edema has an upcoming performance. This approach is combined with improvements in laryngeal hygiene and conservative voice use. Laryngeal edema commonly occurs during repetitive recording sessions or after extensive rehearsals before major tours or performances. Corticosteroids are also beneficial when singers have mild viral laryngitis, to decrease the vocal fold edema and to help control significant allergic reactions. Corticosteroids can be given for a severe case of laryngitis, but the vocalist will risk laryngeal damage by performing. Systemic corticosteroids are frequently given for vocal fold hemorrhage to decrease the deposition of scar tissue in the superficial layer of the lamina propria, to prevent polyp formation, and to decrease the overall inflammatory response. However, no scientific evidence exists that corticosteroids are beneficial in this clinical situation.

Management with corticosteroids varies according to the severity of the problem. Combinations of short- and long-acting corticosteroids (dexamethasone 4 mg with methylprednisolone 80 mg) can be given intramuscularly if a performance is to be given within 24 hours. In subacute situations, stress-dose corticosteroids taken orally for 3 to 5 days with a rapid taper are appropriate.

Idiosyncratic reactions to corticosteroids can occur, in which case the performer's voice actually worsens rather than improves. In addition, corticosteroid-induced psychiatric changes may occur. Because of these reactions, systemic corticosteroids should not be used for the first time in any patient before a performance except in the most dire of circumstances. Corticosteroids are best used initially before routine studio recordings or song-writing sessions. This situation allows the physician and the performer to gauge the response and creates a better understanding of how the patient would respond to corticosteroids in other situations. The singer should not depend on corticosteroids but use them only when required.

Most antihistamines have a significant drying effect on mucous membranes because of their anticholinergic effects. In patients requiring significant management of allergies, it is best to begin with topical nasal corticosteroids. These are effective for the relief of allergic rhinitis and do not adversely affect the voice. Some of the newer, nonsedating antihistamines may be useful.[93] For patients with more severe allergic symptoms, formal allergy testing should be performed early. After the identification of the specific allergens, avoidance or environmental therapy is attempted, but this approach can be difficult because of travel. If possible, the performer's travel schedule should be arranged to avoid certain environments where seasonal plants are in bloom. Allergic immunotherapy is very helpful in patients with allergies.

Allergic vocal fold edema
Vocal fold hemorrhage

Decongestants often provide symptomatic relief in a performer with an upper respiratory infection. Combination preparations that include an antihistamine should be avoided in professional voice patients because of the drying effects of medications on mucous membranes.

Aspirin use is not advised in vocal professionals. Aspirin inhibits platelet function and can increase the risk of submucosal vocal fold hemorrhage. Professional voice patients should check the labels of nonprescription medications and should avoid those with aspirin.

Although once very popular with vocalists, topical anesthetic solutions for sore throats or laryngitis can harm the voice. By decreasing the sensitivity of the oropharynx or supraglottal larynx, these solutions allow the patient to overwork an injured area, possibly leading to submucosal hemorrhage, mucosal tears, or a granuloma. If a performer believes that work is not possible without such an analgesic, he or she should not perform.

Patients complaining of a dry throat or a cough often initiate management with nonprescription cough or topical preparations. These preparations frequently contain menthol, which is initially soothing. Menthol, however, is a drying agent and is habit forming in some patients.

Antibiotics are prescribed for singers in accordance with standard management indications. Overdispensing of antibiotics, a major problem in our health care system, should be avoided. Antibiotics can be prescribed to a singer who is about to go out of town or on an extended tour. Written instructions outlining when to use the antibiotics should be given. If the performer feels the need to use the medication, he or she should contact the physician.

Mucolytic agents (e.g., guaifenesin) are commonly used by singers as a pharmacologic adjunct to thin secretions, thereby improving the lubrication of the vocal folds. Although not proven to be effective, guaifenesin and similar agents appear to benefit some vocal professionals.

Role of the Speech Language Pathologist and Vocal Pedagogue

The speech language pathologist and vocal pedagogue work with patients to improve singing and speaking efficiency, to eliminate vocal abuse, to correct misuse, and to encourage vocal hygiene. Singers should understand that vocal abuse during speaking is intimately connected with the singing voice. They are taught to avoid cervical strain, and they learn proper breathing patterns, improve posture, and develop a soft glottal attack when speaking. The goal is to improve laryngeal efficiency and thereby limit laryngeal trauma during singing and speaking.[30]

The role of the vocal pedagogue is complex. Classical vocalists should improve classical technique. Commercial singers, however, should optimize glottal efficiency when singing without producing a classical sound. Training, therefore, differs for classical and commercial vocalists. Areas emphasized for classical artists include breath support, body alignment, stable laryngeal position low in the neck, and maintenance of a lower subglottal pressure than for other singing styles.[94] This lower pressure enables the classical vocalist to produce the singer's formant, allowing greater voice projection with less vocal effort. Nonclassical or commercial singers should also concentrate on breath support and body alignment, but they do not incorporate the singer's formant. Therefore, these performers must sing more loudly to be heard over instruments and other singers. Commercial singers must be educated on the proper use of electronic amplification, which is a substitute for loud singing. Other considerations for commercial singers are precise vowel integrity, phrasing similar to that of speech, and delayed onset of vibrato. Vocal efficiency should be improved without changing the performer's style or developing a classical sound. The use of full-length mirrors and videotaped recordings while performing help educate the performer. Vocal efficiency is also improved with appropriate warm-up and range-building exercises.[95] Sabol and associates[33] used objective aerodynamic testing to show the benefit of vocal exercise in singers.

Surgical Therapy

Before surgical intervention, behavioral and medical interventions should be maximized. Vocal hygiene, avoidance of vocal misuse, and resolution of vocal abuse should be accomplished. Patients failing to achieve these goals will have recurrent problems. Surgery is relatively contraindicated in patients who cannot comply with the recommendations of hygienic voice production from a speech language pathologist and vocal pedagogue. All patients learn to develop a soft glottal attack, which is vital for postoperative rehabilitation. The overall effect of maximizing medical and behavioral management is to reduce the need for surgery, lessen the incidence of lesion recurrence, shorten the postoperative recuperative time, and improve the overall postoperative outcome.

The decision to operate on the larynx of a vocal professional is often difficult. The singer should evaluate the risks and benefits and obtain a second opinion. It is important to realistically counsel the patient about the possible outcomes. The singer should understand that the singing or speaking voice may never be the same and that he or she may never perform at the same level again. Rehabilitation and healing after microsurgery of the larynx require 3 to 9 months and are often frustrating for the vocal professional. It is this period, working with the speech language pathologist and vocal pedagogue, during which the vocal professional needs the greatest amount of determination and encouragement. In most cases, surgery is performed only when the patient cannot perform at the required level or cannot maintain an acceptable performance schedule. Recurrent vocal fold hemorrhage from a varix and an enlarging lesion in the presence of efficient voice production styles are other indications for surgery.

After the need for surgery has been determined, atraumatic establishment of the airway in the surgical suite is the next concern. This task should be performed not by an inexperienced physician but by the surgeon or an experienced anesthesiologist. Gentle intubation should be performed with an endotracheal tube of the smallest possible caliber. The laryngologist should consult with the anesthesiologist before a vocal professional is intubated for any procedure. If possible, the laryngologist should offer his or her services for the intubation. Photographic documentation in the operative suite is performed immediately before and after the procedure. Zero-, 30-, 70-, and 120-degree telescopes can be used as needed to obtain optimal views of the vocal folds and to examine areas difficult to access, such as the depths of the laryngeal ventricle and the undersurface of the vocal folds.[96,97] The procedure is videotaped through the operating microscope.

The major determinants of a good postoperative result during laryngeal microsurgery are the conservation of normal mucosa, integrity of the vocal ligament, and the creation or maintenance of a straight vocal fold edge (see Fig. 61-5).[53,98,99]

Superficial Vocal Fold Lesions

Vocal fold nodules that have not resolved with medical and speech therapy and polyps that cause dysphonia can be surgically excised. Bilateral vocal fold lesions are of significant concern. It is common to remove the larger lesion in the hope that the smaller lesion will resolve. However, a lesion of any sort on the opposite fold may imply technical problems or hyperfunctional technique. Bilateral lesions predispose the patient to a less than optimal result; because bilateral lesions are more likely to be associated with hyperfunctional techniques, the resolution of the smaller lesion is the exception rather than the rule. Often, both lesions should be surgically removed, creating the risk of scarring and stiffness on both vocal folds.

Surgical therapy is always individualized. The choice of surgical approach is based on a thorough understanding of vocal fold anatomy and physiology. The goal of surgery is to restore the normal glottal configuration without the removal of uninvolved surrounding mucosa or excessive dissection in the superficial layer of the lamina propria. Superficial lesions represent a response to injury and reside almost exclusively in the superficial layer of the lamina propria. Therefore, surgery is limited to this region. A microflap approach with a medially placed incision is well suited to removal of these types of lesions.[100] After vasoconstriction of the laryngeal mucosa, an incision is made just over the lesion; the vocal ligament is identified through the use of a combination of blunt and sharp dissection with microsurgical instruments. The mucosa and superficial layer of the lamina propria encompassing the lesion are freed from the underlying vocal ligament by dissection in the superficial layer of the lamina propria, with great care

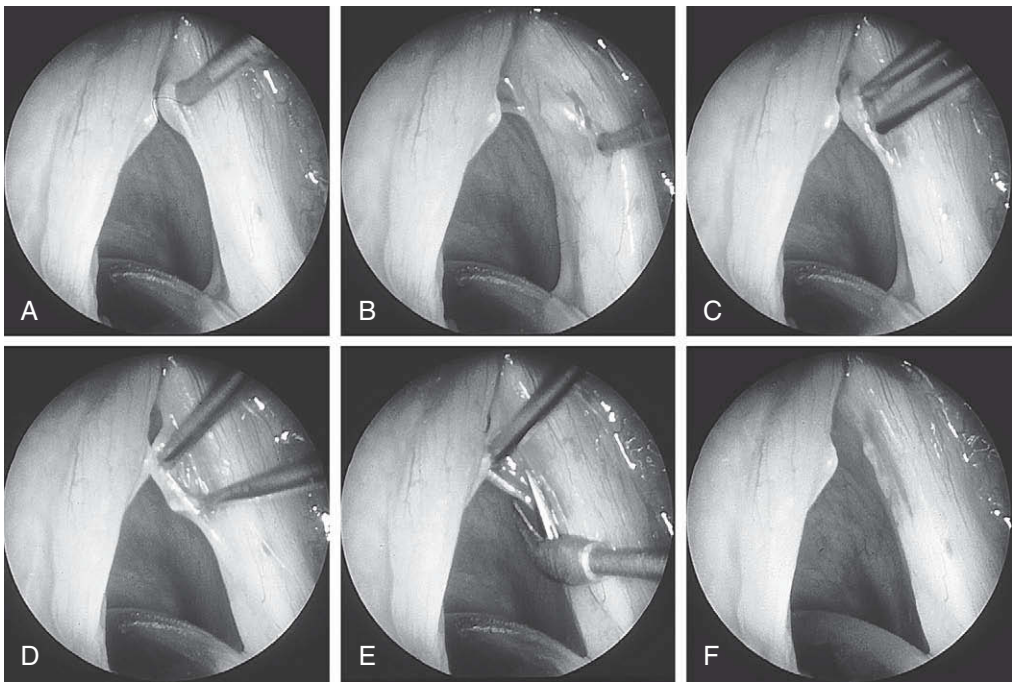

Figure 61-6. Intraoperative photographs of lesion excision through a medial microflap approach. **A,** The sickle knife is used to make an incision over the lesion on the medial surface of the vocal fold. **B,** A small angled probe, a flap elevator, is used to elevate mucosa from the medial and superior surfaces of the vocal fold around the lesion. **C,** The lesion is bluntly dissected free from the underlying vocal ligament. **D,** The lesion is peeled off a portion of the overlying vocal fold cover. **E,** The lesion and a small portion of the cover are excised. **F,** The previously created flaps are redraped in position to cover the medial surface of the vocal fold. *(From Courey MS, Garrett GG, Ossoff RH. The medial microflap for excision of benign vocal fold lesions.* Laryngoscope. *1997;107:340.)*

taken to remove only the involved mucosa. This approach often leaves a nearly imperceptible mucosal defect at the conclusion of the procedure (Fig. 61-6).

Cysts

Vocal fold cysts are diagnosed and differentiated from nodules or polyps by laryngovideostroboscopy. Cysts that fill the superficial layer of the lamina propria are often tethered to the vocal ligament, frequently resulting in a loss of the mucosal wave over the lesion. More superficial lesions such as nodules tend to be associated with a dampened yet perceptible mucosal wave.[32] Cysts and other lesions that do not separate easily from the vocal ligament on intraoperative palpation are approached via a lateral microflap technique.[31,101] This technique involves an incision along the superior aspect of the vocal fold lateral to the intracordal lesion. The vocal ligament is identified, and dissection occurs in the superficial layer of the lamina propria medially toward the lesion. The microflap is gently retracted medially, usually with a velvet eye microlaryngeal suction or with a flap elevator, and the cyst is sharply and bluntly removed from the vocal ligament and the overlying mucosal cover layer. After it is removed, the mucosal flap is redraped in place (Fig. 61-7).

Vocal Fold Varix

Varices of the vocal fold are evaluated under high magnification, and palpation is used to alternately occlude and examine the feeding and draining vessels. Then the vessels undergo vasoconstriction with chilled 1 : 10,000 epinephrine, and an iced saline pledget is placed deep to the vocal fold to protect the endotracheal tube cuff. The carbon dioxide laser is slightly defocused and used at 1- to 2-W power. The feeding and then the draining vessels are photocoagulated. The medial surface of the vocal fold is avoided. The vascular malformation is then coagulated. If still present, the mass is removed with use of the medial microflap approach.[59] Clinical experience from a few centers using angiolytic lasers (pulsed potassium titanyl phosphate and pulsed dye laser)[102] suggests that they may play a role in the treatment of these lesions; however, large feeding vessels may still require excision (Fig. 61-8).

Postoperative Care

After the surgery, general laryngeal hygiene is reemphasized to the patient. In addition to hydration and the use of guaifenesin, perioperative antireflux medications are strongly recommended for most patients. Complete voice rest is instituted after surgery. In patients with minimal mucosal excision and limited disruption of the submucosal layer of the lamina propria, this period may last 5 to 7 days. Ten to 14 days of complete voice rest is recommended in cases in which extensive vocal fold dissection or revision surgery has been performed.

Healing after laryngeal microflap surgery can be divided into four phases (Table 61-3). The first phase in the immediate postoperative period lasts 5 to 14 days and consists of complete voice rest and hydration. Healing occurs between the vocal fold cover and the underlying vocal ligament. In cases in which mucosal excision is required, healing by secondary intention occurs.

The second phase begins 1 to 2 weeks after surgery. This is a time of voice rehabilitation that occurs under the guidance and observation of a speech language pathologist. Laryngovideostroboscopy is usually performed after the second or third week. Pliability of the vocal fold and return of the mucosal wave are assessed. Rarely, vocal fold hemorrhage is noted, and further voice rest is required. This phase begins with graduated voice use. The first day, the patient speaks for 5 minutes. The phonation time is doubled each day until the patient is returned to full conversational speech, usually by the end of the third or fourth postoperative week. If voice use causes pain, the patient is asked to decrease the amount of speaking and to contact the physician. The speech language pathologist stresses easy-onset phonation, avoidance of vocal abusive behaviors, and the need to use appropriate pitch and vocal intensity. Biofeedback retraining is used during this time.

The third phase of healing occurs during the second and third months after surgery. The behaviors learned from the speech language pathologist are continued, and vocal and singing reeducation is begun

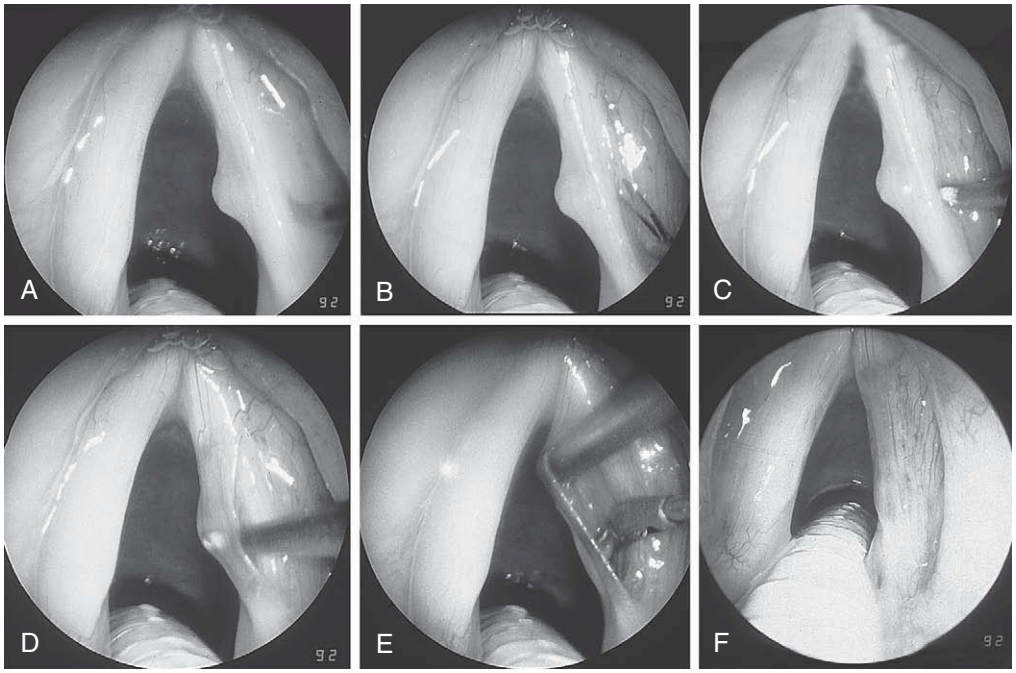

Figure 61-7. Intraoperative photographs of lesion excision through a lateral microflap approach. **A,** A sickle knife is used to make an incision on the superior surface of the vocal fold. **B,** The incision is further defined with upcutting scissors. **C,** A flap elevator is used to elevate the microflap. **D,** Dissection occurs between the vocal ligament and mucosa. **E,** The lesion is removed from the vocal ligament. **F,** The mucosal microflap is redraped into position. *(From Courey MS, Gardner GM, Stone RE, Ossoff RH. Endoscopic vocal fold microflap: a three year experience.* Ann Otol Rhinol Laryngol. *1995;104:267.)*

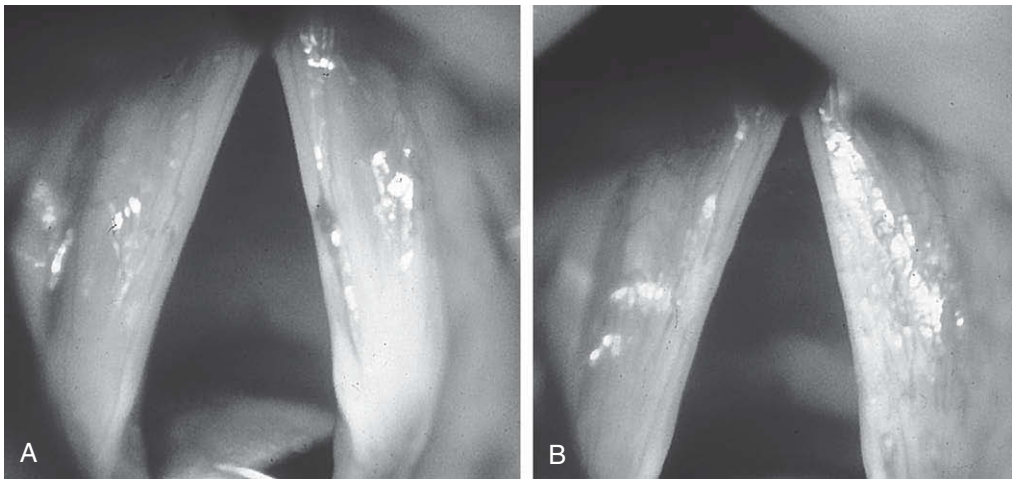

Figure 61-8. A professional singer with a microvascular lesion of the true vocal fold. **A,** Preoperative photograph. **B,** Postoperative appearance immediately after photocoagulation with the carbon dioxide laser at 1500 watts/cm^2. *(From Rubin JS, Sataloff RT, Korovin GS, eds.* Diagnosis and Treatment of Voice Disorders. *Clifton Park, NY: Thomson/Delmar Learning; 2003.)*

under the guidance of a vocal pedagogue. All singers work with a vocal pedagogue regardless of their style of singing or previous vocal training. The patient relearns how to sing from the basic level. Maladaptive behaviors are noted early and addressed by the pedagogue.

After 3 months, the average patient can return to professional activity, which constitutes the fourth phase of healing. Patients should be monitored with interval examinations for 24 months after surgery to assess for continued improvement or potential recurrence of the lesion.

Related Surgical Procedures

Professional voice patients undergo many nonlaryngeal surgical procedures involving the upper airway. They should understand that any procedure that potentially alters the anatomy or function of the supraglottal vocal tract (e.g., tonsillectomy, septoplasty, sinus surgery, palatal surgery) can alter the vocal resonance. Professional voice patients should be counseled about this possibility.

A well-performed tonsillectomy should not cause vocal professionals significant long-term difficulty. It does, at least transiently, affect the ability to modify that area of the resonator.[103] Tonsillectomy alters the frequency of the fourth formant in nonsingers but not in classically trained vocalists.[104] However, any significant palatal or faucial arch scarring could lead to laryngeal hyperfunction, which is caused by altered oropharyngeal sensation. The singer's vocal feel or sensory feedback is altered, resulting in a change in the singer's delivery.

Table 61-3

Phases of Postoperative Recovery after Laryngeal Microflap Surgery

Phase	Time	Activity
I	7-14 days	Voice rest
II	7-28 days	Graduated voice use with speech language pathologist
III	4-12 weeks	Vocal reeducation (singing with pedagogue)
IV	3-18 months	Professional activity

Laser-assisted uvulopalatoplasty has become a popular management for snoring. This procedure should result in at least a temporary voice change. Compensation should be possible for well-trained vocalists, much as for those undergoing tonsillectomy. If the surgery is performed, the stages should be spread out over many months to allow the artist to compensate for the palatal changes.

Adenoidectomy, septoplasty, sinus surgery, or turbinectomy in a singer with a significant nasal obstruction should be done very conservatively, if at all. The development of even a small degree of hypernasality could significantly alter the patient's singing voice.[105,106]

Hearing is often neglected in singers. Classical singers are taught to sing by feel and not by what they hear. However, many singers have difficulty in doing so. Baseline audiometric evaluations are recommended in all professional and serious amateur singers. Ear-level monitors with selective input have been of benefit to commercial singers. These monitors deliver stage sounds, mixed by the sound engineer, back to the performer at a comfortable intensity. They allow singers to protect their hearing, sing at the proper intensity level, and not succumb to the tendency of oversinging in the concert environment (the Lombard effect).

Conclusion

A singer's body is a vocal instrument, of which the larynx represents the most important portion. Education and behavior modification can enable singers to maximize their gifts. The maintenance of good vocal hygiene and regular reminders about abusive speaking and singing behaviors are part of this process. Even the most experienced singers may have to return to work with a vocal pedagogue after an upper respiratory infection or when they are busy recording or touring.

Professional vocalists are an interesting and challenging group of patients. Management should be undertaken by a coordinated team of professionals well versed in their care.

CHAPTER SIXTY-TWO

Benign Vocal Fold Mucosal Disorders

Robert W. Bastian

Key Points

- The two most common risks for vocal fold mucosal vibratory injury are high intrinsic tendency to use the voice (talkativeness, extroversion) and a high extrinsic "opportunity or necessity" to use the voice (driven by occupation, family needs, social activities, and avocations).
- Visible vocal fold lesions from overuse may not cause an audible change in the *speaking* voice.
- Visible vocal fold lesions causing phonatory mismatch at the free margin or mucosal stiffness are "always" detectable *audibly*, in the singing voice, provided that the examiner knows how to elicit upper-range vocal tasks.
- Small or subtle vocal fold lesions may escape *visual* detection until the larynx is viewed with high magnification, sometimes requiring topical anesthesia, with vocalization in the upper range.
- With few exceptions, brief initial speech pathology evaluation and treatment are indicated when vocal fold injury is clearly due to overuse, misuse, or abuse of the voice. Speech therapy alone may suffice if vocal improvement is adequate to patient needs, otherwise it serves as preparation for vocal fold microsurgery.
- Key requirements for successful vocal fold microsurgery are (1) detailed knowledge of vocal fold microarchitecture and vibratory physiology to guide surgical precision, (2) proven technical ability of the surgeon, (3) preoperative and postoperative laryngeal videostroboscopy examination to diagnose clearly at patient presentation, and to assess results, with the patient as a participant, after surgery, and (4) access to voice-qualified behavioral (speech pathology) support.
- Singing voice symptoms of mucosal injury are loss of high soft singing, increased day-to-day variability of singing voice capabilities, phonatory onset delays, reduced vocal endurance, and a sense of increased effort.
- Capillary ectasia can be an incidental finding not requiring treatment. Surgical intervention may be indicated, on the other hand, when the ectasia causes one or more of the following: a tendency to decreased vocal endurance (reduced voice use time to huskiness), intermittent bruising, and a hemorrhagic polyp.
- Contact ulcer and granuloma are best thought of as an exuberant healing response to injury. Injury may be from aggressive chronic throat clearing, aggressive coughing, or endotracheal tube injury. Some believe that acid reflux is a major contributor. Treatment is generally supportive over many months during the wait for maturation, pedunculation, and spontaneous detachment; surgical removal is nearly always followed by recurrence.
- Marsupialization of saccular cysts is sometimes followed by recurrence. Therefore, when possible, complete removal of saccular cysts appears to be preferred.
- Recurrent respiratory papillomatosis is caused by the human papillomavirus.

Benign vocal fold mucosal disorders (e.g., vocal nodules, laryngeal polyps, mucosal hemorrhage, intracordal cysts, mucosal bridges, glottic sulci) seem to be caused primarily by *vibratory injury* (excessive amount and/or manner of voice use). Review of thousands of patients reveals that an expressive, talkative personality correlates best with most of these disorders. Occupational and lifestyle vocal demands appear to be additional but lesser risks, unless these demands are extreme. Occasionally, injury can occur as a "fluke" based on one episode of vocal strain in an otherwise moderate voice user. Cigarette smoking is a cofactor for smoker's polyps (Reinke's edema). Infection, allergy, and acid reflux may also potentiate vibratory injury.

Nonsingers with benign vocal fold mucosal disorders present because of change in the sound or capabilities of the *speaking* voice. By contrast, *singers* may have no issues with their speaking voices but may seek help because of *singing* voice limitations, usually in the upper range. Benign vocal fold mucosal disorders are significant because of the importance of spoken or sung communication and the voice's contribution to identity.

Benign vocal fold mucosal disorders are common. More than 50% of patients seeking medical attention because of voice change have a benign mucosal disorder. Even before the laryngeal videostroboscopy era, when subtle and small lesions may have been missed, Brodnitz[1] reported that 45% of 977 patients had a diagnosis of nodules, polyps, or polypoid thickening. From the same era (1964-1975), Kleinsasser[2] reported that slightly more than 50% of 2618 patients seen for a voice complaint had one of these benign entities.

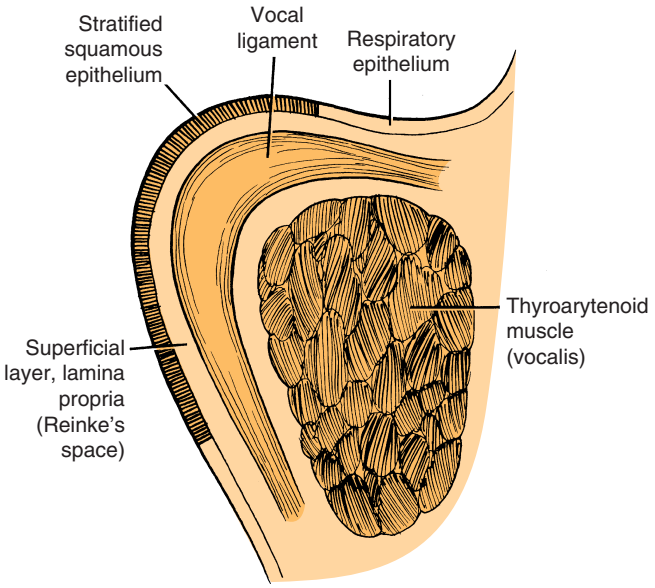

Figure 62-1. Cross section of the vocal fold.

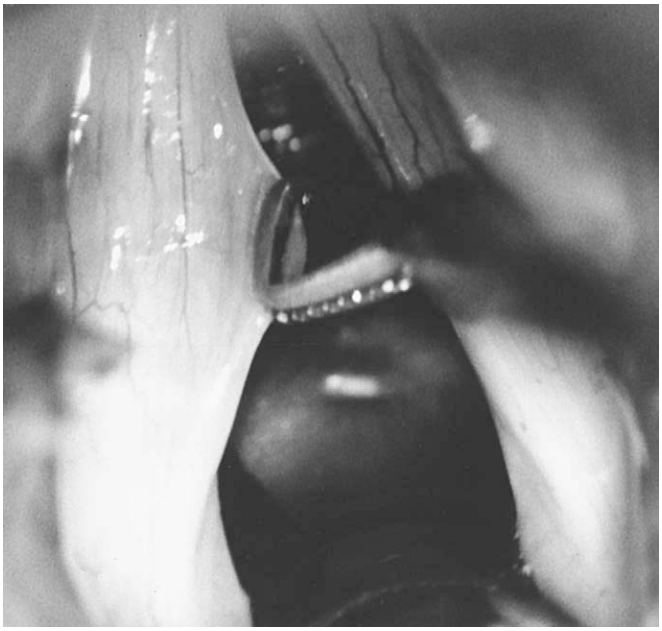

Figure 62-2. Gentle medial retraction shows the relative decoupling of the mucosa from the underlying, nondeformed vocal ligament.

Anatomy and Physiology

The anatomy most relevant to the benign vocal fold mucosal disorders is the microarchitecture of the vocal folds, as seen on whole-organ coronal sections in a study of cancer growth patterns[3,4] and in the work of Hirano.[5] Medially to laterally, the membranous vocal fold is made up of squamous epithelium, Reinke's potential space (superficial layer of the lamina propria), the vocal ligament (elastin and collagen fibers), and the thyroarytenoid muscle. Perichondrium and thyroid cartilage provide the lateral boundary of the vocal fold (Fig. 62-1).

The vocal folds move *as a whole* between abducted and adducted positions for breathing and phonation, respectively. The mucosa (epithelium and superficial layer of the lamina propria [Reinke's potential space]), which covers the vocal folds, is the chief oscillator during phonation (continuous adduction during expiratory flow of pulmonary air); thus, one might speak of vocal fold *mucosal* vibration rather than vocal *fold* vibration. In a canine study that supports this idea, Saito and associates[6] placed metal pellets at varying depths into the vocal fold (e.g., epithelially, subepithelially, intramuscularly) and used radiographic stroboscopy to trace their coronal plane trajectories during vibration. Pellet trajectories of the mucosa were far wider than those of the ligament or the muscle. Thus, primarily the vocal fold mucosa oscillates to produce sound.

'The work of Hirano[7] provides an explanation for these observations. Hirano described the vocal fold muscle as the body of the fold, the epithelium and superficial layer of the lamina propria (Reinke's potential space) as the cover, and the intermediate layers of collagenous and elastic tissue (vocal ligament) as the transitional zone (see Fig. 62-1). Because of the different physiologic stiffness characteristics of these layers, they are somewhat decoupled mechanically from each other during phonation. Decoupling is graphically illustrated in Figure 62-2 (mucosa being stretched). This decoupling allows the mucosa to oscillate with some freedom from the ligament and muscle. An analogy can be made to the relative freedom from the paddle experienced by the red rubber ball and elastic band in a child's paddleball toy. During phonation, pulmonary air power supplied to adducted vocal folds is transduced into acoustic power. To accomplish this, pulmonary air is passed between appropriately adducted vocal folds. At this point, the vocal fold mucosa vibrates passively according to the length, tension, and edge configuration determined by the intrinsic muscles and elastic recoil forces of the vocal fold tissues. Figure 62-3 shows the maximum open and closed phases of one vibratory cycle, as seen during laryngeal videostroboscopy. Further details concerning the mucosa's vibratory behavior can be found in the works of Baer[8] and Hirano[5] and in Chapter 57.

Other important microanatomy includes glands in the supraglottic, saccular, and infraglottic areas, which produce secretions that bathe the vocal folds during vibration.

Evaluation of the Patient: General Principles

The *necessary* and *sufficient* elements for diagnosis and management of benign mucosal disorders are (1) a skillful history, (2) a perceptual assessment of vocal capabilities and limitations, particularly through elicitation of vocal tasks designed to detect mucosal disturbances, and (3) a high-quality laryngeal examination (often including laryngeal videostroboscopy). In addition, certain measures of phonatory function (aerodynamic, acoustic), although not crucial for diagnosis, may be of interest for study, documentation of the disorder's physiologic effects, and assessment of improvement after treatment.

History

Besides the usual items in the general medical history, the voice history should focus in particular on the following list of items, which may be best captured via use of a questionnaire[9,10]:

1. Onset and duration of vocal symptoms.
2. Patient beliefs about causes or exacerbating influences.
3. Common symptom complexes.
4. Talkativeness profile (intrinsic, personality-based tendency to use voice).
5. Vocal commitments or activities (extrinsic requirement, invitation, or opportunity to use voice), including voice type and training, if patient is a performer.
6. Other risk factors.
7. Patient perception of the severity of the disorder.
8. Vocal aspirations and consequent motivation for rehabilitation.

Onset

It is appropriate during history-taking to test the hypothesis that a patient who complains of frequently recurring bouts of vocal dysfunc-

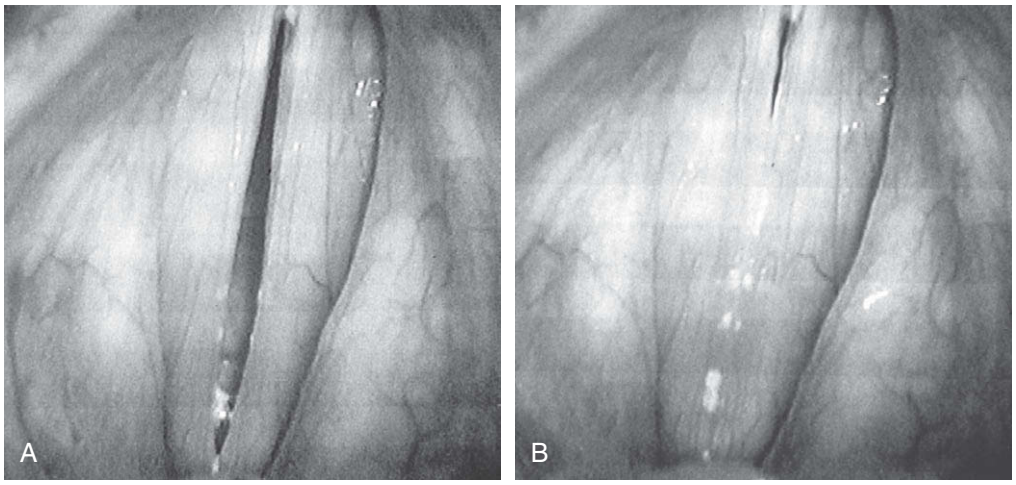

Figure 62-3. The maximum open **(A)** and closed **(B)** phases of an apparent single vibratory cycle as seen during videostroboscopy. The moving part is primarily mucosa, with little participation of ligament or muscle.

tion may be experiencing exacerbations of a more chronic overuse disorder. Such a patient, who is often found to be living "at the edge" vocally on the basis of an assessment of vocal personality, lifestyle, vocal commitments, and voice production, may present because a small increase of vocal activity or an upper respiratory infection has thrown him or her "*over* the edge." In this situation, without appropriate care, both the patient and the clinician may tend to focus on the recent or current upper respiratory infection (e.g., providing supportive treatments or antibiotics) rather than seeing past this acute issue to recognize the need for the more sophisticated behavioral therapy appropriate for a chronic "vocal overdoer."

Patient Beliefs about Causes

Clinicians may prudently maintain flexibility in their own minds regarding patient beliefs. Example: A patient may insist that the voice disorder results from allergies or acid reflux. After thorough consideration, the clinician may instead find that the patient's "vocal overdoer" status (see later) is primary, and that allergy and acid reflux in that patient actually happen to be inconsequential by comparison—if present at all! Of course, in this instance, considerable time for teaching, meeting objections, and so on, at the conclusion of the consultation is required.

Common Symptom Complexes

As for many other types of voice disorders, a characteristic symptom complex accompanies benign mucosal disorders. Nonsingers, who often have moderate to large mucosal disturbances before they seek medical attention, usually describe chronic hoarseness with exacerbations at times of increased voice use. Singers may *not* note speaking voice symptoms but rather describe (1) exaggeration of day-to-day variability of singing capabilities, (2) increased effort necessary for singing, (3) reduced vocal endurance, (4) deterioration of high soft singing, and (5) delayed phonatory onset and air wastage (breathiness).

Talkativeness Profile (The "Vocal Overdoer" Syndrome)

The factor that correlates most strongly with the formation and maintenance of many benign vocal fold mucosal disorders appears to be personality. A simple but powerful way to assess this issue is to ask the patient to rate himself or herself on a 7-point talkativeness scale, in which 1 is very untalkative, 4 is averagely talkative, and 7 is unusually talkative. (In asking this question, one must stress that this scale deals with innate predisposition, not the demands of work or lifestyle.) Virtually all patients with nodules and polyps, and even cysts and sulci, rate themselves at 6 or 7, except for persons who work in vocally extreme occupations (e.g., financial trading).

Vocal Commitments

To assess vocal commitments and activities, the clinician or questionnaire should inquire briefly about occupation, voice type and level of training, and the nature and extent of vocal activities related to family life, child-care, politics, religion, hobbies, athletics, and musical rehearsal and performance.

Other Risk Factors

Other risk factors are tobacco and alcohol use, acid reflux, insufficient fluid intake, certain drying medications, systemic illnesses, and allergies. Even when the history is positive for one of these factors, it is usually a secondary issue in comparison with "7-ness."

Patient Perception of Severity and Vocal Aspirations and Consequent Motivation for Rehabilitation

Exploration of the patient's perception of the severity of the voice problem, vocal aspirations, and motivation also is important. For example, the clinician may be confronted by a patient who only wants to be reassured that the problem is not cancer. Even with a diagnosis of large smoker's polyps with severe range virilization and dysphonia, management for such a patient might appropriately be short-term and supportive, consisting primarily of counseling about smoking cessation education. Another patient may have a normal speaking voice but have upper singing voice limitations caused by small nodules. In this patient, therapy might be intense and eventually include surgery for the patient with a normal speaking voice who, to pursue a competitive singing career, must be relieved of extreme upper singing voice limitations due to small nodules.

Vocal Capability Battery

The vocal capability battery is an auditory-perceptual assessment of vocal capabilities and limitations. It assesses, macrophenomenologically, the two crucial questions "What can't this voice do that it should be able to?" and "What does this voice do that it shouldn't?" This process involves *elicitation* of a variety of vocal tasks, followed by auditory-perceptual assessment of the voice production that results. The vocal capability battery is an often-neglected part of the diagnostic process that provides the best means of understanding the nature and severity of the voice disorder. To be most efficient, this part of the diagnostic process is performed by the same clinician who takes the history and performs the laryngeal examination. Alternatively, a second clinician can perform this assessment, but for best results, the findings of vocal capability elicitation are immediately correlated with the other two components of the diagnostic process.

Vocal capability elicitation and interpretation require that the examiner have good pitch-matching abilities, a reasonably normal

voice, extensive familiarity with his or her own vocal capabilities (and limitations, if any), intimate familiarity with normal singing voice capabilities according to age, sex, and voice classification, and the willingness to model and elicit with his or her own voice. Also needed is a frequency reference, such as a small electronic keyboard.

In voice clinics where expert vocal capability elicitation and assessment are not available or are not immediately correlated with history and laryngeal examination, clinicians may overlook or reject the power and centrality of this part of the evaluation. They may instead rely on various items of equipment that measure components of vocal output (e.g., acoustic, aerodynamic). Although useful for quantification, documentation, and some biofeedback applications, this equipment is cumbersome and expensive, and the data it collects are time-consuming to interpret and, most importantly, diagnostically weak in comparison with those of the vocal capability battery, which can answer far more quickly, powerfully, and synthetically the question "What's wrong with this voice?"

The basic vocal capabilities and phenomena to be tested are (1) average or anchor speech frequency, (2) maximum frequency range, (3) projected voice and yell, (4) very-high-frequency, very-low-intensity tasks that detect mucosal disturbances,[11] (5) register use and phenomena, (6) maximum phonation time, and (7) instability and tremors.

The ability to perform high-frequency, low-intensity tasks is the single most important part of the vocal capability battery in persons with benign mucosal disturbances. Upon elicitation of these sorts of tasks, mucosal disorders are suggested by a loss of expected range under these performance constraints, as well as onset delays, air escape, and lack of tonal clarity. The clinician should also search for inconsistencies between spoken and sung capabilities and should informally note the patient's sincerity of effort and skill. Basic vocal capability testing requires only a few minutes to perform because the examiner focuses primarily on the extremes of physical capability and secondarily on vocal skill.

As stated, the vocal capability battery—coupled with the initial voice history and then subsequent laryngeal examination—is crucial in diagnosing a voice disorder and in directing subsequent management. For example, signs of a mucosal disturbance (e.g., detection of air escape, onset delays, loss of clarity and range) during assessment of the ability to perform high-frequency, low-intensity tasks minimize the possibility that a singer's normal-sounding speaking voice during history-taking will subconsciously bias the clinician to selectively perceive normal vocal folds when, in fact, small vocal nodules are present.[11a] The vocal capability battery also provides insight into the severity of the patient's vocal limitations, which can then be correlated with the visual examination to help determine, along with the patient's needs and motivation, the intensity and direction of management.

Office Examination of the Larynx

The laryngeal mirror should provide three-dimensional viewing and good color resolution but, in practice, offers poor visualization in many cases. In other cases, visualization is good, but only during phonation, because the view is obstructed by the epiglottis during respiration. In addition, no permanent image of the larynx results from this examination technique. Because the physician must therefore remember the lesion or document it with a simple sketch, precise critique of the effectiveness of the therapy chosen may not be possible. Rigid and also flexible laryngeal scopes often allow a clearer view, particularly during respiration. When used with the naked eye, however, they have similar disadvantages to those of the mirror. The fiberoptic nasolaryngoscope or a newer "chip-tip" video-endoscope is especially important in a patient who is difficult to examine because of unusual anatomy or an exceptional gag reflex. Even with these technologies, however, it is possible to overlook subtle-to-small mucosal changes unless the larynx is topically anesthetized to allow a close approach of the tip of the fiberscope to the vocal folds. With topical anesthesia, the vocal folds, subglottis, and trachea can be examined easily (Fig. 62-4).[12,13]

Strobe illumination added to any of these examining instruments allows mucosal vibratory dynamics to be evaluated in apparent slow motion (e.g., to understand mucosal scarring, to distinguish cysts from nodules). Adding a video camera and recording device (computer hard drive or tape) to the rigid or flexible scopes brings additional advantages; for example, a patient's understanding and motivation are facilitated if he or she views the video documented examination. Also, such recordings enable other clinicians (otolaryngologists, speech pathologists, voice teachers) to participate more easily in assessment and management, serve as permanent records that document the result of voice therapy or surgery, and enhance teaching of residents.

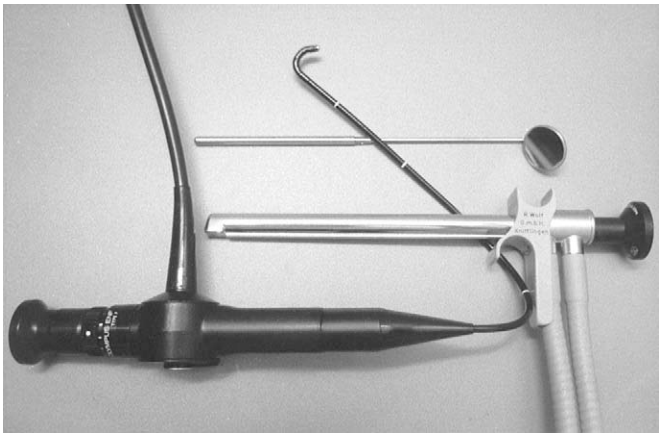

Figure 62-4. Three of the most commonly used tools for viewing the larynx: a mirror, a 90-degree telescope, and a flexible fiberoptic nasolaryngoscope. A later addition, the distal chip endoscope, which looks nearly identical but has an internal video chip rather than optics, is supplanting the fiberoptic scope.

Objective Measures of Vocal Output

Skillful "triangulation" on the voice problem through the use of the voice history, auditory-perceptual evaluation of vocal capabilities and limitations, and high-quality laryngeal examination is sufficient for a clear diagnosis and description of the problem. Although weak diagnostically due to nonspecificity, aerodynamic and acoustic information may be useful to quantify and document severity and change in response to treatment, to deepen understanding in the research arena, and to assist in some helpful biofeedback applications.

Direct Laryngoscopy and Biopsy

When videostroboscopy with magnified viewing is available, lesions that are suspicious for cancer or papillomatosis can nearly always be distinguished easily from nodules, polyps, and cysts. Therefore, removal of these latter entities is appropriate only within a comprehensive plan for treatment or voice restoration and rarely, if ever, for preliminary tissue diagnosis.

General Management Options

Hydration

Adequate hydration promotes free flow of lubricating secretions, which help the vocal fold mucosa withstand the rigors of vibratory collisions and shearing forces. Consistent supply of fluids seems to be particularly important. An expectorant, such as guaifenesin, may also help when secretions are viscid.

Sinonasal Management

Patients often incorrectly attribute chronic hoarseness to sinonasal conditions. Existing sinonasal problems should be managed on their own merits; however, the clinician may need to help diminish the patient's perception of the contribution of these problems to a voice disorder in favor of more likely behavioral causes. When optimal laryngeal function is of concern, as in a vocal performer, nasal conditions should be managed locally (topically) when possible. The reason is that many systemic drugs (e.g., oral decongestants, antihistamine-decongestant combinations) dry not only nasal secretions but also secretions in the larynx, where a continuous secretional flow is important for proper vibratory function and mucosal endurance, particularly under demand-

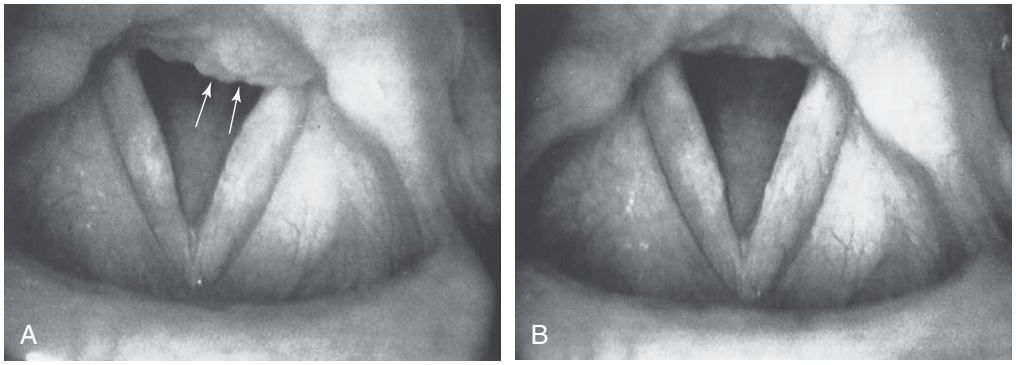

Figure 62-5. Chronic laryngitis in a patient with severe acid reflux, a history of smoking, and excessive voice use. **A,** Note the interarytenoid pachyderma (*arrows*) and loss of normal color differential between the true folds and supraglottic mucosa. Broad-based convexity of the true vocal fold margins suggests diffuse submucosal edema. **B,** Appearance 3 weeks after institution of antireflux measures. Note the resolution of the interarytenoid pachyderma.

ing phonatory conditions. Medications that affect voice minimally are the topical nasal decongestants, which should be used for only a few days before the nasal mucosa is allowed to rest, so as to avoid *rhinitis medicamentosa*. Profuse rhinorrhea that accompanies the common cold can also be managed with ipratropium bromide inhalations.[14,15] Corticosteroid inhalers are invaluable for the management of nasal allergies. Activating pump-action nasal inhalers without any inspiratory airflow avoids the alleged risk of the effects of nasally applied corticosteroid on the vocal folds.

Management of Acid Reflux Laryngopharyngitis

In a person with an incompetent lower esophageal sphincter or hiatal hernia, acid reflux into the pharynx and larynx during sleep can lead to chronic laryngopharyngitis. Such persons may or may not experience one or more of the following symptoms: exaggerated "morning mouth," excessive phlegm, scratchy or dry throat irritation that is usually worse in the morning, habitual throat clearing, and huskiness or lowered pitch of the voice in the morning. The larynx may show characteristic erythema of the arytenoid mucosa, interarytenoid pachyderma, or contact ulcers; laryngeal findings may, however, be subtle (Fig. 62-5).

Basic management of this condition consists of avoiding caffeine, alcohol, and spicy foods; eating the last meal of the day (preferably a light one) no fewer than 3 hours before retiring; using bed blocks to place the bed on a mild head-to-foot slant; and taking an antacid at bedtime, an H_2 blocker 2 or 3 hours before bed, or a proton pump inhibitor 30 to 60 minutes before dinner.

Acute Mucosal Swelling of Overuse

Public speakers or singers may sometimes perform of necessity despite acute, noninfectious mucosal swelling resulting from recent overuse of the voice. A careful strategy of *relative* vocal rest in context is needed, and pre-performance warm-up, along with solid vocal technique, may be sufficient for the patient to "get through." A short-term, high-dose, tapering regimen of corticosteroids can also be useful in this context, as part of a larger strategy to help the patient through the performance.

Laryngeal Instillations for Mucosal Inflammation

In past years more so than currently, laryngologists have used drugs such as mono-*p*-chlorophenol, topical anesthetics, mild vasoconstrictors, sulfur vapors, certain oils, and other substances for reduction of swelling, soothing effect, or promotion of healing. Some physicians and patients believe in the efficacy of such management, though it is supported only by anecdotal reports.

Systemic Medicines that May Affect the Larynx

Medicines that patients take for other reasons (e.g., antidepressants, decongestants, antihypertensives, diuretics) may dry and thicken normal secretions, thereby reducing their protective lubricating effect on the vocal folds and conceivably making the vocal fold mucosa more vulnerable to the development of benign disorders. History-taking should include inquiry about these medicines.

Voice Therapy

A course of therapy by a voice-qualified speech pathologist is frequently appropriate in patients with benign vocal fold mucosal disorders, given the common relationship of such disorders with vocal overuse, abuse, or misuse. Vocal nodules in particular are expected to resolve, regress, or at least stabilize under a regimen of improved voice hygiene and optimized voice production. In some cases, however, success is defined as having achieved a more consistent voice, without the exacerbations of hoarseness and even aphonia, even if that now-more-reliable voice remains somewhat husky. In other cases, success may require resolution of all upper voice limitations. If surgery becomes an option because the mucosal disorder has not resolved completely and the patient regards residual symptoms and vocal limitations as unacceptable, voice therapy will have optimized the patient's surgical candidacy, by educating him or her additionally about the surgical process, and decreased the risk of postoperative recurrence.

During evaluation, the speech pathologist gathers information on behavior that may adversely affect the voice and establishes a program to eliminate injurious behavior. Voice-qualified speech pathologists also model and elicit a battery of spoken and sung vocal tasks to make plain to themselves and patient the type and degree of impairment from the lesion. They also assess the skill and appropriateness of voice production for both speaking and singing. Depending on the results of this second part of the evaluation, the speech pathologist may help the patient optimize the intensity, average pitch, registration, resonance characteristics, overall quality, general and vocal tract posture, and respiratory support for voice production. For singers, the singing teacher plays an invaluable role in this process, particularly with respect to singing voice production.

Finally, in this technologic era, voice clinicians increasingly document various aspects of vocal tract output, using acoustic analysis, spirometric measures to test respiratory adequacy, frequency and loudness measures, translaryngeal airflow rates, and other measures under various conditions. Speech pathologists may use this equipment for biofeedback (e.g., using a visual electronic frequency readout to modify average pitch for speech in a tone-deaf patient). For obligate false vocal fold phonation and intractable psychogenic disorders of voice production with visible vocal fold posture abnormalities, therapy room videoendoscopy can also be converted into an effective biofeedback tool (Fig. 62-6).[11,16]

Surgery

Some lesions are known at diagnosis to be irreversible other than via surgery. Aside from these exceptions, vocal fold microsurgery should follow an appropriate trial of voice therapy. Patients are typically reexamined (vocal capability battery and videostroboscopy) at 16-week intervals after diagnosis. When a compliant patient does not improve

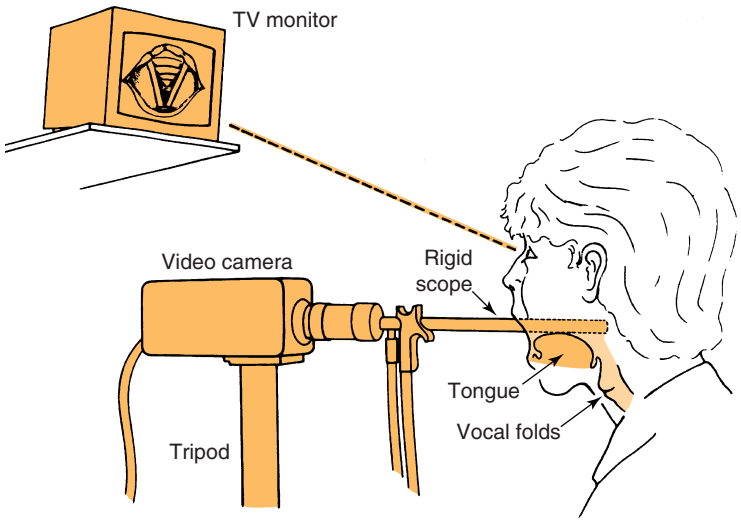

Figure 62-6. A patient learning to modify laryngeal posture by use of laryngeal image biofeedback. With a telescope rather than a fiberscope, pure vocal fold behavior is retrained initially (without speech gestures). Clearer optics and less mobility of the epiglottis permit a clearer and more stable view.

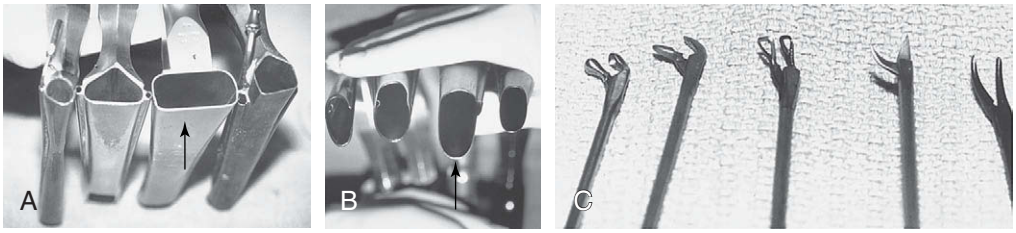

Figure 62-7. **A,** The viewing ends (*left to right*) of the Holinger hourglass, Jako-Cherry, Bouchayer, and Dedo laryngoscopes. **B,** The distal ends of these laryngoscopes (*same order*). The Bouchayer scope (*arrow*) is most useful for microsurgery. **C,** *From left*, The up-cup forceps, smaller biting forceps, Bouchayer microring forceps, curved scissors, and curved alligator forceps.

after two or more successive examinations and remains unhappy with the voice's capabilities, surgery may be considered. Good surgical results are directly related to diagnostic accuracy, surgical judgment and precision, and the patient's compliance with proper voice care.

Although specific techniques vary for each disorder, the basic requirements for successful laryngeal microsurgery for all benign vocal fold mucosal disorders are the same. An understanding of vocal fold microarchitecture and vibratory dynamics (see earlier discussion) is a prerequisite, and preoperative and postoperative videostroboscopic evaluation is necessary so that the patient and surgeon can see the results together.

The first principle of surgery is that microlaryngoscopy (not direct laryngoscopy with the unaided eye) and extreme technical precision are required to minimally disturb mucosa. Because the disorder is benign and confined to the mucosa, including Reinke's potential space, the cancer concept of surgical margins does not apply. Every case should be approached with the awareness that overly aggressive or imprecise surgery of the vocal fold mucosa can have disastrous results caused by scarring of regenerated or surgically manipulated mucosa to the underlying vocal ligament.

A set of laryngoscopes, microlaryngeal forceps, scissors, dissectors, and knives should be on hand. In the face of the plethora of instruments currently available, the comment by Kleinsasser[2] that a relatively simple set suffices the experienced surgeon remains true (Fig. 62-7)!

The carbon dioxide laser has become an important part of the surgeon's armamentarium, and many have discussed its application to benign laryngeal disorders. Tissue effects of the laser depend on spot size and focus, wattage, duration of beam activation, waveform mode (pulsed vs. continuous), and, perhaps most important, surgical precision. Cold microdissection may be safer than laser techniques, provided that the surgeon is equally proficient in both. Norris and Mullarky,[17] comparing continuous-mode carbon dioxide laser with the cold scalpel for incising pig skin, reported that a short-term advantage resulted after laser incision with regard to the speed of reepithelialization; no long-term difference in healing was noted. However, although the fact was not noted in their report, these investigators' histologic sections clearly showed a wider zone of tissue destruction beneath the epithelium with laser than with scalpel. Duncavage and Toohill[18] compared healing response in dogs after traditional fold stripping and after carbon dioxide mucosal vaporization. They concluded that, until late in healing, more edema and giant-cell reactions to bits of charred debris, and greater subepithelial fibrosis occurred with the laser technique than with the cup forceps alone. Manipulation of wattage, focus, and mode of laser irradiation of tissues may decrease thermal injury, charring, and other adverse effects of the laser.

The preceding studies date from the early era of the carbon dioxide laser. The microspot carbon dioxide laser appears to diminish these disadvantages,[19,20] although a systematic comparison of functional results (including vocal capabilities and videostroboscopy) is not available to guide the surgeon in choosing between laser and microdissection methods. With a caseload approaching 1000 singers and double or triple that number of non-singers—for whom laser and non-laser methods have been used on an individualized basis—I believe that surgical technique and skill are preeminent over the specific tools used.

After surgery, vocal *quality* and *capabilities* should show good to excellent improvement; however, patients should be counseled preoperatively what the risk of worsening the voice is predicted to be: For *nodules* it may be appropriate to say, "This surgery typically restores the voice to 'original equipment status,' but there is a *small risk* that you will experience a large improvement but not to fully normal; and there is a *remote, rare risk* that your voice will be worse after surgery." By contrast, one may say to the person with bilateral sulci in whom mucosa

is thin, "I am expecting a modest improvement of your voice, but it will take many months to experience this improvement, and there is a quite significant chance your voice will be no better, and even possibly worse." For the experienced surgeon who uses dissection, rather than microavulsion techniques, along with preoperative and postoperative videostroboscopy as his or her "teacher," the question in the general case becomes not so much one of possibly making the voice worse, but rather, "Can I make this patient's speaking and singing capabilities normal, and if not, how close can I come?" Cornut and Bouchayer's[21] experience operating on 101 singers and Bastian's[22] experience in the same population established a role for laryngeal microsurgery in restoring vocal capabilities and in abolishing or diminishing limitations.

Specific Benign Vocal Fold Mucosal Disorders

Vocal Nodules

The term nodules should be reserved for lesions of proven chronicity. Recent or acute mucosal swellings, which disappear quickly in response to simple voice rest and perhaps supportive medical management, are thus excluded when one is referring to *nodules*.

Epidemiology

Vocal nodules occur most commonly in boys and women. Such persons are almost always vocal overdoers (i.e., rating 6 or 7 on the 7-point talkativeness scale). Intrinsic talkativeness correlates more consistently than occupation, unless the occupation is extraordinarily demanding vocally (e.g., rock singer, stock trader). Comparatively, nodules develop frequently in children with cleft palates, presumably from their use of glottal stops to compensate for velopharyngeal incompetence.

Pathophysiology and Pathology

Only the anterior two thirds (membranous portion) of the vocal folds participates in vibration because the arytenoid cartilages lie within the posterior third of the glottic aperture. Vibration that is too forceful or prolonged causes localized vascular congestion with edema at the midportion of the membranous (vibratory) portion of the vocal folds, where shearing and collisional forces are greatest. Fluid accumulation in the submucosa from acute abuse or overuse results in submucosal swelling (sometimes unwisely called incipient or early nodules). Long-term voice abuse leads to some hyalinization of Reinke's potential space and, in a subset of cases, some thickening of the overlying epithelium. This pathophysiologic sequence explains the easily reversible nature of most acute nonhemorrhagic swellings, in contrast to the slower, incomplete, or failed resolution of chronic vocal nodules. Whether acute edema or more chronic nodules, the change in mucosal mass, lessened ability to thin the free margin, and incomplete glottic closure caused by the nodules account for a constellation of vocal symptoms and limitations that is characteristic of mucosal swelling.[11,22]

Diagnosis

History

A pediatric patient with vocal nodules is usually described by the parent as vocally exuberant. An adult patient, virtually always a woman who rates herself as a 6 or 7 on the talkativeness scale (discussed earlier), describes experiencing chronic hoarseness or repeated episodes of acute hoarseness. Sometimes the initial onset is associated with an upper respiratory infection or acute laryngitis, after which the hoarseness never clears completely, leading the patient to incorrectly attribute the voice problem to the infection and to neglect more relevant ongoing behavioral causes. Singers with chronic nodules are usually relatively unaware of speaking voice limitations unless the nodules are at least moderate in size. More sensitive symptoms of vocal nodules, including very small ones, are as follows:

- Loss of the ability to sing high notes softly
- Delayed phonatory onset, particularly with high, soft singing
- Increased breathiness (air escape), roughness, and harshness
- Reduced vocal endurance ("I get husky more easily than others.")
- A sensation of increased effort for singing
- A need for longer warm-ups
- Day-to-day variability of vocal capabilities that is greater than expected for the singer's level of vocal training

Vocal Capability Battery

In patients with moderate to large vocal nodules, the speaking voice is usually lower than expected, husky, breathy, or harsh. Patients with subtle to moderate swellings often have speaking voices that sound normal; the speaking voice is an insensitive indicator of mucosal disorders in comparison with the singing voice. In patients with subtle or small swellings (usually only singers present with small mucosal disturbances), vocal limitations (e.g., delayed phonatory onset with preceding momentary air escape, diplophonia, inability to sing softly at high frequencies) may become evident only when high-frequency, low-intensity vocal tasks for detecting swelling are elicited.[11a] At high frequency, short-segment vibration may occur; in other words, the nodules stop vibrating and the short segments of mucosa anterior or posterior to them, or both, vibrate.

Many patients with nodules may have undergone indirect laryngoscopy and have been told that their vocal folds were normal or have been given a nonspecific diagnosis such as "laryngeal irritation." Use of vocal tasks that detect swellings and videostroboscopy, when indicated (see Figs. 62-3 and 62-4), protect the laryngologist from missing the most subtle vocal fold swellings. The ability to diagnose tiny nodules is crucial, because failure to make such a diagnosis can have serious consequences for the professional voice user.

Laryngeal Examination

Nodules can vary in size, contour, symmetry, and color, depending on how long they have been present, the amount of recent voice use, and interindividual differences in mucosal response to voice abuse. Also, some variability exists in the correlation between size of nodules and their effect on vocal capabilities. Nodules do not occur unilaterally, although one may be larger than the other. It is important to distinguish between nodules and cysts, because management of these conditions differs. The correlation between nodule appearance and reversibility with voice therapy is imperfect. The larynx should be examined at high frequency (500-1000 Hz) to visualize subtle to small swellings, which can be poorly appreciated at lower frequencies.

Management

Medical

Good laryngeal lubrication should be ensured through general hydration. Allergy and reflux, when present, should be treated.

Behavioral

Vocal nodules arise from the vocal overdoer profile, so speech (voice) therapy plays a primary role initially. Typically, the nodules and their more obvious symptoms regress, particularly if the patient is not a singer. However, the most skilled behavioral (voice) therapy sometimes fails to achieve complete visual resolution of nodules that have been present for many months to years. Sensitive singing tasks that detect impairment (not the size of persistent swellings) are generally more helpful in the decision whether to consider their surgical removal.[11,22]

Surgical

Surgical removal becomes an option when nodules of whatever size persist and the voice remains unacceptably impaired (from the patient's perspective) after an adequate trial of therapy (generally a *minimum* of 3 months). Some writers prefer precise removal using microdissection techniques (Fig. 62-8). Vocal fold stripping has no place in the surgery of nodules. The proper duration of voice rest is controversial; some

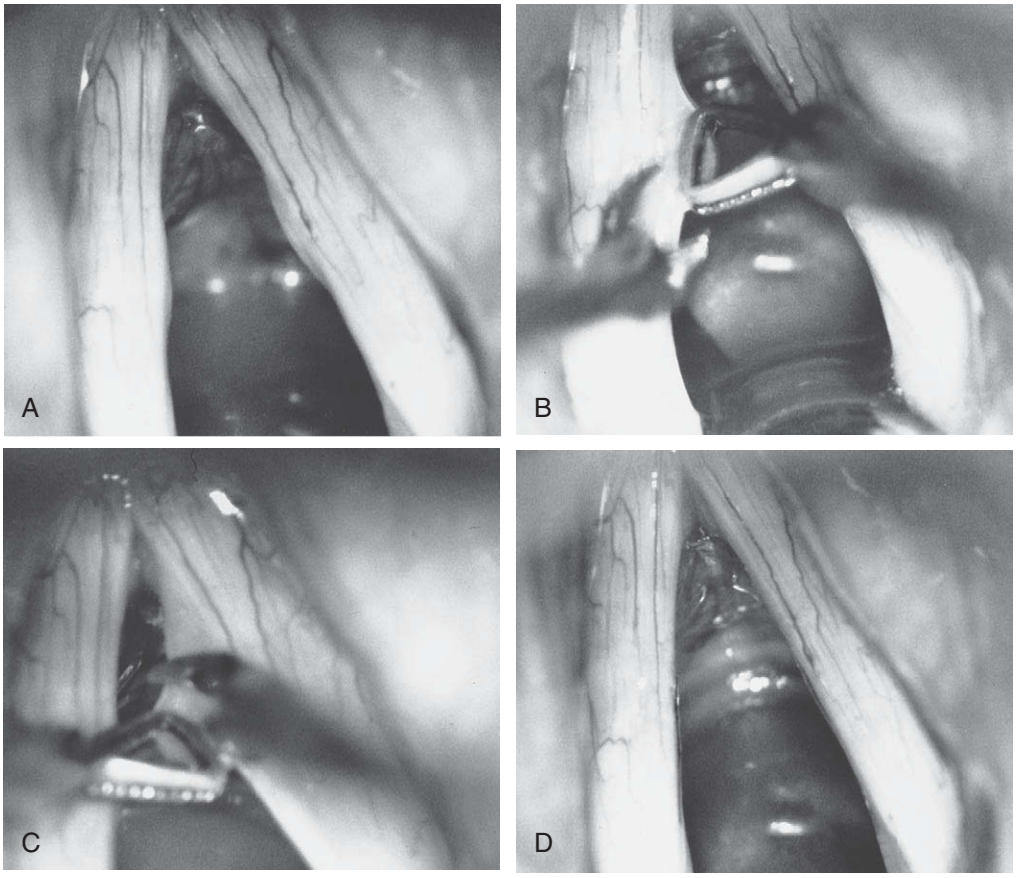

Figure 62-8. The operative sequence in a professional musical theater actress who had been experiencing vocal symptoms and limitations compatible with fusiform vocal nodules for more than 2 years. **A,** The operative view after many months of conservative management. Not all fusiform swellings are reversible with conservative measures alone. **B** and **C,** A polypoid nodule is grasped superficially and tented medially with Bouchayer forceps. Scissors, which curve away from the vocal fold, are used for removal. The nodule is thus removed in a very superficial plane, thereby minimizing the risk of engendering scar between the remaining and regenerated mucosa and the underlying vocal ligament. **D,** The vocal fold appearance after excision. The patient experienced dramatic normalization of vocal capabilities, and there was no evidence of scarring on postoperative stroboscopic examination. The dilated capillaries may predispose to recurrent nodule formation and can be spot-coagulated with a micro-spot laser.

writers prefer a relatively short period. Typically, the patient is asked not to speak for 4 days, although sighing sounds begin 1 day after surgery. Beginning on the fourth day, the patient gradually progresses over 4 weeks to full voice use under a speech pathologist's supervision. Early return to nonstressful voice use, as described in Table 62-1, seems to promote dynamic healing. The results of precision surgery are typically remarkably good, even in singers. Cornut and Bouchayer[21] stated, in their study of approximately 160 singers treated with surgery, "As long as certain management principles are followed in a majority of cases, laryngeal microsurgery enables the singing voice to regain the whole of its functioning."

Capillary Ectasia

Epidemiology

Capillary ectasia seems to happen most often with vocal overdoers (Figs. 62-9 to 62-11). Because of the female preponderance of this disorder, some writers have speculated about an estrogen effect.

Pathophysiology and Pathology

Repeated vibratory microtrauma can lead to capillary angiogenesis. In a circular fashion, abnormally dilated capillaries seem to increase the mucosa's vulnerability to further vibratory trauma. In particular, mucosal swelling, when present with capillary ectasia, appears to be larger on the side with greater ectasia. It seems that capillary ectasia predisposes to one or more of the following: increased vulnerability to mucosal swelling (reduced vocal endurance), a small incidence of vocal fold hemorrhage, and hemorrhagic polyp formation.

Diagnosis

History

Capillary ectasia is diagnosed most often in female singers who complain that they become a little hoarse after relatively short periods of singing (reduced vocal/mucosal endurance). When this complaint is associated with mucosal swelling, additional symptoms reminiscent of nodules (e.g., delayed phonatory onset, loss of high soft singing, increased effort) may also be noted. The occasional singer with capillary ectasia may have experienced one or more episodes of acute vocal fold hemorrhage, which may precipitate the patient's first visit; capillary ectasia may be discerned only after the bruising has resolved.

Vocal Capability Battery

Without mucosal swelling, the voice's capabilities in a patient with capillary ectasia may be entirely normal. With swelling, vocal limitations may be similar to those detected in the patient with nodules. If mucosal hemorrhage is recent, the speaking voice and singing voice may be very hoarse.

Laryngeal Examination

Capillary ectasia may manifest as abnormal dilation of the long arcades of capillaries that proceeds mostly from anterior to posterior (see Figs.

62-9 to 62-11). However, aberrant clusters of dilated capillaries also may be seen. Occasionally, a vascular dot may appear when a loop comes from within Reinke's space to the surface and doubles back down into the submucosa. Finally, some dilated capillaries are confluent or become so large as to almost resemble a chronic hemorrhage; this variant can be termed a *capillary lake*.

Table 62-1

General Guidelines for Initial Voice Use after Vocal Fold Microsurgery

Time After Surgery*	Talking†	Singing (for Singers)
Days 1 to 4	None	Gentle attempts at yawn or sigh for approximately 30 sec, 6-8 times per day‡
Week 2 (begins day 5)	3	Same exercise 5 min twice per day (after first postoperative exam)
Week 3	4	Same exercise 10 min twice per day§
Week 4	5	Same exercise 15 min twice per day§ (after second postoperative exam)
Week 5	4 or 5	Same exercise 20 min twice per day§
Weeks 6-8	4 or 5	Same exercise, up to 20 min three times per day¶

*After fourth examination, return to performance should be considered.
†Based on a 7-point talkativeness scale, in which 1 = very untalkative, 4 = average, and 7 = extremely talkative.
‡Accept what comes out, even if it is only air or is very hoarse.
§With emphasis on ease, clarity, and agility, not voice building. The entire expected range should be practiced in each session, with gentle insistence on high notes that do not want to sound. In general, practice mostly a mezzo piano dynamic and only occasionally a mezzo forte.
¶Same as preceding footnote, with the addition of gradually increasing the dynamic range and insistence.

Management

Medical

Use of drugs that have anticoagulant effects (aspirin, nonsteroidal anti-inflammatory drugs) should cease if medically appropriate. These drugs do not appear to increase the *incidence* of hemorrhage but may increase the *severity* of bruising when it does occur. In addition, acid reflux may have an amplified effect on the mucosa when capillary ectasia is visible; thus, management of reflux is particularly important.

Behavioral

Many persons with capillary ectasia are vocal overdoers; therefore, the behavioral changes appropriate for persons with nodules are advocated. In particular, patients are warned about sudden, explosive use of voice. The duration of voice use per practice session should also be reduced (e.g., three 20-minute sessions per day vs. one 1-hour session).

Surgical

If the patient cannot accept residual vocal symptoms and limitations (e.g., decreased vocal endurance) after medical and behavioral management, laryngeal microsurgery is an excellent option.[22,23] Dilated capillaries are spot-coagulated to interrupt blood flow every few millimeters (see Fig. 62-9C). Capillaries proximal to each interrupted segment may subsequently dilate. Even so, not all visible dilations should be ablated; those that remain visible at the end of the procedure and even at the first postoperative visit routinely involute within a few weeks. If mucosal edema is minimal, management of the capillaries alone often leads to edema resolution.

Vocal Fold Hemorrhage and a Unilateral (Hemorrhagic) Vocal Fold Polyp

Epidemiology

The occurrence of vocal fold hemorrhage (see Fig. 62-10) and a unilateral hemorrhagic vocal fold polyp is more common in men, particularly those who engage in intermittent severe voice abuse or who work in noisy environments. Some patients have a history of aspirin or other anticoagulant use.

Pathophysiology and Pathology

Shearing forces acting on capillaries within the mucosa during extreme vocal exertion lead to capillary rupture. Capillary ectasia seems to predispose to this sort of injury. Breakage of *superficial* capillaries may lead to a thin, widely suffused, superficial bruise without vocal fold margin convexity. Within a few days, this type of hemorrhage often may have little effect on mucosal oscillation. Resolution of the bruise may be complete within 2 weeks. By contrast, extravasation of blood from a *deeper* capillary may lead to focal accumulation of blood, similar to a

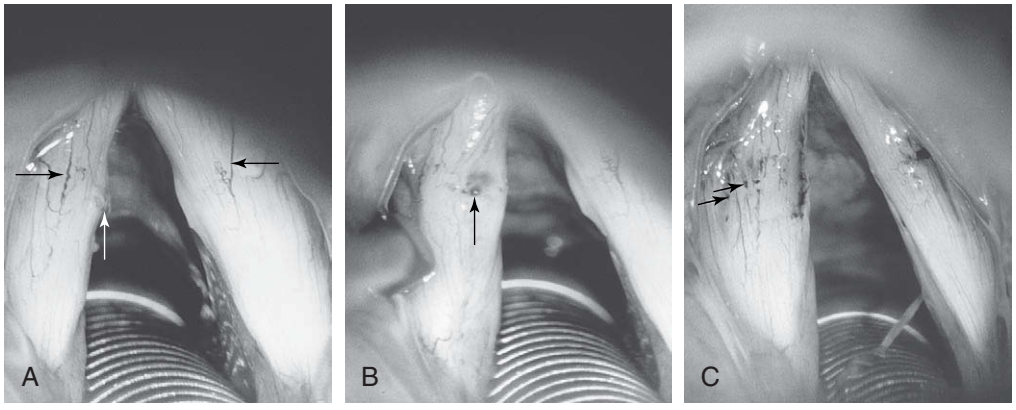

Figure 62-9. Vocal nodules with associated capillary ectasia. **A,** Superficial ectasia is seen (*black arrows*); the *white arrow* indicates deeper ectasia seen within left-sided nodule. **B,** The left vocal fold margin is rolled up onto the superior surface of the fold so that ectasia within the nodule can be seen more clearly (*arrow*), particularly the knuckle variant. **C,** Nodules have been removed (see Fig. 62-8), but spot-coagulation of dilated capillaries is present at approximately 2-mm intervals (*arrows*).

blood blister. This type of hemorrhage alters the margin contour and stiffens the mucosa, as seen stroboscopically. It causes significantly more and longer-lasting hoarseness and may be the precursor of a hemorrhagic polyp. In this case, microscopic examination would reveal a relatively rich vascular stroma and areas of hyalinization, although a unilateral, nonhemorrhagic, often pedunculated polyp may also be seen as the end stage of a hemorrhagic polyp.

Diagnosis

History

The history of abrupt onset of hoarseness during extreme vocal effort, such as at a party or sporting event, or even after a loud sneeze is classic but not universal in patients with vocal fold hemorrhage and a unilateral hemorrhagic vocal fold polyp.

Vocal Capability Battery

Vocal capabilities vary according to the size, age, turgidity, and pedunculation of the polyp. Some patients have a normal-sounding speaking voice, except for intermittent subtle aberrant sounds. Other patients have a normal speaking voice but an impaired or nonexistent falsetto register. Some patients also manifest chronic vocal huskiness.

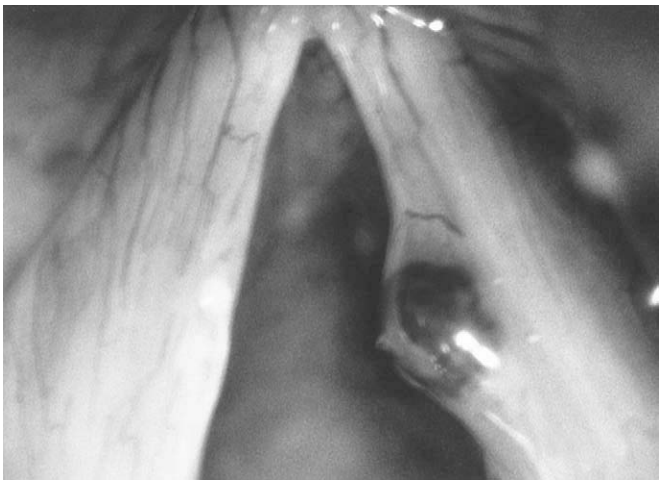

Figure 62-10. Operative view of a hemorrhagic polyp on the right true vocal fold of 14 months' duration. Note the capillary ectasia.

Laryngeal Examination

Laryngeal examination demonstrates a largely unilateral lesion in the node position, a contact reaction—or nodule if the person is a vocal over-doer-—on the fold opposite the polyp. In the case of the chronic vocal overdoer, a hemorrhagic polyp may represent an acute injury superimposed on chronic nodules. The hemorrhagic polyp is usually much larger than the typical nodule and may appear dark and filled with blood in early stages. Depending on when the submucosal bleeding occurred, discoloration may be in any stage of bruise evolution. Long-standing, hemorrhagic polyps may lose their vascular appearance and become pedunculated, moving in and out of the glottis with inspiration and expiration, respectively. During phonation, this end-stage polyp may be displaced upward onto the fold's superior surface, interfering little with basic phonation.

Treatment

Medical

If possible, the intake of anticoagulant medications (e.g., aspirin, nonsteroidal anti-inflammatory drugs, warfarin) should be stopped. Because acid reflux can increase hyperemia and dilate normal and abnormal capillaries, this condition should be controlled.

Behavioral

A short course of voice therapy is appropriate, mainly to instruct the patient in voice care. The occasional small, early hemorrhagic polyp resorbs completely with many months of conservative measures, but typically, surgical removal is required to return the vocal fold to its normal appearance and vibratory function and the voice to normal capabilities.

Surgical

Evacuation of blood through a tiny incision in a recent large hemorrhage that looks like a blood blister may be appropriate, because one would expect a long wait for resorption (in the best case) and likely progression to a chronic hemorrhagic polyp. After microsurgical evacuation of the hematoma, care should be taken to detect the large capillaries within Reinke's space, because these also should be interrupted, although a slightly deeper coagulation may be required to reach the level of the capillary. A long-standing polyp—whether hemorrhagic or

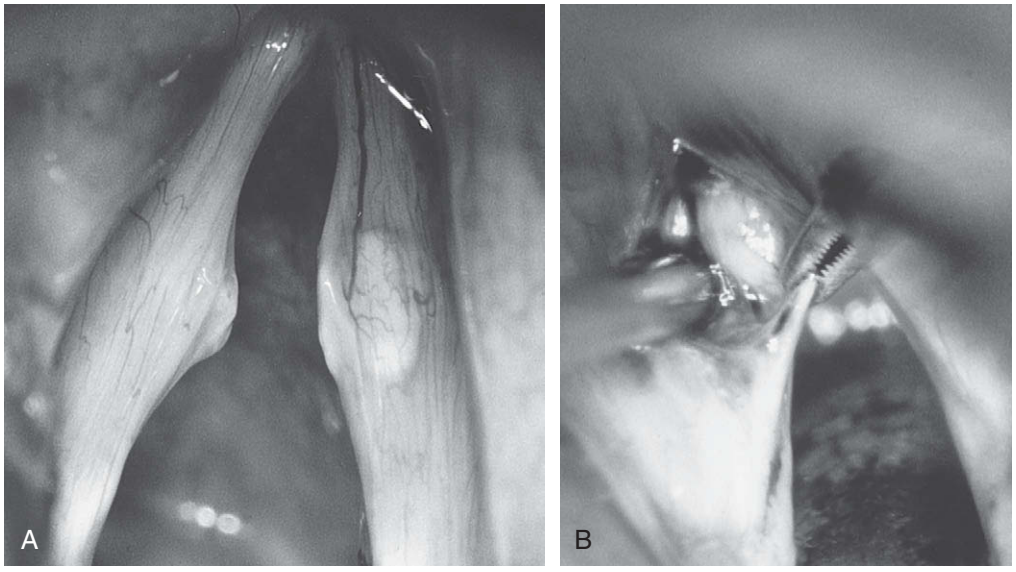

Figure 62-11. **A,** A large right epidermoid inclusion cyst with a characteristic dilated capillary. Note the large left nodule. **B,** An epidermoid inclusion cyst in another patient is delivered through a cordotomy incision.

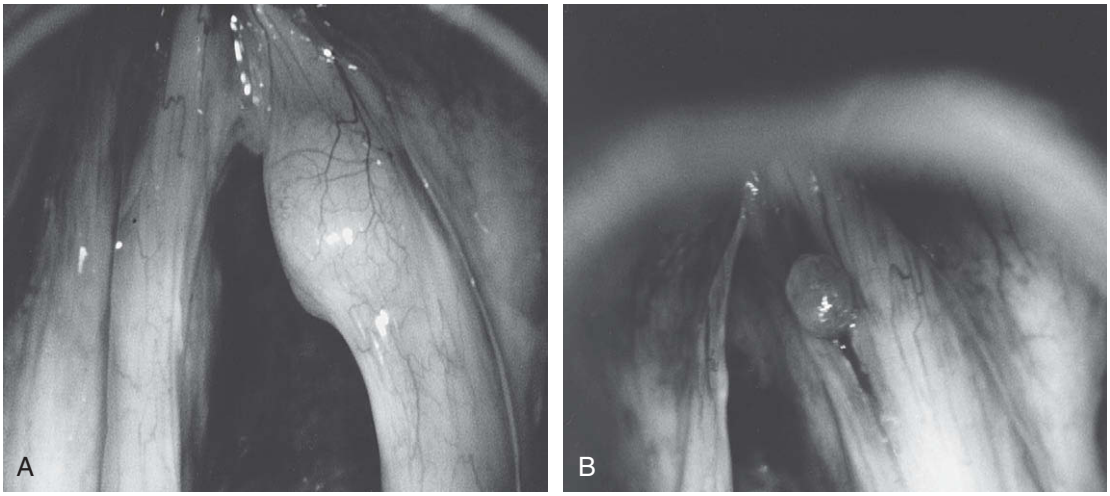

Figure 62-12. **A,** A mucus retention cyst of the right vocal fold. Note the relatively greater margin deformation caused by this cyst in comparison with that caused by an epidermoid inclusion cyst. **B,** In another patient, a cyst is delivered through cordotomy incision.

end-stage and pale—should be trimmed away superficially at the time the spot coagulations take place. Prognosis for full return of vocal functioning after precision surgery is excellent.

Intracordal Cysts

Epidemiology

The most prominent epidemiologic finding is a history of vocal overuse. This is routine for the epidermoid cyst, but less so for the mucus retention variety.

Pathophysiology and Pathology

Histologically, intracordal cysts are classified as either mucus retention or epidermoid inclusion types (Figs. 62-11 to 62-13). Mucus *retention (ductal) cysts* (see Fig. 62-12) arise when the duct of a mucus gland becomes plugged and retains glandular secretions; *epidermoid cysts* (see Fig. 62-13) contain accumulated keratin.[24-27] Two theories state that the epidermoid cyst results from a rest of epithelial cells buried congenitally in the subepithelial layer or from healing of mucosa injured by voice abuse over buried epithelial cells. In time, cysts may rupture spontaneously. If the resulting opening is small in relation to the overall size of the cyst, some epidermoid debris may be retained and may create an *open cyst*; if the opening is as large as the cyst, the resulting empty pocket becomes a *glottic sulcus*.

Diagnosis

History

A patient with epidermoid cysts has many of the same symptoms and voice abuse factors as a patient with nodules. Mucus retention cysts can arise seemingly spontaneously, without relation to amount or manner of voice use.

Vocal Capability Battery

The vocal capability battery uncovers vocal limitations similar to those for a patient with vocal nodules. Patients with epidermoid cysts are more likely to experience diplophonia in the upper voice, and they may manifest an abrupt and irreducible transition to severe impairment at a relatively specific frequency rather than a more gradual transition to greater degrees of impairment, as often noted in patients with nodules. Mucus retention cysts often cause less vocal limitation than anticipated from the laryngeal appearance; epidermoid inclusion cysts often cause more limitation than expected.

Laryngeal Examination

Mucus retention cysts often originate just below the free margin of the fold with significant medial projection from the fold. For this reason, mucus retention cysts are sometimes misdiagnosed as nodules or polyps. Epidermoid cysts project less from the fold and are harder to diagnose when small. An inexperienced clinician may be more aware of what appear to be nodules than the faint cyst outline on the superior surface of the fold (see Fig. 62-13). In an open cyst, the sphere may be less discrete and may have a more mottled appearance on the superior surface of the vocal fold (Fig. 62-14). Under strobe illumination, as the fundamental frequency of phonation increases, the mucosa overlying the cyst often stops vibrating before the mucosa anterior and posterior to the cyst. Even so, diagnosis can be confirmed in some patients only at the time of microlaryngoscopy.

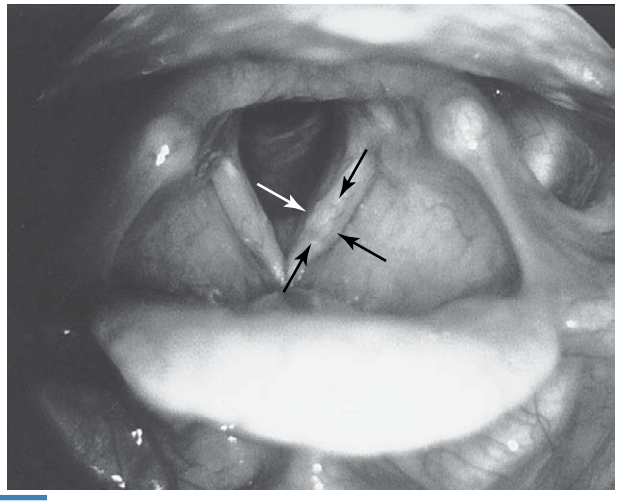

Figure 62-13. A 90-degree telescope view shows the faint spherical outline of a small epidermoid inclusion cyst (*arrows*).

Treatment

Medical

General supportive measures (e.g., hydration, potential acid reflux management) may be helpful but will not resolve this problem.

Behavioral

Voice therapy is more appropriate for persons with epidermoid cysts and often is not needed (beyond teaching in preparation for surgery) in those with the mucus retention variety. The reason is that persons with epidermoid inclusion cysts are by far the more likely of the two to be vocal overdoers. Of course, speech (voice) therapy may also be

warranted for the mucus retention variety if the person is a vocal overdoer, not to resolve the lesion, which is "surgical," but to avoid the risk of another (this time vibration-induced) lesion.

Surgery

Patients with large mucus retention cysts and no history of voice abuse may be scheduled for surgery promptly. If under the edge of the vocal fold and extremely superficial and translucent (resembling a polyp), the cyst may be removed in its entirety with a small slip of overlying mucosa when its wall is so thin as to make its dissection from the overlying mucosa virtually impossible. In this case, mucosal oscillation will still be normal after healing is complete. More typical mucus retention cysts are removed as described in the following paragraph, via dissection that leaves overlying mucosa intact.

A small, extremely shallow incision is made on the fold's superior surface. Careful dissection reveals that the swelling is indeed caused by a cyst. Taking care to avoid any injury to mucosa, other than that of the incision, the surgeon dissects the cyst free of the mucosa and vocal ligament (Fig. 62-15). The opposite fold should be examined carefully because of the possibility of a more subtle cyst or sulcus. Results are not as uniformly good as for nodules and polyps. Considerable improvement is expected, however, and some patients achieve excellent results. Patients should also know that postoperative recovery takes longer than for nodule or polyp surgery (many months rather than a few weeks). Bouchayer and colleagues[26] reported a series of 148 patients managed for cysts, sulci, or mucosal bridges (very difficult surgical problems compared with nodules and polyps), of whom 10% had an overall excellent result, 42% a good result, 41% a fair result, and 5% a poor result. Follow-up supportive voice therapy from the speech pathologist or singing teacher assists vocal rehabilitation. A return to active voice use or training should occur within a few days of surgery, because the amount of mucosal disturbance required leads to a greater tendency to mucosal adherence and stiffness.

Figure 62-14. Bilateral open cysts. Because the openings are small in relation to the size of the cysts, partial emptying of the keratin contents causes a mottled appearance.

Glottic Sulcus

Epidemiology

Although some writers believe sulci to be congenital, this entity appears to occur exclusively in vocal overdoers (Figs. 62-16 to 62-18).

Pathophysiology and Pathology

Bouchayer and colleagues[26] reviewed acquired and congenital theories for these conditions. They described the appearance of the sulcus as an epithelium-lined pocket whose lips parallel the free edge of the folds and suggested that a sulcus may represent an epidermoid cyst that has spontaneously emptied, leaving the collapsed pocket behind to form a sulcus. In effect, a mucosal bridge is the result of two parallel sulci arising from a single cyst (see Fig. 62-18).

Diagnosis

History

The patient with a glottic sulcus often has a history of voice overuse and complains of chronic hoarseness.

Vocal Capability Battery

Typically the voice is noticeably hoarse. Upper voice limitations, particularly diplophonia, are obvious. As is the case for cysts, the transition between hoarse phonation and aphonia may occur abruptly, almost at a specific frequency, generally in the middle of the singing range.

Laryngeal Examination

Laryngeal examination may initially reveal fewer findings than expected to account for the abnormal speaking voice or reduced singing voice capabilities. Because the patient is likely a vocal overdoer, associated fusiform vocal fold margin swellings might also be seen. Stroboscopic evaluation shows a segment of reduced vibration. The entire length of the mucosa may oscillate at lower frequencies; at higher frequencies,

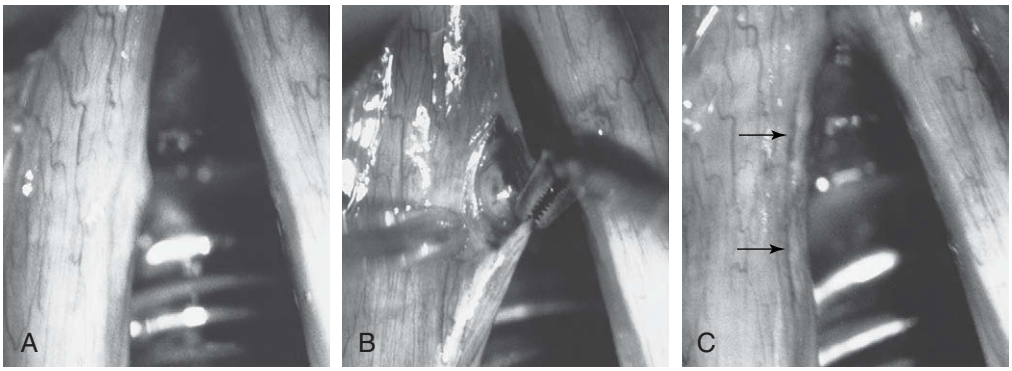

Figure 62-15. Operative sequence for removal of a small mucus retention cyst in a patient previously diagnosed as having vocal nodules. **A,** Initial operative view, left vocal fold. **B,** The cyst is exposed through an incision made on the superior surface of the fold. **C,** After removal of the cyst and redraping of undamaged overlying mucosa, only an incision line is seen (*arrows*). The patient's vocal fold was stiff under strobe illumination for several weeks postoperatively but ultimately regained full vibratory amplitude and mucosal wave as compared with the unoperated cord. Vocal capabilities also returned to normal. With larger cysts, some postoperative stiffness can be permanent, particularly as the patient phonates at high frequencies.

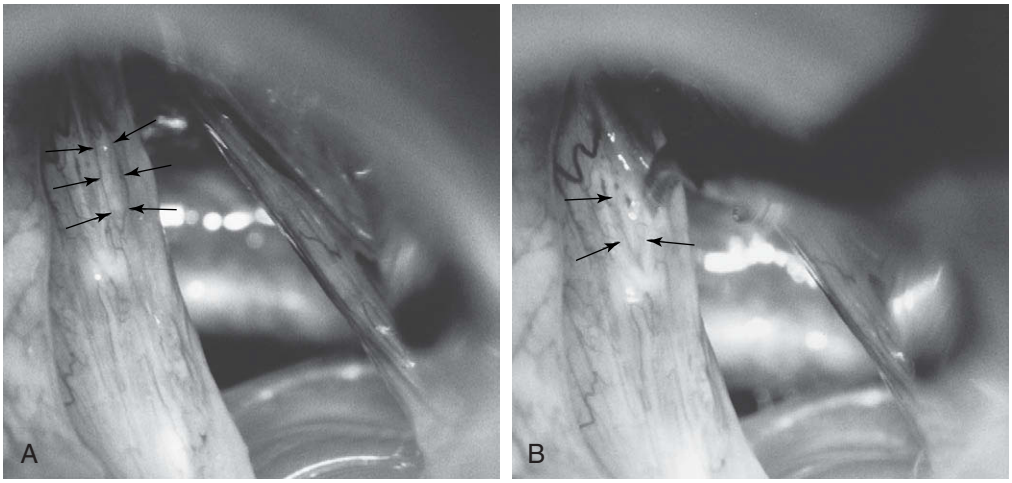

Figure 62-16. Sulcus of the left true vocal fold seen **(A)** undisturbed and **(B)** with forceps used to spread open its lips.

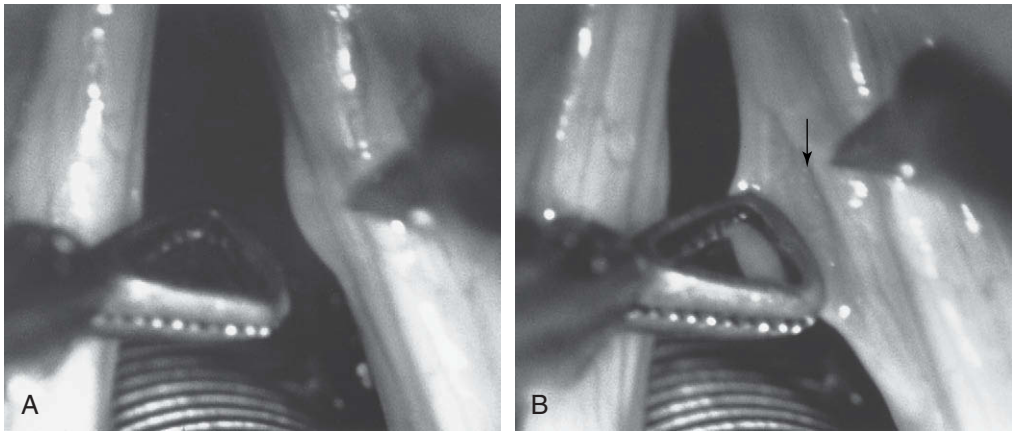

Figure 62-17. **A,** Operative view of a chronic polypoid nodule. **B,** At the time of medial tenting of the mucosa preparatory to excision, a previously unsuspected sulcus is discovered (*arrow*). In this case, excision of the polypoid nodule alone without specifically addressing the sulcus resulted in marked improvement of vocal capabilities and eliminated this nonsinging patient's chronic hoarseness of the speaking voice.

Figure 62-18. A mucosal bridge of the right vocal fold (with forceps passed under it) in the same patient seen in Figure 62-16.

the midportion of the mucosa stops oscillating and short-segment vibration begins to occur. Microlaryngoscopy is often required for definitive diagnosis because the lips of the sulcus are not always visible with inspiratory phonation during the office or voice laboratory examination.

Management

Medical

Medical management for glottic sulcus is supportive as appropriate, but it is not expected to resolve this structural abnormality.

Behavioral

A short preoperative course of voice therapy is indicated if the patient with glottal sulcus is a confirmed vocal overdoer, because the behavioral goal for patients with cysts initially is selection and preparation for surgery; restoration of the mucosa to normal cannot be achieved by medical or behavioral treatment.

Surgical

Sulcus removal is technically demanding, and it involves considerable surgical disturbance of the vocal fold mucosa in comparison with surgery for nodules. Bouchayer and colleagues[26] described the steps for removal of a glottic sulcus (Fig. 62-19), including cordal injection to make the sulcus lips spread and the sulcus more shallow and to accomplish some hydrodissection. This step is followed by circumcision of

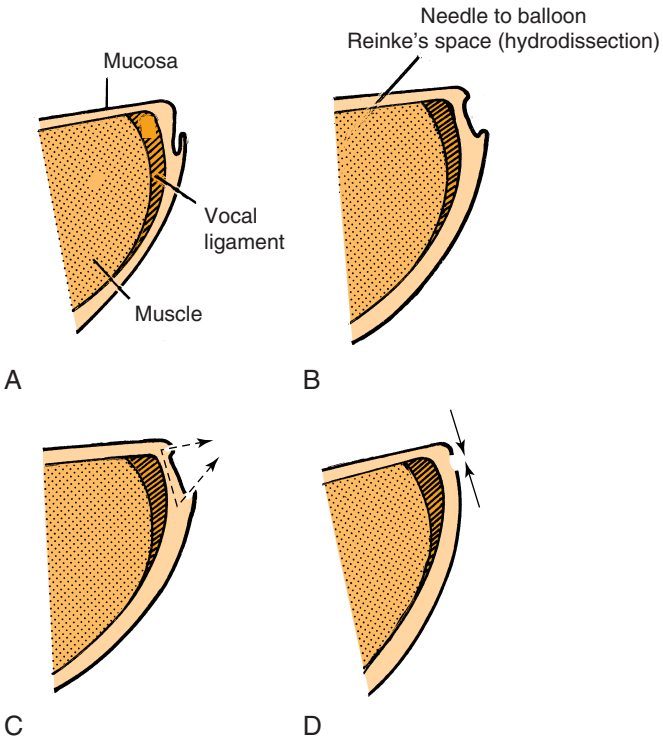

Figure 62-19. Removal of a glottic sulcus. **A,** A vocal fold coronal section shows the sulcus. **B,** Injection of 1% lidocaine with epinephrine into Reinke's space spreads the lips of the sulcus. **C,** Incisions at the sulcus lips and dissection off the vocal ligament. **D,** After removal of the sulcus.

the lips of the sulcus and dissection of the invaginated mucosal pocket from the underlying fold without injuring the vocal ligament. Results seem to depend not only on excellent surgical skill but also on the thickness of the mucosa. A thick, almost polypoid mucosa may yield a normal voice on occasion. In the patient in whom the mucosa is very thin and more widely adherent to the ligament, voice is typically better than before surgery but residual mucosal stiffness may occur even after optimal surgery.

Bilateral Diffuse Polyposis

Epidemiology

Voice change caused by bilateral diffuse polyposis (chronic Reinke's edema or smoker's polyps) (Fig. 62-20) typically becomes noticeable enough to prompt a laryngeal examination in middle-aged, *talkative* women who have been long-term smokers.

Pathophysiology and Pathology

There seems to be an individual susceptibility to this condition because it develops in only a small percentage of persons at risk (e.g., smokers who use their voices a lot). As detailed by several writers, chronic smoking and voice abuse result in edema, vascular congestion, and venous stasis.[28,29] These conditions cause diffuse polypoid changes that become permanent, although the degree of edema or turgidity and consequent voice disturbance may rise and fall with voice use.

Diagnosis

History

The combination of smoking and avid voice use is classic for this entity. A woman with smoker's polyps may complain of being called "sir" on the phone, or she may have problems with increasing hoarseness during the day.

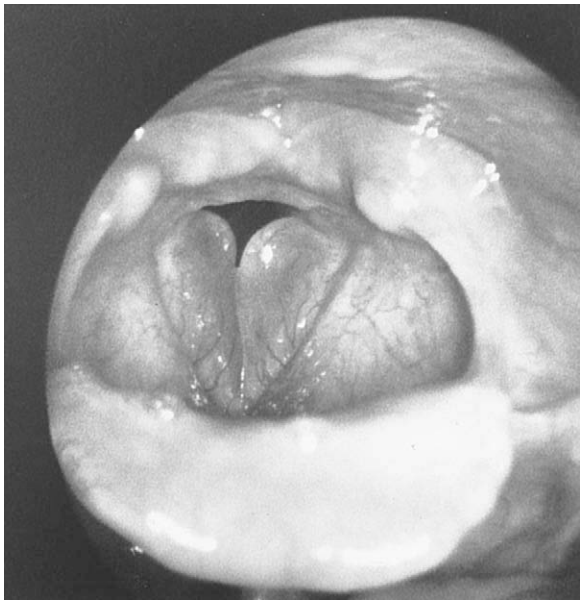

Figure 62-20. Moderately large unilocular smoker's polyps (inspiratory view through a rigid laryngeal telescope).

Vocal Capability Battery

The voice examination demonstrates lower pitch than would be expected, often well into the masculine range when the condition is seen in women. Upper voice is lost, and the female patient can often phonate through the range of a true bass singer! With large polyps, the voice may even be hypermasculine.

Laryngeal Examination

Laryngeal examination usually reveals pale, watery bags of fluid attached to the superior surface and margins of the folds. Large smoker's polyps may cause an involuntary laryngeal snore on sudden inhalation. A to-and-from motion is often seen with respiration. In severe cases, clusters of polyps on polyps may be seen. Small smoker's polyps are easily overlooked unless the patient is instructed to phonate on inspiration, when the polypoid tissue is drawn from the superior surface of the folds into the glottic aperture and thereby made more visible as a greater-than-normal convexity of the margin. (Virilization of the singing range noted during the vocal capability battery directs the examiner to elicit inspiratory phonation and look for this type of lesion.)

Management

Medical

The patient with bilateral diffuse polyposis is encouraged to give up smoking. Thyroid function tests can be performed if hypothyroidism is suspected. This latter entity has often been invoked as causal in this condition, although diffuse polyposis is extremely rare in the absence of smoking and avid voice use.

Behavioral

Short-term voice therapy may be appropriate to introduce optimal vocal behavior. These measures alone may reduce the polyps' turgidity, with a corresponding modest improvement in vocal functioning.

Surgical

Microsurgery for polyp *reduction* is necessary when the voice remains objectionable to the patient. The older common practice of stripping the polyps away often results in aphonia for many weeks postoperatively, and the final voice achieved may sound unacceptably high and husky to the patient. Polyp reduction with mucosal sparing (Fig. 62-21) is recommended for earlier and optimal return of voice (usually begin-

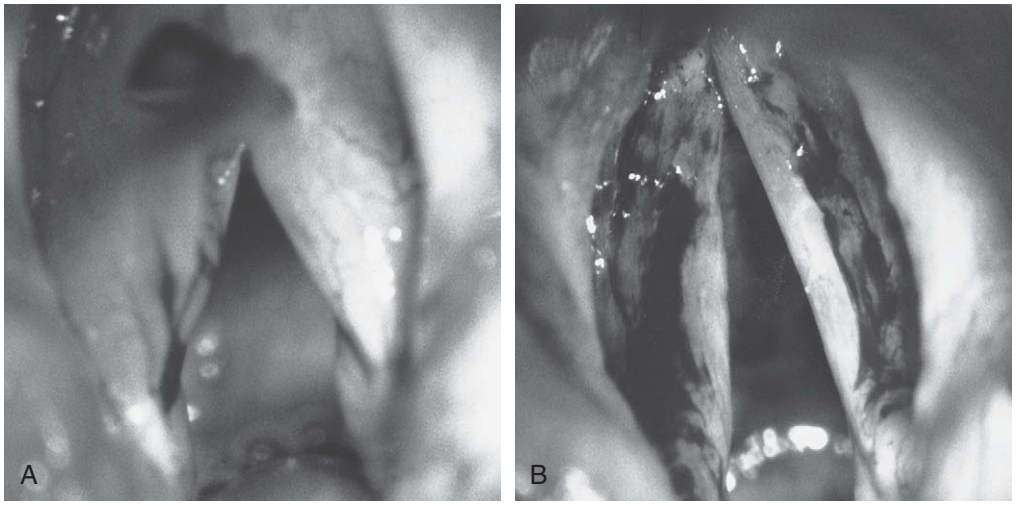

Figure 62-21. **A,** This operative view is seen after a left vocal fold polyp has been bivalved in the axial plane. Bouchayer forceps are holding the superior half of the polyp in preparation for removal. **B,** The final view after the upper part of the polyp has been removed and myxoid material has been suctioned and dissected from between the mucosal flap and vocal ligament; the resulting inferiorly based mucosal flap has been redraped over a free edge of the vocal fold. This female patient's speaking voice was markedly virilized preoperatively and considerably feminized postoperatively. The patient was aphonic for only 7 days postoperatively, whereas after traditional stripping, she may not have regained voice for many weeks.

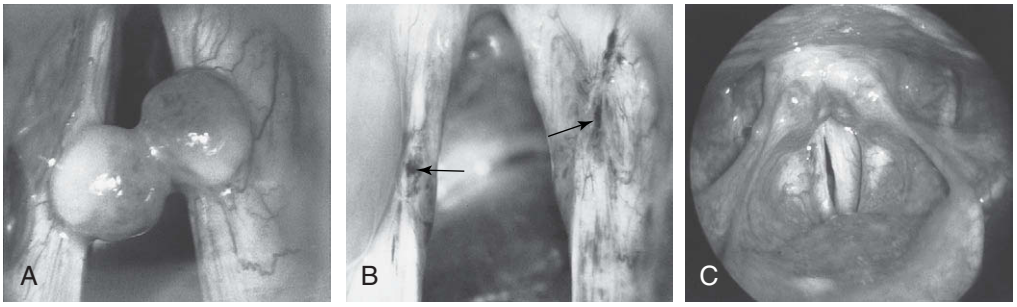

Figure 62-22. Iatrogenic mucosal scarring. This patient underwent bilateral vocal fold "stripping" elsewhere for persistent dysphonia, which was subsequently diagnosed as spasmodic dysphonia. The patient was reportedly aphonic for many weeks postoperatively. **A,** This operative photograph was taken 4.5 months after the original surgery. Granulomas are highly pedunculated and may have eventually detached or regressed spontaneously. Note the medial-to-lateral reorientation of vocal fold capillaries, a common finding after vocal fold stripping. **B,** The same patient after granuloma removal. Attachment points of the granulomas are marked at *arrows*. In this view, the vocal folds are rolled superiorly, and considerable scarring is evident, particularly on right vocal fold. **C,** The same patient as viewed through a laryngeal telescope a few weeks later. The larynx shows pseudobowing caused by mucosal loss rather than by vocal fold atrophy. Under strobe illumination, these vocal folds were very stiff with minimal mucosal wave evident even at low frequencies. With a voice-building regimen and scar maturation, a serviceable but limited voice was achieved.

ning within 10 days). It is better to leave the patient with a voice that still sounds rich (even with some residual polyposis and mild vocal virilization) than to strip the folds and leave the patient with a voice that sounds thin, insubstantial, and effortful.

Postoperative Dysphonia

Epidemiology

Vocal fold surgery performed without extreme precision can lead to permanent *postoperative* dysphonia (Figs. 62-22 and 62-23) that can be worse than the hoarseness of the lesion that was operated on.[30,31] The prior surgeon may have performed vocal fold stripping or laser vaporization of the mucosa. The pathology report from that operation frequently describes a fairly large specimen that may contain fibrous tissue or even muscle, suggesting that the removal went deeply into the vocal fold.

Pathophysiology and Pathology

Dysphonia can result from a scarred, stiff vocal fold cover, from phonatory mismatch of the vocal fold margins, or from both. Scarring adheres mucosa to underlying vocal ligament, abolishing the ability of mucosa to oscillate with any freedom from the underlying vocal ligament. Mismatch may arise from a divot caused by overzealous removal or from pseudo-bowing, such as that from not sparing enough mucosa during smoker's polyp reduction. With few exceptions, postoperative dysphonia can be avoided by use of an appropriately precise surgical technique and by early graduated resumption of voice use after surgery (see Table 62-1).

Diagnosis

History

A history of prior surgery is common to all cases, but a clear understanding of the original lesion should be sought, as well as any history indicating continuing vocal abuse that might indicate recurrent mucosal injury, rather than scarring, as a possible explanation.

Vocal Capability Battery

The voice may vary from aphonia to a harsh whisper to a relatively normal speaking voice, but it is accompanied by disastrous limitation

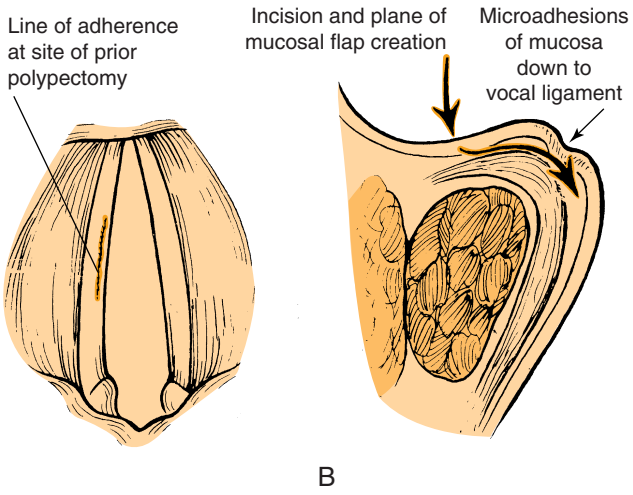

Figure 62-23. Postoperative dysphonia (severe diplophonia) from suspected overly aggressive polypectomy. **A,** The operative view from above shows a longitudinal scar. **B,** Cross-sectional view shows the surgical approach releasing microadhesion of mucosa down to the vocal ligament. The patient experienced immediate and enduring relief of diplophonia.

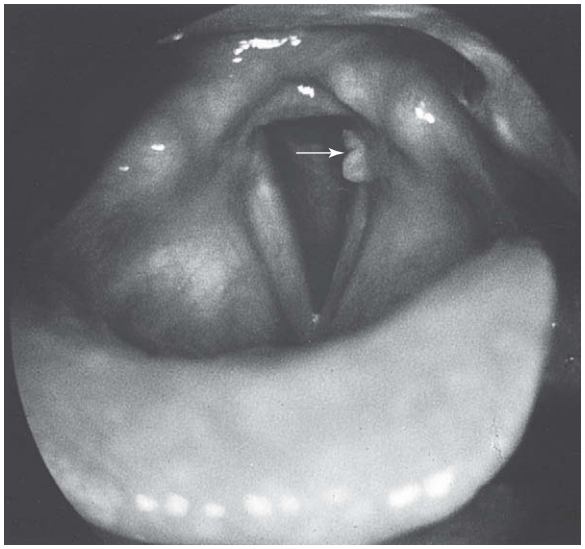

Figure 62-24. Contact granuloma, left vocal fold. The general appearance and the cleft (*arrow*) where the opposite vocal process fits are typical.

of the upper singing voice with diplophonia and loss of the expected upper range.

Laryngeal Examination

Laryngeal videostroboscopy is essential for patients with possible postoperative dysphonia. The technique allows careful analysis of mass lesions, areas of asymmetry, and the mucosa's vibratory pattern, from which a clear diagnosis and a therapeutic plan can be generated.

Management

Medical

General medical issues that relate to the voice should be optimized in the course of management.

Behavioral

If stiffness, scarring, and tissue loss are problems, voice therapy is tried first, with a voice-building approach. A person who is resting the voice should instead resume talking per routine. In addition, the individual is coached to sing with moderately great vigor for 10 minutes two or three times per day at all vocal frequencies of his or her range. Using the facilitating vowel /oo/ is helpful in cases of severe dysphonia. When only a very narrow frequency range is available to a patient because of postoperative scarring, the patient is asked to start phonating at a frequency that works (often quite high in the expected vocal range) and to coax the voice lower and higher from this small area of working frequencies. Some remarkable improvements may be seen with this approach. However, even with achievement of a serviceable speaking voice, the voice's singing capabilities will remain limited in comparison with a normal voice. Proof for this approach is difficult to procure. However, improvement does not seem to arise only from spontaneous softening of scar tissue, because improvement can occur with the preceding "voice-building" strategy in patients more than 1 year after surgery or another scarring event.

The rationale for this aggressive, voice-building strategy may require some explanation for patients whose voice abuse is what caused the problem for which they underwent surgery. A voice-qualified speech pathologist who is comfortable with teaching vigorous voice production throughout the expected range should monitor voice-building exercises initially. Some patients can work independently because of the short duration of exercise sessions and because the overall idea of the voice-building approach is not to scream abusively or, primarily, to enhance vocal skills. Rather, the goals are to strengthen the laryngeal musculature to compensate for—to overdrive—the damaged mucosa and to encourage the mucosa to oscillate more freely because of this sort of "phonatory massage" of the mucosa.

Reoperation is occasionally an option. Ample time (9-12 months) should pass before this idea is entertained, however, because the voice may improve and iatrogenic lesions may diminish slowly for many months after the first operation. A second procedure can be planned to correct the videostroboscopically identified defect in mucosal mass, mobility, or edge configuration. For example, if an iatrogenic mass (granuloma) is causing poor phonatory closure, it should first be allowed to mature and possibly to resolve spontaneously. If it remains after a minimum of 6 months, it can be removed. Injection of collagen into an area of depression has been advocated,[32] but this approach does not yield more than very modest results, and even these occur on an inconsistent basis. Incision and simple mucosal elevation across a limited line of adherence with early postoperative phonation may cure diplophonia or lessen dysphonia, occasionally to a surprising extent. It should be stressed, however, that in some instances little can be done beyond voice building, and avoidance of this problem altogether through precision surgery is the ideal. Some authorities have written of fat injection or medialization thyroplasty, but these approaches remain to be systematically validated and make some sense theoretically primarily if there is a significant gap between the folds, and not simply mucosal stiffness.

Contact Ulcer or Granuloma

Epidemiology

Contact granuloma or ulceration is seen primarily in men (Fig. 62-24). Chronic coughing or throat clearing and reflux of acid from the stomach into the posterior larynx during sleep also seem to cause contact ulceration.[33] Some writers have also suggested that patients with this entity are experiencing psychological stress or conflict.

Pathophysiology and Pathology

The thin mucosa and perichondrium overlying the cartilaginous glottis become inflamed, perhaps as a result of overly forceful apposition (slamming together) of the arytenoids at the onset of voicing (glottal stroke) or during chronic coughing or throat clearing. Acid reflux may also increase inflammation of the vocal process area. The traumatized area ulcerates or produces a heaped-up granuloma.

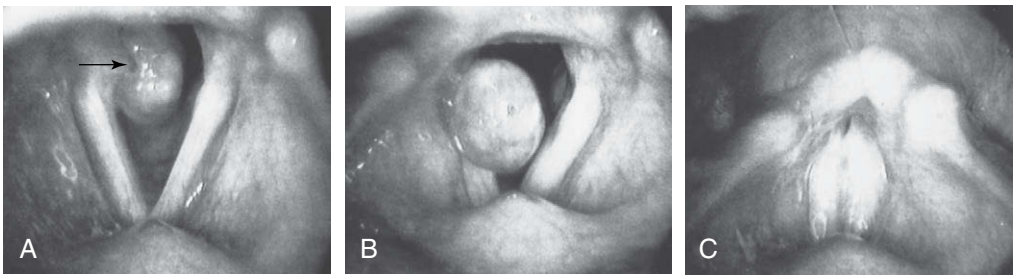

Figure 62-25. Video photographs through a laryngeal telescope of highly pedunculated right contact granuloma. **A,** The granuloma is drawn into the subglottis during sudden inspiration, thereby revealing its pedicle more clearly (*arrow*). **B,** Sudden exhalation blows the granuloma upward into the laryngeal vestibule. **C,** During phonation, the granuloma remains below the level of the vocal fold. Vocal fold closure is thus excellent, and speaking voice quality is remarkably undisturbed.

Diagnosis

History

The clinician inquires about caffeine and alcohol consumption as well as late-night eating, along with more specific acid reflux symptoms (e.g., acid eructations, raw throat in the morning with sour taste, unusually low-pitched, gravelly morning voice, heartburn). Frequent symptoms include unilateral discomfort over the midthyroid cartilage, occasionally with referred pain to the ipsilateral ear. When contact granulation tissue becomes large, hoarseness can occur.

Vocal Capability Battery

The speaking voice of a patient with contact ulcer or granuloma may sound normal or only slightly husky. The patient may be noted to be speaking habitually in an overly low frequency range, often with a "held back" vocal quality but sometimes with a kind of "constrained emphasis." In particular, the voice characteristics of the held-back quality, habitual coughing or throat clearing, and low and monotone voice use are typical.

Laryngeal Examination

A depressed, ulcerated area with a whitish exudate clinging to it or a bilobed, heaped-up lesion on the vocal process may be noted. At the instant of glottal closure, the vocal process of the uninvolved side can be seen to fit into the cleft of a bilobed granuloma. Erythema is also usually apparent on the vocal process and coming upward on the medial surface of the arytenoid cartilage. A mature, soon-to-detach granuloma may be pedunculated and may flip above and below the plane of the vocal fold margin with expiratory and inspiratory phonation, respectively (Fig. 62-25).

Management

An antireflux regimen should be started on an empirical basis even for patients with no symptoms of reflux. The necessity of routine barium or pH monitoring studies remains controversial. Maturation and resolution of the granuloma can often occur spontaneously over 3 to 6 months. Thus, the role for voice therapy to abolish throat clearing, raise average pitch for speech, and so forth, is indeterminate.

Indirect injection of a depot corticosteroid directly into the lesion and the area around its base can be accomplished in a videoendoscopy procedure room with the patient sitting in a chair.[12] Anecdotally, this technique has worked especially well for some granulomas but poorly for contact ulcers. Visible lesions tend to diminish in size, and the symptoms disappear. The use of inhaled triamcinolone (Azmacort, Abbot Laboratories, North Chicago, IL) 150 µg orally 3 times a day for 6 to 8 weeks has also been used for treatment and avoids systemic side effects.

Surgery should be a last resort because postoperative recurrence of the ulcer or granuloma is predictable. Furthermore, when the lesion has a classic appearance and can be visually monitored, there is little need for tissue diagnosis: visual criteria are sufficient. Microlaryngoscopy may be justified, however, if after a several-month trial of management an uninflamed, pedunculated lesion remains and is causing symptoms. Removal should be limited, leaving the base or pedicle undisturbed.

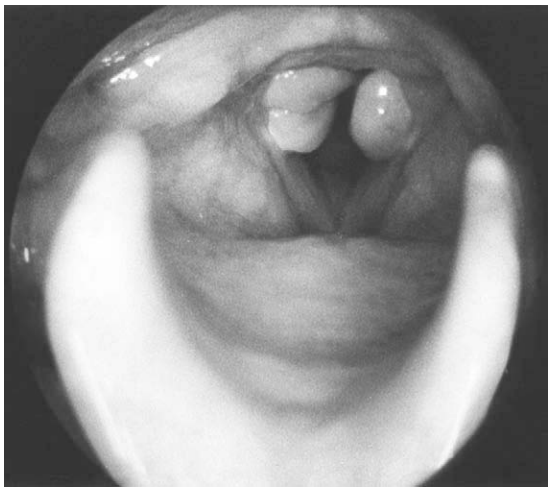

Figure 62-26. Postintubation granulomas.

Intubation Granuloma

Epidemiology

Intubation granuloma occurs in patients who have undergone endolaryngeal surgery affecting the arytenoid perichondrium, acute or chronic intubation, rigid bronchoscopy, or other direct laryngeal manipulations (Fig. 62-26).

Pathophysiology and Pathology

Granuloma after intubation can occur because of direct abrasion of the arytenoid perichondrium, a break in the mucosa covering it as a result of coughing on an endotracheal tube, or long-term pressure necrosis of the vocal process area. The resulting reparative granuloma may initially progress from fairly sessile to large and pedunculated, but it may then regress entirely with maturation over several months.

Diagnosis

History

The history of a patient with intubation granuloma includes a fairly recent event during which the larynx was subjected to direct instrumentation or intubation.

Vocal Capability Battery

The speaking voice of a patient with intubation granuloma may not sound abnormal because the membranous (vibratile) portion of the vocal folds may be unaffected by the granuloma, which may sit above or below the vocal process during phonation. The laryngeal appearance,

however, is characteristic. The granuloma can vary in size but is often large and spherical with some pedunculation. The granulomas are attached directly to the vocal process and are frequently bilateral. In cases of long-standing intubation, there may be associated findings such as tissue loss with resulting posterior glottic incompetence. In even more severe cases, there may be partial or complete fixation of one or both arytenoid cartilages. An interarytenoid synechia may also be noted on occasion.

Management

Regarding the management of intubation granuloma, if the history and physical examination findings are unequivocal, patience is recommended. If the injury is recent, antibiotic coverage for several weeks seems to be helpful. Voice therapy may have a role on a highly individualized basis. With time and use of these measures, intubation granulomas usually mature and "fall off." If they become mature and persistent, however, surgery or a trial of indirect corticosteroid injection in the office may be an option. During microlaryngoscopy, corticosteroid injection into the base of the granuloma before its removal is suggested. Any identifiable stalk should be left with the patient to minimize the size of the surgical wound. Topical application of mitomycin C has also come into use, to inhibit fibroblast proliferation that might lead to the reformation of granulation tissue.

Summary

The benign vocal fold mucosal disorders are important because of their impact on identity and communication and their commonness. For optimal results, diagnosis should include a skillful history, vocal capability elicitation, and laryngeal videostroboscopy. Intervention, whether medical management, voice therapy, surgery, or some combination, should match the diagnosis.

Saccular Disorders

At its anterior end, the normal laryngeal ventricle has a small outpouching called the *saccule* or *laryngeal appendix*. This structure is a blind sac that extends upward between the false vocal fold and thyroid cartilage, just posterolateral to the edge of the epiglottis at the level of the petiole. Containing many mucous glands, the saccule empties through an orifice in the anterior part of the ventricle. In a study of 100 random cadaver larynges, Broyles[34] found significant variation in the size of this normal structure, with 75% measuring 6 to 8 mm in length, 25% measuring 10 mm or greater, and 7% of the 25% measuring 15 mm or more. Although these structures may represent vestigial air sacs, their function is unknown in humans, besides perhaps to supply lubrication to the true folds via the many glands that line a saccule. For review of this anatomy, see Figure 62-27A.

Etiology of Saccular Disorders (Laryngocele and Saccular Cysts)

In infants, saccular disorders appear to be congenital. Otherwise, the cause of an air-filled laryngocele may be uncertain for the individual case. Some writers have cited an increase in transglottic pressure, such as that seen in trumpet players, glass blowers, and people using the voice in unusually forceful ways. Others, such as Stell and Maran,[35] believe that the relationship of laryngocele to these activities may have been overstated, because few reported patients with such disorders described in the world literature had hobbies or occupations requiring high transglottic pressures. A perhaps more clearly documented, although uncommon, cause of saccular cysts is laryngeal carcinoma, which causes obstruction of the saccular orifice.[36] I have also seen saccular cyst months or years after successful excision of a large supraglottic carcinoma with the laser, which left remnants of the saccule buried.

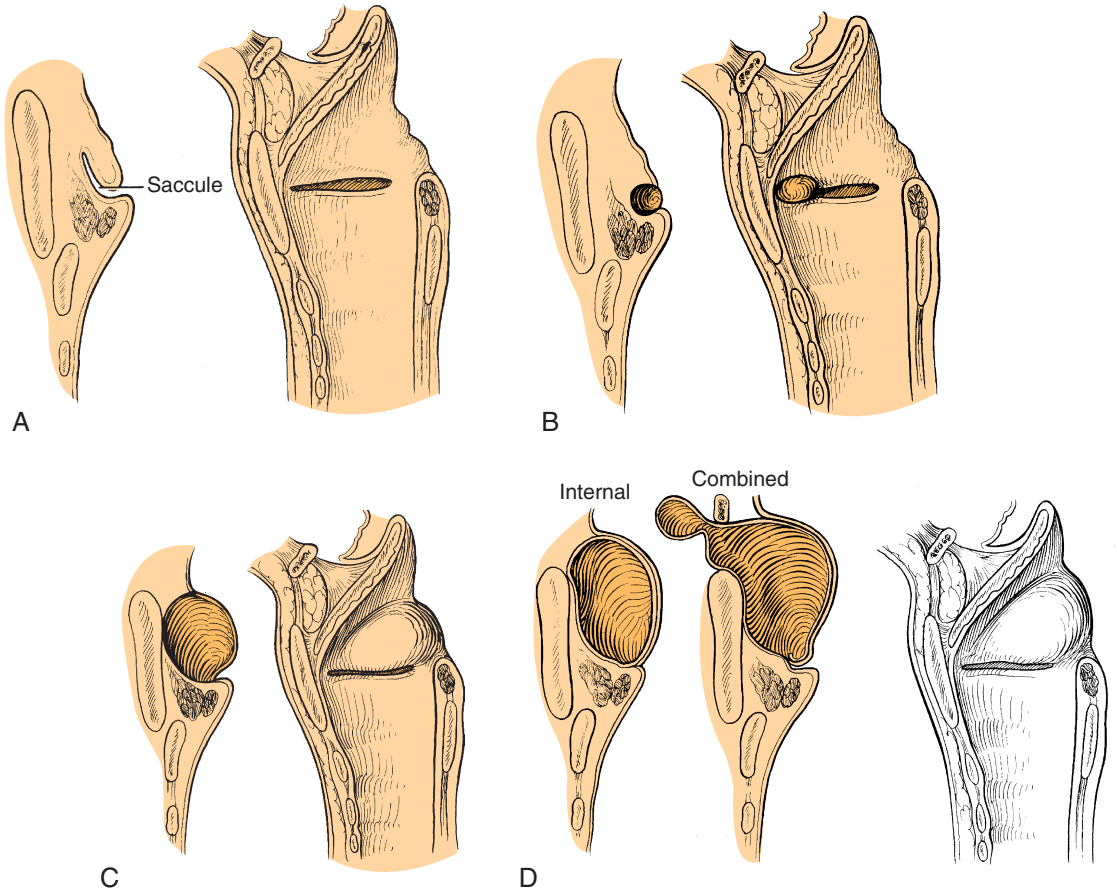

Figure 62-27. The classification scheme for a laryngocele or saccular cyst. **A,** Normal anatomy. **B,** Anterior saccular cyst. **C,** Lateral saccular cyst. **D,** Laryngocele types.

Clinical Scenario

Holinger and associates,[37] in their review of 46 patients with laryngocele or saccular cyst, found that in the 41 cases involving a saccular cyst, 10 occurred in infants and children and 31 in adults. Of the 31 adult cases, 22 were anterior saccular cysts and 9 were lateral saccular cysts. Four cysts in the infants and children were anterior, and 6 were lateral. When a saccular cyst occurs in infancy, it usually appears early, even at birth, as respiratory distress with inspiratory stridor. The infant's cry is abnormal, and cyanosis and dysphagia can occur. In adults, hoarseness seems to be the most common complaint, although dyspnea, dysphagia, pain, and a neck mass can occur with large or infected lateral saccular cysts (laryngopyoceles).[37]

Classification

Saccular disorders can be classified in various ways (Figs. 62-27 to 62-30).[37-40] It seems reasonable to think first of the *contents of the dilated saccule,* as in the following classification:

- Air-filled = *laryngocele* with patent saccular orifice
- Mucus-filled = *saccular cyst* with blocked orifice
- Purulence-filled = *laryngopyocele* with blocked orifice

A second classification might be by the *size and direction of cyst dissection* within the larynx, as follows:

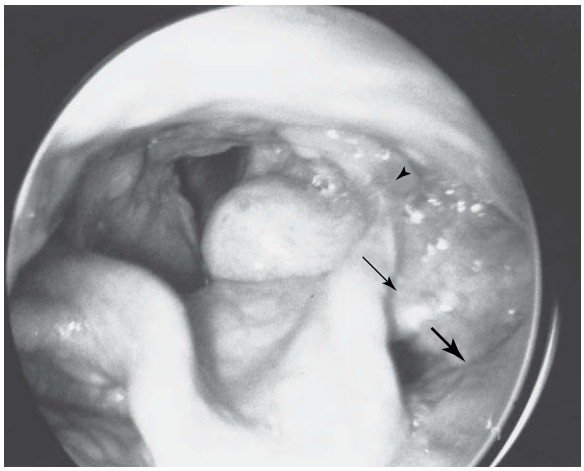

Figure 62-28. A saccular cyst, left, obscures most of the left vocal fold. A slightly larger cyst can be seen at the medial wall of the pyriform (*arrowhead*), at the pharyngoepiglottic fold (*small arrow*), or through the thyrohyoid membrane and into the neck (*large arrow*).

Anterior saccular cyst. Tends to protrude from the anterior ventricle toward the laryngeal vestibule. When large, it may "push down" on the vocal fold and cause dysphonia.

Lateral saccular cyst or laryngocele, internal only. This lesion tends to dissect more superiorly and laterally up into the false and aryepiglottic folds, sometimes bulging not only those structures (medially), but also the medial wall of the pyriform sinus (laterally) or even to fill the vallecula.

Lateral saccular cyst or laryngocele, internal/external. This variant tends to dissect as described for the lateral cyst, but also to penetrate through the thyrohyoid membrane and to appear as a swelling palpable in the neck.

Diagnosis

The diagnosis and classification of disorders of the laryngeal saccule are made through a combination of careful history, detailed examination of the larynx and neck, and computed tomography to determine contents (air vs. fluid) as well as the precise size and direction of expansion or dissection of the process. *Symptoms* depend somewhat on whether the laryngocele is internal, external, or combined. The usual symptoms are hoarseness, generally from downward pressure on the vocal fold or premature closure of the laryngeal vestibule at the false fold level during phonation, and (in decreasing order of frequency) stridor, dysphagia, sore throat, snoring, and cough.

Examination of the head and neck in a person with laryngocele reveals submucosal swelling protruding from the anterior ventricle in the case of an anterior saccular cyst or of the false vocal fold and aryepiglottic fold to a degree commensurate with the laryngocele's size. If a component of the laryngocele extends through the thyrohyoid membrane, a mass is palpable in the lateral neck in that location.

Treatment

Management is surgical. In infants with congenital lateral saccular cysts who have weak cry, stridor, and cyanosis, the airway should first be secured. This is followed by aspiration of the cyst contents through a direct laryngoscope or by endoscopic marsupialization with or without stripping of the cyst lining. Abramson and Zielinski[41] described application of the carbon dioxide laser to incise the cyst and to vaporize its lining. Booth and Birck,[42] reporting on laryngocele and lateral saccular cyst in neonates, described using simple cup forceps to unroof both lesions, followed by a 3-day intubation to act as a stent and to maintain the infant's airway. A 5-year follow-up revealed no recurrences. Frederick[43] describes endoscopic excision of internal laryngoceles. Holinger and coworkers,[37] in their report of 10 infants with saccular cysts, described direct laryngoscopy and aspiration of the cyst. They noted that a mean of 7.5 aspirations were required for each infant, 5 of whom later needed endoscopic marsupialization. One child had external excision of a persistent laryngeal cyst after 11 direct laryngoscopies. These

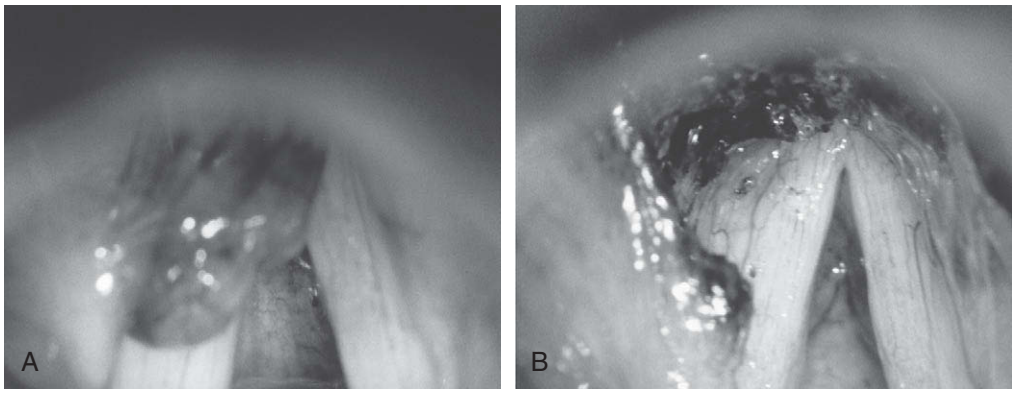

Figure 62-29. **A,** A moderate-sized anterior saccular cyst obscures the anterior left true vocal fold. **B,** After complete excision with a laser (not marsupialization).

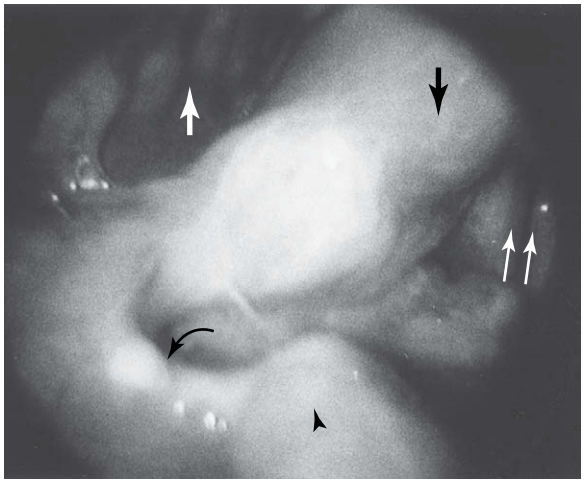

Figure 62-30. A voice laboratory view 1 week after complete endoscopic excision (not marsupialization) of a large lateral saccular cyst that had penetrated above the thyroid cartilage (direction of *curved arrow*) and outside the confines of the larynx. Parallel *small white arrows* demarcate the vocal folds. The *large white arrow* indicates the right pyriform sinus, and the *large black arrow* shows the right arytenoid apex. The wall of the cyst was followed surgically through the aryepiglottic fold, detaching the cyst from the epiglottis (*arrowhead*).

investigators also described the necessity for tracheotomy in 6 of 10 children, with a mean tracheotomy duration of 17 months. On the basis of this report, earlier definitive removal or aggressive marsupialization seems like a better option.

DeSanto and colleagues[38] reported on adult patients with saccular cysts and described endoscopic cyst avulsion for 29 cases of anterior cysts. Only one patient had recurrence of the cyst, which was later removed via laryngofissure. These researchers found anterior saccular cysts in association with laryngeal carcinoma in two of their cases, another finding that points to the need to rule out a small ventricular cancer in cases of saccular cysts or laryngoceles.

The experience of Holinger and coworkers[37] concerning 22 adults with anterior saccular cysts involved direct laryngoscopy and endoscopic removal with cup forceps. With this method, no cyst recurred. I have found that anterior saccular cysts are not infrequently incidental findings on examination performed for another reason; they can be followed if they are not causing symptoms.

For the larger lateral saccular cysts and laryngoceles, some controversy exists in the literature on the merits of primary endoscopic marsupialization versus an external approach.[35-45] Most writers seem to prefer the external approach for definitive removal in adults, particularly when an external component is present. This transcervical approach involves following the external portion (neck presentation) of the laryngocele or cyst sac through the thyrohyoid membrane. Some writers believe that removal of the upper portion of one side of the thyroid cartilage may be necessary to provide easier access to the endolarynx. The lesion is then transected as close as possible to the orifice of the saccule.

Many writers have cited the need for careful endoscopic examination and multiple biopsies to rule out laryngeal carcinoma in the ventricle as the cause of the laryngocele before definitive surgery. Removal of small internal laryngoceles, which are relatively rare, through laryngofissure or microlaryngoscopic techniques has been reported. Much of the literature seems to favor an external approach, but Hogikyan and Bastian[45] described complete endoscopic removal of large or recurrent saccular cysts. Their report on seven large lateral saccular cysts is well documented with preoperative and postoperative computed tomography scans and endoscopic photos. These researchers affirm complete *endoscopic excision* instead of endoscopic marsupialization or transcervical removal, even for large recurrent lateral saccular cysts. In this series, complete excision was possible on an outpatient basis for four of seven patients, and three were admitted for a single night's observation. None of the patients required tracheotomy, and none of the lesions has recurred several years later (Fig. 62-30). Since the time of this publication, I have also removed two combined internal-external saccular cysts with palpable neck components completely via endoscopic methodology. This approach requires following the cyst wall *endoscopically* over the top of the thyroid cartilage and into the neck.

The reader attempting complete removal of a saccular cyst via the endoscopic approach should note that even a large lateral cyst bulging dramatically during awake endoscopy can virtually disappear under conditions of direct laryngoscopy with general anesthesia. I have found that when that happens, one can begin by excising the false fold, during which maneuver the wall of the cyst is invariably encountered. In small and moderate lesions, one can often deliver the entire cyst intact by dissecting carefully along its external wall. When the lesion is unusually large, one may need to transect the presenting part of the cyst, decompress its gluelike contents, and then deliver the rest of the cyst by retracting or releasing its wall progressively into view through the laryngoscope.

Summary

Saccular disorders, whether laryngoceles or saccular cysts, can be easily diagnosed through appropriate history-taking, physical examination, and radiologic evaluation. Initial evaluation in adults should exclude the presence of an occult laryngeal carcinoma involving the ventricle, the region of the saccular orifice, or the saccule. Whether to use an endoscopic or external approach depends on the classifications of laryngocele or saccular cyst, its size, patient factors, and, perhaps most of all, surgeon experience and preference.

Benign Mesenchymal Neoplasms

Compared with the benign vocal fold mucosal disorders (e.g., nodules, polyps, cysts, sulci, contact ulcers), neurologic disorders, scarring or stenosis problems, malignant tumors of the larynx, and benign tumors of the larynx are rare. The literature sometimes incorrectly includes nonneoplastic mucosal reactive disorders (i.e., response to chronic injury), such as polyps and nodules, in the category of benign neoplasms.[46,47] Even when nonneoplastic reactive lesions are excluded, the cases of benign tumors in the literature are comparatively few when one considers the number of years covered by the reviews describing them. And if papillomas are excluded, laryngologists can expect to see only a few nonmalignant laryngeal neoplasms during their careers.

Epithelial Tumors

Recurrent Respiratory Papillomatosis

Squamous papillomas caused by the human papillomavirus (HPV), are the most common benign neoplasms seen by laryngologists (Figs. 62-31 and 62-32). Jones and colleagues,[47] who found that 84% of the benign laryngeal tumors they managed were papillomas, noted that this statistic matches those of other large series. On the basis of physician questionnaires about patients with recurrent respiratory papillomatosis, it is estimated that this entity occurs at a rate of 4.3 per 100,000 children and 1.8 per 100,000 adults.[48] HPV infection can be separated into many different serotypes by means of polymerase chain reaction methodology. The majority of infections are the result of subtypes 6 and 11. Type 11 appears to predispose to more aggressive disease, more frequent need for surgical intervention, and a higher risk of tracheopulmonary involvement.[49,50] Weiss and Kashima[51] reviewed 39 cases and also reported that a history of tracheotomy, a high number of endoscopic procedures, and a long duration of the disease seem to correlate with an increased incidence of tracheal involvement. I have also seen types 16 and 18, which are known to pose a higher risk of malignant transformation.

An association between genital condylomata in the mother and recurrent respiratory papillomatosis (RRP) in the child is known; however, the fact that only approximately 1 in 400 children at risk because of maternal infection actually experience RRP, as reported by Shah and associates,[52] suggests relatively low infectivity. Another study of 3033 births to mothers with genital condylomata yielded 57 cases

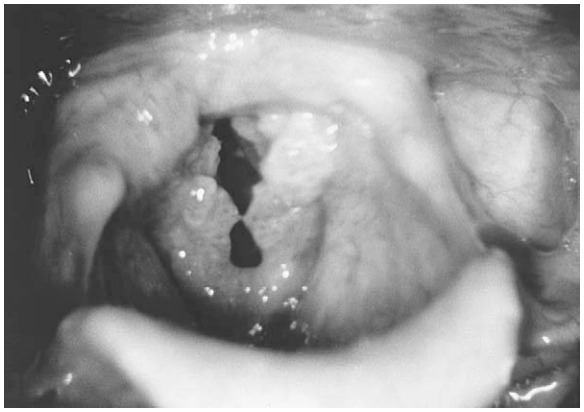

Figure 62-31. Diffuse recurrent respiratory papillomatosis distorts the contour of both true vocal folds and the right arytenoid apex. The dark dots represent the fibrovascular core within each papilloma.

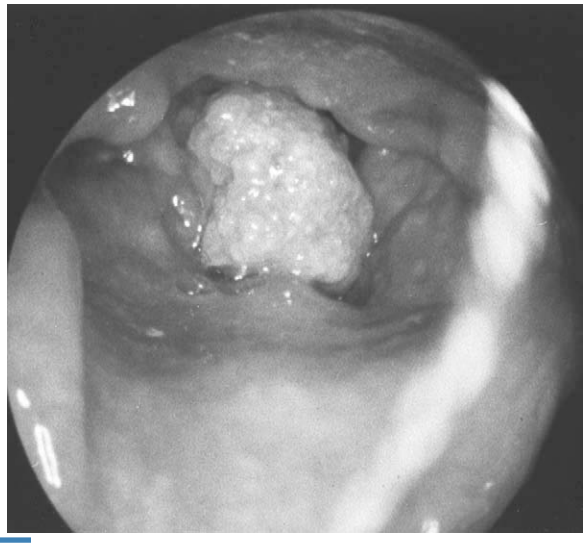

Figure 62-32. A large mass of papillomas obscures the vocal folds and airway. The patient has a tracheostomy tube.

of RRP, for a rate of 7 per thousand births to genitally infected mothers, a markedly greater incidence than that seen in uninfected mothers. Nevertheless, somewhat counterintuitively, cesarean delivery was *not* found to be protective against respiratory papillomatosis.[53] These kinds of findings make the question whether to perform cesarean section in the context of maternal infection controversial. A different question is whether children born to women with RRP (genital status unspecified) are likely to develop RRP themselves. Gerein and colleagues[50] found no cases of RRP among children and grandchildren of a group of German mothers with RRP or among those of a second group of Russian women with this disease. All the same, Mammas and associates[54] found HPV DNA in the specimens of 9 of 106 (8.5%) children after removal of hyperplastic tonsils and adenoids in whom no clinical papillomas were found.[54]

RRP may commence in childhood or adulthood. The juvenile form, almost always due to type 6 or 11 and commonly designated papillomatosis because of diffuse involvement of the larynx, usually manifests in infancy or childhood as hoarseness and stridor. This form of papillomatosis is often aggressive and rapidly recurrent, requiring frequent laryngoscopic removal for management. Rarely, papillomas may regress spontaneously, especially at puberty. On laryngoscopic examination, exuberant tissue resembling miniature clusters of grapes may be seen, especially on the anterior part of the true vocal folds, the false folds, and the epiglottis (see Fig. 62-32). The bulk of papilloma tissue can be so great as to obscure normal laryngeal landmarks.

Adult-onset papillomas are occasionally solitary or at least more localized than juvenile-onset lesions and are more likely to be of the "carpet variant." The latter morphology does not show the typical exophytic growth pattern, instead causing a velvety appearance with little projection from the surface. The red "dots" on the surface representing the fibrovascular core of each papilloma are still visible, however. Behavior of adult-onset papillomatosis may also be less aggressive, and, rarely, a single removal leads to "cure." However, adult-onset papillomatosis can also behave like the more aggressive juvenile-onset form.

The carbon dioxide laser remains the most widely accepted management for papillomas in the larynx; more than 100 laryngoscopic removals may be required to control these lesions during childhood, and sometimes they must occur every few weeks. The laser is useful because of its hemostatic properties (papillomas tend to be friable and vascular). In addition, the precision of the micro-spot laser allows for vaporization of the lesion plane by plane to avoid harming the underlying vocal fold. The microscopic débrider instrument is particularly useful in friable, exuberant cases that would require markedly more time to remove via laser "excision" or planar coagulation. That tool, however, is not very useful for the precise removal of the last "5%," nor for very flat "carpet" morphology.

Many other management modalities have been tried. Systematic reviews of the English literature suggest that the strongest current interest might be in the antiviral agent cidofovir.[55-57] Options such as cryotherapy, irradiation, photodynamic therapy, and vaccines such as Gardasil (Merck & Co., Inc., Whitehouse Station, NJ) are not yet validated or are even rejected by some for *treatment* of existing disease, although Freed and Derkay[58] have advocated use of the vaccine to *prevent* not only genital HPV infection but also RRP.

Although dramatic responses to interferon have been observed in some cases, the agent's long-term role in the management of laryngeal papillomatosis appears to be limited at best. In 1983, McCabe and Clark[59] reported a series of 19 patients with moderate to severe RRP that was managed with interferon. They found that 6 patients were disease free by visual criteria, 7 had a small amount of visible disease but not enough to require surgery, and 2 showed no response to interferon. These investigators also noted that the papillomas tended to regrow upon cessation of interferon therapy. Overall, they thought that during the time administered, interferon spared patients the need for multiple operations. In a later study, Leventhal and colleagues,[60] using higher doses and longer duration of interferon therapy, noted a significantly higher response rate; some responses appeared to be long-term. Similar findings arose in an even larger study by Gerein and coworkers.[50] Ogura and associates[61] reported the recurrence of papilloma after a 6-year interval in a patient who seemed to have achieved a durable response to interferon. I have used interferon according to the Leventhal criteria in 12 adults. Three achieved long-term remission after 6 months of treatment. Most of the rest had notable reduction of growth rate of the disease, sometimes on a durable basis, but not remission. Better understanding of the role of interferon in RRP awaits further study.

Another newer medical management modality uses indole-3-carbinol, a natural derivative of cruciferous vegetables such as cabbage and broccoli.[62] Anecdotal reports suggest that some patients who take this medication experience significant benefit. An estimated 30 of 110 patients in my adult practice have used this nutritional supplement, but with somewhat disappointing results. Case reports suggesting good results can be achieved, but perhaps they are more common in persons with more rapid growth of RRP than is often seen in adults.

Avidano and Singleton[63] reported the use of methotrexate in three patients with severe RRP that did not respond to interferon or *cis*-retinoic acid. All three experienced a prolonged interval before repeat surgery and reduced disease severity, but regression was not complete.

European investigators first wrote about the use of intralesional cidofovir as a treatment for DNA viruses, including HPV.[64-66] At least one anecdotal report showed disappearance of a papillomatous lesion of the esophagus injected serially with cidofovir.[67] Subsequently, others have shown good results with this medicine, either for regression or

remission of existing lesions or as an adjunct to surgery.[67-76] In my experience with more than 30 patients, rapidly growing and focal lesions seem to respond best. Some durable remissions are indeed achievable, and pending further experience, long-term remission appears feasible in approximately one in four adult patients when patients with slowly growing papillomas are included. Neither the investigators described nor I have seen scarring believed to be due to the use of cidofovir, except when an overly aggressive "bleb" was raised, depriving the mucosa of blood supply. Chhetri and colleagues,[76] however, in a study using a canine model, found atrophy and scarring that appeared to be worse with number of times injected and with increasing concentration of cidofovir. In this model, use of concentrations higher than 20 mg/mL, in particular, seemed to have this effect. The same group found no change in leukocyte count or renal parameters in doses up to 4.26 mg per kg body weight. The carcinogenic potential has never to my knowledge been proven for intralesional use of cidofovir, and it bears remembering that HPV infection itself has a documented risk for cancer.[50,77,78]

In a pilot study, McMillan and associates[79] described use of the 585-nm pulsed dye laser on three patients with RRP. As had previously been found by Tan and colleagues[80] for cutaneous warts, the hemoglobin in microvasculature selectively absorbed laser energy. In the McMillan study, either the carbon dioxide or the pulsed dye laser was used on different areas of papilloma growth. Papilloma response to both laser treatments appeared to be good, at least to the limited time of follow-up reported. Early edema seemed to be less on the side of the pulsed dye laser. This laser coagulates the microvasculature, owing to the red color of hemoglobin, but leaves the overlying epithelium relatively uncoagulated. The mechanism of action for regression of papillomas was said to be deprivation of oxygen and nutrients to the lesions. Franco and colleagues[81] subsequently used the pulsed dye laser on lesions in 41 patients. In about half of these, papillomas were treated with the laser but not removed. This group also noted marked response without evident scarring. As a continuation of long-established office-based surgery,[12,13] I use two office-based lasers. I use the pulsed potassium titanyl phosphate (KTP) laser, with hemoglobin as the chromophore, for small to moderate disease and especially for carpet-variant papillomas. The less selectively coagulating thulium laser (with the water molecule as the chromophore) is more useful for larger amounts of disease (Figs. 62-33 and 62-34).

Some of these medical management modalities hold promise; all need further investigation and validation. Thus, optimal management for RRP is careful serial laser laryngoscopic treatments with consideration of the investigational use of interferon, indole-3-carbinol, cidofovir, and, perhaps, the HPV vaccine if or when validated for this disease process.

Vascular Neoplasms

Polypoid Granulation Tissue

Fechner and colleagues[82] reviewed 639 vascular lesions of the head and neck, 62 of which were found in the larynx or trachea, and reported that polypoid granulation tissue is the most common vascular tumor in the larynx. They also noted that pyogenic granuloma does not occur in the larynx. Pyogenic granuloma, as seen most often on the tongue, consists of distinct lobules of capillaries separated by fibromyxoid stroma, whereas polypoid granulation tissue consists of radially arranged capillaries. These investigators attribute formation of polypoid granulation tissue in the larynx to one of several forms of trauma (i.e., caused by laryngeal biopsy, intubation, direct external trauma to the larynx, and an external penetrating wound). Granulation tissue in the larynx should be handled primarily by conservative measures, including removal of the source of any ongoing irritation (e.g., from inappropriate voice use or acid reflux laryngitis) and intralesional corticosteroids. For nonresponse and continuing symptoms, careful endoscopic removal may be considered after the granulation tissue has been allowed to mature and to become less active and vascular.

Laryngeal Hemangiomas

Infants with laryngeal hemangiomas often have associated cutaneous hemangiomas. These infants typically have respiratory symptoms

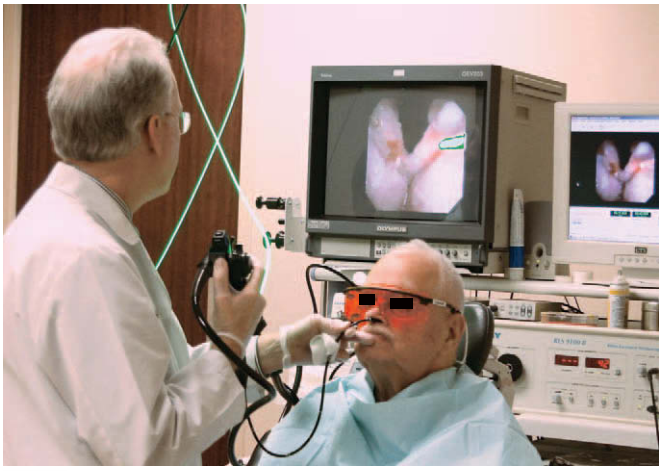

Figure 62-33. Pulsed KTP (potassium titanyl phosphate) laser treatment of chronic and recurrent keratosis with atypia.

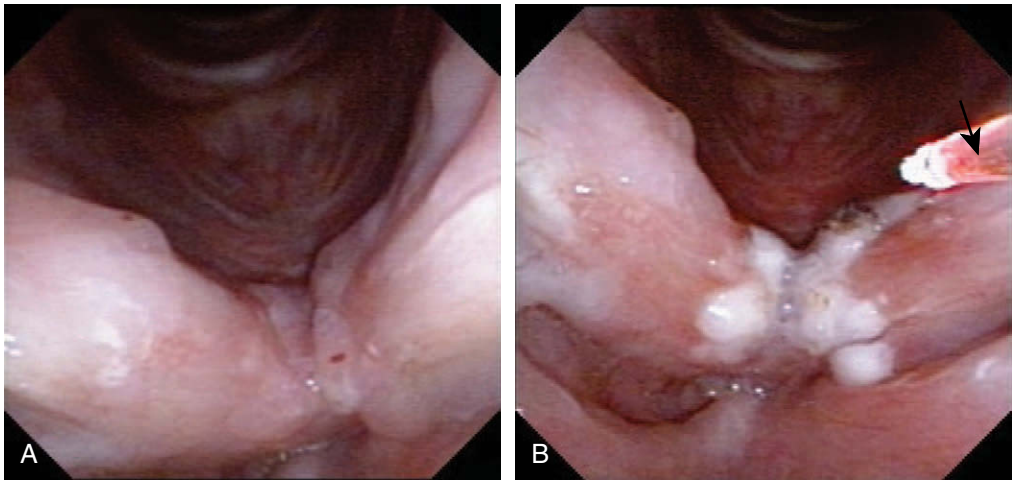

Figure 62-34. A, Papillomas primarily at the anterior commissure, before pulsed-KTP (potassium titanyl phosphate) laser treatment. **B,** Same larynx after treatment. Note the delivery glass fiber (*arrow*).

such as stridor and pseudocroup, usually within the first 6 months of life.

During direct laryngoscopy, a mucosa-covered mass with or without bluish coloration may be seen in the subglottis. Other suggestive findings are compressibility with palpation and shrinkage with administration of epinephrine.

In his review of the management of subglottic hemangioma in 1968, Calcaterra[83] addressed the then-prevalent practice of low-dose irradiation for subglottic hemangioma in infants. On the basis of experience in an infant with a large cavernous hemangioma that did not respond to irradiation as well as general knowledge of radiation's effect on vascular tissues, Calcaterra[83] suggested that this therapy was inadvisable. He suggested that tracheotomy be done when indicated for airway protection. This step allows the tracheal lumen to enlarge with growth of the child and, more importantly, gives the hemangioma an opportunity to involute spontaneously, as most such lesions do if they are left alone.

Later reports by Healy and colleagues[84] and Mizono and Dedo[85] explored the usefulness of the carbon dioxide laser for the management of this lesion. On the basis of 11 cases in the three centers reported by the authors, the researchers concluded that for the usual capillary hemangioma in the infant subglottis, the carbon dioxide laser is clearly superior to radiotherapy or corticosteroid therapy. They described the procedure as beginning with removal of tissue for histologic examination followed by simple vaporization of remaining abnormal tissue. These researchers also believe that if the tracheotomy was not required before the procedure for airway maintenance, it is probably unnecessary, provided that intense humidification is supplied in the immediate postoperative period. None of the patients reported in this series had significant complications, although four required a second treatment with laser for a satisfactory final result. All patients with previously placed tracheotomy tubes were successfully decannulated.

Adult hemangiomas are usually found at or above the level of the vocal folds. Because they are more often the cavernous form and are usually covered by thinner mucosa than the congenital hemangioma, adult hemangiomas appear more often as bluish, discolored masses.

Bridger and associates[86] reviewed literature on hemangioma in the adult patient, noting that in contrast to the congenital form, symptoms of this lesion may have been present for many years. Hoarseness is the expected symptom, and respiratory distress never occurs. Although hemorrhage may occur spontaneously, it is usually a surgical complication. These investigators advised that adult laryngeal hemangiomas be left alone if at all possible. They recommended that corticosteroid therapy or radiotherapy be used when necessary and that surgery of adult laryngeal hemangioma be undertaken when the hemangioma shows a tendency to involve progressively additional parts of the larynx, as occurred in one reviewed study. The carbon dioxide laser is not generally advised for adult cavernous hemangioma because the diameter of the vascular spaces exceeds this laser's coagulating ability.

Muscle Neoplasms

Rhabdomyoma

Most extracardiac rhabdomyomas are found in the head and neck region, especially in the pharynx and larynx. Winther[87] found 53 cases involving the hypopharynx or larynx in the literature up until 1976 and also supplied two case reports. He noted that none of these tumors recurred after local excision and advised that the approach be as conservative as possible for complete removal. He also noted that rhabdomyoma can be confused with a granular cell tumor or a rhabdomyosarcoma. Modlin[88] also stressed the need to differentiate between rhabdomyoma and granular cell tumor and noted that complete local excision is curative.

Neoplasms of Adipose Origin

Lipoma

Zakrzewski,[89] in his review of the literature through 1965, believed that only 70 of many cases reported as laryngeal lipomas actually involved the larynx and were sufficiently described to allow for analysis of this entity. He noted, however, that 23 of the 70 cases had some other tumor characteristics, such as fibrolipoma, myxolipoma, nervous tissue, cyst fragments, and angiolipoma. Although laryngeal lipomas were sometimes seen among persons with numerous lipomas in other body areas, most were isolated occurrences.

Of 70 cases, 54 were designated extrinsic, whereas only 16 were classified as true intrinsic laryngeal tumors. Because lipomas occurred more frequently in parts of the larynx in which fat was a normal part of the subepithelium, most tumors arose on the aryepiglottic fold and epiglottis (the periphery of the laryngeal vestibule). Of the intrinsic tumors, the most common site of origin was the false vocal fold. Only one case involved a true vocal fold.

Because lipomas are slow growing, symptoms were often present for many years before diagnosis. In general, respiratory symptoms were most common, and hoarseness was relatively infrequent.

Surgical management was successful. Procedures such as endoscopic removal, subhyoid pharyngotomy, lateral pharyngotomy, and laryngofissure were used according to tumor size and location. The guiding principle was conservative with complete removal or enucleation because incompletely removed lipomas regrow.

Benign Neoplasms of Glandular Origin

Benign Mixed Neoplasm

Benign mixed tumors (pleomorphic adenomas) are extremely uncommon in the larynx. Som and coworkers[90] found only 27 cases of this tumor involving the larynx in the literature up to 1979, and they supplied one case report. Most of these tumors involved the subglottic laryngeal region, and only 6 involved the supraglottis. These researchers described the typical appearance as that of a smooth, ovoid submucosal mass. As is the case for most other benign laryngeal tumors, the approach to surgical excision of a benign mixed neoplasm of the larynx depends on the tumor's size and location.

Oncocytic Neoplasms of Larynx

According to the literature, oncocytic tumors are actually oncocytic metaplasia and hyperplasia of the ductal cell portion of glandular tissue. Gallagher and Puzon[91] found that 18 of 19 cases in their series were cystic and concluded that these lesions represent duct metaplasia and hyperplasia rather than true neoplasia. One solid tumor in their series was considered an oncocytic adenoma, as seen in the parotid gland.

Lejeune and associates[92] reported a case of a woman with numerous cystic oncocytic lesions of the epiglottis, aryepiglottic folds, false vocal fold, and right true vocal fold, supporting the opinion of Gallagher and Puzon.[91] Lundgren and colleagues[93] presented a series of seven oncocytic cysts of the larynx and agreed that these lesions represent glandular duct metaplasia and hyperplasia rather than true neoplasia.

All of these writers seem to agree that simple excision, by whatever approach necessary according to lesion size and location, is the management of choice.

Cartilaginous Neoplasms

Chondroma

Although an attempt to differentiate histologically between chondroma and low-grade chondrosarcoma has been made, Mills and Fechner[94] believe that the behaviors of the chondromas and the low-grade chondrosarcomas are so similar that histologic distinction has little practical significance. Because neither grows quickly or metastasizes, the clinical approach to these entities can be the same. Neel and Unni,[95] in their experience with 33 patients, noted that most patients had an "obvious smooth rounded mass covered by mucous membrane in the subglottic region of the larynx," and in most cases this mass was situated posteriorly and laterally.

Neel and Unni[95] did not tabulate symptoms separately for benign and malignant cartilaginous tumors; symptoms consisted mainly of hoarseness, dyspnea, neck mass, and dysphagia. These writers used laryngofissure most often for tumor removal and total laryngectomy for high-grade malignant tumors.

Singh and associates,[96] in a review of laryngeal tumors seen at four major hospitals between 1960 and 1977, found only two cartilaginous tumors of the larynx, but they found 177 cases reported in the English literature. Of cartilaginous tumors, 70% arose in the cricoid cartilage, primarily from the posterior plate. The growth of these tumors is mostly intraluminal, with a rare case appearing externally into the neck. These writers believed that because chondrosarcomas are usually indolent and rarely metastasize, local resection, if technically feasible, is adequate management. They described laryngofissure with submucosal resection as the most common approach to these tumors, unless the cricoid would be collapsed entirely by its subtotal removal.

Hyams and Rabuzzi,[97] in a series of 31 cartilaginous tumors of the larynx, found 15 chondromas and 16 chondrosarcomas. The chondromas occurred in a slightly younger age group than the chondrosarcomas. However, the chondromas included nine "chondromas of the true vocal cord," which probably represent metaplasia of the elastic connective tissue of the vocal fold rather than true chondromas.

Neoplasms of Neural Origin

Granular Cell Neoplasms

Mills and Fechner[94] noted evidence indicating that granular cell tumors originate in Schwann cells; these tumors had previously been called granular cell myoblastomas because they resemble muscle tissue with standard staining techniques. A notable characteristic of granular cell tumors is frequent association with overlying pseudoepitheliomatous hyperplasia of the mucosa. Insufficiently deep biopsy of this lesion can lead to an incorrect diagnosis of epidermoid carcinoma.

Although granular cell neoplasm can involve any part of the larynx, the middle to posterior part of the true vocal fold is the most common site, and hoarseness is thus the most common complaint. Conservative but complete local excision is considered definitive therapy.[98-101]

Neurofibroma

Chang-Lo[102] reviewed 19 previously reported cases of von Recklinghausen's disease with laryngeal involvement and supplied 1 case. Supance and colleagues[103] reported that solitary neurofibromas of the larynx not associated with von Recklinghausen's disease were more common than those associated with the disease. The most common symptoms in patients with laryngeal involvement by von Recklinghausen's were hoarseness, dyspnea (most striking), and dysphagia. On physical examination, lobulated nodules ranging from less than 2 to 8 cm in diameter were noted, and the most common site of origin was the arytenoid or aryepiglottic fold.

Because these lesions are benign, the surgical approach should balance conservatism with the need for complete excision. For larger tumors, an external approach (e.g., lateral pharyngotomy, laryngofissure, lateral thyrotomy) may be needed.[104]

Neurilemmoma

Neurilemmomas are less common than neurofibromas and usually involve the aryepiglottic fold and false vocal fold. Symptoms correspond with the slow growth of these lesions and can include a sensation of fullness in the throat, voice change, and slow development of respiratory distress. Management should consist of conservative but complete removal by an approach consistent with tumor size and location. Neurilemmomas are more encapsulated than neurofibromas; simple enucleation (e.g., by a lateral thyrotomy) with removal of a portion of the thyroid cartilage is believed to be adequate management.[105,106]

Summary

True benign neoplasms of the larynx do not include benign (reactive) vocal fold mucosal disorders. If papillomas are excluded, the number of persons with laryngeal neoplasms is small; busy laryngologists infrequently see these lesions. The basic management principles are similar for these tumors, regardless of the cell of origin. Removal should be complete but conservative (to spare the voice), with the approach determined primarily by tumor size and location.

CHAPTER SIXTY-THREE

Acute and Chronic Laryngitis

Albert L. Merati

Key Points

- Acute and chronic laryngitis overlap and do not correspond to causes of inflammation.
- The impact of laryngitis includes both short-term dysfunction during the acute phase of inflammation and secondary effects of the inflammatory process, such as scar formation.
- The most common cause of *chronic laryngitis* in patients cared for by otolaryngologists is reflux. The most common cause of *acute laryngitis* in the general population is viral, as part of an upper respiratory infection. The true incidence of these two entities is not known.
- Candidal laryngitis is common and can occur in immunocompetent individuals.
- New investigation into individual susceptibility to various laryngeal injuries may explain the variation of clinical presentations in gastroesophageal reflux.

Of all the terms in the realm of the otolaryngologist, "laryngitis" may feature the greatest discrepancy between its familiar meaning for the lay public and its broad implications for specialists in the field. Although *laryngitis*, or inflammation of the larynx, does indeed include many varied and complex abnormalities, the basic distinction between *acute* and *chronic* laryngitis is reasonable and will serve to organize this chapter. In the following sections, disorders resulting in laryngeal inflammation are presented along with general concepts about laryngeal tissue response to injury and the larynx as an immunologic organ.

Why Does Laryngitis Matter?

There are several broad reasons why laryngitis is significant. *Functio laesa*, the often overlooked "fifth sign" of inflammation (along with *rubor, tumor, dolor,* and *calor*), describes the loss of function in an inflamed organ, be it the liver in hepatitis or the hoarse voice of a patient with vocal fold edema related to viral laryngitis. The inflamed larynx does not phonate, swallow, or breathe well. In the extreme, this condition can lead to airway obstruction as seen in *epiglottitis*. Function may also be impaired after the resolution of the inflammatory process. In an important paper, Squire and associates[1] demonstrated that the introduction of bacteria into an acquired airway injury in the rabbit model resulted in a higher rate of stenosis than seen in the controls; this effect was muted by the addition of antibiotics to the model. Fine degrees of dysfunction from bacterial infection have not been clearly described, however. In an innovative study, Reidy and colleagues[2] exposed subjects to aerosolized antigens (to which they were known to have skin-test responsiveness). In this investigation, the subjects' larynges did demonstrate greater mucus and other signs of irritation after exposure; their objective laryngeal parameters, such as acoustic voice parameters, did not change.

Finally, although it is not proven, many have suspected the relationship between laryngeal inflammation and malignant transformation. The most commonly considered mechanism is injury from refluxed materials. It was proposed many years ago by Ward and Hanson[3] and has been further supported by the work of Koufman[4] and Qadeer and associates.[5-8]

Acute Laryngitis

Phonotrauma

Vocal abuse, misuse, and overuse can contribute to phonotrauma. This may result in vocal fold hemorrhage and edema in addition to incurring changes at the molecular level.[9,10] Although this process does not represent the usual concept of infectious or "exogenous" sources of inflammation, the tissue response to injury can be quite profound. The problem of vocal abuse and strain may be exacerbated by dehydration through its effect on phonation threshold pressure.[11,12] On the basis of common clinical experience, many practitioners believe that vascular lesions of the vocal fold may begin or may be exacerbated by acute phonotrauma. In the case illustrated in Figure 63-1, a young singer noted the moment her voice changed during a performance. Examination of her vocal folds in the clinic revealed a left true vocal fold lesion with feeding vessels. Despite excellent hygiene, voice therapy, and conservative management, the lesion did not resolve, and she required phonosurgical intervention.

In the great majority of cases involving phonotrauma, medical attention is not sought. A patient who does seek care from an otolaryngologist is most likely to have recurrent or severe symptoms—or to be particularly sensitive to his or her vocal health. Clinical examination should include a detailed history and fiberoptic examination and stroboscopy, if available. There is little to no scientific basis for the usual treatments—voice rest, steroids, and other medications. Anecdotally, however, voice rest is quite useful to reduce further acute injury, particularly if there is a hemorrhagic component to the laryngeal injury. Paradoxically, some degree of mechanical strain (in the truest physics sense of the word) may be beneficial to appropriate vocal healing. Branski and colleagues[13] have elegantly shown that low levels of mechanical activity may actually reduce inflammatory activity in vocal fold fibroblasts. This finding may be elucidated by further investigation

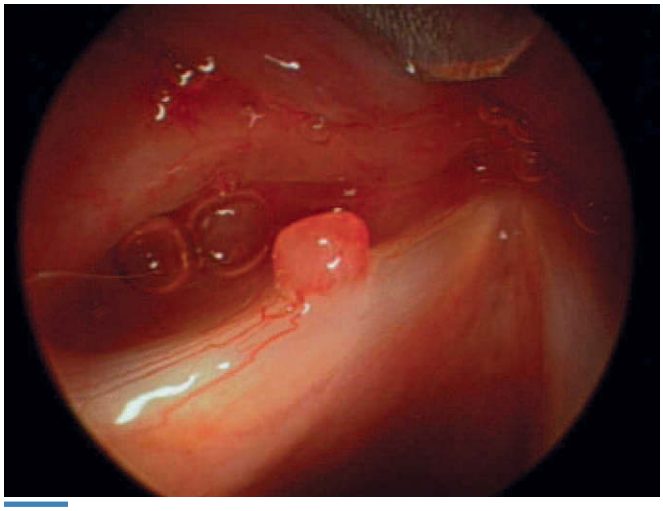

Figure 63-1. Intraoperative photograph from a 70-degree telescope of the left true vocal fold of a young singer who reported acute vocal changes during a performance. Clinical examination revealed this pedunculated lesion with surrounding inflammatory vessels. Medical and speech language intervention did not resolve her condition. She underwent successful phonosurgical removal of the lesion. Note the absence of pathologic vessels on the right vocal fold.

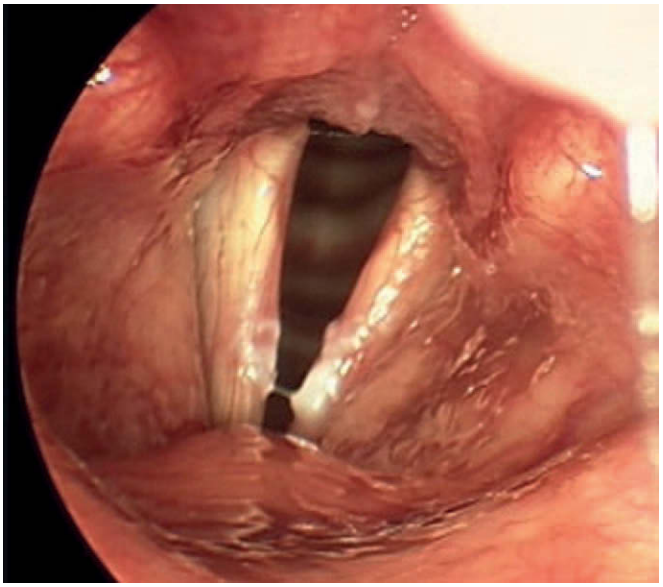

Figure 63-2. 60-year-old woman with several months of hoarseness. She had been using a steroid inhaler. Examination with a transoral rigid laryngoscope showed raised whitish plaques of the membranous vocal folds. These responded promptly to antifungal treatment. *(Image courtesy of Lucian Sulica, MD, Cornell University School of Medicine, New York.)*

as our understanding of the molecular basis of vocal fold injury improves.

Viral Laryngitis

The precise incidence of viral laryngitis is not known, reflecting its familiarity and its association with the ubiquitous viral "upper respiratory infection." When it does occur, it may be due to typical "common cold" viruses, such as the rhinovirus. Many other viruses have been implicated in cases of acute viral laryngitis, including herpes zoster,[14,15] coronavirus,[16] as well as less familiar agents. There is no specific knowledge that antiviral treatments have any predictable impact on the clinical course of viral laryngitis. Supportive care, including rehydration and vocal rest, are commonly recommended. In one double-blind, placebo-controlled study, flurbiprofen, an anti-inflammatory medication, was shown to decrease discomfort in patients with viral laryngitis.[17]

In severe cases resulting in airway embarrassment, this aspect of clinical care naturally takes precedence. Medical management of the impaired and inflamed airway is familiar to readers from the airway chapters in this volume; it includes the use of steroids, antibiotics for secondary infections, proton pump inhibitors, and humidification. Although much of this approach has remained experiential and anecdotal, one prospective, double-blind, randomized study in children demonstrated better outcomes when dexamethasone was used in acute laryngotracheitis (croup) if given in the first 24 hours of treatment.[18]

Acute Bacterial Laryngitis

Much of this discussion, historically as well as in this edition, deservedly rests in the pediatric section. Epiglottitis—or, more properly, supraglottitis—continues to be a life-threatening infection of the upper airway in adults as well. Despite the great success of the *Haemophilus influenzae B* vaccine in limiting the frequency of this disorder,[19] the clinical entity acute upper airway obstruction from bacterial infection of the larynx continues to occur. The presentation is often quite dramatic, with an urgent call to the emergency department for a drooling, febrile patient in respiratory distress. Depending on the acuity of the airway embarrassment, the *adult* patient may be examined fiberoptically to characterize the nature of the obstruction; determination of the severity of the obstruction and the clinical decision-making, however, are based on a generalized assessment of the patient's overall appearance in addition to nonlaryngeal airway considerations, such as body habitus, jaw and mouth opening, and neck extension. If the patient requires airway intervention, intubation in a controlled setting (such as the operating room) or awake tracheotomy may be appropriate. This having been said, a review of 23 adult supraglottitis cases revealed that the minority (3/23) of cases required airway intervention.[20] The remainder may be managed supportively, with humidification, intravenous antibiotics, close observation, and even with steroids.[21]

Laryngeal infection with *Klebsiella rhinoscleromatis*, part of the disorder known as rhinoscleroma, is another clinical entity that can affect the larynx. The disease may progress to airway obstruction with tracheal involvement but may be limited to rhinologic and vocal fold involvement. The disease is diagnosed from the identification of the causative organism, a gram-negative coccobacillus, within macrophages obtained from mucosal biopsy specimens. These are the characteristic Mikulicz cells of rhinoscleroma. The disease may be treated with fluoroquinolone antibiotics, tetracycline, and supportive airway management.[22] Patients with this disease may also need acute as well as long-term surgical airway management; Amoils and Shindo[23] reported on a series of 22 patients with rhinoscleroma, 13 of whom had laryngeal involvement.[23] Of these 13, 3 had undergone tracheotomy at some point during the clinical course.

Acute Fungal Laryngitis

In this section, laryngeal dysfunction from *Candida albicans* is discussed; several other pathogenic fungal species are more appropriately reviewed in the chronic laryngitis section. As in many sections of this chapter, the distinction between acute and chronic inflammation is somewhat arbitrary; many of the disorders feature both acute and chronic inflammation.

Candidal laryngitis is probably quite common, although its recognition as a clinical entity has increased. Sulica[24] provided a succinct review of this disorder in 2005. Patients typically present with hoarseness with or without accompanying throat discomfort. The most characteristic finding is a diffuse, whitish speckling of the vocal folds or supraglottis (Fig. 63-2); this can be quite similar to that seen in thrush affecting the oral cavity and soft palate. Perhaps the most important lesson in the clinical recognition of laryngeal candidiasis is for the

physician to suspect its presence in both immunocompromised and immunocompetent individuals. There are very few causes of white lesions on the surface of the vocal fold epithelium; the differential diagnosis includes hyperkeratosis/leukoplakia, malignancy, thick mucus, and candidal infection. Although formal culture is required to confirm the diagnosis, it is neither practical nor common. It has been theorized that patients with local risk factors, such as the recent use of broad-spectrum antibiotics or topical (inhaled) corticosteroids, are more prone to development of this problem. This theory is clinically reasonable but such an association is not exclusively the case; *Candida* should be included in the differential diagnosis of a great range of patients with epithelial abnormalities of the larynx.[25]

Candida may also become invasive with fulminant inflammation and erosion. This development requires aggressive medical treatment, including consideration for parenteral antifungal medication and airway support.[22]

Chronic Laryngitis

As noted previously, the distinction between acute and chronic laryngitis is not necessarily a strict one; many of the disorders discussed in the section on acute laryngitis may also contribute to chronic dysfunction. In this section, several key infectious causes of chronic laryngitis are reviewed along with reflux-associated laryngeal inflammation.

Bacterial Laryngitis

Although most otolaryngologists associate bacterial infection of the larynx with an acute process, chronic, even life-threatening disease may arise in this situation. Superinfection of the larynx may complicate intubation injuries or larynges already damaged from relapsing polychondritis, for example. Eliashar and colleagues presented several case examples of this occurrence.[26] In each of the three cases outlined, purulent chondritis was noted in patients with prolonged (longer than 1 month) of hoarseness and stridor. These patients required surgical drainage and ongoing medical treatment. In two of the three cases, the pathogen was *Staphylococcus aureus*. Clinicians should suspect bacterial infection, regardless of its relative rarity, in patients who have persistent chronic inflammation of the larynx. Culture and drainage of abscess spaces may be required. The role of hyperbaric oxygen is not widely agreed upon for this disorder or even for chondroradionecrosis of the larynx, which is discussed elsewhere in this volume.

Fungal Laryngitis

The larynx may also become infected with pathogenic fungal species. The organisms include *Blastomyces, Histoplasma, Coccidioides, Paracoccidioides,* and *Cryptococcus* spp. In general, the clinical presentation of laryngeal fungal infection is not specific to the pathogen, but reflects general disturbance of laryngeal function—that is, consists of hoarseness and throat discomfort. Tissue biopsy and fungal stains are needed to confirm the diagnosis. The less common pathogens are not discussed in detail, although laryngeal infection with *Sporothrix,*[27] *Aspergillus,*[26,28] and *Cryptococcus* spp.[29,30] have been reported.

Blastomycosis

Blastomycosis is endemic in several areas, including the southern parts of the United States.[31] Although this fungus enters the system by inhalation, laryngeal infestation is thought to arise, like infestation of other organs, from hematogenous spread.[32] In a major paper from the Mayo Clinic, 102 cases of blastomycosis were found in a retrospective review of patients seen between 1960 and 1990.[33] In these 102 cases, the minority affected the head and neck area; in blastomycosis of this area, the skin was the most common site impacted. Only 5 of the 102 cases featured laryngeal involvement. The diagnosis is made when suspicious lesions are noted in the larynx, often involving the glottis. Fungal stains of the involved tissue may reveal the broad-based budding yeast. Treatment includes systemic therapy, such as with amphotericin B, ketoconazole, or itraconazole. The practitioner must be particularly cautious to distinguish blastomycosis from laryngeal carcinoma; like many inflammatory disorders, fungal laryngitis may manifest in a clinical picture similar to that seen in a new laryngeal cancer; furthermore, biopsies of involved tissue may reveal *pseudoepitheliomatous hyperplasia,* which may be mistaken for the advancing front of an epithelial malignancy.[34]

Paracoccidioidomycosis

Paracoccidioides appears to be one of the leading pathogens in invasive fungal laryngitis. Although not common in comparison with other laryngeal maladies, paracoccidioidal infection of the larynx affects a significant fraction of patients in South America. As in most of these disorders, the primary manifestation is dysphonia with dyspnea.[35] Most of the patients in the series reported by Sant'Anna and associates[35] were male farm workers. Laryngeal examination revealed both ulcerative and exophytic lesions, which like those in blastomycosis resembled carcinoma. Silva and colleagues[35a] looked retrospectively at a series of 24 patients with granulomatous laryngitis, 10 of which proved to have paracoccidioidal infection. Treatment is with systemic antifungals.

Coccidioidomycosis

Coccidioidomycosis is a disease of the southwestern United States and Mexico; it is thought that the larynx may be the site of inoculation in some patients. Little has been written about this disorder, however. A 1991 review from Boyle and coworkers[36] noted 12 cases of laryngeal coccidioidomycosis, 7 of which were in children. Most cases were in boys or men, who presented with airway obstruction.

Histoplasmosis

The causative agent in histoplasmosis, *Histoplasma capsulatum*, is a fungus endemic to areas of the United States; it is found in the Ohio and Mississippi River valleys, and its spores may be inhaled, leading to localized pulmonary infection or dissemination. It is possible for this infection to occur outside of endemic areas. There are few reported cases of laryngeal histoplasmosis; Gerber and colleagues[37] reviewed a series of 115 patients with disseminated disease in order to characterize the incidence of otolaryngologic findings. Seven of these patients had oral cavity/oropharyngeal infection; only two cases featured laryngeal disease. Eight of the 9 patients with otolaryngologic manifestations were immunocompromised, such as from human immunodeficiency virus disease, kidney transplant medication, and diabetes. In 8 of these 9 patients, the response to fungal staining of the acquired tissue sample was positive. Gerber and colleagues[37] reported better treatment results with amphotericin than with fluconazole. As with other fungal and atypical laryngeal infections, writers have cautioned against the misdiagnosis of histoplasmosis as carcinoma.[38]

Mycobacterial Laryngitis

Laryngeal tuberculosis may affect patients with and without disseminated tuberculosis (TB). The bulk of this discussion reviews existing knowledge regarding laryngeal TB. One other mycobacterial infection, *leprosy*, also deserves mention here. In this generally tropical disease, the causative agent, *Mycobacterium leprae*, is transmitted via aerosolized droplets and may remain highly contagious, although it does not always lead to clinical disease.[32] This disease is found in South America, Africa, and the Asian subcontinent; the countries with the highest incidence are Brazil, Mozambique, and India. More than a third of patients with disseminated leprosy in India were noted to have laryngeal involvement.[32] As in TB, staining of tissue biopsy specimens demonstrates acid-fast bacilli and granuloma formation (Fig. 63-3). Multiple-drug regimens may be required for more than 1 year to eradicate the disease.

The recognition and treatment of laryngeal TB requires an awareness of the typical clinical scenario and laryngeal findings associated with the disorder. In the past, laryngeal TB was highly associated with disseminated disease or at least with active pulmonary TB. In a paper from Korea, however, Lim and colleagues[39] reviewed 60 cases of laryngeal TB over a 10-year period. The mean age of the patients was 50 years; there was a 2:1 male preponderance in the series. Hoarseness was nearly uniform in these patients. Laryngoscopic findings were divided between granulomatous and ulcerative lesions, with an increasing likelihood of polypoid and unilateral findings. The true and false vocal folds were the most commonly affected sites. Twenty-eight of the

60 patients (47%) had *active* pulmonary disease; 20 of the 60 (33%) had inactive pulmonary TB, and 9 (15%) had isolated laryngeal TB. Lim and colleagues[39] made special note of the focal, atypical, and unilateral laryngeal findings in patients without active pulmonary disease. In another study, a series of 319 Turkish patients with pulmonary TB were assessed for laryngeal disease[40]; 5 of the patients (1.5%) had apparent laryngeal symptoms and findings. In this study, odynophagia, not hoarseness, was the most common complaint. In a separate paper, several of the authors of the first paper demonstrated perceptual and objective improvement of vocal parameters in patients with laryngeal TB who were undergoing medical therapy.[41]

Noninfectious Laryngitis

The most clinically significant causes of laryngitis in the otolaryngologist's practice are often related to poor laryngeal hygiene (tobacco, alcohol, and caffeine consumption) or to the refluxate of gastric and duodenal contents. A detailed description of the impact of reflux on the larynx as well as other organs in the head and neck is given elsewhere in this volume. The topic deserves some discussion here, however.

Reflux Laryngitis

The larynx may be affected by contact with refluxed material from the lower foregut. The vast majority of such contact events are thought to be acidic in nature; the recognition of acidic injury to the larynx has been one of the key advancements in laryngology in the past few decades.[4] This issue is not without controversy, however. The rates of medical management of presumed reflux affecting the larynx and pharynx have risen[42] despite the lack of compelling evidence in double-blind, placebo-controlled trials.[43] The complete discussion of the impact of acidic refluxate on the larynx is found elsewhere in this text. It is possible, however, that investigation into nonacidic reflux as well as into the significance of patient susceptibility to injury in reflux (and perhaps other laryngeal disorders) will yield a deeper understanding of this issue.

Bile has been implicated as a possible source of laryngeal injury for many years. The presence of biliary (alkali reflux) continues to be a possible explanation for the lack of response to anti-acid therapy in chronic laryngitis. In an elegant animal study, however, Adhami and colleagues[44] showed that bile was injurious to laryngeal mucosa, but only in the presence of acidification. In contrast, Sasaki and coworkers[45] demonstrated epithelial injury in the rat laryngeal model when the larynx was exposed to certain bile salts at neutral pH, that is, in the absence of an acidic environment. Although this key theoretical foundation of our understanding of bile injury continues to be evaluated, Galli and associates[46] have provided some interesting observations

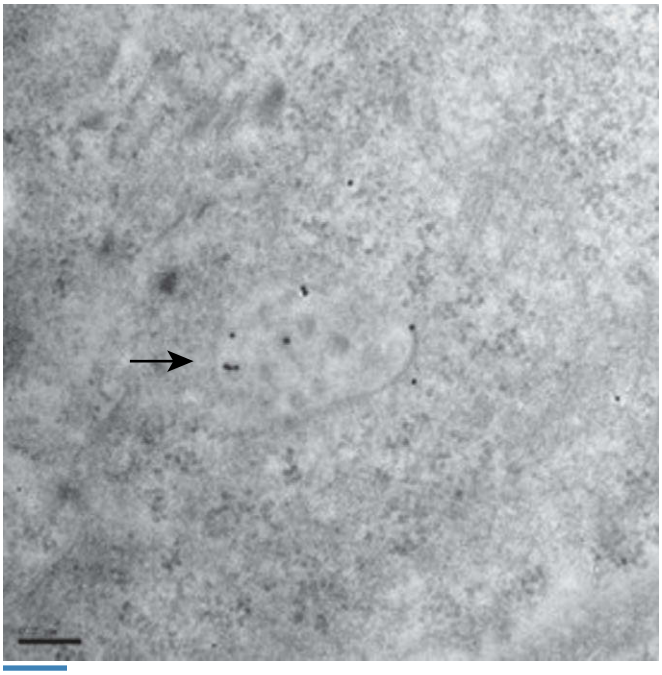

Figure 63-4. Pepsin (*arrows*) within an intracellular vesicle of human laryngeal epithelium from a patient with laryngopharyngeal reflux (*bar* = 0.2 μ). *(Image courtesy of Nikki Johnston, PhD, Medical College of Wisconsin, Milwaukee.)*

about reflux and its association with laryngeal carcinoma; their case-control study of 21 patients with laryngeal and hypopharyngeal carcinoma revealed a higher than suspected incidence of malignancy in patients who had undergone previous gastrectomy, suggesting a correlation to chronic exposure to duodenal contents and biliary reflux.

Pepsin is another agent suspected in the ongoing description of laryngeal injury from reflux. The main proteolytic agent produced by the stomach, pepsin is active principally at acidic pH. In the animal study previously cited,[44] pepsin clearly demonstrated the ability to create laryngeal epithelial injury at acid pH. Later studies, however, have expanded our understanding of pepsin's role in laryngeal damage. Johnston and colleagues[47] demonstrated that pepsin is present intracellularly in patients with the clinical diagnosis of laryngeal reflux and is not present in controls; its presence was also correlated with the depletion of intracellular carbonic anhydrase (type III). Pepsin was found to maintain its proteolytic activity at pH above 4 and was able to be "reactivated" even after being in a neutral environment.

The significance of these findings may prove to be great; the model for treating acidic injury of the larynx has depended on neutralization of the proton pump in the stomach. If indeed pepsin can maintain the ability to damage tissue even after neutralization (particularly after receptor-mediated uptake into epithelial cells[48]), the paradigm of reflux disease and the larynx must be reconsidered (Fig. 63-4). Patient-to-patient variability in ability to prevent and withstand injury, such as manifested by differing levels of protective intracellular enzymes, may also play an important role in this clinical entity. In two patients with the same DeMeester score or acid exposure time on a 24-hour pH probe, for example, laryngeal injuries may differ greatly.

The Larynx as an Immunologic Organ

Although great attention has understandably been focused on other areas of the head and neck with regard to immunologic manifestation of disease, the larynx's role is not well defined. Barker and colleagues[49] have described the presence of major histocompatibility complexes (MHCs) in the porcine larynx and have estimated that this finding is a marker of the role that the larynx might play in the afferent aspect of environmental allergy and defense. Interestingly, the immunogenicity of the larynx has been investigated not for the ubiquitous issues of

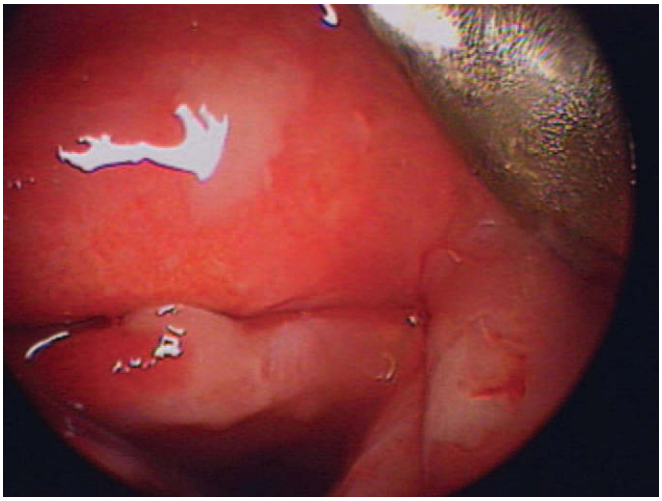

Figure 63-5. Pemphigus vulgaris in a 57-year-old woman who presented with throat pain and hoarseness. This image of the left false and true vocal folds was obtained with a 70-degree telescope during direct laryngoscopy.

mild chronic laryngitis but in order to better understand and potentially overcome obstacles in the path towards the lofty (and controversial) goal of human laryngeal transplantation.[50] Rees and associates[51] have also investigated a particularly compelling aspect of laryngeal immunology as it relates to possible carcinogenesis. Laryngeal mucosal biopsy specimens from 63 patients were assessed for various cell surface markers; those from smokers, for example, had increased numbers of $CD4^+$ T cells. Older patients also had higher numbers of these cells, but in contrast, female patients had lower counts of $CD4^+$ positive cells. Several other markers were tested as well, with some being affected by patient factors and some not. The investigators concluded that laryngeal T-cell populations may be influenced by smoking (as well as age and gender), and that this influence itself contributes to the genesis of inflammatory and even neoplastic disease of the laryngeal epithelium.

The larynx may be the end-organ affected by autoimmune disorders, such as pemphigoid and pemphigus (Fig. 63-5). Severe epithelial loss and inflammation may occur from the effect of either intraepithelial (pemphigus vulgaris) or subepithelial (pemphigoid) antibodies. Hale and Bystryn[52] noted that as many as 80% of the patients with pemphigus in their study had otolaryngologic signs and symptoms, of which 40% were laryngeal in nature. Several patients had coexistent fungal infection. Alexandre and coworkers[53] published a prospective paper describing the manifestations of *pemphigoid* in a series of 110 patients over an 8-year period. Thirty-eight of these patients (35%) were found to have some symptoms related to the head and neck; 87% of these 38 patients had physical findings at that time. The majority had nasal symptoms; 19 (50%) had pharyngeal complaints, and 10 (26%) had laryngeal symptoms; nearly 50%, however, had laryngeal findings, indicating that laryngeal involvement was asymptomatic in a large fraction of patients. The presence of advanced ocular pemphigoid was predictive of laryngeal involvement, as was the presence of concomitant nasal and pharyngeal disease.

Conclusion

As we move forward in our understanding of the pathophysiology of laryngeal inflammation and infection, a complete appreciation of each patient's inherent tissue response to injury and genetic resistance may be of greater importance to the clinician. This may manifest through diagnosis and management of laryngeal immunologic abnormalities or by affecting a patient's ability to negate the effect of intracellular pepsin, for example. At present, however, we must recognize the varied pathogens and agents that may induce inflammation of the larynx and affect its function. The possibility of neoplasm should always be considered when signs point to infection; the possibility of infection, however, should be considered when neoplasm seems like the "obvious" clinical diagnosis.

CHAPTER SIXTY-FOUR

Laryngeal and Tracheal Manifestations of Systemic Disease

Kevin P. Leahy

Key Points

- The spectrum of laryngeal and tracheal symptoms of systemic disorders can vary from mild to severe, including hoarseness, cough, stridor, and airway compromise.
- Many systemic disorders that affect the larynx may mimic laryngeal carcinoma.
- A systemic process should be suspected in a hoarse patient with no obvious lesion.
- Many systemic disorders require a multidisciplinary approach to achieve optimal results, involving a speech pathologist, rheumatologist, infectious disease specialist, and otolaryngologist.

The number of problems that can affect the larynx and trachea are protean. Their manifestations can range from mild hoarseness to airway obstruction. Thankfully, most manifest as the former. In evaluation of a patient with a laryngeal or tracheal complaint, the problem may be classified as either malignant or nonmalignant. However, this is not accomplished so easily, because many nonmalignant processes can mimic malignancy, at least prior to biopsy. It is therefore up to the otolaryngologist to remain suspicious and think on a broader scale. Such an approach requires that a basic understanding of the variety of disease states that affect the larynx is an integral part of the otolaryngologist's armamentarium.

This chapter focuses on nonmalignant diseases that affect the larynx and trachea. Many of the infectious processes otolaryngologists encounter, especially those affecting the pediatric population, are covered in other chapters. This chapter provides a summary of the many systemic and infectious diseases that can manifest as laryngeal and tracheal dysfunction and describes their etiology, diagnosis, and treatment.

Wegener's Granulomatosis

Wegener's granulomatosis is a multisystem inflammatory disease characterized by necrotizing granulomatosis and necrotizing vasculitis of small arteries, arterioles, capillaries, and venules.[1,2] It primarily involves the upper and lower respiratory tracts, including the larynx and trachea, and kidneys.[1] Other areas of involvement are the oral cavity, skin, joints (polyarteritis), and orbit.[1] In the airway, the subglottis and trachea are more commonly affected (Fig. 64-1).

Airway involvement usually occurs in the presence of systemic disease but may be the only sign of the illness. Specifically, 10% to 20% of patients with Wegener's granulomatosis present with subglottic involvement and subsequent stenosis.[1,3,4] As a result, patients may be incorrectly diagnosed as having asthma when stridor is mistaken for wheezing. Glottic involvement manifests as voice changes. Most patients with Wegener's granulomatosis have a positive ANCA (antineutrophil cytoplasm antibody) test result, but up to 20% of patients who have the disease with respiratory involvement have negative ANCA test results.[2]

Common symptoms of Wegener's granulomatosis of the airway include hoarseness, cough, hemoptysis, dyspnea, stridor, and wheezing. Progressive respiratory difficulty with stridor can be the first signal of airway involvement. Pulmonary function testing with flow-volume loops can be helpful in distinguishing a fixed extrathoracic lesion (i.e., subglottic stenosis) from parenchymal disease.[2] The typical pattern of flattening of both inspiratory and expiratory phases is seen in fixed lesions.[2]

Management of the disease is complex and usually requires a multidisciplinary approach. Systemic manifestations are treated with systemic corticosteroids and other immunomodulating agents, depending on disease severity. First-line treatment is with steroids plus cyclophosphamide.[2,4] Once remission has been achieved, methotrexate or azathioprine is used.[2] Airway disease in Wegener's granulomatosis presents a complex challenge because it frequently behaves independently of the systemic disease. Treatment should be tailored to the presenting symptoms and level of distress.

In the presence of acute airway obstruction, tracheostomy placement can be lifesaving. With current endoscopic techniques, however, many patients can be managed without tracheostomy.[3-5] Although techniques differ, dilation of the stenosis with injection of intralesional steroids is the mainstay of treatment. There are reports of the use of topical mitomycin C after dilation.[6] Depending on the severity of narrowing or the level of the stenosis, dilation can be achieved with rigid dilators or balloon dilation.[2-4] The carbon dioxide laser has also been used to treat subglottic stenosis.[6] In patients with difficult stenoses, stents or tracheostomy can be used. Finally, resection and

reanastomosis have been used to remove the stenotic segment, but this step is usually reserved for mature stenoses and inactive disease.

Relapsing Polychondritis

Relapsing polychondritis is a rare inflammatory disease of unknown etiology that causes episodic inflammation of cartilaginous structures throughout the body.[7] Commonly affected areas are the ears, nose, eyes, larynx, bronchi, costal cartilages, and articular joints. Males and females are affected equally, with an annual incidence of 3.5 per million.[8] All ages can be affected, but peak onset is somewhere in the fourth to fifth decade. Only about 14% of patients present with airway symptoms, but 50% to 55% of patients eventually have them.[7] Diagnosis is based on the presence of multiple criteria, first described by McAdam and colleagues[7] and later modified by Damiani and Levine.[9] The most common finding is bilateral auricle chondritis. Respiratory involvement is less common but more damaging. In 25% to 35% of patients with relapsing polychondritis there is a preceding autoimmune process.[8,10]

Involvement of the respiratory tract can have serious consequences. Typically patients present with hoarseness, cough, choking, wheezing, dyspnea on exertion, stridor, or tenderness of the laryngeal framework.[7-9] Mortality rates are reported anywhere from 10% to 50% when the laryngotracheobronchial tree is involved.[8] The airway can be involved at various levels, making treatment difficult. Upper airway obstruction can occur with laryngeal involvement. Collapse of the trachea or bronchi happens when the more distal airway is affected. Respiratory distress may occur by either of two mechanisms, collapse of the central airway from destruction and fibrosis of the laryngeal and tracheal cartilages or peripheral airway narrowing from inflammation and cicatricial fibrosis.[11] Patients may ultimately require tracheostomy for airway stabilization.

Imaging can be helpful in the diagnosis of relapsing polychondritis. Plain films can demonstrate the nonerosive arthropathy seen in the disease.[9] Airway fluoroscopy has been implemented to evaluate for central airway collapse during expiration.[11] Magnetic resonance imaging and computed tomography are complementary in the diagnosis of relapsing polychondritis. Typical computed tomography findings include subglottic stenosis, tracheobronchial luminal narrowing, dense calcification and thickening of tracheal cartilages, peripheral bronchial narrowing, and bronchiectasis[11]; the most common finding is increased attenuation and smooth thickening of the airway walls.[11] Magnetic resonance imaging is very sensitive for visualization of soft tissue inflammation. Such inflammation tends to be hyperintense on T_2-weighted images, and to enhance with gadolinium on T_1-weighted images.[8]

Histologic examination shows chondritis with a mixed inflammatory cell infiltrate composed of polymorphonuclear leukocytes, lymphocytes, plasma cells, and eosinophils, depending on the stage at which the lesion is sampled.[7,9] The primary change is the loss of matrix mucopolysaccharides followed by a secondary perichondrial inflammatory reaction.[12]

In addition to surgical measures, relapsing polychondritis is managed with high-dose corticosteroids. Maintenance therapy consists of methotrexate and low-dose corticosteroids. Azathioprine, cyclophosphamide, cyclosporine, and dapsone have been tried in refractory cases.[8] There have also been case reports of the use of infliximab, which blocks tumor necrosis factor α, to treat refractory cases.[13]

Sarcoidosis

Sarcoidosis is a chronic granulomatous disease of unknown etiology. It is characterized by noncaseating granuloma formation with clusters of tubercles in the same stage of development.[14,15] It can affect any organ system within the body.[14] Nine percent of all patients with sarcoidosis have head and neck manifestations.[14] The first histopathologic diagnosis of laryngeal involvement was confirmed by Poe in 1940, despite its earlier description in the literature.[14,15] The estimated incidence of laryngeal sarcoidosis is between 1% and 5%.[14] Although rare, laryngeal sarcoidosis can be the only manifestation of the disease.

Symptoms are generally mild despite extensive tissue involvement. The progression of the disease is slow and is characterized by many relapses and remissions.[15] With respect to laryngeal involvement, symptoms typically include hoarseness, dyspnea, stridor, dysphagia, and cough.[14,16,17] However, patients can be asymptomatic. Rarely, airway obstruction may be the presenting symptom.[14]

The supraglottic larynx is affected most often, followed by the subglottis. The vocal folds are frequently spared. The epiglottis is the most common subsite, followed by the arytenoids, aryepiglottic folds, and false vocal folds.[14] When airway involvement is suspected, laryngoscopy is a key step in the diagnosis.

The classic appearance of the larynx affected by sarcoidosis is described as "turban-like thickening" (Fig. 64-2).[15] This thickening is due to the pale, pink, diffuse induration and swelling of the supraglottis. Flexible fiberoptic examination may reveal the presence of edema and erythema, punctate nodules, mass lesions, and ulcerations.[14] Biopsy of affected areas shows lymphocytic infiltration and noncaseating epithelioid granulomas.[14] The pathologic findings can be confused with those in other granulomatous diseases, and additional studies and cultures are recommended.[14]

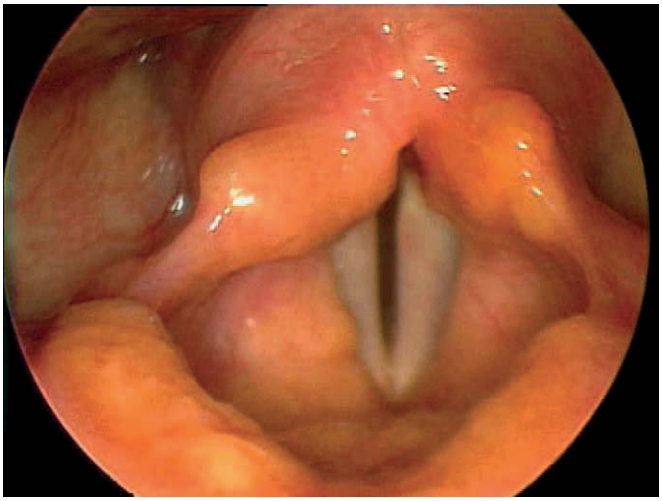

Figure 64-3. Laryngeal amyloid deposition in the supraglottis (right ventricular fold, laryngeal surface of epiglottis) and sparing of the true vocal folds. The patient presented with hoarseness and a nonproductive cough.

Treatment of the laryngeal manifestations of sarcoidosis can be achieved with systemic corticosteroids. For lesions that are small and well circumscribed, some writers have performed intralesional injection of corticosteroids.[14,17] In cases in which there is airway obstruction, excision with the carbon dioxide laser or Microdebrider can be performed to prevent the need for a tracheostomy. It is preferable to treat lesions when they are nonobstructing so as to avoid the need for a tracheostomy.[17] Due to the risk of laryngeal involvement, it is recommended that patients with sarcoidosis who begin to have airway symptoms be evaluated by an otolaryngologist.[15]

Amyloidosis

Amyloidosis is an idiopathic disorder characterized by the extracellular deposition of insoluble fibrillar proteins. Interestingly, the origins of these fibrillar proteins are their normally soluble variants. These deposits were initially described by Rokitansky in 1842.[18] The first laryngeal case was described by Borow in 1873.[18] Since then it has rarely been described as affecting the larynx, accounting for as little as 0.2% of benign tumors of the larynx.[19] However, laryngeal deposition of amyloid is the most common involvement within the head and neck.[18] Other deposits can occur anywhere in the upper and lower aerodigestive tract.

Amyloidosis is classified on the basis of the following three parameters: the fibrillar protein making up the deposits, the precursor protein from which the amyloid protein was derived, and the clinical description of the associated disease process (primary, secondary, myeloma-associated, familial, or hemodialysis-associated amyloidosis).[18] Laryngeal amyloidosis is usually a localized and primary disease but may be found in association with an underlying disorder, such as multiple myeloma.[18]

Presenting symptoms vary with the amyloid deposition. The most common location within the larynx is deposition in the true and false vocal folds and the ventricles (Fig. 64-3).[20] Frequently complaints revolve around hoarseness or cough, but if deposition is significant, dyspnea or stridor may also be seen.

Biopsy of the primary lesion is the mainstay of diagnosis. On light microscopy, amyloid exhibits an acellular, amorphous, homogeneous, eosinophilic appearance after hematoxylin and eosin staining.[18] The classic findings of bright green birefringence under polarizing light microscopy are seen after staining with Congo red. Other diagnostic tests that should be performed are complete blood count, liver function tests, renal function studies, and urinalysis to look for the Bence-Jones protein.[18] A referral to a hematologist or oncologist is appropriate, given the association of amyloidosis with multiple myeloma.

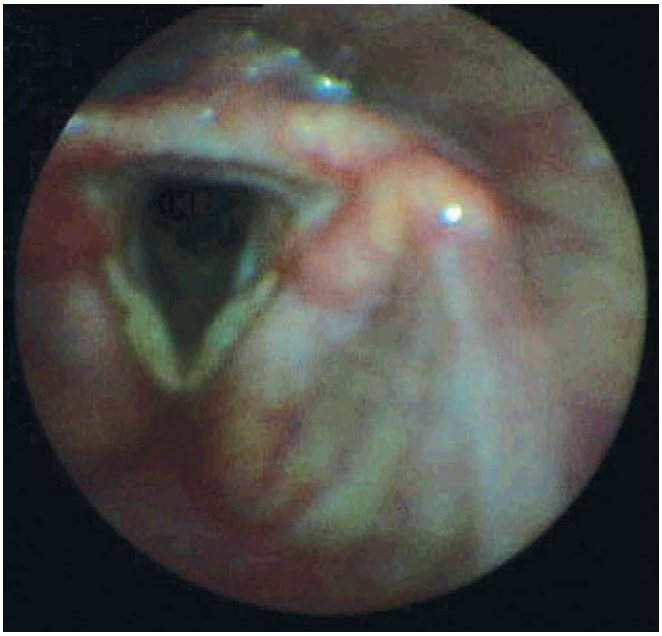

Figure 64-4. This patient was known to have rheumatoid arthritis. She experienced hoarseness, and fiberoptic examination showed bilateral midfold thickening.

Treatment is focused on maintaining airway patency and improving hoarseness while minimizing the effects on voice quality.[18,20] The treatment is routinely performed during suspension microlaryngoscopy with excision. Microdebrider excision and carbon dioxide laser excision are two modalities currently employed. Recurrence of amyloid deposits is common and is managed with reexcision. Rarely, tracheostomy is needed.

Rheumatoid Arthritis

Rheumatoid arthritis is a common autoimmune disease that involves inflammation of the synovial tissue.[21] Women are two to three times more likely to have the disease. The larynx is involved in 25% to 30% of cases. The symptoms vary from hoarseness and dysphagia to globus sensation and even stridor.[22]

Rheumatoid arthritis affects the larynx in two forms. In the active form, there is acute involvement of the larynx with tenderness and erythema. Laryngoscopic examination often shows red, swollen arytenoids.[23] The chronic form typically causes cricoarytenoid joint involvement with ankylosis.[23] This can result in bilateral impairment of vocal fold motion requiring urgent intervention, with both medical and surgical treatments.[24,25]

In addition to joint involvement, submucosal nodules can develop on the vocal fold (Fig. 64-4). Their histologic appearance is similar to that of rheumatoid nodules found elsewhere in the body. Most often, these nodules lead to hoarseness, and when removed, the voice quality improves.[22] There have been case reports of patients treated with methotrexate in whom giant rheumatoid nodules developed within the larynx, causing airway obstruction.[21,23]

Pemphigus

Pemphigus is a rare autoimmune disease that affects the skin and mucous membranes. The loosening of the epidermal-dermal junction leads to the characteristic formation of blebs. The disease is most commonly encountered by dermatologists; however, in the experience of Hale and Bystryn,[26] laryngeal complaints were not uncommon when nasal complaints were also present. Pemphigus may be isolated to the larynx, but this is unusual.[27] Most often, precedent nasal or oral lesions are found. The most common laryngeal presentation of this disease is hoarseness, although progressive stridor and dyspnea may be the presenting symptoms.[28] On fiberoptic examination, one will typically see supraglottic involvement affecting the laryngeal surface of the epiglottis,

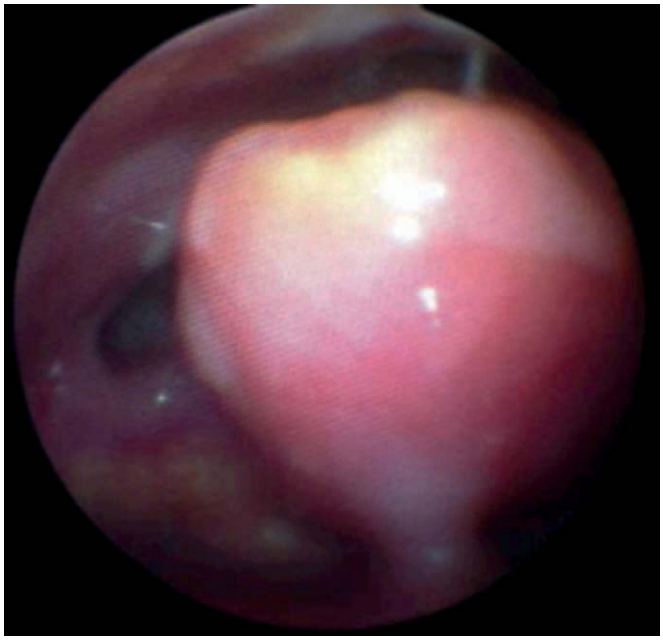

Figure 64-5. Progressive dyspnea. The fibrinous exudate is classic for pemphigus. Bullae typically are not seen in the upper aerodigestive tract because they rupture and slough off, leaving behind the fibrinous exudate as seen here.

aryepiglottic folds, and the arytenoid mucosa. The lesions that are encountered do not have the typical bleb appearance because the epidermis is sloughed off by swallowing. What is left is a tan fibrinous base with a halo of erythema (Fig. 64-5).[28,29] If this condition is encountered, a thorough inspection of the oral cavity mucosa (most common site in the head and neck)[27] and nasal cavity may reveal other lesions.[26] Because of the underlying inflammatory response, scarring can be prevalent and can lead to supraglottic narrowing.

Diagnosis relies on tissue biopsy. Because of the fragile nature of the mucous membranes, care should be taken in the performance of endoscopy. The classic histologic finding is intraepithelial acantholysis.[28,29] Pemphigus typically has acantholytic lesions that are subepithelial with basement membrane involvement. Direct immunofluorescence in pemphigus has an intracellular pattern. Indirect immunofluorescence can measure the amount of circulating antibodies and correlates with disease severity.[27]

Treatment is based on oral corticosteroids. High doses are given at first and are then tapered to a maintenance regimen. Azathioprine, cyclophosphamide, and cyclosporine have been used as maintenance medications for pemphigus.[27,28]

Whooping Cough

Whooping cough, caused by *Bordetella pertussis*, has been increasing in frequency in the United States.[30] Originally a disease of childhood, it is now more commonly seen in infants, adolescents, and adults. The reason for this increase is unknown. It is believed that despite vaccination, the maximum protection is conferred for 3 years, with decreasing effectiveness each year thereafter.[31]

Adults who become infected do not typically experience the catarrhal stage with fever and leukocytosis,[32] but instead have a severe protracted cough. Treatment with antibiotics, typically erythromycin, does not change the clinical course but does prevent transmission.[30] Azithromycin has also been found helpful in prophylaxis.

Tuberculosis

Over the years, the clinical presentation of laryngeal tuberculosis has changed. Usually laryngeal tuberculosis developed in the presence of severe pulmonary tuberculosis, secondary to expectorated secretions containing the organism.[33] Most patients who present today are without pulmonary symptoms or a history of pulmonary tuberculosis. It is theorized that laryngeal disease is the result of hematogenous or lymphatic spread.[34,35] Despite these changes, the most common presenting symptom is hoarseness.[34-36] Other symptoms are dysphagia, odynophagia, cough, and weight loss.[34,36] Despite the lack of pulmonary involvement, the purified protein derivative test result is usually positive.[37,38]

The location within the larynx has also changed with time. The most common location was the posterior glottis. It has been supplanted in frequency by various other subsites of the larynx: vocal folds, ventricular folds, aryepiglottic folds, as well as the posterior glottis.[33,36] The lesions may be nodular, exophytic, or ulcerative.[33,36-38] Because of the appearance of the lesions, laryngeal tuberculosis can be mistaken for squamous cell carcinoma.[36]

Diagnosis is usually made by the combination of sputum culture, biopsy specimens testing positive for acid-fast bacilli, and chest radiographs.[36] Medical therapy can alleviate symptoms and expedite the improvement in hoarseness. During the workup for laryngeal tuberculosis, patients should be screened for human immunodeficiency virus, given the high incidence of co-infection with the two pathogens.

Histoplasmosis

Histoplasmosis is caused by the dimorphic fungus *Histoplasma capsulatum*.[39,40] Endemic regions in the United States include the Ohio and Mississippi river valleys. Infection varies according to the initial exposure. It may manifest as either an acute or chronic pulmonary infection or an acute or chronic disseminated infection with systemic symptoms.[40] Both of the pulmonary processes are usually self-limited, unless concomitant immunosuppression is present (i.e., due to human immunodeficiency virus).[39,40] Acute disseminated histoplasmosis is almost always fatal.[41] Chronic disseminated disease usually manifests as focally destructive lesions.[39,40]

Mucosal involvement is common and can resemble lesions of squamous cell carcinoma or tuberculosis.[42-44] Biopsies can show the presence of poorly defined granulomas with macrophages and multinucleated giant cells.[40,42] Periodic acid–Schiff and Grocott stains can show intracellular *H. capsulatum*.[42-44] These ulcers begin as flat, plaque-like, nontender elevations that become painful after ulceration.[43] Treatment is with intravenous amphotericin B.

Blastomycosis

The organism responsible for blastomycosis is the dimorphic fungus *Blastomyces dermatitidis*. This soil saprophyte can be found throughout the United States and Canada but is endemic along the Mississippi and Ohio river basins. The primary portal of entry is through the lungs.[39] Hematogenous spread accounts for other organ involvement. Skin is the most commonly affected system, in contrast to the larynx, which can be involved in about 2% of cases.[39,45] Prior to antifungal therapy, the mortality of blastomycosis exceeded 60%.[39]

Laryngeal involvement typically leads to hoarseness as the chief complaint.[45,46] Examination typically reveals exophytic masses, but ulcerative lesions have been described. The true vocal folds are the most common subsite, with extension to the ventricular folds. Because these lesions can be mistaken for squamous cell carcinoma, biopsy is critical for diagnosis.

The typical histologic findings include acute and chronic inflammation, microabscesses, and giant cell formation. The hallmark finding is pseudoepitheliomatous hyperplasia.[39] Fungal stains (e.g., Gomori methenamine silver) show the organism as a double-walled sphere 8 to 15 mm in diameter with single broad-based buds.[39] In addition to histologic identification, culture of the organism is performed in enriched agar medium. For uncomplicated cases, prolonged oral ketoconazole or itraconazole treatment can be given. Amphotericin B is also effective, especially in cases with central nervous system involvement.

Cryptococcosis

Cryptococcosis is a systemic infection caused by *Cryptococcus neoformans*, a yeastlike fungus with a thick polysaccharide capsule.[39] It is found in areas contaminated with pigeon droppings.[39] As in blastomycosis, infection is through inhalation of the spores. The pulmonary disease in nonimmunocompromised patients is generally subclinical. However, in

immunocompromised patients, systemic involvement is typical. The most commonly affected system is the central nervous system, leading to meningitis. Most cases of laryngeal involvement occur in immunocompromised patients, but there are rare cases in immunocompetent patients.[39,47] The true vocal folds are the only site affected, with subsequent hoarseness. On biopsy, budding yeast can be seen. As seen in blastomycosis, pseudoepitheliomatous hyperplasia may be identified. Depending on the severity of the infection, treatment involves amphotericin B or fluconazole.[39,47]

Coccidioidomycosis

Coccidioides immitis, the fungal organism responsible for San Joaquin Valley fever, is endemic to the southwestern United States and northern Mexico.[39] Spores are inhaled, and 60% of infections go unrecognized. In the remaining 40%, flulike symptoms occur 1 to 3 weeks after infection.[39] Most cases of laryngeal involvement occur in disseminated coccidioidomycosis. Symptoms range from hoarseness, pain, and odynophagia to airway involvement with stridor.[48,49] Amphotericin B is the mainstay of treatment.

Actinomycosis

Actinomycosis is a chronic suppurative infection characterized by the presence of purulent drainage from chronic discharging sinus tracts containing the pathognomonic sulfur granules.[39] The causative organism is *Actinomyces israelii*, an anaerobic or microaerophilic, non–acid-fast, gram-positive organism. These organisms are endogenous to the oral cavity and can be found in carious teeth, plaque, and tonsillar crypts.[39] Cervicofacial actinomycosis accounts for 50% to 60% of all cases.[39] Laryngeal and tracheal cases have been reported.[50] Treatment involves prolonged antibiotic therapy; the mainstay is penicillin, although clindamycin has also been used.[39,50]

Candidiasis

Candidiasis affecting the larynx tends to be associated with oral and esophageal involvement as well. Affected patients are typically immunocompromised owing to chemotherapy or acquired immunodeficiency syndrome. Isolated laryngeal candidiasis has been seen, especially in patients using inhaled corticosteroids.[51-53] The lesions are usually white sessile plaques on an erythematous base; however, ulceration may be noted.[51] Therapy is focused on eliminating the causative agent (i.e., steroid inhaler) and the addition of an oral antifungal agent, such as fluconazole.[51,53] Also, candidal overgrowth is associated with failure of a tracheoesophageal puncture voice prosthesis.

CHAPTER SIXTY-FIVE

Upper Aerodigestive Manifestations of Gastroesophageal Reflux Disease

Jonathan E. Aviv

Savita Collins

Key Points

- Laryngeal edema, not laryngeal erythema, is the clinical hallmark of laryngopharyngeal reflux disease.
- Office-based transnasal esophagoscopy without sedation is becoming a viable alternative to facility-based transoral esophagoscopy with sedation for examining the esophagus.
- Extraesophageal symptoms of acid reflux disease, in particular cough and hoarseness, better predict the presence of esophageal adenocarcinoma than traditional gastroesophageal reflux symptoms, such as heartburn and regurgitation.
- Multichannel intraluminal impedance testing with a pH sensor will become an increasingly essential part of the workup of the patient with acid reflux disease.

Gastroesophageal reflux (GER) is defined as the retrograde movement of material from the stomach into the esophagus in the absence of belching or vomiting.[1-3] *Gastroesophageal reflux disease* (GERD) occurs when GER is associated with symptoms or complications. When GER affects the laryngopharynx, the disease entity is called *laryngopharyngeal reflux* (LPR). Another term used to describe nonesophageal manifestations of the regurgitation of gastric contents is *extraesophageal reflux* (EER).[4,5]

It has been estimated that 30% of Americans suffer from GERD, with 7% to 10% of adults experiencing daily heartburn and 29% to 33% having symptoms weekly.[1,6-8] Twenty-five million to 75 million people in the United States are affected by GERD, and 13% of Americans use indigestion aids at least twice weekly.[8] The incidence of GERD in patients presenting to an otolaryngology practice has been estimated to be 4% to 10%.[5] GERD is not rare in children; it has been described in 18% of children, with a higher incidence in children with esophageal atresia, tracheoesophageal fistula, or neurologic impairment.[9] Unfortunately, accurate estimates of the incidence of LPR are not available. Koufman and colleagues[10] reported that 50% of all patients presenting to their center with laryngeal and voice disorders had LPR as documented by dual pH probe studies. A retrospective review of patients presenting with common cervical symptoms demonstrated that GERD was detected in 73% of patients, and symptomatic relief after antireflux medical treatment resulted in symptomatic improvement in 84%.[11]

The role and incidence of LPR in the development of otolaryngologic disorders are controversial among otolaryngologists. A survey of members of the American Broncho-Esophagological Association showed that 75% of respondents estimated that less than 50% of their patients had disorders related to LPR, and there was a lack of consensus regarding evaluation and treatment modalities.[12] LPR has been implicated in several clinical disorders, including chronic laryngitis,[10,13,14] chronic dysphonia,[10,13,14] laryngotracheal stenosis,[15,16] head and neck carcinoma,[17-21] cough,[22-26] asthma,[22,25-27] otitis media,[28] dental caries and erosion,[29] laryngeal papilloma,[30] vocal fold granulomas and ulcers,[22,31-33] laryngospasm,[34-37] recurrent croup,[9] paradoxic vocal fold movement disorder,[38,39] and laryngomalacia.[40] The goals of this chapter are to review the pathophysiology, clinical manifestations, diagnoses, and treatment of EER.

Pathophysiology

The esophagus is the conduit for the transfer of material from the pharynx to the stomach. The esophagus acts as a vent for the stomach, allowing some normal retrograde flow of gases and gastric contents.[41] The gatekeepers for the ingress and egress of material are the upper esophageal sphincter (UES) and lower esophageal sphincter (LES). The four main constituents of the barrier to reflux are the UES, the LES, esophageal acid clearance, and epithelial resistance.[14,42] Laryngopharyngeal diseases associated with EER are thought to result from both direct and indirect pathways,[11,34,43] which are detailed in the section on mechanisms.

Upper Esophageal Sphincter

The UES is functionally defined as the area of the distal pharynx and proximal esophagus that maintains a closed pharyngoesophageal segment and opens for specific physiologic demands (e.g., swallowing, belching). Anatomically, the UES is made up of the cricopharyngeus, the thyropharyngeus, and the proximal cervical esophagus.[41,42,44] Unlike other muscular sphincters, the UES is not a complete muscular circle

but rather a C-shaped sling that attaches to the cricoid cartilage. The pharyngeal plexus innervates the UES and receives contributions from the vagus nerve (superior and recurrent laryngeal nerves), the glossopharyngeal nerve, and the sympathetic nerves from the superior cervical ganglion.[44] The motor neurons that control the cricopharyngeus are found in the brainstem in the nucleus ambiguus, and stimulation of the nucleus tractus solitarius (the afferent nucleus of the vagus) results in contraction of the cricopharyngeus.[44] In canine studies, vagal nerve stimulation produced UES relaxation, and sectioning of both vagus nerves produced severe dysphagia.[14] Sensory information from the UES is transmitted via the glossopharyngeal nerve and the sympathetic nerves.[44]

The UES maintains a closed pharyngoesophageal segment via tonic contraction of the cricopharyngeus.[41,44] During swallowing, UES relaxation occurs, and the cricoid cartilage is pulled upward and anteriorly by the laryngeal musculature, thereby resulting in a stretching of the cricopharyngeus, thus allowing for bolus passage.[41] The UES tonic pressure is increased in response to laryngeal stimulation (laryngo-UES contractile reflex).[7,42] UES pressure is increased with acidification of the distal esophagus.[14,42,44] UES pressure increases with slow balloon distention of the distal esophagus.[44] General anesthetics, sleep state, cigarette smoking, and peppermint consumption are associated with decreased UES pressure.[14,42,44] Koufman[14] reported that smoking and peppermint consumption produced a 50% reduction in UES resting pressure in healthy volunteers within minutes.

The UES is the final gatekeeper in the antireflux barrier, and UES dysfunction may be associated with head and neck manifestations of EER. Deveney and collegues[45] showed an increased incidence of UES hypotonia in patients with pulmonary problems associated with GERD. In patients with inflammatory lesions of the larynx, they found UES pressures that were somewhat lower than normal.[45] Ulualp and Toohill[42] did not see significant differences between resting UES pressures in patients with posterior laryngitis and normal controls.

Lower Esophageal Sphincter

The LES is the most critical antireflux defense mechanism.[1,46] It is located at the gastroesophageal junction, and it is not as anatomically distinct as the UES. Contraction of the LES results in circular closure that prevents the egress of gastric contents. Relaxation of the LES occurs during swallowing, belching, and vomiting. The LES is anatomically surrounded by the diaphragmatic crura, which mechanically augment the sphincter mechanism and are believed to contribute to 25% of LES competence.[14] Manometric measurements at the LES reflect the combined contributions of the esophageal LES and the diaphragmatic crura. The intrinsic resting pressure of the LES varies with the phase of the respiratory cycle as a result of differential diaphragmatic contraction.[46] During episodes of straining, LES pressure is increased as a result of greater diaphragmatic activity, yielding a stronger diaphragmatic squeeze of the LES.[41,46] Hormonal control of LES activity is complex. Gastrin, pitressin, angiotensin II, and motilin increase contractile tone, whereas secretin, cholecystokinin, glucagon, and vasoactive intestinal peptide reduce LES pressure.[14,46]

To prevent GER, the LES must maintain a resting pressure that is higher than the gastric pressure. GER occurs when there is a reversal of this gastric-to-LES pressure gradient.[41,46] Retrograde flow occurs with relaxation of the LES, with chronic hypotonia of the LES, or with increases in gastric pressure that overcome the LES resting pressure. Transient relaxation of the LES occurs in normal healthy adults and children.[46] Research has shown that transient relaxation of the LES is the most critical mechanism in the production of GER.[21,94] Dent[46] demonstrated that 63% to 74% of GER episodes were associated with transient LES relaxation. Chronic hypotonia of the LES is thought to be associated with GER episodes in a smaller percentage of patients, but perhaps with more severe esophagitis.[46] Lower LES's resting pressures are seen in patients with CREST (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasia) syndrome, scleroderma, and isolated Raynaud's phenomenon. Although chronic hypotonia of the LES results in more severe reflux, it is an uncommon mechanism for GERD.[46,47] Large hiatal hernias may result in disruption of the relationship of the LES to the diaphragmatic crura, which may in turn impair the ability of the LES to act as an antireflux barrier by removing the additional pressure generated by the squeeze of the diaphragm.[14,46] Although hiatal hernias may play a role in GERD in some patients, not all patients with hiatal hernias have GERD.[1] Box 65-1 lists agents that affect the LES pressure.[1,14]

Box 65-1

Factors That Increase or Decrease Lower Esophageal (LES) Pressure

Increase

Protein
Bethanechol
Metoclopramide
Antacids
α-adrenergic drugs

Decrease

Fat
Carbohydrates
Alcohol
Cigarettes
Carminatives (peppermint, spearmint)
Theophylline
Calcium-channel blockers
Nitrate drugs
Atropine
β-adrenergic drugs
Dopamine
Sedatives

When gastric pressure exceeds LES pressure, reflux can occur. "Stress reflux" is seen with increased intra-abdominal pressure during bending over, heavy lifting, straining, and coughing.[14] Excessive gastric distention resulting in higher gastric pressure can occur postprandially after a large meal and with severe gastroparesis. Impaired gastric emptying is more common in patients with GERD.[47] Pregnancy, in which abdominal pressure is increased, is a risk factor for GERD.

Esophageal Acid Clearance

Because some GER is normal, mechanisms exist to clear and neutralize gastric contents when they pass into the esophagus. Esophageal peristaltic waves—along with the effect of gravity—act to mechanically clear the esophagus. Weakened or ineffective peristalsis allows for refluxed materials to have longer contact time with esophageal tissues.[47a] Knight and colleagues[47] studied 100 subjects with EER and noted that 52% had ineffective esophageal motility. Primary esophageal peristalsis in patients with GERD and posterior laryngitis has been shown to be similar to that in normal controls.[42] In patients with GERD, secondary esophageal peristalsis was noted to be decreased in comparison with that in normal controls.[42] Increased numbers of GER episodes seen in patients with GERD, when supine, can be partially explained by the loss of gravitational effects. Acidic refluxate left in the esophagus can be neutralized by gastric glandular secretions and buffering agents in saliva.[14] Xerostomia, which can be caused by Sjögren's disease, certain medications, and previous radiotherapy, may abolish this important antireflux barrier.[14] The low pH of gastric material is damaging to epithelium, but alkaline pH pancreatic and bile juices, when present, can also injure tissues.[1,14]

Epithelial Resistance Factors

When the antireflux barriers fail, the severity of tissue damage is determined by epithelial resistance factors. There are pre-epithelial, epithelial, and intracellular protective mechanisms. The epithelium is preceded by a mucus layer and an aqueous layer with high bicarbonate content.[14,42] Mucus resists penetration by large molecules such as

pepsin, but it does not prevent the ingress of acid. The aqueous layer is alkaline, and it buffers acid material. At the cellular level, the cell membrane and the intracellular junctions resist acid and pepsin.[14] Different tissues have variable epithelial resistance, with esophageal epithelium being more resistant than respiratory epithelium.[11,14,42,43,45] Even slight amounts of GER in the hypopharynx or larynx may cause significant injury, whereas reflux to the same degree in the distal esophagus would be easily resisted.[11,14,42,43,45] Hanson and Jiang[31] postulate that the posterior glottis is especially susceptible to the effect of EER. They theorize that the cilia beat material to the posterior glottis, thereby resulting in longer contact with refluxate and, therefore, more injury to this epithelium.

Mechanisms of Symptoms due to Extraesophageal Reflux

Head and neck disorders associated with EER are postulated to occur via the following mechanisms: direct mucosal damage and direct effect on mucociliary clearance from exposure to gastric contents; GER-related distal esophageal damage that results in vagally mediated, referred symptomatology; and laryngeal reflexes mediated by the stimulation of distal esophageal afferents.[11,34,43] Gaynor[32a] studied the effects of direct exposure of gastric contents on rabbit and canine larynges. In the rabbit, direct exposure at a pH of 4.0 resulted in an inflammatory response that involved the submucosa and muscle, and the extent of damage worsened with longer durations of exposure. When a pH of 1.4 was used, "severe mucosal ulceration, submucosal and deeper hemorrhage with marked inflammatory response as well as necrosis were noted."[43] In canines, an effect on mucociliary flow was noted to begin at a pH of 5.0, and no mucociliary flow was observed at pH of 2.0. Ciliary activity persists after the cessation of mucociliary flow. Alteration of pH has a direct effect on mucociliary transport and may lead to increased viscosity of the mucus blanket.[43] A reduction in mucociliary transport may decrease resistance to infection and has been theorized to contribute to the pathogenesis of subglottic stenosis.[43]

Pepsin, which is found in gastric contents, is maximally active at pH 4.5, and its enzymatic activity produces tissue damage.[14] Koufman[14] demonstrated the importance of pepsin in the production of epithelial damage in canine larynges. He created subglottic mucosal injuries in dogs and then compared healing and injury in control, acid-only, and acid- and pepsin-exposed conditions. The acid-only group had inflammatory lesions that healed in twice the time it took for the control group lesions. None of the acid- and pepsin-treated larynges showed healing, and they were noted to develop ulceration and granulation.[14]

Gaynor,[32a] monitoring patients receiving intensive care who were intubated for prolonged periods, found lower pharyngeal pH readings ranging from 2.4 to 7.0. Forty percent of the patients were noted to have reflux episodes with pH less than 4.0. In patients treated with antacids or histamine H_2 blockers, pH readings ranged from 4.7 to 8.9. The works of Koufman,[14] Gaynor,[32a] and Maronian[47b] support the use of anti-acid therapy in cases of potential subglottic trauma (e.g., intubation), because it may help prevent irreversible mucosal damage.

Direct stimulation of sensory receptors in the larynx by aspirated or refluxed material can result in reflexive vocal fold adduction or laryngospasm.[34,36,48] This laryngeal chemoreflex is associated with bradycardia, central apnea, and hypotension.[9] Partial or complete laryngospasm and cough can also be triggered by GER to the distal esophagus via a vagally mediated reflex.[1,7,27,34] Laryngospasm associated with distal esophageal GER can be associated with bronchospasm, increased secretions, tachycardia, and hypertension.[9] These reflexes have implications for respiratory manifestations of EER and in the mechanisms involved with sudden infant death syndrome and recurrent laryngospasm.[34,36,43,48]

Diagnostic Evaluation

History

A good case history is very critical to both diagnosis and treatment in patients with EER. The clinician must identify not only symptoms but also behavioral and medical risk factors. It is also critical to patient compliance with treatment that the patient be actively involved in the identification of the risk factors that he or she can modify. Common symptoms described in association with EER are listed in Box 65-2.[1,5,11,12,22-24,31,49-56]

Box 65-2

Common Symptoms of Extraesophageal Reflux*

- Hoarseness/dysphonia (episodic or chronic)
- Globus sensation
- Chronic throat clearing
- Vocal fatigue
- Voice breaks
- Sore throat
- Neck pain
- Excessive throat mucus
- Chronic or nighttime cough
- Dysphagia
- Odynophagia
- Postnasal drip
- Halitosis
- Ear pain
- Laryngospasm
- Asthma exacerbation
- Loss of upper singing range
- Prolonged warmup time in singers
- Heartburn/regurgitation

*Listed in order of frequency.

In a retrospective review of 216 patients with cervical symptoms that were believed to be associated with EER, Rival and associates[11] found that the most common complaint was cervical dysphagia (33%), followed by globus (19%), sore throat (17%), and chronic throat clearing (14%). The researchers found that 66% of the patients complained of classic symptoms of GERD, such as acid regurgitation and heartburn.[11] Fraser and coworkers[52] prospectively reviewed patients with symptoms believed to be associated with EER in whom pH probe study results were positive and found cough and hoarseness as the most common symptoms; 77% of their patients also complained of classic symptoms of GERD. Other investigators report lower rates of symptomatic GERD in patients with EER, with estimates of 20%,[5] 43%,[14] and 55%.[54] In a survey of American Broncho-Esophagological Association members, respondents believed that the most common symptoms related to EER were throat clearing, persistent cough, heartburn/dyspepsia, globus sensation, and voice quality change.[12] The importance and relevance of these findings are supported by the work of Reavis and associates,[57] who showed that laryngopharyngeal manifestations of acid reflux, specifically cough and hoarsenesss, better predict the presence of adenocarcinoma of the esophagus than "classic" GERD symptoms such as heartburn and regurgitation.

Belafsky and colleagues[49,50,58] developed the Reflux Symptom Index (RSI), a self-administered survey of nine questions used to assess patients with EER (Box 65-3). They demonstrated that the instrument is reliable and that it provides reproducible and valid findings. Normative data gathered by these researchers support that an RSI of more than 10 is associated with a high likelihood of positive results of a dual-channel pH probe study.[59] They prospectively evaluated 40 patients with EER documented by dual pH probe studies and 2 months of medical management. The RSI was noted to show improvement before changes were seen in physical findings. The mean RSI at initiation of the study was 19.3, which improved to a mean of 13.9 after 2 months.[49]

Physical Examination and Laryngeal Endoscopy

The physical examination can yield several clues to EER. Observations of the quality of the voice, frequent throat clearing, cough or stridor, muscle tension in extralaryngeal musculature, and general body habitus are important to the evaluation. The larynx can be evaluated with indirect laryngoscopy along with rigid and/or flexible laryngoscopy.

Box 65-3

The Reflux Symptom Index

Within the past month, how did the following problems affect you? Rank them from 0 (no problem) to 5 (severe problem).

1. Hoarseness or a problem with your voice
2. Clearing your throat
3. Excess throat mucus or postnasal drip
4. Difficulty swallowing food, liquids, or pills
5. Coughing after you have eaten or after lying down
6. Breathing difficulties or choking episodes
7. Troublesome or annoying cough
8. Sensations of something sticking in your throat or a lump in your throat
9. Heartburn, chest pain, indigestion, or stomach acid coming up

Table 65-1

The Reflux Finding Score

Pseudosulcus	0, absent; 2, present
Ventricular obliteration	0, none; 2, partial; 4, complete
Erythema/hyperemia	0, none; 2, arytenoids only; 4, diffuse
Vocal fold edema	0, none; 1, mild; 2, moderate; 3, severe; 4, polypoid
Diffuse laryngeal edema	0, none; 1, mild; 2, moderate; 3, severe; 4, obstructing
Posterior commissure hypertrophy	0, none; 1, mild; 2, moderate; 3, severe; 4, obstructing
Granuloma/granulation	0, absent; 2, present
Thick endolaryngeal mucus	0, absent; 2, present

From Belafsky PC, Postma GN, Amin MR, Koufman JA. Symptoms and findings of laryngopharyngeal reflux. *Ear Nose Throat J*. 81(Suppl 2):10, 2002.

Videoendoscopy and stroboscopy are very useful, especially for documenting treatment effects and for visualizing subtle signs associated with acid reflux.

The majority of laryngeal findings seen in patients with chronic laryngitis associated with EER are edematous changes, as opposed to erythematous changes, seen in the posterior larynx. Posterior laryngitis manifests as edema, loss of clear epithelial markings, and increased vascularity of the posterior commissure and arytenoids.[5,13,60] Chronic irritation can result in a thickening of the posterior laryngeal mucosa with hyperkeratosis, which is also called pachydermia laryngeus.[5,13] Hanson and colleagues[13] describe this posterior mucosal thickening with increased granularity and rough cobblestone appearance as "granular mucositis." Increased mucus formation and thickness, along with mucus stranding and pooling, may result from chronic irritation and alterations of mucociliary flow.[5,43] Laryngeal ulceration, granuloma formation, scarring, and stenosis may indicate more severe EER.[13,30-32] Cherry and Margulies first identified extraesophageal reflux of gastric acid as being associated with contact ulcers.[43]

Although it has been traditionally thought that erythema of the posterior larynx is the key sign of EER,[13,31] it is really the edema consequent to acid reflux–induced trauma to the larynx that is the clinical hallmark of EER.[59,61-63] Habermann and colleagues,[60] reviewing the endoscopic findings in 29 patients with chronic dysphonia and chronic laryngitis, showed that edema of the posterior glottic mucosa was the most common finding. The researchers noted significant improvement in these changes with therapy. Alterations of the true vocal fold mucosa and false vocal folds were also noted to improve with treatment. Shaw and Searl[64] assessed 96 patients who had symptoms suggestive of EER and noted that posterior glottic edema and nodularity were the most "severe and frequent" findings. Only 47% of patients were found to have ulceration, and 3 patients were found to have granulomas. Branski and coworkers[62] performed a prospective, randomized, blinded study to assess the reliability of the laryngoscopic evaluation of patients with EER. They found that both intrarater reliability and inter-rater reliability were poor; raters demonstrated a poor agreement on the severity of endoscopic findings for LPR. The investigators concluded that using laryngoscopic findings alone for the diagnosis of EER was highly subjective.

Pseudosulcus has been described as a common endoscopic finding in EER.[50,59,65] The term *pseudosulcus* refers to the edematous changes that take place along the undersurface of the vocal fold from the anterior to the posterior commissure.[50,50,65] By contrast, true sulcus vocalis involves the free edge of the fold and terminates at the vocal process. Belafsky and colleagues,[59] evaluating pseudosulcus in 30 patients with EER (i.e., with positive pH probe results) and 30 control patients, found pseudosulcus in 70% of patients with EER and in 30% of controls. Patients with pseudosulcus were 2.3 times more likely to have pH probe–documented EER. The sensitivity and specificity of pseudosulcus were estimated to be 70% and 77%, respectively.[59] Hickson and colleagues[65] prospectively assessed, with dual-channel pH probe studies, 20 patients in whom endoscopic evaluation had confirmed pseudosulcus; EER was identified with positive pH probe results in 18 of the 20 patients. These researchers estimated that the positive predictive value of pseudosulcus for EER was 90%.[65]

Belafsky and coworkers[59] have developed an endoscopic grading scale for EER. The Reflux Finding Score (RFS) consists of eight findings, seven of which are related to edematous changes in the endolarynx and only one to redness of the endolarynx, that are graded as to severity to a score from 0 to 26 (Table 65-1). The researchers report that an RFS of more than 7 is associated with a high likelihood that dual pH probe results will be positive.[59] The RFS was tested in 40 control subjects and 40 patients with clinical history positive for EER and pH probe studies. This review showed excellent interobserver and intraobserver reliability for the RFS. The mean RFS for control subjects was 5.2, whereas the mean RFS at entry for the EER group was 11.5, and an individual with an RFS of more than 7 was noted to have EER with 95% certainty.[58]

Beaver and colleagues[61] conducted a prospective study of the videostroboscopic images of 49 patients diagnosed with laryngopharyngeal reflux disease on the basis of two or more symptoms (i.e., throat clearing, hoarseness, cough, globus, or excessive mucus) along with physical findings of chronic laryngitis. Subjects were evaluated before and after 6 weeks of high-dose proton pump inhibitor (PPI) therapy. Ten control patients without any symptoms of EER were included. Three otolaryngologists evaluated the photographs in a blinded manner and in random order and gave each a score using the Laryngopharyngeal Reflux Disease Index (Box 65-4). The mean index value for patients was significantly higher than that of controls (9.50 vs. 2.92, respectively), and posttreatment mean scores were significantly lower than pretreatment scores (7.35 vs. 9.50, respectively). The most useful items on the scoring system were as follows: supraglottic edema and erythema, glottic edema and erythema, and subglottic edema and erythema. Items 7 through 12 were not believed to be as useful, and very few patients had positive scores on these items. The key factor in the endoscopic assessment of acid reflux–induced changes in the laryngopharynx is that edema, not erythema, is the clinical hallmark of EER.

Box 65-4

The Laryngopharyngeal Reflux Disease Index

Grade each using a scale of 0 to 3 (0, absent; 3, most severe):

1. Edema of posterior supraglottis
2. Edema of vocal folds
3. Edema of subglottis
4. Erythema of posterior supraglottis
5. Erythema of vocal folds
6. Erythema of subglottis

Grade as 1 if present and 0 if absent:

7. Leukoplakia
8. Nodules or prenodules
9. Polyp(s)
10. Posterior pachydermia
11. Web (may be anterior microweb)
12. Contact granuloma

Voice Analysis

Hanson and colleagues[66] reviewed voice quality and measures of jitter, shimmer, and signal-to-noise ratios in 16 patients undergoing treatment for chronic posterior laryngitis. Perceptual analysis did not show correlation with acoustic measures, and it did not show significant change with treatment. The investigators did demonstrate that measures of jitter, shimmer, and signal-to-noise ratio improve significantly with antisecretory and antireflux treatment of chronic posterior laryngitis. Shaw and Searl[64] noted significant improvement in measurements of jitter, shimmer, habitual frequency, and frequency range with antireflux treatment in their series of patients with a pretreatment complaint of hoarseness. Hamdan and coworkers[53] did not find any change in acoustic parameters in patients undergoing medical treatment of EER.

Esophagram

Barium esophagram is a convenient, inexpensive, and noninvasive diagnostic test. It is a useful method to diagnose structural and functional abnormalities of the esophagus, including hiatal hernia, erosive esophagitis, strictures, Barrett's esophagus, esophageal rings, extrinsic compression, motility disorders, diverticula, possible malignancy, cricopharyngeal spasm, aspiration, and esophageal shortening.[5,9,14,67,68] Barium studies have significant use for planning of antireflux surgery. Fluoroscopic evaluation is often used to look for the presence of reflux, and it is often combined with provocative maneuvers, such as Valsalva's maneuver, cough, rolling from the supine to the right lateral position, and the water siphon test (the patient drinks 60 mL of water through a straw while supine). The sensitivity of barium esophagram to detect GER is between 20% and 60%, with a specificity of 64% to 90% and an accuracy of 69%.[9] Thompson and associates[68] assessed 117 patients with clinical GERD and compared the results of esophageal pH probe studies with those of barium esophagrams. They demonstrated that barium studies showed unprovoked reflux in 26% of subjects with positive pH probe study results. The addition of the water siphon test increased the sensitivity of barium esophagram in the evaluation of reflux to 70%, with a specificity of 74% and a positive predictive value of 80%.[68]

The relevance of barium esophagography in patients with EER is less clear. In Toohill and Kuhn's[5] series of 286 patients with dysphonia and various laryngeal disorders, 79.9% had abnormal esophagram findings. Rival and colleagues[11] showed that 22 out of 73 patients with EER symptoms had normal barium swallow study results, with 50% of these patients demonstrating EER on subsequent diagnostic testing. Giacchi and colleagues[2] reviewed 28 patients with otolaryngologic manifestations of EER, reporting that barium esophagram revealed reflux in 45% of patients and that 50% had normal findings.

Laryngeal Sensory Testing

Laryngeal sensory testing alone, without evaluation of swallowing, can be used to diagnose EER.[68a,b] The concept is that the posterior laryngeal edema that results from acid reflux can be quantified with laryngeal sensory testing. With laryngeal sensory testing, a pressure- and duration-controlled pulse of air is administered to the arytenoid epithelium in order to induce the laryngeal adductor reflex, a brainstem-mediated, airway-protective reflex. The practical way to regard laryngeal sensory testing is that an edematous arytenoid would require a stronger air pulse pressure to cause indentation of the arytenoid epithelium than the air pressure required to "indent" arytenoid epithelium that is not edematous.

Two studies have demonstrated that laryngeal sensory testing can be used to quantify the edema that results from LPR. In one study, 76 patients were prospectively evaluated to determine the relationship between double-probe pH testing results, laryngopharyngeal sensory testing results, and transnasal flexible laryngoscopy (TFL) findings.[69] All 76 patients underwent dual channel 24-hour pH testing after 7 days with no PPI treatment, laryngopharyngeal sensory testing, and TFL performed by otolaryngologists who were blinded as to the patients' pH status and laryngopharyngeal sensory testing results. There were three patient groups: Group A (the study group) consisted of patients with GERD who had LPR symptoms; Group B (GERD controls) had GERD but no LPR symptoms; and group C (normals) had no GERD and no LPR symptoms. GERD was defined as a distal probe pH of less than 4 more than 5.4% of the time during a 24-hour period.[70] Patients with GERD and LPR symptoms (group A) had significantly higher posterior laryngopharyngeal sensory thresholds than both patients with GERD but no LPR symptoms and controls with no GERD and no LPR symptoms. Sensitivity of blinded TFL findings versus dual-channel 24-hour pH testing was 50%, and specificity was 83%. However, adding the finding of air pulse pressure greater than 5 mm Hg on laryngopharyngeal sensory testing increased the sensitivity to 88% and specificity to 88%. This study showed that LPR is associated with a posterior laryngeal sensory neuropathy with impairment of the laryngeal adductor reflex. The investigators reasoned that because a greater air pulse strength was required to elicit the laryngeal adductor reflex in the patients with documented acid reflux than in the controls without acid reflux, this finding effectively represented an alteration in laryngeal sensory nerve function; hence their use of the term "neuropathy." Furthermore, the combination of sensory testing, specifically a sensory deficit greater than 5 mm Hg air pulse pressure, TFL findings were essentially as sensitive and specific as 24-hour pH testing for diagnosis of acid reflux disease.

Another key prospective study compared 15 patients who had chronic cough (no asthma, no rhinitis) and 24-hour pH probe–documented GERD with 10 healthy controls.[71] The patients in both study groups had laryngeal sensory testing before and after laryngopharyngeal infusions of normal saline and 0.1 N hydrochloric acid (on separate days). The baseline threshold for eliciting the laryngeal adductor reflux was significantly greater for both patients with pH probe–documented acid reflux disease and patients and controls exposed to 0.1 N HCL. The researchers concluded that the sensory integrity of the laryngopharynx is significantly impaired after exposure to even small amounts of acid and that patients with cough and proven GERD have reduced laryngopharyngeal sensitivity compared with healthy controls—which could result in a higher risk of aspiration.

Practically, what these studies mean for the patient and for the clinician is that a brief in-office test, laryngopharyngeal sensory testing, can serve the same purpose as a 24-hour pH probe test to diagnose reflux disease. Therefore, these results suggest that with the application of sensory testing techniques, identification of reflux disease can be made quite readily by most practicing physicians who see patients with laryngopharyngeal reflux symptoms. This is not to suggest that patients who might be contemplating surgical treatment of acid reflux disease, such as a laparoscopic fundoplication, avoid pH probe testing. Rather, there are reliable office-based alternatives to diagnose acid reflux disease

enabling immediate diagnosis so that treatment may be initiated at the time of testing.

Esophageal Endoscopy—Transoral and Transnasal Esophagoscopy

The esophagus can be examined endoscopically via either a transoral approach or a transnasal approach. The transoral route is performed either in an operating room with use of a rigid scope and the patient under general anesthesia or in an endoscopy suite with use of a flexible scope and the patient under intravenous, or conscious, sedation. The reason patients typically need general anesthesia or intravenous anesthesia for transoral esophagoscopy is that, in both instances, a rather large-caliber endoscope is passed along the dorsal surface of the tongue, thereby necessarily engaging the gag reflex. Alternatively, esophagoscopy can be performed transnasally with an ultra-thin-caliber endoscope passed via a topically anesthetized nasal cavity. The transnasal approach is called transnasal esophagoscopy (TNE). Peroral rigid esophagoscopy has been performed by otolaryngologist–head and neck surgeons since the 1890s.[72-74] Flexible esophagoscopy, performed transorally in the endoscopy suite with use of conscious sedation, has been performed by gastroenterologists since the late 1950s.[75,76]

The transnasal era of esophagoscopy was first reported by Prescott,[77] an otolaryngologist, who described TNE in children in 1993. In 1994, Shaker,[78] a gastroenterologist, published the first paper on unsedated, transnasal EGD in adults, performed with the patients sitting upright in an examining chair. In 1998, at the annual meeting of the American Broncho-Esophagological Association, an otolaryngologist performed TNE live on a healthy control in order to demonstrate the ease and reliability of the technique.[79] Since that time, TNE is fast becoming, in the otolaryngology world and beyond, a safer alternative to both traditional flexible esophagoscopy with conscious sedation and rigid esophagoscopy with general anesthesia.[80-82]

Since 1996 numerous studies have compared unsedated transnasal and sedated transoral upper endoscopy. These studies showed no difference between the two techniques with respect to safety, feasibility, and patient tolerance.[83-86] As to whether an endoscopic examination of the esophagus, without a detailed examination of the stomach and small intestine, is sufficient to diagnose acid reflux disease, Wildi and colleagues[87] demonstrated that for patients who have traditional esophageal reflux symptoms—heartburn, regurgitation, dysphagia—but who do not have other gastric or duodenal symptoms—abdominal pain, nausea or history of gastric or duodenal ulcer—an endoscopic examination of the esophagus alone is sufficient. Furthermore, two studies have clearly shown that TNE with small-caliber endoscopes is as accurate as conventional upper endoscopy to detect Barrett's esophagus.[88,89] The implication here is that TNE is not only technically feasible and well tolerated but also accurate in screening for Barrett's esophagus, despite yielding a smaller biopsy specimen. In the not too distant future, office-based, unsedated TNE has the potential to eliminate the infrastructure and cost required by intravenous sedation for screening for and surveillance of Barrett's esophagus.

It is essential to endoscopically examine the esophagus in patients with suspected acid reflux disease because of the proven relationship between acid reflux esophagitis and esophageal adenocarcinoma.[90-94] Patients with acid-induced reflux esophagitis may have pathologic changes in the esophageal epithelium whereby the normal stratified squamous epithelium of the distal esophagus is replaced by columnar cells that typically are found in the stomach lining. This condition is called Barrett's esophagus. In 1975, GERD was linked to Barrett's esophagus and esophageal adenocarcinoma.[95]

The incidence of esophageal adenocarcinoma has been rising markedly since the 1970s in both the United States and Western Europe.[96,97] The risk factors for esophageal adenocarcinoma are presence of Barrett's esophagus and gastroesophageal reflux. As Barrett's esophagus may be seen in 5% to 15% of Americans with GERD, the potential public health problem in this country is daunting.

Unlike laryngeal squamous cell carcinoma, which can cause symptoms—hoarseness, cough—when a vocal fold lesion is miniscule, esophageal adenocarcinoma generally manifests when the esophageal lesion is so large that the patient presents with dysphagia. As a result, most esophageal cancers are detected at an advanced stage when the chance of survival is dismal. Specifically, the 5-year survival rate of symptomatic esophageal adenocarcinoma is less than 10%.[98,99] However, in the rare instances that esophageal cancer is detected early, usually as an incidental finding during an otherwise routine upper endoscopy or barium swallow study, it becomes a curable disease, with 5-year survival rates between 80% and 90%.[100]

So how can early detection of esophageal cancer be achieved? One way is for physicians and their patients to be educated about the presenting symptoms of the disease. As mentioned earlier, laryngopharyngeal symptoms such as cough and hoarseness are better predictors of the presence of esophageal cancer than heartburn and regurgitation.[101] Therefore, for patients with persistent laryngopharyngeal symptoms despite antacid therapy, an endoscopic examination of the esophagus is indicated. Patients may balk at the notion of having to undergo an endoscopic procedure that requires conscious sedation. This is a reasonable concern because most complications related to esophagogastroduodenoscopy (EGD) are related not to perforation but to the risks of conscious sedation. Cardiac and respiratory problems as a consequence of conscious sedation account for more than 60% of all major complications of EGD.[102-104] With TNE, no sedation, intravenous or otherwise, is required. So the major risk associated with conventional upper endoscopy is suddenly removed.

Esophagogastroduodenoscopy is useful for the direct visualization of the esophagus, along with collection of biopsy and culture specimens in patients with esophagitis and gastritis. In patients with GERD, EGD may be valuable in the search for esophageal mucosal irritation and to rule out Barrett's esophagus. Deveney and colleagues[45] evaluated a small series of patients with laryngeal inflammatory lesions and found that three out of seven (43%) had esophagitis, although none had Barrett's esophagus. Smit[105] found pH probe–proven GER in 72% of patients with globus and hoarseness, in 35% of patients with hoarseness alone, and in 30% of patients with globus alone. Abnormal EGD findings were noted in 65% of the patients in this group who had concurrent GER. On the basis of the findings of a high prevalence of pathologic GER in subjects with globus and hoarseness, Smit[105] recommended that patients with symptomatic EER and concurrent GERD be evaluated with EGD. In a small prospective study in patients with chronic laryngeal symptoms associated with EER and concomitant GER as documented by pH probe study, EGD showed grade II or higher esophagitis in all of the subjects and Barrett's esophagus or peptic esophageal stricture in 50% of these individuals.[54,106]

Tauber and associates[107] prospectively evaluated the incidence of gastroenterologic diseases in patients presenting with nonspecific laryngopharyngeal symptoms that were believed to be associated with EER. Thirty such patients refused pH probe studies and were evaluated with EGD. GERD was seen in 43%, gastric culture was positive for *Helicobacter pylori* in 23%, and 73% had some form of gastrointestinal disease diagnosed by EGD or biopsy. Medical therapy for reflux and *H. pylori* (in patients found to have the infection) resulted in a 90% therapeutic success rate for symptom resolution.[107]

McMurray and colleagues,[37] studying pediatric patients who were undergoing evaluation for airway reconstruction, found that significant reflux as demonstrated by the lower esophageal pH probe did not correlate with positive esophageal endoscopic findings or biopsy-proven inflammation of the upper or lower esophagus. A weak correlation was seen between laryngoscopic findings of EER and postcricoid biopsy findings.[37] The necessity of esophageal endoscopy in patients with EER without GERD is unclear, and the procedure may be unnecessary.[14]

Manometry

The use of manometric evaluation for patients with GERD is well documented. Knight and coworkers[47] documented the significance of esophageal dysmotility in patients with EER. These investigators used manometric studies of 100 patients with EER to show that 29% had normal motility, 48% had ineffective motility, 10% had a hypertensive lower esophageal sphincter, 9% had nutcracker esophagus, and 4% had esophageal achalasia. Rival and associates[11] noted low LES pressure in 60% of the patients they studied who had cervical symptoms of EER. Esophageal manometric evaluation is critical to surgical planning for

antireflux surgery.[67] Although manometry is valuable in a certain subset of patients with EER, it may not be useful as a diagnostic test for EER. Because it is only one measurement in time and transient relaxations of the LES are important in the pathogenesis of EER, manometry may not accurately assess patients for the absence of relaxations of the LES and, therefore, for EER.[9]

pH Probe Monitoring

Continuous pH monitoring studies are believed to be the "gold standard study" for diagnosing GERD and EER.[9,14,108] Probes that sense pH changes can be placed in different locations in the esophagus, pharynx, and hypopharynx. Probe placement can be verified with manometry, endoscopy, or fluoroscopy. Manometric localization of pH probe location is the most commonly used technique. Single pH probe techniques that involve the use of a probe placed 5 cm above the manometrically determined site of the LES are commonly employed for the evaluation of patients with GERD. With the recognition of extraesophageal symptoms of EER, the importance of adding a second probe above the UES has been elucidated. Postma[108] describes a review of patients with otolaryngologic complaints associated with EER who underwent dual pH probe testing at Wake Forest University, 59% of whom would have been inappropriately assumed to have a negative pH probe study result if the diagnosis had been based solely on the readings from the esophageal probe. In these patients, the pharyngeal sensor was needed to document EER.[109] In a similar study, Koufman and colleagues[110] showed that 11% of patients had a positive upper probe result with normal esophageal pH probe acid exposure time. Little and associates[111] demonstrated the importance of the proximal probe in children and noted that 46% (78 of 168) of subjects were found to have EER by proximal probe in spite of negative lower esophageal probe results.

Although the advent of dual pH probe studies has added significantly to our diagnostic armamentarium, it is not without its limitations. It is an invasive test, and its sensitivity is no more than 75% to 80%.[95] Hanson and colleagues[112] stated that the false-negative rate may approach 50%. Noordzij and associates[113] compared dual pH probe findings with symptom severity in patients with EER and showed that a dual pH probe positive result had poor predictive value for symptoms or signs of EER. Small variations in technique for probe placement or calibration can significantly affect accuracy.[108] Careful documentation of patient position (supine or upright), diet, and symptoms are equally important during the study. The patient should maintain his or her usual dietary and smoking habits and activity level during the study.[108,114,115]

Although there is a consensus about norms for the distal esophageal pH probe, considerable controversy exists with regard to findings in the proximal pharyngeal probe. Some researchers report that a single pharyngeal reflux event as determined by a drop in pH to 4 or less is diagnostic of EER.[108,114] Unfortunately, several studies have documented that a small percentage of normal subjects have proximal probe pH drops to less than 4.[55,116,117] Vincent and colleagues[55] showed that normal subjects were judged positive for reflux with the proximal probe (median of one event), with 80.4% of the events occurring while the subjects were upright. In addition, these investigators examined the Reflux Area Index, which incorporates the number and duration of events of pH less than 4. They state that "the reflux area index appears to be the most useful parameter to measure laryngopharyngeal reflux severity."[55] Normative data for pediatric patients is also lacking, and there appears to be considerable age-related variation.[9,40] Bauman and associates[35] performed a retrospective review in pediatric patients undergoing pH probe testing at their institution. Sixty-eight patients were noted to have EER symptoms, underwent empiric medical treatment, and were reviewed. Chronic cough, apnea, and recurrent pneumonia were the most commonly documented extraesophageal symptoms. Eight-five percent of subjects were noted by their caretakers to have symptomatic benefit from antireflux therapy. The positive predictive value of the distal esophageal probe study was more than 90%, but the negative predictive value was less than 50%. The researchers noted that the reproducibility of results on different days was poor; only a small number of subjects underwent dual pH probe study, and for those subjects, the mean percentage of time that the pH was less than 4 in the upper probe was 2.6%.[35]

Contencin and Narcy,[118] Hanson and colleagues,[112] and Koufman[14] have argued that the criteria of the pH being below 4 may be too stringent. Contencin and Narcy[118] showed that drops in pH to 6 or less at the proximal probe in children with laryngotracheitis may be significant. Pepsin, which has been shown to be critical in the pathogenesis of tissue damage, is active at pH levels of up to 5.[14] Hanson and Jiang[31] cautioned against stringent use of the pH value of 4 criterion in patients who have had prior radiotherapy, because irradiated tissue may be less resistant to reflux trauma.

Several writers have shown the importance of a positive proximal pH probe result, yet one must be careful when interpreting a negative study result in patients with EER. Many patients with respiratory tract manifestations of EER may not have reflux into the proximal esophagus, but they may have symptoms as a result of a vagally mediated reflex, as discussed previously.[114] In addition, there is a potential for sampling error, because EER may potentially cause disease but it may be infrequent and therefore not documented in a 24-hour study period.

There are several problems with catheter-based, ambulatory esophageal pH probe testing, including patient discomfort, the alteration of the patient's typical activities because a catheter is taped to the cheek for 24 hours, and early removal of the catheter.[119] A solution to these issues has been developed with the advent of wireless esophageal pH monitoring systems.[120] The wireless systems may ultimately replace the more uncomfortable, unwieldy catheter-based pH probe systems. The wireless system involves attachment of a pH capsule to the esophageal mucosa at the time of an upper endoscopy. The pH capsule can be delivered to the esophagus either transorally or transnasally.[121] Data from the pH signal is then wirelessly transmitted to a receiver that is on or near the patient. The patient may be monitored for 24 or 48 hours.[122] Wireless pH testing technology is more comfortable for the patient, is more reliable than catheter-based techniques, and provides more time to obtain pH data so that the diagnosis can be more securely made.[123]

Impedance Testing

The introduction of the multichannel intraluminal impedance technology using a pH sensor (MII-pH) allows the detection of nonacidic gastroesophageal reflux.[124] With impedance testing one can detect the presence of liquid or gaseous boluses within the esophageal lumen on the basis of changes in electrical conductivity of what is travelling within the esophagus. MII testing allows one to detect the direction of material flow, antegrade or retrograde. Furthermore, adding pH monitoring to the impedance analysis can detect both acid and nonacid reflux events.[125] It is believed that in EER, it is very often the nonacid reflux events that are responsible for persistent symptoms despite aggressive antiacid pharmacotherapy.[126,127] MII-pH likely will have a significant and growing role in diagnosing patients with EER, because studies have shown that during prolonged monitoring of pH levels, typical GER symptoms are related more to acid reflux events than to nonacid reflux events. However, symptoms that persist during acid-suppressive therapy are often related to nonacid reflux events.[128,129]

The therapeutic options for the nonacid component of the refluxate are varied and, in addition to acid suppression, include prokinetics, baclofen, and mucosal protective agents like alginates. Laparoscopic Nissen fundoplication is an option as well.[128,130]

Treatment

Behavioral Modification

Behavioral changes that are aimed at reducing episodes of reflux may be critical to the successful management of EER. Hanson and colleagues[13] have shown that nocturnal reflux precautions alone result in symptomatic improvement in approximately 50% of patients with posterior laryngitis and chronic dysphonia. Common modifications recommended include the following: avoidance of eating or drinking 3 hours before lying down; avoidance of tobacco products, alcohol,

fried foods, fatty foods, chocolate, caffeine, spicy foods, and peppermints; avoidance of tight-fitting clothing; and elevation of the head of the bed by 6 to 8 inches.[13,42,64] No controlled studies have evaluated behavioral modifications.[42] Giacchi and associates[2] evaluated patient compliance with treatment for EER and found that compliance with behavior modification varied widely. The extent of symptomatic improvement correlated positively with both medical therapy and behavior modification. The changes that most significantly correlated with symptom reduction were avoidance of food and liquid before bedtime and elevation of the head of the bed.[2] Multiple researchers have shown that acid exposure to the lower esophagus is reduced with decreases in fat intake, smoking, elevation of the head of the bed, and allowing at least 3 hours between eating and lying down.[42] Chewing gum for 1 hour after food intake resulted in reduced acid contact time in both controls and patients with reflux,[131] and it raised esophageal and pharyngeal pH.[132] The benefit was more pronounced in patients with reflux and lasted for up to 3 hours.[131] Avidan and colleagues[131] noted that walking for 1 hour postprandially caused a mild reduction of acid reflux, but only for a short time.

Over-the-Counter Antacids

Aluminum- and magnesium-based, bismuth, and bicarbonate-based antacids are very effective, low-cost, nonprescription antacid medications that can alleviate traditional GERD symptoms such as heartburn and regurgitation. These substances neutralize the pH of stomach acid, and they can thereby prevent the tissue damage caused by bile salts and deactivate pepsin at a higher pH.[8] Antacids have been shown to increase LES resting pressure.[1] Gaviscon (GlaxoSmithKline, Uxbridge, UK) contains alginic acid and is effective for reducing GER, but it does not appear to change LES pressure. Gaviscon's mechanism of action is not fully understood.[43] Antacids may be used as first-line therapy in patients with minor EER or as an adjunct to other treatment modalities.[133]

H_2 Blockers

Several H_2 blockers are currently available by prescription and over the counter. These drugs act at the histamine type 2 receptor by competitive binding, and they reduce gastric acid secretion along with pepsin production.[8,43] Some of the H_2 blocker effect is on the hepatic metabolism of other drugs, so patients should consult with their physicians and pharmacists to avoid drug-drug interactions. H_2 blockers may be used as first-line therapy in patients with minor EER, as adjunct therapy, or as step-down therapy to wean patients from PPIs.[133,133a,133b] Of patients with chronic laryngitis who were treated with H_2 blockers and behavioral modifications, 54% noted symptomatic relief after 6 weeks of therapy, with 92% reporting some recurrence of symptoms after cessation of H_2 blocker therapy.[13] Long-term high-dose H_2 blocker therapy was not found to be as effective or as cost effective as PPI therapy for the treatment of significant esophagitis.[134]

Proton Pump Inhibitors

PPIs act against the enzyme hydrogen-potassium adenosine triphosphatase in the parietal cell, thus blocking the final step of gastric acid production.[43] These drugs are more effective than H_2 antagonists for the long-term reduction of basal and stimulated levels of gastric acid production.[134a,134b,134c] Postma and colleagues[133] make the following recommendations: Patients with significant EER are started on twice-daily PPI therapy, along with behavioral modifications (especially if the patients are positive for GERD or have positive lower esophageal pH probe results); they should be reevaluated at 2-month intervals. H_2 blockers may be added to limit nighttime acid breakthrough, but the decision to add them should be based on the pattern of reflux seen on dual-channel pH probe study. Patients are assessed with the RFS and RSI; for the patient with RFS values less than 5 and RSI scores less than 10 on two consecutive examinations, Postma and colleagues[133] recommend tapering PPI therapy. Their recommended protocol for tapering medications involves initially stopping the nighttime dose of PPI and substituting an H_2 blocker. Two weeks later, the morning medication also becomes an H_2 blocker. If the patient experiences breakthrough symptoms, PPI therapy is resumed. For patients who do not show symptomatic improvement at the 4-month mark—despite high-dose PPI therapy—the pH probe study is repeated while the patient is taking medication.[133] A significant number of patients with chronic laryngitis on PPI therapy may show relative PPI resistance.[135] Other reasons for treatment failure are poor compliance and breakthrough with acid suppression therapy.[135]

An immediate-release preparation of the PPI omeprazole has been developed for which the phenomenon of nocturnal acid breakthrough does not occur.[136] A small, prospective, double-blind, placebo-controlled study of the efficacy of twice-daily dosing of omeprazole for patients with chronic laryngitis and at least four episodes of LPR on pH probe study demonstrated a placebo effect.[137] Most symptom scores improved over time for both the omeprazole group and the placebo group. The researchers did not see significant changes in endoscopic laryngeal findings in either group. Hoarseness (when scored low) and chronic throat clearing were noted to improve in the omeprazole group. The duration of this study was short; patients were evaluated at 1 and 2 months.

Promotility Agents

Metoclopramide, a dopamine antagonist, is effective against GER. It raises LES pressure, improves gastric emptying, and may improve esophageal clearance.[43,138] Metoclopramide is the only prokinetic agent that is currently available on the market, although new serotonin agonists are being evaluated by the U.S. Food and Drug Administration. Unfortunately, up to a third of patients may experience side effects from metoclopramide.[43] Patients with diabetes mellitus, dystrophia myotonica, and anorexia nervosa may have significantly delayed gastric emptying and thus may benefit from prokinetic agents.[138] Erythromycin may be used as a prokinetic agent, and it acts as a motilin agonist.[139]

Other Medical Therapy

Sucralfate has been shown to enhance mucosal resistance to trauma, is effective for promoting the healing of duodenal ulcers, and has been shown in animal studies to protect esophageal mucosa against injury from acid.[43] Sucralfate is a salt of sucrose, and it is well tolerated by patients. Its value as a treatment for patients with EER is not well elucidated. Bethanechol is an anticholinergic agent that has been shown to increase LES pressure, decrease GER, and improve salivary flow.[43]

Surgical Treatment

Antireflux surgery involves replacing the LES into the abdomen and then augmenting the LES as an antireflux barrier. The Nissen fundoplication involves the use of a 360-degree wrap of the gastric fundus around the intra-abdominal esophagus.[67] Ten-year success rates for the use of this procedure in treatment of GERD are quoted to be around 90%, with a mortality rate of 1%.[67] Fundoplication can be performed via an open or a laparoscopic approach. Complications of fundoplication are rare and include bleeding, the need for splenectomy, dysphagia, slippage of the fundoplication into the chest, early satiety, bloating, diarrhea, pneumothorax, and gastric ulceration. Deveney and colleagues,[45] assessing 13 patients with persistent laryngeal inflammatory lesions and voice disorders who underwent Nissen fundoplication, found that 73% (11 patients) showed a resolution of symptoms and endoscopic changes. Lindstrom and associates[140] performed a retrospective review of patients with EER who underwent Nissen fundoplication and found that 25 out of 29 patients had near total symptomatic relief and were not taking any antireflux medications. Wright and Rhodes[141] reviewed 145 patients with EER symptoms who underwent the laparoscopic Hill repair and saw statistically significant improvement in EER symptoms postoperatively.

Otolaryngologic Disorders Associated with Extraesophageal Reflux

Chronic Laryngitis

Hanson and colleagues[13,31,66] define chronic laryngitis as a 3 months' or longer history of one or more of the following: hoarseness that worsens with voice use; persistent or recurrent sore throat without throat infec-

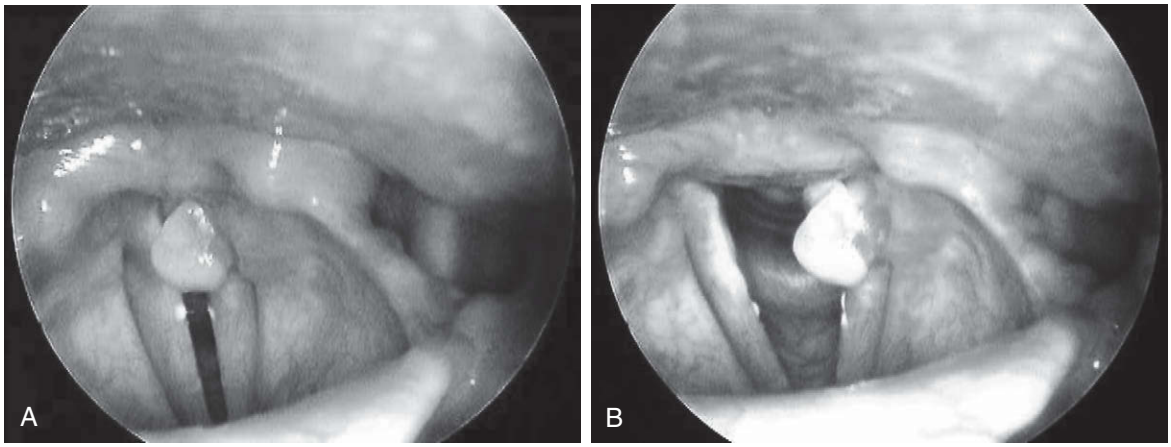

Figure 65-1. A 60-year-old patient with left vocal fold granuloma before treatment. **A,** Vocal fold adduction. **B,** Vocal fold abduction.

tion; sensation of postnasal drip; and throat clearing or cough in the absence of lower respiratory tract or pulmonary disease. The researchers report that the sensation of chronic postnasal drip is the most common and earliest manifestation of chronic irritative laryngitis, throat discomfort and dysphonia being the second and third most common symptoms, respectively. The sensation of constant secretions in the back of the throat is thought to be a result of ciliary dysfunction in the posterior larynx and pharynx.[31] Hanson and Jiang[31] studied 182 patients with chronic laryngitis that was believed to be associated with EER. Ninety-six percent of patients experienced relief with antireflux treatment within 12 weeks. Fifty-one percent (93 patients) showed response to nocturnal antireflux management alone; 48 patients required the addition of an H_2 blocker nightly, and 34 required the addition of 20 mg of nightly omeprazole. Seven patients in the study required higher dosages of omeprazole, all of whom were noted to have severe laryngeal changes at their pretreatment examinations. Symptomatic relapse was common with the discontinuation of therapy. Habermann and colleagues[60] showed that hoarseness, globus pharyngeus, sore throat, heartburn, and coughing were symptoms in patients with chronic laryngitis that showed significant improvement with an empiric 6-week course of a PPI.

Rival and others[11] demonstrated that 84% of patients with cervical symptoms associated with EER had symptomatic improvement with antireflux therapy. Koufman and colleagues,[4,142] Fraser and coworkers,[52] and Postma and associates[133] point to the need for longer duration of treatment, stating that up to 6 months of treatment may be necessary. Koufman and colleagues[4] showed that, with 6 months of antireflux treatment, 85% of patients with chronic laryngitis had evidence of treatment efficacy. They noted that half of these "responders" demonstrated an effect in 3 weeks to 3 months, with the remaining showing an effect by 6 months.[4,49,133] In a prospective study of patients with chronic laryngitis who were treated with a combination therapy of behavioral modifications, PPI therapy, and cisapride, significant therapeutic benefit was noted in patients with chronic hoarseness, but not in those with intermittent dysphonia.[53]

Contact Ulcer and Laryngeal Granuloma

Proposed etiologies for vocal process granulomas include EER, vocal misuse, intubation trauma, smoking, chronic cough, chronic throat clearing, infection, and allergies.[32,32a] In a retrospective review of 55 patients with vocal fold granulomas, there was a 76% incidence of associated EER or GERD.[32] A 50% recurrence rate was seen with surgical excision alone. All but 4 of the 55 patients who were treated with antireflux measures, medications, and voice therapy showed resolution of granulomas. In the recalcitrant four cases, antireflux surgery resulted in resolution of the granulomas.[32] In a retrospective study of 58 men with vocal contact ulcers and granulomas, esophageal dysfunction was found in 74%.[143] Hoffman and colleagues[33] recommend a treatment algorithm for laryngeal granulomas and ulcers that uses surgical intervention as a last step, with the medical management of reflux and voice therapy as the mainstay of treatment; intralaryngeal botulinum toxin is recommended for recalcitrant cases. The use of inhaled triamcinolone (Azmacort, Abbott Laboratories, North Chicago, IL), 150 µg three times a day for six to eight weeks, has also been used for treatment and avoids systemic side effects. Surgical management is reserved for cases in which conservative management has failed, in which airway obstructive symptoms are present, or in which the diagnosis is in doubt.[33] Figures 65-1 through 65-4 show some clinical examples of vocal fold granuloma and its treatment.

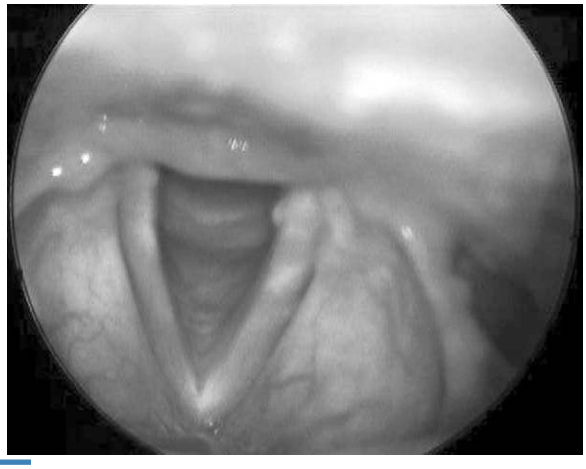

Figure 65-2. The same patient as seen in Figure 65-1, after 4 months of twice-daily proton pump inhibitor therapy and behavioral modifications.

Extraesophageal Reflux and Head and Neck Cancer

EER may play a role in the development of head and neck squamous cell carcinoma, although it has not been established as a cocarcinogen.[19-21] EER may contribute to complications of both surgical management and radiation treatment of head and neck carcinoma.[17] Copper and colleagues[17] prospectively evaluated 24 patients with laryngeal and pharyngeal squamous cell carcinoma and 10 patients who had previously received radiotherapy, all of whom had undergone 24-hour dual pH probe testing before treatment. In 11 of the 24 patients, pathologic reflux was confirmed by both probes, and only 4 patients (17%) had negative results for both probes.[17] In the irradiated patients, pathologic reflux was documented by the upper probe in 60%, by the lower probe in 70%, and by both probes in 40%.[17] A high incidence of LPR was seen in patients with premalignant and early glottic carcinomas, with 85% having positive pH probe results.[19] No significant correlations with severity of reflux or histologic stage was seen.[19] Sung and colleagues[20] studied the effect of bile acid on cultured human pharyngeal

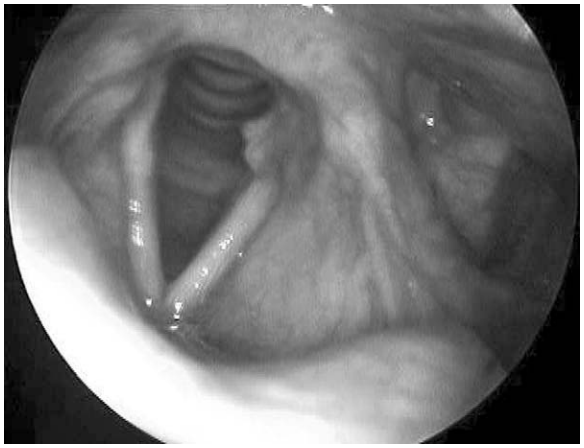

Figure 65-3. A 45-year-old man with recalcitrant left vocal fold granuloma. Prior treatment included removal, voice therapy, and high-dose proton pump inhibitor therapy with botulinum toxin injection. Dual pH probe study revealed moderate reflux in both probes.

cells. Bile acid is known to be associated with tumor formation in the esophagus through the overexpression of cyclooxygenase-2. Bile salts or acidic conditions were noted to induce cyclooxygenase-2 expression in normal pharyngeal mucosa, which may imply a role in tumorigenesis in the pharynx.[20]

Conclusion

There is substantial evidence that many otolaryngologic and respiratory symptoms and disorders can be associated with EER. EER should be considered in patients presenting with laryngeal, pharyngeal, and airway complaints. The evaluation and management of these patients must be individualized. No single diagnostic test available is a definitive gold standard; medical management offers these patients substantial symptomatic relief and often requires a multidisciplinary approach.

Management of Unilateral Vocal Fold Paralysis

CHAPTER SIXTY-SIX

Medialization Thyroplasty

Carole Fakhry

Paul W. Flint

Charles W. Cummings

Key Points

- Both medialization thyroplasty and vocal fold injection can be used successfully to manage glottal insufficiency associated with unilateral vocal fold motion impairment, vocal fold bowing, and soft tissue deficits.
- The choice of medialization thyroplasty, vocal fold injection, or injectable should account for anatomic considerations, duration of symptoms, potential for improvement, and patient health and life expectancy.
- Videostroboscopy is useful for both preoperative and postoperative evaluation of patients with vocal fold motion impairment. Electromyography is the only test available to evaluate the integrity of the laryngeal motor unit.
- Vocal fold injections can be performed percutaneously or transorally with local anesthesia or via direct laryngoscopy with general anesthesia.
- Injections for vocal fold medialization should target the paraglottal space lateral to the vocalis muscle, whereas intracordal injections for soft tissue deficits are more superficial, but deep to the lamina propria, avoiding Reinke's space.
- Complications of vocal fold injections include under-injection, misplaced injection, over-injection, and reaction to foreign material, all of which negatively affect vocal quality.
- Type I thyroplasty makes static changes to laryngeal framework; its lack of effect on vocal fold muscle mass, innervation, and vocal fold motility is the inherent limitation of this procedure.
- Medialization thyroplasty may be performed alone or in conjunction with arytenoid adduction or reinnervation procedures for management of vocal fold paralysis.
- Complications of type I thyroplasty include failure to achieve adequate medialization, penetration of the endolaryngeal mucosa, wound infection, chondritis, implant migration or extrusion, and airway obstruction.

Since the first writing of this chapter, laryngeal phonosurgery has undergone evolution comprising a continuum of procedures designed to rehabilitate the dysfunctional larynx. Phonosurgical procedures may be classified into the following categories: (1) microlaryngeal procedures for excision of benign or malignant disease, (2) vocal fold injection for augmentation and medialization, (3) laryngeal framework surgery, (4) laryngeal reinnervation procedures, and (5) reconstructive and rehabilitative procedures after tumor resection. Laryngeal framework surgery has been further categorized by Isshiki and associates[1] into the following four types of surgical procedures on the basis of the functional alteration of the vocal folds: medial displacement (type I), lateral displacement (type II), shortening or relaxation (type III), and elongation or tensioning procedures (type IV).[2-5] This chapter focuses on laryngeal framework surgery and vocal fold injection in the context of rehabilitation of the paralyzed larynx while specifically addressing the management of glottal insufficiency from unilateral vocal fold motion impairment, vocal fold bowing, and soft tissue deficits.

Historical Aspects

The predominant focus of phonosurgical procedures has been rehabilitation of the paralyzed larynx. With a few exceptions, primary repair by end-to-end anastomosis after injury to the recurrent laryngeal nerve has been universally unsuccessful.[6] Failure of primary repair is ascribed to a random process of axonal regeneration at the site of injury that results in the simultaneous contraction of antagonistic muscle groups, otherwise known as *synkinesis*.[7,8] Alternative methods of reinnervation using ansa hypoglossus nerve–muscle pedicle implants into the posterior cricoarytenoid muscle and phrenic nerve–recurrent laryngeal nerve anastomosis for bilateral vocal fold paralysis have been explored.[9-12] Ansa hypoglossus nerve–nerve anastomosis and nerve-muscle implant techniques have also been applied to unilateral vocal fold paralysis.[11,13] Despite significant efforts in establishing appropriate reinnervation and function after injury to the recurrent laryngeal nerve, debate continues about the efficacy of these procedures. Reinnervation procedures applied to laryngeal rehabilitation are covered in greater detail in Chapter 68.

Vocal Fold Medialization

The first report of a phonosurgical procedure appeared when Brunings[14] introduced the concept of vocal fold medialization by injection of paraffin within the body of the paralyzed fold. This was followed by Payr's[15] description of an external approach for medialization that used a posterior vertical incision through the thyroid lamina, whereby the anterior flap was collapsed inward, resulting in limited medialization. Neither approach gained acceptance.

Almost four decades later, Meurman[16] reported a series of patients with vocal cord paralysis in whom external medialization procedures

were performed with use of a vertical parasagittal incision in the anterior thyroid cartilage and autologous rib cartilage grafts placed between the thyroid ala and the inner perichondrium. Meurman's procedure resulted in a high incidence of complications, probably as a result of perichondrial and mucosal perforations occurring with the anterior midline approach.

In the 1960s, Arnold[17] reintroduced vocal fold injection but with use of an alloplastic material, polytetrafluoroethylene (Teflon). Over the ensuing years, experience with this material has demonstrated a rising frequency of problems related to granuloma formation.[18-20] Subsequently, an absorbable material (absorbable gelatin sponge [Gelfoam]) was applied, allowing temporary vocal fold medialization by injection. Autologous fat has also been used to attempt permanent medialization.[21-23] However, the long-term effectiveness of autologous fat has been shown to be unpredictable, with an overall success rate of 62% at 12 months.[24] Reports of the use of bovine collagen injections for medialization were initially promising; however, soft tissue response led to variable results with respect to phonatory function.[25] At the beginning of this century, micronized AlloDerm Regenerative Tissue Metrix (Cymetra; LifeCell Corporation, Branchburg, NJ) has been applied for vocal fold injection, with early reports indicating improvements in soft tissue response, tissue compliance, and overall phonatory function. Like bovine collagen, Cymetra may last 3 to 9 months and can be used for temporary medialization in patients for whom recovery is likely to occur after recurrent laryngeal nerve injury.[26,27]

Although numerous modifications of external approaches have been reported,[28-32] Isshiki and associates[29] were the first to introduce the concept of alloplastic implant material for medialization. Using an external approach with a Silastic implant, these investigators are credited with the ultimate success and popularity of type I medialization thyroplasty. We are proponents of prefabricated implants with sizing systems. Two systems, VoCoM hydroxyapatite implants (Gyrus ACMI, Southborough, MA) and Montgomery Silastic implants (Boston Medical Products Inc, Westborough, MA), are currently available.[33] More recently, Gore-Tex strips have been used to maintain vocal fold medialization with and without arytenoid adduction.[34-36]

Although type I medialization procedures result in dramatic improvement in glottal efficiency and sound production, a small group of patients continue to have difficulty during phonation as a result of a large posterior glottal chink or vocal folds at unequal levels. To address this specific problem, Isshiki and associates[29] introduced the arytenoid adduction procedure for unilateral vocal cord paralysis. Placement of a suture around the muscular process of the arytenoid with traction in the direction of the lateral cricoarytenoid and thyroarytenoid muscles results in medial rotation of the arytenoid and downward displacement of the vocal process. The posterior gap is reduced, and the paralyzed vocal folds are placed at equal levels. Arytenoid adduction and related procedures are covered in greater detail in Chapter 67.

The advantages of an external approach to modify vocal fold tension and position without altering the structural components (mucosal fold and underlying muscle body) have expanded the role of laryngeal framework surgery. Isshiki and associates[37,38] and Koufman[39] have reported their experiences with medialization and tensioning procedures for the management of vocal fold bowing and dysphonia resulting from sulcus vocalis and soft tissue deficits.

Management of Glottal Insufficiency Associated with Unilateral Vocal Fold Motion Impairment and Soft Tissue Deficits

Several procedures are available to manage glottal insufficiency, including vocal fold injection for medialization, medialization thyroplasty, arytenoid adduction, adduction arytenoidopexy,[40] and a variety of reinnervation procedures. Selection of the appropriate procedure depends on the duration of symptoms, severity of impairment, presence of anatomic or surgical defect, and potential for recovery. In addition, the patient's overall condition and life expectancy should be considered before one embarks on a procedure that may predispose the patient to added morbidity.

Patient Evaluation and Selection

Severity of impairment can be determined from subjective criteria based on the patient's symptoms, such as breathiness, aspiration, and exertional intolerance, or on more objective criteria obtained through a variety of tests. Currently available studies for the objective assessment of laryngeal function include perceptual assessment, simple phonatory function tasks such as mean or maximum phonation time, acoustic parameters (i.e., spectrographic analysis, measurement of fundamental frequency, perturbation of frequency and amplitude, signal-to-noise ratio), and measurement of phonatory airflow. The objective assessment of laryngeal function is covered in greater detail in Chapters 57 to 59.

Videostroboscopy remains the most useful subjective and objective test for preoperative and postoperative evaluation of patients with unilateral vocal fold impairment, providing visual assessment of glottal closure and of the status of the mucosal wave. Reinnervation or denervation may be determined from the presence of abnormal or asymmetric mucosal wave patterns during stroboscopy; however, the absence of a mucosal wave does not necessarily imply denervation. Because the mucosal wave is a passive phenomenon established by adequate vocal fold tension and subglottal pressure, the presence of functional motor units is not a prerequisite for the development of the mucosal wave.[41]

Electromyography (EMG) is the only test available at this time for evaluating the integrity of the laryngeal motor unit in the presence of vocal fold motion impairment. Laryngeal EMG is useful for determining the presence of denervation or reinnervation potentials and is assuming a more active role in the prognostication, timing of intervention, and choice of surgical procedures for the paralyzed larynx.[42,43] Despite normal voluntary electric activity, however, vocal fold immobility may be present as the result of laryngeal synkinesis, joint ankylosis, or cicatricial web formation. Distinction among these processes can be made only by palpation of the vocal process during direct laryngoscopy.

With documentation of denervation by EMG, medialization thyroplasty should be considered early in the presence of aspiration or severe dysphonia. If there is evidence of recovery on visual examination or EMG, medialization by injection using a resorbable material such as collagen may be considered as a temporizing procedure. Patients with mild to moderate symptoms of dysphonia only may be counseled to allow spontaneous recovery to occur before considering permanent medialization procedures. Although type I thyroplasty is considered reversible, voice quality after the removal of implants has not been studied.

Prognosis, when combined with results of objective studies, is useful for choice of treatment. Vocal fold paralysis with a favorable prognosis occurs after blunt trauma, endotracheal intubation, idiopathic vocal fold paralysis, and paralysis associated with viral pathogens (Ramsay Hunt syndrome). In this setting, severity of aspiration, dysphonia, and EMG findings can be used to determine the choice of procedure and timing of intervention, as outlined previously. The group of patients with paralysis who have poor prognosis for recovery includes those with injury after complete nerve section during surgical resection of tumor, with invasion of cranial nerves by tumor, with paralysis associated with thoracic aneurysm, and with paralysis due to progressive neurologic disorders. Unlike peripheral recurrent laryngeal nerve injuries, high vagal injuries can result not only in loss of abductor/adductor function but also in loss of cricothyroid muscle function and deafferentation of sensory fibers. In this condition, vocal folds are more likely to be lateralized with marked bowing and atrophic changes. Patients with such injuries generally have greater difficulty with dysphonia, dysphagia, and aspiration. When denervation is documented or history portends a poor outcome, early medialization by thyroplasty is warranted.

Percutaneous medialization by injection should be considered in patients with short life expectancy and aspiration or severe dysphonia. In this situation, the time and expense of medialization thyroplasty or reinnervation procedures might not be justified.

Vocal Fold Medialization by Injection

Vocal fold medialization by injection remains a standard procedure for laryngeal rehabilitation. In the absence of arytenoid fixation and when

adequate residual vocal fold structure remains to allow needle placement for augmentation, medialization of a paralyzed vocal fold by injection can be performed with use of a variety of materials. Autologous fat and Cymetra are the materials most commonly used today. Cymetra has been shown to provide excellent phonatory results lasting 6 to 12 months with little or no inflammatory response.[44] The hyaluronic acid formulations, such as Hylan B gel (Hylaform, Genzyme Biosurgery Inc., Cambridge, MA), used as an injectable material for medialization have also been shown to have favorable viscoelastic properties.[45,46] Collagen, although not specifically approved by the U.S. Food and Drug Administration for laryngeal injections, has been shown to be effective for management of vocal fold paralysis, sulcus vocalis, and soft tissue deficits.[47] Inflammatory changes associated with soft tissue response after bovine collagen injection can result in greater tissue stiffness and less than satisfactory results. Permanent adverse effects are unlikely to occur, however, because the collagen is ultimately resorbed. The use of polytetrafluoroethylene paste (polytef) for vocal fold injection is discouraged unless long-term patient survival is not anticipated. Adverse effects from development of polytetrafluoroethylene granuloma are well documented and include dysphonia caused by soft tissue reaction and airway obstruction from mass effect.[8]

Calcium hydroxyapatite (Radiesse dermal filler, Bioform Medical, Inc., San Mateo, CA) has also been introduced as a viable material for injection laryngoplasty with longer duration of effect.[48] However, this material has been associated in case reports with a foreign body granulomatous reaction.[49] Affected patients have presented with dysphonia, pain, and vocal cord erythema visualized on fiberoptic examination. In our experience and the other reportable case, patients required suspension microlaryngoscopy, which demonstrated multiple irregular mass lesions on the true vocal folds. In both cases, microflaps were made to excise the injectable material. Histologically, a chronic inflammatory infiltrate with surrounding foreign body giant cells was observed. Therefore, we advocate caution in the use of calcium hydroxyapatite as an agent for vocal fold medialization.

Transoral and percutaneous approaches have added a new dimension to the management of vocal fold paralysis.[50,51] In most patients, medialization can be accomplished quickly and effectively in the office setting. These procedures are relatively simple and yield immediate results with little discomfort to the patient. If recovery of vocal fold function is likely, fat and polytetrafluoroethylene are usually contraindicated, and alternative methods must be considered. Cymetra can be used as a temporizing measure in this setting. Percutaneous injections are performed without sedation, local anesthesia alone being sufficient. Flexible fiberoptic laryngoscopy is required to visualize position and adequacy of injection. Given their advantages and ease of performance, percutaneous injections are becoming the preferred method in many centers. However, when airway management is a potential problem, injection in a controlled setting during direct laryngoscopy should be considered.

Percutaneous Injection

We prefer a lateral, percutaneous approach through the thyroid ala at the level of vocal fold determined by palpation of the thyroid notch and inferior border of the thyroid ala anteriorly (Figs. 66-1 and 66-2). The vocal fold lies perpendicular to this line at the midpoint. Alternatively, an anterior approach can be used through the cricothyroid membrane, with the vocal folds approached from below.[50,51] As the needle is inserted, it is angled superiorly and laterally under direct visualization with a flexible fiberoptic nasopharyngoscope. Rees and colleagues[52] reported their technique using a transthyrohyoid approach with fiberoptic visualization. The primary disadvantage of this technique is related to potential deposition of injectable material within Reinke's space. Given that the material injected in this report is calcium hydroxyapatite, there is potential for adverse outcomes resulting in permanent dysphonia. This issue is addressed by Chheda and coworkers in a report of revision laryngeal surgery after suboptimal injection with calcium hydroxyapatite.[53]

When Cymetra is used for this procedure, it is reconstituted in saline and placed in a Luer-Lok 1-mL syringe with a 1-inch, 23-gauge needle. Controlled pressure is required to pass the needle through the thyroid lamina. Visualization is best achieved with a flexible fiberoptic nasopharyngoscope with digital imaging system. The position of the needle can be visualized easily before the superficial layers of the fold are entered. Optimal results are obtained with placement of the injection just anterior and lateral to the vocal process and on a plane level with the lower border of the medial edge. Material in this location builds up the undersurface of the true fold and minimizes the risk on injecting into Reinke's space. With this technique, approximately 0.5 to 1.0 mL of Cymetra is adequate. In general, slight over-injection with Cymetra and autologous fat is preferred because resorption is anticipated. Patients should be counseled to expect voice change over time.

Figure 66-1. Percutaneous injection with fiberoptic visualization. A lateral approach is used with the needle passed through the thyroid cartilage. The needle is visualized in the paraglottic space anterior and lateral to the vocal process.

Transoral Injection

Transoral injection can be performed in selected patients. Topical 4% lidocaine solution is applied to the pharyngeal and laryngeal mucosa. With the patient holding the tongue forward, allowing indirect visualization, the injection is performed with a curved laryngeal needle. Right and left needles are available, so that the bevel is directed away from the midline to minimize the possibility of an intramucosal injection.

Laryngoscopic Injection

In patients who do not tolerate the flexible fiberoptic examination, laryngoscopic injection via a percutaneous or transoral approach may be necessary. Injection via microlaryngoscopy is also used during ablative procedures in which recurrent laryngeal or vagal nerve resection is anticipated and temporary medialization is performed to minimize immediate postoperative symptoms. The injection can be performed with the patient under general anesthesia with spontaneous ventilation, controlled intermittent apnea, or jet ventilation using the Sanders device.

With the patient in the supine position, and after initiation of appropriate anesthesia, the laryngoscope is introduced and suspended using a suspension apparatus. Care is taken not to place unnecessary tension at the anterior commissure, which would result in distortion of the vocal folds. The arytenoid cartilages are palpated with a spatula to ensure mobility, and the false vocal fold is lateralized, exposing the ventricle (Fig. 66-3).

For injection of Cymetra, a 23-gauge butterfly needle is modified by removing the flange completely on one side and leaving a small flange on the other to grasp with a small alligator forceps. Visualization is best achieved with a 0- or 30-degree, 5-mm laryngeal telescope and digital video system. Telescopic visualization provides better assessment of the depth of injection. The needle is then inserted anterior and lateral

Types of vocal fold injection. **A,** Intrachordal injection for vocal fold paralysis showing the bevel of the needle directed away from the medial edge of the vocal fold. **B,** Intramucosal injection resulting from misplaced injection with the bevel of the needle directed toward the medial edge of the vocal fold. *(From Cummings CW, ed.* Otolaryngology–Head and Neck Surgery: Update I. *St. Louis: Mosby; 1989.)*

to the vocal process approximately 2 mm deep or at the plane level with the lower margin of the true fold. Autologous fat is more viscous and may require an injection gun, such as a Brunings syringe. After injection, a spatula or suction can be used to massage the vocal fold to distribute the injected material more evenly.

Laryngoscopy can also be performed with the patient under local anesthesia to monitor the changes in vocal quality during injection. Superior laryngeal nerve blocks with lidocaine should be avoided because they would alter vocal fold tension through cricothyroid muscle paralysis and thus adversely affect voice quality. After the initial injection, the scope is relaxed and the patient is asked to phonate. Repeat injections are performed as necessary.

A distinction should be made between vocal fold medialization and intracordal injection. With injections for medialization, the material is placed in the paraglottal space lateral to the vocalis muscle, leaving the mucosa overlying the vocal fold unaltered. With intracordal injections to eliminate soft tissue defects, the injectable material (collagen or Cymetra) is placed more superficially, into the area just deep to the lamina propria, avoiding Reinke's space (Fig. 66-4). Polytetrafluoroethylene is contraindicated for intracordal injections because granulomatous reactions to the material can increase vocal fold stiffness and mass, adversely affecting vocal fold vibration.[54,55]

Complications of vocal fold injection include under-injection requiring repeat procedures, over-injection with airway compromise, improper placement causing subglottal extension, and potential stenosis. Migration of polytetrafluoroethylene particles, intracordal injection of polytetrafluoroethylene impairing vibratory capability, and granuloma formation may occur (Fig. 66-5). Management of polytetrafluoroethylene over-injection is a challenging problem and should be counteracted immediately by incising the mucosa over the site of injection and removing excess material with suction. Immediate removal is preferred because delayed removal is made difficult by migration of polytetrafluoroethylene, granuloma, and scar formation. If necessary, delayed removal is generally attempted during microlaryngoscopy using cupped forceps or the carbon dioxide laser. Koch and associates,[56] evaluating the safety of using the carbon dioxide laser on polytetrafluoroethylene, found no evidence or reports of untoward side effects. Endoscopic removal should be attempted initially, although open procedures (thyrotomy) may be required in cases of persistent granuloma. Similarly, Cymetra has been found to migrate and result in a mass extending from the aryepiglottic fold to the piriform sinus, which required suspension microlaryngoscopy and resection. Histologically, the mass was consistent with a foreign body reaction. Of note, in the reported case the patient had received three injections within 12 weeks.[57]

Medialization Thyroplasty

Medialization thyroplasty is now considered by many in the surgical community to be the procedure of choice for management of the paralyzed vocal fold. The procedure can be performed alone or in conjunction with arytenoid adduction or reinnervation procedures. Also classified as a type I thyroplasty by Isshiki and associates,[29,37] this procedure offers the following advantages: (1) it is performed with local anesthesia with minimal or no discomfort to the patient, (2) patient positioning is more anatomic, allowing better assessment of voice during the procedure, (3) it is potentially reversible, and (4) because the prosthesis is placed lateral to the inner perichondrium of the thyroid lamina, structural integrity of the vocal fold is preserved, allowing medialization with effective closure of the prephonatory gap—the end result being a decrease in oscillation threshold and improved vocal efficiency.[2,58,59] Disadvantages include the following: (1) the patient is subjected to an open procedure, (2) the procedure is technically more difficult, and (3) closure of the posterior glottis may be limited.

Medialization thyroplasty is currently used for management of vocal fold paralysis, vocal fold bowing due to aging or cricothyroid joint fixation, sulcus vocalis, and soft tissue defects resulting from excision of pathologic tissue.[1,60] Treatment for paralytic dysphonia is indicated when the likelihood of recovery is negligible. When recovery is anticipated, medialization thyroplasty may be considered for management of aspiration or severe dysphonia as an alternative to repeated injections with Cymetra. Generally, dysphonia by itself should be managed conservatively if recovery is anticipated; however, our experience has not shown an adverse effect in patients who have received a thyroplasty and subsequently recovered function.

Although modifications of Isshiki's description of medialization thyroplasty are abundant, the basic principles remain the same. Factors that affect outcome include size and shape of the implant, position of the implant, maintaining proper position of the implant, and limiting the duration of the surgical procedure. In our experience, the duration of the procedure is directly related to the predictability of the end result. Carved Silastic implants, prefabricated Silastic implants (Montgomery),[31] and dense hydroxyapatite (VoCoM) implants are routinely used. Prefabricated implants with matched-sizing templates allow for more rapid determination of the correct implant position and size (Fig. 66-6). Gore-Tex strips have also been used with success and, in some situations, may provide greater adaptability than prefabricated systems.[36] However, Gore-Tex has not been immune from the potential granulomatous inflammatory responses associated with polytetrafluoroethylene products. In a laryngectomy specimen of a patient who had previously undergone Gore-Tex implantation for recurrent aspiration, histopathologic changes of multinucleated giant cells at the periphery of the Gore-Tex implant were observed.[61]

Figure 66-6. Prefabricated implant system made from hydroxyapatite. Implants vary from 3 to 7 mm of displacement. The implant is stabilized with a 0- to 3-mm offset shim (2-mm offset shim is shown with 6-mm displacement shim).

Technique

With the patient in the supine position and prepared for a sterile procedure, a paramedian horizontal incision is outlined over the middle aspect of the thyroid lamina. Local anesthesia is administered subcutaneously and in four quadrants over the ipsilateral lamina. A 5-cm incision is made through the platysma. Superior and inferior flaps are elevated in the subplatysmal plane, exposing the thyroid notch and inferior border of the thyroid cartilage. The strap muscles are split in the midline and retracted laterally off the thyroid lamina, leaving the outer perichondrium intact. A single large skin hook is implanted in the anterosuperior aspect of the contralateral ala and retracted laterally, providing exposure of the ipsilateral lamina. The cartilage window is outlined by scoring the perichondrium sharply, or with electrocautery applied to a window template. For the VoCoM system, the window measures 6 mm (vertical) by 10 mm (horizontal) (Fig. 66-7). The anterior aspect of the window is positioned 5 to 8 mm posterior to the ventral midline in women, and 8 to 10 mm in men. The superior aspect of the window should be placed at the level of the true fold. A point half the distance between the anterior-inferior border of the thyroid cartilage and the notch defines the level of the true fold. From this point, a line drawn posterior and parallel to the inferior border of the thyroid cartilage will approximate the level of the true fold. The outer perichondrium is incised and elevated from the thyroid cartilage within the confines of the window. Cartilage and osteoid material are removed precisely, preserving the dimensions of the window. If ossification has occurred, the window can be drilled out or removed with a Kerrison

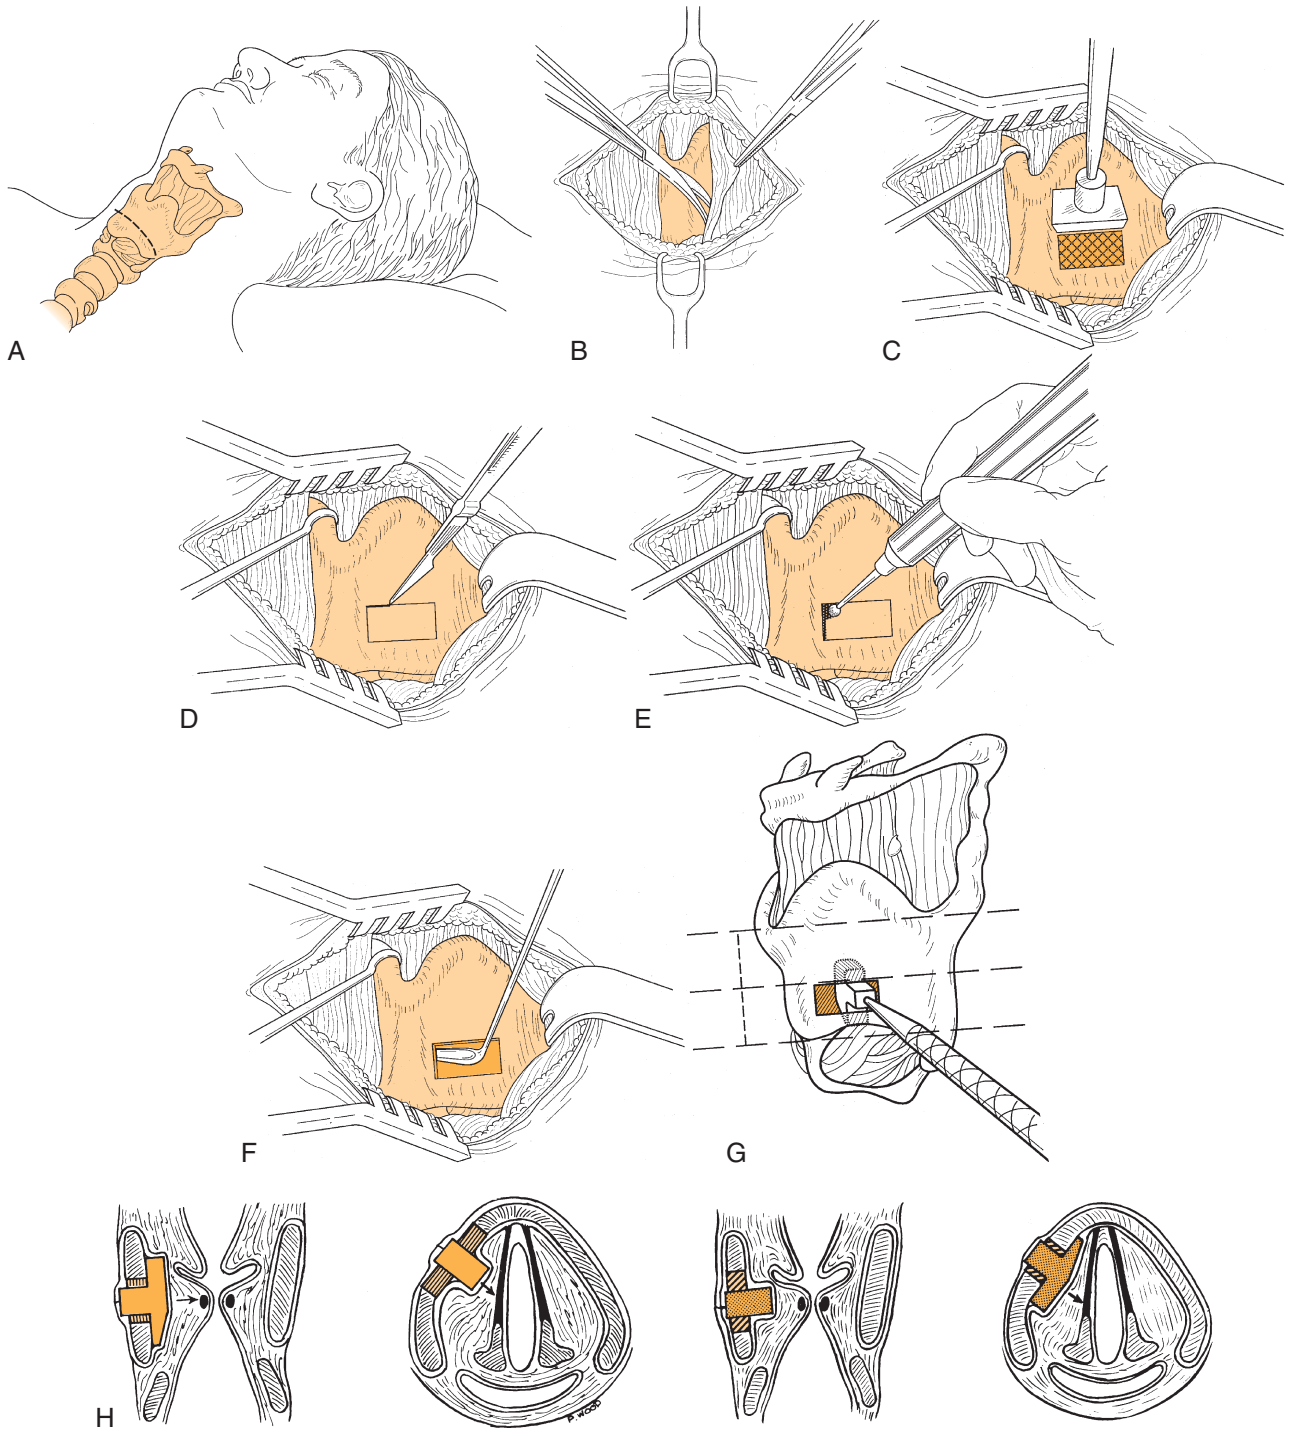

Figure 66-7. Medialization thyroplasty. **A,** Skin incision. **B,** Sternohyoid muscle is elevated off the thyroid cartilage. **C,** The muscle is retracted posterior to thyroid lamina; a cautery template marks the fenestra (6 × 10 mm), and the superior aspect of the window is at the vocal fold level. **D,** The outer perichondrium is incised and removed. **E,** A cutting bur, followed by a diamond bur, is used to remove cartilage and protect underlying periochondrium; a small Kerrison punch may facilitate removal of cartilage from the fenestra. **F,** The inner perichondrium is circumferentially elevated with a blunt dissector. **G,** A template or appropriately sized prosthesis is placed in the most effective position; the appropriate position of the fenestra is shown relative to the vocal fold level based on external landmarks. **H,** Variations in placement of the implant, showing vertical and horizontal implants relative to the plane of the true vocal fold.

punch. Care is taken to preserve the inner perichondrium, which is now elevated in circumferential fashion off the thyroid lamina by means of a laryngeal elevator.

With the VoCoM system, one of five sizing prosthesis templates (3-8 mm) is inserted through the window and rotated 90 degrees with the bevel directed superiorly (Fig. 66-8). This orientation is more likely to produce optimum voice quality; however, placing the bevel of the implant inferiorly or anteriorly in the horizontal plane can be tried. Precut Silastic implants with progressively greater displacement (3-8 mm) may also be used. Rarely are implants with displacement greater than 7 mm required. All retractors are removed, and the patient is asked to phonate while the template is moved through all four quad-

rants of the window to determine the optimal position. Smaller or larger templates can be selected as needed. If medialization appears to be limited by the inner perichondrium and the thyroid cartilage is bowed outward, the inner perichondrium can be incised, releasing tension and enhancing medialization. Once the appropriate size and position have been determined, the retractors are replaced and the implant is inserted and secured with the appropriate shim. If the window is fashioned correctly, the shim will fit securely, preventing migration of the implant. If the shim is not stable, or the cartilage is thin, a suture is passed through the neck of the implant and tied over a titanium mini-construction plate, thus securing the shim. When one is using carved Silastic, the implant can be fashioned with medial and lateral flanges to engage the thyroid cartilage and thus secure it (Fig. 66-9). The wound is then irrigated with antibiotic solution. A small suction drain is placed deep to the strap muscles. Strap muscles and platysma are approximated with 4-0 absorbable suture, and skin is closed with a running 5-0 subcuticular suture. Dexamethasone (Decadron) is given preoperatively to minimize edema, and administration of prophylactic antibiotics is continued for 5 days.

We prefer to use the largest prosthesis possible that maintains quality of voice. Overcorrection is supported by Isshiki and associates,[1] who found deterioration in voice quality over time as intraoperative edema resolved in the postoperative period. When medialization is performed early after the onset of paralysis, muscle atrophy can lead to postoperative voice deterioration. Minimizing operative time is critical in obtaining optimal results.[1] Fabricating implants before the procedure facilitates the intraoperative determination of size and position and optimizes the end result.

Thyroplasty performed with Gore-Tex, as described by McCulloch and Hoffman,[35] is performed in a similar manner. Window location and dimensions do not need to be as precise. The inner perichondrium is opened, and the implant material is simply layered into the paraglottal space (Fig. 66-10).

After its first description in 1999,[62] Nishiyama and colleagues described[63] a modification of thyroplasty using autologous temporalis fascia grafts. In this procedure, temporalis fascia is harvested, dehydrated, rolled, and inserted into the vocal fold under microlaryngoscopy. Among the eight patients these researchers evaluated, phonation time was significantly improved.[63] This technique has been implemented for large glottic gaps, unilateral vocal fold palsy, post-radiotherapy scar tissue, and atrophic vocal fold.

Limitations of type I thyroplasty relate to the mechanical nature of the procedure. The procedure imparts static change to the laryngeal framework but has no influence on dynamic function. There is no effect on vocal fold muscle mass, innervation, or vocal fold mobility. Closure of the posterior glottis may be limited by narrowing of the paraglottal space as the cricoid and thyroid cartilage converge posteriorly. Furthermore, type I thyroplasty may not affect vocal fold level in the vertical plane.

Objective and subjective outcome measures of medialization thyroplasty have revealed significant patient improvements. A prospective cohort study reported significantly improved voice in terms of hoarseness ($P < .001$) and breathiness ($P < .001$). Average phonation time increased from 4.6 to 15 seconds, and voice amplitudes were significantly higher (62.9 dB vs. 68.0 dB, $P < .01$), although preoperative and postoperative frequencies were similar.[64]

Complications associated with type I thyroplasty include penetration of the endolaryngeal mucosa, wound infection, chondritis, implant migration or extrusion, and airway obstruction. Airway compromise, the most serious potential problem, requires overnight inpatient observation.[65,66] Combined medialization thyroplasty and arytenoid adduction increase this risk.[65] Penetration of the endolaryngeal mucosa raises the risk of implant extrusion into the airway and infection. Before placement of the implant, the surgeon should assess the window for air leak by filling the wound with saline while the patient phonates. If communication with the airway has occurred, as determined by air escape, the procedure should be terminated. Intubation soon after medialization can result in displacement of the prosthesis or mucosal erosion resulting from endotracheal tube pressure.

Although the overall complication rate with type I thyroplasty is less than 3%, incomplete glottal closure resulting from undercorrection or improper placement of the implant occurs in approximately 10% to 15% of patients. Incomplete glottal closure is more likely to occur in patients undergoing acute implantation as a result of progressive vocal fold atrophy occurring after denervation. The surgical menu for management of incomplete closure includes revision thyroplasty, vocal fold injection with autologous fat or Cymetra, reinnervation procedures, and arytenoid adduction. Revision thyroplasty is surgically feasible and results in a high rate of improvement over the preexisting condition.[67] Silastic implants may be repositioned, or a larger prosthesis may be fashioned and reinserted through the previously created fenestra. However, removal of the implant with recreation of the surgical envelope and reintroduction of a new prosthesis is more difficult than the initial step in the procedure. In our experience, revision of VoCoM implantations resulted in dramatic improvement over the pre-revision condition (CW Cummings, PW Flint, unpublished data).

Medialization thyroplasty alone offers a simple solution to the management of unilateral laryngeal paralysis. With recognition of the limitations of this procedure, there are situations in which more than one procedure is required. Combining medialization thyroplasty with arytenoid adduction or reinnervation is, at times, necessary. These surgical approaches are discussed in Chapters 67 and 68.

CHAPTER SIXTY-SEVEN

Arytenoid Adduction

Gayle Ellen Woodson

Key Points

- Arytenoid adduction mimics the action of the lateral cricoarytenoid muscle to close the glottis by rotating the arytenoid cartilage.
- Arytenoid adduction is indicated for treatment of laryngeal incompetence due to flaccid laryngeal paralysis.
- This procedure is usually performed simultaneously with a thyroplasty.

The arytenoid adduction procedure addresses laryngeal incompetence in patients with unilateral laryngeal paralysis.[1] It mimics the action of the lateral cricoarytenoid muscle to close the glottis via rotation of the arytenoid cartilage rather than direct displacement of the membranous vocal fold.[2] An adduction suture is placed in the muscular process of the arytenoid, which is the origin of the lateral cricoarytenoid muscle. This suture is passed forward through the paraglottic space and secured to the inferior thyroid ala (Fig. 67-1). This anterior traction pulls forward on the muscular process so that the arytenoid rotates. The vocal process, which is orthogonal to the muscular process, moves medially, dragging the membranous vocal fold with it. Arytenoid adduction can be performed in conjunction with type I thyroplasty. Research in animal models indicates that a combination of the two procedures is more effective than either alone.[3]

Arytenoid adduction is a more invasive procedure than type I thyroplasty and is technically more difficult. It has been reported to carry somewhat greater surgical risks, including airway obstruction, joint dislocation, fistula, and carotid injury.[4,5] A 2001 study compared outcomes of type I thyroplasty alone or in combination with arytenoid adduction in 237 patients. The complication rate was 19% in patients undergoing arytenoid adduction versus 14% in those receiving thyroplasty alone. However, the difference in the complication rate was not statistically significant, and the 2 patients who required emergency tracheotomy for airway obstruction had thyroplasty alone.[6] Arytenoid adduction does provide better closure of the posterior glottis, and research in animal models has objectively documented that acoustic and aerodynamic results for this procedure are better than for those of thyroplasty alone.[7,8] Thus, arytenoid adduction is a valuable component of the therapeutic armamentarium for rehabilitation of patients with laryngeal paralysis, particularly those with significant glottal incompetence.

The clinical impact of laryngeal paralysis varies greatly.[9] Some patients with unilateral paralysis are completely asymptomatic. At the other end of the spectrum, some patients are aphonic and have severe problems with aspiration during swallowing. Such severe symptoms result from laryngeal incompetence—the inability of the glottis to close completely. Two key factors that influence glottal closure in patients with laryngeal paralysis are the configuration of the paralyzed vocal fold and the compensatory function of the contralateral fold.

Several theories have been proposed to explain variations in symptoms and vocal fold positions in patients with laryngeal paralysis, ranging from selective damage to abductor fibers[10] to adductor action of the cricothyroid muscle (Wagner-Grossman hypothesis).[11,12] However, it has been demonstrated that the cricothyroid muscle does not exert an adductor force on the vocal fold.[13-15] It is now generally accepted that a medial vocal fold position results from residual or regenerated innervation of laryngeal muscles.[16-19] When there is significant innervation of adductor muscles, the paralyzed fold is located near the midline, and compensatory activity of the normal side of the larynx can often close the glottis during phonation. In such cases, aspiration is rare, and hoarseness or breathiness responds well to surgical medialization of the membranous vocal fold performed by injection or thyroplasty. On the other hand, complete flaccid paralysis results in a cadaveric position of the vocal fold with more severe glottal incompetence, often referred to as a posterior gap.

It has long been recognized that vocal fold injection, such as with polytetrafluoroethylene (Teflon), cannot restore glottal competence when there is a large glottal gap.[20] There is some controversy regarding the efficacy of Isshiki type I thyroplasty in closing a posterior gap. It has been contended that a posterior extension of the thyroplasty implant can close a posterior gap, based on clinical observation.[21] However, other clinical reports as well as experimental studies indicate that arytenoid adduction is much more effective than thyroplasty in closing the posterior glottis.[7,8]

The concept of a "posterior gap" is not entirely accurate, in that the maximal glottic opening is between the vocal processes. The open glottis actually converges posterior to the vocal processes because lateral displacement of the vocal process involves external rotation of the arytenoid cartilage, not lateral displacement of the arytenoid.[22,23] In other words, the angle between the membranous vocal fold and its posterior cartilaginous portion decreases as the vocal fold abducts (Fig. 67-2).[24] Thus, the posterior portion of the cartilaginous vocal fold is medial to the vocal process in abduction, and it prevents glottic closure even with vigorous hyperadduction of the normal vocal fold (Fig. 67-3). Procedures that medialize the membranous vocal fold may achieve some medial displacement of the vocal process; however, the force vectors created by such procedures are inadequate to effect significant internal rotation of the arytenoid cartilage.

Vocal fold injection and type I thyroplasty do not address differences in the level of vocal folds. The paralyzed vocal fold often lies in a different plane from that of the mobile vocal fold. Although both folds are firmly attached to the anterior commissure, the vocal process may sag on the paralyzed side or lie above the glottic plane, as it does in physiologic abduction. Thus, there can be a significant vertical gap between the edges of the vocal folds, even when they appear to be touching when viewed from above in a two-dimensional image. The paralyzed fold can lie either above or below the glottal plane. In cadaver specimens from subjects who had chronic vocal fold paralysis,

the vocal fold has been reported to be caudally displaced with a wide ventricle and shift of the conus elasticus to a horizontal plane.[25,26] Other reports describe superior displacement of the paralyzed vocal fold, essentially the same position assumed by an actively abducted vocal fold.[2,27]

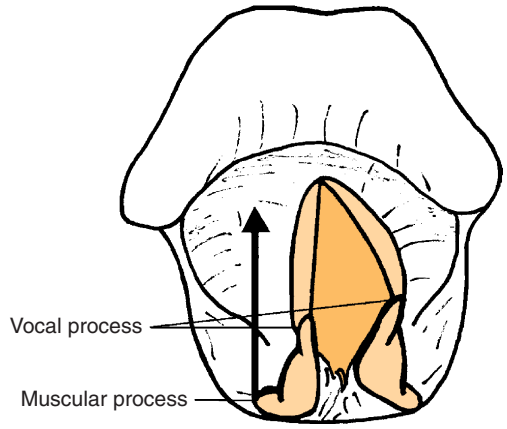

Figure 67-1. Arytenoid adduction procedure. Anterior traction (*arrow*) on the muscular process rotates the arytenoid so that the vocal process moves medially.

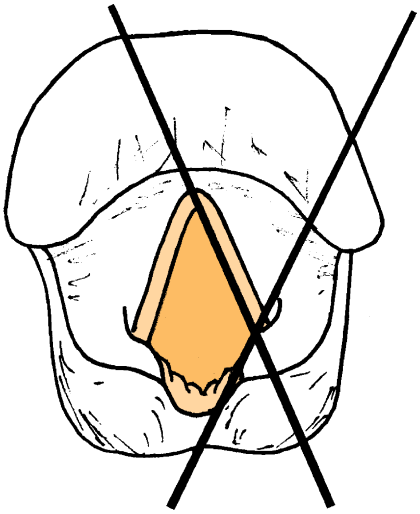

Figure 67-2. Vocal fold angle (*X*) formed by membranous and cartilaginous portions of the vocal fold.

A difference in the level of the vocal folds can often be appreciated with indirect mirror laryngoscopy, which permits binocular vision. In 1932, noting observations with mirror laryngoscopy, New and Childrey[28] stated, "In the absence of any innervation from the recurrent nerve fibers, the cord is somewhat relaxed or bowed; it is, therefore, shortened, somewhat narrowed and depressed, lying at a lower level than normal." In a two-dimensional video image, a level difference is not apparent. What can be perceived is a difference in the apparent length of the vocal folds. Brewer and colleagues[29] noted that a paralyzed vocal fold generally appears shorter than its mobile mate. In patients with significant glottal incompetence, the apparent length of a paralyzed vocal fold during inspiration is approximately two thirds that of the mobile side. During phonation, the mobile vocal fold appears to shorten to nearly the same length as its paralyzed mate (see Figure 67-3). Successful arytenoid adduction increases the apparent length of the paralyzed vocal fold.[30]

Three-dimensional motion analysis in cadaver larynges indicates that the arytenoid adduction procedure does not actually lengthen the vocal fold but instead moves the vocal process caudally. It is this vertical component of motion that is endoscopically perceived as a length change; the visual image shortens owing to rotation of the vocal fold out of the optical plane.[31] In arytenoid adduction, the arytenoid rotates about an oblique helical axis. As the vocal process moves medially, it is displaced caudally as well (Fig. 67-4).[32] Conversely, when the posterior cricoarytenoid muscle abducts the vocal fold, the vocal process moves laterally, rostrally, and caudally (Fig. 67-5).[23] An abducted vocal fold appears shorter when viewed from above because the vocal process has moved rostrally; the vocal fold slopes upward, out of the plane of the image. In adduction and during arytenoid adduction, the vocal process moves caudally, toward the level of the anterior commissure, so that the vocal fold is parallel to the image plane, and the apparent length is longer.[31]

The cricoarytenoid joint is a shallow ball-and-socket, and therefore, it is multiaxial. That is to say, vocal folds do not open and close along a fixed "track," and the rostrocaudal level of the vocal process is not completely dictated by internal and internal rotation. Cadaver studies of simulated muscle contraction demonstrate that the axis of rotation for the posterior cricoarytenoid is quite different from that for the lateral cricoarytenoid muscle (see Fig. 67-5).[23] This means that varying the force of individual muscles enables the rostrocaudal position of the vocal process to be varied independent of its mediolateral position. This is a likely mechanism of compensation by the active vocal fold in patients with laryngeal paralysis.

Because of the multiaxial nature of the cricothyroid joint, the vocal process of a paralyzed vocal fold is not necessarily located along the path of physiologic motion. In a normal larynx, the vocal process moves upward as the vocal fold is adducted. But in flaccid paralysis, the pull of the posterior cricoarytenoid muscle is lost, so that the arytenoid may "tip" forward (see Fig. 67-3A). The vector of the pull in the arytenoid

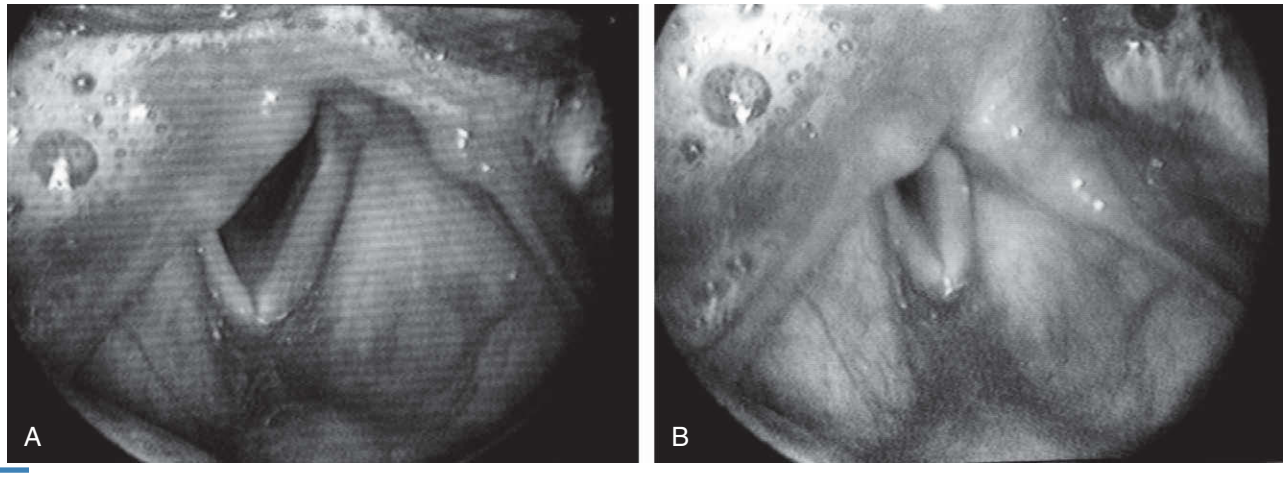

Figure 67-3. **A,** Apparent vocal fold shortening in laryngeal paralysis. **B,** Compensatory shortening of the mobile focal fold.

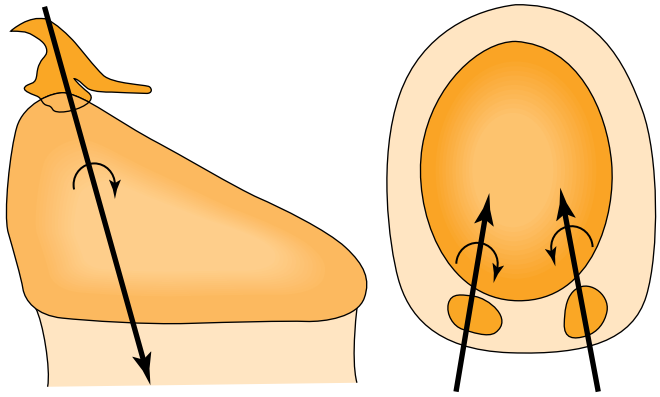

Figure 67-4. Axis of rotation (indicated by *arrows*) in arytenoid adduction, as determined in three-dimensional motion analysis in cadaver larynges.

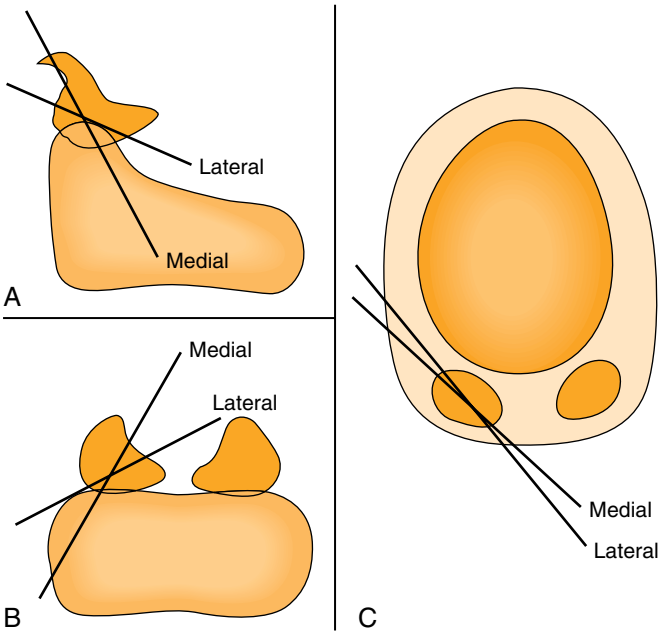

Figure 67-5. Axes of rotation (*X*) with simulated individual contraction of the two bellies of the posterior cricoarytenoid muscle in cadaver larynges. **A,** Sagittal view; **B,** posterior, coronal view; **C,** axial view. These data, as well as those from the study depicted in Figure 67-4, illustrate the multiaxial nature of the cricoarytenoid joint.

adduction procedure is similar to that of the cricoarytenoid muscle, anteriorly and slightly inferiorly. Thus, the procedure cannot correct, and may exacerbate, anterior tip. One approach to correcting the "sagging" arytenoid is a posterior suspension suture, which pulls posteriorly and inferiorly on the vocal process, to "rock" the arytenoid into a position that is nearer than that assumed during normal phonation (Fig. 67-6).[33] Another approach to the sagging arytenoid is adduction arytenoidopexy.[34] However, adduction arytenoidopexy fixes the arytenoid to the cricoid posteriorly and does not provide a medial vector of force at the vocal process. Thus, the vocal process can be pushed laterally by the adduction force of the normal vocal fold during phonation.

The membranous vocal fold is moved medially by arytenoid adduction. However, if the thyroarytenoid muscle is atrophic (which is frequently the case in cadaveric paralysis), there is still a glottal gap anterior to the vocal process. This gap can be addressed by concomitant or subsequent medialization by injection or type I thyroplasty.

Dysphagia can be a significant problem when laryngeal paralysis is the result of a vagus nerve injury. Pharyngeal propulsion is impaired

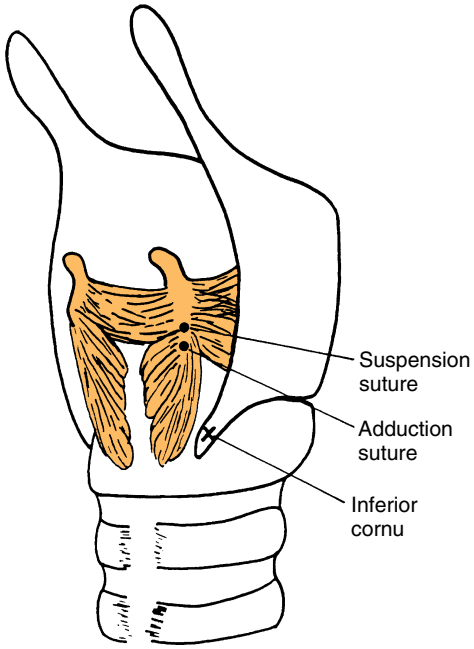

Figure 67-6. Posterior view of larynx demonstrating muscular process attachment of the arytenoid adduction suture and the suspension suture. The suspension suture is anchored to the inferior cornu of the thyroid cartilage.

owing to ipsilateral paralysis of constrictor muscles. But the cricopharyngeal muscle retains tone because it is a continuous muscular sling that receives bilateral innervation. There is inadequate pharyngeal pressure to push the bolus into the esophagus, resulting in stasis of secretions and ingested food in the hypopharynx. In such cases, a cricopharyngeal myotomy can be effective in improving swallowing and reducing aspiration.[21] Cricopharyngeal myotomy is easily performed in conjunction with the arytenoid adduction procedure.[35]

Arytenoid adduction is less effective in patients with long-standing laryngeal paralysis. This limitation does not appear to be due to joint fixation, because the arytenoid can be successfully internally rotated, with objective improvements in maximum phonation time and mean phonatory airflow. But the apparent length, and presumably the vertical position of the arytenoid, is not improved, so compensatory hyperfunction is still required for speech.[30] It is possible that contracture and fibrosis of soft tissues, such as muscle and mucosa, prevent correction of the vertical position of the vocal fold. The outcome of the arytenoid adduction procedure is also less favorable in patients with paralysis due to central neural lesions, such as tumor or stroke, because of associated sensory, reflex, and/or cognitive deficits.

Operative Technique

Anesthesia

Local anesthesia is preferred for arytenoid adduction in most patients so that the changes in voice can be monitored intraoperatively. The correct degree of arytenoid adduction can be ensured, and the potential need for a concomitant thyroplasty can be assessed, by transnasal flexible laryngoscopy. Moreover, glottic configuration can be adjusted without the confounding presence of an endotracheal tube. Finally, the risks of general anesthesia are avoided. Despite the fact that the larynx is rotated 90 degrees or more during the procedure, the airway is usually not appreciably compromised. Intraoperative swelling can compromise the airway and alter glottic closure, making intraoperative assessment less accurate. Therefore, preoperative steroids are recommended to minimize intraoperative swelling. Patients must be sufficiently alert during the procedure to cooperate. A patient who is overly sedated may actually become agitated during the procedure. Thus, sedation is recommended only during injection of local anesthesia. A field block

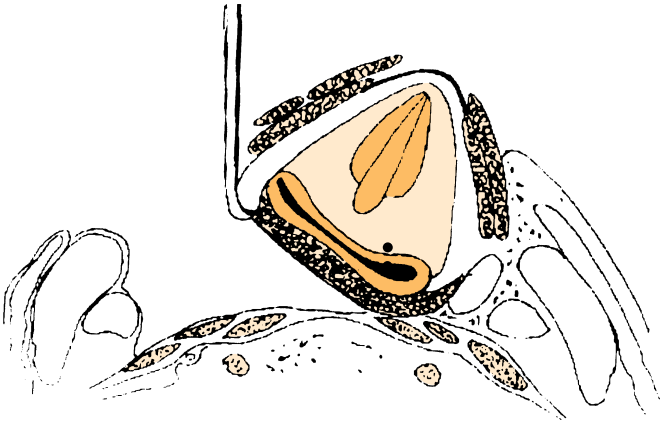

Figure 67-7. Surgical approach to the arytenoid, lateral to cervical strap muscles. The larynx is rotated to the opposite side, by means of traction on the superior cornu of the thyroid cartilage.

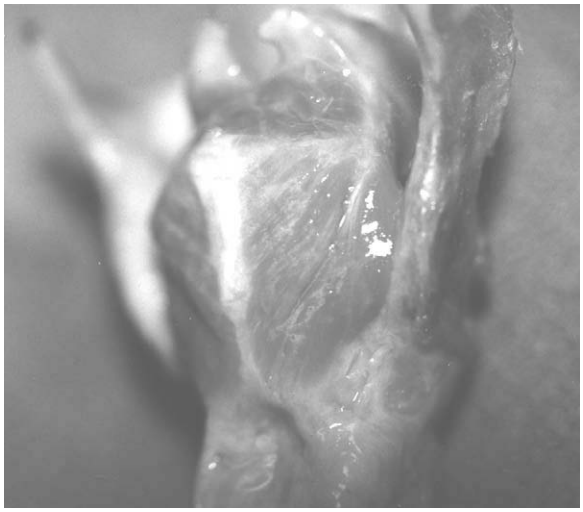

Figure 67-8. Muscular process of the arytenoid cartilage, located at the convergence of posterior cricoarytenoid muscle fibers.

provides adequate anesthesia at the outset; however, supplemental injections are required because the dissection proceeds posteriorly. An ipsilateral superior laryngeal nerve block minimizes coughing during intralaryngeal dissection.

General anesthesia can be used in uncooperative or very anxious patients or in those in whom dissection is anticipated to be difficult, such as very obese patients or those with extensive scarring in the operative field. General anesthesia is also a good option for patients with an existing tracheotomy. When the procedure is performed with the patient under general anesthesia and intratracheal intubation, direct laryngoscopy is used for intraoperative assessment. Obviously, this task is not precise when an endotracheal tube is present. Another approach is to use a laryngeal mask for the airway and flexible endoscopy to monitor the larynx.

Surgical Procedure

The larynx is approached through a horizontal skin incision at the lower border of the thyroid cartilage, extending from the ipsilateral sternocleidomastoid muscle to approximately 1 cm past midline. It is most efficient to create a thyroplasty window at the outset of the procedure. This provides a route for the arytenoid adduction suture to be passed later in the operation, and it also sets the stage for concomitant thyroplasty if it is necessary.

After the thyroplasty window is created, the next objective is to expose the muscular process of the arytenoid. Several approaches have been described. I prefer to dissect lateral to the cervical strap muscles, rotating the larynx away from the opposite side. This rotation displaces the larynx away from the carotid sheath, minimizing risk to those structures. Dissection should "hug" the strap muscles, continuing posteriorly to the inferior constrictor muscle and superiorly to identify the superior cornu of the thyroid cartilage. A sturdy cricoid hook should then be placed on the superior cornu of the thyroid cartilage to rotate the larynx away from the field (Fig. 67-7). Dissection should be continued inferiorly, medial to the thyroid gland, down to the level of the cricoid.

Next, the inferior constrictor muscle is transected over the posterior edge of the thyroid cartilage. Inferiorly, the cricopharyngeal muscle comes into view, and this muscle can then be resected if needed. The muscle can be defined by blunt dissection just behind its attachment to the cricoid, and then a 1- to 2-cm segment of muscle is excised.

A critical step in the procedure is identification and displacement of the pyriform sinus mucosa, to expose the arytenoid cartilage and to avoid entry into the hypopharynx. The pyriform sinus is separated from the medial surface of the thyroid ala by blunt dissection. Identification of the posterior and inferior limits of the pyriform sinus is facilitated by having the patient utter plosive phrases (such as "puppy") that generate gentle positive intrapharyngeal pressure. The pressure distends the pyriform sinus and makes its edges apparent. The sac is then reflected superiorly and anteriorly, exposing the posterior cricoarytenoid muscle. The fibers of this muscle are then followed to their convergence and insertion on the muscular process of the arytenoid. In a man with a large thyroid cartilage, adequate exposure may require transaction of the thyrohyoid ligament to permit greater laryngeal rotation. Alternatively, a posterior portion of the thyroid cartilage could be resected, as described by Netterville and colleagues.[36] Maragos[37] has reported performing arytenoid adduction via a posterior thyroplasty window.

In their original description, Isshiki and colleagues[1] recommended transection of the cricothyroid joint as well as opening of the cricoarytenoid joint to locate the muscular process. These steps potentially destabilized the larynx, and most later writers have not found it necessary to compromise these structures.[38]

The muscular process appears as a white prominence between the attachments of the anterior and posterior bellies of the posterior cricoarytenoid muscle (Fig. 67-8). This is where the adduction suture is placed—a 4-0 permanent suture with a sturdy but small-radius curved needle (I prefer a cardiac valve needle). The muscle tendon is grasped near its insertion, and the needle is passed from back to front through the cartilage process; care should be taken to not injure the pyriform mucosa. The surgeon should then tug the suture while palpating the arytenoid, to assess the "purchase." If the entire arytenoid does not move with traction on the suture, the stitch was passed through soft tissue rather than the cartilage. The suture is then used to provide traction, to stabilize the arytenoid, and to ensure placement in the cartilage. When a satisfactory suture has been placed, it should be tied down securely, leaving two long ends.

The next step is to create a paraglottic tunnel, deep to cartilage and lateral to muscle, extending from the site of the suture to the window that was previously created in the thyroid cartilage. One strand of the suture is then passed through this tunnel. At this point, the larynx should be observed endoscopically to detect arytenoid motion during alternating traction on the anterior and posterior ends of the adduction suture. If appropriate rotation of the arytenoid is not observed, the suture attachment is reassessed.

Once adequate rotation is ensured, the second, posterior end of the arytenoid adduction suture is passed forward through the tunnel, bringing it out under the thyroid cartilage rather than through the window. This allows the stitch to be secured by tying of the suture over the inferior thyroid strut, at the posterior inferior corner of the window (Fig. 67-9). Sutures in this position will not be affected by a thyroplasty implant.

Next, the patient is asked to phonate with the vocal fold adducted so that the need for thyroplasty can be assessed. The thyroplasty can be performed in many ways, as covered in another chapter in this book.

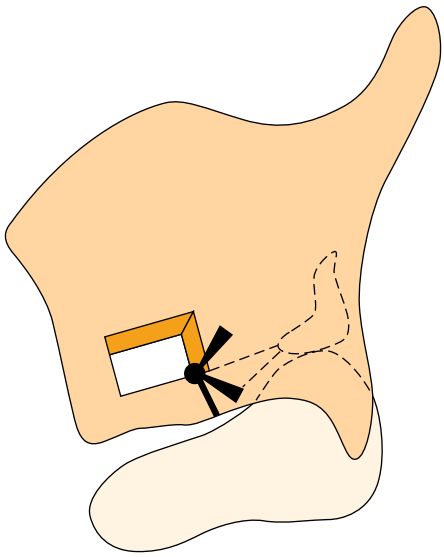

Figure 67-9. Position of arytenoid adduction suture in the posterior inferior corner of the thyroplasty window to allow simultaneous thyroplasty.

A rigid implant is preferred, rather than flexible ribbon, because the paraglottic space dissected to create a passage for the adduction sutures is much larger than needed to accommodate the medialization implant. If a rigid implant is used, the soft tissues will contract around it. However, if flexible ribbon is packed into the space, a larger volume will be required to medialize the vocal fold, and there may be excess or inappropriately positioned medialization.

If the arytenoid sags forward and the vocal fold is in a lower plane than the normal fold, a posterior suspension suture should be considered. The suspension suture is placed in the arytenoid cartilage a few millimeters superior to the muscular process of the arytenoid, on the ridge that extends from the muscular process to the apex of the cartilage (see Fig. 67-6). The suture is then passed through or around the inferior cornu of the thyroid cartilage, and is tied down to provide inferior traction. The larynx is observed endoscopically while tension is adjusted to rock the larynx posteriorly, without canceling out the adduction achieved by the arytenoid adduction suture.

Postoperative Care

In general, patients can resume oral intake within 1 to 2 hours after surgery. I keep patients overnight in the hospital after the procedure to observe for possible airway obstruction. Bleeding into the paraglottic space is the primary cause of postoperative airway obstruction. Thus, it is imperative to leave an adequate drain, to suppress coughing, and to control blood pressure. Maragos[39] has described postoperative airway obstruction due to herniation of pyriform mucosa into the airway. He reports that suture stabilization of pyriform mucosa at the close of the procedure is effective in preventing this complication.

Arytenoid Abduction for Bilateral Paralysis

A variation of arytenoid adduction is arytenoid abduction.[40] The procedure is identical to arytenoid adduction, except that the suture through the vocal process is anchored posteriorly rather than anteriorly. This vector of force rotates the larynx externally to abduct the vocal fold. Arytenoid abduction has been described as a surgical option to improve the glottic airway in patients with bilateral laryngeal paralysis. It can be performed in lieu of an emergency tracheotomy in patients with airway distress. Alternatively, it can be performed in patients with a tracheotomy to facilitate decannulation. In contrast to adduction, arytenoid abduction is performed with the patient under general anesthesia. For patients without an existing tracheotomy, an endotracheal tube provides a stable airway. When a tracheotomy is in place, dissection is more difficult, and the surgery is better tolerated with use of general anesthesia.

Arytenoid abduction, in contrast to other procedures to widen the glottis, has the potential to preserve phonatory adduction in patients who have primarily abductor paralysis with active adduction during phonation. This is a result of the three-dimensional nature of the cricoarytenoid joint. As mentioned previously in this chapter, the axes of rotation for thyroarytenoid and posterior cricoarytenoid muscle activities are different. Therefore, posterior traction on the muscular process moves the vocal fold laterally for an improved airway during inspiration, but does not abolish rotation about the axis for the thyroarytenoid muscle. Arytenoid abduction is less effective for patients who have significant synkinetic reinnervation, with reinnervation of the adductor muscles by nerve fibers that fire in inspiration and originally supplied the posterior cricoarytenoid muscle. In such a situation, the traction exerted by the abduction suture is counteracted by inappropriate inspiratory adduction.

Future Directions

Arytenoid adduction is an effective means of altering the position of the arytenoid. However, the ideal position of the arytenoid has yet to be determined. Moreover, there are currently no means of precisely measuring the spatial displacement accomplished by arytenoid adduction in vivo. It is likely that the "ideal" position varies, not only among patients, but also with variation in vocal pitch, amplitude, and quality. Advances in three-dimensional imaging will provide important information about laryngeal motion that will allow refinement of this procedure or development of better ways of restoring dynamic laryngeal function.

CHAPTER SIXTY-EIGHT

Laryngeal Reinnervation

George S. Goding, Jr.

Key Points

- Ideal rehabilitation of unilateral vocal fold paralysis would involve restoration of vocal fold movement, position, bulk, and tone.
- Complete recovery from unilateral paralysis can happen only through the spontaneous and appropriate regeneration of the recurrent laryngeal nerve.
- Reinnervation options for laryngeal paralysis include (1) the neuromuscular pedicle procedure, (2) ansa hypoglossi (cervicalis)–recurrent laryngeal nerve anastomosis, and (3) direct implantation of a nerve (ansa hypoglossi) into the denervated muscle.
- Laryngeal reinnervation as yet does not result in coordinated movement of the vocal fold and is used clinically for unilateral paralysis.

Complete recovery from laryngeal denervation may occur with spontaneous and appropriate regeneration of the recurrent laryngeal nerve (RLN). Surgical intervention cannot reliably provide appropriate vocal fold movement or the rapid and fine adjustments required for continuous vocal fold symmetry. Vocal cord medialization and augmentation allow for improved positioning of the paralyzed vocal fold. The RLN, however, supplies both adductor and abductor laryngeal muscles. Reinnervation procedures designed to generate muscle movement must bypass the main trunk of the nerve and address individual muscles directly or at the most distal branches of the RLN. Reinnervation at the level of the RLN trunk can provide improvement in laryngeal muscle tone and mass.

In 1909, Horsley[1] reported the first successful vocal cord reinnervation. He performed a neurorrhaphy of the RLN in a patient who had been shot in the neck, who had nearly complete recovery of laryngeal function. A number of writers have independently reported recurrent nerve repairs with return of function.[2-4]

In most cases vocal fold motion does not return after RLN anastomosis. Instead, a laryngeal synkinesis occurs with adductor and abductor nerve fibers nonselectively innervating the laryngeal muscles.[5-8] The result of this neuromuscular mismatching is that counteracting forces are applied to the arytenoid by all the muscles innervated by the RLN and little or no functional movement occurs.[9] An inspiratory medial bulging is seen that is thought to arise by the inappropriate activation of the thyroarytenoid muscle by abductor axons. The majority of RLN repairs, however, are incapable of producing abduction and adduction in functional coordination with the respiratory cycle.

The activity of the phrenic nerve during inspiration makes it an excellent candidate for reinnervation of the posterior cricoarytenoid (PCA) muscle. A similar muscle fiber–type profile between the diaphragm and the PCA also exists.[10] Abductor mobility of the vocal fold had been obtained in multiple animal models.[11-15] Experimental reinnervation with the phrenic nerve after a 9-month delay is successful but the functional recovery is reduced.[16] Attempts at creating vocal fold motion with phrenic nerve reinnervation in humans, however, were unsuccessful.[17]

Because of the inability to consistently obtain cyclical motion of the vocal cords in coordination with respiration, reinnervation at the level of the nerve trunk has not gained acceptance as a clinical modality for bilateral vocal cord paralysis.[18] Selective innervation of individual laryngeal muscles (in particular the PCA muscle) by neuromuscular transfer technique,[19] selective anastomosis,[20,21] or direct nerve implantation[22,23] is required.

Although desirable, cyclical vocal cord motion is not mandatory for the successful rehabilitation of unilateral vocal cord paralysis. This fact has led to the successful use of vocal cord medialization techniques to improve the primary functions of the larynx (closure, respiration, and phonation). The vocal cord medialization techniques currently in use include thyroplasty, arytenoid adduction, and vocal fold injection. Laryngeal reinnervation at the level of the RLN can also take advantage of the resultant synkinesis to provide vocal fold position, bulk, and tone.

The two most common reinnervation techniques that have been applied to the problem of laryngeal paralysis in patients are the neuromuscular pedicle (NMP) and the ansa cervicalis–recurrent laryngeal nerve (ansa-RLN) anastomosis. The two techniques take advantage of the same donor nerve (ansa cervicalis), but otherwise they differ.

The NMP procedure, developed in the 1970s, involves placement of the distal portion of the ansa cervicalis branch to the omohyoid muscle along with a small block of muscle into a denervated laryngeal muscle. The procedure is indicated in patients with either unilateral or bilateral vocal fold paralysis, with different muscles being treated in each case. Depending on the success of reinnervation and the nature of the stimulus, there is a potential for recovery of vocal fold motion. In patients with unilateral vocal fold paralysis, the technique can be combined with a thyroplasty.[24]

The ansa-RLN anastomosis as an attempt to restore vocal fold movement was first reported by Frazier[25] in 1924 and Frazier and Mosser[26] in 1926. The current use of the technique was reported in 1986.[27] An end-to-end anastomosis of the proximal ansa cervicalis nerve to the distal stump of the RLN is performed. The procedure is indicated for unilateral paralysis because vocal fold motion is not restored. Instead, muscle tone is restored to the entire hemilarynx,

providing appropriate vocal fold position, bulk, and tone. The result is the potential for a near normal vocal ability.

Physiologic and Anatomic Issues in Laryngeal Reinnervation

There is substantial evidence that reinnervated muscle takes on the characteristics of the donor nerve (see Talmadge[28] for review). This process appears to happen as the reinnervating nerve imposes a pattern of activity on the muscle fibers it contacts. Thus the selection of a donor nerve should ideally take into account the fiber type and contraction characteristics of the muscle to be reinnervated.

Nerve Characteristics

The RLN contains 1000 to 4000 motor axons, efferent axons, and sympathetic and parasympathetic secretomotor fibers, depending on the level at which the count is made. The RLN gives off branches to the cricopharyngeus and upper esophageal muscles[29] as well as a sensory branch that communicates with the superior laryngeal nerve prior to entering the larynx. Five hundred to a thousand fibers are in the motor branches of the RLN.[30] Before branching within the laryngeal framework, the motor fibers to the various muscles are intermixed throughout the RLN nerve trunk, making selective reinnervation at this level impractical.[31] The anterior motor branch of the RLN enters the larynx posterior to the cricothyroid joint. The first branches that emerge from the RLN innervate the PCA muscle and often have connections to the midline interarytenoid muscle. The branch to the PCA muscle has characteristics of a slow-twitch motor nerve, with axons containing 200 to 250 muscle fibers in each motor unit.[32] The interarytenoid muscle also receives a separate branch from each RLN, resulting in bilateral innervation. The terminal branches of the RLN innervate the lateral cricoarytenoid (LCA) and thyroarytenoid (TA) muscles. The axons in this branch are more characteristic of fast-twitch fibers, with motor unit sizes of 2 to 20 muscle fibers.[33] In some larynges a connection between the superior laryngeal and the terminal fibers of the RLN can be seen within the TA.[34]

Except for proprioceptive fibers carried within the nerve, the ansa cervicalis is a purely motor derivative of the ventral rami of the cervical plexus. Fibers from the first cervical nerve join the hypoglossal nerve until it curves anteroinferiorly. At this point the first cervical nerve fibers leave the hypoglossal nerve to form the superior root of the ansa cervicalis. The geniohyoid and thyrohyoid are supplied entirely by these fibers. The branch to the superior belly of the omohyoid muscle typically originates from the superior loop of the ansa cervicalis. Because of its proximity to the thyroid ala and infrahyoid position, this branch has been frequently used as a donor for reinnervation using the NMP technique. The other strap muscles receive motor fibers from second and third cervical nerves primarily via the inferior root of the ansa cervicalis. The lower portions of the sternothyroid and sternohyoid muscles receive terminal nerves that branch off the loop of the ansa cervicalis as it passes deep to the omohyoid muscle.[35]

Muscle Fibers in General

The performance of a particular muscle depends on the character of the individual muscle fibers it contains. On the basis of their histochemical and contraction properties, the fibers of skeletal muscle can be classified as slow fatigue-resistant (type 1), fast fatigue-resistant (type 2A), or fast fatigable (type 2B). Several other classifications and subtypes exist (see Staron[36] for review). Type 1 fibers are characterized by a low peak tension, slow contraction time, a low threshold of recruitment, fatigue resistance, and a dependence on aerobic metabolism. Muscles that are required to produce low tension over a prolonged period generally have a high proportion of type 1 fibers. Type 2 fibers are found to play a prominent role in muscles that can generate high tension for short periods. Type 2B fibers have a fast contraction time and can generate a higher tension. They are more easily fatigued, have a higher threshold of activation, and depend on anaerobic metabolism. Type 2A fibers are intermediate in tension, fatigability, and threshold, and they make use of both aerobic and anaerobic metabolism. The laryngeal muscles also have a high-velocity, low-tension fiber types (2L or mixed fiber type) that may be similar to those found in extraocular and jaw-closing muscles.[37-40]

Most mammalian skeletal muscles are made up of multiple fiber types. Because of these combinations the various whole muscles have a variety of contraction and relaxation characteristics. The peak contraction time of the extraocular muscles is the fastest and that of the soleus muscle is the slowest.

Laryngeal Muscles

Activity of the PCA muscle is synchronous with inspiration and precedes activation of the diaphragm by 40 to 100 msec.[41] The amount of activity varies directly with ventilatory resistance. Activity of the PCA produces lateral turning of the arytenoid, resulting in abduction of the vocal fold. Loss of PCA muscle tone results in instability of the arytenoid cartilage. On the basis of gross anatomy[42] and innervations,[43] the PCA muscle in humans can be divided into a horizontal compartment and a vertical/oblique compartment.[43] Some researchers have reported that the PCA in laryngectomy specimens consists of nearly equal percentages of type 1 and type 2 fibers.[44] A similar ratio is seen in the primate PCA.[45] Other writers have found the PCA to have a higher percentage of type 1 fibers.[10] The remainder of the muscle fibers appears to be mostly of the intermediate (type 2A) variety. These findings are consistent with the peak contraction time of the PCA, which is approximately 40 msec.

Reinnervation occurs most easily at the sites of the original motor end plates. It is possible that placement of a reinnervating NMP near a large population of motor end plates could improve the end result.[46] The motor end plates of the human PCA muscle are distributed in a loosely arranged arc in the midportion of the muscle. The density of end plates is higher in the deeper portions of the PCA.

TA activity increases with phonation and reflex protection of the airway. Contraction of the TA is critical to the fine control of the mass and tension of the phonating edge of the vocal fold. Atrophy of the TA muscle results in a reduced vocal cord volume and glottic incompetence. Paralysis of the LCA and interarytenoid muscles severely compromises the ability to adduct and stabilize the vocal process of the arytenoid. Bilateral innervation of the interarytenoid muscle is not sufficient to compensate for this loss.

The TA and LCA are faster muscles. Their peak contraction times of 14 msec (TA) and 19 msec (LCA) make them some of the more rapid muscles in the body.[45,47] The composition of muscle fibers in the TA is approximately 40% type 1, 55% type 2A, and 5% type 2B. The higher frequency of oxidative fibers characterizes the muscle as having aerobic metabolism, resistance to fatigue, and fast contraction.[48] The faster response characteristics of these muscles are appropriate for their phonatory and protective functions.

The pattern of motor end plate distribution in the TA and cricothyroid (CT) muscles is more diffuse than that in the PCA. In the CT muscle the majority of the motor end plates are in the medial two thirds of the muscle[49] while in the TA the end plates are scattered throughout the muscle.[50] Placement of a NMP, or a direct nerve implant in precise locations, therefore, may offer a limited advantage in reinnervating the PCA and CT muscles. These diffuse patterns differ from skeletal muscles elsewhere in the body where they form a narrow band at the midpoint of the muscle.[49]

Both adductor and abductor laryngeal muscles contribute to the position and stability of the arytenoid cartilage.[51] Restoration of adductor and abductor muscle tone should allow appropriate arytenoid position and stability.

The CT muscle participates in deep inspiration, expiration and phonation. The CT is innervated by the superior laryngeal nerve and is not addressed by ansa-RLN reinnervation. Cricothyroid contraction pulls the vocal process in an anterior and slightly medial direction. This anterior pull is offset by the stabilizing effect of PCA and LCA contraction.

Infrahyoid Muscles

The ansa cervicalis provides motor supply to the infrahyoid muscles and is the most commonly used donor nerve in laryngeal reinnervation. The peak contraction times of the thyrohyoid and sternothyroid

muscles are approximately 50 msec.[52] Approximately two thirds of the muscle fibers are type 1.[53] The infrahyoid muscles have enzyme profiles similar to those of limb muscles and lack the faster mixed fibers found in the laryngeal muscles.[54]

In the hope of obtaining vocal fold movement, the activity of the various infrahyoid muscles has been examined. The strap muscles extending below the larynx function as accessory muscles of inspiration in varying degrees. The sternohyoid muscle has consistently shown little to no consistent activity with respiration. In the canine, a regular contraction of the sternothyroid muscle is seen with quiet respiration, but all strap muscles lack phasic activity in the primate. With greater airway resistance and hypoxia, inspiratory activity in the primate is greatest in the omohyoid, followed by the sternothyroid muscle .[55] The sternothyroid in labored respiration can result in vocal cord lateralization even if the larynx is paralyzed, by means of the sternothyroid muscle's effect on the laryngeal skeleton.[56]

The thyrohyoid muscle can similarly assist in adduction of the vocal cords. Medial positioning of the vocal folds is assisted by this muscle's action of displacing the thyroid cartilage upward. On the basis of activity relative to the respiratory cycle, the nerve supply to the sternothyroid and omohyoid muscles would be acceptable candidates for use in reinnervation for laryngeal abduction. The thyrohyoid muscle's activity makes its branch of the ansa cervicalis nerve an appropriate choice for laryngeal adduction. Because specific laryngeal muscles are not reinnervated in isolation with the ansa-RLN anastomosis, the activation patterns of the infrahyoid muscles become less meaningful with this technique. Denervation of an infrahyoid muscle does occur and may result in a change in vocal quality immediately after surgery. Sacrifice of the sternothyroid muscle can result in a decrease of lateral pull on the thyroid ala and a medialization effect. The opposite effect can occur with sacrifice of the thyrohyoid muscle.

The infrahyoid muscles are a less than perfect histochemical match to the recipient laryngeal muscles. After reinnervation for unilateral vocal fold paralysis with the ansa cervicalis, changes in the fiber type composition of the laryngeal muscles would be expected.

Effects of Denervation

With denervation, the area of sensitivity to acetylcholine, which is limited to the end plate region in the intact muscle, spreads out over most of the external membrane.[57] Denervation also eliminates both the trophic and activity-related influences on the muscle, resulting in muscle atrophy. Without reinnervation there is progressive atrophy and eventual destruction of the muscle despite an adequate supply of all nutrients.

Reinnervation becomes less effective the longer a muscle is denervated. The different laryngeal muscles appear to atrophy at different rates that vary with the muscles' fiber composition. In a study on primate larynges, the faster TA muscle showed a far greater reduction in fiber size than the slower CT or PCA muscle. By 8 weeks of denervation, however, all laryngeal muscles were fibrosed.[58] Muscle atrophy in human skeletal muscles apparently proceeds at a slower pace, with muscles surviving at least 3 years after denervation. Successful laryngeal reinnervation has been claimed as much as 50 years after onset of laryngeal paralysis.[59] It is possible that some nerve sprouting occurs, resulting in a low-grade but functionless innervation that preserves the muscle's ability to be reinnervated.[60] Innervation of laryngeal muscles can also come from misdirected reinnervation from autonomic nerves.[61]

Restoration of Function

Successful regeneration of injured nerves requires (1) a neuron responding to the injury with the metabolic changes necessary to support axonal regrowth, (2) an environment around the injured axon that permits axon growth, and (3) guidance clues for restoration of function.

Regeneration is pointless unless the regenerating axons grow back to reinnervate the original targets. Motor axons preferentially reinnervate distal motor branches of a severed nerve. The specificity is gained primarily through pruning of misdirected fibers.[62] Some evidence for a neurotrophic mechanism of directional nerve regrowth exists,[63] but the usual outcome of nerve injury suggests the specificity is low. A major problem is that after division of a nerve, a functional specificity in motoneuron regeneration for the original muscle does not exist.[64-66] The result, in a regenerating nerve supplying several muscles such as the RLN, is synkinesis.

Muscle fiber types can change under the influence of activation pattern[67] and altered innervation.[68] The changes following reinnervation with a different donor nerve may be related to a different pattern of activity imposed by the new nerve supply. Fiber type grouping is thought to be a result of this process.[69] Mechanisms for directing the regenerating motor axons within a single muscle leading slow- and fast-twitch axons to the appropriate muscle fibers have some influence on reinnervation.[70] The effect, however, is not enough to prevent changes in muscle fiber type. Reinnervation with a new donor nerve would be expected to change the fiber type composition of the reinnervated muscle and thus its contraction characteristics.

The Neuromuscular Pedicle

The NMP technique attempts to transfer a nerve with a portion of its motor units intact to a denervated muscle. Preservation of motor units is brought about by the inclusion of a small block of muscle at the distal end of the donor nerve. This inclusion distinguishes the technique from nerve anastomosis, implantation of a nerve stump, and direct electrical stimulation of muscle fibers.

Reinnervation with the Neuromuscular Pedicle

Successful reinnervation with an NMP depends partly on the ability of the transplanted axons to reach receptive sites on the recipient muscle fibers and partly on the ability of the muscle fibers to accept innervation from foreign nerves. With partial denervation of the transferred nerve, the remaining intact motor neurons develop sprouts that provide reinnervation preferentially at the original end plate sites of the denervated muscle fibers.[71,72] This phenomenon is important to successful transfer of the NMP, because a portion of the nerve fibers in an NMP may have an intact motor unit.[73] Axon sprouting results in a larger number of motor fibers innervated by each nerve. Mature nerve terminals appear to be limited in functional expansion to three to five times the normal terminal field.[74]

Laboratory Investigations

In early experiments a block of muscle containing the terminal branches of the recurrent laryngeal nerve was removed and reimplanted into the larynx.[73,75] A small portion of muscle was incorporated at the distal end of the transferred nerve to transfer intact nerve fibers. The short time to functional recovery (2 to 6 weeks) was thought to be secondary to the avoidance of degeneration and regeneration before effective reinnervation.

In 1973, reinnervation of the canine larynx with an NMP derived from the ansa cervicalis nerve and its insertion into the sternohyoid muscle was described.[76] The technique was modified because of the unavailability of the RLN in most cases of laryngeal paralysis and the unsuitability of preserving a portion of the larynx in the presence of cancer.[77] Return of function was seen at approximately 6 weeks after surgery. Reinnervation could be successful up to 6 months after denervation.[78]

Evidence for reinnervation with the NMP has included muscle response to pedicle stimulation, demonstration of neural tracer in the central motor nuclei of the donor nerve,[79] and glycogen depletion in fiber of reinnervated muscles.[80] Successful use of the NMP technique in animal models has been reported by multiple researchers.[19,81-85] In their studies, electrical stimulation of the transferred nerve or induction of greater respiratory effort was required to produce gross motion.

In other studies, the presence of vocal fold movement under hypercarbic conditions was not associated with evidence of reinnervation by either direct stimulation[86-88] or histologic evaluation.[88] Other maneuvers, such as division of the inferior pharyngeal constrictor[86] or of the superior laryngeal nerve or the strap muscles,[87] were effective in eliminating the observed vocal fold motion. Postoperative scarring, which could stabilize the arytenoid and lateral tethering of the arytenoid to the thyroid cartilage, is a potential explanation for vocal fold motion not related to reinnervation.[89]

A modification of the NMP technique involves using a transferred NMP as a means of providing access to a denervated muscle for long-term electrical stimulation.[90-92] A cuffed electrode can be placed around the nerve component of an implanted NMP. This should avoid deterioration at the electrode-muscle interface. Successful pacing was accomplished for the sternothyroid[90] and PCA[91] muscles with the use of tracheal motion with respiration as the triggering signal.

Indications

Bilateral Paralysis

The NMP technique can be considered for any patient with bilateral vocal cord paralysis that has persisted for 6 months[59] to a year.[93] In practice, however, only half of such patients are suitable candidates.[94] Fixation or limitation of the cricoarytenoid joint is the most common contraindication, affecting approximately one third of patients.[93] Direct laryngoscopy and palpation of the arytenoids prior to proceeding with the NMP procedure is recommended.

The ansa cervicalis nerve and its insertion into the appropriate strap muscle must be available for this technique. Any prior surgery or trauma that may have injured the ansa cervicalis should be carefully reviewed. Other causes of airway obstruction should be resolved before reinnervation.[93]

Central nervous system disease resulting in vocal cord paralysis is a relative contraindication. Tucker[93] has reported only a 40% to 50% success rate in patients with such diseases, which may also disrupt the function of the ansa cervicalis nerve.

Finally, the laryngeal muscles must be able to accept reinnervation. Although successful reinnervation has been reported after 22 and 50 years of denervation, muscle atrophy probably plays a role in hampering the outcome. The incidence of cricoarytenoid fixation may increase with time[95] but this finding has not been confirmed hstologically.[96]

Unilateral Paralysis

Consideration of reinnervation is usually delayed in patients with unilateral paralysis until enough time has passed to make spontaneous recovery unlikely. In patients who have difficulty with aspiration, vocal fold injection has been recommended. Prior injection of polytetrafluoroethylene (Teflon) into the vocal cord, however, has had a poor vocal result.[97] The procedure has also been limited to patients who require above-average vocal quality.

Like patients with bilateral vocal cord paralysis who are being considered for an NMP procedure, the patient with unilateral paralysis must be able to tolerate the procedure, and the ansa cervicalis nerve must be intact, the selected adductor muscle must be in suitable condition for reinnervation, and there must be a mobile arytenoid muscle on the paralyzed side. Inability to visualize the larynx by normal endoscopic methods, which precludes transoral injection, is an additional indication for NMP reinnervation.[97]

Technique

The description of the NMP procedure below is that first described by Tucker[59]with modifications by other writers as noted (Fig. 68-1).[77,93,95,98]

In Bilateral Paralysis

When performed in a patient with bilateral paralysis, the procedure begins with laryngoscopy and palpation of the arytenoids with the patient under general anesthesia and muscular paralysis but with no endotracheal tube. Once it is determined the arytenoids are freely mobile, the patient is intubated, and a tracheotomy is performed if one is not already present.

A horizontal incision is made near the lower border of the thyroid cartilage. The anterior border of the sternocleidomastoid muscle is exposed and retracted laterally. Dissection of the anterior belly of the omohyoid muscle and the fascia overlying the internal jugular vein is completed. The branch of the ansa cervicalis supplying the anterior belly of the omohyoid muscle can be identified in either of the following two ways: (1) by finding the main trunk of the ansa cervicalis as it crosses the internal jugular vein and tracing it proximally and distally until the appropriate branch is recognized or (2) by mobilizing the medial border of the omohyoid near its attachment to the hyoid and dissecting in a medial to lateral direction along the muscle. The nerve is usually accompanied by a small arterial vessel, which is preserved. If the nerve is injured, the branch to the sternothyroid is also acceptable.[89,99]

After the point of entry into the muscle is determined, dissection of the nerve is continued distally until its terminal branches are identified. This may require an additional 2 to 3 mm of dissection from the entrance of the nerve into the muscle. A block of muscle large enough to include the terminal branches (usually 2-3 mm on a side) is dissected free with the attached nerve. The muscle block is kept as small as possible because it will act as a free graft. The proximal portion of the omohyoid branch of the ansa cervicalis is mobilized, with care taken to preserve the accompanying vessel.

The lateral margin of the thyroid cartilage is identified and is used to rotate the larynx toward the opposite side. With the dissection kept close to the lateral edge of the thyroid ala, the fibers of the inferior constrictor are bluntly separated. Dissection is continued until either the pyriform sinus is encountered or the PCA muscle is seen. The mucosa of the pyriform sinus is bluntly displaced superiorly if necessary. The PCA muscle can be recognized from its fibers, which pass at right angles to those of the inferior constrictor.

The NMP is then sutured to the PCA with two or three sutures of 5-0 nylon. Abrasion of the surface of the PCA is not necessary for reinnervation to occur. Closure of the fibers of the inferior constrictor muscle is not necessary. A drain is placed, and the wound is closed in layers. Postoperative antibiotics are not routinely used.

Unilateral Paralysis

The direct laryngoscopy and harvesting of the NMP are the same for unilateral vocal cord paralysis as for bilateral paralysis. No tracheotomy is performed. The recipient muscle in unilateral paralysis is the LCA, and the second portion of the operation varies accordingly.

The thyroid cartilage on the denervated side is exposed, and the lower half of the perichondrium of the thyroid cartilage is incised in the midline. A posteriorly based perichondrial flap exposing the lower half of the thyroid ala is created. A block of thyroid cartilage is removed from this area, leaving the underlying perichondrium and the inferior margin of the thyroid cartilage intact. The inner perichondrium is incised to expose the denervated LCA muscle, and the NMP is sutured in place with two or three sutures of 5-0 nylon. The outer perichondrial flap may be sutured back in place, and the wound is closed in layers with a drain. One modification consists of placement of two pedicles (each from a separate strap muscle) into the recipient muscle.[100]

Intravenous dexamethasone has been given to reduce laryngeal edema in the early recovery period after NMP in unilateral vocal paralysis.[99] Voice rest and postoperative antibiotics are not necessary.

Reported Results

In 1976, Tucker[77] reported using the NMP in humans for bilateral vocal fold paralysis. All five patients he studied demonstrated vocal cord abduction with inspiration within 6 to 8 weeks after the procedure. In two patients with a marked improvement in exercise tolerance, vocal cord motion was not seen without an increased respiratory effort. In 1978, Tucker[59] reviewed 45 cases of NMP laryngeal reinnervation for bilateral vocal cord paralysis, reporting an 88.8% (40/45) success rate. Duration of follow-up ranged from 3 months to 4 years, and duration of paralysis ranged from 6 months to 50 years. The time to return of function varied from 6 to 12 weeks.

In 1982, Tucker[93] divided results of NMP reinnervation for bilateral vocal cord paralysis into three categories. In approximately 40% of his cases, airway improvement was accompanied by visible motion of the vocal cord with inspiratory effort; 20% of patients had no airway improvement. The remaining patients had airway improvement but little vocal cord motion. Most of the patients in this last group demonstrated vocal cord motion or tonic abduction only with increased respiratory demand. A second NMP procedure to the opposite PCA muscle has been performed successfully in patients in whom the first procedure had an inadequate result.[93]

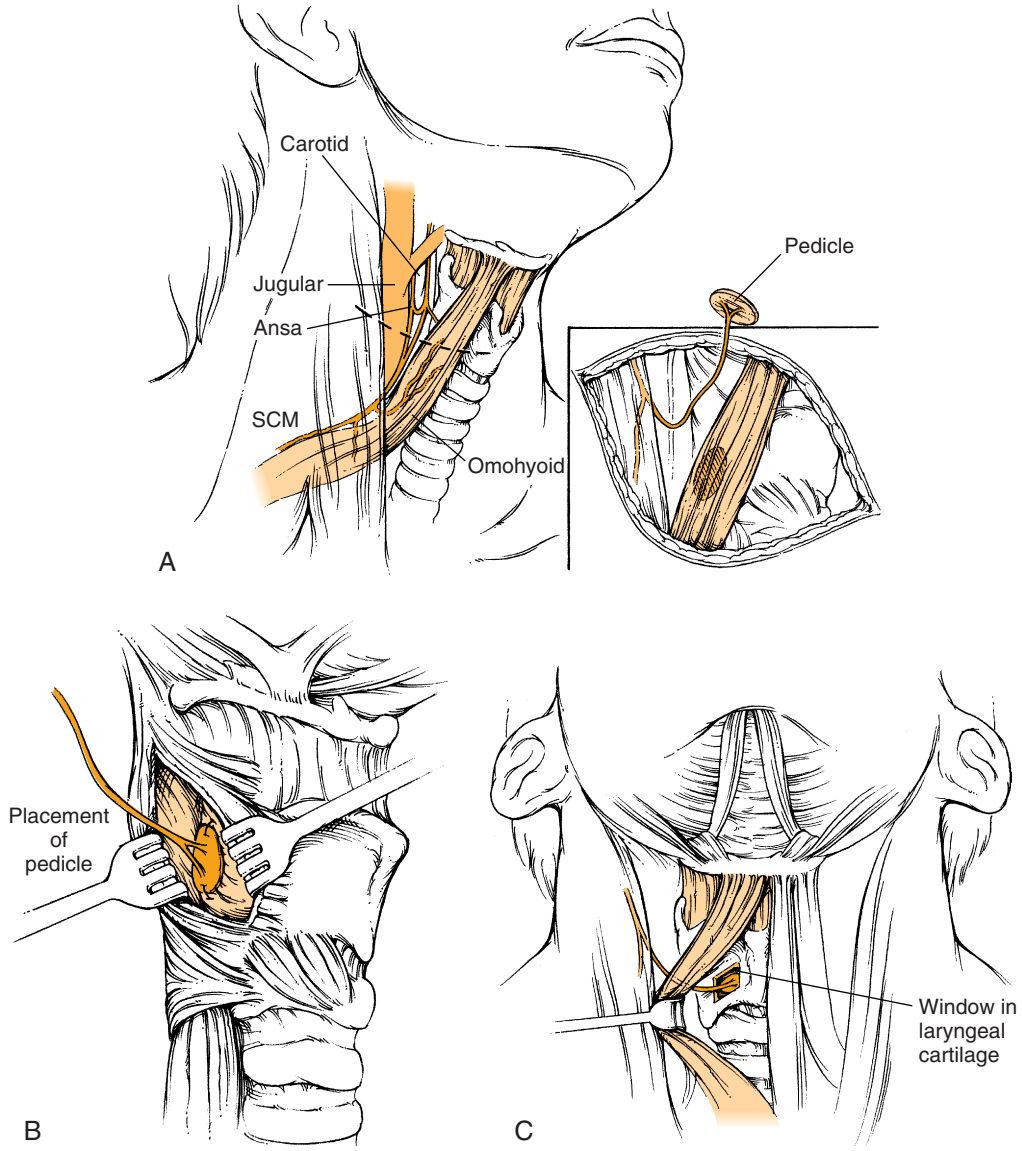

Figure 68-1. Neuromuscular pedicle (NMP). **A,** NMP harvested from omohyoid muscle. The branch of the ansa cervicalis nerve to the omohyoid is removed with a 2- to 3-mm attached block of muscle. SCM, sternocleidomastoid muscle. **B,** NMP placed into the posterior cricoarytenoid muscle after rotation of the larynx and separation of the fibers of the inferior constrictor for the treatment of bilateral paralysis. **C,** NMP placed into the lateral cricoarytenoid muscle via a window in the thyroid ala for the treatment of unilateral paralysis.

A review of 214 patients with bilateral vocal cord paralysis demonstrated a 74% long-term success rate.[94] In 48% of patients, tracheotomy was performed at the time of reinnervation. Success was defined as decannulation with improved airway that did not limit regular daily activities or exacerbate acute upper respiratory disease. Minimum follow-up was 2 years. Six-month results showed an 89% success rate, but 31 patients had subsequent deterioration of the airway. In a majority of patients with late failure who were evaluated, fixation of the cricoarytenoid joint was identified.

In 1977, Tucker reported the use of the NMP procedure in 9 patients with unilateral vocal cord paralysis.[98] Recovery of adductive function was seen 2 to 12 weeks after surgery in all of the patients. Only 6 patients had a satisfactory improvement in vocal quality, and a subsequent polytetrafluoroethylene injection was required in the other 3. In a subsequent report on the use of the NMP in unilateral vocal cord paralysis, improvement was found in 25 of 27 patients undergoing a NMP procedure to the LCA.[99]

In a 1989 study, NMP procedures for unilateral paralysis were reported to have a success rate of 88%.[94] Success was established by voice improvement, vocal cord adduction, and change in cord tension with elevated pitch. Voice results were noted to improve for several months and were aided by the addition of speech therapy.

May and colleagues[101] reported their results with the NMP procedure in 1980. Of 8 patients undergoing NMP reinnervation of the PCA for airway obstruction only 3 experienced improvement; 13 of 15 patients with disordered phonation and/or deglutition were improved by NMP reinnervation of the LCA. Applebaum and associates[100] reported successful results in all 6 of their patients undergoing the NMP technique. Four of the patients had bilateral vocal cord paralysis, with 1 requiring a tracheostomy. Dyspnea and stridor were relieved in all 4 patients, in whom vocal cord movement was seen only after physical exertion.

For isolated unilateral recurrent laryngeal paralysis, May and Beery[97] reported improvement in the voice in 19 of 20 (95%) patients treated with NMP implantation into the LCA muscle. Observable movement of the reinnervated cord was seen in only 1 patient, suggesting that enhanced muscle tone or a slight change in position was responsible for voice improvement. The degree of voice improvement was substantially less in patients with multiple cranial nerve deficits or vocal cord fixation.

Complications

The main complication of the NMP technique is failure to obtain a satisfactory result. Many of the patient selection factors listed previously as contraindications are a result of these experiences. Relatively few operative complications associated with the NMP procedure are described. In 214 patients undergoing an NMP procedure for bilateral vocal cord paralysis, Tucker[99] noted only four complications. Three were wound infections, and the fourth was related to the previously placed tracheotomy. No complications were reported in 73 patients undergoing NMP for unilateral paralysis. No operative complications were reported in other series.[97,100]

Future of the Neuromuscular Pedicle Procedure

Despite its successful use in a few writers' experiences, widespread use of the NMP has not materialized. Reinnervation can occur with implantation of an NMP into denervated muscle, but the ansa cervicalis continues to be an imperfect source for neural input. Even in the absence of movement with respiration, the NMP can maintain muscular tone.

The NMP can provide a mechanism to access a denervated muscle for long-term pacing.[90,91] With electrical pacing, the options for a potential triggering source and the stimulus for muscle contraction are increased, providing a potentially more effective treatment of airway impairment secondary to bilateral vocal fold paralysis.

Ansa Cervicalis–Recurrent Laryngeal Nerve Anastomosis

The current use of the ansa-RLN anastomosis is in unilateral vocal fold paralysis. No motion of the reinnervated vocal fold with respiration or phonation is expected. A variation of this technique involves a hypoglossal nerve–RLN anastomosis.[102,103] Use of the ansa cervicalis as a donor nerve has gained the widest acceptance because of the lower morbidity associated with the sacrifice of this nerve.

Advantages

The procedure is relatively easy to perform in an unoperated neck for any surgeon familiar with head and neck anatomy. The primary difficulty is associated with identifying the appropriate nerves when excessive scar is present. There is typically no "learning curve" with respect to the ultimate vocal result, because fine adjustments of vocal fold position are not required. In contrast, the ultimate vocal result for vocal cord injection and thyroplasty is determined at the time of surgery and depends on the expertise of the surgeon.

The ansa-RLN procedure provides tone, position, and bulk to the denervated muscles, resulting in less asymmetry between the normal and reinnervated vocal cords. This result offers the opportunity for an outstanding rehabilitation of unilateral vocal cord paralysis. Improvement in vocal quality can also continue to occur after the initial improvement seen during the first year after surgery.

The sacrifice of the sternothyroid muscle is clinically insignificant and may theoretically improve vocal function. The resting tone of the sternothyroid muscle slightly lateralizes the normal vocal cord.[56] Loss of this tone may result in a slight medialization of the paralyzed vocal cord and an improvement in vocal quality early after surgery.[60]

The procedure is primarily extralaryngeal and can be reversed by division of the anastomosis at a later time. Because the thyroid ala and intrinsic muscles of the larynx are not violated, the subsequent use of vocal fold injection or thyroplasty is not limited. The impact of the delay prior to reinnervation can be reduced when the procedure is combined with injection of absorbable material into the vocal fold at the time of surgery. No permanent implant material is used, so the potential for implant migration or foreign body reaction at the level of the vocal cord is eliminated.

Disadvantage

The ansa-RLN transfer procedure requires a deeper level of dissection in the neck and typically takes longer to perform than thyroplasty or vocal fold injection. The time for completion of the ansa-RLN is estimated at 2 hours.[104] Although thyroplasty is typically performed with the patient under sedation and vocal fold injection can be performed in the clinic, ansa-RLN anastomosis is performed under general anesthesia.

The possibility of spontaneous recovery of vocal fold function is eliminated with the division of the RLN prior to ansa-RLN anastomosis. It is important to wait until the possibility of spontaneous recovery is minimal before performing this procedure.

There is a delay of 5 to 9 months before substantial improvement in the voice occurs, in addition to the several-month delay of waiting for the possibility of spontaneous recovery before the procedure is performed. Often an initial improvement can be seen as early as 3 to 4 months after surgery. Improvement, however, can continue for several years.

The procedure requires one intact ansa cervicalis and the intact distal stump of the RLN. This requirement can be difficult to satisfy after thyroid surgery or impossible after bilateral neck surgery in which the ansa cervicalis is sacrificed. In cases of unilateral neck surgery the contralateral ansa cervicalis can be used. Unlike in thyroplasty, the consequences of performing the procedure on the wrong (nonparalyzed) side are severe. With division of the only remaining intact RLN, a bilateral vocal fold immobility and resultant airway obstruction are likely consequences.

Surgical Indications and Contraindications

Ansa-RLN anastomosis is indicated for the treatment of unilateral vocal fold paralysis in which there is minimal chance for spontaneous recovery. The most common waiting period prior to consideration of reinnervation is 12 months. The distal stump of the RLN must be available for anastomosis. In the presence of extensive scar, the RLN can be found behind the cricothyroid joint. A donor nerve must also be available. The ansa cervicalis, however, can be prepared from either the ipsilateral or contralateral side. The patient must be able to tolerate both general anesthesia and the wait for substantial improvement from reinnervation.

Absolute contraindications include glottic airway compromise, bilateral vocal fold paralysis, absence of the distal RLN, bilateral absence of the ansa cervicalis, and poor general health.

The relative contraindications to ansa-RLN anastomosis include limitations of time, voice, and surgery. Time limitations primarily focus on the delay after surgery for the voice improvement. Is the wait worthwhile for the patient? Time can be limited by either social or work considerations or by the patient's life expectancy. If the patent's life expectancy is less than 5 years, the delay for improvement with reinnervation may not be worthwhile. The procedure also appears to be less successful in the elderly and in patients who have had paralysis for several decades. Voice limitations focus on the fact that ansa-RLN anastomosis fixes only the position, bulk, and tone of the paralyzed vocal fold. Is there other pathology that will limit the voice result, such as dysarthria associated with multiple cranial nerve defects or stroke? Other vocal fold pathology that will limit the ultimate result, such as the presence of a vocal fold scar, web, or polyp, must be considered. If a near-normal voice is not the anticipated result, the use of ansa-RLN anastomosis should be considered carefully. Fixation of an arytenoid in a lateral position also has an adverse effect on the expected outcome.

Surgical considerations also come into play when prior surgery has occurred in the area of the RLN. Is there extensive scarring or atrophy of the nerve? The possibility of not finding an adequate nerve for anastomosis must be considered, and alternative plans for intraoperative management reviewed with the patient.

Surgical Technique

An incision in a natural crease of the neck is made below the level of the cricoid cartilage, often at the level of a thyroidectomy incision (Fig. 68-2). The incision need not cross the midline, and 4 cm is usually adequate. The strap muscles are separated vertically in the midline, and the RLN is identified in the tracheoesophageal groove. The nerve is dissected to its entrance into the larynx. In the presence of local scar tissue, the RLN can be found behind the cricothyroid joint. A vessel loop can be placed around the nerve. The anterior border of the sternocleidomastoid muscle is identified. The ansa cervicalis nerve can be

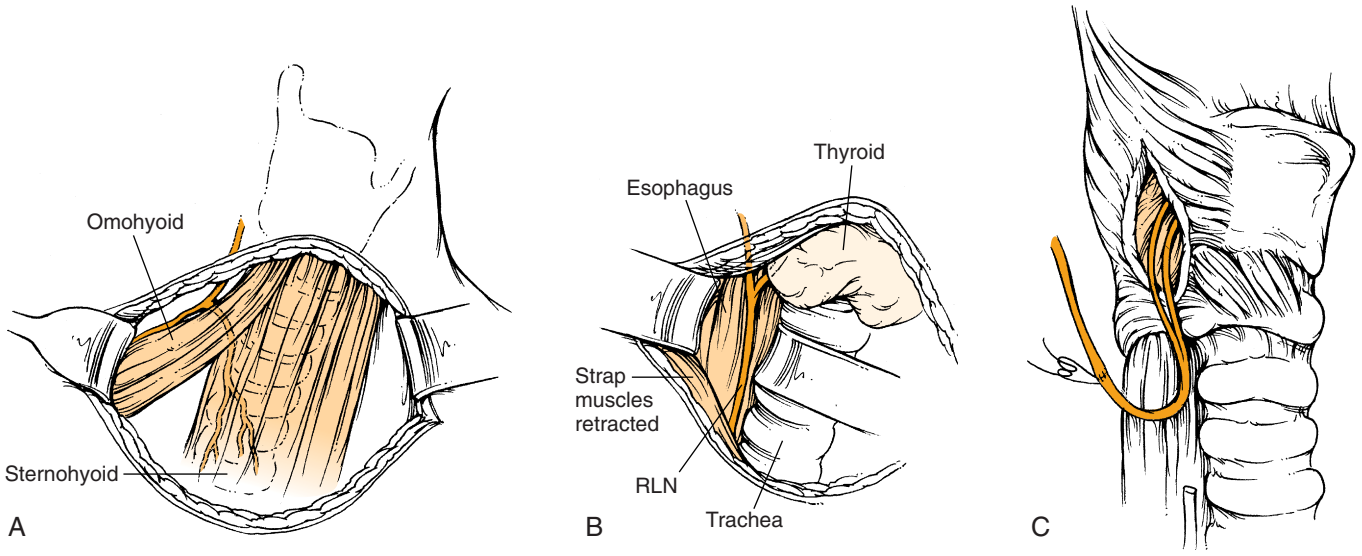

Figure 68-2. Ansa cervicalis to recurrent laryngeal nerve (RLN) anastomosis. **A,** Exposure of branch to sternohyoid muscle. **B,** Exposure of RLN in the tracheoesophageal groove. **C,** Ansa-RLN anastomosis.

identified along the lateral border of the sternothyroid muscle, at the level of the omohyoid muscle, or along the internal jugular vein.

After both nerves are identified and the distal RLN is confirmed to be intact, the ansa cervicalis nerve and RLN are transected. Each nerve should be divided inferiorly enough to allow a tension-free anastomosis. A tunnel deep to the sternohyoid and sternothyroid muscles connects the two operative sites and facilitates the anastomosis. The anastomosis is performed with the use of 9-0 or 10-0 nylon sutures. Two or three epineural sutures are adequate. Magnification with either a surgical microscope or loupes can be used. The wound is closed in layers with an appropriate drain.

An absorbable material can be injected at the time of surgery to provide an initial improvement in vocal quality. After 2 to 3 months the voice may deteriorate to the preoperative level. At 4 to 6 months after surgery, a gradual improvement in vocal quality begins. On laryngeal examination after ansa-RLN transfer, the reinnervated cord is immobile or demonstrates only minimal movement. The procedure produces a synkinesis that allows the mobile vocal fold to approximate the reinnervated fold in the midline.

Clinical Results

Ansa-RLN anastomosis has produced near-normal vocal quality in most reports. The initial two reports by Crumley and colleagues[27,105] described success in two patients and four patients. In one of these patients the contralateral ansa cervicalis nerve served as the donor nerve. No motion of the reinnervated vocal fold was seen in reinnervated patients. The vocal improvement was believed to be secondary to precise positioning of the reinnervated vocal fold. Reinnervation of the of PCA, LCA, and TA muscles appears to provide the needed tone to stabilize and position the arytenoid properly.[51]

A series of 20 patients undergoing ansa-RLN anastomosis was reviewed by Crumley[60] in 1991. Vocal quality was judged to be normal or near normal in 18 of 20 cases. In the one failure, identification of the RLN was in doubt secondary to local scar formation from multiple prior procedures. A second patient demonstrated improvement but to a lesser extent. Lateralization of the arytenoid and the patient's age (65 years) were cited as possible factors contributing to the lesser result. Several patients in whom the delay between injury and reinnervation exceeded 8 years had successful results.

Ansa-RLN anastomosis was successful in two elderly patients (66 and 71 years old) following resection of mediastinal tumors with early reinnervation.[106] Zheng and coworkers[107] presented eight cases with one disappointing result. They used an anterior branch of the RLN. Slight improvement was seen early after surgery, with additional improvement seen at 2 to 3 months. Electromyographic confirmation was obtained in five patients. Passive arytenoid mobility was important in achieving good results and was related to the one substandard result.

Similar results in terms of mean phonation time and vocal fold position are seen after a direct anastomosis of the RLN, a free nerve graft reconstructing the RLN, a vagus nerve–RLN anastomosis, and an ansa-RLN anastomosis performed during the course of thyroid surgery.[108] The ansa-RLN anastomosis has several advantages over other means of reconstruction of a divided RLN during the course of thyroid or other neck surgery. These include the requirement of only one anastomosis performed at a relatively accessible level in the neck, a relatively short time to recovery because the anastomosis is close to the larynx, and availability when the RLN is injured within the mediastinum. Performing the anastomosis behind the thyroid cartilage[108] as well as using the contralateral ansa cervicalis as a donor nerve[109] improves the chances of successful reconstruction.

Olson and colleagues[110] performed a quantitative analysis of 12 patients with ansa-RLN anastomosis for unilateral vocal fold paralysis. Improvement in vocal quality was demonstrated. Results of acoustic analyses in postoperative patients were similar to those in a control group of normal subjects. Patients with isolated vocal fold paralysis had the best results. Improvement in overall severity, roughness, and breathiness of the patient's voice more than 6 months following ansa-RLN anastomosis has also been demonstrated.[111] The greatest improvement was seen with breathiness measures. Postoperative electromyographic studies of patients undergoing reinnervation with an ansa-RLN anastomosis as well as NMP implantation into the TA have shown activation of the reinnervated muscle with speech and head elevation.[112] Head elevation maneuvers that directly activate the strap muscles were routinely found to result in greater activation of the TA and LCA muscles. Activation of the TA muscles with speech was found to increase with time.

Chhetri and colleagues[113] reported that the addition of ansa-RLN anastomosis to arytenoid adduction did not result in better acoustic results than arytenoid adduction alone. All patients in their series had significant perceptual improvement in voice, but these investigators questioned the relationship of surgical repositioning of the arytenoid and reinnervation in unilateral paralysis.

Direct Nerve Implant

Early in the 20th century, direct implantation of a nerve into a denervated muscle was shown to produce successful reinnervation in experimental models.[114-116] Insertion of a nerve ending into skeletal muscle results in the establishment of neuromuscular junctions.[117,118] Using

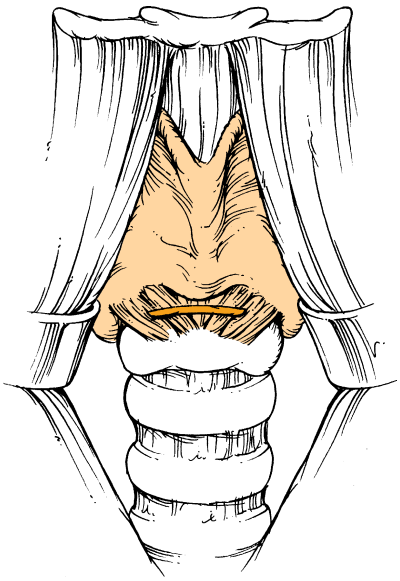

Figure 68-3. Muscle-nerve-muscle graft between the innervated and denervated cricothyroid muscle.

multiple implants distributed over a wide area increases the effectiveness of reinnervation with the direct nerve implantation technique.[119] Direct nerve implants have been successfully used in 10 patients, with active muscle movement occurring in all 10 patients.[120] A short period of denervation, a healthy donor nerve, and a wide distribution of nerve fibers entering the muscle had a positive effect on the outcome.

Early experiments investigating direct nerve implantation also examined the value of the technique in laryngeal reinnervation.[121,122] Direct implantation of the RLN into the PCA muscle was successfully performed in the canine and proposed as a promising method for reinnervation.[4,123]

Comparisons of the NMP procedure with direct implantation of the ansa cervicalis nerve into denervated muscle have shown mixed results. Meikle and associates[82] showed no advantage of one method over the other, whereas Hall and colleagues[83] found the NMP procedure to produce stronger evoked contractions and to involve a shorter time to return of function. Both groups judged that their results were consistent with the action of the NMP as a source for multiple direct nerve implants rather than a predominant reliance on transfer of intact motor units. Because of the need to support a distal muscle pedicle, the NMP procedure was inferior to the direct nerve implantation when the reinnervation procedure was extended with a cable graft.[84]

Direct nerve implantation of the TA muscle was performed in ten patients with unilateral paralysis.[124] Improvement of voice was seen in eight, with a return to "normal" or "great improvement" in 6 patients. Reinnervation was supported by electromyography in all four patients tested.

A variant of this technique, in which a nerve acts as a conduit from an innervated muscle to the contralateral, denervated muscle (muscle-nerve-muscle), has been successfully used.[125] Selective cricothyroid reinnervation with a muscle-nerve-muscle graft from the contralateral cricothyroid was used in combination with ansa-RLN anastomosis in three patients (Fig. 68-3). All patients had improved voice and electromyographic evidence of cricothyroid muscle reinnervation.

Management of Acquired Disorders and Trauma

CHAPTER SIXTY-NINE

Chronic Aspiration

Steven D. Pletcher

David W. Eisele

Key Points

- Intractable aspiration results in chronic soilage of the lower respiratory tract and life-threatening pulmonary infections.
- In adult patients, cerebrovascular accident with subsequent lower cranial nerve palsies is the most common cause of intractable aspiration; other causes are neuromuscular disorders, tumors (brainstem or laryngeal), postoperative aspiration, and traumatic or anoxic brain injury.
- Causes of intractable aspiration in pediatric patients include cerebral palsy, anoxic encephalopathy, sequelae of neurologic trauma or surgery, tracheoesophageal fistula, and other severe congenital or acquired neurologic disorders.
- Initial conservative treatments of chronic aspiration include nothing-by-mouth status with an alternative route of alimentation, head of bed elevation, and aggressive pulmonary toilet.
- Patients who continue to aspirate despite such conservative measures are deemed to have intractable aspiration; surgical management should be considered in these patients.
- Control of aspiration, phonation, and swallowing should all be considered in the choice of surgical approach for aspiration.
- The Lindeman procedures (tracheoesophageal diversion and laryngotracheal separation) have gained popularity owing to their high rate of success in controlling aspiration as well as their technical simplicity.

The three major functions of the larynx—respiration, phonation, and airway protection—are intimately related. Impairment of laryngeal protective function can result in aspiration, the laryngeal penetration of secretions such as saliva, ingested liquids or solids, or refluxed gastric contents below the level of the true vocal cords.

A certain amount of aspiration is known to occur normally. Scintigraphic evaluation of healthy persons during sleep reveals aspiration in nearly 50%.[1] A certain amount of aspiration may be tolerated without complications, provided that tracheobronchial clearance is normal and defense mechanisms are intact. Contamination of the respiratory tract associated with aspiration can result in a spectrum of bronchopulmonary complications. The severity of complications depends on the volume and the character (e.g., pH) of the aspirated material. Respiratory complications of aspiration include bronchospasm, airway obstruction, tracheitis, bronchitis, pneumonia, pulmonary abscess, sepsis, and death.[2-4] Significant aspiration results in a high mortality rate.[5]

Aspiration may be an isolated event related to temporary impairment of normal swallowing mechanisms and airway protection. Typically, isolated aspiration occurs secondary to neurologic dysfunction. This dysfunction may in turn be secondary to a depressed state of consciousness related to drugs, alcohol, or metabolic derangement. In addition, seizure, injury, or infection may cause isolated aspiration. Elderly patients are more likely to experience aspiration, presumably in relation to physiologic and neurologic changes associated with age.[6-8] Patients with dentures experience impaired swallowing with decreased oral sensation and oral control, which may contribute to aspiration.

Chronic or intractable aspiration entails repeated episodes of aspiration. Patients with chronic aspiration require evaluation and effective management to prevent life-threatening complications. This chapter discusses the evaluation and management of patients with chronic aspiration and emphasizes surgical management.

Etiology

Chronic aspiration usually results from a severe loss of laryngeal protective function related to impaired motor activity or sensory loss. Chronic aspiration can occur, despite healthy laryngeal function, if dysfunctional swallowing is significant.

Box 69-1 lists causes of chronic aspiration. The most common origin is associated with cerebrovascular accidents, particularly those involving the brainstem with bilateral cranial nerve (CN) deficits.[9] In addition, degenerative neurologic diseases are frequently associated with chronic aspiration. Peripheral nerve disorders, particularly those involving the cranial nerves, as well as neuromuscular diseases and muscular disorders, can cause recurrent aspiration. Diffuse neurologic dysfunction from head injury, anoxic brain injury, infection, or drug toxicity can cause severe dysfunction and chronic aspiration.[10-12] Chronic aspiration also can result from disorders of the pharynx and the esophagus, including neoplasms, postoperative and postirradiation dysfunction, Zenker's diverticulum, stricture, and severe gastroesophageal reflux.[13]

Chronic aspiration can occur in pediatric patients, in whom it is usually related to severe neurologic dysfunction resulting from cerebral palsy, anoxic encephalopathy, sequelae of neurologic trauma or surgery, tracheoesophageal fistula, or other severe congenital or acquired neurologic disorders.[14]

Symptoms

Patients may be aware of recurrent aspiration and describe episodes of coughing or choking during swallowing. Some patients, however, may

experience silent aspiration, whereby cough does not occur after laryngeal penetration.[15-17] Fever and respiratory symptoms such as productive cough with purulent sputum may occur, indicating an infectious complication. Patients may have weight loss, dysphonia, pain, dysphagia, odynophagia, or other symptoms, depending on the cause of the underlying disorder.[9] Frequently, patients are severely ill because of their disease and secondary infectious complications.

Evaluation

In the evaluation of a patient with chronic aspiration, a detailed medical history is important. Frequently, the cause of aspiration is apparent from the history. The medical history and history of prior surgery or injury should be thoroughly investigated.

A multidisciplinary approach to patients with chronic aspiration is important.[18] Frequently, an otolaryngologist–head and neck surgeon is consulted after complications of chronic aspiration have occurred. Once chronic aspiration has been identified, consultation with specialists in speech-language pathology, neurology, internal medicine, rehabilitation medicine, radiology, gastroenterology, thoracic surgery, and psychiatry may be beneficial. A cooperative effort in which each specialist provides special expertise ensures optimal care for the patient.

Physical examination should be thorough, with careful examination of the head and neck, including cranial nerve evaluation. Examination of the hypopharynx and larynx is performed with indirect mirror examination or fiberoptic nasopharyngoscopy. If these structures are not adequately visualized by these methods (e.g., in an endotracheally intubated patient), direct laryngoscopy is recommended. Esophagoscopy is performed if an esophageal abnormality is suspected. Pulmonary function tests help assess pulmonary function and reserve.

Radiography provides important diagnostic information and should include chest radiography and swallowing evaluation. A videofluoroscopic swallowing study reliably provides information about the precise physiologic nature of aspiration and swallowing disturbance and about the severity of aspiration.[19,20] Logemann[21] described a modified barium swallow study in which small amounts of barium are used because of the risk of aspiration. Different consistencies of contrast material are used to assess whether consistency alteration has any effect on aspiration reduction. A videofluoroscopic swallowing study performed in conjunction with a speech-language pathologist allows radiographic assessment of the effects of swallowing therapy and maneuvers on control of aspiration.[22,23]

Functional endoscopic evaluation of swallowing (FEES) was proposed by Langmore and associates[24] in 1988 as an alternative to videofluoroscopy for the evaluation of dysphagia. In this study, dyed pudding and liquids are swallowed by the patient during nasopharyngeal fiberoptic observation. The swallow is recorded and reviewed for evidence of oral leakage, pharyngeal stasis, laryngeal penetration, and aspiration. Evaluation of FEES suggests that it is similar in sensitivity and specificity to videofluoroscopic examination with the advantages of lower cost, decreased radiation exposure, and bedside availability.[25-29] In general, the choice between videofluoroscopy and FEES depends on multiple factors, including physician and speech-language pathologist preferences and hospital availability.

Scintigraphy may help quantify the magnitude of aspiration[30,31] but in general adds little information, beyond that obtained from a FEES or a videofluoroscopic swallowing study, for the management of aspiration. Other imaging studies that may provide important information are computed tomography (CT) or magnetic resonance imaging (MRI) of the head and neck, and soft tissue radiography of the neck.

Comprehensive evaluation of the patient with aspiration ideally determines the cause of the underlying disorder or disorders causing the aspiration. A thorough search for any correctable cause of aspiration (e.g., obstructing lesion, Zenker's diverticulum, cricopharyngeal muscle dysfunction, esophageal motility disorder) is important to management.

Frequently, progressive functional deterioration can be anticipated for certain degenerative neurologic diseases and malignant neoplasms. It can be extremely difficult, however, to predict the time course of improvement and recovery for cerebrovascular accidents, head injuries, anoxic brain injuries, postoperative dysfunction, and other disorders. Multispecialty input is helpful in planning management for these difficult cases.

Nonsurgical Management

Initial management of the patient with chronic aspiration should include appropriate antibiotics for any infectious complications. Aggressive pulmonary therapy is instituted. All oral intake is discontinued, and an alternative route of alimentation is provided. Enteral routes of alimentation include small, soft nasogastric feeding tubes, cervical esophagotomy, piriform sinusotomy, gastrostomy, and jejunostomy. Gastrostomy can easily be performed percutaneously with minimal morbidity. Patients with significant reflux may benefit from a tube passed through a gastrostomy into the small intestine or jejunostomy.

Depending on the cause of aspiration, alimentation by nasogastric feeding tube decreases but does not eliminate the risk of aspiration.[32] Some researchers believe that nasogastric feeding tubes may actually predispose to aspiration.[33,34] In addition, nasogastric feeding tubes can be uncomfortable and aesthetically displeasing when used for long periods. Gastrostomy alone has been shown not to reduce aspiration in neurologically impaired patients. [35,36] Some patients may be candidates for parenteral hyperalimentation if gastrointestinal function is impaired (e.g., patients with acute severe brain injury).[37]

Proper nursing care includes special positioning of the patient, such as elevation of the head of the bed for patients with severe reflux. However, one study showed no significant difference in aspiration with respect to patient position in the patient with endotracheal intubation.[34] Frequent suctioning of the oral cavity and oropharynx is also important.

Tracheotomy

A tracheotomy tube with a low-pressure cuff provides comfortable airway control for patients requiring intubation and facilitates pulmonary toilet in patients with copious secretions. Tracheotomy also effectively reduces the pulmonary dead space. Despite these advantages, tracheotomy cannot be relied upon to eliminate aspiration.[38,39] In addition, tracheotomy has been implicated as a causative factor in aspiration. The proposed mechanisms include esophageal compression via inflated tracheotomy cuff,[40] desensitization of the larynx from diversion of airflow through the tracheotomy,[41] impairment of laryngeal elevation through tethering of the larynx by the tracheotomy tube,[42] disruption of the normally closed aerodigestive system,[43] disorder of laryngeal reflexes due to chronic upper airway bypass,[1,44,45] reduced effectiveness of cough to clear secretions from the upper airway,[43,46] and the inability to generate subglottic air pressure.[47,48] Despite these proposed mechanisms, no clear causal relationship between tracheotomy and aspiration exists. In a study of 20 patients evaluated with FEES before and after tracheotomy (within 1 month), no causal relationship between tracheotomy and aspiration was demonstrated.[49]

The use of a tracheotomy tube for aspiration control requires close attention and skilled care, particularly for the debilitated patient. Several studies have examined the effect of endotracheal and tracheotomy tube cuffs on the prevention of aspiration. Although low-pressure, high-compliance cuffs are the most effective in minimizing cuff leak, they do not prevent aspiration.[50-52]

Vocal Cord Medialization

Vocal cord paralysis can result in chronic aspiration, particularly when combined with a laryngeal sensory deficit (e.g., a high vagal lesion). Vocal cord injection with materials such as collagen derivatives or hydroxyapatite can be performed endoscopically or transcervically to achieve vocal cord medialization and may prevent aspiration related to vocal cord paralysis.[53-55] Bilateral vocal cord injection with permanent materials such as polytetrafluoroethylene, however, has been shown to be an unreliable method for the prevention of chronic aspiration.[56]

Alteration of the laryngeal framework by medialization laryngoplasty using an implant is another excellent technique for vocal cord medialization.[57,58] Carrau and associates[59] reported that 94% of patients with high vagal lesions experienced improved swallowing after medialization thyroplasty with or without arytenoid adduction. In the same study 79% of patients who presented with tracheotomies underwent successful decannulation following laryngeal framework surgery.

Surgery

Sometimes a correctable cause of chronic aspiration is not identified, and nonsurgical and minor surgical procedures (e.g., tracheotomy, vocal cord medialization) do not prevent chronic aspiration. In these cases, surgical separation of the upper digestive tract from the upper respiratory tract is necessary to prevent the morbidity and mortality of recurrent respiratory tract soilage. A reasonable probability and duration of survival are necessary prerequisites for this surgery.

Clinical judgment should be used to determine the likelihood of recovery of laryngeal protective function and to identify patients who require prompt surgical intervention to separate the upper digestive and respiratory tracts to prevent death. The patient's general medical and mental status, severity of illness, and potential quality of life should be addressed.[60] Patients may have to sacrifice normal phonation and laryngeal respiration to ensure restoration of airway protection. This difficult issue requires thorough discussions of management options and sequelae with the patient and family members.

Vertical laryngoplasty

Irreversible Procedures

Subperichondrial cricoidectomy
Narrow-field laryngectomy
Glottic closure

"Ideal" Surgical Procedure for Chronic Aspiration

The ideal surgical procedure for chronic aspiration would be uniformly effective in preventing aspiration, be simply achieved, and have few complications and low morbidity. This procedure could be performed with local anesthesia for debilitated patients. In addition, the ideal procedure would allow phonation and deglutition and would be reversible if the underlying cause of aspiration were to improve. Many surgical options have been described for the management of chronic aspiration (Box 69-2).

Laryngectomy

Before 1970, laryngectomy was considered the surgical procedure of choice for management of chronic aspiration. This procedure provides definitive separation of the upper digestive and respiratory tracts. Narrow-field laryngectomy (Fig. 69-1) is used, in contrast to the total laryngectomy performed for malignancy. It preserves the hyoid, strap muscles, and as much hypopharyngeal mucosa as possible. Closure without tension and with reinforcement minimizes the potential postoperative complications of pharyngeal stenosis and fistula.[61] A staple-assisted laryngectomy technique designed specifically for treatment of aspiration may provide technically straightforward method to decrease the postoperative fistula rate.[62]

Laryngectomy also is practical because of the low likelihood of recovery of most patients with chronic aspiration.[63,64] However, because of the negative psychosocial aspects of laryngectomy, most patients and family members are reluctant to consent to laryngectomy for chronic aspiration. Narrow-field laryngectomy can be performed with local anesthesia. Tracheoesophageal puncture and placement of a voice prosthesis can be used for vocal rehabilitation after laryngectomy in selected patients. Because of the disadvantage of irreversibility of laryngectomy and the observation that some patients with chronic aspiration recover, other surgical procedures have been developed since the 1970s for the surgical management of chronic aspiration.

Subperichondrial Cricoidectomy

An option for definitive surgical separation of the upper respiratory and digestive tracts when recovery of function is expected is subperichondrial cricoidectomy (Fig. 69-2).[65] In this technique, the anterior aspect of the cricoid cartilage is exposed. The perichondrium of the anterior cricoid cartilage is divided vertically in the midline to expose the cricoid cartilage. The outer cricoid perichondrium is elevated with an elevator to the posterior cricoid lamina, and the inner cricoid perichondrium is elevated from the cricoid cartilage circumferentially. The cricoid carti-

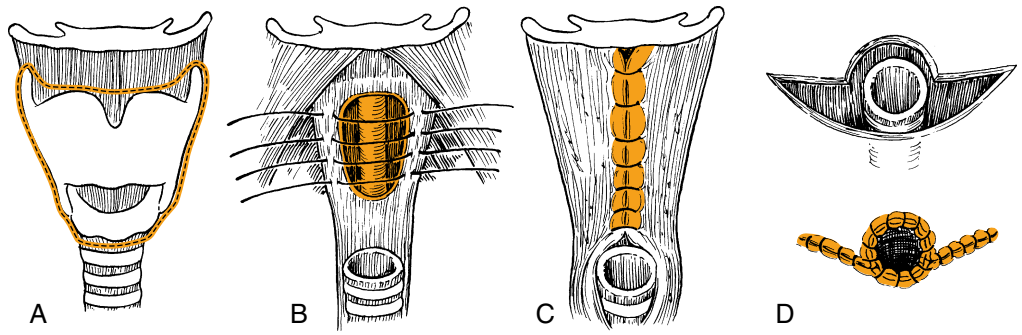

Figure 69-1. Narrow-field laryngectomy. **A,** Outline of larynx removal; the hyoid is preserved. **B,** Closure of the pharynx. **C,** Closure is reinforced with sternohyoid muscles. **D,** A tracheostoma is created.

lage is then removed piecemeal bilaterally with biting forceps, and the posterior cricoid lamina is preserved. The inner perichondrium and subglottic mucosa are transected horizontally, inverted, and closed, creating a subglottic pouch. The closure is buttressed by approximation of the strap muscles, and the wound is closed in layers over a drain. A tracheotomy is necessary.

Advantages of this technique include a high success rate, simplicity, and low morbidity. For these reasons, subperichondrial cricoidectomy may be preferable to narrow-field laryngectomy and other procedures for chronic aspiration when recovery of laryngeal protective function is not expected. This procedure can be performed easily with use of local anesthesia. Disadvantages include the need for a tracheotomy and the remote possibility of fistula into the upper trachea. The procedure was not designed to be reversible, and no reversals have been reported.

Partial Cricoidectomy

Krespi and associates[66] described subtotal and submucosal cricoid resection for the control of chronic aspiration after extensive surgical resection of pharyngeal and base-of-tongue tumors, particularly for patients undergoing myocutaneous flap reconstruction. The posterior cricoid perichondrium is elevated, and the posterior half of the cricoid lamina is removed without entering the mucosa. A cricopharyngeal myotomy also is performed. A tracheotomy is necessary. Partial cricoidectomy enlarges the pharyngeal inlet, facilitating deglutition, and narrows the laryngeal inlet, reducing aspiration and preserving the voice.

Biller and Urken[67] described partial cricoid collapse for the prevention of aspiration after extended horizontal partial laryngectomy. Vertical segments of the hemicricoid are removed. The hemicricoid is then collapsed with stabilization of the cricoid segments to a midline position, narrowing the laryngeal opening and correcting glottic incompetence.

Endolaryngeal Stents

Several types of endolaryngeal stents have been used to prevent chronic aspiration. Weisberger and Huebsch[68] reported the use of a solid silicone laryngeal stent, which was placed endoscopically and secured transcervically with sutures (Fig. 69-3). A tracheotomy tube was necessary. Aspiration was prevented and oral intake tolerated in three of seven patients with chronic aspiration. Perioperative mortality was high in this series and was thought to be related to tracheotomy tube obstruction. Endoscopic reversal of the stent procedure was reported in two patients; however, both required stent replacement for aspiration control.

Eliachar and coworkers[69,70] reported two types of vented silicone laryngeal stents for control of aspiration (Fig. 69-4). The newer of the two stents is inserted through a tracheotomy and secured by a flexible strap of silicone extending from the tracheotomy tract above the tracheotomy tube. Eliachar and Nguyen[69] reported aspiration control in 11 of 12 patients with chronic aspiration with the newer stent. For 1 patient in whom the initial procedure failed, placement of a larger stent achieved aspiration control. The stent was reportedly used for up to 9 months. Of 3 patients who survived and underwent successful stent removal, 1 experienced laryngeal granulation tissue requiring laser excision, and an anterior subglottic web developed in another.

Laryngeal stents are easily introduced and, if properly sized for the patient, prevent aspiration.[69,71] Laryngeal stents, however, have the disadvantages of a lack of uniform success caused by leakage around the stent or extrusion. Because of the potential for endolaryngeal injury from the stent or tracheotomy tube displacement with airway occlusion by the stent, short-term use is recommended. Other disadvantages of stents are patient discomfort, the need for stents of different sizes, and the potential for life-threatening complications such as stent dislodgement. For these reasons, endolaryngeal stents have failed to gain wide acceptance for control of chronic aspiration.

Epiglottic Flap Closure of the Larynx

Habal and Murray[72] described an epiglottic flap technique of supraglottic closure. With this technique, the supraglottic larynx is approached through an infrahyoid pharyngotomy. The supraglottic larynx is closed after the edges of the epiglottis, aryepiglottic folds, and arytenoids are denuded (Fig. 69-5). A tracheotomy is required.

Since this initial report, several modifications and refinements of the procedure have been described. Strome and Fried[73] described (1) diminishing the tensile strength and elasticity of the epiglottic cartilage by morcellation, linear striations, or wedge excision and (2) severing the hyoepiglottic and thyroepiglottic ligaments. These modifications lessened dehiscence of the posterior flap.[72,74,75] However, this frequent complication allowed speech in some patients.

A further modification of the epiglottic flap closure procedure purposefully leaves the posterior laryngeal inlet open to allow phonation.[74,76] Another modification of this procedure suspends the larynx to the mandible to provide additional laryngeal protection.[75] Denuding the false vocal cords of mucosa and approximating the false vocal cords provide an additional layer of closure for laryngeal inlet obliteration.[77]

Epiglottic flap closure of the larynx prevents chronic aspiration in only approximately 50% of the procedures reported, although revision surgery is successful if the first procedure fails.[78] Reports of reversal of epiglottic flap closure are uncommon; successful reversal with endoscopy has been achieved.[73]

Advantages of epiglottic flap closure include reversibility, allowance of deglutition, and speech preservation if the posterior laryngeal inlet is left open or if dehiscence of the closure occurs. In addition, the true vocal cords are not injured by this procedure. Disadvantages of the epiglottic flap closure procedure include a high rate of flap dehiscence and failure and the need for a transcervical approach and tracheotomy. Supraglottic stenosis is a potential complication after reversal.[74]

Vertical Laryngoplasty

Biller and coworkers[5] described vertical laryngoplasty for the prevention of aspiration in patients who required total glossectomy for advanced carcinoma of the tongue (Fig. 69-6). In this technique, an incision is made along the outer borders of the epiglottis and carried inferiorly and posteriorly along the aryepiglottic folds over the arytenoids and

Figure 69-2. into the interarytenoid area. The epiglottis and supraglottic larynx are then closed vertically in two layers as a tube, with a small opening left superiorly. This technique also has been applied to patients with chronic aspiration with satisfactory results, allowing deglutition and speech.[60] Failure secondary to posterior dehiscence may limit the efficacy of this technique. Attempts to perform this procedure through an endoscopic approach have also been limited by posterior dehiscence and persistent aspiration.

Several modifications of the procedure have been proposed. Miller and Eliachar[71] described scoring the epiglottic cartilage in order to eliminate the cartilaginous spring and thus minimize dehiscence of the closure. A variation of the Biller vertical laryngoplasty has also been combined with a partial closure of the posterior glottis in an attempt to minimize failure due to persistent aspiration. This modified technique requires a permanent tracheotomy, but speech may still be attained with occlusion of the tracheotomy site.[79]

Glottic Closure

Glottic closure was described by Montgomery.[80] In this procedure, the larynx is closed at the level of the true and false vocal cords (Fig. 69-7). A midline thyrotomy is performed initially, exposing the endolarynx. The true and false vocal cords, ventricles, and posterior commissure are denuded of mucosa. Nonabsorbable monofilament sutures are used to approximate the glottic surfaces to provide glottic closure. In addition, absorbable sutures are used to approximate margins of the false vocal cords. A tracheotomy tube is necessary. Sasaki and colleagues[45,81] modified glottic closure, adding a sternohyoid muscle flap to provide an additional layer of laryngeal closure.

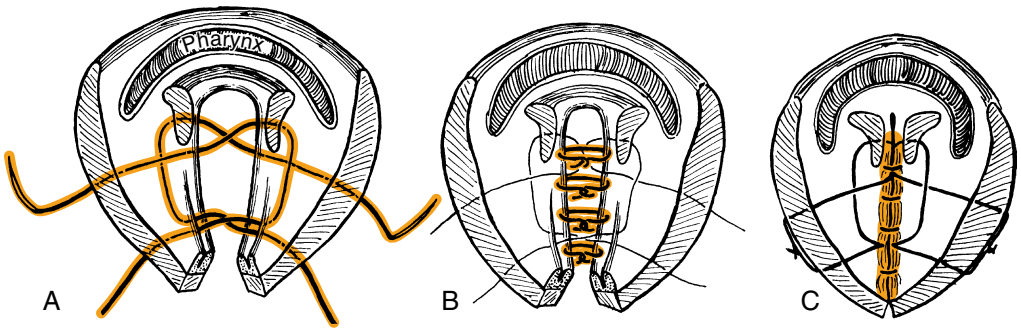

Figure 69-7. Glottic closure procedure. **A,** Midline thyrotomy, removal of the glottic mucosa, and placement of transglottic sutures for closure. **B,** False vocal cords are approximated. **C,** The glottis is closed.

The results of glottic closure for the prevention of aspiration are reported to be excellent (success rate, approximately 95%). There has been only one report of successful reversal of the glottic closure procedure.[82]

Advantages of the glottic closure procedure include high success rate for prevention of aspiration, allowance of deglutition, and potential reversibility. Glottic stenosis, however, makes reversal difficult. Disadvantages of the glottic closure procedure include the need for a transcervical approach and thyrotomy, loss of phonation, need for a tracheotomy, and endolaryngeal injury involving the true vocal cords. Performing the procedure is technically challenging; the interarytenoid closure is the most difficult step. A preexisting laryngeal abnormality is a contraindication for this procedure.

A dynamic glottic closure technique using implanted electrodes to stimulate the recurrent laryngeal nerve at the time of swallow has been proposed as a new method for prevention of aspiration without surgical manipulation of the endolarynx.[83] Along with the obvious benefit of preservation of respiration and phonation, a preliminary report of the use of these electrodes in two patients with stroke suggests efficacy in control of aspiration.

Tracheoesophageal Diversion and Laryngotracheal Separation

Lindeman[84] described tracheoesophageal diversion in 1975. This procedure for chronic aspiration was devised with the objective of developing a reliable surgical technique that would control aspiration for an indefinite period while preserving the larynx and the integrity of the recurrent laryngeal nerves. The procedure was designed to be reversible if healthy laryngeal protective function returned.

Tracheoesophageal diversion is performed by horizontal division of the trachea at the fourth and fifth tracheal rings (Fig. 69-8). The proximal tracheal segment is anastomosed in an end-to-side fashion to an opening in the anterior esophagus. The distal tracheal segment is used to create a tracheostoma.

In 1976, a similar surgical procedure for chronic aspiration, laryngotracheal separation, was described.[85] Laryngotracheal separation was designed for patients with chronic aspiration who had previously undergone high tracheotomy, which prevents establishment of a tracheoesophageal anastomosis, as performed in tracheoesophageal diversion. Laryngotracheal separation is performed by division of the trachea horizontally between the second and third tracheal rings or at the level of an existing tracheotomy (Fig. 69-9). The proximal tracheal edges are closed onto themselves anteroposteriorly as a blind pouch. The tracheal closure is buttressed with rotated sternothyroid muscles. The distal tracheal segment is used to create a tracheostoma.

A modification of tracheoesophageal diversion has been described; an anterior tracheal flap is created by removal of the inferior half of the cricoid cartilage and the anterior aspects of the first and second tracheal rings (Fig. 69-10).[12] This modification creates a soft flap, which allows tracheoesophageal diversion in patients who have undergone prior tracheotomy. This modification may jeopardize the reversibility of the procedure.

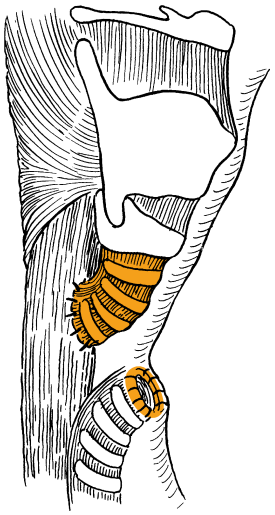

Figure 69-8. Tracheoesophageal diversion.

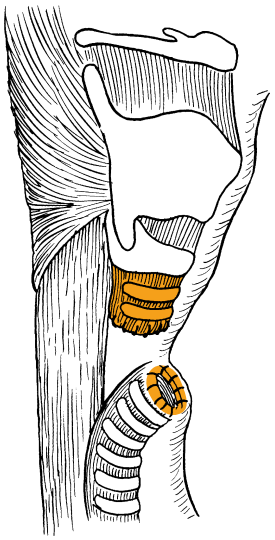

Figure 69-9. Laryngotracheal separation.

Tucker[86] proposed division of the trachea and externalization of the proximal trachea between the fibers of the sternocleidomastoid muscle to the cervical skin. It was theorized that sternocleidomastoid muscle compression would collapse the trachea, thus limiting external leakage of secretions. This procedure effects definitive separation of the respiratory tract and the digestive tract and prevents aspiration. Tra-

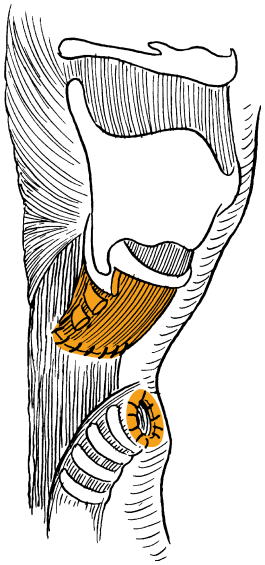

Figure 69-10. Modified tracheoesophageal diversion.

cheal secretions draining onto the neck, however, are aesthetically displeasing and require local care.

Many writers have reported uniform success in control of chronic aspiration with tracheoesophageal diversion and laryngotracheal separation.[11,87-92] Postoperatively, most patients can tolerate a normal diet, depending on their neurologic function. Reversals of both procedures with restoration of voice, deglutition, and respiration have been reported.[89,90,92-95] Both procedures can be performed with local anesthesia if necessary. Zocratto and associates[92] describe the use of laryngotracheal separation in conjunction with ablative surgical treatment of upper aerodigestive tract malignancies to prevent postoperative aspiration. Subsequent surgery for reversal was performed in 38% of their patients with aspiration. Tracheal stenosis occurred in more than 50% of patients who underwent reversal.[92]

Tracheoesophageal diversion has been recommended for patients with chronic aspiration who have not had high tracheotomy.[96] Tracheoesophageal diversion allows secretions and oral intake that have penetrated the larynx to pass into the esophagus. However, laryngotracheal separation is technically easier to perform than tracheoesophageal diversion. These techniques appear equally effective in controlling chronic aspiration. Complications are uncommon; they include postoperative fistula, which usually closes spontaneously with local care and antibiotics. Fistula formation is more common in patients with prior tracheotomy.[88] Ultimately, the decision whether to perform the diversion or separation procedure is determined by the presence of a tracheotomy and the surgeon's experience.

Candidates for reversal of tracheoesophageal diversion or laryngotracheal separation are considered on the basis of neurologic improvement and the results of laryngoscopy and videofluoroscopic swallowing evaluation. Reversals of these procedures have been performed most commonly in patients who have recovered from cerebrovascular accidents or who have undergone resection of benign intracranial tumors.[88] Surgical reversal may require partial resection of scarred tracheal remnants and mobilization of the laryngeal and tracheal segments in order to achieve a tension-free closure.[55,94] Excellent long-term speech and swallowing capabilities have been demonstrated in patients who have undergone reversal procedures.[55,94]

Advantages of tracheoesophageal diversion and laryngotracheal separation are that they are the most dependable of the reversible techniques for preventing chronic aspiration. These procedures allow oral alimentation and are reversible because the endolarynx is avoided and the larynx is not injured. Tracheoesophageal diversion has also demonstrated shorter operative time and less intraoperative blood loss than narrow-field laryngectomy.[97]

Disadvantages include the need for a transcervical approach and the loss of capacity for air-powered speech. Most patients, depending on their neurologic function, communicate with an electrolarynx after these procedures. Tracheotracheal and tracheoesophageal puncture with placement of a Blom-Singer voice prosthesis and resultant successful speech rehabilitation have been reported after laryngotracheal separation.[98-101] Carefully followed criteria, including sufficient manual dexterity and visual acuity, are necessary to select candidates for these rehabilitative procedures after laryngotracheal separation.

Tracheoesophageal diversion and laryngotracheal separation have also been successfully performed with satisfactory results in children with chronic aspiration.[14,26,91,102]

Summary

Chronic or intractable aspiration is a serious problem usually related to severe neurologic dysfunction. Chronic aspiration requires a thorough evaluation and the management of any correctable causes. Surgical separation of the upper respiratory and upper digestive tracts may be necessary to prevent repeated soilage of the respiratory system with recurrent infectious complications and to avoid death.

If there is no chance of recovery of neurologic function, surgical options for control of chronic aspiration include subperichondrial cricoidectomy and narrow-field laryngectomy. If recovery is possible, laryngotracheal diversion and separation are effective and reversible surgical techniques that prevent chronic aspiration.

CHAPTER SEVENTY

Laryngeal and Esophageal Trauma

Guri S. Sandhu

S. A. Reza Nouraei

Key Points

- Laryngeal trauma is rare (1:137,000) but acutely life-threatening and, if not promptly recognized and treated, can cause significant long-term morbidity.
- External laryngeal trauma can be blunt or penetrating. Internal trauma is most commonly due to translaryngeal intubation but can also be secondary to caustic ingestion or inhalation burns.
- The first priority in managing laryngeal trauma is establishing a safe airway. Definitive treatment must be provided within 24 hours.
- External laryngeal trauma should be managed by a multidisciplinary trauma team, and associated cervical and remote injuries should be systematically sought and treated.
- Approximately 40% of patients with laryngeal trauma can be managed conservatively, and in those patients who require surgical treatment, the extent of the original injury correlates with the long-term outcome.
- The incidence of laryngeal injury is 10% after short-term translaryngeal intubation and rises to 90% after long-term intubation and ventilation. It can be prevented with early tracheotomy in the intensive care unit.
- Inhalation injury to the larynx occurs in 6% of patients with burns and in 40% of patients with caustic ingestion. Both types of injuries, if not recognized and treated promptly, can lead to severe long-term complications.
- Esophageal injuries occur in 6% of patients with penetrating neck trauma and 14% of patients with laryngotracheal trauma. They can be managed conservatively if recognized early but may require surgical exploration and drainage.
- Caustic esophageal injuries are almost always accidental in children but due to suicide attempts in adults. They are associated with stricture formation in 10% to 35% of cases as well as with a markedly elevated incidence of esophageal carcinoma.

The larynx contains the narrowest region of the ventilatory conduit,[1] houses the phonatory apparatus, and functions to protect the airway during swallowing. External laryngeal trauma—the primary focus of this chapter, is an acutely life-threatening injury[2-4] that, if not promptly recognized and adequately treated, can also cause significant long-term morbidity in as many as a quarter of patients owing to any combination of dysphonia, aspiration, and airway stenosis.[4-6] Laryngeal trauma is often associated with concomitant cervical and intracranial injuries and frequently occurs as part of multisystem polytrauma.[4] It is vital therefore that all patients with suspected laryngeal injury be managed by a multidisciplinary trauma team according to Advanced Trauma Life Support guidelines.

Mechanisms of Injury

Laryngeal and esophageal trauma can be broadly divided into external trauma, which can be blunt or penetrating, and internal trauma, which can be caused by iatrogenic, thermal, caustic, or foreign body injuries (Fig. 70-1).

Laryngeal Trauma

External Laryngeal Trauma

Incidence

External laryngeal trauma is rare. It has a population incidence of 1 in 137,000 in adults[4] and accounts for 0.5% of trauma admissions in children.[7] Other studies estimate the incidence of this injury to be between 1 in 5000[8] and 1 in 30,000[9] emergency room visits.

Etiology

The larynx is well shielded by the mandible superiorly, the sternum inferiorly, the sternomastoid muscles laterally, and the spinal column posteriorly. Further protection is afforded through its mobility. It is however susceptible to crushing anterior cervical trauma, which compresses the organ against the spinal column (Fig. 70-2). Laryngeal injury is also compounded by the process of calcification that begins during the third decade of life and affects men to a greater degree than women.[10]

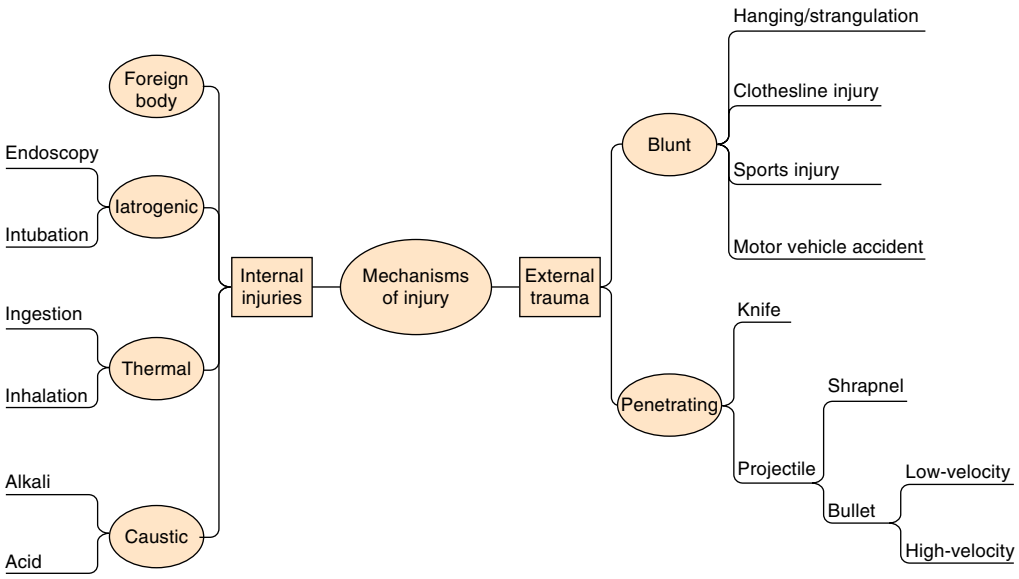

Figure 70-1. An overview of the mechanisms of laryngeal and esophageal injury.

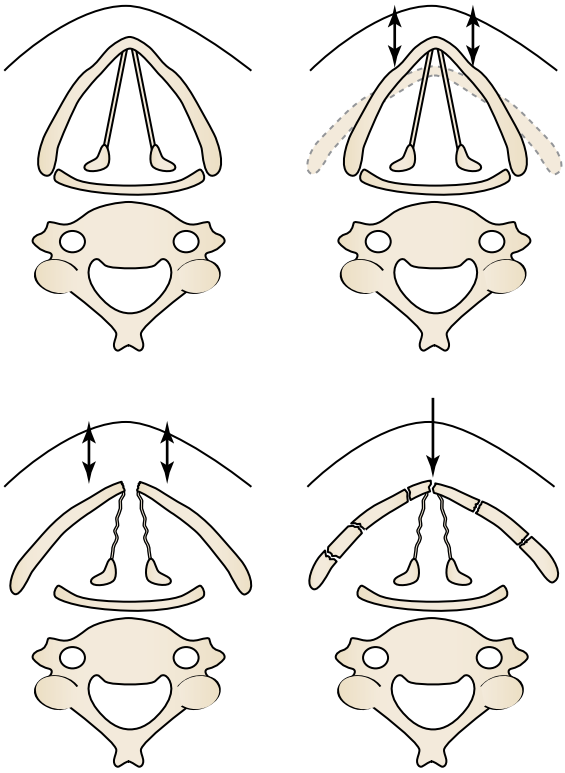

Figure 70-2. Impact of anterior cervical trauma on the larynx. *Top,* Uncalcified thyroid cartilage may spring back. *Bottom,* Calcified cartilage may shatter, and the larynx appears flattened.

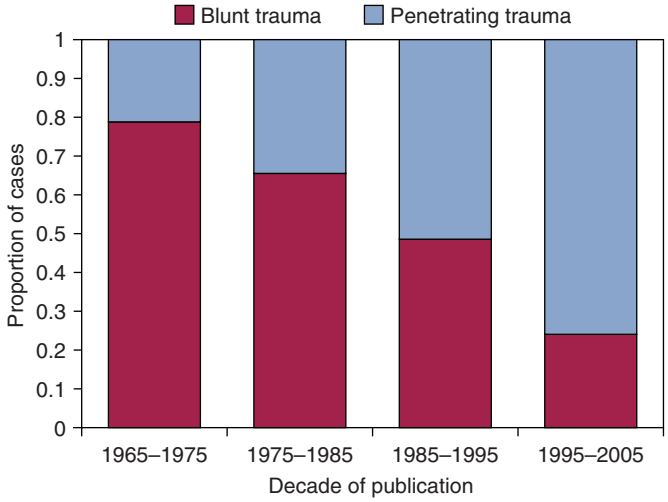

Figure 70-3. Change in the relative composition of blunt and penetrating laryngeal trauma as reported in several sources from 1965 through 2005. *(Data from references 2, 3, 6, 8, 9, and 16-21.)*

Being often asymmetric in respect to the extent of calcification of both the inner and outer surfaces of the thyroid cartilage and each hemilamina,[11] laryngeal calcification increases the likelihood of fractures after trauma and creates stress risers that can cause framework comminution. Motor vehicle accidents have historically been the main cause of external laryngeal trauma.[12] The injury typically occurs when a person not wearing a seat belt or wearing only a lap belt is subjected to rapid deceleration, which thrusts the hyperextended neck onto the dashboard or the steering wheel.[13] Other causes of blunt external laryngeal trauma are clothesline injury (in which the rider of a motorcycle encounters a fixed horizontal object at neck level), sports-related injuries,[14] and suicidal or homicidal strangulation. Penetrating laryngeal trauma is due predominantly to interpersonal violence in civilian practice and is the main cause of laryngeal injuries sustained in the theater of war.[15] Over the past four decades the composition of laryngeal trauma in the United States has changed substantially, due on the one hand to reductions in speed limits, mandatory seat belt laws, and better public education—reducing the incidence of blunt trauma due to motor vehicle accidents—and on the other hand to an increase in penetrating trauma secondary to a greater use of guns and knives (Fig. 70-3).[2,3,6,8,9,16-21]

Diagnosis

Pertinent Features in the Mechanism of Injury

The mechanism of injury has a significant bearing on the likely pattern and severity of laryngeal trauma. Speed and configuration of the vehicles involved in an accident and the use of lap and shoulder seat belts should be determined. Clothesline injuries are often associated with major trauma to the neck because they impart a large force over a small area.[22,23] There are also significant differences in the pattern of injury

Table 70-1

Symptoms and Signs of External Laryngeal Trauma in 33 Cases

Symptom or Sign	No. of Cases (%)
Hoarseness	28 (85)
Dysphagia	17 (52)
Pain	14 (42)
Dyspnea	7 (21)
Hemoptysis	6 (18)

From Juutilainen M, Vintturi J, Robinson S, Back L, Lehtonen H, Makitie AA. Laryngeal fractures: clinical findings and considerations on suboptimal outcome. *Acta Otolaryngol.* 2008;128:213-218.

between suicidal and homicidal strangulation,[24] with the latter being more likely to cause laryngotracheal separation and concomitant neurovascular injuries. Strangulation injuries can cause loss of airway due to laryngeal edema some time after the event, despite minimal initial findings. Penetrating trauma is more likely to damage additional cervical structures, with the extent of injury being proportional to both the weight and velocity of the penetrating projectile ($E = \frac{1}{2}\ mv^2$, where E is energy, m is mass, and v is velocity). As such, information about the type of weapon used and the distance from which it was fired is useful. With knife injuries, information about the blade and depth of entry is helpful.

Symptoms of Laryngeal Trauma

Laryngeal trauma manifests as a spectrum of symptoms and signs ranging from cardiopulmonary arrest due to airway obstruction to subtle changes in voice quality. The most common presenting feature of laryngeal trauma is hoarseness, followed by dysphagia and pain (Table 70-1).[5]

Examination and Initial Management

Examination and initial management of laryngeal trauma should be part of primary and secondary surveys according to Advanced Trauma Life Support guidelines, to ensure that concomitant injuries are not missed (Table 70-2).[4] The over-riding priority is to establish a safe airway with cervical spine protection, which may, and often does, necessitate performing an emergency tracheotomy with the use of local anesthesia. Endotracheal intubation is not a preferred method of airway control in laryngeal trauma, because it can exacerbate a laryngeal injury[25] and precipitate total airway obstruction. Endotracheal intubation can be particularly difficult to perform in the presence of concomitant maxillofacial injuries in a patient with an immobile neck. If endotracheal intubation has been performed, it is converted at the earliest opportunity to a tracheotomy to prevent long-term laryngeal injury. In selected cases transtracheal jet ventilation or cricothyroidotomy may be a helpful temporizing measure. No manipulation of the neck is permissible until the cervical spine has been "cleared"—that is, until injuries to the cervical spine have been ruled out in a systematic manner.

The neck is inspected for evidence of injury such as skin abrasions, bruising, and entry and exit wounds in penetrating trauma, and is palpated for crepitations, laryngeal tenderness, and any obvious changes in laryngeal anatomy, such as loss of the prominence. Open wounds should not be explored at this stage because instrumentation may restart hemorrhage. Flexible nasoendoscopy is then performed, and the oropharynx and hypopharynx are examined for injuries. The laryngeal mucosa is examined for lacerations and hematomas, and particular care is taken to assess the vibratory edge of the vocal cords and the anterior commissure. Arytenoid adduction is examined during phonation, and abduction is assessed by asking the patient to sniff. Impairment of arytenoid mobility may be secondary to structural damage or due to recurrent laryngeal nerve injury. Note is taken of any exposed or protruded cartilage or submucosal distortion of the framework. A sign of cartilaginous injury is failure of the vocal cords to meet in the same horizontal plane.

Table 70-2

Concomitant Primary Diagnoses Recorded along with Laryngeal Trauma

Injury	Percentage of Cases
Open neck injury	18
Maxillofacial fractures	18
Intracranial injuries	17
Cervical spine fracture	13
Chest injury	13
Other facial injury	10
Skull fracture	7

Box 70-1

National Emergency X-Radiography Utilization Study (NEXUS) Criteria for Cervical Spine Imaging in Trauma Patients

According to NEXUS low-risk criteria, cervical spine radiography is indicated for trauma patients unless they exhibit *all* of the following criteria (sensitivity 99%):

- No posterior midline cervical tenderness
- No evidence of intoxication
- Normal level of alertness
- No focal neurological deficit
- No painful distracting injuries

Use of Computed Tomography

In our practice, multislice computed tomography (CT) (Fig. 70-4) is performed in all patients presenting with "impending airway obstruction" once their airways have been secured, and in those patients with "stable airway" who are found, on flexible nasoendoscopy to have endolaryngeal abnormalities, because imaging may reveal further injuries not readily identifiable with flexible nasoendoscopy. CT scanning can be deferred only in those patients with a history of relatively minor trauma to the neck, no laryngeal tenderness or surgical emphysema, stable airway, and the finding of minimal laryngeal injuries on flexible laryngoscopy. It is important to appreciate that laryngeal trauma is associated with a cervical spine fracture at a rate approaching 10%.[4] At the same time, injuries that occur close to the cervical spine are known to be more likely to mask a spinal injury than injuries further away.[26] We take the view therefore that all but the most minor of laryngeal injuries constitute a "distracting injury" and mandate cervical spine radiography under National Emergency X-Radiography Utilization Study (NEXUS) criteria (Box 70-1).[27] Our practice of using CT to clear the cervical spine irrespective of plain radiography findings is informed

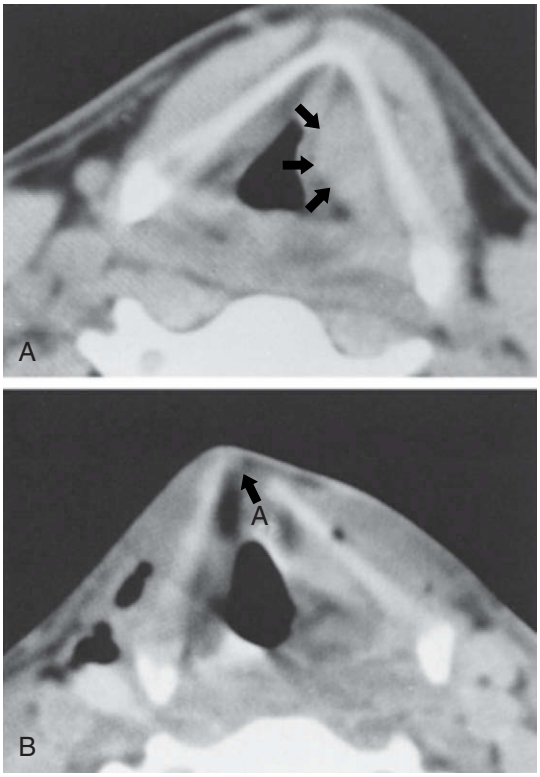

Figure 70-4. A, Computed tomography shows a hematoma involving the right vocal fold (*arrows*) with the thyroid cartilage intact. The injury was completely resolved with only medical management. **B,** Fracture of the right anterior thyroid lamina with angulation (A, *arrow*) is seen. The management consisted of open reduction and internal fixation.

by a growing body of evidence demonstrating a much higher sensitivity for CT over plain radiography in diagnosing spinal injuries.[28,29] Overall, therefore, detailed radiologic imaging of the larynx is available in the majority of patients with laryngeal trauma both because of primary laryngeal indications and as a by-product of "clearing" of the cervical spine.

Classification

Laryngeal trauma can be classified according the Schaefer-Fuhrman[25,30] (Table 70-3) or Lee-Eliashar[31] system. We use the Schaefer-Fuhrman system but also formally and separately document the extent of injuries to the laryngeal mucosa and framework, the vibratory mechanism, and the laryngotracheal complex (Table 70-4).

Management

Airway Management

The first priority in managing laryngeal trauma is to assess and secure the airway while protecting the cervical spine. We take a stepwise approach to securing the airway based on information available at the different stages of clinical assessment (Fig. 70-5). A stridulous patient with respiratory distress at presentation should immediately undergo tracheotomy with local anesthesia. If the airway is judged to be stable following initial history and examination, the patient undergoes flexible nasoendoscopy. In a small number of cases, unexpected airway-encroaching injuries are identified at this stage and tracheotomies are performed. More subtle endolaryngeal injuries are further assessed with CT, and again, if airway-encroaching injuries are identified, a tracheotomy is performed.

Surgical versus Nonsurgical Therapy.

The decision as to the most appropriate therapy for laryngeal trauma rests on assessing the stability of, and the extent of injury to, the *laryngeal framework*, the extent of *mucosal injuries*, the presence of injury to the *vibratory apparatus*, and the integrity of the *laryngotracheal junction*. Jewett and colleagues[4] showed that 37% of patients with laryngeal trauma could be managed with no airway intervention and that a further one sixth of patients required only a tracheotomy.

Table 70-3

Schaefer-Fuhrman Classification of Laryngeal Trauma

Group 1	Minor endolaryngeal hematomas or lacerations No detectable fracture
Group 2	Edema, hematoma, minor mucosal disruption without exposed cartilage Nondisplaced fracture Varying degrees of airway compromise
Group 3	Massive edema, large mucosal lacerations, exposed cartilage Displaced fracture(s) Vocal cord immobility
Group 4	Same as group 3 but more severe with: Severe mucosal disruption Disruption of the anterior commissure Unstable fracture, two or more fracture lines
Group 5	Complete laryngotracheal separation

Conservative Management

Patients in whom nasoendoscopy has found the endolarynx normal, as well as patients with minimal endolaryngeal abnormalities and a stable laryngeal framework whose airway patency has been confirmed by CT, can be conservatively managed (see Fig. 70-5). Conservative management consists of a minimum of a 24-hour admission to a high-dependency unit, with regular observations, serial flexible nasoendoscopy examinations, and use of humidified oxygen. A mixture of oxygen and helium should be on standby in case respiratory embarrassment develops. The patient's head is elevated to reduce further edema, and corticosteroids are administered if presenting within 24 hours of injury. All patients are prescribed a proton pump inhibitor and, if the laryngeal mucosa has been breached, are also given prophylactic broad-spectrum antibiotics.

Surgical Management

Patients with more significant injuries require surgical intervention. The optimal timing of repair is a subject of debate, and in patients with polytrauma, laryngeal surgery may have to be coordinated with other procedures. We aim to repair all laryngeal injuries within 12 hours of presentation and are reluctant to accept delays beyond 24 hours. Delays in treatment can lead to granulation and scar tissue formation, which can progress to laryngeal stenosis (Fig. 70-6), a difficult surgical problem to correct.

DIAGNOSTIC OR THERAPEUTIC ENDOSCOPY. All patients who are not managed conservatively should undergo microlaryngoscopy and tracheoscopy, direct pharyngoscopy, and direct esophagoscopy. In a proportion of patients definitive, endolaryngeal treatment can be undertaken endoscopically. Hematomas can be drained, mucosal and selected vocal cord lacerations can be repaired, and dislocated cricoarytenoid joints can be reduced. If there have been extensive injuries to opposing laryngeal mucosal surfaces, stents can also be deployed endoscopically to prevent adhesions.[32]

OPEN LARYNGEAL REPAIR. The main indications for open repair are unstable or comminuted laryngeal fractures, cricotracheal separation, detachment of the anterior commissure, and extensive mucosal

Table 70-4

A Systematic Approach to Documenting Laryngotracheal Injuries and Determining the Need for Surgical Intervention

Laryngeal framework	Stable: No fractures A single undisplaced fracture Unstable: A single displaced fracture >1 fracture line Cricoid fracture Potentially nonviable: Framework comminution with devitalized cartilage fragments
Laryngeal mucosa	Intact/minimally injured: No mucosal injuries Small submucosal hematoma Linear laceration with no exposed cartilage Injured: Jagged/multiple linear lacerations Large hematoma(s) Exposed cartilage Massively injured: Significant loss of mucosa Devitalized mucosal tissue
Vibratory apparatus	Intact Injured: Anterior commissure Vibrating edge of the vocal cord(s) Arytenoid dislocation
Laryngotracheal junction	Intact Any degree of laryngotracheal separation

disruption. For open exploration, a transverse neck incision is placed over the cricoid, and subplatysmal flaps are elevated. Strap muscles are separated in the midline and retracted. In some patients with unstable laryngeal fractures but with minimal or endoscopically treatable endolaryngeal injuries, a thyrotomy can be avoided. Repair of the anterior commissure or significant endolaryngeal injuries is achieved through an anterior vertical laryngofissure. However, a paramedian fracture close to the midline may also be used. Hematomas are evacuated and mucosa tears repaired with 5-0 or 6-0 absorbable sutures. Mucosal loss can often be reconstructed with local mucosal flaps, and, in particular, posterior commissure injuries can and should be reconstructed with piriform fossa or supraglottic mucosa to prevent laryngeal stenosis. The anterior margins of the vocal folds are attached to the anterior limit of the thyroid cartilage or its outer perichondrium with a slow-absorbing monofilament suture. It is very important to reestablish the appropriate height of the vocal folds to optimize voice outcomes. Thyroid cartilage fractures are repaired with the use of permanent or resorbable miniplates. Even in the older patient, the cricoid arch is not fully calcified and can be repaired with suture material alone (Fig. 70-7).

ENDOLARYNGEAL STENTING. The indications for stenting are controversial because the need for endolaryngeal support must be weighed against the potential for further mucosal injury. Our primary indication for stenting is significant framework comminution. Stents can also be used to prevent anterior commissure webbing in cases of bilateral vocal fold epithelial loss. We prefer to use soft polymeric silicone (Silastic) stents for this purpose (Figs. 70-7B and 70-8) in order to *minimize* further mucosal injury and foreign-body reaction associated with the use of stents fashioned from endotracheal tubes. Endolaryngeal stents are commercially available but can also be fashioned from the vertical limb of a Montgomery T-tube that is oversewn at the top. The stent is held in place with a 2-0 polypropylene (Prolene) suture passed through the anterior stent and laryngeal ventricles and knotted over the larynx after closure of the laryngofissure. The stent is removed endoscopically 10 to 14 days later. The securing suture can be cut flush with the endoluminal airway or removed via a small neck incision.

TREATMENT OF VOCAL CORD IMMOBILITY. Vocal cord mobility can usually be determined during preoperative flexible laryngoscopy. Cricoarytenoid joint mobility can be assessed preoperatively, but definitive assessment of joint mobility requires microlaryngoscopy and instrumentation. Vocal cord immobility due to cricoarytenoid joint dislocation can often be managed with endoscopic manipulation and reduction. Recurrent laryngeal nerves can be severed in penetrating trauma or during cricotracheal separation, or crushed during laryngeal trauma. Only if a complete palsy is confirmed should exploration of the affected nerve be considered. Anatomically intact nerves should be allowed to regenerate. When possible, severed nerves should be repaired in a tension-free manner. If such repair is not possible, a cable graft using the greater auricular or sural nerve should be considered. The other option is to consider ansa cervicalis–recurrent laryngeal nerve repair. Nerve repairs do not restore the intricate motor function of the larynx but may provide sufficient muscle tone to improve vocalization.

MANAGEMENT OF CRICOTRACHEAL SEPARATION. After surgical exposure in a patient with cricotracheal separation, a tracheotomy is fashioned or moved to a healthy part of the lower trachea prior to reanastomosis. A small reinforced endotracheal tube is placed through the tracheotomy for ventilation during surgery and is replaced with a small tracheotomy tube at the end of the procedure. The surgeon begins the repair with the posterior anastomosis, using a combination of 3-0 absorbable and nonabsorbable sutures, and works toward the anterior trachea (see Fig. 70-7C). All knots are extraluminal, and the sutures are run through the submucosal plane. Avascular and damaged tissue is resected. If there is an associated crush injury to the trachea, a temporary soft polymeric silicone stent may have to be placed in the lumen prior to anastomosis.

PARTIAL OR TOTAL LARYNGECTOMY. In cases of massive laryngeal injury with significant tissue loss (Fig. 70-9), partial or total laryngectomy may be indicated, although this situation is rare in civilian practice.[9]

Postoperative Care

Any repairs to the vocal folds should be followed by strict voice rest for 48 to 72 hours. A nasogastric tube should be inserted at the time of surgery and should remain in situ until the safety of swallowing is confirmed. All patients with mucosal tears should be started on antireflux and prophylactic antibiotic therapy. The patient is nursed in the head-up position to minimize edema, and standard tracheotomy care is provided. Early ambulation is encouraged. Stents are removed at 10 to 14 days, and the patient is decannulated. Regular endoscopic examinations are undertaken, during which granulation tissue is removed to prevent long-term scarring. In patients with cricotracheal separation, the neck is kept in flexion for 7 days postoperatively to prevent traction on the anastomosis. A large monofilament suture from the submental skin to the anterior chest skin, placed at the time of surgery, may be necessary for the first few days after surgery. The tracheotomy can be removed at 7 days, and the airway stent can be removed endoscopically at 10 to 14 days.

Sequelae

All patients with laryngeal trauma should be regularly monitored for a minimum of 12 months. Long-term morbidity occurs from any combination of laryngeal stenosis, dysphonia, and aspiration, owing to both structural and neurovascular injuries. Vocal cord paralysis should be

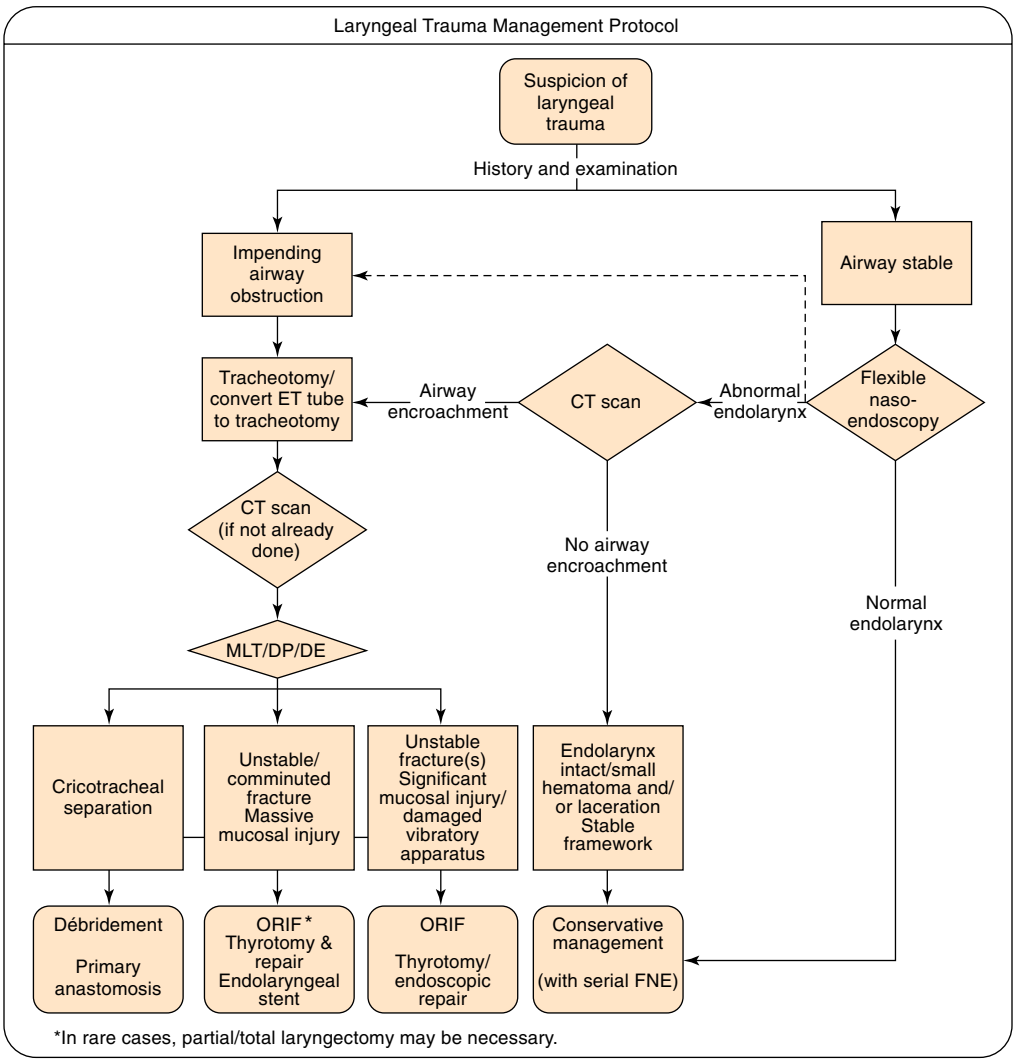

Figure 70-5. A proposed protocol for managing laryngeal trauma. CT, computed tomography; DE, direct esophagoscopy; DP, direct pharyngoscopy; ET, endotracheal; FNE, flexible nasoendoscopy; MLT, microlaryngoscopy; ORIF, open reduction and internal fixation.

carefully observed for recovery, and in patients with a normal vibratory apparatus structure and unilateral vocal cord paralysis, definitive medialization procedures should be attempted only after 9 to 12 months of observation for functional recovery. In the interim, the voice can be temporarily improved by collagen or fat injection. In cases of bilateral vocal cord palsy causing laryngeal inlet obstruction, consideration should be given to retaining the tracheotomy in preference to performing an early laser arytenoidectomy, in anticipation of return of vocal cord function. Laryngeal stenosis due to posterior commissure or tracheal granulation tissue should be promptly treated with intralesional steroid injections and reduction of granulation tissue. The granulation tissue should not be allowed to mature into a scar, because it is a much more difficult problem to manage.[33] In our experience, the most difficult injury to manage is laryngeal inlet obliteration (Fig. 70-10), followed by interarytenoid scarring or webbing (Fig. 70-11). The treatment of glottic stenosis is almost always a compromise between voice, airway, and swallowing; gains in one domain are often made at the expense of another.

Outcome

Outcome depends both on the nature and severity of the original injury and on whether it was promptly recognized and adequately treated. Schaefer[9] and more recently, Juutilainen and colleagues[5] found that the voice outcome, but not the airway outcome, correlates with the severity of the initial injury as determined by Schaefer's classification system (Table 70-5), whereas Bent and associates[8] reported that intervention within 48 hours was associated with an improved outcome. Delays in intervention can lead to complete laryngotracheal stenosis (Fig. 70-12).

Special Considerations in Pediatric External Laryngeal Trauma

The larynx lies at the level of C3 in the neonate and descends during the first 3 years of life to its adult position at the level of C6. The pediatric larynx is smaller in absolute and relative dimensions compared with the adult larynx. Furthermore, laryngeal mucosa is less firmly adherent to the cartilaginous framework in infants and children than in adults. The result of this combination of factors is that, although the pediatric larynx is better shielded and is therefore less liable to injury, an injury is more likely to result in loss of the airway owing to mucosal edema and hematoma formation.[7,34] Furthermore, it is usually not possible to perform a tracheotomy with use of only local anesthesia in a child. The child is therefore managed along the same lines as a patient with acute epiglottitis. The surgeon is prepared for an emergency tracheotomy, but in most cases the airway can be secured with an endotracheal tube or ventilating bronchoscope, followed promptly by a tracheotomy performed using general anesthesia. CT scanning may then be considered prior to airway reconstruction. As with adult patients, selected, more limited injuries can be managed endoscopically and without tracheotomy.[35]

Iatrogenic Laryngeal Trauma

Incidence

Despite major advances in the design of endotracheal tubes and developments in the management of difficult airways, endotracheal intubation remains by far the most common cause of laryngeal trauma. Approximately 10% of patients have demonstrable laryngeal pathology 1 day following short-term intubation for surgery.[36] With longer-term intubation and mechanical ventilation for critical illness, the incidence of laryngotracheal injuries approaches 90%, with long-term sequelae occurring in 11% of patients.[37] The annual incidence of postintubation laryngotracheal stenosis requiring surgical correction is 1 in 204,000 in adults[38] and 4.9 in 100,000 in children.[39]

Etiology

Endotracheal intubation can cause pharyngeal or laryngeal lacerations, cricoarytenoid joint dislocation, and neuropraxia of the lingual, hypoglossal, and laryngeal nerves. There is no period of endotracheal intubation before which no injury occurs, and after which injury is inevitable. The subglottis is the narrowest part of the pediatric airway, accounting for the fact that most postintubation injuries in children occur at this level. In adults, translaryngeal intubation can lead to pressure necrosis, most commonly of the medial surface of the posterior commissure, on which the tube rests.[40] This can lead to perichondritis, granulation tissue formation,[41] and, in a proportion of patients, interarytenoid scarring and airway compromise due to bilateral vocal cord immobility (see Fig. 70-11). Intubation trauma can also cause bilateral intubation granulomas, which can coalesce to fix the vocal cords in adduction (Fig. 70-13). The larynx can also be injured by a poorly sited tracheotomy either through or adjacent to the cricoid cartilage, with the potential for subglottic airway stenosis. Another iatrogenic cause of laryngeal injury is aggressive treatment of benign laryngeal diseases such as respiratory papillomatosis. Excessive damage to the epithelium can lead to laryngeal scarring with the potential to affect the voice or airway.

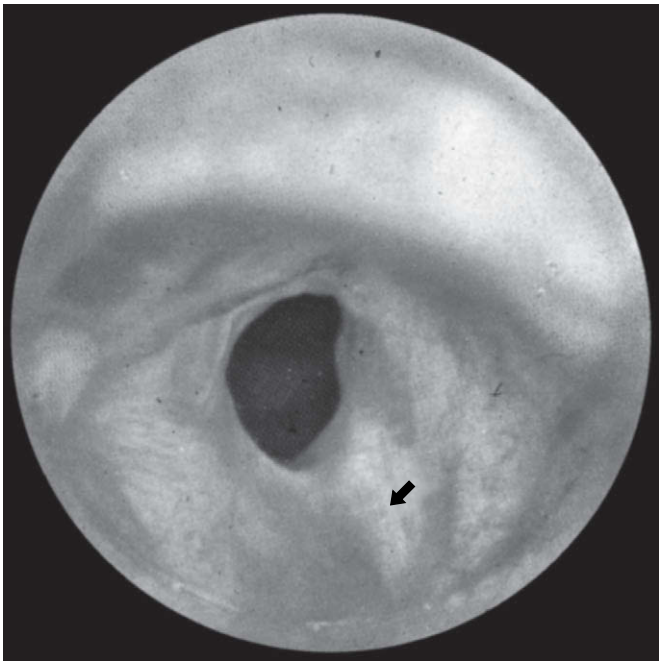

Figure 70-6. Post-traumatic laryngeal stenosis. The *arrow* points to the remnant of the right arytenoid cartilage.

Management

A detailed account of the management of laryngotracheal stenosis is given elsewhere. Laryngeal stenosis—in particular, posterior commissure stenosis due to interarytenoid scarring (see Fig. 70-11)—carries a poor prognosis. Tracheal stenosis, which predominantly affects the airway, is amenable even in its more severe forms to curative therapy with minimal long-term sequelae.[42] Treatment of laryngeal stenosis, as discussed previously, involves compromise among voice, airway, and swallowing functions, and gain in one domain is often achieved through compromise in the function of another. As such, prevention is the best approach in relation to this injury. Posterior commissure stenosis occurs exclusively with translaryngeal intubation, and the likelihood of its occurrence can be significantly reduced by performing early tracheotomy in the intensive care unit. Although tracheotomies are not without complications themselves and can precipitate airway stenosis, tracheotomy-related airway stenosis carries a much better outlook than laryngeal stenosis,[43] and from a laryngologic perspective, preventing the latter injury is sufficient justification to recommend universal early tracheotomy in patients receiving mechanical ventilation for a protracted period. This recommendation is also supported by the findings of a randomized controlled trial that patients undergoing mechanical ventilation who received early tracheotomy (<48 hours) had a 30% absolute risk reduction in mortality and a fivefold reduction in pneumonia in comparison with patients who had prolonged translaryngeal intubation.[44]

Caustic or Thermal Laryngeal Trauma

Incidence

Upper aerodigestive tract injury due to ingestion of caustic substances occurs in 5000 to 15,000 persons in the United States annually, and

Figure 70-11. Postintubation laryngeal stenosis due to interarytenoid scarring.

the majority of injuries are caused by ingestion of alkaline substances.[45] The larynx is involved in approximately 40% of cases.[46] Thermal injury to the larynx is a result of inhaling superheated air. Inhalation burns occur in 30% of all patients with burns, and 20% of patients with inhalation injury have extensive laryngeal injury. A further 7% of patients with inhalation injury have both laryngeal and tracheobronchial injuries.[47]

Etiology

Ingestion of alkali causes liquefaction necrosis of muscle, collagen, and lipids and creates an injury that worsens with time. By contrast, acids cause coagulation necrosis of the superficial tissues. Ingestion of a caustic substance is virtually always accidental in children, in whom small amounts of liquids are taken, but is almost always due to attempted suicide in adults, in whom large volumes of liquid are

involved.[46] The type of liquid taken varies widely with geography, alkaline ingestion being more common in developed countries and acid ingestion in developing countries.[45,48] Inhalation injury typically is a consequence of fires in closed spaces and causes a sixfold increase in the mortality rate associated with the burn.[47]

Figure 70-13. Coalescence of intubation granulomas, as seen at extubation, causing acute airway compromise due to bilateral vocal cord immobility in adduction.

Management

All patients with caustic or thermal laryngeal injuries should be admitted for a minimum of 24 hours for airway observation. The first priority is the establishment of a safe airway, followed by cardiovascular resuscitation as per standard burn care protocols. Presence of facial or body burns and soot in the oral cavity and finding at endoscopy of laryngeal edema predict the need for airway intervention.[49] Endotracheal intubation plays an even lesser role in management of these cases than in cases of external laryngeal trauma. Arevalo-Silva and colleagues[46] found a 100% association between endotracheal intubation and subsequent tracheotomy for airway stenosis in patients with laryngeal injury due to caustic ingestion. The situation with airway management in thermal injuries is somewhat less clear, because there have been reports of higher stenosis rates with tracheotomy than with intubation in patients with inhalation injury.[50] However, unless there are strong contraindications to performing a tracheotomy, such as extensive cervical burns, we iterate the view that because glottic stenosis has a far worse prognosis than tracheal stenosis, a possible increase in the change of post-tracheotomy stomal stenosis is an acceptable tradeoff.

If patients are to undergo microlaryngoscopy, tracheobronchoscopy, or esophagoscopy, the procedure should be performed within 24 hours of injury. Beyond this period edema and ulceration are more marked, and instrumentation may exacerbate subsequent problems. The upper aerodigestive tract should be irrigated in cases of caustic injury to remove any residual substances. Further treatment depends on the nature and extent of injuries found and the consequences of healing and scarring.

Caustic and thermal injuries can cause laryngeal and tracheal airway strictures, whose severity is reported to be greater than that of strictures associated with postintubation laryngotracheal stenosis.[51] Dysphonia is present in as many as 70% of patients with inhalation injuries 16 to 25 years after initial injury.[52]

Esophageal Trauma

Traumatic Injuries

Esophageal injuries are reported in 14% of patients with laryngotracheal trauma[8] and 6.5% of patients with penetrating trauma to the neck.[53] Isolated esophageal trauma due to external trauma to the neck is uncommon, but it can occur as a result of barotraumatic perforation of Killian's

dehiscence and injury caused by the thyroid cartilage. Iatrogenic injuries also occur from attempted endotracheal intubation and esophagoscopy.

Cervical crepitus or surgical emphysema often accompanies esophageal injury, although both signs occur more commonly in patients with hypopharyngeal and laryngeal injuries.[54] Other presenting features are pain, dysphagia, and aspiration, and patients with a delayed presentation or diagnosis may also exhibit symptoms and signs of sepsis. Plain radiographs and CT scans of the neck and chest may demonstrate surgical emphysema, pneumomediastinum, or pneumothorax, all of which point toward the diagnosis, although in many cases esophageal injury is identified during panendoscopy or following radiocontrast swallow studies.

Conservative management, consisting of "nothing by mouth" status, broad-spectrum antibiotics, and peripheral nutrition, is the cornerstone of managing esophageal injuries, provided that they are recognized early. When there has been a significant delay in presentation or recognition of the injury, and the patient exhibits signs of infection, exploration and drainage of any purulent collection is urgently indicated. Nothing by mouth status is usually maintained for 8 to 10 days, and healing is assessed with a radiocontrast swallow study. The prognosis of traumatic cervical esophageal injuries is favorable, and survival rates between 90% and 100% have been reported.[54]

Caustic Injuries

Details about the incidence and etiology of caustic upper aerodigestive tract injuries were given in the discussion of caustic and thermal laryngeal injuries. The management of caustic ingestion depends on the extent of injury. Esophageal injuries can be endoscopically graded as follows[46]:

- Normal
- First-degree injury: of mucosal erythema
- Second-degree injury: erythema with noncircumferential exudation
- Third-degree injury: circumferential exudation
- Fourth-degree injury: circumferential exudation with esophageal wall perforation

As many as 30% of patients with caustic esophageal injury do not show any evidence of oropharyngeal damage,[48] so the absence of oropharyngeal injury does not exclude an esophageal injury. Evaluation with the patient under anesthesia should be deferred unless it can occur within 24 hours of injury,[48] and endoscopes should not be forced beyond areas of circumferential mucosal injury. The earliest opportunity should be taken to irrigate the upper aerodigestive tract to remove any remaining caustic substances. The severity of injury is greater in adult patients than in children, given the fact that caustic ingestion in adults almost exclusively occurs in the setting of attempted suicide, in which large volumes of the caustic substance are taken. Management consists of insertion of a large-bore nasogastric tube to maintain esophageal patency, steroids, broad-spectrum antibiotics, and antacid therapy.[46] In the most severe cases, esophageal resection with gastric pull-up or bypass surgery may be necessary.[55] Peripheral nutrition is continued until safety of swallowing is confirmed.

The incidence of esophageal stricture after caustic ingestion is 10% to 35%.[46,56] In many cases the stricture can be managed with endoscopic dilatation. It is very important to note, however, that as many as 1 in 7 patients with a caustic esophageal stricture go on to have esophageal carcinoma.[57] Many authorities therefore advocate regular esophageal surveillance after caustic ingestion, although the latent period for the development of cancer may be as long as 50 years.[58]

CHAPTER SEVENTY-ONE

Surgical Management of Upper Airway Stenosis

Ayesha N. Khalid

David Goldenberg

Key Points

- Accurate preoperative assessment of laryngotracheal stenosis is critical to a successful repair, including use of multiple staging systems to evaluate diameter and levels of airway stenosis.
- The primary goals of surgical intervention are to establish an adequate airway and enable eventual decannulation.
- Timing of surgical intervention is important; chronic airway stenosis may be electively repaired following proper preoperative evaluation of possible inflammatory and autoimmune etiologies in idiopathic stenosis cases.
- The advent of endoscopic microlaryngeal instrumentation has enabled photodocumentation and decreased morbidity of neck incisions when performed by experienced surgeons.
- Laryngeal lesions may undergo microsurgical débridement or laser therapy, and each technique has its advantages and disadvantages; similarly topical applications (such as mitomycin C).
- Successful surgical repair hinges on providing an adequate skeletal framework as scaffolding, followed by the need for grafts to avoid scarring and tethering.
- Sources of cartilage grafts include vascularized thyroid and hyoid, as well as auricular and nasal cartilages. Sources of muscular flaps (for example, skin) and mucosa may also be utilized.
- Stents are useful in limited instances, with the need to maintain a patent airway being balanced by risk of ischemic mucosal injury and increased risk of infection of underlying grafts.
- Controversy surrounding the effect of endotracheal intubation leading to airway stenosis from compression has led to improvements in endotracheal tube design, with the largest impact on the size of the tube and its cuff on the posterior glottic region.
- Traumatic laryngotracheal stenosis may lead to airway stenosis, with surgical intervention ranging from tracheotomy to tracheal resection with postoperative stent placement.

Successful repair of upper airway stenosis requires establishing an adequate airway while preserving the laryngeal functions of airway protection, phonation, and sustained glottic closure to increase intrathoracic pressure. Laryngotracheal injuries vary widely and can differ in location, severity, duration, cause, and extent of functional impairment. Selection of the appropriate surgical repair should consider all these factors within the context of the patient's concurrent injuries and medical stability.

Pathophysiology

Adult laryngotracheal stenosis has numerous etiologies (Box 71-1). The pathophysiology of the specific cause plays a role in the timing of surgical management as well as the surgical procedure chosen.

The most common causes of laryngotracheal stenosis are external trauma to the neck and prolonged endotracheal intubation. Both may result in acute stenosis and chronic stenosis; which occur through different pathophysiologic processes. Anatomically, the larynx and trachea can be regarded as a semirigid tubular structure. When the laryngotracheal complex is injured by external trauma, disruption of the cartilaginous framework, hematoma in the laryngeal spaces, and mucosal disruption usually result. Resorption of the hematoma can cause cartilage loss and extensive deposition of collagen. Subsequent scar contracture leads to stenosis and loss of mobility. The location, mechanism, and severity of the laryngeal injury caused by external trauma vary.[1]

In contrast, the injury from endotracheal intubation is usually initiated by ischemic necrosis of the mucosa from pressure of the cuff of the endotracheal tube or the endotracheal tube itself.[2] Mucosal ulceration in the presence of bacterial infection can lead to perichondritis and chondritis with subsequent cartilage resorption. Healing occurs by secondary intention with subsequent submucosal fibrosis and scar contraction. Injuries from endotracheal intubation occur primarily in the posterior glottis as a result of pressure exerted by the wall of the tube and the pressure of the cuff on the tube's tip. The latter injury has been reduced significantly with low-pressure, high-volume cuffs. Other factors, including tube size and composition, duration of intubation, and laryngeal movement, contribute to the development of laryngotracheal stenosis. With the widespread acceptance and use of endotracheal intubation to provide ventilatory and airway support, efforts have been directed to modifying endotracheal tube design.[3]

Box 71-1

Causes of Adult Laryngeal and Upper Tracheal Stenosis

Trauma
External laryngotracheal injury
- Blunt neck trauma
- Penetrating wound of the larynx

Internal laryngotracheal injury
Prolonged endotracheal intubation
- Tracheotomy
- Surgical procedure
- Irradiation therapy
- Endotracheal burn
  - Thermal
  - Chemical

Chronic Inflammatory Disease
Bacterial diphtheria
Syphilis
Fungal histoplasmosis
Tuberculosis
Leprosy
Sarcoidosis
Scleroma

Benign Neoplasms
Intrinsic
- Papillomas
- Chondromas
- Minor salivary gland
- Neural

Extrinsic
- Thyroid
- Thymus

Malignant Neoplasms
Intrinsic

- Minor salivary gland
- Sarcomas
- Lymphoma

Extrinsic
- Thyroid

Collagen Vascular Diseases
Wegener's granulomatosis
Relapsing polychondritis
Other

Patient disease has also shown to be correlated with the development of subglottic and tracheal stenosis. Diabetes mellitus, congestive heart failure, and a history of stroke have been shown to be associated with a higher incidence of severe acute laryngeal injury from intubation. In some cases, this condition prompts early tracheotomy.[4] Laryngopharyngeal reflux in the setting of gastroesophageal disease has also been demonstrated to be a causative agent and potentiator of laryngotracheal stenosis. Treatment with H_2 blockers and proton pump inhibitors in the perioperative and acute injury phases has been demonstrated to prevent scar formation and subsequent contracture.[5]

Classification of Stenosis

Multiple staging systems exist for airway stenosis; these are based on function or location of the stenotic section. As shown in Table 71-1, the most prevalent is the Cotton-Myers classification; however, the McCaffrey system and others also add to the diagnostic and therapeutic plan in providing not only size of stenosis but location and inclusion of multiple subsites, which are associated with a poorer prognosis following surgery.

Table 71-1

Classification and Staging Systems for Airway Stenosis

Myers-Cotton Classification: circumferential stenosis limited to subglottic region	
Grade I	Obstruction of 0%-50% of the lumen
Grade II	Obstruction of 51%-70% of the lumen
Grade III	Obstruction of 71%-99% of the lumen
Grade IV	No detectable lumen; obstruction of 100% of the lumen
McCaffrey Classification: laryngotracheal stenosis based on the subsites and length of the stenosis	
Stage I	Subglottic or tracheal lesions < 1 cm long
Stage II	Subglottic lesions > 1 cm long
Stage III	Subglottic/tracheal lesions not involving the glottis
Stage IV	Glottic lesions
Lano Classificaiton: based on number of subsites involved	
Stage I	One subsite involved
Stage II	Two subsites involved
Stage III	Three subsites involved

Surgical Principles

Goals and Assessment

The goal of any surgical procedure addressing laryngotracheal stenosis is to establish a satisfactory airway, and eventually, to decannulate the patient. In addition, every effort should be made to preserve other important laryngeal functions—phonation, airway protection, and glottic closure. Surgical procedures designed to improve the airway often compromise other laryngeal functions. The anticipated overall function of the larynx should be carefully discussed with the patient so that expectations are reasonable.

Several factors should be considered, including the location, dimensions, and quality (soft vs. fibrous) of stenosis, associated vocal fold motion impairment, and extent of functional impairment. Initial evaluation should involve a thorough history that includes details of the degree of subjective impairment (perceived by the patient) along with objective measures (e.g., observing the patient walking 200 feet, climbing a flight of stairs, pulmonary function testing).[6] Pulmonary function testing is helpful in delineating the site of obstruction and severity of airway compromise (Fig. 71-1).

Physical examination, including an indirect laryngeal examination followed by direct laryngoscopy and bronchoscopy, is essential (Fig. 71-2). High-resolution computed tomography of the larynx and trachea may be useful in assessing the level and extent of the stenosis. Three-dimensional computed tomography with volume rendering or virtual endoscopy has been employed to evaluate the extent or severity of the stenosis.[7,8]

An important consideration is whether the site of stenosis requires reestablishment of structural support, usually by repositioning of existing cartilage or, more commonly, through the use of cartilage or bone grafts.[9] Even with grafts, the preservation of existing mucosa and the judicious use of antibiotics, stents, skin or mucosal grafts are all adjunctive treatments intended to minimize formation of granulation tissue, and subsequent deposition of collagen.

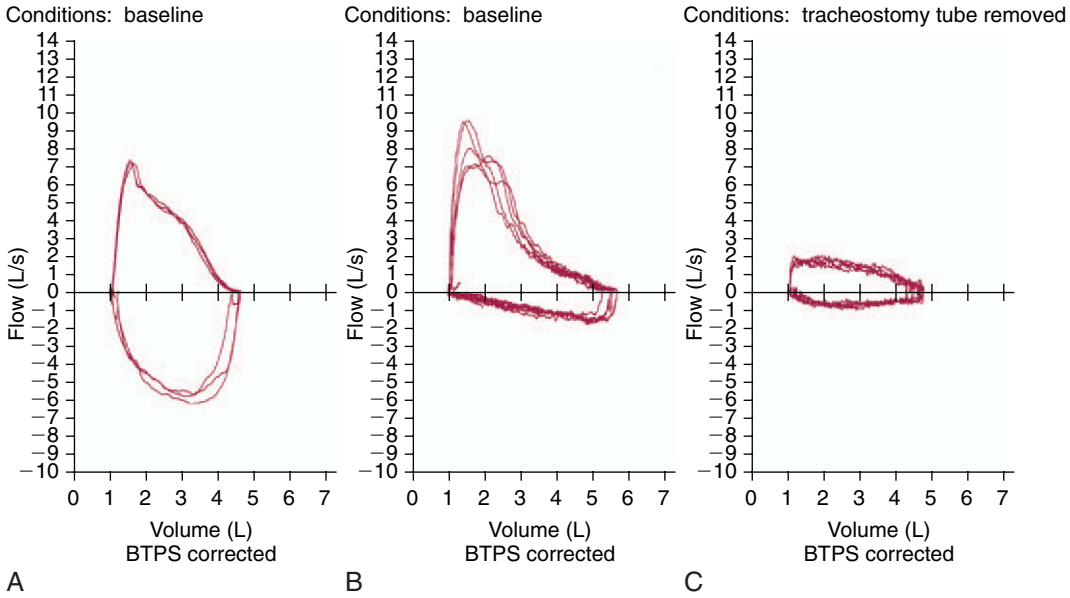

Figure 71-1. Flow-volume loop for assessing adequacy of the upper airway. **A,** Normal result shows expiratory flow, indicated by positive deflection, and inspiratory flow, indicated by negative deflection. **B,** Loop from a patient with bilateral vocal fold motion impairment shows variable extrathoracic obstruction with a mid–vital capacity inspiratory flow rate (Vi_{50}) of less than 1.5 L per second. **C**, Loop from a patient with an infiltrative tumor and a fixed obstruction. BTPS, body temperature, pressure saturation.

Timing of Repair

A chronic laryngotracheal stenosis repair is generally elective, once the appropriate workup is completed. The onset of symptoms may be insidious, depending on the extent of scar formation and contracture, and in intubated patients, several attempts at extubation usually fail, requiring tracheotomy.[13] Such patients subsequently cannot be decannulated or, after a brief decannulation, experience gradually progressive upper airway symptoms. Irreversible stenosis is usually diagnosed at this time, and repair can be performed electively after thorough evaluation. A key consideration is that patients with inflammatory or autoimmune diseases require stabilization of their underlying disease processes before surgical management of the stenosis.

Endoscopic versus Open Repair

Beginning in the 1940s, the literature describes the use of endoscopic division of webs and subsequent keel placement. These early endoscopic techniques included scar removal via instruments or lasers followed by application of mitomycin-C. The evolution of powered instrumentation such as better microlaryngeal instrumentation and refinements in laryngoscopes have both enhanced visualization and maneuvering and have led to an increase in the numbers of laryngeal lesions removed via endoscopic techniques that previously required open approaches. Duration of inpatient hospital stay and morbidity of procedures have both declined with endoscopic techniques; however, the skill and comfort level of the surgeon with these newer tools cannot be overemphasized.

The last few decades have seen the growing popularity of the carbon dioxide (CO_2) laser, which offers the advantages of delayed formation and maturation of collagen in wounds, thus allowing reepithelialization before scar formation as well as minimal deep tissue injury. The laser has enabled precise control of the areas removed and hemostasis with the aim of preserving existing mucosa that may be utilized for the repair. Limitations of the CO_2 laser include the risk of an airway fire, and the danger of the laser plume for the surgeon and hospital staff if they are working with infectious lesions.[10] In addition, it is often difficult to control thermal injury, which may result in perioperative edema and postoperative scarring of the vocal folds.[11] "Due to these risks," some authors advocate initial endoscopic management of chronic laryngotracheal stenosis, reserving open repair for patients whose stenosis does not resolve with endoscopic management.[12] The advantage of this approach is that an open surgical repair may be avoided in some instances; however, several endoscopic procedures may be required for long-term success. Current recommendations include treatment of mild stenosis (Cotton-Myer grades I and II) with endoscopic techniques. Failure of initial endoscopic technique is associated with previous surgery, circumferential scarring, loss of cartilaginous support, exposure of cartilage leading to chondritis, posterior inlet scarring with subsequent arytenoid fixation, postoperative bacterial infection, and initial poor choice of candidates, such as patients with combined laryngeal and tracheal stenosis or vertical scar length greater than 1 to 1.5 cm. With prudent choice of candidates and careful postoperative care and monitoring, success of decannulation at 1 year after endoscopic surgery for stenosis has risen from 60% to 65% to 80% to 85%.

Postoperative management should include antibiotics for 1 to 3 weeks, antireflux management, and subsequent wound reassessment in 6 weeks via endoscopy. Patients with more severe stenosis may be better served with an initial open technique, although this does not guarantee higher success rates in such difficult cases.

Box 71-2

Indications for and Contraindications to Usage of a Laryngeal Microdebrider

Indications

Internal laryngoceles
Tumor debulking
Supraglottic, glottic, subglottic, and tracheal lesions
Removal of polytetrafluoroethylene (Teflon) granulomas
Subglottic and tracheal stenotic lesions
Excision of tracheostomal granulation tissue
Respiratory papillomatosis
Laryngeal cysts
Anterior commissure lesions (only in conjunction with CO_2 laser or monopolar suction cautery for hemostasis)

Relative Contraindication

Vascular lesions

Microsurgical Débridement

Much like the impact of advanced instrumentation for endoscopic techniques in laryngeal surgery, the success of powered instrumentation in many arthroscopic procedures has led to the popularity of microsurgical debriders in airway surgery. This technique combines the use of flexible forceps and a microsurgical debrider with videoendoscopic control.[14] The debrider has a powered rotating blade and suction so that soft tissue lesions are aspirated into the tip of the blade and cleanly cut. Use of this instrumentation in endoscopic sinus surgery provided for more efficient and precise tissue removal and reduced injury to normal mucosa. Development of a laryngeal microsurgical shaver in the 1990s allowed for removal of bulky, exophytic laryngeal papilloma in patients with recurrent respiratory papillomatosis, obstructing carcinoma, and Reinke's edema.[15-17] In comparison with the carbon dioxide laser, the laryngeal microsurgical debrider eliminates the risk of airway fire because there is no laser plume and therefore a lower infectious risk for the operating room staff. Anecdotal data show that use of this instrument in patients with recurrent respiratory papillomatosis, which was previously treated with the laser, have less postoperative pain and a quicker return to a usable speaking voice. A decrease in operative time has also been observed, thus reducing both the patient's exposure to a general anesthetic and overall operating room costs.[18]

We use the microdebrider for many laryngeal lesions (Box 71-2) by maneuvering the rigid telescope with the laryngeal shaver, thus promoting camera steadiness and good visualization of the blade tip relative to the lesion as it is removed. Subglottic and tracheal stenotic lesions are typically removed with a surgical microdebrider (4-mm) subglottic blade to excise the fibrous scar. Softer, bulky lesions, such as laryngeal and tracheal papilloma, are rapidly removed with the 4.0-mm round window (skimmer) blade. Papillomas and other lesions involving the true vocal folds are removed with the 3.5-mm round window (skimmer) laryngeal blade (Figs. 71-3 and 71-4).

Local Application of Mitomycin C

Topical mitomycin C may be useful for the treatment and prevention of subsequent re-stenosis and scar formation in the larynx and trachea. Mitomycin C is an antineoplastic antibiotic that acts as an alkylating agent by inhibiting DNA and protein synthesis. It can inhibit cell division, protein synthesis, and fibroblast proliferation.[19]

The use of topical mitomycin C remains controversial, with one study demonstrating that after 15 months of mitomycin application, all patients had clinical improvement of symptoms without evidence of recurrence.[19] Another study performed on the pediatric airway found no statistical difference between a single topical dose of mitomycin and isotonic sodium chloride after laryngotracheal reconstruction.[20] Animal studies have shown a statistically significant reduction in the rate of restenosis after surgical lysis with the use of mitomycin C.[21]

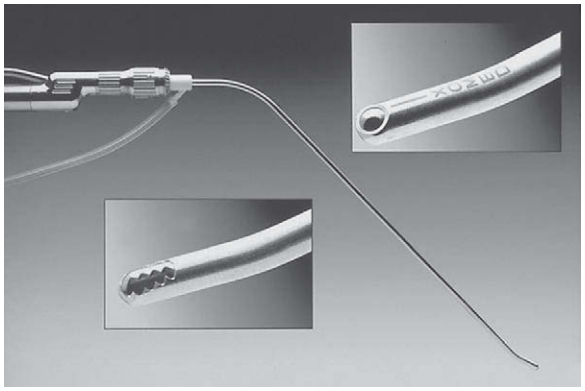

Figure 71-3. Powered instrumentation. Microdebrider blade (*upper inset*), for use in larynx, subglottis, and trachea, and skimmer blade (*lower inset*), for removal of mucosal lesions.

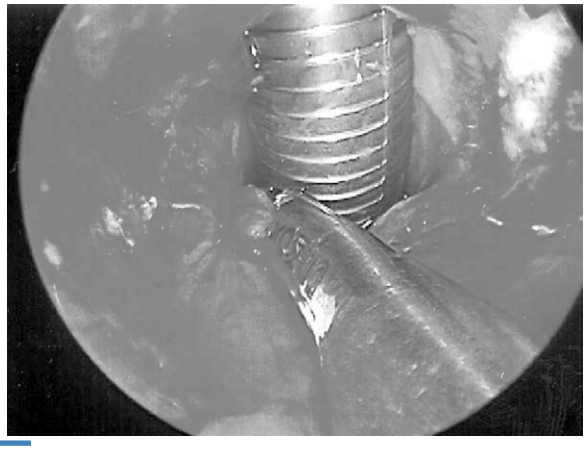

Figure 71-4. Endoscopic view of endolaryngeal lesion removal using the round blade of a microdebrider.

Surgical Planning for Repair

The first consideration for successful repair of acute or chronic laryngotracheal stenosis is the establishment of an intact, reasonably shaped skeletal framework to provide a scaffold for the airway. Acute, blunt injuries to the larynx, in which cartilage is fractured and displaced, are generally best managed with open reduction and stabilization of the fragments. In contrast, chronic injuries often are devoid of cartilage as a result of resorption of devitalized segments or of chondritis and subsequent chondromalacia or necrosis. The cartilage has often been replaced by scar tissue, so cartilage or bone grafts are necessary to reestablish structural support and to provide luminal augmentation. There is no consensus as to the ideal graft materials, and the grafts described in the literature use rib, iliac crest, hyoid bone, epiglottis, thyroid cartilage, composite auricular cartilage, and nasal septal cartilage.

Each of these graft materials may be limited by size, lack of pliability, and variable resorption due to lack of blood supply. The rib or costal cartilage graft is most commonly used because of its size, strength, and relative ease of harvesting. Vascularized hyoid and thyroid cartilage grafts have shown considerable success[22,23] but are limited by the amount of cartilage available. Composite auricular and nasal septal cartilage has the advantage of providing simultaneous epithelial repair, but it generally lacks adequate size and rigidity for cases in which large grafts are required. Vascularized perichondrial grafts and periosteal grafts have been evaluated for their chondrogenic or osteogenic capabilities and show potential for providing a pliable, vascularized graft that generates viable rigid bone or cartilage. In a rabbit model, vascularized perichondrium was shown to form significantly more cartilage when placed in a subglottic defect, and it tolerated a 2-hour ischemia time[24]; it has also been successfully maneuvered into tube form for

reconstruction of a segmental tracheal defect.[25] The sternocleidomastoid myoperiosteal flap has been successfully used for subglottic and tracheal reconstruction, with a low incidence of bony overgrowth on long-term follow-up.[26]

Use of Skin and Mucosal Grafts

The second consideration of the successful repair of acute and chronic laryngotracheal stenosis is the establishment of a completely epithelialized lumen of reasonably normal size and shape. In acute injuries, the ideal method is primary closure of mucosal lacerations after minimal débridement of nonviable tissue. In chronic stenosis, scar tissue should be excised, with preservation of as much overlying mucosa as possible. Small mucosal defects can be left to remucosalize, resulting in minimal detrimental effects.[27] The controversy arises in the use of epithelial grafts to resurface large defects in acute and chronic stenosis. Wounds that heal by secondary intention form granulation tissue and deposit collagen, which may contract until later covered by epithelium.[27] When the denuded area is secondarily infected—particularly after tracheotomy—epithelialization can be prolonged, leading to excessive granulation tissue and scar formation.[28]

Epidermal grafts have been advocated to interrupt this process and to result in healing similar to that of primary intention with minimal collagen deposition. When a stable cartilaginous framework is present, the tendency for the epidermal graft to contract is less, because the laryngeal skeleton acts as an external splint.[29] The techniques of skin grafting as an important adjunct in laryngotracheal reconstruction have been well described.[30]

However, the disadvantage of epidermal grafts in laryngotracheal reconstruction is that the larynx is not an ideal site to accept free epidermal grafts. The larynx is in constant motion with swallowing and neck movements, and the bed is potentially contaminated when a tracheotomy is present. A nonvascularized epidermal graft in the airway can become infected, thereby exacerbating the process of healing by secondary intention. The benefit of an epidermal graft must be weighed against the possibility of infection, especially in the context of an underlying skeletal reconstruction.

Stent Placement

Internal laryngeal and subglottic stenting is widely used with acceptable results; however, questions about the indications for stenting, the optimal type of stent, and the duration of stenting are largely unanswered. Internal stenting with soft or firm materials increases the risk of local infection, mucosal ulceration, and granulation tissue, which is directly related to the duration of stenting. Capillary blood flow ceases with a pressure of 20 to 40 mm Hg in mucosa closely adherent to cartilage, possibly initiating ischemic mucosal injury.[31] Therefore, several writers advocate avoiding internal stenting (unless absolutely necessary) and minimizing the duration of stenting. However, internal stenting is commonly used for the following specific indications: (1) to provide support for cartilage and bone grafts or to splint displaced cartilage fragments in the desired position, (2) to allow approximation and immobilization of epidermal grafts to a recipient site, (3) to separate opposing raw surfaces during healing, and (4) to maintain lumen in a reconstructed area that lacks adequate cartilaginous support and requires scar formation.

The optimal stent has not been determined, and a variety of options exist. A tantalum[32] or umbrella silicone[33] keel is useful for anterior glottic webs, but for more severe laryngotracheal stenosis, various stents are commonly used, including the Montgomery laryngeal stent (Fig. 71-5), the Aboulker stent, the "Swiss roll" siliconized rubber stent, and the finger cot stent; each has proponents who describe good results.[34,35] In general, a soft stent should be used to minimize pressure on mucosal surfaces when cartilaginous support is satisfactory and when the indication for stenting is to splint an epidermal graft or to separate opposing raw mucosal surfaces. A finger cot with a povidone-iodine–soaked sponge is an excellent soft stent; an alternative is a Montgomery laryngeal stent, which is firm but conforms to endolaryngeal contours. A firm stent is needed when the cartilaginous framework or graft requires splinting or when inadequate cartilage is present, thereby requiring that luminal support be achieved through collagen deposition and scar contraction. A solid stent is preferable to a hollow stent to minimize aspiration. However, a soft, hollow stent such as the Montgomery T-tube allows phonation. The T-tube is commonly used for subglottic and upper tracheal stenosis; appropriate patient selection and education are essential, because this is a single-lumen tube with a greater risk of airway obstruction.[36] An Aboulker stent can be used for subglottic or combined subglottic and laryngeal stenosis. The advantage of this stent is that it is used with a double-cannula metal tracheostomy tube, and is secured to the tube, thus preventing removal. Modifications of this technique that allow tracheotomy changes have been described.[37]

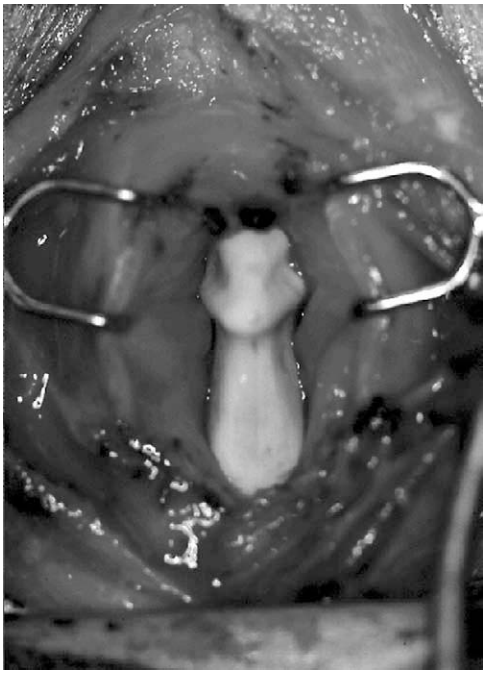

Figure 71-5. Thyrotomy with Montgomery stent in place.

There is no uniformly accepted optimal duration of stent placement. Most authorities recommend 6 to 8 weeks, but the duration varies from 2 weeks to several months.[38] Usually 1 to 3 weeks is sufficient if only mucosal healing or epidermal graft take is required. If the laryngeal skeleton is adequate but requires splinting to maintain the appropriate position, 6 to 8 weeks is the generally accepted time frame.

However, if the cartilaginous framework is deficient and mature scar is important for structural strength, prolonged stenting is indicated to allow scar contraction around an inert, firm object. Successful prolonged stenting has been reported for intervals of up to 14 months. In this situation, the problem arises in premature stent removal, usually before sufficient scar contraction has occurred.[38] The presence of a paratubal air envelope, which manifests as linear air densities between the outside wall of the stent and the inside wall of the larynx and trachea, is reported to be a reliable indicator of laryngotracheal structural integrity and functional stability and is a useful measure to determine optimal timing for stent removal.[39]

Surgical Management of Chronic Stenosis

Supraglottic Stenosis

Chronic hypopharyngeal stenosis usually results from unrecognized acute blunt injury to the hyoid and thyrohyoid membrane. The direction of force is posterior to superior and results in the following discrete injuries: (1) the epiglottis can be adherent to the posterior or lateral hypopharyngeal walls, (2) the hyoid bone can be fractured and displaced posteriorly with the epiglottis, thereby producing laryngeal inlet stenosis, (3) a horizontal web of the posterior hypopharyngeal wall may form at the level of the superior aspect of the epiglottis, or (4) postcricoid stenosis may result in stenosis of the esophageal introitus.[40]

The surgical approach is through a transhyoid pharyngotomy. Tracheotomy is essential if it has not been previously performed. A horizontal skin incision is made over the hyoid bone, which is then identified. If the hyoid is fractured, attempts are made to reduce and wire it into its normal anatomic position; otherwise, the body of the hyoid can be excised. The vallecula is entered, and the mucosal incision can be extended to a lateral pharyngotomy, if needed, with care taken to preserve the superior laryngeal neurovascular pedicles and hypoglossal nerve. After satisfactory exposure has been provided, attention is directed to repair of the stenosis.

Adhesions of the epiglottis to the hypopharyngeal walls may be managed by division of the adhesion along its long axis, submucosal excision of scar tissue, and primary mucosal closure. When a horizontal web or shelf is present, a vertical incision is made through the web, and scar tissue is excised. Mucosal flaps are undermined to allow closure of the incision in a horizontal line. If necessary, superiorly based mucosal advancement flaps can be used. If the hypopharyngeal stenosis is extensive, the division of bands and the excision of scar tissue may result in an extensive denuded area over the constrictor muscle, and skin grafting should be considered. Hollow silicone esophageal stents have also been used to assist in the healing of a skin graft.[40] If resection of scar tissue results in an extensive full-thickness pharyngeal defect, a radial forearm revascularized flap may be used to provide thin, pliable, soft tissue, which may, however, result in an adynamic hypopharyngeal segment.

Laryngeal inlet stenosis results from posterior displacement of the hyoid and epiglottic cartilage and can be accompanied by a fracture through the thyroid notch. This injury is approached through a laryngofissure approach with division of the thyrohyoid membrane and elevation of the mucoperichondrium on the laryngeal surface to allow for excision of this inverted wedge of the base of the epiglottic cartilage, perichondrium, fascia, and scar. With suturing of the resultant flaps to the free edge of the anterior epiglottic perichondrium, the thyrotomy is closed, and stenting is not required.[40]

Glottic Stenosis

Anterior Glottic Stenosis

Anterior glottic stenosis may be caused by external trauma resulting in a thyroid cartilage fracture and mucosal disruption or from circumferential scarring after denuding of mucosa by an endotracheal tube. A thin web that extends more than 3 to 4 mm posteriorly along the vocal fold can produce hoarseness, whereas a thicker web or a web that extends farther posteriorly can cause significant airway obstruction.[41] Hoarseness or airway compromise is an indication for surgical intervention. Excision of the anterior glottic scar recreates the conditions that caused the original stenosis. Successful surgical repair requires physical separation of the opposing edges until remucosalization is complete; this may be done endoscopically when the web does not extend below the inferior edge of the true vocal fold and the posterior commissure is normal.[42] Microlaryngeal instruments allow for better development and preservation of mucosal flaps than are possible with the laser. Excess scar tissue is removed, and a keel is placed and secured externally with wires or with a heavy suture placed through the thyrohyoid membrane. Alternatively, a mini-cricothyrotomy may be performed to place the keel with endoscopic visualization. Differing keel designs and compositions have been described. In principle, the keel should be composed of an inert material of sufficient length to extend from the cricothyroid membrane to at least 2 to 3 mm above the anterior commissure; if the keel extends superiorly over the petiole of the epiglottis, the anterior edge of the keel should make a 120-degree angle (i.e., the angle of the epiglottis and the anterior tracheal wall) to minimize granulation tissue formation at the petiole of the epiglottis. Of note, the posterior wing of the keel should lie at the vocal processes and should not touch the posterior commissure.[41,42] The keel is usually removed after 2 to 4 weeks with any granulation tissue adherent to it.

If the anterior subglottic stenosis extends more than 5 mm subglottically, an external laryngofissure approach should be utilized. Resection of scar tissue should not be overzealous, and mucosa should be preserved whenever possible. When mucosa is deficient, Isshiki and others[52] have described obtaining superior voice results by resurfacing the vocal fold with labial mucosa instead of split-thickness skin grafts and short-term stenting. Successful results have been achieved with the Montgomery umbrella silicone keel used for 2 to 3 weeks or with the McNaught tantalum keel.[41]

Posterior Glottic Stenosis

Posterior glottic stenosis is most commonly caused by endotracheal intubation, although mechanical fixation may also occur from cricoarytenoid joint arthritis. Posterior glottic stenosis may be confused clinically with bilateral vocal fold paralysis before direct laryngoscopy. It should be considered when the history is appropriate and when there are indirect laryngoscopy findings of anteromedial displacement of the arytenoid cartilages, which thus obscure the posterior commissure scar, with a pseudo-foreshortening of the anteroposterior length of the membranous folds or glottic aperture.

Mechanical fixation and neurogenic paralysis are differentiated by direct laryngoscopy, and palpation of the arytenoid to assess mobility is essential. Joint excursion should be uninhibited. Passive medial movement of the contralateral arytenoid when the ipsilateral arytenoid is displaced laterally suggests interarytenoid scar. Electromyography findings of denervation or action potentials of the vocalis muscle are very useful to document neurologic integrity, particularly when results of direct observation of the vocal fold movement are equivocal. Patients with such findings may have a preexisting tracheotomy, which decreases posterior cricoarytenoid muscle activity, thereby making active lateral vocal fold excursion difficult to visualize unless the tracheotomy is plugged temporarily.

The extent of injury is variable. Type III and type IV posterior glottic stenoses are difficult to manage successfully, particularly when they are associated with subglottic stenosis.[3,43] The major therapeutic challenges are to reestablish a satisfactory airway and to preserve the voice, which is often normal.

Endoscopic repair of posterior glottic stenosis is successful in carefully selected cases. Patients with an interarytenoid web and posterior sinus tract have been managed with a simple division of the web. Many patients experience restenosis, particularly those who have had a tracheotomy.[44] A soft, sponge-filled finger cot stent has been advocated in this situation to separate the raw opposing surfaces; it can be placed endoscopically and remain for 2 weeks.[45]

Posterior commissure stenosis can be managed endoscopically with a CO_2 laser or a laryngofissure approach. Creation of a posterior micro-trapdoor flap is successful when a posterior sinus or a 3- to 4-mm posterior interarytenoid scar is present.[44] This technique fails when there is arytenoid fixation or a scar that is more than 1 cm in height. When posterior interarytenoid mucosa is insufficient to create a trapdoor flap (>3-4 mm), interarytenoid scar tissue is resected, with the mucosa preserved through a hockey-stick incision.

A synthetic implantation fabric keel may be placed endoscopically and left in place for 4 to 6 weeks to cause sufficient widening of the interarytenoid mucosa to allow for a micro-trapdoor flap. However, Dedo and Sooy,[44] who first described this procedure, reported that failures occurred in all of their patients who had arytenoid fixation. Several other writers recommend open repair through a laryngofissure approach.[45,46] The surgeon effects such a repair by developing a superiorly based mucosal flap, excising scar tissue and fibrosed interarytenoid muscle, and repositioning the mucosal flap to provide immediate epithelial coverage. Internal stenting is not required when both arytenoids are mobile. Care is taken to not enter the cricoarytenoid joints if both arytenoids are mobile. Successful surgical repair is an elusive goal.

Posterior glottic stenosis with arytenoid fixation has been traditionally managed through an external approach. If, after development of a mucosal flap and resection of scar, one arytenoid is freely mobile, resection of the fixed arytenoid is unnecessary. When bilateral arytenoid fixation exists, removal of the less mobile arytenoid is necessary to achieve a satisfactory airway. Denuded mucosal surfaces are covered with mucosal flaps, skin, or mucosal grafts. Stenting for 2 to 3 weeks with a conforming silicone laryngeal stent or with a soft finger cot stent is required. A posterior cricoid split with rib graft may also be considered (Fig. 71-6).

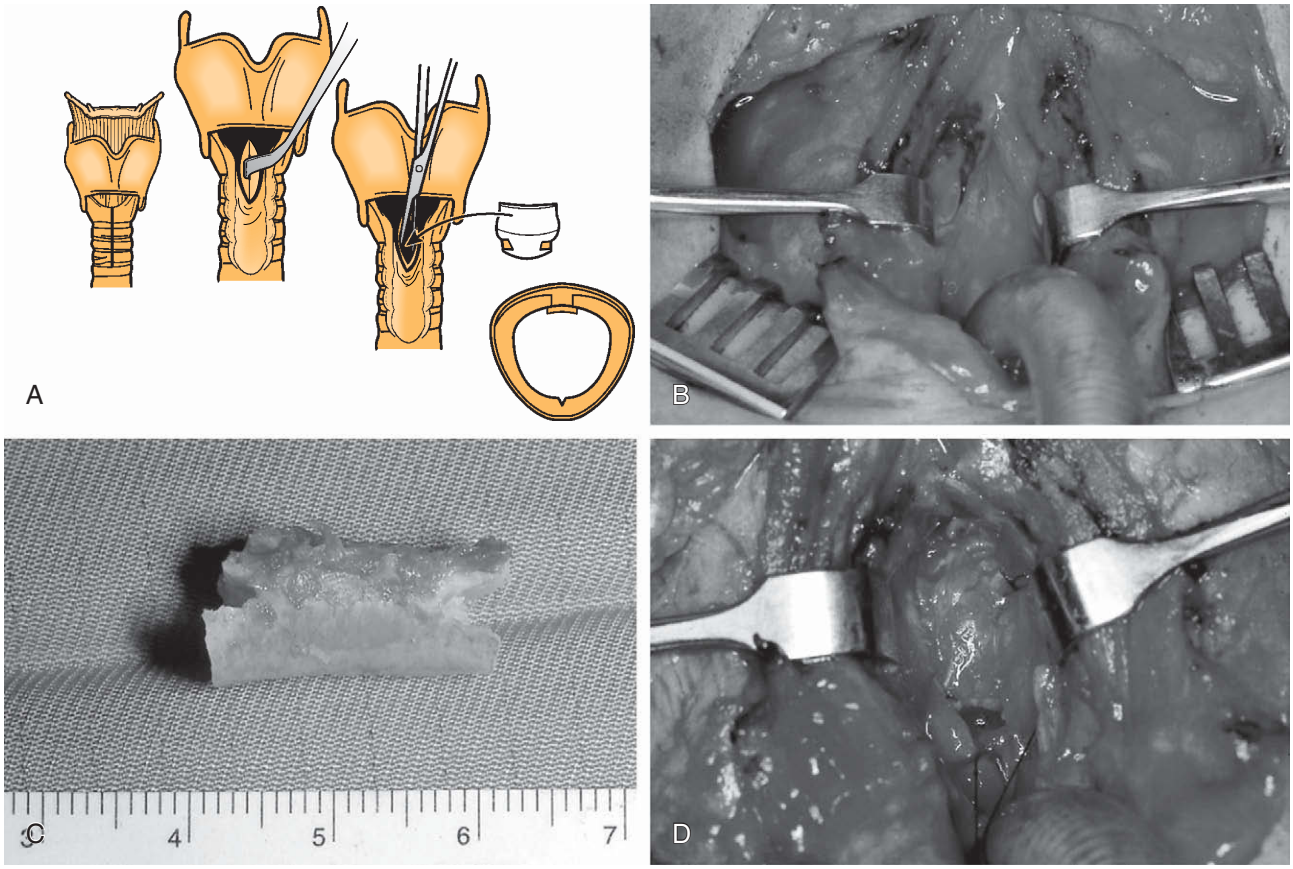

Figure 71-6. Rib graft for posterior subglottic stenosis. **A,** Schematic of anterior wall defect and graft placement. **B,** Anterior wall defect (intraoperative photo). **C,** Rib graft. **D,** Rib graft in place.

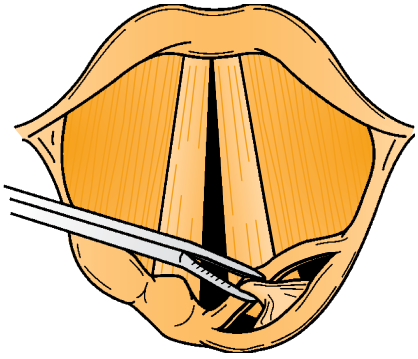

Figure 71-7. Endoscopic view of an arytenoidectomy.

In 1983, Ossoff and associates[47] first described complete arytenoidectomy via an endoscopic approach. Endoscopic laser arytenoidectomy is also useful for managing type IV posterior commissure stenosis when subglottic involvement is limited, because this procedure avoids the complications of an external approach and allows for the immediate assessment of airway size (Fig. 71-7). Endoscopic laser arytenoidectomy requires the removal of the entire arytenoid except for the muscular process. Arytenoid perichondritis is a potential complication, and the administration of perioperative antibiotics and antireflux measures, as always, are recommended. The degree of vocal fold lateralization obtained is variable, and the use of a lateralization suture or a finger cot stent may improve the final result by controlling the extent of lateralization.

The external approaches for an arytenoidectomy are through a laryngofissure or a Woodman arytenoidectomy. The latter approach exposes the arytenoid cartilage through a posterolateral extralaryngeal approach and the entire arytenoid cartilage is resected, except for the vocal process. A submucosal suture is placed through the vocal process and anchored around the inferior thyroid cornu to lateralize the vocal fold (6 mm in men, 5 mm in women).[48] Other writers believe that tethering the vocal process around the inferior thyroid cornu may reposition the vocal fold inferior to the opposite fold; they recommend suturing to the thyroid lamina at the vocal fold level[5] or around the superior cornu (success rate, 60%-80%).[43] If the procedure is unsuccessful, completion arytenoidectomy through a laryngofissure approach with suture lateralization of the vocal fold can be performed.[49]

Exploration of the fixed cricoarytenoid joints with lysis of adhesions without arytenoidectomy has also been advocated. Fibrous bands on the medial aspect of the cricoarytenoid joints are divided, and the arytenoids are stented in full abduction for 2 to 3 weeks; stent removal and aggressive speech therapy follow. Return of vocal cord mobility has been described in 90% of patients managed in this way.[50]

Complete Glottic Stenosis

Complete glottic stenosis usually results from unrecognized severe extralaryngeal trauma, in which injury is rarely isolated to the glottis and associated subglottic injury is common. Endoscopic management is rarely indicated because of the severity and nature of the injury, and only a few instances have been reported in the literature. The mainstay of management involves an open laryngofissure approach. The stenosis should be divided at the midline and excessive scar tissue resected; the mucosa is preserved and mucosal flaps are developed from the aryepiglottic folds for coverage. If extensive areas are devoid of mucosa, epithelial grafts of buccal mucosa, grafts of nasal septal mucosa, or split-thickness skin grafts may be used. Large split-thickness skin grafts may cause excessive crusting. The grafts are sutured in place and stented with a form-fitting laryngeal stent for 4 to 8 weeks.[51] When the stent is removed, an umbrella keel is placed into the anterior commissure for 2 weeks.

An alternative approach is reconstruction with an epiglottic flap. This approach is indicated in the following situations: severe glottic stenosis, a more than 50% reduction in the anteroposterior dimension of the glottis, glottic-subglottic stenosis, and glottic-supraglottic stenosis with an intact epiglottis.[52,53] The repair is approached through a midline thyrotomy, and the thick scar is transected in the midline. Submucosal excision of scar tissue can be attempted, and the mucosa can be repositioned and secured with chromic suture. The base of the epiglottis is identified, and the median thyroepiglottic ligament is transected. The epiglottis is pulled inferiorly to reach the anterior cricoid arch, and the epiglottic flap is sutured to the outer anterior edges of the thyroid cartilage laterally and to the cricoid cartilage inferiorly. This procedure results in an epithelialized, widened anterior commissure. Several cartilage-splitting incisions may be used to allow the petiole to be folded onto itself to make a sharper anterior commissure.[36]

Subglottic Stenosis

Endoscopic management of subglottic stenosis requires careful patient selection. The predictive factors for failure were described earlier.[43,54,55] CO_2 laser excision followed by repair with a micro-trapdoor flap is moderately reliable for managing circumferential subglottic stenosis; it requires laser incision of the superior surface of the scar and the submucosal excision of scar tissue. An inferiorly based rectangular mucosal flap is created by two lateral knife incisions. The preserved flap does not completely cover the lasered area, but it does divide the raw concave area into two flat lateral raw areas, which heal rapidly. One study reported a 90% success rate in all patients undergoing the procedure, in whom scars that were less than 10 mm in height.[43] A large flap that can potentially obstruct the airway through a ball-valve effect should not be created. Other writers[44] have confirmed the efficacy of this procedure in adults and emphasize that it is useful when the stenosis is less than 10 mm in height, but a tracheotomy should be performed if the flap is longer than 4 mm. The procedure is uniformly unsuccessful in children, however.[55] Failure also occurs if associated posterior glottic stenosis or arytenoid fixation is present. Shapshay and coworkers proposed an alternative method, consisting of radial incisions followed by bronchoscopic dilation.[56] Their series of patients was small, however, and follow-up observation was only 1 year; thus, success was not assumed.

Subglottic and tracheal stenotic lesions may be microsurgially debrided with use of a microdebrider (4-mm) subglottic blade. External repair is indicated when endoscopic techniques fail or when the extent of the stenosis is severe and factors are unfavorable for an endoscopic approach. Various techniques are available, and the selection of the appropriate repair technique should anticipate the amount of rigid support required for luminal augmentation and the possibility that scar resection requires epithelial grafting. Subglottic stenosis due to extensive mature scar with adequate cartilaginous support can be repaired via a laryngofissure approach.

Subglottic scar is resected to cricoid perichondrium and is relined with the buccal mucosa or a split-thickness skin graft. The graft is preferably sewn around a stent that is fixed in place. When cartilaginous support or luminal augmentation is also required, various autogenous cartilage grafts are available. The hyoid-sternohyoid muscle interposition graft has been extensively used, with a success rate of approximately 70% in adults.[57] This technique can be applied to isolated subglottic stenosis or subglottic stenosis in combination with anterior glottic or tracheal stenosis.

The procedure uses a vascularized segment of the body of the hyoid pedicle on the sternohyoid muscle and its adjacent periosteum. The length of bone can be tailored to the length of the stenosis; it is interposed vertically into the stenosis and secured with four-point fixation. A stent is not used unless an epidermal graft is required after scar excision to minimize possible graft resorption by pressure necrosis.

The advantages of this technique include immediate reconstruction with a single operative field, theoretically better tissue survival with minimal graft remodeling, and versatility in augmenting glottic, subglottic, and upper tracheal stenosis. The long-term survival of the bone graft has not been conclusively shown; the graft is limited in the amount of augmentation it provides because of its narrow width and concave shape. Additional procedures are often required to remove granulation tissue. The thyroid-cartilage-sternothyroid pedicle composite graft was developed to overcome the limitation of the hyoid-sternohyoid graft. A large central piece of thyroid ala attached to the sternothyroid muscle through its perichondrium is harvested. A flap of contralateral thyroid alar perichondrium is harvested in continuity with the ipsilateral perichondrium and serves as internal lining when the composite graft is transposed. Stenting for 1 to 6 weeks is required. This technique also offers the advantages of the hyoid-sternohyoid graft, except that it cannot be used for glottic stenosis. A larger piece of cartilage, however, is available to reconstruct more extensive defects. The internal perichondrial transposition allows for remucosalization with minimal granulation tissue formation.

Various free autogenous cartilage grafts have been used for luminal augmentation. These grafts have variable amounts of resorption and require prolonged stenting to allow resorbed graft to be replaced by firm, mature scar tissue. Costal cartilage grafts have the advantage of providing large grafts that are easily sculpted. Specific details of graft tailoring have been well described.[55] Composite nasal septal cartilage grafts have been used successfully in patients with stenosis of the larynx and upper trachea.[15] Stenosis of up to 3 cm in height can be repaired, and the respiratory epithelium is a theoretic advantage, because it provides immediate resurfacing with a match of epithelium from the stenotic area. In children, a stent is not used, and the graft is not used so as to prevent injury to nasal growth centers. Various other autogenous grafts, including auricular cartilage, clavicular bone, and free hyoid bone, have been used but they have not received uniform acceptance.

Division of the posterior cricoid lamina should be considered when severe subglottic stenosis is present with posterior glottic stenosis or for complete glottic and subglottic stenosis. It is approached through an anterior cricotracheal fissure, avoiding disruption of the anterior commissure. The entire posterior cricoid lamina is divided vertically in the midline to the level of the postcricoid submucosa. Scar tissue excision is not necessary, and the interarytenoid muscle is divided if it is fibrosed. Prolonged rigid internal stenting is required for at least 3 months. Interposition cartilage grafts with perichondrium can be harvested from the thyroid lamina for posterior support, and anterior luminal augmentation can be performed.

Partial cricoid resection with thyrotracheal anastomosis is considered when other methods have failed. Several investigators reported good results and specific technical details. This procedure should be performed only in adults and is limited to stenosis involving the cricoid and upper trachea. There should be approximately 1 cm of normal lumen below the glottis. The main risks of this procedure are injury to the recurrent laryngeal nerves and anastomotic dehiscence with restenosis.

The procedure involves exposure of the involved laryngotracheal section with preservation of the recurrent laryngeal nerves. Identification of the nerves is often risky because of extensive scarring; therefore, dissection of the trachea is performed in the subperichondrial plane. The inferior resection line is immediately below the stenosis, beveling the anterior tracheal wall. The superior limit can include the cricoid up to the posterior lamina just below the cricothyroid joint. Care is taken to not injure the recurrent laryngeal nerves, which pass immediately posterior to the cricothyroid joints. The tracheotomy can be lowered if three of four tracheal rings can be interposed between the anastomosis and the tracheotomy; otherwise, the patient should be intubated and the anastomosis accomplished with 3-0 interrupted sutures placed submucosally and tied extraluminally. Laryngeal release procedures are usually necessary, and the neck is kept in flexion for 7 to 10 days postoperatively to minimize tension on the anastomosis. If a tracheotomy is not used, the patient is extubated in the operating room in 3 to 4 days.

Grillo and others[58,59] refined this procedure to incorporate a posterior membranous tracheal wall flap to resurface the bared cricoid cartilage. In a series of 80 patients with subglottic and upper tracheal stenosis, these researchers reported failure in only 2 out of 77 patients with at least 6 months follow-up; one perioperative death occurred. Of 77 patients, 66 had no restriction of daily activities due to dyspnea, and tracheotomy was rarely required.

Box 71-3

Surgical Management of Tracheal Stenosis

Open resection and repair
Endoscopic dilatation/laser excision
Stent placement:
- Silicone stent (e.g., Dumon, Rusch Y)
- Expandable stent (e.g., Gianturco Z, Wallstent, Nitinol)
- Flexible silicone stent (e.g., PolyFlex)

A sliding flap tracheoplasty has been described, which is a variation of the cricoid resection and thyrotracheal anastomosis. The procedure involves resection of the anterior cricoid arch and the first two tracheal rings, with development of an inferiorly based anterior tracheal wall flap from the third through sixth rings; this is advanced and anastomosed to the thyroid cartilage superiorly. Patients for whom this procedure is selected should have a subglottic stenosis involving only the anterior cricoid arch and the first ring, an intact posterior wall, mobile vocal folds, and an uninvolved segment of mucosa below the glottis.

Cervical Tracheal Stenosis

Cervical tracheal stenosis in adults most commonly results from trauma produced by either intubation or tracheotomy, or blunt external trauma to the neck. Other causes are benign and malignant neoplasms, inflammatory diseases, and systemic autoimmune disease.

When surgical repair of tracheal stenosis is considered (Box 71-3), regardless of the cause, it is essential to determine the location, length, composition, extent of airway stenosis, and neurologic integrity of the larynx through indirect laryngeal examination, bronchoscopy, and radiography. In most instances, cervical tracheal stenosis can be categorized as cicatricial membranous stenosis, anterior wall collapse, or complete stenosis. Airway management should be considered preoperatively and discussed with the anesthesiologist, as for all of these procedures. If a tracheotomy is not present or is not planned, it is safest to have the patient breathe spontaneously until the airway is secured. If a Montgomery T-tube is used as part of the reconstruction, the patient should breathe spontaneously after the T-tube is inserted (Fig. 71-8). If the airway is 5 mm or smaller at the time of reconstruction, dilation is performed initially with use of general anesthesia; microsurgical debridement resection may also be performed. If the lumen is larger than 6 mm in diameter, intubation is carried out above the lesion, and dissection is performed carefully to prevent airway obstruction. If a postoperative tracheotomy is planned, it should be performed with use of local anesthesia at the outset of the reconstruction procedure.

Cicatricial Membranous Stenosis

Granular or fibrous stenosis of the cervical trachea with intact cartilage can initially be managed endoscopically. CO_2 laser excision of granular stenosis is useful because tracheotomy can be avoided, and the granular stenosis can be resected accurately with minimal bleeding. If the stenosis is circumferential, partial resections should be staged 2 to 4 weeks apart to prevent the formation of a circumferential denuded area of trachea in which restenosis can occur. Fibrous stenosis can be excised with a micro-trapdoor technique.[44]

Open repair of a cicatricial membranous stenosis requires approaching the stenosis via a vertical midline incision through the anterior tracheal wall to expose the entire length of the stenosis. Care is taken to prevent lateral dissection, because the vascular supply to the cervical trachea from the inferior thyroid artery enters laterally. Submucosal excision of scar tissue is accomplished under direct visualization, and the tracheotomy may be moved to below the stenosis. An epidermal graft is useful to cover the denuded area, and it is usually fixed over a stent. Luminal augmentation is often required, and the type of graft used depends on the size of the graft needed and the surgeon's experience and preference. The pedicled thyroid-cartilage-sternothyroid graft or a composite septal cartilage–mucoperiosteal graft seems to be reasonably successful.

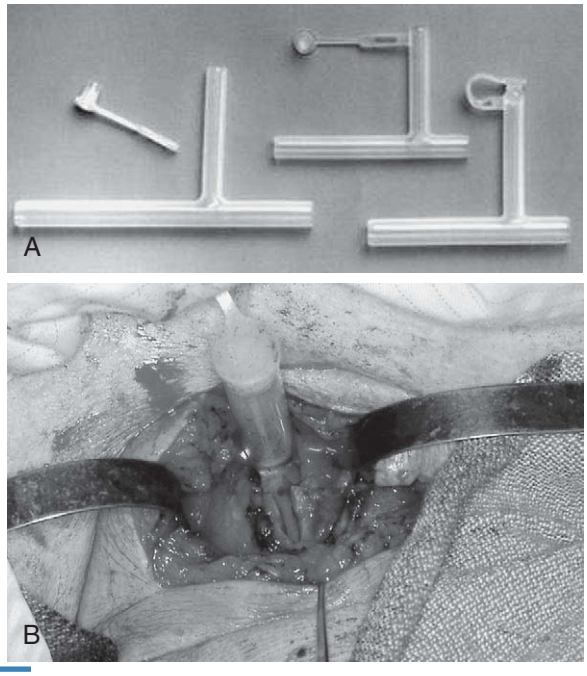

Figure 71-8. A, Silicone T-tube stents for tracheal stenosis. **B**, Open placement of a T-tube.

Anterior Wall Collapse

Collapse of the anterior laryngeal wall can result from anterior blunt neck trauma, but it more commonly results from tracheotomy. Montgomery categorizes these injuries as suprastomal, stomal, or infrastomal.[32] In this type of stenosis, a well-mucosalized posterolateral wall and residual cartilage in the area of the stenosis should be present.[36]

A suprastomal and stomal stenosis can be approached and managed as described for cicatricial membranous stenosis. However, restoration of the anterior wall is essential. The surgeon can accomplished this restoration by (1) stenting the lumen open with a T-tube or a firm stent of a tracheostomy tube, such as the Aboulker stent, and repairing the anterior wall with a cartilage graft or (2) mobilizing the sternohyoid muscles and securing them together over the defect. In both instances, prolonged stenting is required.[36]

Wedge resection of an anterior tracheal wall stenosis can be considered if (1) the stenosis is limited to two or three rings, with significant loss of cartilage that would preclude stenting, (2) the posterior wall mucosa is intact, or (3) the stenosis is stomal or suprastomal. The procedure involves adequate exposure of the involved trachea, including at least one ring above and one ring below the stenosis. Subperichondrial dissection is carried out carefully around the involved trachea to prevent injury to the recurrent laryngeal nerves. The stenosis is resected, with care taken to preserve posterior tracheal wall mucosa. An oroendotracheal tube is passed through the anastomosis, and the cartilaginous trachea is reanastomosed with submucosal sutures tied extraluminally. The patient is extubated when awake and alert, and granulation tissue is excised endoscopically as early as possible.[36]

Complete Tracheal Stenosis

Segmental resection and primary anastomosis provide optimal results for complete tracheal stenosis. The average length of the adult trachea is 11 cm (range, 10-13 cm), and there are 14 to 20 tracheal rings. With hyperextension of the neck, 50% of the trachea is cervical. Approximately 50% of the trachea (5-7 cm) can be safely resected and anastomosed primarily with appropriate mobilization techniques. Other factors also should be considered in the determination of how much

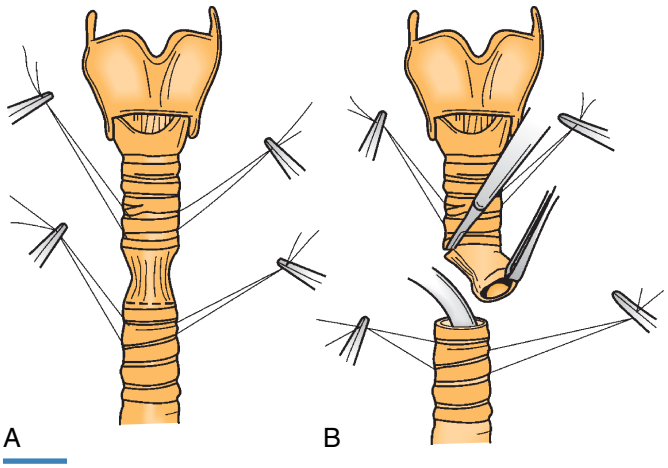

Figure 71-9. **A,** Near-complete tracheal stenosis. **B,** Segmental resection with primary anastomosis.

trachea can be resected. Older patients with calcification between tracheal rings may have less tracheal elasticity; a patient with a short, thick neck may have a deep trachea, with the cricoid at the level of the sternal notch. Tracheal mobilization is limited in a patient with decreased ability to extend the neck. The procedure is essentially the same as a wedge resection, except that dissection requires excision of the posterior membranous wall. The anterior cricoid arch and the posterior cricoid lamina are resected to just below the cricothyroid joints. An oroendotracheal tube is passed distal to the anastomotic site, and the anastomosis is performed with submucosal sutures placed around a trachea ring and tied extraluminally. Adequate mobilization of the larynx and trachea is required to relieve tension from the anastomosis. The neck is placed in extreme flexion, and a stay stitch is placed from chin to sternum.[36]

Segmental resection with primary anastomosis shows promise as the most efficacious procedure for managing near complete or complete tracheal stenosis (Fig. 71-9). In patients in whom stenosis is limited to the trachea and subglottis and the glottis is normal, success rates in several large series are 95% to 97%.[59] When the stenosis also involves the glottis, resection with end-to-end anastomosis has been performed simultaneously with laryngofissure and decannulation repair of the glottic stenosis, which is achieved in approximately 95% of patients. In these instances, a Montgomery T-tube and prolonged stenting were uniformly used.

Extensive cervical and laryngotracheal stenosis not amenable to segmental resection and anastomosis can be managed with a multistaged trough reconstruction technique. The essential steps require the creation of a large tracheostoma by sewing cervical neck skin to residual tracheal mucosa. The second stage requires the formation of a rigid anterior wall by the insertion of Marlex mesh under adjacent cervical skin. Finally, the closure is obtained by tubing skin and Marlex mesh anteriorly to close the stoma and then advancing cervical neck skin as a second layer.

Laryngeal Release Procedures

Tracheal mobilization and laryngeal release techniques are required when a gap greater than 3 cm in tracheal continuity occurs in young patients. Older patients lose elasticity of the annular ligaments of the trachea and therefore require release procedures when more than 1 to 2 cm is resected. Three techniques can gain extra length for end-to-end anastomosis. The first is incision of the annular ligaments, which can add up to 2.5 cm but is most useful in younger patients. Incisions should be placed on one side of the lateral trachea above the anastomosis and on the opposite side below the anastomosis to preserve the blood supply to both tracheal segments. The second technique is superior mobilization of the distal trachea from the thorax, which can result in the achievement of 6 cm of mobilization. This technique requires transection of the left mainstem bronchus and end-to-side anastomosis with the right mainstem bronchus, and it carries a risk of mediastinal dissection. The third technique involves laryngeal release procedures, which can gain 5 cm of tracheal mobilization. The infrahyoid release involves transecting the sternohyoid, omohyoid, and thyrohyoid muscles at the level of the superior border of the thyroid cartilage. The greater cornua of the thyroid cartilage are divided bilaterally, and the thyrohyoid membrane is sectioned. This procedure carries a risk of injury to the superior laryngeal nerve and is associated with prolonged dysphagia.

Suprahyoid laryngeal release is often preferred. This technique requires transection of the insertion of the mylohyoid, geniohyoid, and genioglossus muscles to expose the preepiglottic space. The stylohyoid insertions are transected, and the body of the hyoid is transected medial to the insertion of the digastric tendon. This procedure allows the body of the hyoid, the thyroid cartilage, the cricoid cartilage, and the proximal trachea to drop inferiorly. Flexion of the neck affords an additional 1 to 2 cm of length.

Conclusion

Management of the patient with airway stenosis requires a comprehensive operative and perioperative team and an adequate preoperative workup to determine the most appropriate procedure for each patient. Whether the procedure is performed endoscopically or via an open approach, the results of any of these operations may be very gratifying if the surgeon and patient have reasonable expectations and are prepared for possible complications.

CHAPTER SEVENTY-TWO

The Esophagus: Anatomy, Physiology, and Diseases

Michael F. Vaezi

Key Points

- Primary symptoms of underlying esophageal disorders, most often due to mechanical or motility disturbance, include heartburn, dysphagia, odynophagia, and regurgitation.
- Indications for endoscopy are presence of weight loss, upper gastrointestinal bleeding, dysphagia, odynophagia, chest pain, poor response to therapy, and for evaluation for Barrett's esophagus.
- Esophageal manometry measures coordination of intraluminal pressure activities of the three functional regions of the esophagus: the lower esophageal sphincter, esophageal body, and upper esophageal sphincter; it is used in patients with dysphagia and noncardiac chest pain suggesting motility disorders.
- Indications for 24-hour pH monitoring are to document excessive acid reflux in patients with suspected gastroesophageal reflux disease without endoscopic findings and to assess the efficacy of medical or surgical therapy.
- Development of the wireless pH monitoring capsule has improved sensitivity for detecting reflux events through prolonged monitoring, improved patient compliance, reduced impairment of patients' daily activity, and decreased likelihood of catheter movement during the study.
- Multichannel intraluminal impedance probes measure both acidic and nonacidic reflux of liquid or gas by measuring the resistance to current flow between adjacent electrodes.
- Empiric therapy for classic gastroesophageal reflux disease is recommended. Additional studies are considered in patients with no response and in patients with dysphagia, odynophagia, weight loss, chest pain, or choking.
- Antireflux surgery is not advised in patients whose reflux disease is unresponsive to proton pump inhibitor therapy and who have no evidence of esophageal acid exposure or nonacid regurgitation.
- Patients with Barrett's esophagus require continued endoscopic surveillance to detect the development of dysplasia and adenocarcinoma.
- The cardinal symptom of infectious esophagitis, commonly found in immunosuppressed patients, is odynophagia.

Normal Esophageal Anatomy and Physiology

The *esophagus* is a muscular tube connecting the pharynx to the stomach that acts as a channel for the transport of food. However, its structure and function are much more complex. A thorough understanding of the anatomy and physiology is essential to understanding esophageal disease states.

The proximal margin of the tubular esophagus is the upper esophageal sphincter (UES), the functional unit correlating anatomically with the junction of the inferior pharyngeal constrictor and cricopharyngeus.[1] The esophagus extends distally 18 to 26 cm within the posterior mediastinum as a hollow muscular tube to the lower esophageal sphincter (LES) (Fig. 72-1). The LES is a 2- to 4-cm–long focus of tonically contracted thickened circular smooth muscle that lies within the diaphragmatic hiatus.[2]

The esophageal wall is composed of four layers: mucosa, submucosa, muscularis propria, and adventitia. The esophagus has no serosa, making it unique to the rest of the gastrointestinal tract. The mucosa is normally composed of stratified squamous epithelium, lamina propria, and the muscularis mucosa. Lymphatic drainage begins in the lamina propria. The muscularis propria consists of both skeletal muscle and smooth muscle. The proximal 5% to 33% is skeletal muscle, the middle 35% to 40% is mixed, and the distal 50% to 60% is smooth muscle.[3] The muscles are arranged into inner circular and outer longitudinal layers.

The smooth muscle portions of the esophageal body are innervated by the vagus nerve, which controls peristalsis under physiologic conditions. Neural innervation of the esophagus is from the myenteric or Auerbach's plexus, located between the two muscle layers, and Meissner's plexus, located in the submucosa.[4] The myenteric plexus is responsible for esophageal peristalsis, whereas Meissner's complex is the site of afferent sensory input (Fig. 72-2). Although the precise interaction between morphology and function of the nerve plexuses is not entirely clear, there are two main neurotransmitters within the myenteric plexus. Excitatory stimulation from acetylcholine mediates contraction of both the longitudinal and circular muscle layers. Inhibitory neurons predominantly affect the circular muscle layer via nitric oxide (NO). Excitatory stimulation from acetylcholine has its largest effect proximally, whereas the inhibitory effect of nitric oxide is seen distally.[5]

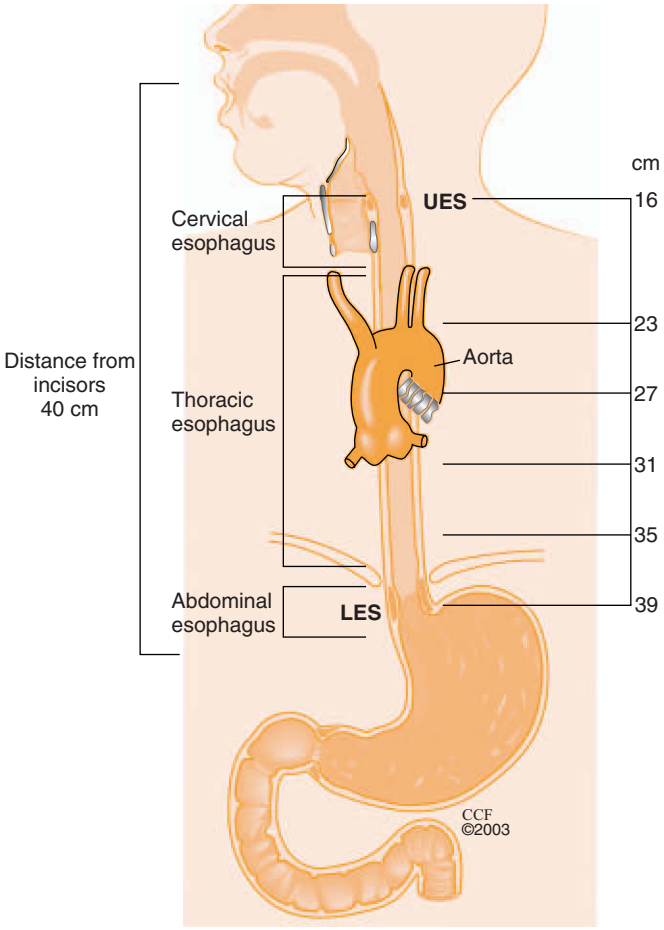

Figure 72-1. Schematic view of the esophagus and its relationship to neighboring structures. LES, Lower esophageal sphincter; UES, upper esophageal sphincter. *(Reprinted with the permission of the Cleveland Clinic Foundation.)*

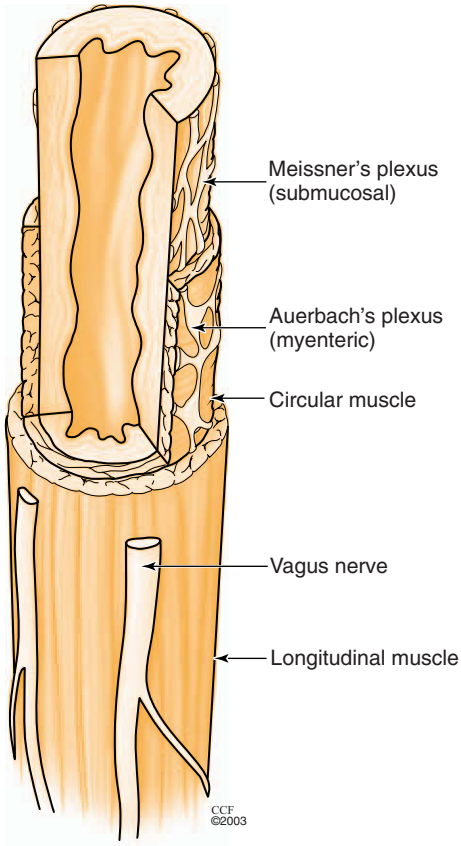

Figure 72-2. Cross-sectional anatomy of the esophagus. Note the outer longitudinal layer and inner circular layer of smooth muscle. Auerbach's plexus, which is responsible for peristalsis, is located between the two muscle layers. Meissner's plexus, responsible for sensation, is in the submucosa. *(Reprinted with the permission of the Cleveland Clinic Foundation.)*

Functionally, the UES, the esophageal body, and the LES act in a coordinated manner to allow normal swallowing. Swallowing begins when a food bolus is propelled into the pharynx from the mouth. This oropharyngeal phase of swallowing is voluntary, but the esophageal phase that follows is involuntary. In rapid sequence and with precise coordination, the larynx is elevated and the epiglottis seals the airway. A rapidly progressing pharyngeal contraction then transfers the bolus through the relaxed UES into the esophagus. As the UES closes, a progressive circular contraction begins in the upper esophagus and proceeds distally along the esophageal body to propel the bolus through the relaxed LES (Fig. 72-3). Peristaltic pressures normally ranging from 30 to 180 mm Hg are generated.[6-8] The measured pressure tends to be lower in the more proximal portions of the esophagus and greater in the distal smooth muscle portions.[8] The pressures may also vary with the consistency of the bolus itself. The LES subsequently closes with a prolonged contraction, preventing movement back into the esophagus. The mechanical effect of peristalsis is a stripping wave, so called because it strips the esophagus clean from its proximal to its distal end.

Secondary peristalsis is a progressive contraction in the esophageal body that is induced by stimulation of sensory receptors, rather than a swallow. Distention by residual food bolus or the refluxed gastric contents is usually the stimulant. It begins approximately at or above the level of the stimulus and resembles primary peristalsis. Its function is to clear the esophagus of food contents that were poorly cleared by the primary peristalsis and to push refluxed gastric contents back into the stomach.

Both the UES and LES are tonically contracted at rest. The closed state for the UES is a result of continuous neural excitation, with a small passive component to tone.[9] The UES pressures are asymmetric, being higher anteriorly and posteriorly. During general anesthesia or sleep, this pressure falls to 10 mm Hg as a result of cessation of neural discharge.[10] It is believed that the tonic contraction of the LES is a function of the muscle itself and is not dependent on neural innervation. Stimulation of inhibitory fibers results in LES relaxation. The resting tone of the LES is typically between 15 and 45 mm Hg and is affected by a wide array of events, foods, drugs, and hormones.[8] LES relaxation occurs not only in response to swallowing but also in response to esophageal distention (secondary peristalsis) or without peristalsis. The latter is referred to as a *transient lower esophageal sphincter relaxation* (TLESR). TLESR is a vagally mediated reflex that is a part of normal digestion and is triggered by gastric distention. It represents the primary mechanism for gastroesophageal reflux in normal individuals and patients with mild gastroesophageal reflux disease (GERD).[11]

Esophageal Symptom Assessment

Primary symptoms suggesting the presence of an underlying esophageal disorder typically include heartburn, dysphagia, odynophagia, and regurgitation. Heartburn, or pyrosis, is classically described as a substernal burning sensation usually occurring within 30 minutes to 2 hours after meals and made worse by lying down or bending over. Large meals, especially if containing fat, chocolate, coffee, or alcohol, are particularly likely to precipitate heartburn. Relieving factors often include drinking milk and taking an antacid. The presence of recurrent heartburn, as an isolated symptom, strongly suggests the diagnosis of GERD.

Dysphagia refers to the sensation of food being delayed in its normal passage from mouth to stomach. Patients often complain of a sensation of food "sticking." It may be classified anatomically into two

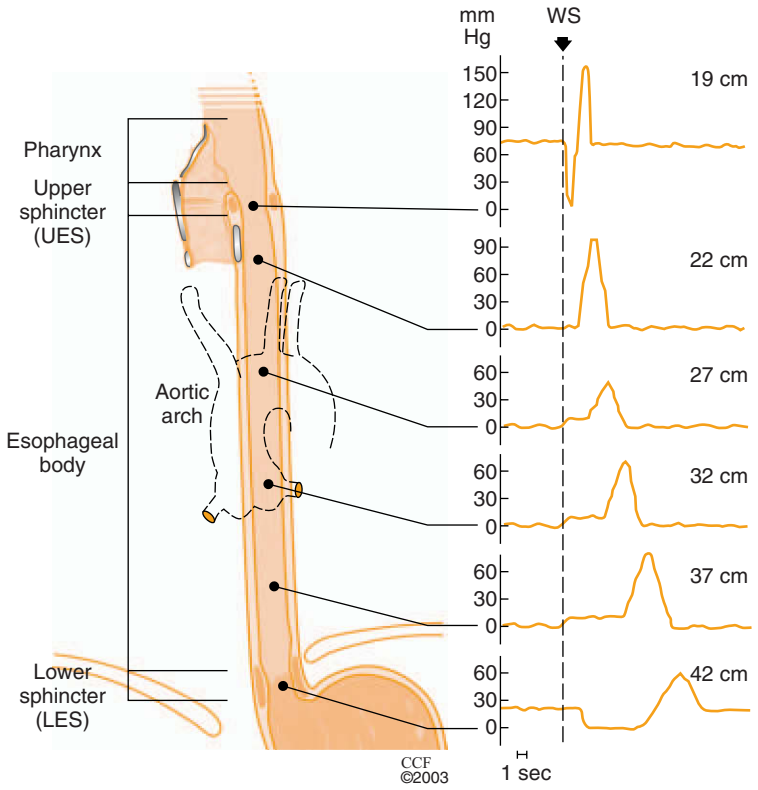

Figure 72-3. Normal esophageal peristalsis. The esophageal body and sphincters are intricately coordinated. Upper esophageal sphincter pressure (located at 19 cm) falls quickly at swallow initiation (wet swallows [WS]), followed by initiation of esophageal body peristalsis, and then lower esophageal sphincter relaxation (located at 42 cm). The peristaltic pressure tends to be lower in the proximal and middle esophagus and higher in the distal smooth muscle portion of esophagus. *(Reprinted with the permission of the Cleveland Clinic Foundation.)*

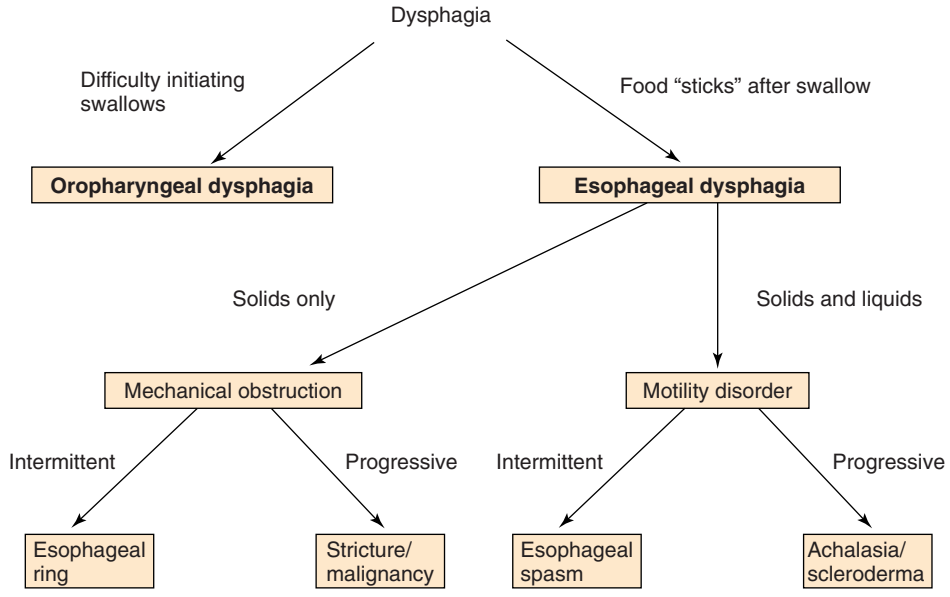

Figure 72-4. Algorithm for the evaluation of dysphagia.

separate clinical entities, oropharyngeal and esophageal. Oropharyngeal dysphagia, discussed later in this chapter, is the difficulty in initiating a swallow. Esophageal dysphagia results from difficulty transporting food down the esophagus secondary to structural or neuromuscular defects in the smooth muscle portion of the esophagus. Further history can often establish the diagnosis in patients with esophageal dysphagia (Fig. 72-4). Patients with primarily solid food dysphagia typically have a structural lesion, such as a peptic stricture, ring, or malignancy. Esophageal rings tend to cause intermittent solid food dysphagia, whereas strictures and cancer cause progressive dysphagia. Patients with both solid and liquid dysphagia are more likely to have a motility disorder such as achalasia or scleroderma. The site at which a patient localizes dysphagia is of limited value. Although dysphagia in the retrosternal or epigastric areas frequently corresponds to the site of obstruction, dysphagia localized to the neck may be from either lower in the esophagus or the hypopharyngeal area.[12,13]

Oropharyngeal or transfer dysphagia is an abnormality related to the movement of a food bolus from the hypopharynx to the esophagus. Oropharyngeal dysphagia arises from disease of the upper esophagus, pharynx, or UES, in contrast to esophageal dysphagia, which is the difficulty in propagating food down the esophagus. Esophageal dysphagia arises within the body of the esophagus, as a result of either a mechanical or motility disturbance. A careful history may be adequate to make this distinction.[14] Patients with oropharyngeal dysphagia typically present with difficulty initiating a swallow and immediately experience coughing, choking, gagging, or nasal regurgitation when attempting to swallow. Although patients with oropharyngeal dysphagia accurately localize the problem to the cervical or throat region, up to 30% of patients with esophageal dysphagia secondary to distal esophageal obstruction can localize the problem to the same area.[12,13] Dysphagia must be distinguished from globus sensation. *Globus* is a sensation of a lump in the throat in which food transport is not limited. A key distinction is that globus is not related to swallowing and, in fact, may improve with swallowing. Most patients with globus do not give a history of dysphagia with food.

The distinction between oropharyngeal dysphagia and esophageal dysphagia is crucial, because the conditions have distinctly different causes (see Fig. 72-4). Oropharyngeal dysphagia is most commonly caused by disruptions in the finely coordinated act of swallowing secondary to neuromuscular dysfunction. In this setting, the symptoms may be more severe during the swallowing of liquids. History and physical examination should concentrate on neurologic signs and symptoms. Both sensory and motor injury may result in an inability to accomplish the transfer of a bolus to the esophagus. Any disease that affects the nerves or muscles can produce oropharyngeal dysphagia; the more common associations are cerebrovascular accidents, amyotrophic lateral sclerosis (ALS), Parkinson's disease, myasthenia gravis, and tardive dyskinesia. Rarely, structural abnormalities, such as cervical osteophytes, hypopharyngeal diverticulum (Zenker's diverticulum), tumors, and postcricoid webs, can cause oropharyngeal dysphagia. Affected patients typically note difficulty with a solid food bolus leaving the mouth. Although these structural abnormalities occur rarely, they are important to identify, because they may be amenable to endoscopic or surgical therapy.

The oropharyngeal swallow is best assessed by videofluoroscopy, also known as the modified barium swallow study. Videofluoroscopy not only serves to confirm the presence of oropharyngeal dysfunction but also can assess the degree of aspiration. It is helpful to have an experienced speech pathologist present at the time of videofluoroscopy to identify these abnormalities and assist with specific swallow therapies. Assessment of aspiration risk and its treatment are essential in the management of patients with such problems, because aspiration carries a high risk of morbidity and mortality.

Dysphagia must be distinguished from *odynophagia*, which is pain caused by swallowing. This important symptom is clearly indicative of a pharyngeal or esophageal problem. Most often it is an inflammatory condition of the esophagus, such as erosive esophagitis, pill-induced esophagitis, or infectious esophagitis.

Regurgitation is the effortless appearance of an acid or bitter taste in the mouth. Regurgitation may be particularly severe at night and may awaken a patient from sleep with coughing and choking. Esophageal problems do not cause true vomiting, but patients may complain of "vomiting" when they are experiencing regurgitation. The term *water brash* describes the sudden filling of the mouth with clear, slightly salty fluid. The fluid is salivary secretions, not regurgitated gastric contents, and the mechanism is vagally mediated.

A number of other ancillary symptoms may be of esophageal origin. *Chest pain* is a common atypical symptom of esophageal disorders. Esophageal disorders are probably the most common causes of noncardiac chest pain. Chest pain can be indistinguishable from angina, but chest pain of esophageal origin tends to be of longer duration, positional, related to meals, and associated with other gastrointestinal symptoms. Esophageal causes of chest pain include GERD and motility disorders. The easily recognized hiccup may be associated with esophageal reflux or obstruction. *Globus* sensation, defined as feeling of a lump, fullness, or "tickle" in the throat, is another frequently encountered symptom. This symptom is usually psychologic and related to increased visceral sensation, but a thorough investigation of the pharynx, larynx, neck, and esophagus should be pursued. Asthma, cough, hoarseness, sore throat, and repetitive throat clearing may be secondary to atypical reflux disease.

Esophageal Testing

Endoscopy

Endoscopy is the technique of choice to evaluate the mucosa of the esophagus and detect structural abnormalities. The modern endoscope uses fiberoptic technology to capture and transmit the image from the distal end of the endoscope. Four-way tip deflection is permitted by use of two control knobs, one with up/down movement and the other with right/left movement. The endoscope is equipped with internal channels for air, water, and suction. Air is used to insufflate the esophagus and stomach, which are normally decompressed. A separate instrument channel is present, allowing the passage of biopsy forceps, heater probes, injection needles, and other equipment that will be used for biopsy and treatment of upper gastrointestinal disorders. The standard upper endoscope measures 9 mm in diameter, but both smaller and larger scopes are available. The "therapeutic" endoscope contains a larger instrument channel that permits passage of "jumbo" biopsy forceps and larger coagulation devices. Endoscopes as small as 4 mm are also available, allowing transnasal or oral endoscopy without sedation.

In the United States, upper gastrointestinal endoscopy is routinely performed with the patient under conscious sedation. After local anesthetic is sprayed on the posterior pharynx and intravenous sedation is given, the examination begins with insertion of the endoscope into the posterior pharynx. The posterior pharynx and larynx are examined for abnormalities. The endoscope is advanced under direct vision into the tonically closed UES. The patient is asked to swallow in order to relax the UES, and the endoscope is advanced into the proximal esophagus. The esophageal mucosa normally appears smooth and light pink. The mucosa should be thoroughly inspected for any abnormalities, including mucosal breaks, ulcers, strictures, and lesions. The area of the gastroesophageal junction (GEJ) must be carefully examined in order to identify specific landmarks. The squamocolumnar junction can be recognized from the irregular Z line demarcating the interface between the light pink esophageal squamous mucosa and the red columnar gastric mucosa (Fig. 72-5).[15] The GEJ is defined by the proximal margin of the gastric folds. Although, the squamocolumnar junction and GEJ are normally located at the same level (Fig. 72-6A), the two

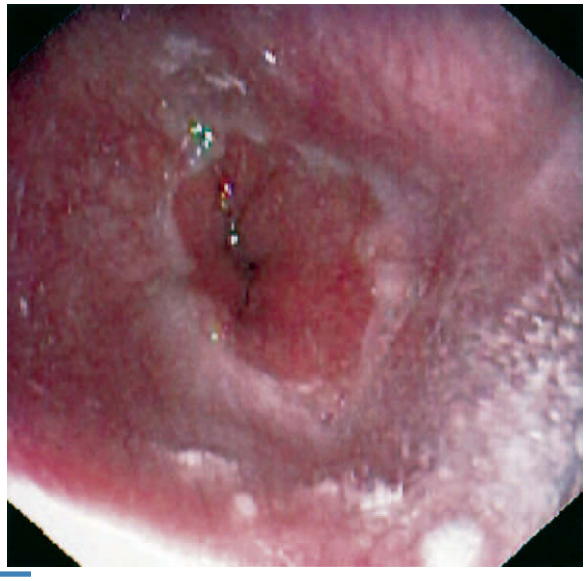

Figure 72-5. Normal squamocolumnar junction. The squamocolumnar junction is recognized from the irregular Z line marking the interface between the light pink esophageal squamous mucosa and the red columnar gastric mucosa.

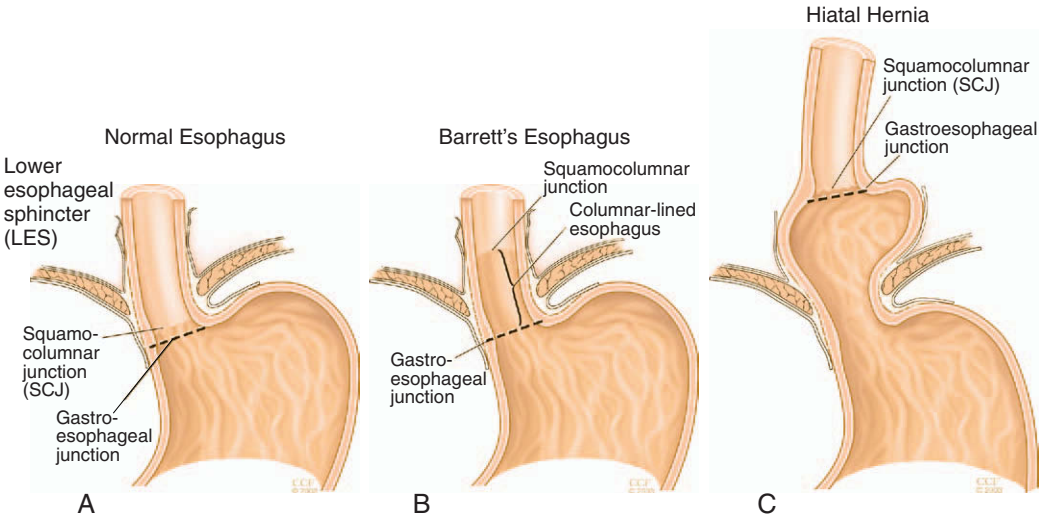

Figure 72-6. Anatomy of the gastroesophageal junction. **A,** Normal gastroesophageal junction, the squamocolumnar junction, and diaphragmatic hiatus are all at the same level. **B,** Barrett's esophagus; the squamocolumnar junction is proximal to the gastroesophageal junction. **C,** Hiatal hernia; the gastroesophageal junction is proximal to the diaphragmatic hiatus. *(Reprinted with the permission of the Cleveland Clinic Foundation.)*

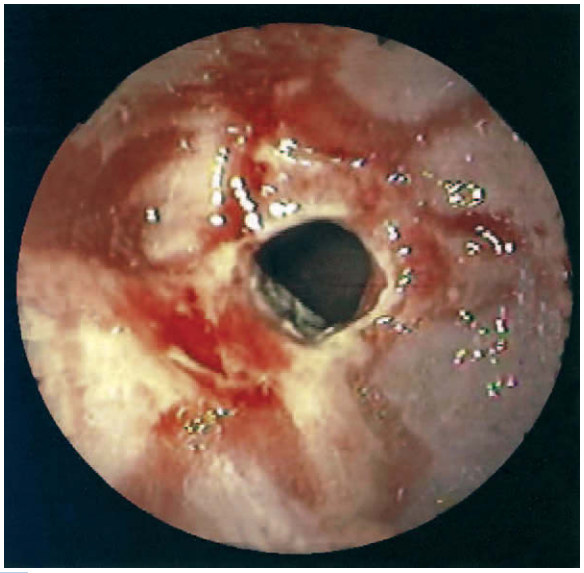

Figure 72-7. Endoscopic view of the gastroesophageal junction with severe esophagitis. There is circumferential ulceration with surrounding erythema and a moderate-size stricture.

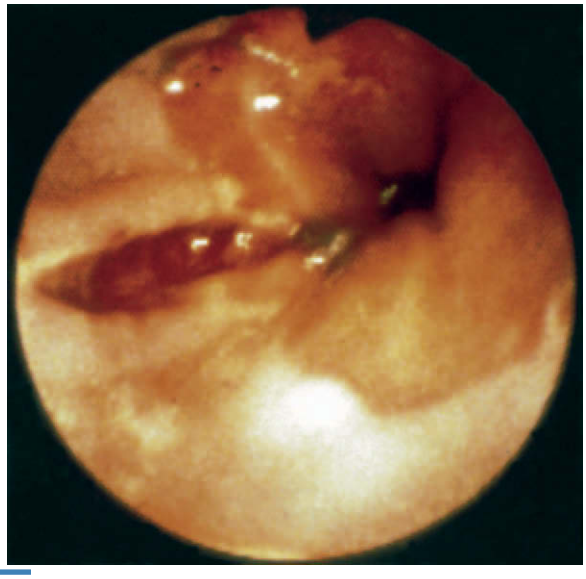

Figure 72-8. Endoscopic view of the gastroesophageal junction with a Mallory-Weiss tear. The tear is the mucosal break located on the *left* side of the figure. Mallory-Weiss tears, which often occur after vomiting or retching, are common causes of upper gastrointestinal bleeding.

are not synonymous. In patients with Barrett's esophagus, the squamocolumnar junction is more proximal in the esophagus than the GEJ (see Fig. 72-6B). Endoscopy can also be used to diagnose the presence of hiatal hernia. In patients with a hiatal hernia, the GEJ is more proximal than the diaphragmatic indentation (see Fig. 72-6C) visualized by diaphragmatic contraction noted during patient respiration.

The current indications for endoscopy include presence of warning symptoms such as weight loss, upper gastrointestinal bleeding, dysphagia, odynophagia and chest pain, partial or no response to empiric therapy, and evaluation for Barrett's esophagus. Esophageal causes of bleeding include severe esophagitis (Fig. 72-7), Mallory-Weiss tears (Fig. 72-8), and esophageal varices (Fig. 72-9).

Esophageal Manometry

Esophageal manometry is a diagnostic test that measures intraluminal pressures and coordination of the pressure activities of the three functional regions of the esophagus: LES, esophageal body, and UES. Manometry is commonly used in the assessment of patients with symptoms suggestive of esophageal motor dysfunction, such as dysphagia and noncardiac chest pain. A manometric study is also indicated for evaluation of esophageal peristalsis prior to antireflux surgery.

Manometry is commonly performed with the use of a water-infusion catheter and less commonly with a solid-state catheter system. Solid-state catheters contain embedded microtransducers that directly measure the esophageal contractions, but they are limited by a small number of recording sites. Water-perfused catheters contain several, small-caliber lumens that are perfused with water from a low-compliance perfusion device. When a catheter port is occluded by an esophageal contraction, water pressure builds within the catheter, exerting a force that is conveyed to an external transducer. With either catheter system, the electrical signals from the transducers are transmitted to a computer, which produces a graphic record.

The technique of manometry involves inserting the catheter into the esophagus via the nares. The catheter is then advanced to approximately 60 cm, which should be well within the stomach. At this point,

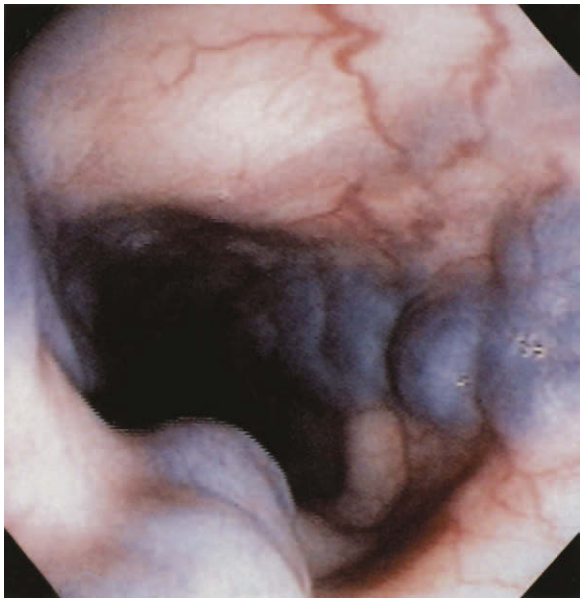

Figure 72-9. Endoscopic view of the distal esophagus. Three columns of esophageal varices (*blue*) are present.

the patient is placed supine on the left side, and the catheter calibrated. The station pull-through technique is then employed. This involves slowly withdrawing the catheter through the LES, esophagus, and UES. Resting LES pressure and relaxation, esophageal peristalsis, and UES pressure and relaxation are thus evaluated with a series of wet swallows (Fig. 72-10).

Manometry is the accepted standard for diagnosis of motor disorders of the esophageal body and LES. Manometric evaluation of the LES can accurately assess basal pressure and relaxation of the sphincter during swallowing. The esophageal body can be assessed for amplitude and duration of contractions and peristalsis. Peristalsis is defined by a coordinated contraction sequence and is quantified by the percentage of swallows with peristalsis. Through the use of these characteristics of the LES and esophageal body, a number of esophageal manometric disorders can be diagnosed (Table 72-1).

Manometric evaluation of UES often yields limited information, partly because of a great variability in what are considered normal values for UES resting pressure. Resting UES pressure is asymmetric, with greater values anteriorly and posteriorly than laterally.[16] Also, the technique of measurement may stimulate sphincter contraction. In addition, the duration of UES relaxation depends on the volumes of swallow boluses. Because of these limitations, disorders of the UES may be better defined by barium radiography.

A solid-state high-resolution system has become available that is able to monitor esophageal function without the need for water perfusion. The solid-state manometry probe has 36 circumferential sensors spaced at 1-cm intervals. Each of the 36 pressure-sensing elements contains 12 circumferentially isolated sectors detecting pressure over a 2.5 mm length. The procedure involves simply placing the catheter in the esophagus, allowing a brief adjustment period, recording 10 swallows, and withdrawing the probe. Pressures detected by each sector are averaged to obtain a mean pressure measurement for each sensor, making each of the 36 sensors a circumferential pressure detector. The data are processed by a computerized program to create the plots that can be viewed as conventional line traces or switched to high-resolution plots. This method has significant potential advantages over conventional methods. It is simple, faster, and more precise. The software simplifies data collection and gives more accurate diagnostic information while shortening procedure time by 50% to 200%. Additionally, this novel technique provides a complete observation of motor function from the pharynx to the esophagus to the stomach without the need for catheter repositioning. The computer program is customized for processing the data into an isocontour pressure plot (Fig. 72-11).

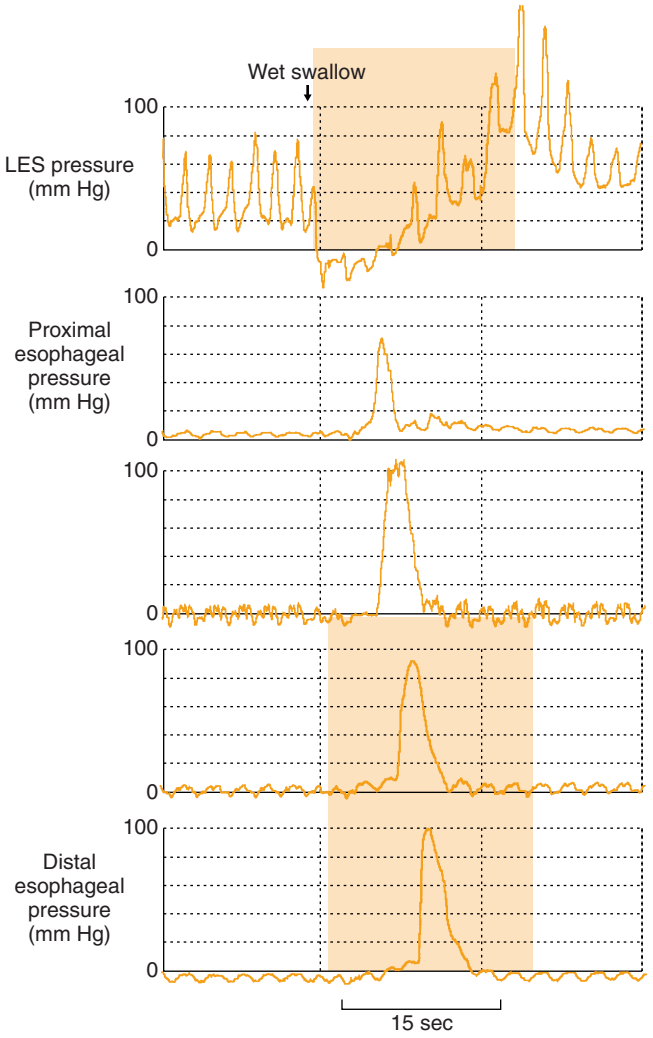

Figure 72-10. Normal esophageal manometry. The wet swallow initiates a progressive peristaltic contraction in the body of the esophagus with wave amplitudes of 30-180 mm Hg. The lower esophageal sphincter (LES) relaxes completely to gastric baseline at the end of peristalsis.

Ambulatory 24-Hour Esophageal pH Monitoring

Ambulatory 24-hour esophageal pH monitoring is an important tool in the diagnosis and management of GERD. Esophageal pH monitoring can detect and quantify gastroesophageal reflux and correlate symptoms temporally with reflux. The primary indications for ambulatory 24-hour esophageal pH monitoring are (1) to document excessive acid reflux in patients with suspected GERD but without endoscopic esophagitis, and (2) to evaluate the efficacy of medical or surgical therapy.

Standard pH monitoring measures distal esophageal acid exposure by using a single pH electrode catheter that is passed through the nose and positioned 5 cm above the superior margin of the manometrically determined LES. Although other techniques for electrode placement exist, such as pH step-up (rise in pH from stomach to esophagus), and endoscopic and fluoroscopic placement, they are less accurate and not standardized.[17-19] After catheter placement, the patient is encouraged to have a typical day without dietary or activity limitations. The pH is recorded every 6 to 8 seconds, and the data are transmitted to an ambulatory data logger. Typical pH units have an event marker that can be activated by the patient during the study to indicate the timing of symptoms, meals, and recumbence (Fig. 72-12). The patient also records these events on a diary card so that specific symptoms can later be correlated with the esophageal acid exposure recorded by the pH

Table 72-1

Esophageal Manometric Findings in Normal Patients and in Patients with Motility Disorders

Finding	Normal	Achalasia	Diffuse Esophageal Spasm	Nutcracker	Ineffective Esophageal Motility
Basal lower esophageal sphincter (LES) pressure	10-45 mm Hg	Normal or high	Normal	Normal	Low or normal
LES relaxation with swallow	Complete	Incomplete	Normal	Normal	Normal
Wave progression	Peristalsis	Aperistalsis	Peristalsis with at least 20% simultaneous contractions	Normal	30% or more failed nontransmitted contractions
Distal wave amplitude	30-180 mm Hg	Usually low (may be normal or high)	Normal	High	30% or more <30 mm Hg

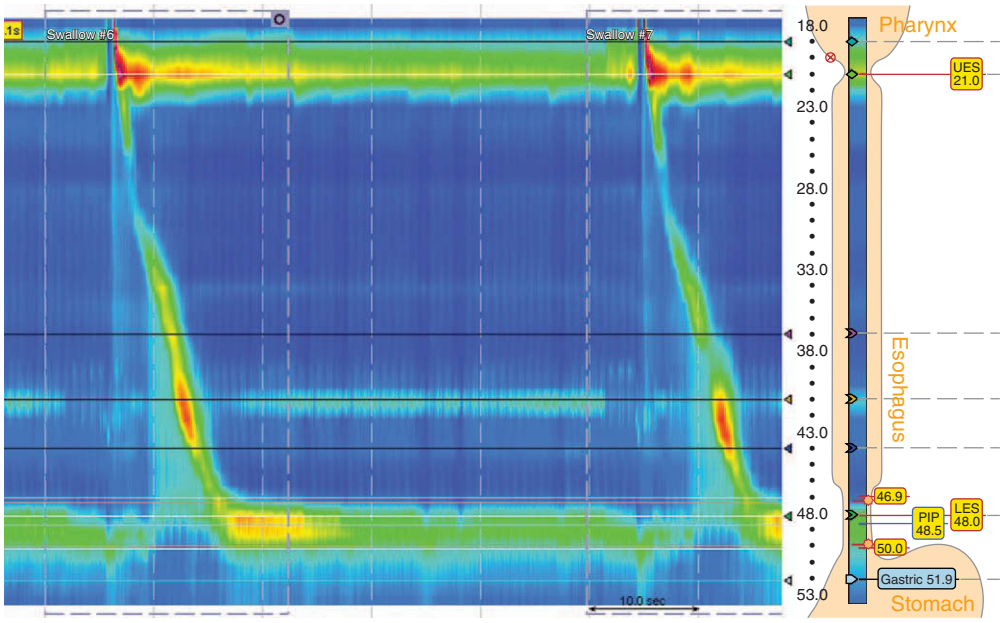

Figure 72-11. Isocontour plot of two swallows showing relaxation of the upper esophageal sphincter (Swallow #6) and peristaltic contractions in the esophagus. The pressure profile typically is low pressure (*blue*) to high pressure (*red*).

Figure 72-12. Typical pH unit used for ambulatory pH monitoring. The unit has buttons that can be activated by the patient during the study to indicate symptoms, meals, and recumbency.

probe. At the end of the study, data are downloaded to a computer, which generates a pH tracing and a data summary (Figs. 72-13 and 72-14).

A reflux episode is defined when the esophageal pH drops below 4.0. This value is chosen on the basis of the proteolytic activity of pepsin, which is most active at and below this pH. Additionally, a pH value less than 4.0 best distinguishes between symptomatic patients and asymptomatic controls.[20-23] Some gastroesophageal reflux is physiologic and may be seen in normal individuals, especially after meals. Although many scoring systems and parameters have been evaluated, the percentage of time that the pH is less than 4 is the single most important parameter to measure and is calculated in most software programs used in the analysis of pH monitoring. Results are generally considered abnormal when the total time that the pH is less than 4 is exceeds 4.2% of the study period.[24,25] Stratification by supine time and upright time is also reported by all software programs.

Although the pH software automatically calculates the total, upright, and supine reflux times, manual review of the pH tracing to exclude artifact is essential for precise interpretation. A typical reflux event involves an abrupt drop in pH (see Figs. 72-13 and 72-14). This

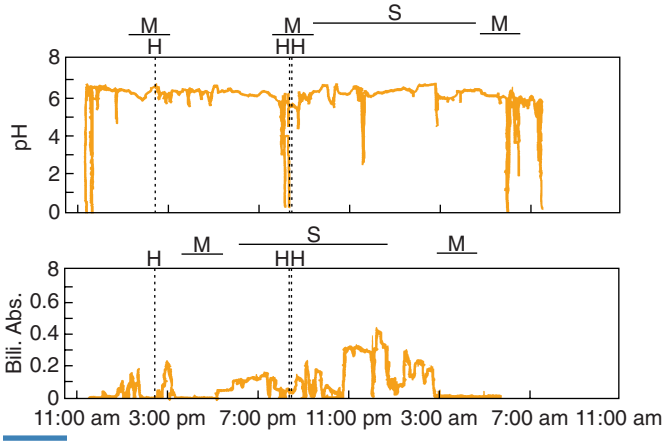

Figure 72-13. Normal pH tracing as generated by computer software. Symptoms, meals, and recumbency are recorded on the tracing. A reflux event occurs when the baseline pH drops abruptly to less than 4.0. Several short episodes of reflux with meals are demonstrated, as well as one spontaneous event related to recumbency. Although there are several reflux events, the total time during which the pH value is less than 4 is normal, and this patient would not be considered to have gastroesophageal reflux disease. Bili. Abs., bilirubin absorbance; H, heartburn; M, meal; S, supine.

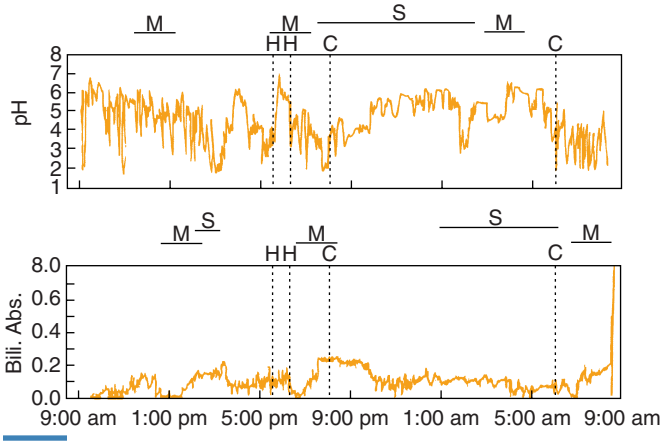

Figure 72-14. pH tracing of a patient with gastroesophageal reflux disease (GERD). Although the baseline pH varies considerably, several long episodes of reflux with pH less than 4 are shown. These events occur postprandially, not exclusively in relation to a meal as such events are in Figure 72-13. The total time during which the pH value is less than 4.0 is abnormal, and thus, the patient has GERD. The patient's symptom of chest pain (C) correlates with episodes of reflux. Bili. Abs., bilirubin absorbance; H, heartburn; M, meal; S, supine.

must be distinguished from a slowly drifting pH value, which may be secondary to the probe's losing contact with the esophageal mucosa and drying out. Probe dysfunction or disconnection can result in a reading that drops to zero. In addition, some patients may sip on acidic carbonated or citrus beverages, causing prolonged periods during which pH is less than 4. These artifacts should be identified and their corresponding time excluded from the calculation of acid exposure times.

One potential advantage of ambulatory pH monitoring is the ability to correlate symptoms with reflux episodes. However, even in patients with well-documented GERD, less than 20% of reflux episodes are associated with symptoms. This observation has led to the development of several scoring systems. The "symptom index score" is defined as the percentage of symptom episodes related to reflux events during the study period.[26] Good correlation is considered to be 50%. The "symptom association probability" (SAP) score is a statistical probability calculation in which the entire pH tracing is separated into 2-minute intervals and each segment is evaluated for reflux and symptom episodes; a modified chi-square test is used to calculate the probability that the observed distribution could have occurred by chance.[27] Unfortunately, no clinical trials prove that either of these symptom scores predicts a cause-and-effect relationship. This relationship can be confirmed only by the response to appropriate antireflux therapy.

Monitoring of pH may be performed with or without medical therapy. In monitoring performed without medical therapy, patients are asked to stop proton pump inhibitor (PPI) therapy for at least one week, histamine H_2 blocker therapy for 48 hours, and antacid use for 2 hours.[28] Whether the study should be performed with or without therapy depends on what information the clinician desires to gain. A pH study without therapy simply documents whether acid reflux is present, such as in a patient considering antireflux surgery or with atypical GERD symptoms. The study performed in a patient undergoing therapy documents whether continued acid reflux is the cause of symptoms in patients with poor or incomplete response to therapy.

Multiple-probe catheters have additional pH electrodes located more proximally in the esophagus or the hypopharynx. These electrodes allow the detection of proximal esophageal and pharyngeal acid reflux events, which may be useful in the evaluation of extraesophageal GERD symptoms, particularly laryngitis, chronic cough, and asthma. The conventional location of the proximal esophageal pH probe is 15 cm to 20 cm above the LES, with a normal value for total time with pH below 4.0 being less than 1%.[29,30] The hypopharyngeal probe is usually placed 2 cm above the manometrically determined UES. Although normal values are not clearly defined, more than two or three episodes of hypopharyngeal reflux is considered abnormal. It is again critical to review the pH tracings to be sure that proximal esophageal or hypopharyngeal reflux events are accompanied by distal esophageal reflux and are not secondary to artifacts. The clinical utility of these multiple-probe catheters is considered later in the atypical reflux discussion.

Ambulatory 24-Hour Bile Monitoring

Duodenogastroesophageal reflux (DGER) refers to regurgitation of duodenal contents through the pylorus into the stomach, with subsequent reflux into the esophagus. DGER may be important because factors other than acid, namely bile and pancreatic enzymes, may play a role in mucosal injury and symptoms in patients with GERD.[31-33] Initially esophageal pH greater than 7.0 during pH monitoring was considered a marker of such reflux, but alkaline reflux was later proved to be a poor marker for DGER.[31] This finding led to the development of a fiberoptic spectrophotometer (Bilitec 2000, Synectics, Stockholm), that detects DGER in an ambulatory setting independent of pH (Fig. 72-15).[34] This instrument utilizes the optical properties of bilirubin, the most common bile pigment. Bilirubin has a characteristic spectrophotometric absorption band at 450 nm. The basic working principle of this instrument is that absorption near this wavelength implies the presence of bilirubin and, therefore, represents DGER.

As in pH monitoring, data from the bilirubin spectrophotometer are usually measured as percentage of time that bilirubin absorbance is greater 0.14 and can be analyzed separately for total, upright, and supine periods (Fig. 72-16). Percentage of time bilirubin absorbance exceeds 0.14 is commonly chosen as a cutoff because studies show that values lower than this number represent scatter owing to suspended particles and mucus present in the gastric contents.[34] In a study using 20 healthy controls, the 95th percentile values for percentage of total, upright, and supine times that bilirubin exceeded 0.14 were 1.8%, 2.2%, and 1.6%, respectively.[35] Several reports have indicated a good correlation between Bilitec fiberoptic spectrophotometer readings and bile acid concentration measured by duodenogastric aspiration studies.[34,36-38] Validation studies have found that this instrument underestimates bile reflux by at least 30% in an acidic medium because of bilirubin isomerization with a shift in wavelength absorption.[35] Therefore, the instrument's measurement of DGER must always be accompanied by simultaneous measurement of esophageal acid exposure by means of prolonged pH monitoring. Furthermore, a variety of substances may result in false-positive readings by this instrument, because it indiscriminately records any substance with an absorption band

Figure 72-15. The Bilitec 2000 monitor (Synectics, Stockholm) for detection of duodenogastroesophageal reflux. The probe is a fiberoptic spectrophotometer designed for the detection of bilirubin in the distal esophagus.

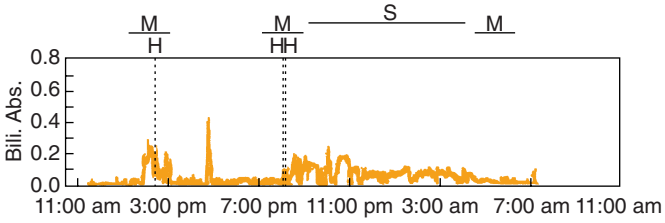

Figure 72-16. Tracing from a Bilitec 2000 monitor (Synectics, Stockholm) for a patient with duodenogastroesophageal reflux. *Reflux* is defined as bilirubin absorbance (Bili. Abs.) value > 0.14. This patient has several postprandial episodes of reflux associated with heartburn (H). Also note the prolonged episode of duodenogastroesophageal reflux while the patient was supine (S).

around 470 nm. This fact necessitates the use of a modified diet to avoid interference and false readings.[34,38] Also, it is important to remember that the Bilitec spectrophotometer measures reflux of bilirubin and not bile acids or pancreatic enzymes, thereby assuming that the presence of bilirubin in the refluxate is accompanied by other duodenal contents.

Development of this instrument was an important advancement in the assessment of DGER, but its clinical role is limited, and it is no longer available. Esophageal studies with this device were instrumental in showing that acid reflux and bile reflux occur together, making it difficult to incriminate duodenal contents alone as the cause of damage to the esophagus.

New Technologies

Because of the limitations of standard 24-hour pH monitoring, several new diagnostic modalities for GERD are under investigation. These include multichannel intraluminal impedence (MII) and the wireless Bravo pH Monitoring System (Medtronic Inc, Minneapolis, MN) and the Restech pH probe (Restech Respiratory Technology Corporation, San Diego, CA).

The Bravo is a catheter-free monitoring system in which a pH monitoring probe approximately the size of a medication capsule is placed endoscopically (Fig. 72-17). A standard upper gastrointestinal endoscopy is performed to locate the GEJ. The endoscope is removed, and an introducer with an attached pH capsule probe is inserted. The introducer is advanced and the capsule probe is placed 6 cm above the GEJ (Fig. 72-18). pH data are then transmitted to a recording device on the patient's waist. Besides being catheter free, the wireless system has the advantage of recording 48 hours of pH data. The capsule pH probe falls off after 4 to 10 days and is passed in the stool. The wireless system is significantly better tolerated, causing less interference with daily activities, and having a higher overall satisfaction rate and better quality of life for patients with GERD. The second, often discussed, and important advantage of the Bravo system is its greater sensitivity for detecting reflux events due to (1) prolonged monitoring (48 hours vs. 24 hours), (2) improved patient compliance, (3) reduced impairment of patients' daily activity, and (4) decreased likelihood of catheter movement during the study.

Figure 72-17. The Bravo wireless pH capsule (Medtronic Inc, Minneapolis, MN). It is approximately the size of a medication "gel cap." Placement of the capsule onto the esophageal mucosa with endoscopic assistance eliminates the need for a pH catheter.

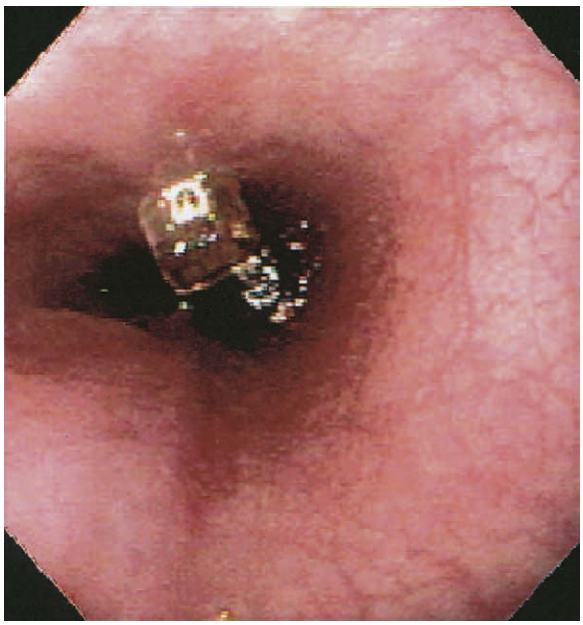

Figure 72-18. The Bravo wireless pH capsule (Medtronic Inc, Minneapolis, MN) attached to the distal esophageal mucosa after deployment.

The latest pH monitoring system is the Restech Dx–pH Measurement System, a highly sensitive and minimally invasive device for detection of acid reflux in the posterior oropharynx. It uses a nasopharyngeal catheter able to measure pH in either liquid or aerosolized droplets. The probe is a 1.5-mm–diameter oropharyngeal catheter with a wireless digital ZigBee transmitter attached to the shirt collar. The catheter employs a 3.2-mm teardrop tip to aid in insertion and to ensure that the sensor is positioned in the airway. The tip has a colored light-emitting diode (LED) for oropharyngeal visualization, to aid proper placement (Fig. 72-19). The sensing element consists of a circular 1-mm antimony surface and a reference electrode separated by a 0.05-mm polymer insulator (Fig. 72-20). Moisture from exhaled air condenses on the sensor surface, creating a fluid layer that bridges the gap between the antimony and reference sensor elements. The sensor records pH values twice every second (2 Hz), and it features a hydration monitor to eliminate data if the tip dries out. Special circuitry monitors each reading to ensure sufficient sensor hydration. This circuitry prevents the inclusion of dryout-related "pseudo-reflux" events in the data. The potential clinical utility of this device is in patients with extraesophageal reflux disease. Clinical data are needed to assess the future role of this device.

Multichannel intraluminal impedance (MII) is a relatively new technique that measures both acidic and nonacidic refluxates of liquid or gas consistency.[39] This ZepHR impedance/pH recorder (Sandhill Scientific Inc, Highlands Ranch, CO) is capable of measuring characteristics of gastroesophageal reflux that are not detectable by the current "gold standard," the pH probe. *Impedance*, a measure of the total resistance to current flow between adjacent electrodes, is capable of differentiating between liquid and gas refluxates on the basis of their inherent current and resistance properties. Combined MII-pH measurement has an advantage over standard pH monitoring, which does not detect nonacidic reflux. Hence, clinically this approach may be most useful for further evaluation of typical or atypical reflux symptoms refractory to acid suppression therapy, in assessing the role of nonacid and/or nonliquid reflux. Although there is no doubt that MII-pH measurement is currently the most accurate and detailed method to detect reflux of all kinds, the clinical indications for its use are still evolving, and its role in the management of patients with GERD awaits further definition for two main reasons: (1) the relevance of nonacid reflux in specific clinical settings has to be further discerned, and (2) there is a paucity of high-quality blinded, randomized, controlled studies examining the benefit of treating nonacid reflux.

Provocative Testing

Provocative testing in the esophagus is mostly of historical value. Such testing arose because of the difficulty in evaluating patients with noncardiac chest pain. The Bernstein test, introduced by Bernstein and Baker[40] in 1958, is an acid perfusion test used as an objective method to reproduce symptoms of acid related injury. After a brief control period, consisting of intraesophageal saline infusion, 0.1 N hydro-

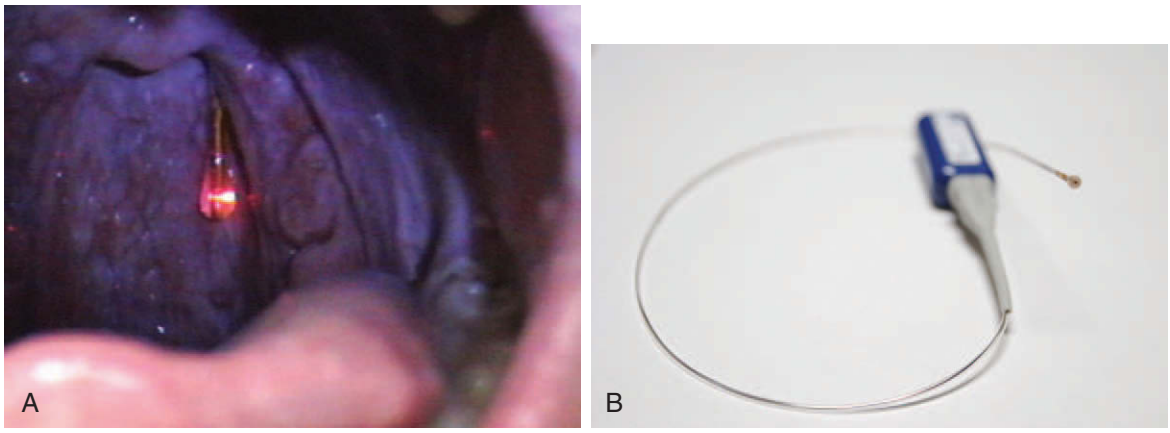

Figure 72-19. **A,** Oropharyngeal pH probe with light-emitting diode (LED) tip in the posterior aspect of the mouth. **B,** The probe transmitter.

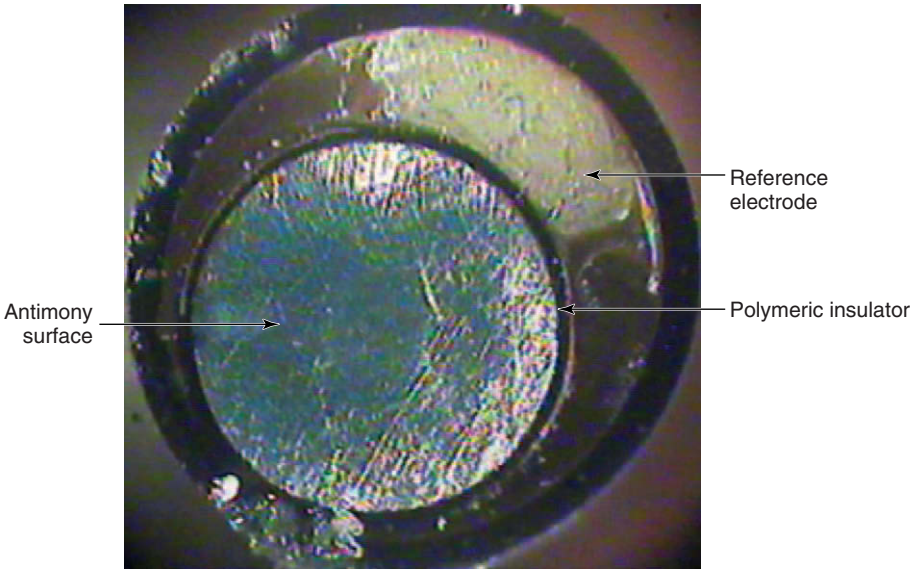

Figure 72-20. Magnified cross-sectional view of the Dx–pH probe (Restech Respiratory Technology Corporation, San Diego, CA) (×75).

chloric acid is infused in the esophagus. If the infusion produces the patient's chest pain and saline does not, the result is considered positive. Because of its low sensitivity, especially in comparison with pH monitoring, the Bernstein test is now rarely used.[41,42]

The edrophonium test is a provocative test designed to implicate esophageal motility disorders as a cause of chest pain. Edrophonium, a parasympathomimetic, increases the amplitude and duration of esophageal contractions. The tests consists of an intravenous injection of 80 μg of edrophonium, which reproduces esophageal manometric changes and chest pain in 20% to 30% of patients with noncardiac chest pain.[43,44] As with the Bernstein test, the sensitivity of this test is low and varies widely in the literature. Also, studies have shown poor correlation between increased amplitude and duration of esophageal contractions and patient's symptoms of chest pain.[44-46]

Esophageal Disease States Causing Dysphagia

Esophageal Motility Abnormalities

Box 72-1 highlights the latest classification system for esophageal motility disorders.[47] This system categorizes such disorders according to four major patterns of esophageal manometric abnormalities: inadequate LES relaxation, uncoordinated contraction, hypercontraction, and hypocontraction.[47] Most esophageal motility abnormalities fall predominantly into one of these four major categories, although there can be considerable overlap.

Processes that affect the inhibitory innervation of the LES (e.g., achalasia) can interfere with LES relaxation and thereby delay esophageal clearance. In the body of the esophagus, abnormal motility is characterized by uncoordinated contraction, hypercontraction, and hypocontraction. Uncoordinated esophageal contractions (i.e., contractions that are not peristaltic and directed toward the stomach) can delay esophageal clearance. Such uncoordinated contractions are the hallmark of diffuse esophageal spasm. Hypercontraction abnormalities are those that are characterized by contractions that are of high amplitude, long duration, or both. The putative disorders of hypercontraction (e.g., "nutcracker esophagus," isolated hypertensive LES) are perhaps the most controversial of the abnormal esophageal motility patterns, because it is not clear whether esophageal hypercontraction has any pathophysiologic significance. In contrast, hypocontraction abnormalities that result from weak (low-amplitude) muscle contractions can cause ineffective esophageal motility, which delays esophageal clearance, and LES hypotension can result in GERD.

Achalasia

Achalasia is a primary esophageal motility of unknown etiology characterized by insufficient LES relaxation and loss of esophageal peristalsis. Available data suggest hereditary, degenerative, autoimmune, and infectious factors as possible causes.[48,49] Pathologic changes occur in the myenteric plexus, consisting of a patchy inflammatory infiltrate of T lymphocytes, eosinophils, and mast cells, loss of ganglion cells, and myenteric neural fibrosis.[50] These changes result in selective loss of postganglionic inhibitory neurons, which contain both nitric oxide and vasoactive intestinal polypeptide. The postganglionic cholinergic neurons of the myenteric plexus are spared, leading to unopposed cholinergic stimulation.[51] This condition produces high basal LES pressures, and the loss of inhibitory input results in insufficient LES relaxation. Aperistalsis is related to the loss of the latency gradient along the esophageal body—a process mediated by nitric oxide.

The most common symptoms of achalasia are dysphagia for solids and liquid, regurgitation, and chest pain. Most patients are symptomatic for years before seeking medical attention. Patients with achalasia tend to localize their dysphagia to the cervical or xiphoid areas. Initially, dysphagia may be for solids only, but most patients have dysphagia for solids and liquids at the time of presentation.[48] Patients tend to accommodate for their problem by using various maneuvers, including lifting the neck or drinking carbonated beverages to help empty the esophagus. Regurgitation occurs in 75% of patients with achalasia and becomes a greater problem as the esophagus dilates with progression of the disease.[52] It occurs most commonly in the recumbent position and may awaken the patient from sleep because of choking and coughing. Chest pain is experienced by approximately 40% of patients with achalasia.[52] Weight loss occurs in 60% but is usually minimal.[53]

When the diagnosis of achalasia is suspected, a barium esophagram with fluoroscopy is the best initial diagnostic study. This test reveals loss of primary peristalsis in the distal two thirds of the esophagus. In the upright position, there is poor emptying, with retained food and saliva often producing a heterogeneous air-fluid level at the top of the barium column. The esophagus may be dilated (Fig. 72-21). In early disease the dilation is often minimal, but in chronic disease it can

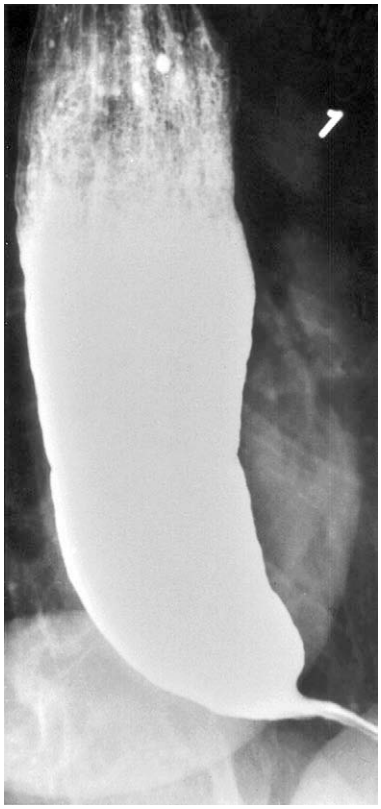

Figure 72-21. Classic esophagram of a patient with achalasia. The esophagus is dilated with a "bird's beak" tapering of the distal esophagus. Retained secretions form the heterogeneous air-fluid level seen at the top of the barium column.

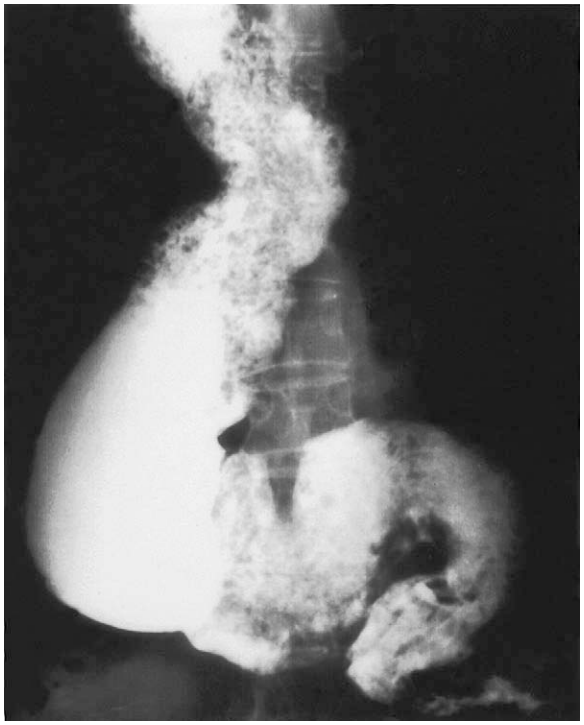

Figure 72-22. Esophagram of late-stage achalasia. The esophagus now has a sigmoid-like tortuosity with a large amount of retained debris.

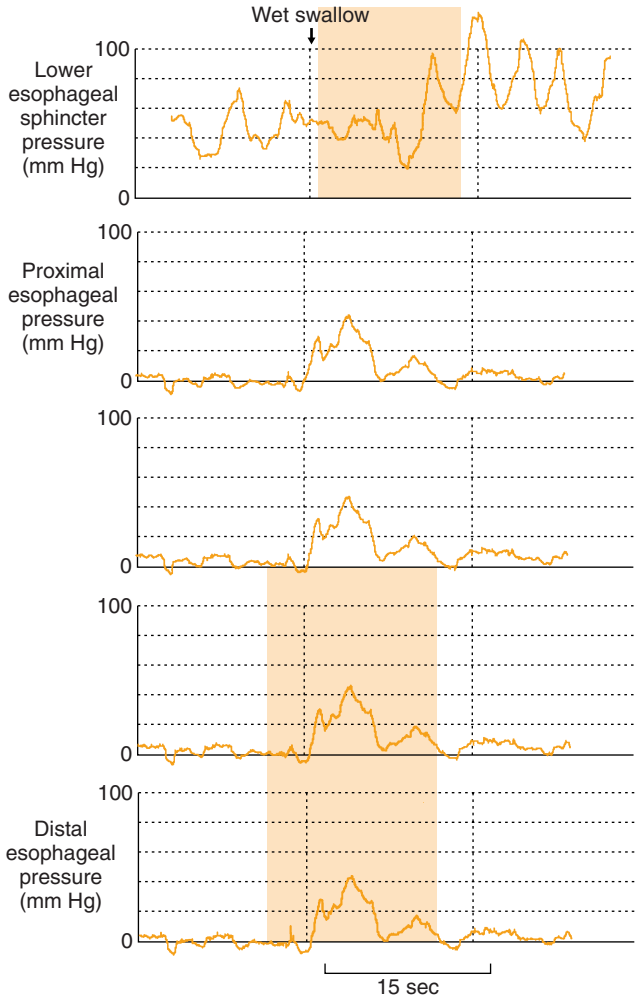

Figure 72-23. Manometric findings in achalasia. There is aperistalsis, manifested by isobaric contractions without propagation. The lower esophageal sphincter pressure, which is elevated, shows minimal relaxation with swallowing.

be massive with a sigmoid-like tortuosity (Fig. 72-22). There is a smooth tapering of the lower esophagus leading to the closed LES that resembles a bird's beak. The presence of an epiphrenic diverticulum may also suggest the diagnosis of achalasia.[54]

Esophageal manometry may also be used to establish the diagnosis (Fig. 72-23).[55] In the body of the esophagus, aperistalsis is always present. This means that all swallows are followed by simultaneous contractions, typically with low contraction amplitudes. Abnormal LES relaxation is seen in all patients with achalasia. About 70% to 80% of patients have absence or incompleteness of LES relaxation with swallows; in the remainder, the relaxations are complete but are of short duration. The baseline LES pressure is usually elevated but may be normal in up to 45% of patients; however, a low LES pressure is never seen in untreated patients with achalasia.

All patients with achalasia should undergo upper endoscopy to exclude pseudoachalasia arising from a tumor at the GEJ. Pseudoachalasia may mimic classic achalasia both clinically and manometrically. This diagnosis should be suspected in patients of older age with a short duration of symptoms and more significant weight loss.[56] At endoscopy, the esophageal body in classic achalasia often appears dilated and tortuous. Retained secretions and food debris may be encountered (Fig. 72-24). The LES region usually appears puckered and remains closed with air insufflation; however, with gentle pressure the endoscope can transverse this area. The GEJ and gastric cardia must be examined closely for the presence of tumors in order to rule out pseudoachalasia.

There is no cure for achalasia, but most patients can obtain relief of symptoms and improvement in esophageal emptying. The two most effective treatments are graded pneumatic dilation and surgical myotomy. All patients considered for pneumatic dilation should be surgical candidates, because the procedure is associated with a 2% to5% risk of esophageal perforation.[49,57] Pneumatic dilation, performed endoscopically, uses air pressure to dilate and disrupt the circular muscle fibers of the LES. Balloon dilators, available in three diameters (3, 3.5, and 4 cm) are positioned over a guidewire at endoscopy. The most important aspect of an effective pneumatic dilation is accurate positioning of the balloon across the LES, followed by fluoroscopic visualization of effective obliteration of the balloon waist. After pneumatic dilation,

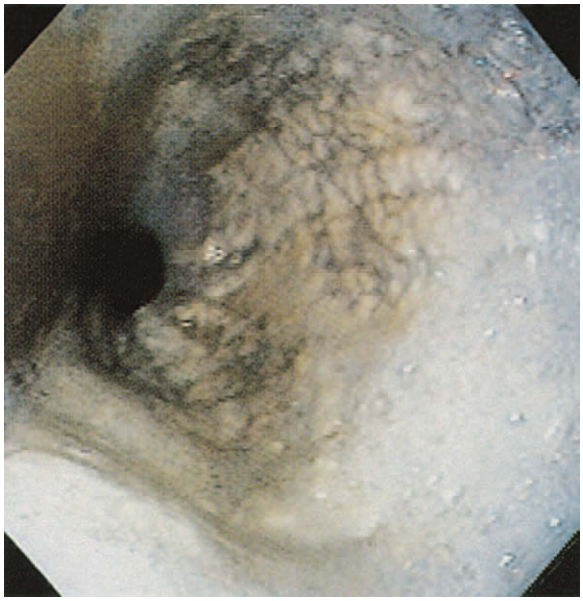

Figure 72-24. Endoscopic view of the distal esophagus in a patient with achalasia. The esophagus is dilated with retained fluid and debris.

all patients should undergo a (Gastrografin) study followed by barium swallow to exclude esophageal perforation.[58] Studies to date indicate good-to-excellent relief of symptoms in 50% to 93% of patients in whom the graded dilators were used.[49] The clinical response improves in a graded fashion with increasing size of the balloon diameter.[57] Surgical myotomy for achalasia involves performing an anterior myotomy across the LES (Heller's myotomy) usually associated with an antireflux procedure. Myotomies are increasingly being performed by laparoscopy, which has a good-to-excellent response rate of 80% to 94%.[49] A potential complication of myotomy is GERD, which occurs in 10% to20% of cases.[59]

For patients who are at high risk for pneumatic dilation or surgery, endoscopic injection of the LES with botulinum toxin (Botox) or pharmacologic treatment with nitrates or calcium channel blockers may be acceptable alternatives. Botulinum toxin injection, which inhibits the release of acetylcholine from nerve terminals, is initially effective in about 85% of patients.[49] However, symptoms recur in more than 50% of patients at 6 months.[60] Therefore, botulinum toxin injection is reserved for elderly patients for whom surgery poses a high risk. Calcium channel blockers and long-acting nitrates are effective in reducing LES pressure and temporarily relieving dysphagia but do not improve either LES relaxation or peristalsis.[61,62] The clinical response is short acting, the agents usually do not provide complete symptom relief, and their efficacy decreases with time. Given these limitations, pharmacologic therapy is recommended only for patients who are not candidates for pneumatic dilation or surgical myotomy and in whom botulinum toxin injections fail.[63]

Nonachalasia Motility Disorders

There are a number of other described primary motility disorders of the esophagus. These disorders are defined on the basis of presence of specific manometric criteria (see Table 72-1 and Box 72-1),[47] but, for most, the clinical relevance of these manometric findings is questionable.[64] Most often they are noted on manometry performed in patients with chest pain or dysphagia.

Diffuse esophageal spasm is the best recognized of these conditions. Manometric changes include the presence of simultaneous and repetitive contractions in the esophageal body, but unlike in achalasia, some normal peristalsis is maintained. LES relaxation is also normal in diffuse esophageal spasm (Fig. 72-25). The classic finding on esophagogram is the "corkscrew" esophagus (Fig. 72-26). Patients with this disorder may present with chest pain, if the contraction amplitudes are high, or dysphagia, if the contraction amplitudes are low. The treatment of diffuse esophageal spasm consists of medications that relax the esophagus, such as nitrates and calcium channel blockers, but is usually not completely effective.

"Nutcracker esophagus" is another common manometric diagnosis in patients with noncardiac chest pain. It is defined by high-amplitude peristalsis. This condition appears unlikely to be a true primary motility disorder but rather a marker for increased visceral pain perception.

Ineffective esophageal motility is a hypocontractile disorder with relevant clinical associations. It is defined by a distal esophageal contraction amplitude of less than 30 mm Hg in 30% or more of wet swallows. Ineffective esophageal motility has been demonstrated to be reproducible manometrically, and studies have demonstrated a higher incidence in patients with GERD, especially in those with respiratory symptoms.[65,66] Given the ineffective nature of the contractions, a food bolus may not be effectively transported, resulting in dysphagia in some patients.

Secondary motility disorders are commonly a result of systemic conditions. The most common condition affecting esophageal motility is scleroderma, or progressive systemic sclerosis (PSS). Other systemic conditions that can result in esophageal hypomotility are hypothyroidism, diabetes mellitus, and amyloidosis. These disorders are discussed in more detail later.

Strictures

An *esophageal stricture* is defined as any loss of lumen area within the esophagus. The normal esophagus measures 20 mm in diameter. The

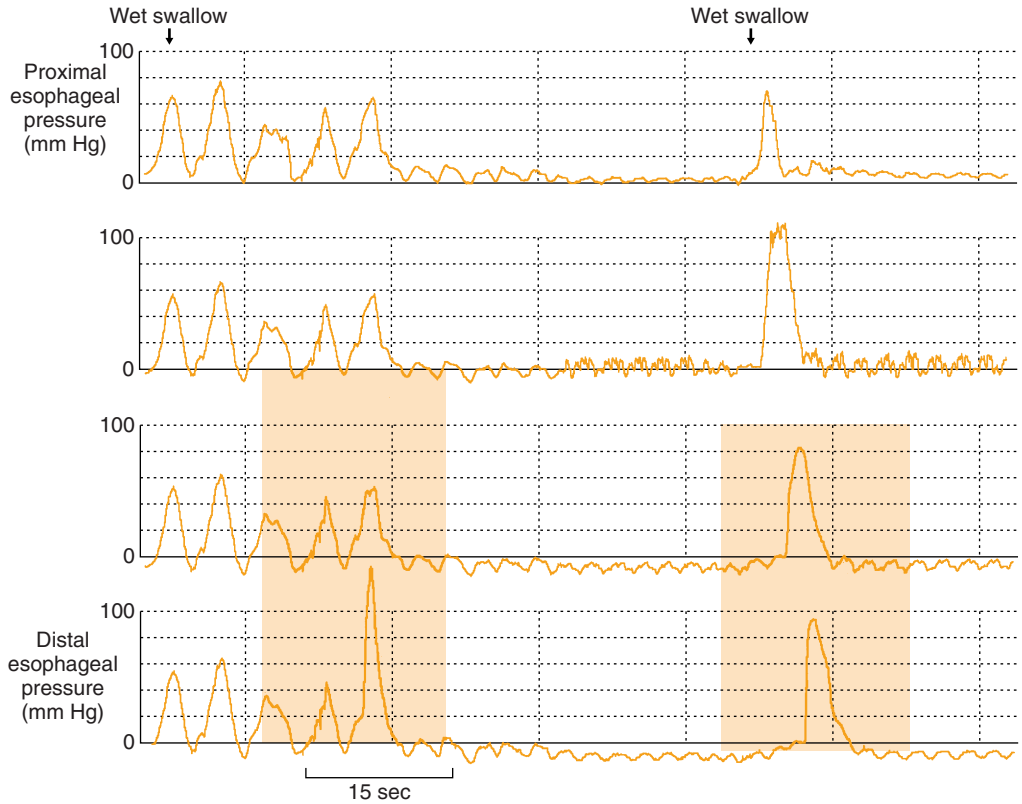

Figure 72-25. Manometric findings in diffuse esophageal spasm. There are repetitive simultaneous contractions in the esophageal body, but some normal peristalsis is maintained. Lower esophageal sphincter relaxation is normal and complete.

Epidermolysis bullosa

Extrinsic Strictures

Pulmonary/mediastinal malignancies
Anomalous vessels and aneurysms
Metastatic submucosal infiltration (breast cancer, mesothelioma, adenocarcinoma of gastric cardia)

predominant clinical symptom of strictures is dysphagia, which is usually most prevalent when the luminal diameter is less than 15 mm. Even less severe strictures can cause intermittent dysphagia to large food pieces such as meat and bread. There are multiple intrinsic and extrinsic causes for esophageal strictures (Box 72-2). Intrinsic strictures are most common, with acid or peptic causes accounting for the majority of cases (60% to 70%) (Figs. 72-27 and 72-28).[67] Rings or webs and malignant strictures are discussed later separately.

Regardless of etiology, the foundation for treatment of benign stricture disease is esophageal dilation. The different types of dilators are (1) mercury-filled, rubber Maloney bougies, (2) wire-guided rigid Savary-Gilliard dilators, and (3) balloon dilators, which can either be through-the-scope (TTS) or wire-guided. Choice of dilator often depends on anatomy of the stricture and operator experience. In general, Maloney bougies are used in uncomplicated short straight strictures. The wire-guided Savary-Gilliard dilator and TTS balloons are both best suited for long, tight, or tortuous strictures. Complications of esophageal dilation are uncommon, but perforation (0.5%), bleeding (0.3%), and bacteremia (20% to 50%) are not rare.[68] Patients with radiation-induced or malignant strictures are at higher risk of perforation. To minimize the risk of perforation, the "rule-of-threes" applies—that is, no more than three sequential dilators to be used per session. The goal of esophageal dilation is to obtain an objective diameter greater than 15 mm. Approximately 90% of patients in whom the esophagus was dilated to 15 mm have no recurrence at 24 months.[69]

Refractory esophageal strictures are defined by lack of response to two or more dilations. The causes for refractory stricture include ongoing insults from pills or nonsteroidal anti-inflammatory drugs (see discussion of pill-induced injury), uncontrolled acid reflux, and inadequate lumen diameter achieved by dilations. PPIs are superior to H_2 blockers in preventing recurrence of acid-related strictures.[70] Treatment of refractory strictures includes elimination of offending agents (pills and acid) and gentle dilation to 15 mm. Intralesional injection of steroids before dilation is safe and probably effective for refractory strictures.[71] Surgery is now extremely rare for benign disease but may be considered in strictures that fail to respond to aggressive medical therapy and dilation.

Rings or Webs

Esophageal rings and webs are common findings on upper endoscopy, and many are asymptomatic. However, some patients do experience significant symptoms from these structural abnormalities. Symptoms

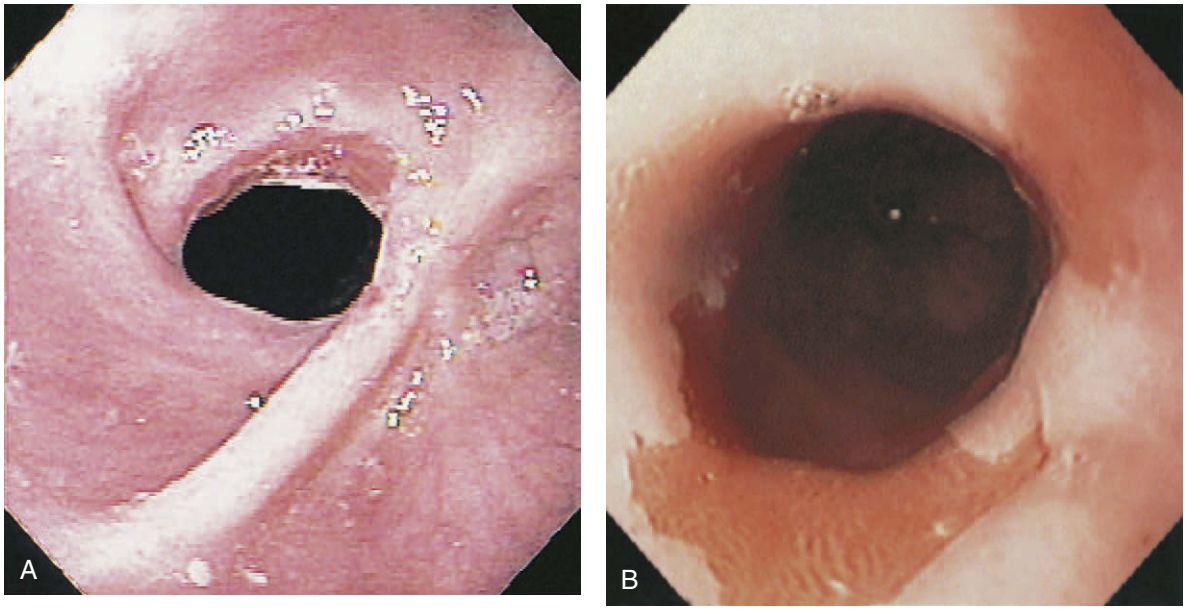

Figure 72-28. Endoscopic views of esophageal strictures. **A,** Anastomotic stricture with normal smooth mucosa. **B,** Subtle distal esophageal stricture with Barrett's metaplasia (salmon-pink mucosa extending above the strictured area).

include intermittent solid food dysphagia, aspiration, and regurgitation. Although the terms "esophageal ring" and "esophageal web" have been used interchangeably, there are subtle differences in what defines each. Rings are circumferential, can consist of mucosa or muscle, and most commonly occur in the distal esophagus.[15] Esophageal webs occupy only part of the esophageal lumen, are always mucosal, and are usually located in the proximal esophagus.

Esophageal webs can in found in as many as 5% of asymptomatic individuals.[72] When symptomatic, they usually cause dysphagia. An association between esophageal webs and iron deficiency was noted by gastroenterologists Plummer and Vinson in the United States and otolaryngologists Paterson and Kelly in the United Kingdom.[73-75] Their descriptions have given the name Plummer-Vinson or Paterson-Kelly syndrome to the triad consisting of proximal esophageal webs, iron deficiency anemia, and dysphagia.[76,77] Barium radiography is the most sensitive means of diagnosing esophageal webs (Fig. 72-29). Endoscopic visualization is also possible, in which the web will appear as a thin, eccentric lesion with normal-looking mucosa. Some webs are located so proximally that routine passage of the endoscope through the UES fractures the web before its presence is known. Treatment of symptomatic esophageal webs consists of mechanical disruption, which can be accomplished with bougie or balloon dilators.

Schatzki's ring (also known as B ring) occurs at the GEJ at the distal margin of the LES and is the most common cause of intermittent solid food dysphagia and food impaction (Figs. 72-30 and 72-31). The presence of symptoms depends on the luminal diameter. If the ring diameter is less than 13 mm, the patient has symptoms; if the diameter is greater than 20 mm, the patient almost never has symptoms.[78] For diameters between 13 and 20 mm, which account for the majority of Schatzki's rings, symptoms are variable. The pathogenesis of esophageal rings is controversial. Some writers believe that the rings are congenital lesions, and others suspect a role for GERD.[79-81] The most sensitive test for detecting a Schatzki's ring is the barium swallow study, but with patience and air insufflation, most rings can also be identified at endoscopy. Treatment is required only in symptomatic patients, in whom mechanical bougienage is usually employed. Recurrent symptoms requiring repeat dilation are not uncommon, and some authorities recommend maintenance therapy with acid suppression, given the possible association of Schatzki's ring with GERD.

The second type of esophageal ring is the A ring, a muscular ring most commonly detected on barium swallow study. This lower esophageal muscular ring, which is rarely symptomatic, occurs at the proximal margin of the LES approximately 2 cm proximal to squamocolumnar junction.

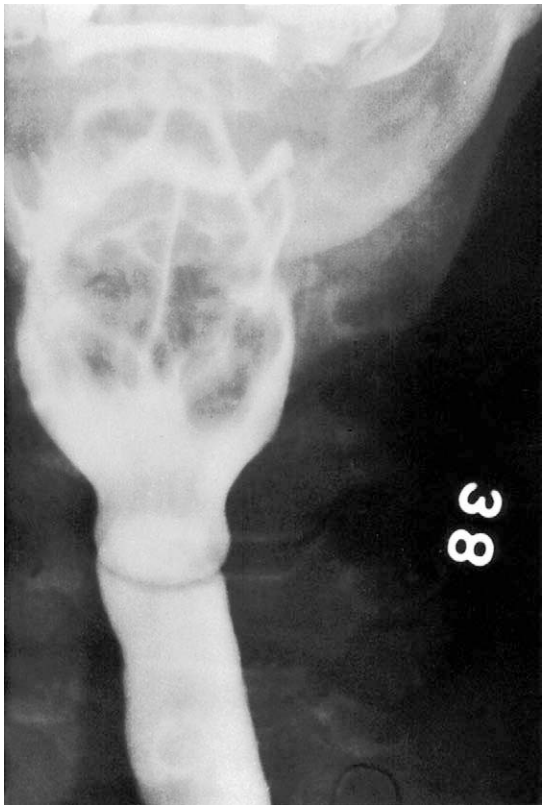

Figure 72-29. Proximal esophageal web on barium swallow study in a patient with Plummer-Vinson syndrome.

Eosinophilic Esophagitis

Also known as "ringed," "feline," or corrugated esophagus, eosinophilic esophagitis has rapidly become an increasingly recognized cause of dysphagia and often food impaction in young adults.[82,83] The syndrome

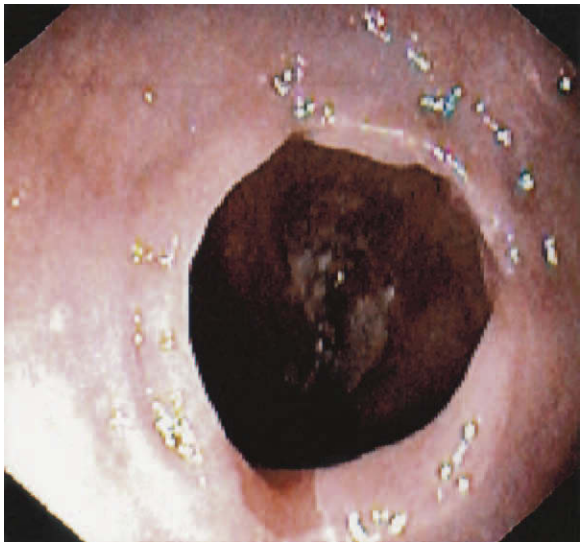

Figure 72-30. Endoscopic view of a Schatzki's ring. Note the significant narrowing in the esophageal lumen.

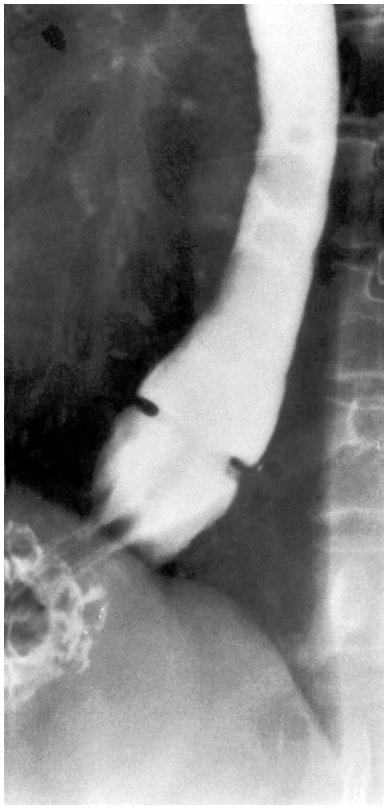

Figure 72-31. Esophagram of the Schatzki's ring in the patient from Figure 72-30.

consists of endoscopic findings of multiple esophageal rings in patients with dysphagia (Fig. 72-32). The etiology is unclear, but GERD, congenital abnormality, and possible allergic conditions have been implicated.[84-86] Eosinophilic esophagitis is characterized by esophageal eosinophilia of greater density than found in acid reflux. The eosinophil density required for the diagnosis of eosinophilic esophagitis is more than 15 eosinophils per high-power field (eos/hpf) in the mucosa that does not clear after appropriate treatment with PPI.[83] Eosinophilic esophagitis is often associated with other atopic diseases. Patients may also have a strong family history of atopy.[83]

Given the limitations of the unknown natural history of eosinophilic esophagitis and the lack of consensus on the therapeutic goal, a number of medical, dietary, and endoscopic therapies are reported. Current studies do not support a significant role for GERD in the majority of patients with eosinophilic esophagitis, but there is clearly a role for acid suppression in those complaining of GERD symptoms. Treatment consists of dilation with bougienage with or without acid suppression. In many cases more than one treatment session is required to obtain a desired esophageal lumen of 15 mm. Patients with eosinophilic esophagitis are also at higher risk of painful deep mucosal tears with dilation. Pharmacologic treatment of eosinophilic esophagitis has been shown to improve clinical symptoms and histology in the majority of patients. Therapeutic options include pharmacologic treatments such as oral and topical corticosteroids and leukotriene receptor antagonists. Dietary modification and food elimination have been effective in the pediatric population, suggesting that certain foods may serve as environmental triggers for the eosinophilic infiltration. Because many adults present with strictures, endoscopic esophageal dilation is another management modality. Despite these treatment options, several controversies exist as to the recommended treatment strategy. Whether the goal of therapy is resolution of symptoms or of tissue eosinophilia or both remains unclear owing to a paucity of data on the natural history of the condition.

Other Esophageal Disease States

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease is defined as chronic symptoms or mucosal damage secondary to the abnormal reflux of gastric contents into the esophagus.[87] *Reflux esophagitis* refers to a disorder in a subgroup of patients with GERD consisting of histopathologically demonstrated characteristic changes in the esophageal mucosa. *Nonerosive reflux disease* is the presence of typical GERD symptoms in a patient without endoscopic findings of esophageal erosion. In the spectrum of GERD, nonerosive reflux disease accounts for approximately 50% of cases, reflux esophagitis for 30% to 40%, and Barrett's esophagus for 10% to 20%.[88]

GERD occurs when the normal antireflux barrier between the stomach and the esophagus is impaired, either transiently or permanently. Therefore, defects in the esophagogastric barrier, such as LES incompetence, TLESRs, and hiatal hernia, are the primary factors involved in the development of GERD.[89] As discussed previously, TLESRs are short relaxations of the LES that do not occur in response to swallow. Studies have demonstrated that TLESRs are the primary mechanism for gastroesophageal reflux in normal individuals and in patients with mild GERD. Conversely, those with severe GERD and complications are more likely to have a permanent structural alteration, such as low LES pressure or a large hiatal hernia.[90] Delayed gastric emptying can also be a contributing factor to the development of GERD. Symptoms develop when the offensive factors in the gastroduodenal contents, such as acid, pepsin, bile acids, and trypsin, overcome several lines of esophageal defense, including esophageal acid clearance and mucosal resistance. As more components of esophageal defense break down, the severity of reflux increases.

Symptoms

Classic symptoms of GERD are heartburn, defined as a retrosternal burning discomfort, and acid regurgitation. Symptoms often occur after meals and may increase when a patient is recumbent. Other ancillary symptoms seen in typical reflux are dysphagia, odynophagia, and belching. Atypical GERD symptoms (discussed later) include asthma, chest pain, cough, laryngitis, and dental erosions.

Diagnosis

There is no diagnostic gold standard for the detection of GERD. Classic symptoms of acid regurgitation and heartburn are specific but not sensitive for the diagnosis of GERD, as determined by abnormal 24-hour pH monitoring. Therefore, it is reasonable to consider an initial empiric trial of antisecretory therapy in a patient with classic GERD symptoms in the absence of alarm signs, such as dysphagia,

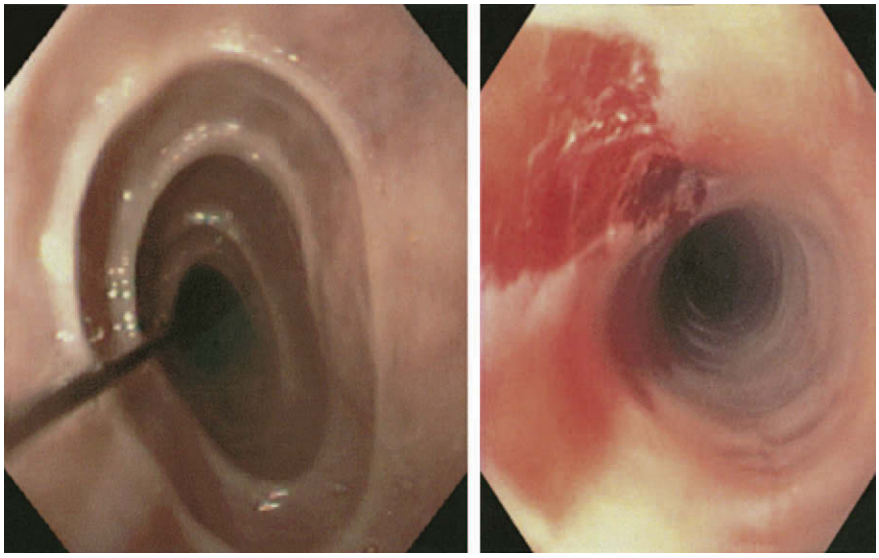

Figure 72-32. Endoscopic views of the esophagus of a 25-year-old man with a 3-year history of severe dysphagia. *Left,* There are multiple rings consistent with "ringed esophagus." *Right,* After bougie dilation, a deep mucosal tear is evident; this is a common complication after dilation for "ringed esophagus."

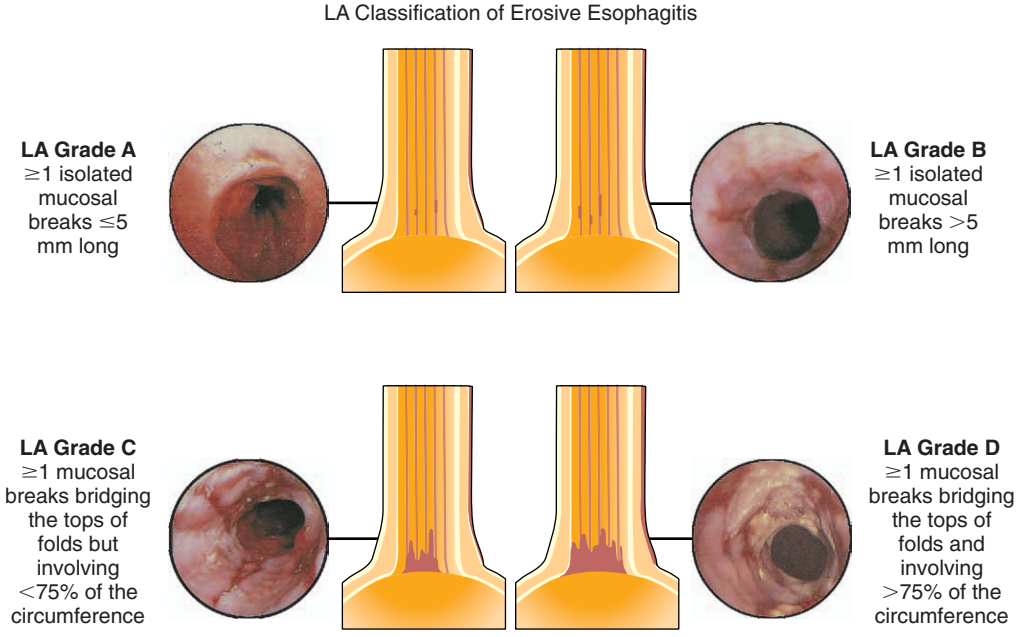

Figure 72-33. Los Angeles (LA) classification of erosive esophagitis. Note that mucosal breaks are necessary for a diagnosis of esophagitis. Subtle findings such as erythema and edema of the gastroesophageal junction are not a part of this classification scheme because they are not specific to gastroesophageal reflux disease.

odynophagia, weight loss, chest pain, and choking. Further diagnostic testing should be considered if there is no response to an empiric course of antisecretory therapy or if alarms signs are present.

Endoscopy is the technique of choice to evaluate the mucosa in patients with symptoms of GERD. Reflux esophagitis is present when erosions or ulcerations are present at the squamocolumnar junction (see Fig. 72-7). There are many grading systems to characterize the severity of esophagitis, the most common of which is the Los Angeles (LA) classification (Fig. 72-33).[91] The presence of esophagitis as well as the finding of Barrett's esophagus are diagnostic of GERD. Although ambulatory 24-hour pH monitoring has long been thought to be the gold standard for the diagnosis of GERD, this test has limitations that remain underappreciated. Results are normal in 25% of patients with erosive esophagitis and in approximately 33% of patients with nonerosive reflux disease.[92] Nevertheless, 24-hour pH testing can be useful to quantitate esophageal acid exposure and allows for the correlation of symptoms to reflux events. Given the lack of a reliable standard test, clinical response to acid suppression is a good indication that a patient's symptoms may be due to GERD.

Treatment

The goals of treatment in GERD are to relieve symptoms, heal esophagitis, prevent recurrence of symptoms, and prevent complications. A variety of lifestyle modifications are recommended in the treatment of GERD. These include avoidance of precipitating foods (fatty foods, alchohol, caffeine), avoidance of recumbency for 3 hours postprandially, elevation of the head of the bed, smoking cessation, and weight loss.[93] However, although these measures make sense physiologically,

little data are available in the literature to support them. Additionally, with the availability of potent acid-suppressive agents, dietary modification as the primary therapy for GERD is no longer overly emphasized.

Antacids and alginic acid can provide temporary relief of episodic heartburn. Despite the wide use of these over-the-counter products, surprisingly few data are available as to their utility for healing reflux esophagitis or for the long-term management of GERD symptoms. Sucralfate, a complex metal salt of sulfated sucrose, is an exceptionally safe medication that has some demonstrated efficacy in the treatment of mild reflux esophagitis. Few published data are available on the use of sucralfate in GERD, however, and the drug has never achieved popularity as antireflux therapy.

In theory, prokinetic agents may decrease gastroesophageal reflux by raising LES pressure and enhancing esophageal and gastric clearance. Currently, metoclopramide is the only prokinetic agent available in the United States for the treatment of GERD. Metoclopramide is a dopamine antagonist, and its use is limited by side effects such as agitation, restlessness, somnolence, and extrapyramidal symptoms, which occur in up to 30% of patients. Cisapride, a serotonin-4 (5-HT_4) receptor agonist, demonstrated efficacy in mild GERD, but this agent was withdrawn when it was found to cause lethal cardiac arrhythmias in patients with a number of predisposing conditions.

The cornerstone of GERD therapy is the administration of agents that decrease gastric acid secretion, thereby reducing esophageal acid exposure. Histamine receptor antagonists (H_2 blockers) in standard divided doses achieve complete symptom relief in approximately 60% of patients and heal esophagitis in about 50%. The H_2 blockers are most useful for patients with GERD of mild to moderate severity, in whom the highest rates of healing can be anticipated. However, healing rates with these agents are poor in patients who have severe reflux esophagitis. High doses of H_2 blockers (up to eight times the conventional dose) have been used effectively to treat esophagitis in severe cases of GERD, but this approach is generally not recommended. Few data document the long-term efficacy of H_2 blockers used in any dosage, and tolerance to the antisecretory effects of these agents develops in many patients. For patients with severe GERD, most authorities prescribe PPIs rather than high-dose H_2 blocker therapy.

PPIs are superior to H_2 blockers in both healing erosive esophagitis and relieving symptoms, with healing rates approaching 90%.[94] For most patients, GERD is a chronic relapsing disease with almost universal recurrence of symptoms after treatment withdrawal; thus, it requires maintenance therapy in many patients. Long-term therapy with PPIs, which maintains remission in 80% of patients, is superior to that with H_2 blockers, which achieve a remission rate of 50%.[95] With more than a decade of clinical experience with PPIs in the United States, initial concerns regarding the long-term safety of these agents remain unsubstantiated.[96] In clinical practice, "step-down" therapy is recommended in patients in whom GERD is suspected. Patients are initially treated with PPIs; and once clinical response is noted, patients are treated with H_2 blockers or PPI on an as-needed basis.

Antireflux surgery, now performed primarily by the laparoscopic approach, remains an option for carefully selected patients with well-documented GERD.[97] The ideal candidate is the patient with typical symptoms that respond completely to antisecretory therapy. The patients who opt for surgery typically have concerns about the cost or potential adverse effects associated with long-term PPI therapy. Patients with large hiatal hernias and predominant regurgitation symptoms are also good candidates. However, in some patients, GERD is refractory to acid suppression with high-dose PPI therapy; any consideration of surgery in such patients must be guarded, and the clinician should document continued evidence of ongoing esophageal acid exposure or damage during therapy. Studies with impedance pH monitoring in patients with GERD refractory to PPI therapy suggest a possible benefit of surgery in those with continued nonacid reflux; however, controlled studies are needed before surgery can be recommended in this group. At this time, surgery is not advised in patients with GERD unresponsive to PPIs who have no evidence of esophageal acid exposure or nonacid regurgitation.

There has been some interest in endoscopic therapy for GERD.[98,99] Several such therapies have become available and are undergoing clinical trials. These techniques include endoscopic suturing, injectable agents for bulking the GEJ (Enteryx, which was withdrawn from the market; and Gatekeeper Reflux Repair System, Medtronic, Inc., Minneapolis, MN), and radiofrequency energy delivery to the GEJ. All are shown to result in improved LES pressure; however, most studies of endoscopic therapy have only limited follow-up information in a relatively small number of patients. Therefore, the durability of these devices is unknown. Serious adverse events were reported with Enteryx, which led to the voluntary withdrawal by the manufacturer in September 2005 and suspension of the Gatekeeper clinical program in late 2005. A number of other endoscopic antireflux procedures are under investigation. Small studies describe promising results, but the safety and efficacy of these procedures are not yet known, and their role in the treatment of GERD is not clear.

Extraesophageal Gastroesophageal Reflux Disease

GERD may manifest as symptoms other than heartburn and regurgitation. They include asthma, chest pain, chronic cough, laryngitis, and dental erosions. Although the relationship between each atypical symptom and GERD varies, there are some common themes. In addition to the lack of the classic heartburn and regurgitation symptoms, esophagitis or Barrett's esophagus is usually not present. Additionally, response to antireflux therapy in patients with these symptoms is often less predictable. In general, an empiric trial of twice-daily PPI therapy is indicated as initial treatment because there is no definitive diagnostic standard for GERD. If treatment fails, full investigation with ambulatory pH testing is recommended to ensure that medical therapy has been intensive enough (Fig. 72-34). The diagnosis of GERD can be confirmed only when the symptom is relieved consistently with specific antireflux therapy.

Laryngitis

There is increasing evidence that GERD causes laryngeal signs and symptoms. This is often referred to as "reflux laryngitis" or "laryngopharyngeal reflux." In fact, it is estimated that 4% to 10% of patients presenting to otorhinolaryngologists do so because of symp-

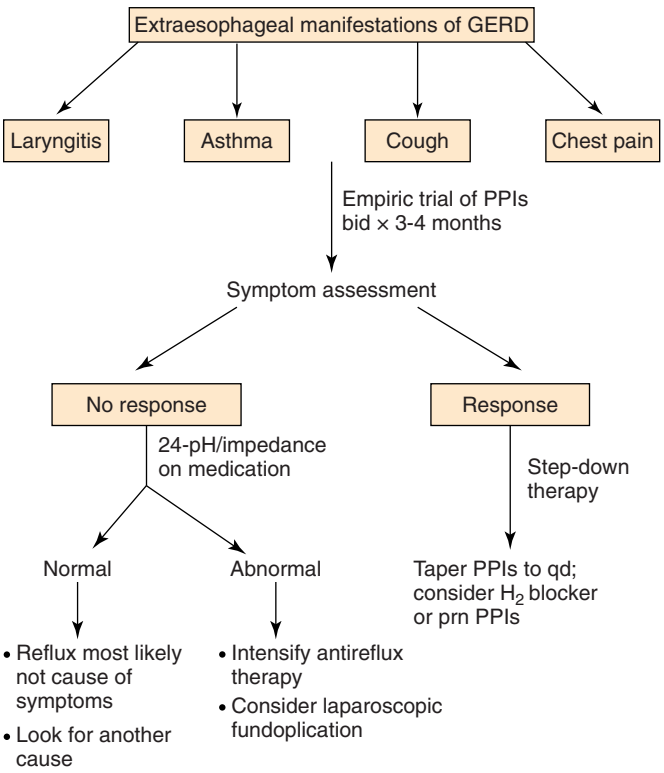

Figure 72-34. Treatment algorithm for extraesophageal manifestations of gastroesophageal reflux disease (GERD). bid, twice daily; pm, evening dose; qd, once daily; PPIs, proton pump inhibitors.

toms in part related to GERD.[100] Symptoms of reflux laryngitis include hoarseness, throat clearing, dysphagia, increased phlegm, and globus sensation.

GERD may be responsible for causing significant laryngeal changes, including erythema, edema, pharyngeal ulcerations, vocal cord nodules and polyps, granulomas, and even leukoplakia and cancer. Although some writers believe that these laryngeal signs are specific for acid-related problems, others suggest that these changes may also be secondary to smoking, excessive alcohol use, allergies, asthma, viral illnesses, or voice abuse. One study investigated the baseline prevalence of laryngeal signs in 105 healthy subjects without reflux or laryngeal complaints; the majority of these normal subjects (87%) had at least one abnormal finding in the larynx.[101] The three most common laryngeal findings were interarytenoid bar, arytenoid medial wall erythema, and posterior pharyngeal wall cobblestoning, all of which had previously been considered pathognomonic for GERD. Importantly, these signs in healthy subjects were associated with the presence of other ear, nose, and throat irritants, including chronic nasal congestion, postnasal drip, alcohol use, and asthma. Therefore, this study suggests the potential for overdiagnosis of GERD due to the poor specificity of some of the currently designated laryngeal signs of the disease. Studies comparing laryngeal signs in normal volunteers with those in patients with GERD suggest that two laryngeal findings may be more specific for GERD-induced laryngeal injury, vocal cord lesions, and arytenoid medial wall erythema and edema.[102] These encouraging data suggest a likelihood of identifying more specific laryngeal sites in patients with GERD.

Despite compelling epidemiologic data, there is still controversy about the prevalence of GERD-related laryngeal signs and symptoms, in part because of the lack of consensus about the utility of 24-hour esophageal pH monitoring in diagnosing this disorder. Studies have clearly shown that 24-hour pH monitoring may not be the perfect test for diagnosing atypical GERD. Overall, only 50% of patients with laryngoscopic signs of GERD have abnormal esophageal acid exposure, irrespective of the location of the pH probe (distal or proximal esophagus or hypopharyngeal). This low rate may be due either to overdiagnosis of GERD as the cause of laryngeal pathology or to the lack of sensitivity of the pH probes in diagnosing acid-related disease in this group of patients. Distal and proximal esophageal pH probes are at best 75% and 50% sensitive, respectively, for detection, of acid reflux in a group of patients with classic acid reflux disease (i.e., heartburn, acid regurgitation, and, possibly, esophagitis).[103] Furthermore, studies using distal, proximal, or hypopharyngeal probes in patients with laryngeal pathology yielded conflicting data on the ability to predict clinical improvement on the basis of abnormal findings for each of the pH probes.

Owing to the unpredictable response to acid suppression, there are currently no accepted protocols for the most cost-effective treatment of patients with GERD and laryngeal signs and symptoms. H_2 blockers usually produce only mild to moderate improvements, at best. However, PPIs may be more effective and should be the first line of therapy in patients in whom reflux-related laryngeal signs and symptoms are suspected.[104,105] Clinical response rates ranging from 60% to 98% have been reported with medical therapy. However, there is a lack of consensus on dosing, frequency, and duration of therapy in this group of patients. Initial aggressive therapy with twice-daily dosing followed by tapering to once-daily in patients showing response to therapy is the treatment approach currently recommended (see Fig. 72-34).

The negative results for PPI therapy obtained by placebo-controlled studies in this field[106] reflect the lack of a standard in identifying patients with a true GERD-related cause for their laryngeal signs and symptoms. Nonetheless, results of open-label studies suggest that PPIs may be more effective than H_2 blockers and should be the first line of therapy in patients suspected of having reflux-related laryngeal signs and symptoms.[107,108]

Asthma

There is a clear association between asthma and GERD. Approximately 70% to 80% of patients with asthma have GERD.[109-111] The two major pathophysiologic mechanisms proposed for acid-induced asthma are (1) proximal esophageal reflux leads to microaspiration/bronchospasm, and (2) a vagally mediated esophageal-bronchial reflex results in bronchospasm.[112] Patients with adult-onset asthma, no family history of asthma or atopy, and heartburn, especially if it precedes the onset of asthma, may have GERD-related asthma. Similarly, wheezing that is exacerbated by meals, exercise, or the supine position and nocturnal wheezing may be GERD related.[113] As with laryngitis, diagnostic testing with ambulatory pH monitoring for asthma possibly related to GERD is controversial, especially because vagally mediated bronchospasm may not be associated with proximal reflux. Clinical data, based on meta-analysis, suggest that treatment of GERD in patients with asthma usually improves respiratory symptoms in 69% of patients and reduces asthma medication use by 62%.[109,112] However, objective improvements in pulmonary function tests have not been consistently reported. In clinical practice, most patients with asthma are treated with a PPI to suppress GERD and possibly help with control of GERD and asthma symptoms.

Chest Pain

Noncardiac chest pain has been a clinical conundrum for decades. Patients classically present with recurring angina-like, substernal chest pain for which the cardiac workup results are negative. Noncardiac chest pain may have a pulmonary, musculoskeletal, or esophageal cause, with the esophagus often implicated as the culprit. The primary esophageal cause is GERD, present in 40% to 60% of patients.[113] Once cardiac disease is ruled out, the most cost-effective initial therapy is a trial of PPIs for 3 months (see Fig. 72-34). One study reported a 92% rate of response, defined as more than 50% improvement in symptoms, in patients with noncardiac chest pain undergoing PPI therapy.[114] Another prospective placebo-controlled study in 36 patients with noncardiac chest pain and GERD demonstrated a reduction of chest pain score in 81% of the treated group, compared with 44% in the placebo group.[115] Endoscopy has a limited role in noncardiac chest pain. The prevalence of erosive esophagitis in patients with noncardiac chest pain is less than 10%.[116] Endoscopy is indicated only if there are other symptoms, such as dysphagia, odynophagia, and weight loss, and in patients with chronic reflux symptoms.

Chronic Cough

GERD is the third most common cause (after postnasal drip and asthma) of chronic cough, which is defined as cough duration greater than 3 months, accounting for 21% of cases of chronic cough.[117] The pathophysiology of GERD-related cough includes both irritation of the upper respiratory tract (with or without aspiration) and stimulation of an esophageal-bronchial cough reflex. Patients with chronic cough from GERD have normal chest radiograph findings, are nonsmokers, are not taking medications known to cause cough (such as angiotensin-converting enzyme inhibitors), and have had no response to treatment for asthma and postnasal drip. Between 43% and 75% of patients with GERD-related cough have no typical reflux symptoms.[117,118] The best initial evaluation is a trial of PPI therapy, which must be maintained for 3 months because GERD-related cough can take this long to resolve (see Fig. 72-34).[119] Despite the limitations noted previously, 24-hour pH monitoring may be helpful in the management of GERD-related cough. It also allows temporal correlation between reflux events and cough. If the cough is produced by GERD, the pH drop should occur simultaneously or within 5 minutes after a reflux episode.[118,120] On the other hand, cough preceding a pH drop suggests secondary reflux. Patients who have normal pH study results with a poor relationship to symptoms have no response to acid suppression, and GERD-related cough is excluded. Alternatively, a positive pH study result does not adequately predict response to therapy. In one study of patients with chronic cough and abnormal pH testing results, only 35% had relief with sustained acid suppression.[121]

Dental Erosion

Dental erosion is a loss of tooth structure secondary to a chemical rather than bacterial cause. An association of dental erosion with GERD has

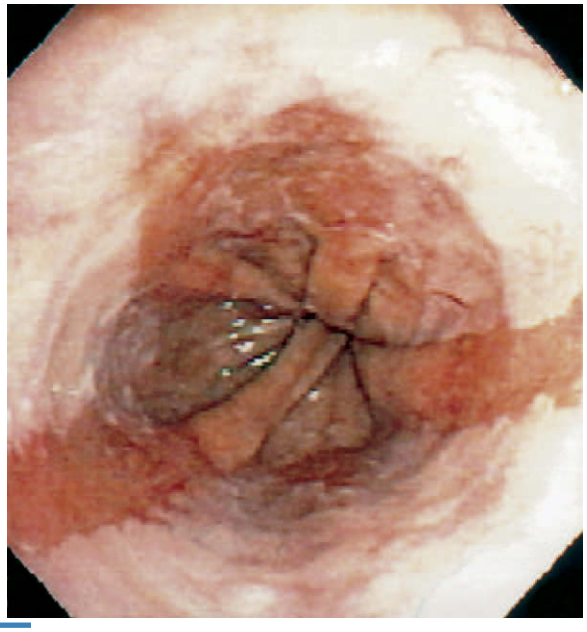

Figure 72-35. Short-segment Barrett's esophagus. "Tongues" of red columnar mucosa extend less than 3 cm above the gastroesophageal junction.

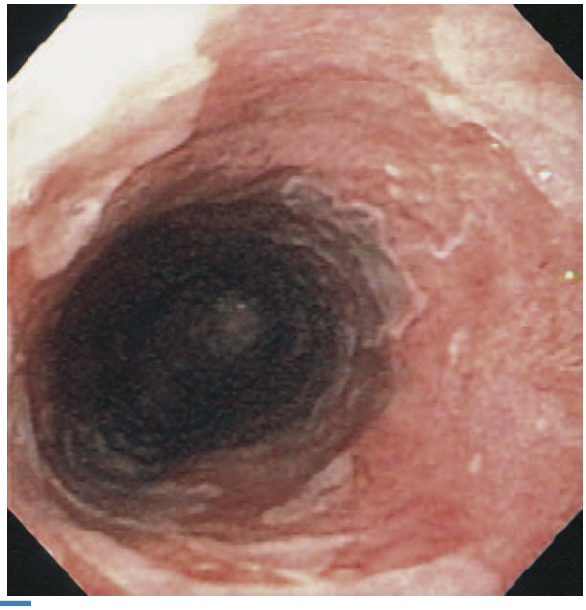

Figure 72-36. Long-segment Barrett's esophagus. The columnar mucosa extends longer than 3 cm above the gastroesophageal junction. Islands of normal squamous mucosa are present within the Barrett's metaplasia.

been demonstrated, and thus dental erosions are considered an atypical expression of GERD. The reported prevalence of dental erosions in patients with GERD has varied from 17% to 68%.[122] The pathophysiology is simple: Chronic exposure to acid can lead to loss of enamel and tooth substance. This complication of GERD is important to recognize because treatment can limit the damage. In addition, referral to a dentist can lead to prompt diagnosis and treatment of dental lesions and institution of preventive dental therapy.

Barrett's Esophagus

Barrett's esophagus is a potentially serious complication of long-standing GERD. Barrett's esophagus is present when the normal stratified squamous epithelium of the distal esophagus has been replaced by intestinal columnar metaplasia. It is the most significant outcome of chronic GERD and predisposes to the development of esophageal adenocarcinoma.

Barrett's esophagus is suspected endoscopically when the pale pink squamous mucosa of the distal esophagus is replaced to various length with salmon-pink columnar mucosa (Figs. 72-35 and 72-36). In Barrett's esophagus, the squamocolumnar junction is displaced proximal to the GEJ, and the diagnosis is confirmed with a biopsy finding of intestinal metaplasia, which is different from normal esophageal mucosa lined by stratified squamous mucosa (Figs. 72-37 and 72-38). Intestinal metaplasia is characterized by mucin-containing goblet cells, which can be detected by routine hematoxylin and eosin stain or accentuated with an alcian blue stain. Barrett's esophagus may be divided into short segment (SSBE) and long segment (LSBE) types (see Figs. 72-35 and 72-36) according to whether the metaplasia is longer or shorter than 3 cm. It is more common to find to dysplasia and cancer in a patient with LSBE, but patients with SSBE are also at increased risk.

It is estimated that 6% to 12% of patients undergoing endoscopy for GERD are found to have Barrett's esophagus.[123] The risk is highest in the older white males. Unfortunately, most cases of Barrett's esophagus go undetected in the general population, and it is estimated that for every known case of Barrett's, 20 cases are not identified.[124] Although there are no specific symptoms related to Barrett's esophagus, it is clearly associated with more severe gastroesophageal reflux. Patients with this disorder tend to have reflux at a younger age, have a long duration of reflux symptoms, are more likely to have nocturnal symptoms and hiatal hernias, and have increased complications from GERD,

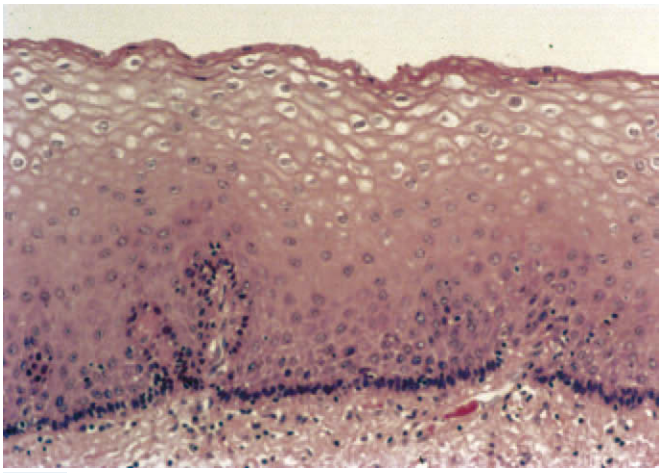

Figure 72-37. Histologic appearance of normal esophagus with stratified squamous epithelium.

such as esophagitis and strictures. However, some patients have impaired sensitivity to acid and their symptoms are no worse than those of uncomplicated GERD. Thus it is recommended that patients with prolonged GERD symptoms, especially middle-aged white men, undergo endoscopic screening for Barrett's esophagus.[125]

If Barrett's esophagus is confirmed, these patients require continued endoscopic surveillance to detect the development of dysplasia and adenocarcinoma. The risk of esophageal adenocarcinoma in Barrett's esophagus is approximately 0.5% annually.[126] The goal of surveillance is to detect cancer at an earlier and potentially curable stage. Several retrospective studies demonstrate that for patients with Barrett's esophagus in whom adenocarcinoma was detected in a surveillance program the cancer is detected at an earlier stage and 5-year survival is better than for similar patients not undergoing routine surveillance.[127-129] Current endoscopic surveillance guidelines suggest 4-quadrant biopsies at 2-cm intervals along the entire length of Barrett's esophagus every 3 years.[125] Special attention should be paid to any and all mucosal

Figure 72-38. Histologic appearance of distal esophageal biopsy specimen showing goblet cells diagnostic of Barrett's metaplasia.

Table 72-2

Surveillance of Barrett's Metaplasia

Dysplasia	Confirmation	Intervention
None	Two EGDs with four-quadrant biopsy specimens every 2 cm	Surveillance endoscopy every 3 years
Low-grade	Highest grade on repeat EGD with biopsy remains low	Surveillance endoscopy every year until no dysplasia
High-grade	Repeat EGD with four-quadrant biopsy specimens every cm Expert pathologist confirmation	Focal high-grade dysplasia: surveillance endoscopy every 3 months Multifocal high-grade dysplasia: esophagectomy, ablation therapy, or esophageal mucosal resection

EGD, esophagogastroduodenoscopy.

abnormalities. Even with this extensive biopsy protocol, there is potential for sampling error because the distribution of dysplasia and cancer is variable. Surveillance endoscopy should not be performed until any active inflammation of GERD is controlled, because landmarks are more difficult to identify in the presence of inflammation, and reparative changes make interpretation of biopsies for dysplasia difficult.

Surveillance biopsy specimens are examined for the presence and degree of dysplasia. Dysplasia should be categorized on the basis of expert consensus into one of the following categories: (1) negative for dysplasia, (2) indefinite for dysplasia, (3) low-grade dysplasia, (4) high-grade dysplasia, and (5) carcinoma.[130,131] Surveillance intervals for Barrett's esophagus are based on the presence and extent of dysplasia, as outlined in the updated practice guidelines of the American College of Gastroenterology (ACG) (Table 72-2).[125] Patients with no evidence of dysplasia on two consecutive biopsies can be followed every 3 years. Those in whom low-grade dysplasia is the highest grade after follow-up endoscopy with concentrated biopsies in the area of dysplasia should be followed annually until there is no dysplasia. The natural history of low-grade dysplasia is variable, but the variability may in part be due to interobserver variability in establishing the diagnosis. In one study of patients with low-grade dysplasia who were followed up for a mean of 26 months, 28% progressed to have high-grade dysplasia or adenocarcinoma, 62% had regression of the dysplasia, and 12% continued to have low-grade dysplasia.[132]

High-grade dysplasia is a concerning finding that requires further investigation. Unsuspected carcinoma has been detected in esophagectomy specimens in approximately 40% of patients with high-grade dysplasia.[133] On the other hand, progression to adenocarcinoma can take many years and is not inevitable. Studies have shown variable rates of progression to cancer, as high as 59% at 5 years and as low as 20% at 7 years.[134,135] Given these facts, the treatment of high-grade dysplasia is controversial. It is essential that an expert gastrointestinal pathologist confirm that high-grade dysplasia is present.[125] Focal high-grade dysplasia may be followed with intensive surveillance (3-month intervals), and intervention should be considered in patients with multifocal disease. Intervention may involve esophagectomy, mucosal ablation with photodynamic therapy, or endoscopic mucosal resection for mucosal irregularities.

Neoplasia

Neoplasia in the esophagus is relatively uncommon but when present is typically malignant. Approximately 12,000 cases of esophageal carcinoma occur in the United States each year.[136] The two main culprits are esophageal squamous cell carcinoma and esophageal adenocarcinoma. More than half the U.S. cases are now adenocarcinoma, which has been increasing in frequency dramatically over the past half-century.

Although the two malignancies have similar presentations and staging, their epidemiologic patterns are quite different. Squamous cell carcinoma (SCC) of the esophagus is typically a disease of African-American men and is associated with alcohol and tobacco abuse. Patients with a history of caustic esophageal injury are also clearly at increased risk. Other conditions, including achalasia, Plummer-Vinson syndrome, tylosis, and a history of head and neck SCC, may also confer increased risk. Esophageal dysplasia and SCC have also been associated with human papillomavirus. On the other hand, adenocarcinoma is predominantly a disease of white men and has a well-documented association with GERD and Barrett's esophagus, as discussed previously.[137] The midesophagus is the most common site of SCC, followed by the distal esophagus, and then the proximal esophagus, whereas adenocarcinoma occurs predominantly in the distal esophagus and at the GEJ (Fig. 72-39).

Patients with esophageal malignancy typically present with rapidly progressive solid food dysphagia secondary to mechanical obstruction. Less commonly, patients may present with odynophagia, iron deficiency, or hoarseness from recurrent laryngeal nerve injury. Up to 75% of patients experience weight loss prior to presentation. SCC is an aggressive locally invasive malignancy, and complications related to local invasion are common. These include tracheoesophageal fistulas and recurrent laryngeal nerve injury with vocal cord paralysis. Distant metastases occur to the lung, liver, bone, and brain. Adenocarcinomas, although not as locally invasive, often have lymphatic and liver metastases. Most patients have advanced disease at the time of presentation because the esophagus has a rich lymphatic supply extending into the lamina propria.

Once a malignancy has been diagnosed by endoscopy with biopsy, rigorous staging is employed. The stage of the disease at diagnosis determines outcome and treatment options. Staging is accomplished through a combination of computed tomography and endoscopic ultrasonography. Computed tomography can accurately identify metastatic disease, but evaluation of the depth of invasion is best accomplished by endoscopic ultrasonography. Staging is based on the TNM classification (Box 72-3).[138] Patients who have early stage disease, namely T1 or T2 without nodal or metastatic disease, can be treated with surgery alone. Patients with more advanced disease, such as T3 or N1, may benefit from neoadjuvant chemotherapy/irradiation before surgical

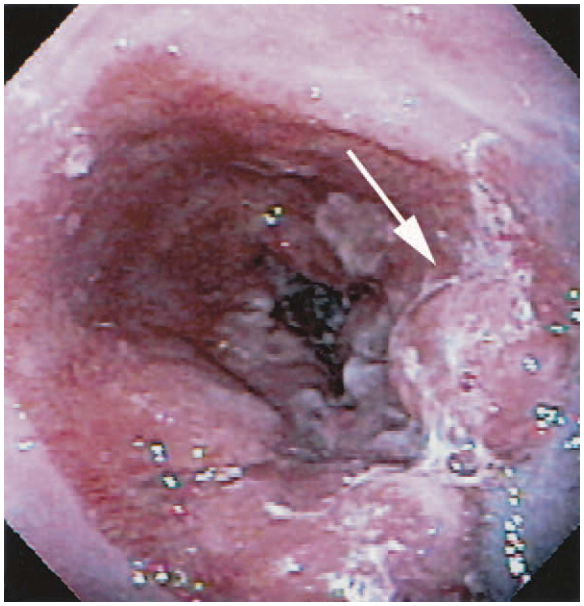

Figure 72-39. Esophageal adenocarcinoma arising in Barrett's esophagus. *Arrow* indicates the nodular mass.

Box 72-3

TNM Staging Classification for Esophageal Cancer

Primary Tumor (T)

TX: Primary tumor cannot be assessed
T0: No evidence of primary tumor
Tis: Carcinoma in situ
T1a: Tumor invades lamina propria
T1b: Tumor invades submucosa
T2: Tumor invades muscularis mucosa
T3: Tumor invades adventitia
T4: Tumor invades adjacent structures

Regional Lymph Nodes (N)

NX: Lymph nodes cannot be assessed
N0: No evidence of lymph node metastasis
N1: Lymph node metastasis

Distant Metastasis (M)

MX: Distant metastasis cannot be assessed
M0: No evidence of distant metastasis
M1: Distant metastasis

resection. Those with late stage disease receive palliative treatment. Palliative endoscopic measures include repeated dilation, laser/photodynamic therapy ablation, esophageal stent placement, and percutaneous endoscopy gastrostomy tube placement.

Under most circumstances, esophageal cancer is identified at a late, incurable stage. Five-year survival rates for SCC are predictably less than 10%. Esophageal adenocarcinoma has a similar poor prognosis, with 5-year survival rates below 15%.[139] Survival is stage dependent, T1 lesions being associated with a 5-year survival of 46%, and T4 lesions with a survival of 7%.[140] There is some hope that with increased screening and surveillance for Barrett's esophagus in patients with GERD, adenocarcinoma can be detected at an earlier and potentially curable stage.

Figure 72-40. Midesophageal traction diverticulum. The true esophageal lumen is located inferiorly. Traction diverticula are the only true diverticula that form in the esophagus.

Esophageal Diverticula

An *esophageal diverticulum* is a sac that protrudes from the esophageal wall. As in the rest of the gastrointestinal tract, a true diverticulum is one that contains all layers of the wall. A false diverticulum contains mucosa and submucosa that have herniated through the muscular wall. Esophageal diverticula are most practically classified anatomically into the following four categories: Zenker's diverticula, midesophageal diverticula, epiphrenic diverticula, and intramural pseudodiverticulosis.

Zenker's diverticulum, first described in 1877, is often referred to as an esophageal diverticulum.[141] However, it is located proximal to the esophagus, above the UES, and should be considered a hypopharyngeal diverticulum. Zenker's diverticula are believed to form as a result of an area of weakness, Killian's triangle, which exists between the cricopharyngeal sphincter and the inferior pharyngeal constrictor muscle. The primary abnormality that leads to the development of the diverticula is incomplete relaxation of the UES. An association between Zenker's diverticulum and reflux has been suggested but not confirmed. Typical symptoms include oropharyngeal dysphagia, regurgitation of undigested food, halitosis, cough, and aspiration pneumonia. The barium swallow study is an excellent test for the diagnosis of Zenker's diverticulum. Many small diverticula are asymptomatic, but symptomatic patients with large diverticula should be offered treatment. The classic treatment is an open surgical resection of the diverticulum with division of the cricopharyngeus muscles.[142] Another option for extremely large diverticula is diverticulopexy, or suspension of the diverticulum in a cranial direction.

Midesophageal diverticula are most commonly asymptomatic and, as their name implies, occur in the mid-esophagus (Fig. 72-40). Traction diverticula form as a result of external pulling of the esophageal wall by neighboring inflammatory or fibrotic tissue, such as adjacent tuberculous mediastinitis.[143] Traction diverticula are located in the middle third of the esophagus. Midesophageal traction diverticula are the only true diverticula in the esophagus. A second type of midesophageal diverticulum is a pulsion diverticulum, which results from internal forces applied to a portion of the esophageal wall. These often relate to motility disorders, and their pathogenesis is similar to that of Zenker's and epiphrenic diverticula.

Epiphrenic diverticula, which are located near the diaphragmatic hiatus, occur in the distal esophagus near the LES (Fig. 72-41). These diverticula are often the result of a motility disorder, such as achalasia or diffuse esophageal spasm.[144,145] It is imperative to obtain manometric studies in patients with epiphrenic diverticulum to rule out an associated motility disorder. Most diverticula are asymptomatic, but

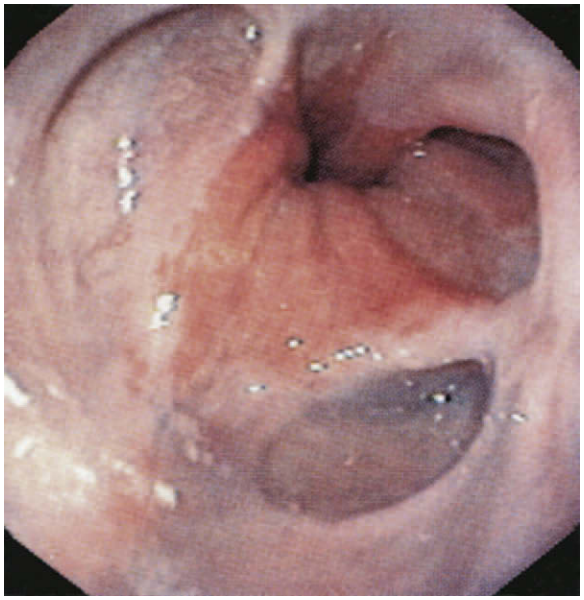

Figure 72-41. Multiple epiphrenic diverticula. Epiphrenic diverticula are located in close proximity to the gastroesophageal junction. These diverticula are strongly associated with motility disorders such as achalasia.

occasionally chest pain or regurgitation can be prominent symptoms. Treatment consists of managing the underlying motility disorder and, for symptomatic diverticula, diverticulotomy with or without myotomy.

Esophageal intramural pseudodiverticula are multiple small outpouchings apparent on barium swallow study or endoscopy (Fig. 72-42). These rare outpouchings are not diverticula but rather dilated submucosal glands. The etiology is not clear, but they are associated with acid reflux, esophageal strictures, and esophageal cancer.

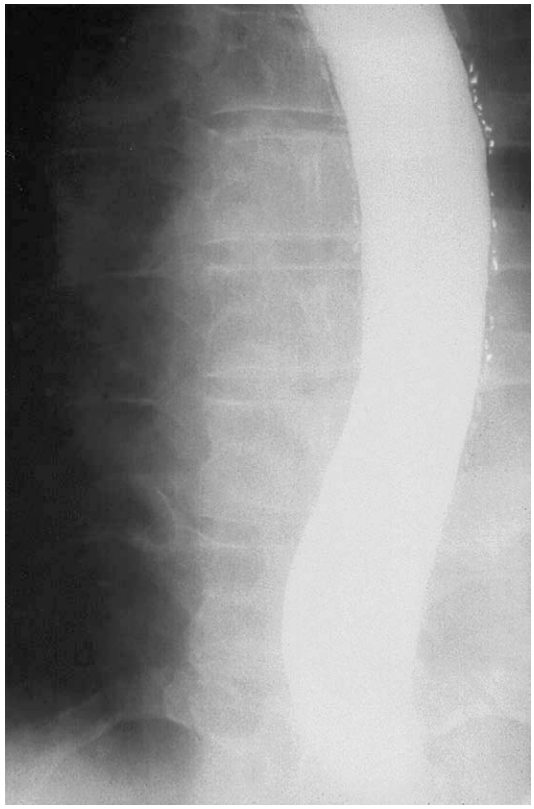

Figure 72-42. Esophageal pseudodiverticulosis. Multiple small outpouchings can be seen emanating from the esophagus. These pseudodiverticula are actually dilated submucosal glands.

Foreign Body

Foreign bodies in the gastrointestinal tract are a common clinical problem. Ingestion of a foreign body, either accidental or intentional, is common in pediatric patients, psychiatric patients, and prisoners. Elderly patients with loose-fitting dentures also pose a unique risk. Management principles are based on the nature of the ingested foreign body and its location within the gastrointestinal tract. The esophagus is one of the foreign body locations for which intervention is often required. Underlying alterations in the lumen of the esophagus play an important role in the risk that a swallowed object may become lodged. The esophagus has several areas of physiologic narrowing where a foreign body may become impacted: the UES, the level of the aortic arch, and the diaphragmatic hiatus/LES. The key to the management of foreign bodies is understanding that different foreign bodies require different interventions. It is important to distinguish a true foreign body from a food impaction.

Food impactions tend to occur in adults with benign structural abnormalities of the esophagus. Patients usually present with the sudden onset of dysphagia in relation to swallowing a large piece of beef, hot dog, or bread. Patients may complain of chest pain and difficulty swallowing their own saliva. Typically, the patient has a history of intermittent solid food dysphagia. Management includes obtaining anteroposterior and lateral chest radiographs to assess for free air and look for bones in the food bolus. A trial of pharmacologic therapy with glucagon, 1 to 2 mg intravenously, which relaxes the LES, can be performed but is rarely successful in relieving a food impaction. The primary therapy for food impaction is prompt endoscopy. If the patient is able to manage his or her own saliva and is comfortable, endoscopy can be performed as a nonurgent procedure, but preferably within 12 hours.[146,147] There is no role for barium swallow studies, except to confirm disimpaction. Endoscopic removal of impacted food can be a difficult procedure, because usually some digestion has taken place and the impacted food cannot be removed easily in its entirety. Although blind pushing with the endoscope is discouraged, the food bolus often passes with a gentle push from the endoscope. If the endoscope can be maneuvered around the impaction and luminal patency confirmed, it is reasonable to attempt once more to push the bolus into the stomach. If the bolus cannot be safely pushed into the stomach, it must be removed with the endoscope. This may require piecemeal extraction with the use of grasping forceps and multiple passes of the endoscope. Other equipment, including snares, nets, and baskets, can also be used under direct visualization. Because of the need for multiple passes and to protect the airway, an overtube is often used. Sometimes, once the bolus has been debulked with a forceps, it passes into the stomach with gentle pressure.

After removal of the foreign body, the esophagus should be assessed for underlying pathology, which is present in approximately 90% of patients.[148,149] It can be difficult to assess because usually some inflammation, edema, and erythema are present. If a benign structural abnormality is present, dilation should be arranged at a later date. If only minimal inflammatory change is present, dilation may be performed safely in the same session.

True foreign bodies are classified according to their physical characteristics: small and blunt, sharp or pointed, or long. Plain neck, chest, and abdominal radiographs are essential to evaluate for perforation and to attempt to localize a foreign body. Any foreign body in the esophagus must be removed because pressure necrosis with resultant perforation might otherwise occur. Sharp or long objects, which carry a risk of perforation of 15% to 35%, should be removed regardless of location.[150] Conversely, most small blunt objects that have passed the esophagus will also pass through the remainder of the gastrointestinal tract without incident.

Small blunt objects, such as coins, can become lodged at areas of physiologic or pathologic narrowing even if they are smaller than the usual esophageal diameter of 20 mm. Small objects can be removed endoscopically from the esophagus, with use of a variety of specialized

Box 72-4

forceps designed for foreign body extraction. As with food impaction, an overtube is often required for airway protection. In children, the procedure is usually performed with the use of general anesthesia and endotracheal intubation to protect the airway.

The presence of a sharp or long foreign body in the esophagus is an emergency, whereas the presence of a foreign body that has passed into the stomach can be addressed urgently. In any attempt to remove a sharp foreign body endoscopically, the object must be grasped from its blunt end, with its sharp end directed distally,[151] to minimize the risk of perforation. Many sharp objects pass through the gastrointestinal tract without difficulty. If the object is not within reach of the endoscope, the patient should be monitored closely with radiographs, and surgery should be considered if there is evidence of perforation, obstruction, or nonprogression.

Pill-Induced Injury

Pill-induced injury to the esophagus is an underappreciated entity. It is estimated that well over 70 drugs are capable of injuring the esophagus.[152] Drugs commonly associated with pill-induced injury are potassium chloride tablets, doxycycline, quinidine, nonsteroidal anti-inflammatory drugs, iron, and alendronate (Box 72-4). Pills damage the esophagus by various mechanisms, such as acidity, size, and contact time with esophageal mucosa. There is a wide spectrum of injury, from acute self-limited esophagitis to refractory strictures. The typical sites of pill-induced injury are at the level of the aortic arch and the distal esophagus, where there is anatomic narrowing. Most patients with pill-induced esophageal injury do not have other esophageal problems, such as strictures and motility disorders. They typically present with chest pain and odynophagia. Dysphagia usually reflects a stricture within the inflammatory changes. In a patient with symptoms, the diagnosis is often made by endoscopy. Mucosal changes found at endoscopy can also vary widely; they include ulcer formation, plaques resembling *Candida* infection, and strictures. Management can be difficult. It involves repeated dilations for strictures and avoidance of the offending agent. To prevent further damage, all medicines should be taken in liquid form. All medications should be taken with sufficient fluids, and the patient should remain upright for 15 to 30 minutes after swallowing pills. Symptoms and endoscopic findings usually resolve within weeks after the patient stops taking the culprit pill.[152]

Infectious Esophagitis

Infectious esophagitis is common, especially in immunosuppressed hosts such as patients with human immunodeficiency virus, patients with transplants, and patients undergoing chemotherapy. The cardinal symptom of infectious esophagitis is odynophagia. However, immunodeficient patients can present with a variety of symptoms, including heartburn, nausea, fever, and bleeding. The three most common causes of infectious esophagitis are *Candida albicans*, cytomegalovirus (CMV), and herpes simplex virus (HSV).

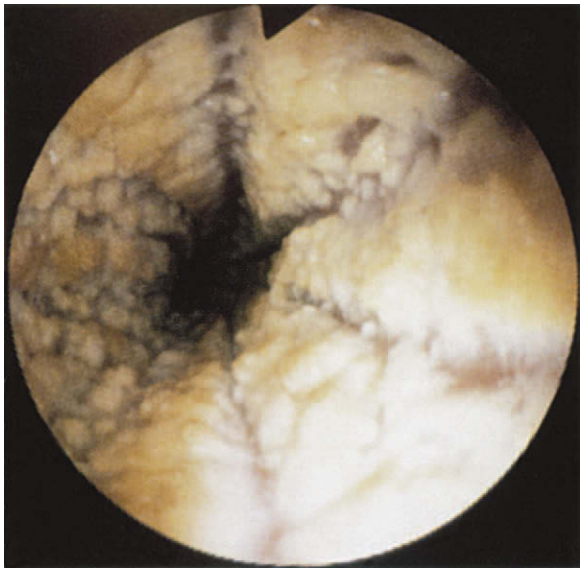

Figure 72-43. Endoscopic view of severe *Candida* esophagitis. The esophageal lumen is obscured by thick adherent white-yellow plaques.

C. albicans, which is normally found in oral flora, is the most common cause of infectious esophagitis in immunocompromised hosts including those with diabetes mellitus, alcoholics, and users of glucocorticoids, in addition to those mentioned previously.[153] Other predisposing factors are advanced age, hypochlorhydria, and motility disorders. Oral thrush, if present, is a helpful diagnostic finding, because 75% of patients with esophageal symptoms also have candidal esophagitis.[63,154] Many patients at risk are treated empirically with antifungal medications, but a definitive diagnosis is made by endoscopy with biopsy and brushings. The classic endoscopic appearance consists of adherent white to pale yellow plaques (Fig. 72-43). It should be noted that this appearance is not pathognomonic for *Candida*, because it can occur with any cause of esophagitis. Examination of brushings of the plaques reveals hyphae and budding yeast in the presence of *Candida*. Treatment consists of antifungal therapy, most commonly with fluconazole, 100 to 200 mg per day for 10 to 14 days. In patients with only mild immunologic deficiencies, the topical antifungals clotrimazole and nystatin are reasonable alternatives. These agents are virtually devoid of side effects but require administration four or five times a day. Patients who are granulocytopenic and more severely compromised may need treatment with amphotericin B to prevent disseminated candidal disease.

CMV is another common cause of esophagitis. This virus infects the submucosal fibroblasts and endothelial cells rather than the squamous epithelium. Because CMV may be a more systemic infection, patients often present with several gastrointestinal symptoms, including abdominal pain, nausea, and vomiting, in addition to painful swallowing. The typical endoscopic findings are serpiginous erosions and ulcers, which may coalesce and form deep, larger ulcers (Fig. 72-44). Tissue diagnosis is needed to confirm the infection. Biopsy specimens should be taken from the bases of the ulcers because CMV infection is subepithelial.[155] The characteristic histologic findings of CMV-infected cells are intranuclear and cytoplasmic inclusions and a halo surrounding the nucleus. Tissue from the ulcer base should also be sent for viral culture, which is more sensitive than histology alone. Both ganciclovir and foscarnet are treatment options. Most immunocompromised patients require maintenance therapy for several weeks after an initial 2-week regimen at the full dose.

Herpes simple virus esophagitis occurs in both immunocompetent and immunocompromised hosts. Most often this is reactivation of

latent viral infection, but it can occur with primary HSV infection as well. The diagnosis is best made by endoscopy. The characteristic early findings include esophageal vesicles, which rupture to create ulcers with raised edges (Fig. 72-45). Unlike CMV, HSV infects epithelial cells. Therefore, biopsy specimens must be taken from the ulcer margins, where squamous mucosa is present. Histologic examination demonstrates multinucleated giant cells and ground-glass intranuclear inclusion bodies, but viral culture is more sensitive for diagnosis (Fig. 72-46). Treatment consists of intravenous acyclovir, 5 to 10 mg/kg every 8 hours, until the patient is able to tolerate oral therapy. Duration of treatment should be 7 to 10 days.

Other infections can rarely cause esophagitis. They include varicella-zoster virus (human herpesvirus 3), Epstein-Barr virus, human papilloma virus, bacteria, diphtheria, syphilis, and human immunodeficiency virus. Of these, human immunodeficiency virus is the most common and can lead to aphthous ulceration in the absence of any pathogens. After other infectious etiologies are ruled out in patients with HIV, the patients are treated with prednisone with good response.

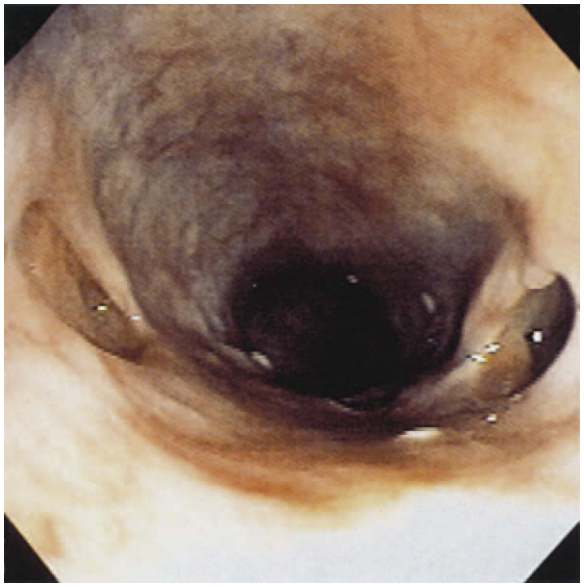

Figure 72-44. Endoscopic view of cytomegalovirus esophagitis. Several deep ulcers are present in the midesophagus. Biopsy specimens should be taken from the ulcer base to make the diagnosis.

Caustic Injury

Caustic ingestion can result in severe injury to the esophagus and stomach. Most ingestions occur accidentally in children, and the remainder in suicidal, psychotic, or alcoholic adults. It is estimated than more than 5000 caustic ingestions occur annually in the United States, and the incidence is rising.[156] A variety of chemicals can be ingested, but strong alkali and acids are most likely to produce injury. Strong alkali is contained in drain cleaners and other household cleaning products. *Lye* is a generic term for a strong alkali, usually sodium or potassium hydroxide, used in these cleansing agents. Injury to the esophagus is more severe with alkali substances than with acid substances,[157] because alkaline materials produce liquefactive necrosis and result in rapid and deep tissue injury. In the stomach, partial neutralization of the ingested alkali by gastric acid results in a more limited injury. Acidic agents produce a coagulation necrosis in the esophagus that may limit penetration and injury.

The clinical features of caustic ingestions vary widely. Early signs and symptoms often do not correlate with the severity and extent of tissue injury.[158,159] Patients may complain of oropharyngeal, retrosternal, or epigastric pain, dysphagia or odynophagia, or hypersalivation. Persistent severe pain may indicate esophageal perforation and mediastinitis. Hoarseness, stridor, and respiratory difficulties are uncommon but can result from burns of the epiglottis and larynx. All patients should be examined for evidence of oropharyngeal injury, and if airway compromise is present, intubation may be necessary. The absence of oropharyngeal burns does not preclude the presence of esophageal or gastric injury. Thus, upper endoscopy should be performed during the first 24 to 48 hours after ingestion in order to evaluate the extent of esophageal and gastric damage, which will establish prognosis and guide therapy. A grading system for esophageal injury to predict subsequent clinical outcome has been developed (Table 72-3).[160]

Patients with grades 1 and 2A injury have an excellent prognosis without acute morbidity or chronic stricture formation. These patients can be started on a liquid diet and advanced to a regular diet in 1- to 2 days. Strictures develop in 70% to 100% of patients with grade 2B or 3A injury. Grade 3B carries a 65% early mortality rate and high need for esophageal resection. Despite this poor prognosis, there is no evidence that medical therapy, such as antibiotics and steroids, is of any

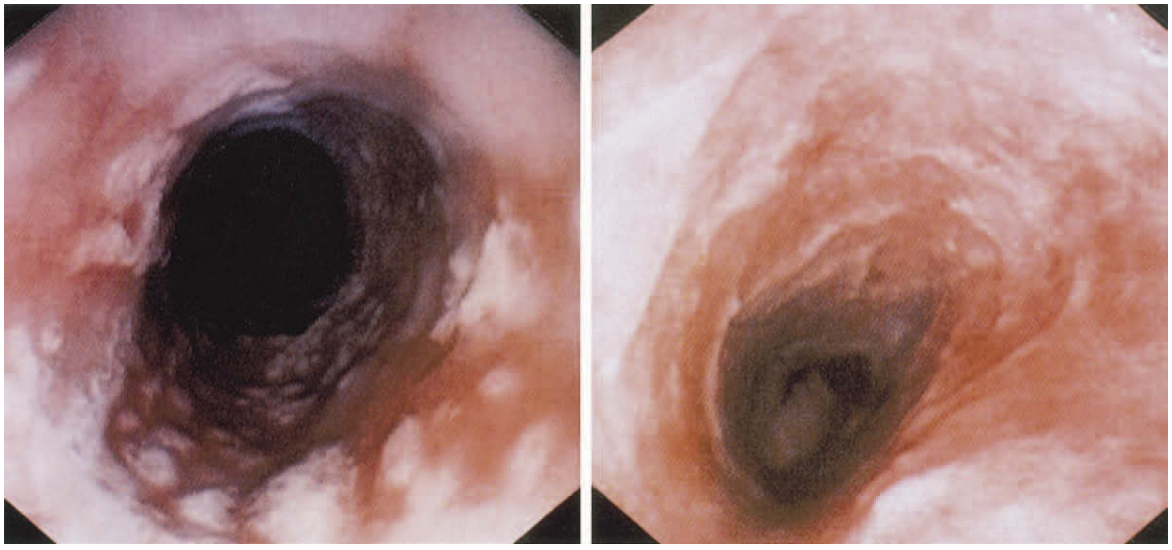

Figure 72-45. *Left*, Early herpes simplex virus esophagitis. Multiple small vesicles and surrounding ulceration. Biopsy specimens should be taken from the squamous epithelium at the edge of an ulcer to make the diagnosis. *Right*, Late herpes simplex virus esophagitis. Vesicles have ruptured to form large shallow ulcers. The esophagus is significantly denuded of squamous epithelium.

Table 72-3

Grading of Caustic Esophageal Injury

Grade	Feature(s)
0	Normal
1	Mucosal edema and erythema
2A	Superficial ulcers, bleeding, exudates
2B	Deep focal or circumferential ulcers
3A	Focal necrosis: deep ulcers with brown, black, or gray discoloration
3B	Extensive necrosis
4	Perforation

Figure 72-47. Tight esophageal stricture resulting from caustic ingestion.

benefit. In-hospital observation for perforation is recommended. If the patient with caustic injury is able to swallow without pain or vomiting, liquids can be started after 48 hours.

If esophageal strictures form, they require esophageal dilation. Esophageal strictures are usually located where caustic agents pool, at the cricopharyngeus, the level of the aortic arch, and the LES. These caustic strictures tend to be longer and tighter than benign strictures of other causes (Figs. 72-47 and 72-48). Thus, they are often refractory to and have a higher rate of complications with dilation. In fact, a significant portion (10% to 50%) may require surgery because of lack of response to dilation.

The other late complication of caustic esophageal injury is SCC of the esophagus. It is estimated that there is more than a thousand-fold increase in the risk of SCC after caustic injury.[161] The mean time to formation of cancer is approximately 40 years after ingestion. This fact has led some groups to suggest endoscopic surveillance for SCC in patients with a distant history of caustic ingestion.[162]

Esophageal Manifestations of Systemic Disease

A variety of systemic diseases can affect the esophagus. Connective tissue diseases, diabetes mellitus, thyroid disease, amyloidosis, and Behçet's disease are the more common systemic disorders with esopha-

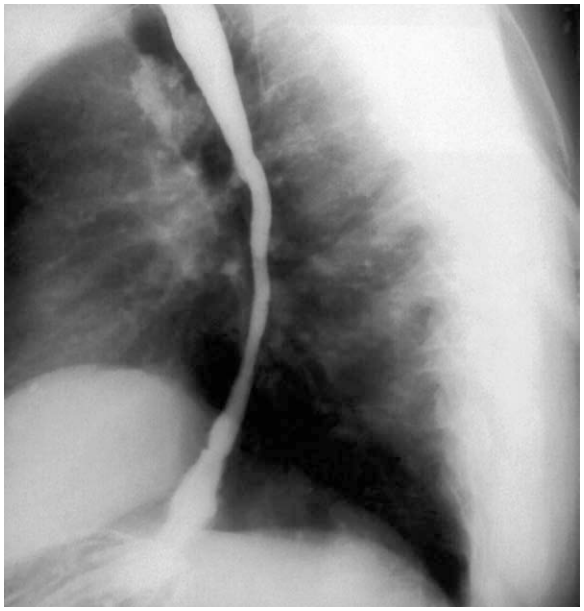

Figure 72-48. Barium esophagram of the stricture shown in Figure 72-44. The stricture extends the entire length of the esophagus.

geal involvement. The severity and frequency of esophageal symptoms vary both within and between these diverse systemic diseases.

Scleroderma, or progressive systemic sclerosis (PSS), reliably has significant esophageal involvement. Gastrointestinal involvement occurs in 90% of patients with PSS, and approximately 50% of these patients experience serious symptoms.[163] Patients with esophageal involvement present with heartburn, regurgitation, and dysphagia. PSS is characterized by small-vessel vasculitis and proliferation of connective tissue with fibrosis of multiple organs. The fibrosis predominantly affects smooth muscle in the gastrointestinal tract, leading to motility abnormalities. In patients with PSS, there is progressive loss of peristalsis in the esophagus and eventual ablation of the LES pressure. This process yields the classic manometric findings of aperistalsis in the distal two thirds of the esophagus and very low LES pressure. Barium esophagrams typically demonstrate a dilated esophagus, a patulous GEJ, and free reflux into the proximal esophagus (Fig. 72-49). Because of the disruption of the antireflux barrier and the inability to clear reflux from the esophagus, patients with PSS are often afflicted with severe, complicated GERD. The sequelae of severe GERD are common: Barrett's metaplasia (up to 37%), esophagitis, and strictures (3% to 42%).[164-166] Dysphagia may result from impaired peristalsis or peptic strictures. Treatment consists of aggressive acid suppression, dilations of strictures, and surveillance of Barrett's esophagus if present. Control of the underlying disease is important but to date is unsatisfactory.

In other connective tissue diseases, including mixed connective tissue disease, inflammatory myopathies, systemic lupus erythematosus, rheumatoid arthritis, and Sjögren's syndrome, esophageal involvement can be a minor manifestation. The myopathies are distinct in that they affect striated muscle with resultant dysfunction in the oropharynx and proximal esophagus and oropharyngeal dysphagia. The other rheumatologic disorders can manifest as hypomotility and, rarely, dysphagia.

Diabetes mellitus is a common disease with potential involvement of many organs in the body, including the stomach and esophagus. Studies have demonstrated predominantly decreased peristalsis and esophageal emptying in diabetic patients with esophageal symptoms. Many patients with diabetes may have gastroparesis, resulting in secondary GERD symptoms. Both the gastric and esophageal changes likely have a neurologic basis. Treatment with promotility agents has been tried for symptomatic patients; it is largely ineffective for the esophageal dysmotility but may help patients with gastroparesis.

Figure 72-49. One view from an upper gastrointestinal radiographic series in a patient with scleroderma. The esophagus is dilated with a patulous gastroesophageal junction. On fluoroscopic imaging, free gastroesophageal reflux was visualized.

Behçet's disease, an idiopathic inflammatory disorder typified by recurrent oral and genital aphthous ulceration, can infrequently involve the esophagus. Esophageal manifestations include ulcerations, erosions, esophagitis, and perforation. When the esophagus is involved, there is usually small bowel or colonic ulceration as well, making this disorder difficult to distinguish from Crohn's disease.

Hypothyroidism is a rare cause of dysphagia. Manometry has documented decreased amplitude and velocity of peristalsis, which improve with thyroid replacement therapy. Esophageal manometric abnormalities may also be seen in up to 60% of patients with amyloidosis.[167] Aperistalsis, hypomotility, incompletely relaxing LES, and decreased LES pressure have all been reported. It is believed this dysmotility results from neurogenic dysfunction rather than amyloid deposition in the esophageal wall. Despite these common manometric findings, esophageal symptoms are rarely prominent in amyloidosis.

Cutaneous Diseases and the Esophagus

Several dermatologic diseases have been associated with esophageal involvement. The most important dermatologic disorders that involve the esophagus are the blistering skin diseases: epidermolysis bullosa, bullous pemphigoid, cicatricial pemphigoid, and pemphigus vulgaris. Epidermolysis actually consists of several disorders typified by initiation of blisters after minor trauma. Dystrophic epidermolysis bullosa is an inherited disorder with autosomal dominant and recessive forms. Esophageal involvement is more common in the recessive form, with blisters of the skin, mouth, and esophagus developing during childhood. Esophageal bullae result from minor trauma from food and can lead to severe dysphagia and odynophagia. The lesions heal with fibrosis, leading to constriction of the mouth and esophageal strictures, which can potentially lead to malnutrition. Endoscopy is relatively contraindicated because it may cause bullae to form, but it may be necessary for the gentle dilation of strictures. Some patients require esophageal resection and replacement, and others need lifelong parenteral nutrition.

Bullous pemphigoid is the most common bullous skin disease. Patients with this disorder have antibodies to the basement membrane, and histologic examination demonstrates subepidermal bullae. The skin lesions consist of pruritic plaques that evolve into bullae. Esophageal involvement is rare and consists of bullae. Glucocorticoid treatment is effective.

Cicatricial pemphigoid is a bullous disorder involving mucosal surfaces, with a minimum or absence of cutaneous lesions. It involves the esophagus in less than 5% of cases but is less responsive to treatment than bullous pemphigoid. Because these bullae heal by fibrosis as well, endoscopic findings include not only bullae but also webs and strictures, usually in the proximal esophagus. Although steroids may be effective, stricture dilation is often required. Both bullous pemphigoid and cicatricial pemphigoid may predispose to esophageal carcinoma.

Pemphigus vulgaris is characterized by formation of intraepidermal bullae in the skin and mucous membranes. It is an autoimmune disease characterized by antibodies to cell adhesion molecule desmoglein 3 in stratified squamous epithelium. The esophagus is frequently involved, along with the mouth, with bullae and erosions. Glucocorticoid treatment is usually effective.

Lichen planus is a disease characterized by skin papules, and mucosal hyperkeratosis and erosions. Esophageal involvement is unusual but can manifest as strictures and dysphagia.

CHAPTER SEVENTY-THREE

Transnasal Esophagoscopy

Neil N. Chheda

Gregory N. Postma

Key Points

- Unsedated transnasal esophagoscopy is a well-tolerated, cost-effective, and safe examination.
- The accuracy of the transnasal esophagoscopy examination is similar to that of conventional endoscopic evaluation.
- Common esophageal indications for endoscopy include dysphagia and screening for Barrett's esophagus. Among the extraesophageal indications are head and neck carcinoma screening, laryngopharyngeal reflux, and chronic cough. Esophageal adenocarcinoma is more frequently heralded by extraesophageal symptoms, such as chronic cough, rather than esophageal complaints.
- A multitude of in-office procedures can be facilitated with use of the transnasal esophagoscope.

History

The work of many pioneers has enabled the modern physician to visualize and study the esophagus.[1] Bozzini, in 1806, was the first physician to report the ability to visualize the proximal esophagus.[2] After studying the performances of sword swallowers, Kussmaul performed the first rigid esophagoscopy in 1868. Advances in equipment continued to be made through the work of physicians such as Von Mikulicz (1881, first electrically lighted esophagoscope), Einhorn (1897, distal illumination in an esophagoscope), and Jackson (advances in endoscopic instruments). Interestingly, Jackson did not use anesthesia, general or local, for esophagoscopy of adults.

While advances in equipment, lighting, and optics were being made in rigid instrumentation, a major advance toward flexible esophagoscopy was made through the work of Hirschowitz and associates,[3] who presented the first fiberoptic gastroscope in 1957. Since that time, the examination of the esophagus has been conducted primarily by gastroenterologists with flexible endoscopes and patient sedation. Shaker,[4] a gastroenterologist, published the first report of unsedated transnasal esophagogastroduodenoscopy (EGD) in 1994. Although initially met with limited interest from gastroenterologists, the appeal of unsedated transnasal esophagoscopy (TNE) grew among the otolaryngology community, particularly after the reports of Herrmann and Recio[5] and the live demonstration by Aviv and colleagues[6] in 2001.

Equipment

One of the primary differences between a transnasal esophagoscope and a standard flexible oral esophagoscope is the instrument diameter—3.1 to 5.1 mm versus 10 to 12 mm. Most transnasal endoscopes are able to suction and insufflate air, and contain a working channel. The working channel can be used for passing biopsy forceps or brushes, laser fibers, guidewires for balloon dilators, and the topical application of anesthesia. However, ultrathin transnasal esophagoscopes may lack these capabilities and require an add-on sheath, which may increase the diameter by 1.3 mm. The length of a flexible laryngoscope is 30 to 35 cm, but that of transnasal esophagoscopes is typically at least 60 cm to allow visualization of the entire esophagus, including a retroflexed view of the gastroesophageal junction.

Two main camera systems exist for TNE. The proximal "add-on" camera is familiar to most otolaryngologists who perform endoscopy. Endoscopes utilizing this tool typically lack a working channel and require an add-on sheath. Alternatively, distal videochip technology has emerged, whereby optical impulses are converted to electric signals without the need for optical fibers.[7] A separate video processor is required for visualization in this system (Fig. 73-1).

Tolerance of Unsedated Examination

Historically, examination of the esophagus has been performed with patient sedation. Analyses of the complication patterns during endoscopy reveal that most adverse events are related to sedation. Cardiopulmonary complications account for more than 50% of all reported complications, with the majority being due to aspiration, over-sedation, hypoventilation, vasovagal episodes, and airway obstruction.[8] A 2007 national survey of endoscopists confirmed that unplanned cardiopulmonary events secondary to conscious sedation constitute the majority of endoscopy complications—67% of complications and 72% of mortalities were cardiopulmonary related.[9]

In addition to the medical risks of sedation, economic factors arise. The increased direct costs of conventional esophagoscopy include a longer procedure time, longer recovery time, and the costs associated with the needed medications, sedation, and recovery teams.[10] Unsedated TNE has been found to be up to two thirds less expensive than conventional esophagoscopy.[11,12] Indirect costs accrued with conventional esophagoscopy include the loss of work time for both the patient and an adult for patient transportation. In contrast, with an unsedated examination, patients are able to resume routine daily activities shortly after completion of the study.

Physiologic studies have verified that unsedated esophagoscopy is a safe procedure. In a prospective study, the changes in systolic and diastolic blood pressures, pulse rate, and rate-pressure product, as well as the drop in arterial oxygen saturation experienced by patients who had conventional transoral EGD, were significantly greater than in those undergoing either transnasal or transoral small endoscopy. Between the two small endoscope groups, these same parameters had a significantly greater change in the transoral group than in the transnasal group

Figure 73-1. Video chip transnasal esophagoscope. An add-on camera is not needed with this system.

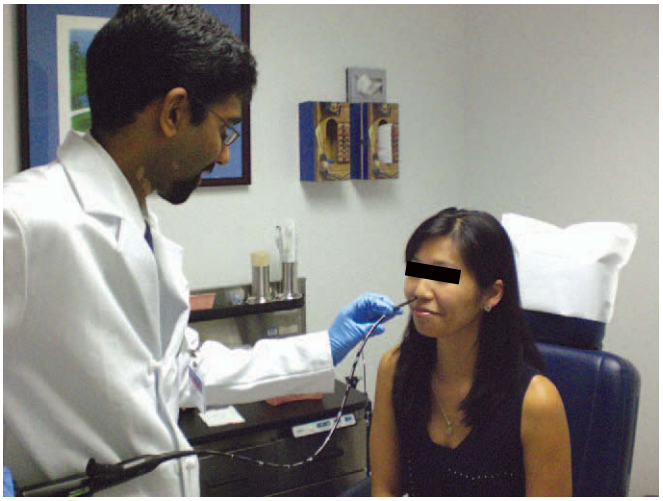

Figure 73-2. Examination technique. The unsedated patient is seated comfortably throughout the entire examination.

at 2 minutes after esophageal intubation.[13] Additional studies have shown that a significant increase in heart rate and a significant decrease in oxygen saturation occur in those undergoing transoral esophagoscopy but not in those undergoing transnasal esophagoscopy.[14]

Although initial patient anxiety is higher before unsedated TNE, numerous studies have demonstrated a very high patient satisfaction rate, usually greater than that for conventional or transoral approaches.[15-18] Crossover studies have shown that in patients who have undergone both sedated and unsedated endoscopy, the unsedated examination was better tolerated.[19] Dumortier and coworkers[20] found that 91% of patients who had undergone unsedated TNE who had also previously had a conventional EGD stated that they preferred the TNE examination. TNE was associated with fewer gagging sensations and was rated with higher patient satisfaction than unsedated transoral examinations.[21-23]

Accuracy of Examination

Dean and associates[24] reported a high degree of correlation between the endoscopic findings (sensitivity 89%, specificity 97%) of TNE examinations and of conventional EGD. Although the biopsy sample size obtained with TNE is generally smaller than that obtained with conventional endoscopy, numerous studies have verified the accuracy of TNE-guided biopsies. In patients with known Barrett's metaplasia, Saeian and colleagues[25] found that the congruence between biopsy samples obtained with conventional endoscopy and those obtained with TNE was 97%. In a crossover study of 121 patients, Jobe and colleagues[26] compared the endoscopic findings and the histologic detection of Barrett's esophagus from biopsy specimens obtained from unsedated TNE and conventional esophagoscopy. A moderate to very good extent of agreement was present for endoscopic findings, such as hiatal hernias and esophagitis, between the two endoscopic modalities. In addition, although the biopsy specimen size was significantly smaller with TNE, there was a moderate extent of agreement in pathologic findings.[26]

Technique

The most important step in performing TNE is proper nasal anesthesia and decongestion. With the patient in a sitting position, the more patent nasal cavity is sprayed with a mixture of a topical anesthetic and decongestant and then packed with a cotton pledget soaked in the same mixture. A topical anesthetic may be administered to the oropharynx. Too much anesthesia may actually make the TNE procedure more difficult owing to the accumulation of secretions in the hypopharynx that may be aspirated and induce coughing.

The endoscope is lubricated and introduced into the naris. It may be passed either along the floor of the nose—the preferred method—or between the middle and inferior nasal turbinates. As the scope approaches the post-cricoid region, the patient's head is flexed toward the chest. The patient performs a swallow as the endoscope is gently introduced into the esophagus. Air insufflation and suction are used, as needed, to improve visualization. The scope is advanced only when the lumen is clearly seen.

The endoscope is advanced into the distal esophagus for visualization of the gastroesophageal junction and the squamocolumnar junction (SCJ), also known as the *Z-line*. The endoscope is advanced more deeply into the stomach and retroflexed to visualize the gastric cardia. The mucosa of the entire esophagus is examined while the instrument is withdrawn. The post-cricoid region is visualized by insufflation of a burst of air as the endoscope is withdrawn from the esophagus (Fig. 73-2).[15]

Normal Findings

The anatomy of the esophagus viewed through a thin endoscope appears different from that obtained through a rigid esophagoscope or a conventional oral esophagoscope.[27] By nature of the smaller size of the scope, TNE does not distort the anatomy of the esophagus, thereby allowing the natural curvatures and external compressions to be easily seen.

Three major curvatures of the esophagus are encountered before the endoscope enters the stomach. At the base of the neck, the esophagus curves to the left with a gentle return to midline at the level of T5. Another left curve is encountered at T7. Finally, an anterior curve occurs in the distal esophagus as it passes through the diaphragm.

Three external compressions are seen during a TNE examination. The first encountered is a pulsatile compression of the left anterolateral wall from the aorta. Approximately 2 cm more distal, the left main bronchus produces an anterior compression. In the distal esophagus, the diaphragm produces a circumferential constriction best visualized by having the patient sniff.

A network of terminal linear vessels can be seen in the distal esophagus that end at the gastric rugae. These vessels do not normally extend below the level of the SCJ. Folds of the gastric rugae form may extend up to 2 cm above the pinch of the diaphragm. Proximal extension of the rugae beyond 2 cm indicates a hiatal hernia. The presence of a hiatal hernia may also be suggested by visualization of a loose diaphragm crus on the retroflexed view.

Esophageal squamous epithelium normally appears as a gray-white color, whereas the gastric columnar epithelium is of a salmon-pink hue. The SCJ occurs at the meeting of the esophageal mucosa and gastric mucosa. An irregularly shaped SCJ may be found and is not always pathologic. The junction of the gastric rugae and the network of terminal linear vessels marks the level of the gastroesophageal junction.

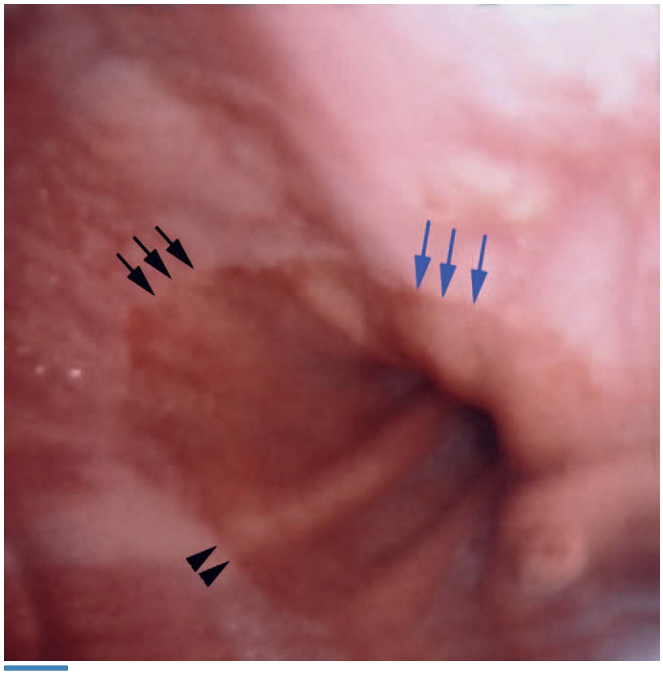

Figure 73-3. Normal transnasal esophagoscopic appearance of the distal esophagus. The junction of the terminal vessels (*short arrows*) and the gastric rugae (*arrowheads*) corresponds to the level of the gastroesophageal junction. The squamocolumnar junction (*long arrows*) coincides with the gastroesophageal junction in this patient. *(From Postma GN, Belafsky PC, Aviv JE.* Atlas of Transnasal Esophagoscopy. *Philadelphia: Lippincott Williams & Wilkins; 2007:18).*

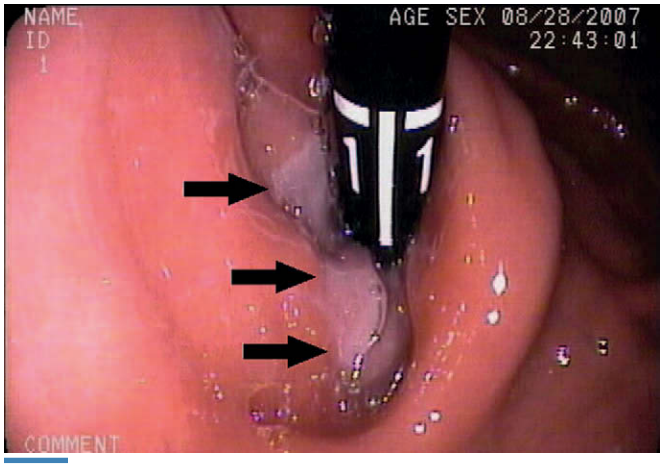

Figure 73-4. Retroflexed view of the squamocolumnar junction (*arrows*). The diaphragm is tight around the endoscope.

The SCJ and the junction should normally coincide. However, finding the SCJ above the gastroesophageal junction represents clinical Barrett's esophagitis (Figs. 73-3 and 73-4).

Indications

The rate at which pathology is found on TNE performed in an otolaryngology practice is high, approaching 50%.[15,28] Indications for TNE can be divided into three major categories: esophageal, extraesophageal, and procedure-related. Esophageal indications include dysphagia, refractory or long-standing gastroesophageal reflux, abnormal radiographic study, and screening for Barrett's metaplasia. Extraesophageal indications include globus pharyngeus, head and neck cancer, laryngopharyngeal reflux, and chronic cough. Reavis and colleagues[29] found that patients with esophageal adenocarcinoma exhibited extraesophageal reflux symptoms more frequently than typical gastroesophageal reflux complaints, with chronic cough being the most common single complaint.[29] Procedures for which TNE may be used are detailed in the following sections.

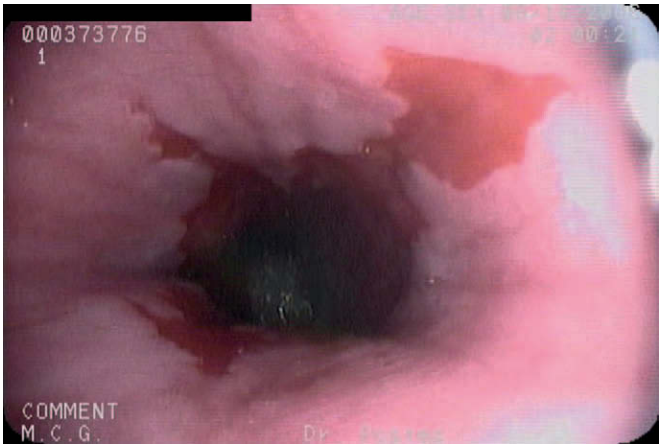

Figure 73-5. Barrett's esophagus. Tongues of gastric columnar epithelium can be seen extending into the squamous epithelium of the mid-esophagus.

Transnasal Esophagoscopy in Head and Neck Oncology

Panendoscopy is considered part of the standard evaluation of patients diagnosed with head and neck squamous cell carcinoma. Often, these patients possess comorbidities that increase the risks of general anesthesia. Unsedated office TNE allows for an examination of the aerodigestive tract without the morbidity of anesthesia. A complete examination can be performed in a high percentage of patients, with series reporting up to 99%.[30] Biopsy specimens can also be obtained on the day of the in-office endoscopy. In patients with presumed head and neck squamous cell carcinoma, a high degree of congruence has been shown between specimens obtained through TNE and those obtained from standard operating room panendoscopy.[31]

Patients requiring extensive resection of a head and neck malignancy may need complex reconstruction, including the use of free tissue flaps. TNE may be used for surveillance of the reconstruction and to check the integrity of the flap both in the immediate postoperative period and during further follow-up examinations.[32]

Transnasal Esophagoscopy in Barrett's Esophagus

Although most cancers in the United States are showing a decline in prevalence, the rate of esophageal adenocarcinoma is on the rise. Barrett's esophagus represents a premalignant state for this type of esophageal neoplasm. TNE is a useful screening examination for this condition. Limitations of TNE include the inability to use jumbo forceps or comfortably to obtain a full four-quadrant range of biopsy specimens spaced every 1 to 2 cm, which are standard during conventional Barrett's esophagus surveillance. Therefore, TNE is not currently recommended for the *surveillance* of Barrett's esophagus (Fig. 73-5).

Transnasal Esophagoscopy in Dysphagia

Dysphagia is a growing clinical concern, particularly among the elderly. TNE complements other diagnostic tools, including manometry, flexible endoscopic evaluation of swallow (FEES), flexible endoscopic evaluation of swallowing with sensory testing (FEESST), and radiographic studies such as the barium esophagram and the modified barium swallow. Unlike these other studies, TNE allows direct visual inspection of the mucosa. An additional advantage of this unsedated examination is the ability to subjectively assess peristaltic activity. A pill, food, or a liquid can be swallowed and observed to travel through the esophagus, in order to localize areas of decreased peristalsis or narrowing. Transit time for a liquid is usually less than 13 seconds. Conditions found during TNE for dysphagia include esophagitis, strictures,

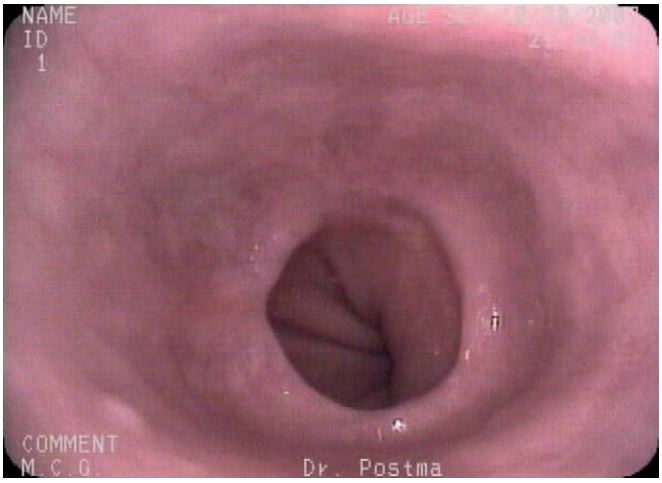

Figure 73-6. Esophageal ring. The type B ring (Schatzki's ring) represents the most common cause of dysphagia to solids in adults.

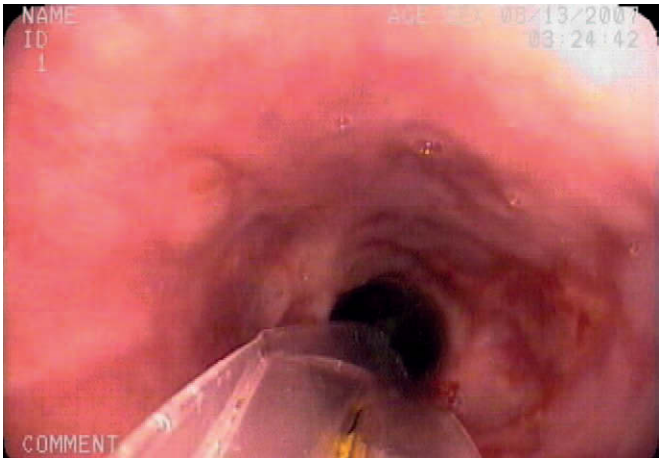

Figure 73-7. Balloon dilation of an esophageal stricture. A partially inflated controlled radial expansion balloon can be seen within an esophageal stricture.

rings, large hiatal hernias, webs, primary or metastatic neoplasms, eosinophilic esophagitis, vascular anomalies, and diverticula. A tight lower esophageal stricture found on endoscopy can also suggest the diagnosis of achalasia rather than the presence of a tumor (pseudoachalasia) (Fig. 73-6).

Additional Diagnostic Applications of Transnasal Esophagoscopy

New indications for TNE are continually being developed. Among its novel applications are documenting the resolution of *Helicobacter pylori* infection and the detection and grading of esophageal varices.[33] The ability to evaluate esophageal pathology without sedation is particularly valuable in patients with cirrhosis in order to avoid the risk of postsedation encephalopathy.[34] Similarly, serial evaluations after a caustic ingestion can be accomplished with TNE without the need for repeated anesthesia. Foreign bodies, such as impacted food, may be diagnosed with TNE and "pushed" into the stomach. It is our opinion that unsedated TNE should not be used for the *removal* of foreign bodies because of airway concerns. Finally, technologic innovations, such as narrowband imaging, may further improve the diagnostic accuracy of TNE.[35]

Procedures

Stricture Dilation

When patients complain of a primarily solid rather than liquid dysphagia, an anatomic etiology is often present, such as a stricture or web. Traditionally, the treatment of esophageal strictures involves mechanical dilation, often with bougies, in the operating room or with sedated endoscopy. Patients may need multiple treatment sessions. The need for numerous anesthetics and "blind" dilation is avoided with the use of unsedated TNE.[36] Controlled radial expansion (CRE) balloons can be passed over a guidewire to dilate narrowed segments.[37,38] Evidence suggests that these balloons may be less traumatic than bougies.[39] Unsedated TNE has been used to successfully dilate esophageal strictures in conditions such as epidermolysis bullosa as well as those induced by reflux or radiation.[40,41] The endoscope can also guide placement of controlled radial expansion balloons to treat radiation-induced stenosis of the nasopharynx. Neopharyngeal strictures that may occur after total laryngectomy have been successfully dilated with the use of office unsedated TNE as well (Fig. 73-7).[42]

Tracheoesophageal Puncture

Tracheoesophageal puncture (TEP) is one of the most commonly used vocal rehabilitation pathways following total laryngectomy.[43] TNE can be used for secondary TEP placement. Traditionally, secondary TEP placement is performed with general anesthesia and a rigid esophagoscope. In addition to the risks associated with general anesthesia, this technique can be complicated by difficulty passing the rigid esophagoscope in patients lacking neck flexion or passing the instrument through friable tissue.[44]

The procedure begins with the endoscope's being passed into the neopharynx. A needle is then passed through the posterior tracheal wall and through the anterior wall of the esophagus, which is observed under direct visualization. Air is insufflated into the neopharynx to promote visualization and protect the posterior esophageal wall from accidental needle penetration. The incision is enlarged and then either a catheter or the TEP prosthesis itself may be inserted. A study found that in-office, unsedated secondary TEP placement was successful in 10 of 11 patients.[45] TNE can also be used to diagnose and replace a TEP device that has failed because of malposition.[46]

Additional Therapeutic Applications of Transnasal Esophagoscopy

Laser fibers can be passed through the working channel for ablation of esophageal papillomas or other small tumors. Unsedated TNE has also been used successfully to position wireless telemetry devices in the esophagus for pH monitoring.[47]

Complications

One of the most feared complications of esophagoscopy is esophageal perforation. Among the thousands of cases performed, only one case of esophageal perforation has been reported, when unsedated TNE was performed by a gastroenterologist.[16] There have been no reported cases of esophageal perforation during TNE performed by an otolaryngologist. Minor complications have been reported. In two of the largest series reported, involving 700 patients from the United States and 1100 patients from France, rates of epistaxis were reported between 0.85% and 2% and those of vasovagal events to be 0.3%.[15,20] Mild, self-resolving nasal discomfort was reported at 1.6%.

Conclusion

Transnasal esophagoscopy is a well tolerated, safe, and efficacious method to evaluate the esophagus without many of the risks associated with conventional endoscopy. Better patient care along with a significant potential cost savings can be achieved with use of TNE rather than the conventional procedure.

CHAPTER SEVENTY-FOUR

Zenker's Diverticulum

Richard L. Scher

Key Points

- Zenker's diverticulum is the most common of the hypopharyngeal diverticula.
- Patients with this disorder most commonly present with dysphagia with food regurgitation.
- Diagnosis is confirmed by contrast radiography of the pharynx and esophagus.
- Treatment is directed toward elimination of symptoms and prevention or treatment of complications such as aspiration and malnutrition.
- Endoscopic treatment with the staple technique has proved to be an effective and safe method of therapy and should be considered the first-line approach.
- Any external surgical approach to treatment should include a cricopharyngeal myotomy.
- Regardless of technique, the most significant complication of surgical therapy is perforation of the hypopharynx or esophagus with associated mediastinitis.

Esophageal diverticula are classified on the basis of anatomic location (pharyngoesophageal, midesophageal, or epiphrenic) and mechanism of origin (pulsion or traction). *Traction diverticula* are a result of pulling forces external to the esophagus that are secondary to inflammatory or neoplastic processes and usually occur on the anterior wall of the esophagus near the bifurcation of the trachea. In contrast, *pulsion diverticula* are a result of herniation of esophageal mucosa and submucosa through an area of weakened esophageal musculature. Of the various types of esophageal diverticula, Zenker's diverticulum (ZD), a pulsion-type diverticulum, is one of the most common symptomatic esophageal diverticula, with an annual incidence of 2 per 100,000 people per year, with men being affected 2 to 3 times more commonly than women.[1-6] For patients referred for an examination of the upper gastrointestinal tract, the incidence can reach 1 in 1000.[4,6,7] ZD is extremely rare in Asia and Africa, where gastroesophageal reflux disease is also uncommon, suggesting that reflux may play a role in its etiology.[5,7,8] Most esophageal diverticula are acquired lesions found in adults, particularly in the seventh and eighth decades. Pediatric hypopharyngeal diverticula along with true ZD are extremely rare, with most cases being congenital in nature and fatal secondary to massive aspiration pneumonia.[9-19]

Zenker's diverticulum is classically defined as a pulsion diverticulum between the cricopharyngeal muscle and inferior constrictor muscle in an area of weakness called Killian's dehiscence or triangle, first described by Killian[20] in 1907 (Fig. 74-1). However, there are other areas of weakness where pulsion diverticula may form, including Killian-Jamieson's area, between the oblique and transverse fibers of the cricopharyngeal muscle, and Laimer's triangle, formed between the cricopharyngeal muscle and the most superior esophageal wall circular muscles (Fig. 74-2).[21] More rarely, pharyngoceles may be found in the posterolateral or lateral areas of the pharynx and hypopharynx (Fig. 74-3).[22] Cases of double pharyngeal pouches have also been described (Fig. 74-4).[23] Interestingly, ZD is found almost exclusively in humans, a fact hypothesized to be secondary to the large size and relatively caudal cervical location of the larynx in comparison with lower animals.[8,21] The caudal location of the larynx results in an oblique orientation of the pharyngeal constrictor muscles, resulting in regions of weakness. Such muscular vulnerabilities are absent in animals because the pharyngeal and esophageal musculatures have a coherent parallel orientation throughout the upper aerodigestive tract. Indeed, ZD has been found in only one animal, the Mangabay monkey, in a single case so far.[21]

Theoretically, a diverticulum herniates to the side of less resistance. Accordingly, it is hypothesized that ZD is more prone to herniate to the left because the carotid artery is more laterally located on this side of the neck, making it less adherent to the adjacent prevertebral fascia, and because there the cervical esophagus has a slight convexity to the left.[21,24] According to one series, although two thirds of Zenker's diverticula are found in the midline, nearly 25% protruded to the left, and only 10% to the right.[25,26]

Presentation

Patient history alone may raise suspicion for ZD. The predominant symptom is progressive dysphagia, which may occur in excess of 90% of patients presenting with the disorder.[27] Regurgitation of food even hours after a meal, unprovoked aspiration, and noisy deglutition (borborygmi) specifically suggest ZD. Other symptoms are belching, hypopharyngeal mucus collection, halitosis, choking, coughing, hoarseness, globus pharyngeus, weight loss, and recurrent respiratory infections. Symptoms may last for weeks to many years before diagnosis and are generally more severe with a larger ZD. Minimal physical findings may include mucus pooling in the hypopharynx that initially clears with swallowing then recurs, emaciation or dehydration, and, only rarely, Boyce's sign, a swelling in the neck that gurgles on palpation.[28] However, it is more often the case that patients are without any specific findings on physical examination. Diagnosis is confirmed by barium swallow radiography, which can also define the size and position of the sac (Fig. 74-5). Fiberoptic endoscopy is also performed to help rule out other potential causes of dysphagia (Table 74-1). Occasionally, ZD may be first discovered during esophagogastroduodenoscopy or rigid cervical esophagoscopy as an incidental finding during the course of a gastrointestinal evaluation. The size of the sac may range from less than

1 cm to a truly enormous 12 cm or more. Rarely, a large diverticulum may be seen on a regular chest radiograph (Fig. 74-6).

Through the years, physicians have attempted to classify ZD on the basis of contrast radiology findings (Table 74-2). In 1930, Lahey[29] described three stages based on radiologic appearance. Morton and Bartley,[30] along with subsequent writers, also described three stages but based them on size.[31] van Overbeek and Groote[5] used cervical vertebral bodies as a standard for comparison rather than absolute size measurements. Brombart and Monges[32] expanded the classification into four stages, incorporating size, appearance, and stage of deglutition. Other workers have created increasingly more complex categories incorporating elements from both Brombart and Monges's and van Overbeek and Groote's systems.[33] Although useful in terms of classifying ZD, these arrangements have limited clinical utility.

Pathophysiology

Although it is widely accepted that ZD is an acquired pulsion diverticulum, considerable controversy exists about the mechanism of its formation. Ludlow[34] in Bristol, England, gave the first anatomic description of a pulsion diverticulum of the hypopharynx in 1769. He believed that this condition was induced in his subject by trauma after the swallowing of a cherry stone. Subsequent pathologists hypothesized traumatic rupture or burn, congenital upper esophageal stricture, thyroid goiter, or foreign bodies as triggers for ZD formation.[21] It was not until 1877 that these hypotheses were rejected as erroneous and the basic pathophysiology was described by, and the diverticulum named after, Zenker, a German pathologist.[35] The original German description was later translated into English in New York in 1878, allowing wider dissemination of Zenker's findings.[21] However, before Zenker, Bell[36] (best known for describing facial nerve palsy) proposed in 1816 that incoordination of the inferior constrictor muscle against a closed cricopharyngeal muscle resulted in this type of outpouching at regions of inherent weakness. This etiology was later supported by other researchers.[37-46] Similarly, the congenital theory describes an unusually weak or large Killian's triangle from birth that with time herniates with normal pharyngeal contraction.[47] Variations on this theme for the mechanism of formation of ZD have been debated ever since.

Patterson[48] in 1919 first proposed cricopharyngeal achalasia as an etiology for ZD. Others noted a higher incidence of reflux and hiatal hernia in patients with ZD as well as epidemiologic observations that ZD occurs predominantly in populations with a high incidence of reflux, suggesting a possible relationship between the two.[7,49] Several writers in the early 1970s suggested that spasm or persistently elevated resting tone of the cricopharyngeus secondary to reflux could cause ZD, although others refuted a direct causal association.[7,49-51] On the basis of histologic studies, Lerut[52] in 1988 proposed a structural abnormality of the cricopharyngeal muscle itself. Cook and associates[53] in 1992 suggested partial, but incomplete, opening of the cricopharyngeal muscle because of fibroadipose tissue replacement as an etiology. Six years later, Walters and colleagues[54] proposed that ZD might be a manifestation of central or peripheral neurologic disease. Regardless of the theory, the cricopharyngeal muscle is the common theoretical culprit behind the formation of ZD, and whether to address this muscle during surgical management has been debated through the years.[55]

Management

The treatment of ZD, as well as other forms of hypopharyngeal diverticula, is surgery. The presence of ZD is an additional risk factor in the

overall health of the elderly patient, who may have concomitant pulmonary, cardiac, and other morbidities. With symptomatic ZD, the patient may have persistent aspiration causing deterioration of pulmonary function. Furthermore, with severe symptoms of dysphagia and aspiration, patients with ZD often become cachectic and dehydrated because of fear or inability to eat or drink. Definitive surgical management is mandated in these patients to prevent continued pulmonary compromise and malnutrition. Generally, all operative procedures addressing esophageal diverticula should be performed with the use of general anesthesia and as elective operations before complications have occurred. However, surgery may become urgent once problems have arisen and a patient's condition is unlikely to be optimized before definitive treatment. In these patients, it is also important to fully evaluate and treat for other etiologies of dysphagia to obtain maximal benefit from surgery (see Table 74-1). Surgery is not necessary if the patient is asymptomatic or if the diverticulum is causing the patient minimal, if any, problems, but the patient does require long-term monitoring.

External Techniques

History

A variety of open, external surgical approaches to treating ZD have been performed, with and without the inclusion of cricopharyngeal myotomy. The first-recorded, but unfortunately fatal, treatment was performed in Vienna in 1877 by Nicoladoni,[56] who established a fistula

to drain the sac, a procedure Bell[36] first proposed in 1816. Zenker and von Ziemssen[35] in 1877 recommended dilations of the esophageal inlet.[21] Niehans[58] unsuccessfully attempted ZD excision in 1884. This procedure, first suggested by Kluge in 1850, resulted in the death of his patient from hemorrhage from the superior thyroid artery.[21,57] Wheeler,[59] 2 years later, successfully excised a diverticulum. Kocher[60] in 1892 performed a diverticulectomy with primary closure. Girard[61] in 1896 inverted the diverticulum, a procedure first described by Keyrat in 1866.[21] Schmid[62] in 1912 described the method of diverticulopexy, which was performed by Hill[63] in 1917. Unfortunately, these procedures, which often necessitated multiple stages, were associated with high mortality, particularly before the discovery of antibiotics to help reduce the morbidity and mortality. With technical advances and the availability of antibiotics, one-stage procedures became standard.

Despite the numerous different theories on the formation of ZD, the vast majority point toward the cricopharyngeal muscle as the etiologic factor. It thus follows that performing a cricopharyngeal myotomy does have a logical role in the surgical management of ZD. Although Richardson[64] in 1899 performed the first cricopharyngeal myotomy with good results, albeit accidentally, it was not until 1936 that Aubin[65] proposed cricopharyngeal myotomy as a useful adjunct to surgical diverticulectomy. Instead of a myotomy, Lahey[66] in 1946 recommended cricopharyngeal dilation. Beginning in the 1950s, performance of a myotomy became a planned component of the surgical treatment of ZD and, in some cases, the sole treatment.[1,67] It is now commonly accepted that surgical treatment of ZD without a cricopharyngeal myotomy is associated with a high recurrence rate.[39,55,57,68-71]

Procedure

Generally, all external procedures (excluding cricopharyngeal muscle dilation) use a transcervical approach to the ZD, using a left lateral neck incision unless the ZD is found on the right side by preoperative barium esophagram. Before incision, however, cervical esophagoscopy is performed to identify the diverticulum and pack it with gauze to help

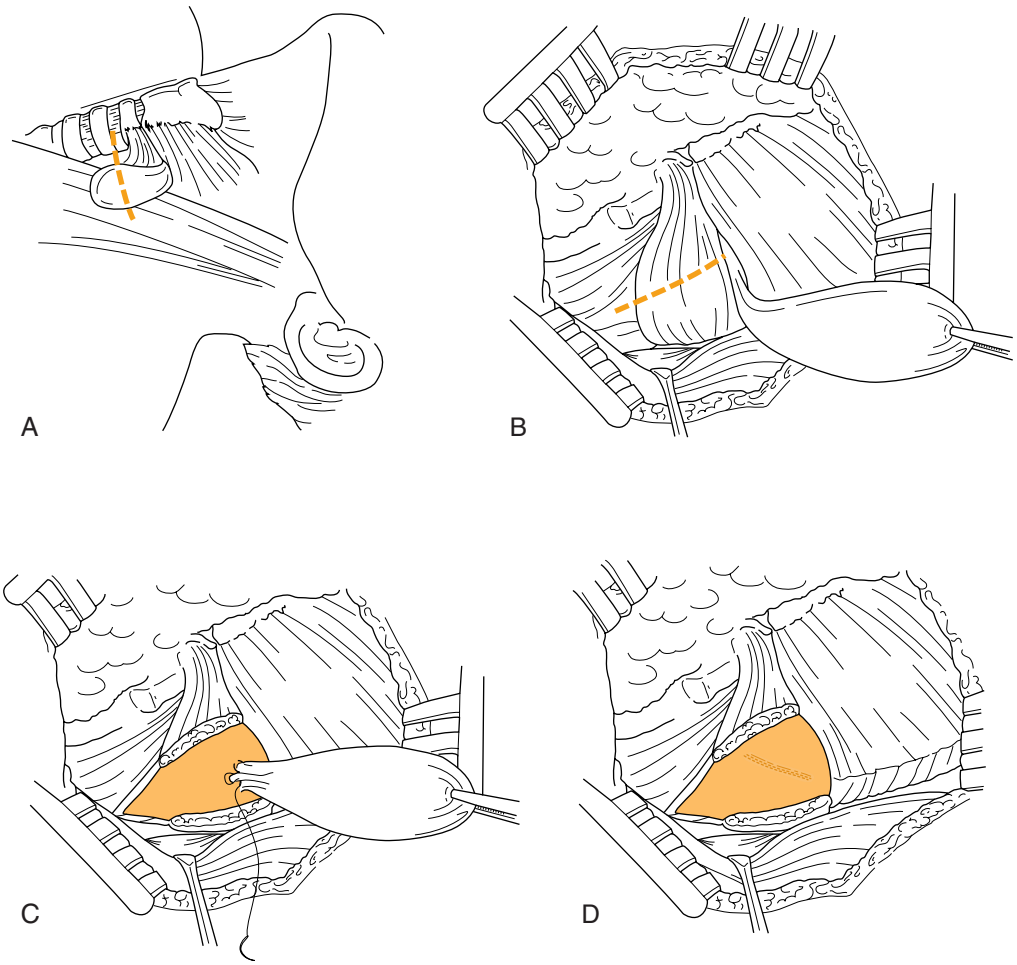

Figure 74-7. Steps of a transcervical diverticulectomy. **A,** Incision line is illustrated. An alternative incision line may be along the anterior border of the sternocleidomastoid muscle. **B,** Soft tissues are dissected away. The trachea, strap muscles, and thyroid gland are retracted medially, and the sternocleidomastoid muscle is retracted laterally. The omohyoid muscle may also be retracted laterally or, alternatively, divided for exposure. Once the diverticulum and cricopharyngeus muscle are identified, a cricopharyngeal myotomy is performed. The diverticulum itself may be excised and the defect closed with a purse-string suture (**C**) or a stapler (**D**).

in identification during transcervical surgical exposure. An esophageal dilator is inserted into the esophagus under direct visualization to assist in cricopharyngeal myotomy and to minimize the risk of esophageal stenosis. A nasogastric feeding tube is also inserted to be used for feeding after surgery.

The standard incision is usually made along the anterior border of the sternocleidomastoid muscle from the level of the hyoid bone to several centimeters above the clavicle. However, a curvilinear transverse incision along a neck crease between the hyoid and clavicle is preferable for cosmesis (Fig. 74-7). Subplatysmal flaps are then raised,

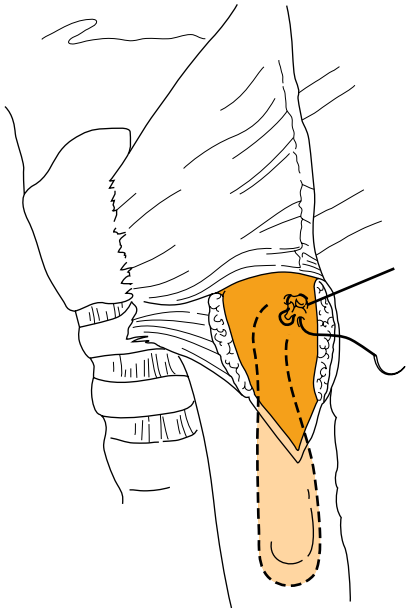

Figure 74-8. Inversion technique. After a cricopharyngeal myotomy is performed and the diverticulum freed, a purse-string 3-0 absorbable (polyglactin) suture is passed extramucosally around the neck of the diverticulum. The pouch is then inverted, and the purse-string suture pulled tight. The muscle fibers may then be approximated over the defect. In this method, no feeding tube is required if the mucosa was not violated.

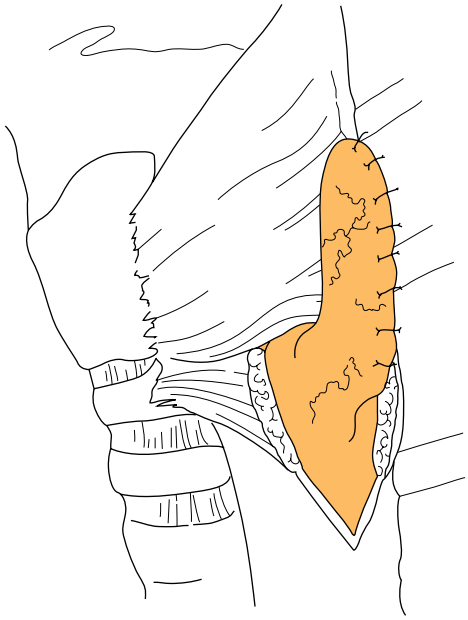

Figure 74-9. Diverticulopexy technique. After a cricopharyngeal myotomy is performed and the diverticulum is freed, the sac is tacked with 2-0 silk sutures superiorly to the prevertebral fascia.

followed by lateral retraction of the sternocleidomastoid muscle. The fascial attachments along the anterior border are divided. The strap muscles may be retracted anteromedially, but for better exposure, the anterior belly of the omohyoid muscle may be divided inferiorly. As blunt dissection is carried out to expose the posterior aspect of the pharynx, larynx, and esophagus, the recurrent laryngeal nerve is identified and protected before the thyroid vessels are ligated and divided, if necessary. Once the diverticulum is identified and freed from the surrounding tissues down to its base attachment to the esophagus, a long cricopharyngeal myotomy is performed. The pouch itself can then be excised, inverted, or suspended by a suturing or stapling technique (Figs. 74-8 and 74-9).[72-74] Each of these techniques has had its advocates.[2,30,68,72,75-82] For small diverticula (1-2 cm), a cricopharyngeal myotomy alone may be sufficient.[28,83,84] The patient generally is fed postoperatively through a feeding tube for several days, after which an oral diet may be resumed.

External procedures for treatment of ZD have long been associated with significant morbidity. Although this association is partly a result of the surgery itself, the vast majority of patients are elderly, often with other medical problems. Despite refined surgical techniques, the rate of symptomatic relief has been reported between 80% and 90%, and complication rates of 10% to 30% (with up to 3% mortality) have persisted for external approaches.[3,68,81,84-87] Engel and Panje[88] summarized the results of surgical complications observed from transcervical approaches in a large series of cases published in the English literature and covering the period from 1985 to 1991. Their compilation reported the following complication rates in 245 patients: fistulas 6.3%, recurrent laryngeal nerve palsy 3.6%, pneumomediastinum 0.8%, mediastinitis 3.1%, and mortality 2%. Payne[84] at Mayo Clinic reported a morbidity rate of 7.9%, a mortality rate of 1.2%, and a recurrence rate of 3.6% in 888 patients. Feeley and colleagues[77] reported a 37% complication rate. In a review of the literature of all studies published in the English literature between 1990 and 2002 by Chang and associates,[27] external techniques had an overall 1.6% mortality and an 11.8% complication rate.

Endoscopic Techniques

History

In an attempt to improve outcome, Mosher[89] in 1917 first described endoscopic esophagodiverticulostomy using a knife to divide the common wall, but he abandoned the procedure after his seventh patient died from mediastinitis. Two decades later, Sieffert[90] re-introduced the endoscopic technique using scissors, but Dohlman and Mattson[91] popularized the procedure in 1960 when they presented the endoscopic management of ZD in a series of approximately 100 patients without deaths or serious complications, 93% of whom reported relief of symptoms, and only 7% symptom recurrence (Fig. 74-10).

Despite these successes, endoscopic management of ZD was not as readily accepted as external techniques because of concerns about dividing the common wall in a "sutureless" manner with the potential for pneumothorax, bleeding complications, or mediastinitis. Various refinements in the endoscopic technique have been introduced to alleviate these concerns and minimize the risk of severe complications. van Overbeek and coworkers[92] introduced the use of the operating microscope and carbon dioxide (CO_2) laser in 1984, and Kuhn and Bent[93] the use of the potassium titanyl phosphate (KTP)/532 laser in 1992. Gastroenterologists Ishioka and associates[94] in Brazil and Mulder and colleagues[95] in the Netherlands simultaneously introduced flexible endoscopic incision using electrocautery in 1995. Two years earlier, Martin-Hirsch and Newbegin[96] in England and Collard and associates[97] in Belgium had simultaneously introduced an endoscopic stapling technique of performing an esophagodiverticulostomy for ZD. The technique later was refined and introduced to the United States by Scher and Richtsmeier.[98,99]

Procedure of Endoscopic Staple Diverticulostomy

Endoscopic techniques involve visualization of the ZD through a modified laryngoscope with division of the common wall between the diverticulum and esophagus using electrocautery, CO_2 laser, or staples (Figs. 74-11 to 74-13). It has been our experience that the endoscopic staple diverticulostomy (ESD) has proved to be the treatment method of choice for patients with ZD. Briefly, the ESD procedure, as with other endoscopic techniques, is performed with the patient under general endotracheal tube anesthesia. After a dental guard is placed to protect the maxillary teeth, the Weerda bivalved laryngoscope (Karl

Storz Endoscopy-America, Inc, Culver City, CA) is introduced into the oral cavity and used to expose the common wall between the esophageal and diverticular lumen (Fig. 74-14). A magnified view of the operative field and all manipulations are visualized using a rigid 0- or 30-degree telescope connected to a video camera (Fig. 74-15). The diverticular pouch is carefully examined and, if any lesions are noted, biopsy specimens are obtained for frozen-section diagnosis. The procedure is aborted and an external diverticulectomy is performed if a malignancy is identified.

Before division of the common wall, 2-0 silk retraction sutures are placed through the lateral edges of the common wall with the ENDOSTITCH autosuture device (Covidien Autosuture, Mansfield, MA). These sutures allow tension to be placed on the common wall to help with stapler positioning for small diverticula (less than 2.0-2.5 cm) to allow effective insertion of the stapler blades, or for assistance in countertraction when the stapler blades are re-inserted for a second or third cut in large diverticula (more than 3.5 cm). The diverticular common wall is then divided with the disposable MULTIFIRE ENDO GIA 30 stapler (Covidien Autosuture). The stapler blade containing the stapler cartridge is placed into the esophageal lumen, and the opposite blade is placed into the diverticulum. The stapler blades are closed around the common wall, and their position is confirmed with the telescope. Activation of the stapler simultaneously cuts and staples the divided mucosal edges of the common wall. Multiple applications may be necessary for large diverticula. By dividing the common wall, an internal cricopharyngeal myotomy is performed, creating a single lumen without removal of the pouch. The retraction sutures are removed after the esophagodiverticulostomy is completed. The telescope is then used to closely examine the esophagus, diverticulum, and incised common wall for any evidence of perforation or foreign debris such as loose staples, which are promptly removed.

The patient is discharged home on the day of surgery after 3 to 4 hours of observation to assess for complications (fever, chest or back pain, subcutaneous emphysema, hemoptysis, tachycardia, tachypnea, respiratory distress). The patient is instructed to have only a clear liquid diet that night, which may be advanced as tolerated to the regular diet the next day. Antireflux medications are prescribed for all patients. Although many observers have used antibiotics in the perioperative period, use of antibiotics on a routine basis before, during, or after surgery has been found to be unnecessary. During the postoperative period, no role for barium esophagography has been found except for evaluation of possible recurrence.[8,100,101] Such radiographic studies,

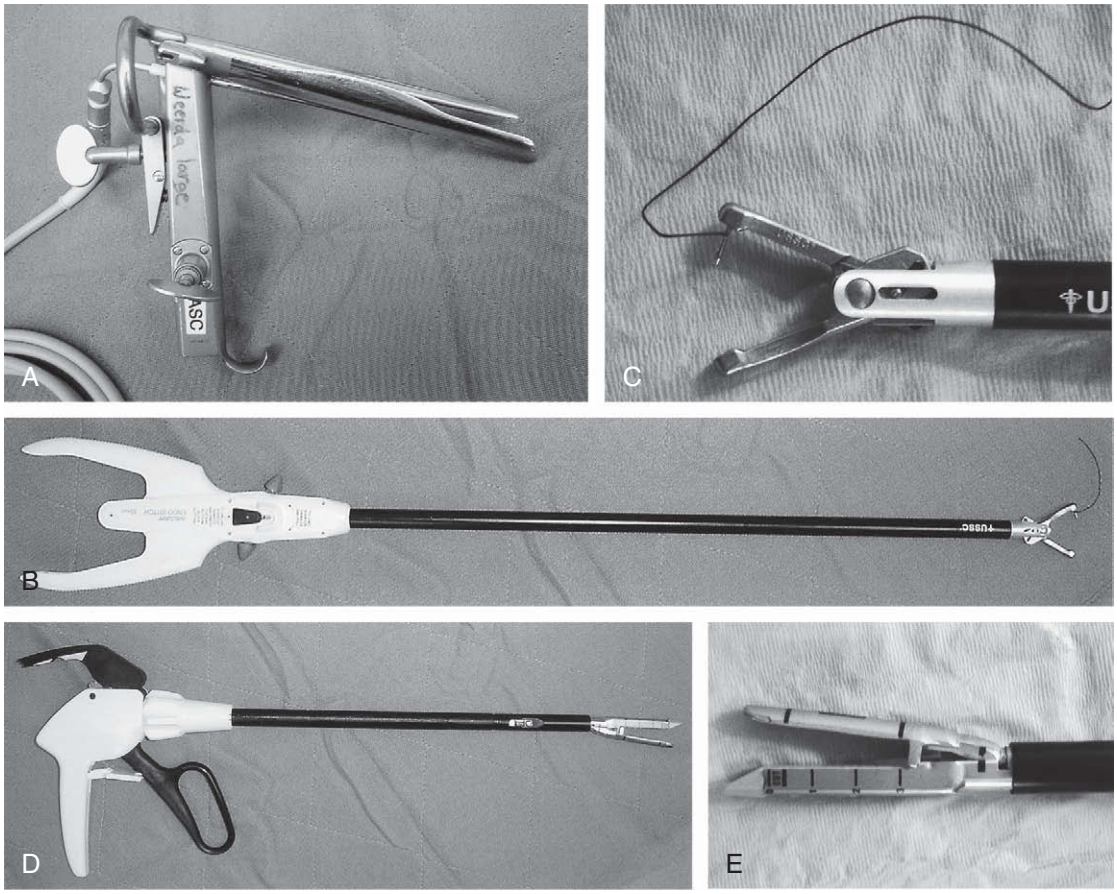

Figure 74-14. Instruments for endoscopic staple diverticulostomy. **A,** Weerda laryngoscope. **B,** ENDOSTITCH suturing device (Covidien Autosuture, Mansfield, MA). **C,** ENDOSTITCH tip. **D,** Endo-GIA 30 stapler. **E,** Stapler cartridges.

when performed in the asymptomatic patient, usually reveal a residual diverticulum that does not retain barium and so has no clinical bearing on, or correlation with, outcome.[100-103]

The procedure itself takes about half an hour to perform.[27] Patients resume an oral diet within 24 hours.[27] Compared with external approaches, endoscopic techniques have shorter, if any, inpatient stay, shorter anesthesia times (which is important in the elderly or the medically infirm), and more rapid convalescence.[98] Furthermore, in patients whose diverticula have recurred after primary external or endoscopic approaches, ESD may be performed without any increase in technical difficulty or morbidity.[27,31,98,104-106] One hospital charge analysis reported that ESD procedures were potentially more cost-effective than external techniques, an important consideration in today's world of health care economics.[107]

The stapling technique does have its limitations, although they are few. Exposure of the diverticulum may be difficult or impossible because of patient anatomy, such as kyphosis, large cervical osteophytes, or a small oropharyngeal opening. In patients with a small ZD (less than 2 cm), an insufficient cricopharyngeal myotomy may be performed, although placement of retraction sutures improves the exposure and divisibility of the common wall. Even with these sutures, retraction of the common wall may not be possible in the patient with recurrent small ZD from an earlier external approach, because of scarring.[98] Collard and associates[97] proposed that by sawing off the distal part of the Endo-GIA 30 stapler anvil, a section of the common wall more distal to the bottom of the diverticulum could be accomplished. However, in addition to its introducing avoidable risks to the procedure by potentially affecting the integrity of the staple closure, we have found such a modification unnecessary.[108]

Last, although the pouch can be inspected thoroughly and biopsy specimens obtained, a complete specimen is not obtained for pathologic assessment. This lack of complete specimen could prevent the discovery of carcinoma within the pouch. Fortunately, carcinoma in a diverticulum is extremely rare, found in less than 0.25% to 0.50% of cases, although in one review of 50 excised ZDs, Bradley and coworkers[25] reported an unusually high percentage, 8% of diverticula in their series containing squamous cell carcinoma or carcinoma in situ. The main factor in ZD carcinoma development is thought to be chronic inflammation of the diverticulum lining through many years from food retention, which would be minimized after ESD.[25,112] Along with intraoperative assessment, possible malignancy may be suggested when there is a sudden increase in severity of symptoms such as progressive dysphagia, pain, hemoptysis, or more marked regurgitation of food.[25,112] A barium swallow study may also suggest a malignancy when it reveals a loss of smooth contour within the pouch interior and a filling defect that does not move between films, although most often it is a result of retained food particles.[25] In these rare situations, ESD is contraindicated and external approaches to excise the diverticulum are recommended.[112]

Current experience suggests that ESD is superior to external, as well as other, endoscopic approaches.[27,31] Because the common wall edges are simultaneously divided and "sutured" with staples, there is a reduced risk of perforation that would allow salivary egress into the mediastinum, predisposing to mediastinitis. Furthermore, thermal damage to the recurrent laryngeal nerve from cautery is avoided, and there is no need for any expensive equipment such as a laser source. ESD procedures are performed faster, and patients recover more quickly than with external and other endoscopic techniques.[27,75,107,113] In addition, ESD may be used not only for ZD but also for other forms of hypopharyngeal and pharyngeal diverticula (see Fig. 74-3).[22,31,98,104-106] Overall, ESD has a reported 2.6% complication rate and 0.3% mortality, which compare favorably to external approaches (11.8% complica-

tion rate and 1.6% mortality) and other endoscopic approaches (7.4%-8.1% complication rate and 0.2% mortality).[27] The 1996-1997 report from the National Confidential Enquiry into Perioperative Deaths in head and neck surgery also concluded that endoscopic surgery is a quicker, less invasive, and safer technique.[114]

Complications unique to ESD exist, but are rare and described in case reports. Esophageal perforation was reported secondary to possible technical failure of the endo-stapler or excessive width of the common wall.[115] However, Richtsmeier and Monzon[116] brought to light that differences do exist between stapler cartridges and discovered that one particular type (TR45B 3.5-mm cartridge for the Endopath ETS Flex45 Endoscopic Articulation Linear Cutter stapler, Ethicon, Inc., Somerville, NJ) was more prone to leaks at the incisional apex at lower intraluminal pressures.[116] Persistent foreign body sensation and odynophagia were reported after ESD because of retention of a clump of staples in one case and a piece of silk retention suture in another.[106,117] Removal of the staples and stitch, respectively, resulted in symptomatic relief. Finally, a fatal case of mediastinitis as a result of delayed perforation on postoperative day 2 has also been reported, although in this case report, no mention was made whether the pouch and divided wall were examined carefully for perforation intraoperatively, a practice that needs to be performed at the conclusion of every procedure.[118]

Recurrence

Regardless of the technique used, whether external or endoscopic procedures, postoperative relief of symptoms has been found to be achieved in more than 90% of patients in the short term. However, the rate of

recurrence of preoperative symptoms after surgery has been found to be variable with the different surgical approaches. Recurrence rates of 0% to 19% for external approaches have been reported with variable length of follow-up.[27] For endoscopic approaches, recurrence rates between 0% and 22% have been reported, also with variable length of follow-up.[27] In a large cohort study of 159 ESD cases with 32.2 months average follow-up, there an 11.8% recurrence was reported.[27] Interestingly, this last study exhibited a bimodal distribution of recurrences, with partial return of symptoms occurring on average 33.9 months after ESD and complete return of symptoms occurring earlier, on average 8.5 months after ESD. Several reasons may explain this distribution. The relatively short interval before complete recurrence may be a result of incomplete division of the cricopharyngeal muscle as well as restenosis of the common wall from scarring. In one patient, the procedure made symptoms worse within 6 weeks. This patient was found at the time of revision ESD (5 months later) to have scar formation across the diverticulostomy of the common wall. Theoretically, reflux may irritate the freshly divided edges of the common wall and encourage scar tissue formation during the healing process, resulting in early restenosis of the common wall and recurrence of symptoms at an earlier time point. Findings of a partial or complete scar band at the earlier ESD diverticulostomy site for revision ESD support such inflammatory factors in wound healing. Furthermore, gastroesophageal reflux has been postulated to lead to cricopharyngeal spasm, which may predispose to the development of ZD.[42,77] Many patients with ZD also have gastroesophageal reflux, correction of which has been shown to lead to normalized upper esophageal sphincter pressures.[42,77]

Patients with minimal return of symptoms, however, may have reformation of ZD because of slow processes similar in pathophysiology to that of the processes that led to its initial formation, a process that takes years, unlike scar formation from aberrant healing, which takes only weeks. It is possible in some of these patients that the cricopharyngeal muscle was incompletely divided, leading to partial reformation of ZD during many months to years that results in partial, but not complete, return of symptoms. However, without performance of a direct laryngoscopy on these patients to assess the ZD, it is impossible to say with certainty, given the aging population, whether other factors unrelated to ZD may be developing, contributing to the appearance of these symptoms (see Table 74-1).

Intraoperative measures to decrease the chance of recurrence and complications include the use of retraction sutures to help position the common wall and allow the stapler to have total access to the cricopharyngeal muscle for maximal sectioning, as well as for the removal of any loose staples or retained sutures immediately after the common wall is divided to prevent mucosal edge irritation and subsequent restenosis.[31] After ESD, several measures may be pursued to help minimize inflammation, which otherwise may lead to restenosis of the common wall. Proton pump inhibitors are routinely prescribed for 2 to 3 months after surgery regardless of whether the patient had symptomatic reflux. Even in the literature for external approaches, some surgeons have advocated treatment of reflux postoperatively to reduce risk of recurrence, although others dispute any role of reflux in recurrence.[7,83] Endoscopic staple diverticulostomy does not induce thermal injury and inflammation to the tissues, as do CO_2 laser and electrocautery, which may encourage scar tissue formation. Finally, control of factors that may affect swallowing other than ZD must be performed to achieve greatest chance of symptom relief.[98]

The vast majority of patients who experience recurrence of ZD after primary excision by the transcervical route or any manner of endoscopic diverticulostomy may undergo revision ESD without any increase in technical difficulty or greater morbidity.[27,31,98,103-105] However, revision ESD may not be the best option for those patients

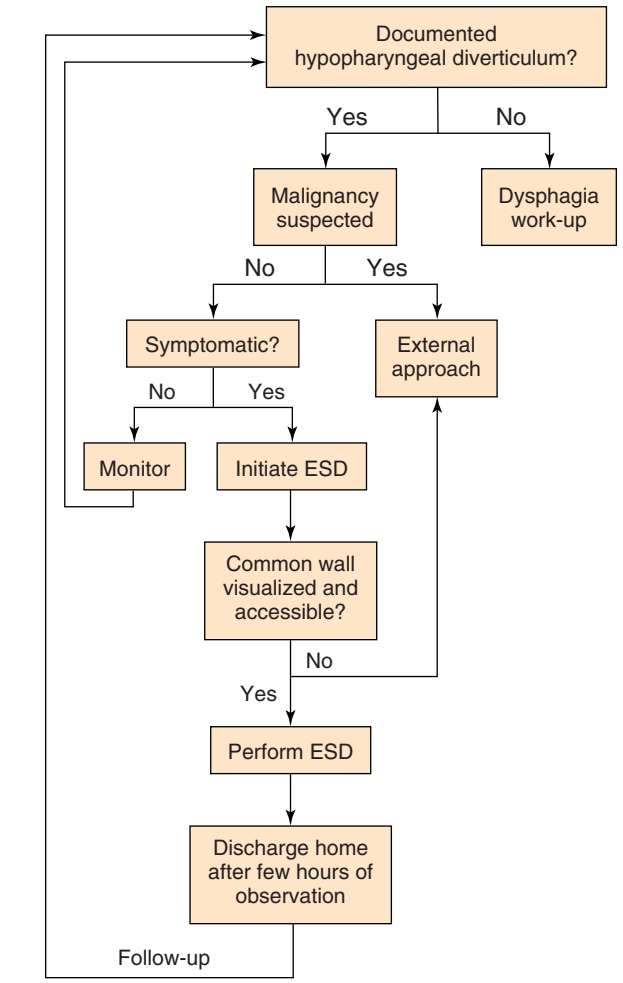

Figure 74-16. Algorithm for the approach to a patient in whom Zenker's diverticulum is suspected. ESD, endoscopic staple diverticulostomy.

with a very small recurrent pouch (1 cm or less) who have had previous external diverticulectomy, because scarring from earlier treatment and small diverticular size make retraction of the common wall into the stapler blades difficult.[98] Such patients should be counseled to undergo observation or external reoperation, depending on symptom severity.[98] Unlike revision ESD, external reoperations are technically demanding and have a much higher incidence of complications secondary to adhesions and distorted anatomy.[1,84] Indeed, Payne[84] reported much higher complication rate (51% vs. 2%) and mortality (3% vs. 0.9%) for further external operations than for primary procedures performed during the same period.

Summary

Zenker's diverticulum is a common acquired pulsion esophageal diverticulum found in the elderly population. Patients become symptomatic, with dysphagia, regurgitation, and aspiration, necessitating surgical correction. The etiology remains unknown but centers on cricopharyngeal muscle abnormalities. Historically, diverticulectomy with cricopharyngeal myotomy has been performed for this condition. However, with technical advances, endoscopic approaches, particularly endoscopic staple diverticulostomy, have become the treatment of choice for both initial presentation and recurrences, because of lower treatment-associated morbidity and mortality as well as shorter convalescent periods. Knowing how to perform all the various external approaches to address ZD is important in the armamentarium of the otolaryngologist–head and neck surgeon for those patients in whom ESD cannot be performed or diverticular carcinoma is suspected. A recommended treatment algorithm is offered in Figure 74-16. As new surgical advances occur, recommendations will be expected to evolve.

CHAPTER SEVENTY-FIVE

Tracheobronchial Endoscopy

Rex C. Yung

Emily F. Boss

Key Points

- The most common standard nomenclature for the bronchi is to label them by generation, whereby the trachea is the zero-generation bronchus, right and left mainstem bronchi are the first-generation bronchi, and so forth.
- Indications for bronchoscopy include the evaluation of respiratory symptoms such as hemoptysis, cough, or dyspnea; the assessment of an endobronchial or mediastinal mass noted on radiographic studies; as guidance during a difficult intubation; and the evaluation of congenital airway anomalies.
- In preparation for diagnostic or interventional bronchoscopy, a contrast-enhanced CT scan is useful to provide spatial relationships between lung pathology and vasculature and to minimize risk of injury during interventional procedures.
- Although flexible fiberoptic bronchoscopy offers great diagnostic and therapeutic opportunities, an important advantage of rigid bronchoscopy is that its wider lumen affords access to larger instruments, which may be necessary for foreign body removal, placement of airway stents, and control of hemoptysis.
- Numerous methods exist to diagnose pulmonary pathology, including bronchial wash, bronchiolar lavage, transbronchial biopsy, and transbronchial needle aspiration. Endobronchial ultrasonography may assist in directing biopsy.
- Tissue débridement via bronchoscopy is generally assisted using freezing, heating, or biochemical methods of causing cell death. Cold techniques include use of forceps, powered microdebrider, or cryotherapy. Heat-assisted resection is performed using laser, argon plasma coagulation (APC), or electrocautery. Photodynamic therapy (PDT) and endobronchial brachytherapy (EBBT) are biochemical destructive methods.
- Balloon bronchoplasty and endobronchial stent placement are techniques that assist in maintaining airway patency in an airway that is narrowed or has been reopened by débridement.
- Autofluorescence bronchoscopy is an evolving method for early detection of preinvasive lung cancers.

Careful consideration of the central and peripheral airways, pulmonary parenchyma, and vasculature is germane to the evaluation of the head and neck. Rapid advances in technology of the realm of imaging are making possible ever more accurate characterization of the anatomic distribution and metabolic properties of normal tissues and pathologic lesions in the head, neck, and thoracic structures. However, there remains no substitute for tracheobronchial endoscopy in the performance of a detailed examination of the airway mucosa and in directing biopsies and interventional procedures.

This chapter reviews the current technology of tracheobronchoscopy with a focus on the advances in flexible bronchoscopy and incorporation of various ancillary diagnostic technologies, such as endobronchial ultrasonography (EBUS) and autofluorescence (AF) bronchoscopy. Therapeutic airway interventions for both benign and malignant lesions will also be briefly reviewed.

Airway Anatomy and Nomenclature

The basic pulmonary function of gas exchange occurs at the level of the alveolus, located in the distal acinus beyond respiratory bronchioles, but for the purpose of the bronchoscopist, it is more important to recognize the more proximal airway divisions. Distal to the trachea and the mainstem bronchi, the lobar bronchus defines the division of the lobes, and the segmental bronchi the pulmonary lobules (Fig. 75-1). There are thus three lobes in the right lung, with normally ten segmental lobules, although there may be some anatomic variants. In the left lung, the left upper lobar segments and the lingular subsegments come off the same left upper lobe bronchial division, which also explains why resection of the left upper lobe often requires inclusion of the lingular, and vice versa. Because of the anatomic divisions, the left lung is often divided into nine segmental lobules, although here again there are anomalies, and the bronchoscopist should be familiar with the variations. Because of the location of the heart, the right lung usually accounts for 55% to 60% of the total lung parenchyma, and the left lung the smaller remainder. This information becomes important in estimations of residual pulmonary function after a planned lobar resection or pneumonectomy.

An additional source of frequent confusion in the naming of the segmental and subsegmental bronchi has to do with the frequent but incorrect interchange of the terms *generation* and *order* of the bronchial segments. Standard nomenclature of the human airways denotes the trachea as the zero-*generation* airway, with each of the right and left mainstem bronchi being the first generation, lobar bronchi the second generation, lobar segmental bronchi the third generation, and so forth. Conversely, *order* of airway segment refers to the retrograde counting from the "lobular bronchiole," which is the first airway segment with a diameter of less than 0.7 mm. Hence, more central airways of a larger

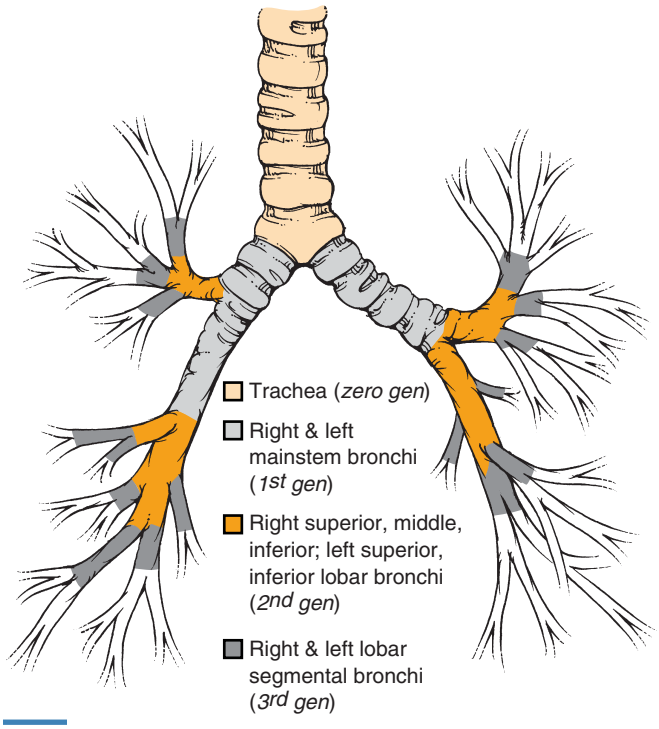

Figure 75-1. Tracheobronchial schema. Gen, generation. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

dimension actually have a higher order.[1,2] However, given the uneven segmentation and subsequent diminution of airway calibers, there is far less uniformity of division of airway in the different lobes, and lobules narrow down to 0.7 mm. Hence, the standard textbook description of the 0.7-mm lobular bronchiole located in the 10th- to 14th-generation bronchi does not match the bronchoscopic findings of airways navigable by a bronchoscope significantly wider than 0.7 mm beyond the number of branchings described previously.[2-4] In summary, it is best to use the term *generation* in the description of sequential airway branching, starting from the trachea. Dr. Shigeto Ikeda,[5] regarded as the founder of modern fiberoptic bronchoscopy, also developed a detailed system of naming segmental and subsegmental airways branchings, but that topic is beyond the scope of this chapter.

Indications and Preparations for Tracheobronchoscopy

Indications

Indications for tracheobronchoscopy include the evaluation of acute or chronic respiratory symptoms such as hemoptysis, nonresolving and worsening cough, and acute or worsening subacute dyspnea that may be accompanied by wheezing or stridor, pleurisy, chest pain, fever, or other symptoms suggestive of a pulmonary process (Box 75-1). Symptoms may be accompanied by radiographic abnormalities suggesting an endobronchial lesion, extrinsic compression of the airways by a mediastinal or lung mass, or presence of an infiltrate. Patients are often also referred for evaluation of asymptomatic lung or mediastinal masses and nonresolving parenchymal lung infiltrates. Pleural effusions usually lead to evaluation of the pleural fluid; however, effusions most often have an underlying parenchymal pulmonary cause, and a nonresolving effusion without an established cause after thoracentesis or thoracoscopy should prompt an examination for endobronchial obstruction. Bronchoscopy is helpful in assessing the placement of endotracheal tubes, especially in difficult intubation cases or when double-lumen tubes are required. A flexible fiberoptic bronchoscope (FOB) can be used to guide placement of an endotracheal (ET) tube in a difficult airway; in such cases, the ET tube is prepositioned and advanced over the bronchoscope. An FOB can also be used to guide percutaneous tracheostomy. Indications for tracheobronchoscopy in children include suspected foreign body, respiratory distress secondary to tracheomalacia or bronchomalacia, and evaluation of other congenital anomalies. Depending on the findings on radiography or during a diagnostic bronchoscopy, therapeutic interventions may be performed with an FOB to maintain airway patency and improve gas exchange.[6,7]

After consideration of the indication for the procedure, the next steps of planning should include the multimodality team of otolaryngologists, pulmonologists, radiologists, anesthesiologists, nurses, respiratory therapists, "backups" in thoracic surgery and interventional radiology if their services may be needed, and, not least, the patient and family for careful discussion and informed consent.

Box 75-1

Indications for Tracheobronchoscopy

Diagnostic Evaluation

Chronic nonresolving or worsening cough, especially with signs of aspiration
Voice change, hoarseness
Stridor
Wheezing unresponsive to bronchodilator
Hemoptysis
Pulmonary infections: acute processes not responsive to empiric therapy; recurring pneumonias in the same location
Progressive dyspnea
Radiographic abnormalities:
- Volume loss with suggestion of central airways obstruction
- Isolated lung mass(es)
- Infiltrate(s), localized or diffuse
- Mediastinal masses, adenopathy
- Nonresolving atelectasis
- Nondiagnosed pleural effusion with underlying lung consolidation

Interventional

Assistance in securing the airway: intubation over the bronchoscope; confirmation of position of endotracheal tube; assistance with double-lumen intubation
Removal of foreign body
Therapeutic aspiration of blood clots, inspissated mucus
Relief of central airways obstruction, both benign and malignant causes:
- Thermal ablation and mechanical removal of tumor
- Débridement of benign stenosis
- Balloon dilation
- Airway stent placement to maintain airway patency
- Guidance of percutaneous tracheostomy

Radiology

Given the millimeter-range high-resolution and rapid multiplanar reconstruction of the airways achievable with multislice spiral computed tomography (CT) scanners, a preprocedural CT scan can help pinpoint the location and extent of disease and reduce the time spent on exploration in patients with limited cardiopulmonary reserve. A contrast-enhanced CT scan is especially useful to provide the spatial relationship between pathology and vasculature and, hence, to minimize the risk of accidental and potentially life-threatening vascular injury from interventions such as laser or mechanical débridement. Contrast-enhanced atelectatic lung parenchyma can often also indicate whether there is viable lung tissue beyond central obstruction. Three-dimensional measurements of airway stenosis length and diameter facilitate the preselection of balloons for bronchoplasty and of airway stents for maintaining patency in an obstructed airway segment. A

thoracic surgeon or interventional radiologist should be consulted before the bronchoscopic investigation of massive hemoptysis, in case the bleeding source can only be identified—but not quelled—by bronchoscopic interventions.

Sedation and Airway Management

Maintaining gas exchange is critical during bronchoscopy, together with the desire of minimizing patient discomfort and anxiety. Some level of sedation, monitoring, and augmentation of oxygenation and ventilation is carried out with the assistance of an anesthesiologist or nursing personnel certified in sedation and airway management. Conscious sedation usually involves intravenous sedation with short-acting benzodiazepines (midazolam is most commonly used) or other anxiolytic agents plus a short-acting narcotic (e.g., fentanyl, meperidine, or morphine sulfate) to help suppress the cough reflex. My colleagues and I also find promethazine (Phenergan) useful in patients who are difficult to sedate or who have a strong gag reflex. The medications are given in measured, small boluses and the patient is appropriately monitored with hemodynamics, cardiac monitors, and pulse oximeters. Not yet routinely used but increasingly available is transcutaneous capnography. Deep sedation with propofol (Diprivan) provides for rapid on-and-off titration of sedation and can be very helpful in some patients who are difficult to sedate. General anesthesia with inhalational anesthetics with or without intravenous sedation provides the greatest control, but this would mandate the use of an ET tube, laryngeal mask airway (LMA) ventilation, rigid endoscopy with side-port ventilation, or a previously placed tracheostomy. It is also contingent on the presence of an anesthesiologist or a nurse anesthetist, who may not be readily available for bronchoscopies performed in endoscopy units separate from the operating rooms.

For patients undergoing bronchoscopy under conscious sedation, topical anesthetics are commonly used to reduce the amount of systemic sedative-narcotics needed to suppress cough, and also to diminish local discomfort in the nasopharynx during the passage of the bronchoscope. Lidocaine and its derivatives are most commonly used and applied topically as a gel to the nasal passage or as a spray to the posterior oropharynx. Solutions with concentrations between 1% and 4% are available, but the operator must pay attention to the total dosage applied because systemic lidocaine toxicities, including inadvertent deaths in healthy research subjects, have been reported when more than 500 to 1000 mg is delivered topically in a single session.[8] Therefore, except for spraying to the posterior oropharynx, we limit the use of topical lidocaine injected via the operating channel of the bronchoscope onto the vocal cords and airway mucosa to less than 3 to 4 mg/kg total dosage (1% lidocaine has 10 mg of lidocaine per 1 mL solution). Cocaine is also a very effective topical anesthetic that has the advantage of vasoconstricting the nasal mucosa membrane; it is, however, not generally available for use in the average endoscopy suite.

Miscellaneous medications that can be used in bronchoscopy include atropine or glycopyrrolate in patients with excessive secretions. Chronic bronchitis patients with acute bronchitis and patients with preprocedural problems handling bronchial secretions may be good candidates for parasympathomimetic agents. Caution should be used because such agents can precipitate tachycardia.

Patient Positioning and Route of Bronchoscope Entry

In a patient under conscious sedation with or without a previously placed tracheostomy, a flexible bronchoscope can be introduced with the patient supine or in a sitting position. It is generally easier for the bronchoscopist to be standing at the head of the bed. If a nasal approach is chosen, a cotton swab soaked with a lidocaine solution or gel is used to determine which of the nares permits easier passage. Studies have found shorter and smaller patients to experience greater postprocedural nasal discomfort when the same-sized bronchoscope is used; hence, for such patients, an oral approach may be preferable. Conversely, because of the sharper angulation of the bronchoscope at the posterior oropharynx when introduced orally, patients tend to have a greater gag response; therefore, a more thorough application of topical anesthetics to the posterior oropharynx is recommended. Because of the risk of trauma to the teeth and the instrument being used, a properly secured bite block is mandatory in this approach. For rigid bronchoscopy, although the early pioneers performed the procedure on fully conscious patients placed in a sitting position, the procedure should be carried out with the patient supine and the neck extended. The patient is almost always fully anesthetized with paralysis to facilitate the passage of the rigid bronchoscope. The rigid bronchoscope can most easily be introduced via the oral route. The insertion and maneuvers of the rigid bronchoscope as well as the proper ventilation and anesthesia are discussed later.

Ventilation and oxygenation can be better maintained in a more upright patient under lighter sedation. With a flexible FOB, the approach is made from the front of the patient. The approach via the nares or an oral passage is similar, although the view on the monitor is inverted because of the position of the bronchoscope tip relative to the approach. Once past the vocal cords, the bronchoscope can easily be turned to regain the familiar view with the ventral or anterior surface of the body facing the top.

In patients under deep sedation or general anesthesia, either a flexible FOB or a rigid bronchoscope can be used to examine the airways. For a flexible FOB, gas exchange is maintained with either an ET tube or a laryngeal mask; the latter is usually sufficiently large such that bronchoscope size is not a factor in limiting adequate ventilation and oxygenation. Prior discussion with the anesthesiologist ensures that a sufficiently large ET tube is inserted to permit smooth passage of the bronchoscope. For therapeutic cases using bronchoscopes with a diameter of 6.0 mm or greater, an ET tube of at least 7.5 mm is needed. Additional options are (1) to perform direct suspension laryngoscopy with intermittent ventilation via an ET tube alternating with bronchoscopic examination and intervention and (2) to perform direct suspension laryngoscopy using spontaneous ventilation and passive oxygenation.

To facilitate passage of the flexible bronchoscope, water-soluble lubricants are applied to the sheath of the bronchoscope. Lubricant jelly has the disadvantage of drying rather quickly, leading to stiffness in maneuvering, especially when the scope is introduced nasally. Lidocaine jelly is a good alternative that also provides some local anesthesia. Newer compounds, such as Endo-Lube (Covidien, Mansfield, MA) provide excellent lubrication and are ideal when the bronchoscope has a tight fit through devices such as an ET tube. Its cost may be higher, and caution is necessary to prevent accidental dislodgement of the ET tube from the ventilator because the lubricant also makes the various connections between the ET tube and ventilator circuit slippery. Mineral oil should not be used if at all possible because of the potential of oil aspiration leading to a lipoid pneumonia.

Patient Discussion and Informed Consent

Well-informed and educated patients and families are more likely to be compliant with therapy. In the case of bronchoscopy, especially in patients undergoing conscious sedation, an explanation of the steps helps alleviate the anxiety over the coughing and gagging that can sometimes force premature termination of the procedure. Ancillary diagnostic and therapeutic procedures, especially on hyperemic inflamed or malignant tissue, often lead to bleeding and postprocedural hemoptysis that should taper off. Similarly, a substantial portion (25%-50%) of patients may experience transient postprocedural fever during the first 24 hours. The cause need not be infectious and may be more common after bronchoalveolar lavage (BAL), which can result in surfactant washout. Informing patients of these two possible minor complications can obviate anxious midnight calls to the physician after a procedure. Conversely, patients should also be warned about prolonged bleeding and delayed pneumothoraces that may not be detected immediately after the procedure. Persistent or high spiking fevers, hemoptysis, and worsening dyspnea should prompt the patient to immediately contact a physician, who may perform a reevaluation with radiograph, physical examination, and other laboratory tests, as indicated.

Rigid Bronchoscopy

Rigid bronchoscopy retains certain important advantages over flexible fiberoptic bronchoscopy, including the much larger lumen that affords access to larger instruments, which may be necessary to remove foreign

bodies, to provide adequate suction in brisk hemoptysis, to place noncompressible polymeric silicone (Silastic) airway stents, and to use the bronchoscope itself to core out tumors and provide direct tamponade to a bleeding source. Rigid bronchoscopy today is performed almost exclusively in patients under general anesthesia, and rarely with the use of only topical anesthesia and conscious sedation without paralytics. More commonly, intravenous deep sedation, with or without inhalational anesthetics, is used. A variety of ventilatory strategies are used, from intermittent apneic ventilation to spontaneous/assisted ventilation. Oxygenation and ventilation can be provided by tidal volume through a closed system or via an open system with side-port Venturi jet ventilation.

Before insertion of the rigid bronchoscope, either alone or with a telescope lens through it to provide a better distal view, the patient must be examined for neck stability and for any loose teeth or dentures. A shoulder roll may give room for added extension of the neck. With or without a tooth guard to protect the upper teeth, the operator's left thumb is placed over the upper teeth and the index finger scissors open to lift up the lower teeth of the relaxed jaw. The bronchoscope with the bevel up is then directed midline and almost perpendicularly toward the hypopharynx until the uvula is passed. The operator thereafter slowly levels the bronchoscope angle toward the horizontal, seeking out the epiglottis while lifting the base of the tongue. When the vocal cords are clearly visualized, the bronchoscope is rotated 90 degrees such that the beveled edge can enter the trachea along the length of the vocal cord, thereby limiting trauma to the cords. Once the tip of the rigid bronchoscope is clearly in the trachea, it is rotated back to its starting position with the bevel up. The operator's left hand and finger positions are maintained to protect the teeth, although it is also necessary to occasionally use the left hand to provide a better seal around the cuffless rigid bronchoscope at the level of the cricoid and thyroid cartilages when ventilation is applied. Because larger operative rigid bronchoscopes with diameters of 11 to 12 mm are now available for insertion of silicone stents, upper airway and vocal cord edema may be a more severe problem at the end of a prolonged procedure; hence careful examination of the cords and hypopharynx is important to avoid postprocedural stridor and upper airway obstruction. With the advent of flexible fiberoptic bronchoscopy, the number of pulmonary teaching programs routinely including rigid bronchoscopy in their training curriculum is falling. Therefore, even though rigid bronchoscopy should be a skill acquired by all bronchoscopists, generally only those being trained in otolaryngology–head and neck surgery, thoracic surgery, or interventional pulmonology generally receive adequate exposure to and practice with this technique.[9]

Flexible Fiberoptic Bronchoscopy

Advances in fiberoptics, illumination, and image capture, including the use of true color-chip charged couple device cameras embedded in the distal tip of the FOB, have greatly improved the imaging capabilities of the FOB. Most new flexible FOBs are now videoscopes with high-resolution true-color rendition of the image captured by the distal chip. The illumination is still delivered via fiberoptic bundles. The improved imaging quality and the ease of recording areas of interest with digital still images or video segments are offset by the cost of these instruments as well as those of the dedicated processor and high-quality video display units. The startup cost of such a setup with two videobronchoscopes is in the $60,000 to $80,000 range. Conventional FOBs, in which the image is relayed via fiberoptic bundles and viewed at the proximal end of the FOB by the eyepiece or connected to a video display, continue to have a role. This is especially true for FOBs used at the bedside or during operations to confirm the position of standard or dual-lumen ET tubes and for the attachment of special illumination and visualization devices, such as during autofluorescent bronchoscopy.

Range of Flexible Bronchoscopes and Special Features

Although there remains the tendency to subdivide bronchoscopes into "adult" and "pediatric" categories depending on their outer diameters, this distinction is arbitrary. Because bronchoscopists venture more peripherally with FOBs to sample focal lesions, and more interventional procedures via a flexible FOB are performed in the pediatric population, it makes more sense to describe the bronchoscopes and leave their judicious application to the bronchoscopist according to experience and the situational need.[3,4]

All FOBs have an illumination fiberoptic bundle and imaging fiberoptics or a camera. With the exception of the very few "ultrathin" bronchoscopes, there is also a channel for suction of secretions and blood, for the passage of topical medication and fluid for washing, and for the passage of various instruments for diagnostic retrieval of tissues or for therapeutic procedures (Table 75-1). The "average" diagnostic bronchoscope has an outer diameter of 5.0 to 5.5 mm and an operating channel of 2.0 to 2.2 mm. This caliber channel admits most cytology brushes, bronchial biopsy forceps, and transbronchial aspiration needles with sheathed outer diameters between 1.8 and 2.0 mm. Smaller bronchoscopes, in the range of 3.0 to 4.0 mm at the outer diameter and correspondingly smaller channels, are usually given a "P" designation (for pediatrics), but they can, of course, be used in the adult airways when narrowing is present because of benign strictures or malignant stenosis. Newer generations of "slim" video and fiberoptic bronchoscopes have a 2.0-mm operating channel with a 4.0-mm outer diameter. The one disadvantage of these bronchoscopes is the sacrifice of a smaller image area because of fewer optical bundles.

Larger "therapeutic" bronchoscopes (often designated with a "T" in the model number) can, of course, also be used for diagnostic purposes, but the larger outer diameter can cause greater discomfort and mucosal trauma in a conscious patient and can be harder to pass through an ET or tracheostomy tube, and thus can also impair gas exchange to a greater degree. Such therapeutic bronchoscopes have outer diameters between 6.0 and 6.3 mm, with operating channel lumens between 2.6 and 3.2 mm. Certain therapeutic instruments, including larger laser fibers, larger electrocautery forceps designed for gastrointestinal endoscopes, cryotherapy probes, and expandable balloons for bronchoplasty, require these larger diameters for their use through FOBs. Prototype bronchoscopes with a 9-mm outer diameter and a 5-mm operating channel have been made, the main application of which is to provide access for therapeutic instruments to airway segments that cannot normally be reached by rigid open-tube bronchoscopes and telescopes (Fig. 75-2).

At the other extreme are the ultrathin bronchoscopes, with outer diameters smaller than 3 mm. The Olympus production models fiber BF-XP40 and video BF-XP160F (Olympus America, Center Valley, PA) have outer diameters of 2.8 mm and operating channels of 1.2 mm. Special instruments (e.g., reusable cytology brush and forceps) of the proper caliber are available for tissue sampling (Fig. 75-3). Handling of these ultrathin bronchoscopes is often more challenging because their very floppy tips make steering more difficult. Suction via the narrow channels is also much more limited. Nevertheless, with practice and the use of small amounts of saline to flush open the distal airways in guiding the bronchoscope forward, the ultrathin bronchoscopes can traverse 12 to 16 generations of airways and, under fluoroscopic or CT guidance, are seen to approach the periphery of the lungs to sample focal lesions.[3,4] The passage of a 2.8-mm instrument beyond the mid-teens division of the lobular bronchiole (measured at 0.7 mm in fixed tissue) calls into question some of the accepted measurements of the adult human airways. To permit the greater distance traversed, such ultrathin bronchoscopes usually have an operating length of 60 cm, 5 cm longer than the older bronchoscopes, although the current generation of videobronchoscopes are all built with a 60-cm working length.

New bronchoscopes manufactured today usually have a white ceramic insulated tip; this feature permits the safe use of electrocautery instruments with reduced risk of retrograde electric shock to the bronchoscopist and damage to the bronchoscope (see Figure 75-2).

Certain bronchoscopes designed for autofluorescence imaging have built-in filter wheels that are adjustable to facilitate imaging at specific spectral frequencies. Autofluorescence bronchoscopy is briefly mentioned in a later section of this chapter.

Care of the Flexible Fiberoptic Bronchoscope

Unlike the sturdy rigid bronchoscope, the flexible FOB is much more delicate, with glass fiberoptic bundles that can be easily damaged by

rough handling or accidental patient bites. Repair of bronchoscopes is costly and makes the use of the instrument temporarily unavailable. The narrow operating channel can also be damaged by a number of instruments, especially when these are too large for safe passage. The two especially vulnerable portions of the flexible FOB are the angulated entry port of the working channel and the distal tip of the bronchoscope. Incompletely retracted transbronchial needle aspiration (TBNA) needles are most frequently the culprits, tearing the channel during their introduction or retrieval by an inexperienced user. Such damages are noted during the "leak test" that should be performed after each use of the bronchoscope and before machine washing. It should also be emphasized that the tip of the bronchoscope should be kept as straight as possible during introduction and retrieval of the instruments. The same care must be exercised in the use of the entire range of diagnostic and therapeutic instruments because tears can also occur with biopsy forceps improperly opened within the channel, pushing and pulling of semirigid instruments through the flexed tip of the bronchoscope, burning on the inside of a bronchoscope channel by improper activation of electrocautery instruments, or firing of laser fibers.

There is growing focus on nosocomial infections resulting from defective endoscopes (loose valves) or from improper cleaning techniques. Thus far, outbreaks of nosocomial bacterial infections (e.g., gram-negative bacilli and *Mycobacterium*) are rare, and there have not been confirmed reports of viral transmission. The prevalence of such infections is very low and should not discourage the appropriate performance of bronchoscopy when it can provide important diagnostic information or can aid therapy. There are a number of accepted cleaning techniques ranging from gas sterilization (ethylene oxide) to formaldehyde-based approaches. It is under the purview of the endoscopy unit or operating room director and nursing director to develop quality control measures.

Diagnostic Fiberoptic Bronchoscopy

General Approaches

Although there is usually one primary indication for bronchoscopy, an orderly and uniform approach should be taken for airway examination so that important pathology will not be missed because of impatience to attend to the primary focus. Starting at the upper trachea, mucosal integrity should be examined. Even when there are no gross endobronchial lesions, the presence of extrinsic tracheal deviation and compression due to paratracheal masses should be noted. TBNA can often successfully provide a tissue diagnosis of extrinsic lesions.[10,11] Still under development is an array of ultrasound devices, balloon probes, and actual dedicated EBUS bronchoscopes that should help in the localization and characterization of such lesions. The posterior membranous portion of the trachea is sometimes the site of airway compromise caused by tracheomalacia or tumor invasion from esophageal cancers, and it is also the site of tracheoesophageal fistula. However, because of inflammation and redundant tissue, a tracheoesophageal fistula may be difficult to locate. Having the patient swallow 15 mL of methylene blue dye or food coloring immediately preceding bronchoscopy can aid in the localization of a tracheoesophageal tear or fistula. The distal trachea and main carina are important sites for examination because malignant diseases often metastasize to the surrounding mediastinal lymph nodes. The subcarinal, anterior carinal, and low paratracheal lymph nodes bilaterally are particularly suitable for TBNA.[10,12]

There is no set rule whether the left-sided or right-sided airways should be examined first. In general, unless marginal pulmonary reserve or cardiovascular instability severely limits the time available for bronchoscopic examination, both sides of the lungs should be examined because unexpected, radiographically occult airway pathology can occur in up to 10% of cases of primary bronchogenic carcinoma, and a smaller percentage in cases of metastatic disease. A thorough lobar and segmental review should not take more than 5 to 10 minutes. Countering the instinct to approach the area of suspected pathology, the bronchoscopist should first focus on the contralateral lung. Furthermore, unless the lesion is central and unavoidable, the bronchoscopist should examine apparently uninvolved lobes and segments to look for unexpected pathology. There are several reasons to practice this patience. First, once the main disease is visualized or diagnostic procedures are started, the bronchoscopist is often too distracted to return to a thorough and careful examination of the remainder of the airways. Second, once the site of primary pathology is sampled, bleeding can degrade the quality of the FOB image, and coughing and oxygen desaturation will limit the time to complete the procedure. Third, there is a danger that samples retrieved from a secondary site that appear abnormal and are found to contain malignant cells can actually represent contamination from cells dislodged during earlier examination of a primary cancer site. Although such false-positive results may have little significance in advanced obstructing central airways disease, this confusion could have the devastating effect of "over-staging" a potentially curable peripheral lesion.

Visual Examination

Less experienced bronchoscopists often regard confirming a positive tissue diagnosis as the main measure of a successful bronchoscopy. One should not, however, discount the value of getting a good "lay of the land" in terms of the dimensions of the airway, any significant anomalies in anatomy, and whether these are normal anatomic variants of the number of airway segments and the location of their branchings or are distortions resulting from prior surgery or endobronchial or extrinsic pathology. Such a "scouting" bronchoscopy with measurements of the length and the extent of airway compromise is especially important to planning potentially complex interventional procedures.

Bronchial Wash

Most often, some form of specimen is retrieved to diagnose pathology or, in the case of suspected opportunistic infections, to rule out with a greater certainty pulmonary infection by certain pathogens. Because there are always some airway secretions and, furthermore, aliquots of lidocaine solution and sterile saline are used to numb the airway mucosa and to clear the view of the airway, collecting a bronchial wash entails no more effort than connecting a "trap" in line between the suction port of the bronchoscope and the vacuum source providing suction. Care should be taken to secure the container used as a trap because if it is left dangling loose, the container could easily be inadvertently tilted or tipped over, with loss of sample easily occurs. The bronchial wash can be sent for cytology and culture. Concerns that the injected lidocaine may act as a bacteriostatic agent and hence may inhibit bacterial pathogen growth are unwarranted when one considers the overall dilutional effect. A much more valid criticism is that pathology such as malignancy or infections uncovered from examination of the wash may represent contamination introduced from the oropharynx and upper airways by the passage of the bronchoscope via the nares or oral cavity. For more peripherally located lesions, such as a lung mass or localized infiltrate, the bronchial wash seldom adds to the more specifically targeted sampling techniques listed here.

Bronchoalveolar Lavage

Accounting for the variations in airway compliance and caliber, the standard diagnostic bronchoscope and even the "pediatric" bronchoscopes with an outer diameter of between 3.5 and 5.0 mm can traverse through, at most, 7 to 10 generations of airways. This means that most

pulmonary masses and infiltrates are not directly visualized. With experience, and especially with the aid of radiographic guidance by fluoroscopy or by CT scanning, such lesions can be successfully diagnosed with different transbronchial techniques; however, the yield always depends on the skill of the operator and also tends to be lower than that of visible lesions, owing to sampling errors arising from the small size of samples retrieved. BAL is a technique that can provide a larger sample volume and also sampling of a larger lung field.

After identification of the region of the lung of interest, preferably down to the lobar segmental or subsegmental level, the bronchoscope is guided into the segment and "wedged" into place—that is, with gentle forward pressure, it is advanced and kept snug against the side walls of a bronchial segment. After the bronchoscope tip is maneuvered to obtain the best straightforward view into distal airway segments, aliquots of sterile saline ranging from 20 to 50 mL are gently infused. There should be a slight blanching of the airways. After each aliquot is infused, often with a column of air within the syringe to help propel the lavage fluid distally, suction is applied, either by depression of the suction button that activates the valve or by withdrawal on the syringe recently used to infuse the saline. The initial return is scant until a certain volume (possibly up to the functional residual capacity) is filled; thereafter, return should be more generous.

No set "standard" aliquot volume or total volume of normal saline is used for BAL, and the amount used depends on the amount of return and an estimate of how much sample is required for the desired battery of studies. In general, for the same total volume infused, a larger number of smaller aliquots of 20 to 30 mL (e.g., 4×25 mL vs. 2×50 mL) will yield a higher percentage of total volume recovered. Small-volume lavage return also appears to better reflect the peripheral lung cellular content. This finding may be the result of a longer dwell time in between aliquots, and because a greater number of sequences of infusion and suctioning can cause greater airway turbulence and agitation with better resultant washout of distal conducting airways and alveolar content.

In a supine patient, the yield is generally also better with BAL of anterior segments of the lungs—that is, lavage of the lingular and left upper lobe anterior segments and of the right middle lobe and right upper lobe anterior segments. In circumstances in which the infiltrate is in a dependent segment, such as the lower lobe superior segments or the posterior segments of the upper lobes, the return can be improved by positioning the patient in an appropriate decubitus position during the BAL. The yield from BAL is higher with infectious causes than with malignancy, although this difference is contingent on the expertise of the microbiology laboratory or cytology services. For certain infections, such as *Pneumocystis carinii* pneumonia (PCP) in a patient who has tested positive for human immunodeficiency virus, cytologic staining of a BAL specimen for PCP has a diagnostic sensitivity greater than 90%, and therefore transbronchial biopsies are not routinely necessary during the initial study. Conversely, other potential opportunistic organisms, such as *Aspergillus* species and cytomegalovirus (CMV) recovered from the BAL may be airway colonizers, and more definitive biopsy proof of tissue invasion may be needed before toxic therapy is initiated. The yield from BAL for malignant invasion of the lung parenchyma by primary bronchogenic or metastatic diseases ranges from 15% to 40% but is generally lower than that from more specifically targeted biopsies.

Complications from BAL are generally self-limited. Increased coughing after BAL is the most common. Whether coughing is due to induced bronchospasm or to washout of surfactant is unclear, and some practitioners advocate using saline warmed to body temperature to reduce bronchospasm. An excessive amount of lavage volume can potentially aggravate hypoxemia in a diseased lung, although the lung's central and peripheral airspace normally has a great reserve to resorb excess fluid, except in the presence of cardiogenic or noncardiogenic pulmonary edema. As previously mentioned, BAL can also increase the incidence of post-bronchoscopy fever, which is usually self-limited.

Endobronchial and Transbronchial Biopsy

A number of biopsy forceps are available for biopsy of bronchial mucosa or endobronchial lesions, and for transbronchial biopsy of airway and parenchyma beyond direct bronchoscopic vision (Fig. 75-4). The catheters are of various diameters and lengths, with larger "therapeutic" forceps fitted with larger forceps cups. The edges of the cups are either smooth-cutting or jagged "alligator" type. A number of the larger forceps are designed primarily as forceps for use in upper and lower gastrointestinal endoscopes, and hence their cables are much longer than the 55 to 60 cm of the bronchoscope working channel. There are additional forceps with a needle or "spike" in the center of the opened jaw near the fulcrum of the opened forceps; this spike aids in the anchoring of the forceps on mucosa, scar tissue, or tumor. These needle forceps are most useful for endobronchial biopsy, especially when the target may be along an airway wall tangential to the bronchoscope and thus cannot be easily grasped by forceps opening at a very shallow angle to the lesion. Some forceps also have an attachment for electrocautery. These may be useful for sampling or removing friable tissue that bleeds, because electrocautery can effectively provide thermal hemostasis.

Figure 75-4. Instruments for use with a flexible fiberoptic bronchoscope *Top to bottom*, Reusable forceps with steel wire catheter sheath (Olympus America, Center Valley, PA); disposable forceps with coated catheter (Microvasive, Boston Scientific, Natick, MA); disposable needle forceps; large electrocautery forceps, which requires a 2.8-mm channel; electrocautery snare; handle with wire attachment for electrosurgical instruments.

The technique for endobronchial biopsy is fairly straightforward. After careful positioning of the opened jaws of the forceps, the forceps is advanced toward the target lesion and is closed when the lesion is within grasp. The challenge comes when the target is small, the airways are moving in response to respiration, or the patient is agitated and coughing. The opened jaws of the forceps can further obscure the view from the bronchoscope. Under these circumstances, the resultant tug of a fairly floppy forceps catheter may yield a disappointingly small specimen. One technique to improve the accuracy and yield of the biopsy is to advance with the bronchoscope closer to the target lesion before advancing the biopsy forceps outward. With closure of the forceps cups, one should pull back gently until the forceps are almost but not fully retracted into the bronchoscope channel. The bronchoscope itself should be pulled back slowly but firmly, and the much larger instrument (bronchoscope vs. the forceps) generally helps pull out a much larger specimen.

Complications from endobronchial biopsy most often involve bleeding due to trauma. Flushing small aliquots (1-2 mL) of a topical vasoconstrictor followed by a saline "chase" of 2 to 3 mL to clear the medication out of the bronchoscope channel helps stem the bleeding. Tamponade with the tip of the bronchoscope until a clot forms may also help, but this is often less effective and risks further obscuring the view with coagulum. Oxymetazoline (Afrin) 0.05% and lidocaine with epinephrine (1:10,000 dilution) are two vasoconstrictors commonly used for this purpose, although oxymetazoline is preferred because it causes less tachyarrhythmia and hypertension. Airway perforation is a theoretic risk but it rarely occurs, except in severely necrotic airways already distorted and destroyed by invasive cancer. Damage to the

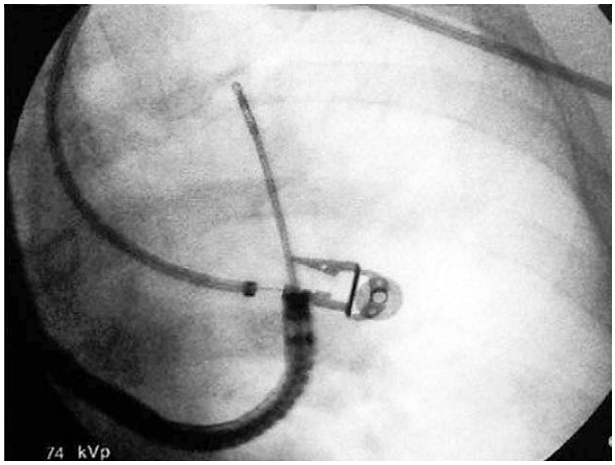

Figure 75-5. Transbronchial biopsy of a peripheral (left upper lobe) lung mass under fluoroscopic guidance.

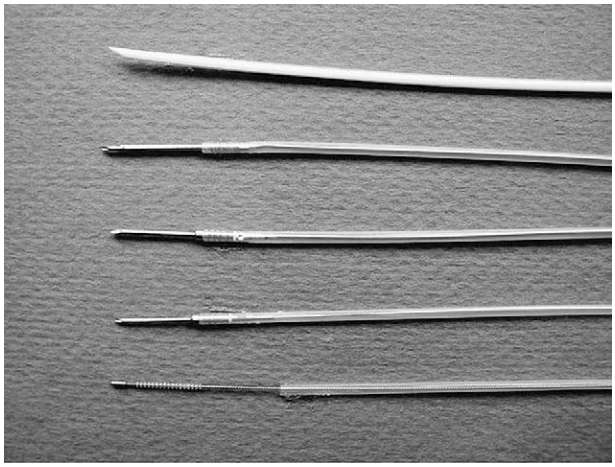

Figure 75-6. Transbronchial needles and cytology brush. *Top to bottom,* 18-gauge Microvasive Sofcor plastic (Boston Scientific, Natick, MA); 19/21-gauge MW 319 histology steel, 15-mm length (Bard/Mill-Rose Laboratories, Mentor, OH); 21-gauge SW121 cytology steel, 15 mm (Bard/Mill-Rose Laboratories); 22-gauge MW122/222/522 cytology steel, 13 mm (Bard/Mill-Rose Laboratories); cytology brush.

bronchoscope is a real concern; this can occur if an inexperienced operator attempts to open the forceps while it is still within the channel, or if an incompletely closed forceps or one with a kinked set of cups is forcibly withdrawn back into the channel. When there is any doubt or if there is obvious kinking of the forceps that cannot be corrected within the airways, the entire bronchoscope must be withdrawn, and the problem fixed outside the patient's airways.

Transbronchial biopsy uses the same instruments, although there is much less reason to use the needle forceps. This procedure is usually directed toward a focal mass lesion most often suspicious for lung carcinoma, or toward focal or diffuse infiltrates suggestive of infection, inflammatory lung processes, fibrotic lung parenchyma, or metastatic carcinoma with lymphangitic or diffuse hematogenous spread. Although it is possible to perform successful transbronchial biopsy without radiographic guidance, the yield is lower and the risk of complications increased; therefore, we prefer the availability of fluoroscopy to guide transbronchial biopsy, especially of smaller, more focal, and more peripheral lesions (Fig. 75-5).[11,13]

For more diffuse peripheral disease, whether guided by fluoroscopy or with use of a "blind" approach, the forceps are advanced slowly in a closed position until gentle resistance is felt or until the tip of the instrument is seen to approach the pleura. Because of the angulation of the segmental airway branchings and the effects of foreshortening, the advancing forceps may not appear to approach the lung periphery on the planar fluoroscope. Once resistance is felt, the forceps are retracted about 2 to 3 cm, the cups are opened, and the instrument is gently pushed forward. After firm closure, the position of the forceps is confirmed by fluoroscopy and the instrument withdrawn. In a patient under conscious sedation, especially when fluoroscopy is not available, we also ask whether there is chest wall pain, which would suggest focal pleural irritation caused by the tip of the forceps and would warn us of the increased risk of pneumothorax. The yield from transbronchial biopsy varies depending on pathology, location and size of lesion, and availability of fluoroscopy. In general, the diagnostic yield for transbronchial biopsy in malignant lesions located centrally and larger than 2 cm is about 50%, compared with only 25% in lesions smaller than 2 cm located in the peripheral one third of the lung.

Complications of TBBX are bleeding and pneumothorax. As aforementioned, performing fluoroscopy and querying for symptoms of pleurisy reduce the risk of pneumothorax to less than 10%, with overall rates of 3% to 20% reported.[11] Significant bleeding is not increased in patients taking aspirin and cannot be predicted by routinely ordering measurements of platelet counts and coagulation parameters. Nevertheless, in critically ill or pancytopenic patients, an attempt is made to keep the platelet counts above 50,000/μL, to correct coagulopathy if present, and to temporarily suspend anticoagulation. Bleeding, when brisk, is managed by tamponading of the bleeding subsegment with the bronchoscope tip. Depending on operator preference, suction can be applied to collapse the segmental airways to prevent further retrograde bleeding into the central airways, and lavage with room-temperature or cooled saline can be performed to slow the bleeding. There are no randomized trials to suggest efficacy of one approach over another. Needless to say, life-threatening hemorrhage from transbronchial biopsy is rare but reported.

Transbronchial Needle Aspiration

TBNA has traditionally been used to sample mediastinal lymph nodes and cysts. Initially TBNA was performed using needles on a long rigid stem introduced via a rigid bronchoscope tube; in fact, the earliest cannulation of the left atrium for measurements of left atrial pressure was performed using this TBNA approach. Diagnosis of benign mediastinal adenopathy (e.g., sarcoidosis) and malignant tissue (e.g., lymphoma, nodal metastases of bronchogenic carcinoma) can be made via rigid TBNA; however, the lymph nodes sampled are often limited to the subcarina and, possibly, the precarina because of the limited angulations achievable with rigid instruments.

The introduction and refinement of TBNA needles attached to a flexible catheter has permitted sampling, with a flexible FOB, of a larger number of lymph node regions, endobronchial lesions in the segmental and subsegmental bronchi, and peripheral, endoscopically occult lesions. The majority of the needles are made of stainless steel with calibers ranging from 22 to 19 gauge (Fig. 75-6). There remains one plastic needle with a flexible tip (Microvasive Sofcor, Boston Scientific, Natick, MA) that may be bent to facilitate passage into subsegments of the upper lobes and certain lower-lobe subsegments that are otherwise often not reachable with metal transbronchial needles because the 13- to 15-mm lengths of these rigid needles reduce the tip angulations of the flexible FOBs.

Although the flexible needles have been divided into smaller gauge (20, 21, and 22 gauge) "cytology" needles and larger gauge (19-gauge metal and 18-gauge Sofcor) "histology" needles (see Figure 75-6), the choice of the needle depends on operator experience, because the larger "histology" needles still provide tissue for cytologic examination by slide smear, and samples aspirated with smaller "cytology" needles can be spun down into a cell block and cut for histologic examination. The longer needle lengths (15 mm) of the 21-gauge and larger needles offer the advantage of greater depth penetration. However, a 19-gauge needle is more unwieldy to maneuver, takes more practice for penetration of the bronchial mucosa, and can potentially cause more trauma. It is often reserved for the sampling of larger lymph nodes suspected of

harboring lymphoproliferative tissue (e.g., lymphoma, Castleman's disease) or granulomatous diseases (e.g., sarcoid, mycobacterial, and fungal adenitis) because, with practice, a 21-gauge core sample can be retrieved.

Mediastinoscopy remains the "gold standard" for examination and sampling of mediastinal lymph nodes; however, access to the subcarina, posterior tracheal, subaortic left-paratracheal/aortopulmonary window and hilar lymph nodes is limited. TBNA via FOB has the advantage of access to a larger number of lymph node stations and of being a less invasive procedure that can be combined with the endoscopic examination of the airways plus as-needed sampling of peripheral lung disease (see Figure 75-6). Therefore, TBNA may be one of multiple procedures performed in a sequence of "one-stop" diagnosis and staging of thoracic malignancies. Certain lymph node stations are also inaccessible to TBNA via FOB; these include the paraesophageal and lateral aortopulmonary-window lymph nodes, which can be sampled by real-time endoscopic ultrasonography–guided fine-needle aspiration (FNA) via the esophagus and by anterior median sternotomy (Chamberlain procedure), respectively.

Technical Aspects

The "abnormal" lymph node has been classified radiographically as one with a short axis measuring more than 1 cm. However, thorough lymph node staging of bronchogenic carcinomas has demonstrated a diagnostic sensitivity and specificity of only about 60% to 70% with this rule applied. 18-Fluorodeoxyglucose positron emission tomography may identify metabolically abnormal lymph nodes and lung nodules even when they do not fulfill this size criterion. After identification of an accessible lymph node suspicious for harboring pathology, a TBNA needle is carefully introduced with tip retracted via the operating channel of the bronchoscope. Regardless of the location of the chosen target, it is best to pass the TBNA through the lumen with the bronchoscope in a fairly central location (i.e., the trachea or mainstem bronchi) with the tip straight or minimally angulated in order to protect the expensive equipment that can be most easily damaged by instruments at its distal flexible end. With the TBNA needle still in its protective hub, the bronchoscope is then maneuvered into a position proximal to the target lesion. After the bronchoscope is centered away from the side-walls, the needle is deployed and locked in place, as care is taken to avoid mucosal trauma that will cause bleeding and obscuration of the bronchoscopic view. The catheter tip housing the beveled metallic needle usually has a protective metal hub that helps prevent inadvertent perforation of the bronchoscope channel. During positioning for TBNA, a portion of the needle or the catheter hub should always be visible; otherwise it is possible that the exposed needle was pulled back into the distal bronchoscope tip, again risking damage. If for any reason the needle is not visible, it should be retracted into the catheter and the entire catheter should be removed from the bronchoscope and properly reset for redeployment.

The actual mucosal penetration and spearing of the mediastinal target can be performed by one of two techniques, the "stab" or the "push-jab."[10] The stabbing approach entails holding the bronchoscope in place and pushing the deployed needle catheter forcefully forward, thus traversing the bronchial mucosal into a lymph node or tumor mass. The limitation of this technique is that it is suited only for lesions that are situated directly in the line of sight of the bronchoscope; the needle will more than likely take a somewhat more oblique pathway across the bronchial mucosa, thus leaving less needle length to penetrate the lesion. In a spontaneously breathing patient, subtle airway motion can translate to missing the lesion or having the needle hang up on bronchial cartilage instead of passing through the membranous portion of the mucosa. Finally, if the bronchoscope-needle setup is positioned too far away from the bronchial mucosa point of entry, pushing the flexible TBNA catheter outside the bronchoscope channel will allow the catheter to bend and kink, further limiting its effectiveness.

For these reasons, the piggy-back "push-jab" technique is preferred. In this approach, the deployed and locked needle is kept partially withdrawn into the distal bronchoscope and the sharp needle tip is carefully directed toward a selected entry point; the membranous mucosa between cartilage rings is chosen. The bronchoscope tip can be partially flexed such that the bronchoscope and needle catheter behave as a curved needle set, with the needle anchored at about a 45-degree angle. Control of both the catheter and bronchoscope is obtained, either by the bronchoscopist alone or with an assistant holding the proximal end of the catheter and being ready to advance it on command, and the bronchoscope is pushed forward firmly as the piggy-backed needle-catheter is jabbed forward. With practice, the TBNA needle can be made to traverse the mucosa at a nearly 90-degree angle, thus affording sampling of lesions in the distal left and right paratracheal angles, anterior precarinal space, and right bronchial lymph nodes (Fig. 75-7). Once the locked needle-catheter set is advanced until the entire length of the needle is buried up to the hub, the clear catheter is pushed from the proximal end until a bit of it is visibly protruding from the distal bronchoscope tip. At this point, inadvertent penetration of one of the major vascular structures, such as the aorta, pulmonary artery branches, superior vena cava, or azygous vein would be obvious from the complete backfill of the distal catheter with blood even without any suction applied. If there is no unexpected return of blood, a cytology or histology sample can be obtained with the forward-and-backward movement of the needle. Although suction has most often been applied by syringe attached to the proximal end of the TBNA catheters, this manipulation is not always necessary because it is really the capillary action plus the regular agitation motion that draws tissue into the lumen of the needle. This principle is especially applicable for looser, less organized malignant tissue, whereas suction may be required for acquisition of an adequate sample of a denser granulomatous or reactive lymph node.

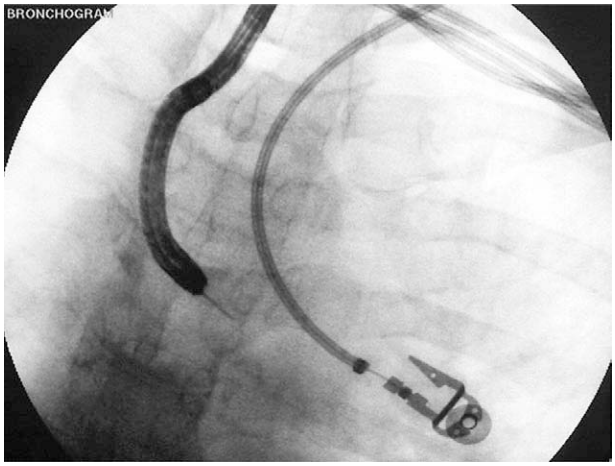

Figure 75-7. Transbronchial needle aspiration of a left paratracheal lymph node, resulting in successful staging of stage IIIA disease.

The same TBNA needles can be used for the transbronchial sampling of peripheral lung masses, although as mentioned earlier, the acute bending of certain lobar segments may preclude successful passage of the TBNA needle into the desired airway segments.[11,13] Unlike in sampling of central mediastinal lesions or endobronchial pathology, the needle is not deployed until the catheter hub with the protected needle tip is advanced into position as indicated by fluoroscopy or CT.

There is some debate as to the ideal method to retrieve the needle-catheter and how to process the sample thereafter. Some experienced practitioners of TBNA withdraw the still extended and locked needle back into the bronchoscope and out the channel while simultaneously straightening the tip of the bronchoscope. The rationale for not first retracting the needle into the safety of the hubbed tip is to avoid sucking back bronchial epithelial cells that may dilute the presumed pathologic cells of interest within the needle. The obvious risk, however, is the much greater chance of damage wrought on the bronchoscope even if the needle is only pulled back, because a rigid needle measuring 13 to 15 mm can scratch and perforate the bronchoscope channel, which can be in a 130- to 180-degree angulation. Current teaching is therefore to always fully retract the needle before pulling the catheter backward, while still straightening the distal tip of the bronchoscope.

The retrieved samples can be prepared and preserved in a number of ways. Generally, more than a single pass is made to ensure adequate sampling, with the maximum yield leveling off after between four and seven passes at a particular site. The presence of rapid on-site evaluation by a pathologist or an experienced cytopathology technician is a helpful adjunct that improves the diagnostic yield of TBNA.[14] The immediate feedback will direct the need for additional TBNA passes. Even when disease is noted, such as carcinoma or abnormal lymphocytes, extra passes for additional material to be spun down for immunostaining or preservation in media for flow analysis may aid in making the identification of a tumor source or cell type, with important implications for prognosis and as a guide for therapy. In the absence of cytopathology assistance, samples can also be injected into an aliquot of preservative solution such as Saccomanno's fixative and spun down in the laboratory for further analysis. Flushing out the needle with 1 to 2 mL of saline after each pass, as reported earlier, is no longer practiced because this dilutes out small quantities of sample, and the needle loses some of its capillary effect when flushed with liquid. We therefore eject the sample from the needle with an air-filled syringe.

Published series quote a diagnostic yield rate of 75% to 90% for TBNA sampling of mediastinal lymph nodes, with lower rates for peripheral pulmonary lesions, once again depending on the location and size of the targets.[10,11,13] TBNA, however, remains an underused minimally invasive sampling technique because of uneven teaching of the technique and the average low yield for the occasional practitioner of this technique.[9] A number of radiographic techniques have been used or are being developed as adjuncts to help in localization and to guide TBNA sampling of lung pathology. Fluoroscopy can help visualize the proper penetration of a lesion in the lung parenchyma but is generally less useful in accurately localizing mediastinal adenopathy and central masses that may be obscured by the cardiac silhouette and other normal mediastinal structures. Spiral CT, either with stopped frames or fluoroscopic, can be used to help localize and prove TBNA penetration of target lesions, but it is cumbersome to perform these bronchoscopic procedures in the CT scanner, and the patient and staff are exposed to a much higher levels of radiation.

The advent of rapid multislice detector CT scanners and the development of software to improve three-dimensional rendering may soon make available a number of high-fidelity "virtual bronchoscopy" programs, including the capability of rendering the airway wall "transparent" and highlighting the adjacent mediastinal structures of interest. The purpose of these programs is not to obviate the need for tissue diagnosis but to guide the approach for procedures such as TBNA and transbronchial biopsy. Another real-time guidance technique is the use of EBUS to localize lymph nodes and other mediastinal structures of interest for tissue sampling.[15,16] Most EBUS procedures use a radial balloon probe introduced via the working bronchoscope channel. After EBUS imaging is completed, the probe is withdrawn and TBNA is performed. Report of simultaneous imaging and sampling via a double-lumen bronchoscope is not generally applicable owing to the rarity of these bronchoscopes, which are largely being phased out, and by the imminent introduction of a dedicated EBUS bronchoscope with an angled side-port for TBNA. EBUS is currently available for clinical use, but in only at a limited number of centers because of the lack of experienced practitioners and the equipment cost.

The primary complication from TBNA of mediastinal structures is bleeding into the airways from puncture of vascular structures or vascular tumors. Less commonly, pneumothorax, pneumomediastinum, or hemomediastinum may occur. Bleeding is generally self-limited, and the bronchoscopist should be focused on clearing the airway of blood that would otherwise obscure the bronchoscopist's view and induce coughing and desaturation. Suction should be directed downstream from the TBNA entry site, presenting no interference with the local formation of a small clot. TBNA of peripheral lung lesions entails the same risk as transbronchial biopsy, including bleeding and pneumothoraces.

Bronchoscopic Brush

The use of a cytology brush for the sampling of an endobronchial lesion or its use under fluoroscopic guidance for the sampling of a peripheral lesion appears a simple enough procedure, but a review of the yield and complications is warranted. Because the stiff metallic bristles of the cytology brush can be traumatic over a larger area, bleeding from bronchoscopic brushing can be severe. In spite of a vigorous effort to retrieve sample, the yield can be disappointingly low for carcinoma and generally ranks below directed-forceps biopsy and endobronchial needle aspiration.[11,13] There are multiple explanations for this apparent paradox. Much as with TBNA, in which active negative-pressure aspiration can cause more trauma and bleeding than agitation without suction, the nonspecific trauma induced by the bristles leads to a usually bloody sample that can obscure the malignant cells behind a field of red blood cells, fibrin, and other debris. The superficial endobronchial layer of a central tumor can often consist of a biofilm of mucus, necrotic cell debris, and recruited inflammatory cells, thus sampling along the surface with a cytology brush may pick up only these nondiagnostic contaminants and miss the underlying true pathology. The yield of a cytology brush for the sampling of peripheral lesions is equally disappointing, also because of the sampling issue of picking up mostly normal or inflamed bronchial or bronchiolar epithelial cells. In a number of instances, unless an airway leads directly up into a tumor mass, the catheter of the cytology brush is directed away from the tumor that pushes away adjacent bronchi.[17] In a similar circumstance, the needle of a TBNA can be extended directly toward a tumor, penetrating the smaller airways as necessary. Therefore, except as a poor substitute for directed-forceps biopsy and TBNA of central endobronchial and peripheral lesions, bronchoscopic brushing for cytology has relatively low merit and rarely adds to the other sampling procedures in cancer diagnosis.

To address the issue of nonspecific bronchial wash or BAL cultures from contamination by upper airways colonizers, a protective microbiologic brush has been developed as an adjunctive method to sample the lower airway. A plastic-bristled brush housed within a catheter capped with a plug is introduced into the airway's segment of interest, and the plug is ejected by the deployed brush, which will then pick up a "true" lower respiratory tract sample. The brush has furthermore been designed to adsorb a fixed quantity of bronchial secretions (0.1 mL), which can be serially diluted 100-fold in the microbiology laboratory to yield a semiquantitative "protected" microbiologic culture. By this method, growth of 1000 colonies of a particular organism would be significant. It is advisable for the bronchoscopist to confer with the institution's microbiology staff before embarking on collecting specimens with the protected catheter brush.

Interventional Bronchoscopic Procedures

General Principles

Virtual bronchoscopy is becoming more popular in simulating diagnostic bronchoscopy to diagnose airway pathology as a prequel to therapy, and minimally invasive therapies are now more and more favored over aggressive operations because of improved technology. Therefore the paradigm of bronchoscopy is shifting slightly from diagnostic implications to treatment with bronchoscopic interventional procedures.[18-20]

Careful selection of a patient eligible for interventional bronchoscopy is critical to maximize benefit to patients who are generally quite ill. Depending on the particular intervention, the nature of the disease state, and the patient's functional status, the risks associated with interventional procedures can be significant. The majority of our currently performed interventional procedures, such as repair of tracheobronchial-esophageal or bronchial-mediastinal fistulas, all strive to maintain airway patency and reestablish normal gas exchange, or to reestablish the airway structure to as near normal as possible.

It is important to recall that for ideal gas exchange to take place, there should be minimal ventilation-perfusion mismatching. Therefore, whereas the removal of a foreign body such as an aspirated object in a toddler or child can lead to immediate and full recovery, simply reestablishing airway patency may not be sufficient in other instances. For thoracic malignancies blocking the airways, whether primary or metastatic, débridement of airway tumor and debris when the accompanying vasculature is also infiltrated and obliterated may simply lead to

increased "dead space." Reestablishing ventilation of nonperfused lung segments can in fact worsen hypercapnia and not improve hypoxemia. A good-quality contrast-enhanced CT scan of the chest is therefore mandatory for review in all cases of airway obstruction, with the exception of patients with recent aspiration of a foreign body.

Knowledge of the position of the vasculature is furthermore critical for the interventional bronchoscopist to avoid potentially life-threatening complications of vascular injury by laser or mechanical débridement. The intravenous contrast agent in the CT scan serves another very important purpose. In the cases of known or highly suspected malignancies blocking the central airways, knowledge of whether there is functioning lung distal to the obstruction will help to predict the likelihood of success and to determine whether patients with tenuous medical status should be subjected to deep sedation or general anesthesia with mechanical ventilation from which they may not be successfully weaned. Experienced radiologists provide a reasonable estimate as to whether an interventional expedition from within the airway lumen will only reveal disease that is the "tip of the iceberg." They can also comment on the presence of concomitant pleural disease that may portend the very poor prognosis of a "trapped" lung, even when the central airways are reopened and pleural fluid removal attempted.

Preparation of the Patient and Selection of Instruments

Careful history-taking should include any use of anticoagulants and antiplatelet agents. Physical examination, review of radiographs (preferably including a recent contrast CT scan), and measurement of platelet counts and other relevant bleeding parameters are routine. Because many of the patients undergoing interventional bronchoscopic procedures often have more advanced pulmonary diseases and possible comorbidities, a baseline electrocardiogram is often requested. Because the purpose of the procedures is often palliative in nature and the procedures are accompanied by higher risk than a standard diagnostic bronchoscopy, a detailed discussion of possible complications and the realistic likelihood of achieving subjective relief should be discussed with the patients and their families. In an airway interventional series of laser débridement in 1585 patients by Cavaliere and associates,[21] the overall procedure-related mortality was 0.3% and the rate of major complications (including significant hemorrhage, pneumothorax, and pneumomediastinum) was 1.5%.

Most interventional procedures can be performed via an FOB, a rigid bronchoscope, or an FOB introduced via a rigid bronchoscope or via direct suspension laryngoscope. There are pros and cons to both approaches, but the operator should be capable of converting a procedure begun with an FOB into one using a rigid bronchoscope when the need arises.[9,18] The larger channel of the rigid bronchoscope facilitates the use of larger-caliber instruments, and certain rigid silicone stents require rigid instrumentation for their deployment. The bronchoscope itself can be used to core out tumor tissue or to tamponade hemorrhage from the side walls. It is also easier to remove noncancerous foreign bodies and to dilate benign stenotic segments via a larger rigid tube. Conversely, the larger and rigid instruments are more liable to cause trauma to the vocal cords and potentially cause a fistula when used to débride necrotic tissue in distorted airways. The constrained angulation provided by manipulation of the patient's head and neck positions can limit the bronchial segments reachable for intervention. The rigid instruments also mandate the use of general anesthesia. When a flexible FOB is chosen for interventional procedures, larger-channel "therapeutic" bronchoscopes that can accommodate flexible interventional instruments are selected, but it is often helpful to also have available thinner pediatric bronchoscopes that can be used to bypass critical narrowings.

In the management of airway obstruction, the choice of the specific intervention depends on the location and severity of narrowing. Certain techniques, such as cryotherapy, photodynamic therapy, and endoluminal brachytherapy, simply do not work on malignant tissue rapidly enough to relieve critical stenosis. The short-term effect is, in fact, tissue edema as tumors undergo cell death and necrosis. In such instances, mechanical débridement with or without one of the heat thermal therapies would be more appropriate. In significant cases of central airway narrowing, in which both mainstem bronchi may be partially compromised, attention should first be directed to the less affected side, most often also the healthier lung, so that adequate single lung ventilation can be established. Even though the majority of airway interventions result in improved pulmonary function, the operating team of otolaryngologists, pulmonologists, anesthesiologists, and nursing personnel should always be prepared for and ready to perform interventions for acute and potentially catastrophic complications. These include turning the patient laterally and keeping the functioning lung upward in case of massive hemorrhage; keeping handy equipment for intubation, including double-lumen ET tubes for split lung ventilation, or at least bronchial blockers to tamponade a bleeding lung; and maintaining the capacity to perform rigid endoscopy if the situation is less dire but larger airway access is needed.

Foreign Body Removal

Although foreign body aspiration (FBA) is classically a pediatric problem, with the highest incidence occurring in children younger than 5 years, bronchial foreign body can occur in adults as well, albeit often with less acute symptoms.[22] The classic signs—witnessed acute choking, wheezing, loss of unilateral breath sounds with corresponding volume loss, or hyperinflation due to air-trapping on the radiographs—have a high sensitivity (about 70%) but variable specificity for FBA. Other findings, such as chronic cough, recurrent pneumonias in the same chest region, atelectasis, and even pneumothoraces or pneumomediastinum, are more common in adults, who may or may not recall an episode of possible aspiration.[18]

Rigid bronchoscopy has been the standard procedure for removal of airway foreign bodies and remains so in the pediatric population. Conversely, in adults, a trial of foreign body removal with instruments compatible with a flexible FOB would be reasonable, although there should always be the backup plan for rigid bronchoscopy should the aspirated foreign body prove too stubborn for removal by the smaller flexible bronchoscopy instruments. Flexible bronchoscopy is indicated for patients with cervical spine instability and skull and jaw fractures, and such trauma patients may be particularly at risk for the aspiration of broken teeth or dentures, or a preceding aspiration leading to near asphyxiation and loss of consciousness may even be the cause of the subsequent head and neck trauma from a fall or a vehicular accident. Helpful adjuncts in directing the foreign body centrally include repositioning the patient in a Trendelenburg or decubitus position, movements that would not interfere with flexible FOB but may prove more challenging with a rigid bronchoscope. A number of "nonpulmonary" instruments can be adapted to assist in the retrieval of a foreign body; these include a Fogarty catheter pushed distal to the foreign body, then inflated and slowly pulled back, simulating the retrograde clot removal from a vascular lumen. Snares and baskets, such as the Roth basket developed for gastrointestinal procedures, can also be used to retrieve smooth or rounded items that are difficult to grasp, such as peanuts and marbles that are akin in texture and size to biliary stones. Cryotherapy probes used primarily for tumor and granulation tissue ablation can also be used to retrieve a foreign body that has a layer of aqueous condensation or secretions around it by virtue of the process of cryoadhesion.[23] (Recall the unfortunate child testing this hypothesis on a cold winter's day and getting his tongue stuck to the metal pole.)

Hemorrhage can occur as a result of inflammation and granulation formation induced by the foreign body; this finding is especially true for certain pill fragments and other caustic compounds, oily food such as nuts, and on a more long-term basis, metal pins and other sharp objects. The manipulation of the various instruments can further aggravate this process. Therefore, having the capacity to provide hemostasis with vasoconstrictor compounds and mucosal surface coagulation is desirable. The routine use of corticosteroids to reduce airway edema has not been rigorously studied but is commonly recommended.

Tissue Débridement

The discussion of interventional bronchoscopic approaches in the débridement of malignant or scar tissue causing airway obstruction often becomes a catalog of technology and devices to deliver these tissue-destructive techniques. However, it is fair to say that the underlying common denominator is mechanical resection assisted by

freezing, heating, or biochemical methods of causing cell death. Cold techniques include use of forceps, powered microdebrider, or cryotherapy. Laser, argon plasma coagulation (APC), and electrocautery are three methods of heat-assisted mechanical resection. Finally, photodynamic therapy (PDT) and endobronchial brachytherapy (EBBT) are biochemical destructive methods. Methods for tissue débridement are detailed in Table 75-2.

Balloon Bronchoplasty

In addition to reopening an obstructed airway, there is the task of maintaining airway patency. Furthermore, endobronchial débridement is not useful when the obstruction is extrinsic in nature. Dilation of a narrowed airway segment by mechanical means may be helpful in reestablishing airway patency, albeit temporarily, until more definitive solutions can be instituted. Through a rigid bronchoscope or a suspended laryngoscope, metal mechanical dilators can be gently corkscrewed through a length of tracheal stenosis from fibrotic tissue or tumor. However, areas beyond the proximal right or left mainstem bronchi are seldom accessible. For more distal portions of the right and left mainstem, and for narrowed lobar and segmental bronchioles, balloon bronchoplasty with fluid-expandable catheter balloons offer another option for mechanical dilation. These balloons were originally designed for endoscopic dilation of the biliary tract and the upper (esophageal and pyloric) or lower (colonic) gastrointestinal tracts. Their diameters at full deployment range from 6 mm (biliary) to 18 mm. The lengths of the balloons are fixed, ranging from 2 cm (biliary) to 8 cm (esophageal and colonic). Dedicated bronchoscopic balloons with a length of 3 cm mounted on shorter catheters have also been introduced. These controlled radial expansion (CRE Pulmonary Balloon Dilator, Boston Scientific) balloons have the additional benefit of being expandable to three sequential diameters, depending on the amount of fluid pressure applied, which can be monitored on a manometer supplied with the balloon kit. The fluid can be sterile water or saline or diluted contrast material, which will render the expanded balloon more visible under fluoroscopy.

Endobronchial Stent Placement

Placement of airway stents may be the definitive treatment or may maintain airway patency long enough for adjunctive treatment to control the underlying disease in a number of obstructive conditions. A large number of endobronchial stents have been developed or adapted for airway use over the past 20 years.[9,18,20,24] A detailed discussion of all of the individual types and their variants goes beyond the scope of this chapter. The stents can be grouped into metallic and silicone types. Most but not all of the metallic stents are self-expanding, whereas most of the silicone stents are fairly rigid and require rigid bronchoscopy or direct suspension laryngoscopy for placement.

The earliest airway stent was the Montgomery T-tube, a stiff acrylic polymer tube later replaced by silicone, but its placement required a tracheostomy. A number of silicone stents, some reinforced with metallic struts embedded circumferentially or three-quarters around to simulate the tracheal cartilage (e.g., Orlowski and Freitag Dynamic Stents, Rüschag, Germany), are available in various lengths and diameters, and there are optional limbs to fit the carina and proximal mainstem. With the exception of a single self-expanding polyester reinforced thinned-walled silicone stent (i.e., Polyflex, Rusch), these stents require rigid instrumentation for placement. Because of the intrinsic thickness of the stent material and the method of insertion, they are useful primarily for placement within the trachea and first- to second-generation airways only.

The earliest metallic stents used in the airways were Gianturco-Z stents adapted from their intended endovascular application. This type of noncovered stent has to be ballooned open, has no protection against ingrowth of tumor, and is associated with an unacceptably high rate of induction of severe granulation and airway or vascular perforation. Therefore, it has no role today in endobronchial stenting, given the number of dedicated endobronchial stents now available. The current generation of metallic stent is self-expandable, comes packaged in a much slimmer profile, can be delivered over a guidewire into the distal mainstem and lobar segments, and hence can be deployed without the need for rigid instrumentation. These self-expandable metal stents are made from stainless steel (e.g., Wallstent, Boston Scientific) or the nickel-titanium blend of nitinol (e.g., Ultraflex, Boston Scientific and Alveolus TB-STS, Alveolus, Inc. Charlotte, NC). They are available in a variety of lengths and diameters, with or without an outer polypropylene covering that helps prevent tumor ingrowth. There can still be the problem of tumor or granulation overgrowing the ends of the stents, and proper sizing is important to prevent excessive movement or excessive tension against the airway wall, either of which may promote the proliferation of granulation tissue. Once deployed, the stainless steel Wallstent with its sharp opened prongs is generally fixed in place, whereas the more pliable nitinol stents are maneuverable at least until granulation or tumor overgrows the open ends.

Complications of stent placement include trauma to a compromised airway during stent insertion, such as inadvertent tears to the tracheobronchial mucosa already compromised by tumor invasion. An improperly sized covered stent can occlude functioning airway segments because it is too large or too long; if it is too small, it can subsequently migrate. All stents, covered or otherwise, interfere with normal mucociliary clearance and, as foreign bodies, will promote biofilm formation. Stents can therefore become quickly overgrown with a variety of microorganisms. The problems of granulation and tumor ingrowth have been mentioned. The metallic stents can suffer metal fatigue and undergo fracture and, with the single strand weave of nitinol, can unravel.[25] This problem is especially prominent with tracheal stents in which the constant change in curvature of the posterior tracheal membrane with breathing in and out results in metal fatigue. We have therefore avoided placing self-expandable metal stents in the trachea if we anticipate long-term need for the stent in benign conditions such as tracheobronchomalacia or if the patient with a malignant condition has an anticipated survival beyond several months.

Esophageal-tracheal and esophageal-bronchial fistulas deserve special mention. The majority of such cases result from malignancies originating from the esophagus and, less commonly, from the bronchus. Fistula formation and poor healing may also be due to radiotherapy. Less commonly, such fistulas are congenital or are caused by acute trauma or chronic erosion from a tracheostomy tube. The most common presenting symptoms are coughing with feeding and other signs of aspiration. Swallow studies using a contrast agent (e.g., Gastrografin) and, occasionally, three-dimensional CT reconstructions may localize the fistula, but failure to demonstrate the defect should be followed by direct visual examination. Having a conscious patient swallow 15 to 30 mL of methylene blue or other dye immediately before the induction of anesthesia may be helpful in pinpointing the site of a small but clinically significant fistula. In the absence of an adequate tracheal replacement and the rarity of being able to resect the length of involved trachea for primary anastomoses, stenting to cover the fistula can provide palliation of symptoms, including aspiration of oral secretions and recurring lower respiratory tract infections, and can allow the patient to swallow for oral gratification in the terminal phase of a malignancy. Close collaboration with an interventional gastroenterologist is necessary for this application.

Innovations and Future Developments

Autofluorescence Bronchoscopy

Autofluorescence bronchoscopy is used to detect early, preinvasive lung cancers and can also help thoracic surgeons in planning lung cancer resection. Since the early 1990s, trials have been ongoing to test and improve systems to detect alteration of tissue autofluorescence in dysplastic and cancerous bronchial tissues. Reduction of tissue autofluorescence in precancerous and cancerous tissue results in a change in the green autofluorescent hue of normal bronchial mucosa toward red-brown to blue-black tints. U.S. trials of several systems, including the LIFE (Laser Imaging Fluorescence Endoscope, Xillix Technologies, Richmond, BC, Canada) and D-Light (Karl Storz Endoscopy-America, Inc., Culver City, CA), validate a higher yield in the detection and localization of severely dysplastic and carcinoma in situ lesions in comparison with conventional white-light broncoscopy.[26-28]

Table 75-2

Interventional Bronchoscopic Methods for Tissue Débridement

	Technical Details	Advantages	Disadvantages
Cold Techniques			
Cold steel débridement	Tip of rigid bronchoscope may be used to core out tumor Forceps may assist with débridement	Readily available equipment Rigid bronchoscope may assist with tamponade	Ineffective for dense scar Length of rigid bronchoscope scope may limit access Hemorrhage may obscure visualization
Powered microsurgical debrider	Longer custom-made blades (37 cm) and curved tips (Xomed Corp) assist with subglottic and tracheal access Microsurgical debrider directed by rigid telescopes	Rapid technique Allows for good visualization	Can be bulky to manipulate Aggressive débridement may endanger walls of airway
Cryotherapy	Allows sudden expansion of compressed gases (nitrous oxide) or liquid nitrogen to cool the metal cryoprobe tip in order to promote cell death, cryothrombosis of vessels, and tissue necrosis (Joule-Thomson effect)	Units are inexpensive and easy to use Little risk of airway or vascular wall perforation Normal nonvascular tissue is cryoresistant and heals almost completely	Slower-growing tumors (carcinoids) may be cryoresistant because of rapid warming effect Not helpful for high-grade central airway obstruction because of need for follow-up débridement
Thermal Ablation			
Laser	Neodymium:yttrium-aluminum-garnet and potassium-titanyl-phosphate most commonly used Pulses should be delivered in a noncontinuous mode starting from a lower power setting	Easy to maintain Ability to achieve powerful débridement without contact	Expensive Risk of airway fire Risk of vascular perforation
Argon plasma coagulation	Achieved by ignition of a charged argon gas plasma generated by a high-voltage, high-frequency electrode Ionized plasma seeks out conductive tissue and can therefore be sprayed onto a surface tangential to the aiming beam	Good for cleaning prostheses, stents overgrown by granulation, tumors, recurrent respiratory papillomatosis, scars Less fire risk	Shallow depth of tissue penetration Lesser capacity to quickly débride bulky tumor Risk of airway fire Risk of vascular perforation Risk of air embolism Risk of electrocution if patient and argon plasma coagulation generator are not grounded properly
Electrocautery	Direct-contact thermal tissue destruction Monopolar and bipolar instruments available	Fast Powerful high-voltage current	Risk of airway fire Risk of vascular perforation Risk of retrograde conduction of current
Photodynamic therapy	Photochemical reactions generate cytotoxic oxygen radicals using hematoporphyrin-derived photosensitizers and photon light source 48-hour interval between drug infusion and light activation	May provide therapy for invasive carcinoma and preinvasive carcinoma in situ Relatively longer duration of response in maintaining airway patency	Delayed response Not good for relief of acute/severe obstruction Systemic photosensitivity for 30-60 days Potential allergy Expensive Enhanced toxicity with chemotherapy or radiotherapy
Endobronchial brachytherapy	Directs high-intensity radiation (iridium-192) originating from a source within the tracheobronchial tree Radiation source passed through temporary bronchoscopic hollow catheters (remote afterloading)	Ability to treat advanced endobronchial cancers in patients who have received the maximal dose of external beam radiation therapy or as a boost to planned external beam radiation therapy in patients with significant endobronchial compromise May be curative for carcinoma in situ or small-volume visible invasive carcinoma May have use in benign stenosis or granulation	Delayed response Radiation exposure Risk of radiation bronchitis Risk of fatal hemoptysis (reported between 2% and 25%)

Endobronchial Ultrasonography

Endoscopic application of ultrasonography for characterization and localization of extraluminal structures such as lymph nodes, masses, and blood vessels has been mostly developed in the gastrointestinal field. The adaptation of a balloon-tipped ultrasound probe for use within the airway lumen allows for a more precise localization of regional lymph nodes for tumor staging and for diagnosis of lymphoma and other lymphoproliferative disorders. Ultrasound probes introduced through the working channel of the bronchoscope and directed peripherally have also been used to characterize pulmonary consolidation and may distinguish malignant from nonmalignant causes.[15,16,18] Higher-frequency high-resolution EBUS can also provide additional information about extrabronchial invasion of the serosal surface or submucosal infiltration by cancer, again with prognostic and therapeutic impact. Currently, sampling with EBUS-directed TBNA requires imaging followed by the removal of the probe and substitution of a sampling needle into the working channel. The next adaptation of ultrasound technology into the airways will be the introduction of a dedicated EBUS bronchoscope with a side-directed radial probe and aspiration port that will allow real-time aspiration.

Endoscopic/Bronchoscopic Lung Volume Reduction

The National Emphysema Treatment Trial established the benefit of surgical lung volume reduction surgery as an alternative to lung transplantation in selected patients with COPD.[29] Parallel studies have been undertaken to examine the possibility of affecting lung volume reduction through selective blockage of segmental bronchi leading to regional atelectasis. A number of such endoscopic/bronchoscopic lung volume reduction studies using biologic or synthetic adhesives, such as fibrin glue and removable valves, are currently ongoing. These procedures hold the promise of either being effective and less invasive methods of lung volume reduction surgery or of offering a less invasive and reversible trial of lung volume reduction before patients are subjected to the rigors of thoracic surgery.[30,31]

Summary

Tracheobronchial endoscopy is an integral part of the multimodality examination of aerodigestive tract diseases. The widespread availability of flexible FOBs facilitates an extended examination of the lower respiratory tract with minimal conscious sedation of the patient. The introduction of high-resolution and easily maneuverable videobronchoscopes coupled with innovative imaging technologies is advancing the ability of bronchoscopists to identify early airway dysplasia, locate extrabronchial targets such as lymph nodes and mediastinal masses for biopsy, and characterize the depth and lateral spread of malignancies with greater accuracy. Diagnostic bronchoscopy is also improved by the availability of an expanding array of instruments that can be deployed through both rigid and flexible bronchoscopes to sample visible central endobronchial lesions or, transbronchially, to sample peripheral lesions. Furthermore, evolving technology in tissue débridement and destruction is aiding the palliation and treatment of airway disease.

General Considerations

CHAPTER SEVENTY-SIX

Biology of Head and Neck Cancer

Steven Chang

Patrick Ha

Key Points

- Head and neck squamous cell cancer results from the accumulation of DNA damage in an entire mucosal field. A molecular progression model has been determined for the evolution of a lesion from mild dysplasia to malignancy.
- The hallmarks of cancer, increased cell proliferation and decreased cell death, are mediated through the inactivation of tumor suppressor genes, the activation of oncogenes, or both. The ways in which these genes are turned on or off may vary, but ultimately all can fit into this scheme.
- The combination of high-throughput molecular biologic techniques and bioinformatics is revolutionizing the way research is being done. It is also accelerating the pace and efficiency with which discoveries are made.
- The molecular biology of head and neck squamous cell cancer is complex and develops from the dysfunction of several interrelated pathways. No single mechanism, pathway, or molecule is responsible for carcinogenesis.
- Molecular biomarkers and targeted therapy are a reality for the treatment of head and neck squamous cell cancer. However, in order for any discovery to affect clinical care, well-run clinical trials must be performed.

There has been an explosion not only of knowledge regarding the molecular biology of head and neck squamous cell carcinoma (HNSCC) but also in the techniques available to study it. With each new discovery, the increasing complexity of cancer has been progressively revealed. Fields of study originally thought to be separate have merged, weaving a complex web of interrelated pathways. The purpose of this chapter is to attempt to break these interrelated pathways into discrete sections for discussion. However, it should not be forgotten that none of these pathways is the sole source of cancer development but simply one piece of the entire puzzle. Part of this complexity is the result of the integration of various high-throughput approaches to studying cancer and the subsequent complex bioinformatics analysis needed to interpret the results. The information technology age has finally pervaded and bolstered the molecular biology field and will continue to be intimately tied to the future of this research. Therefore, the aim of this chapter is both to provide a review of our current understanding of HNSCC and to preview advances in the field. Finally, advances in molecular detection and surveillance of HNSCC are discussed, in addition to the molecular basis for novel, targeted therapies based on molecular alterations in HNSCC.

Background

There are more than 40,000 new cases of head and neck cancer every year in the United States, and 500,000 worldwide, predominantly consisting of squamous cell carcinoma of the upper aerodigestive tract.[1] Despite aggressive multidisciplinary treatment approaches, including preoperative or postoperative chemotherapy, radiotherapy, or both, with reconstructive surgery, there has been only modest improvement in outcomes over the past 20 years. Treatment failures still occur in the form of locoregional recurrence, distant metastases, and second primary tumors. Further insight into the molecular basis of head and neck cancer in general could lead to advances in screening, diagnosis, and treatment with improved clinical outcome.

The mechanisms underlying carcinogenesis in the head and neck are similar to those mechanisms and principles found in other solid tumors. It is generally accepted that cancer arises from the progressive accumulation of genetic alterations that lead to a selection of a clonal population of transformed cells.[2] In an attempt to classify and understand the biology of sporadic and hereditary retinoblastoma, Knudson[3] first put forth his model of the "two-hit" hypothesis in 1971. He described a model in which two copies of the parentally inherited Rb gene were inactivated either by mutation or by loss of chromosomal material, leading to development of hereditary or sporadic retinoblastoma. A model of tumor progression was synthesized by Fearon and Vogelstein[2] into the following three basic tenets:

1. Cancer arises as the result of inactivation of tumor suppressor genes (TSGs) or activation of proto-oncogenes.

2. There is a defined order of genetic events that leads to development of a malignant phenotype.

3. Variations in the order of events can occur, however, and it is ultimately the net accumulation of genetic events that determines the phenotypic expression of malignancy.

In 1993, Renan[4] put forth a statistical model suggesting that between 6 and 10 independent genetic alterations need to accumulate before the development of HNSCC. Although the precise number of events required for HNSCC carcinogenesis is unlikely to be defined, the conclusion from this analysis is that HNSCC requires more genetic alterations in its development when compared to other solid tumors. This series of genetic changes that must occur for frank malignancy to arise is a result of the 20- to 25-year latency period seen in head and neck cancer. During this time, a cumulative exposure to carcinogens—particularly tobacco and alcohol—is believed to be the predominant

cause of specific genetic alterations acquired during HNSCC progression.

Through the examination of premalignant and invasive lesions, many of these initial genetic alterations have been well described in head and neck cancer, and a genetic progression model has been created to detail the evolution of genetic alterations.[5] Using microsatellite analysis, Califano and associates[5] were able to correlate allelic imbalance due to chromosomal loss and gain with varying grades of dysplasia in premalignant lesions. The histologic progression of hyperplasia, dysplasia (mild, moderate, and severe), carcinoma in situ, and, finally, invasive carcinoma provided the structure in which genetic alterations were framed. A genetic progression model was created to examine lesions in each of these categories for similar patterns of allelic imbalance.[5] Even in the earliest of lesions, there were clonal, genetic changes; 30% of benign hyperplastic lesions had loss at 9p21 or 3p, indicating that these losses and the corresponding inactivation of p16 and p14/aRF and putative 3p TSGs are among the first genetic alterations to occur in the progression to cancer. In addition, a transcriptional progression model has been described.[6] These genetic and transcriptional alterations have been correlated with the histopathologic stages of premalignant and malignant mucosal lesions to define the order and time course of molecular alterations in the development of HNSCC.

Later, however, it was found that not just the tumor but the entire field of mucosa undergoes these changes. Slaughter and colleagues[7] first coined the term *field cancerization* in a histologic study examining the epithelium surrounding invasive cancers. They recognized there were histopathologic changes in the epithelia surrounding invasive oral tumors and reported an increased incidence of second primary tumors, usually close to the initial tumor. Other investigators subsequently confirmed a higher incidence of second primary tumors in the upper aerodigestive tract in those patients with initial head and neck primary tumors.[8-10]

Thus, field cancerization originally was a clinical concept describing a mucosal surface in the region near an invasive tumor with premalignant changes and the propensity for second primary tumor development in adjacent mucosa. With the advent of contemporary molecular genetic understanding of malignancy, two theories provide possible explanations for this finding; they are (1) the areas of abnormality represent independent clones, with a unique pattern of genetic alterations, and (2) these areas of abnormality are genetically related and originate from a common cellular clone. Although these theories are not exclusive, it was shown that there was indeed lateral spread of progenitor clones throughout squamous mucosal surfaces rather than independent clones. Further studies looking at second primary head and neck tumors found that these second lesions tended to originate from a common clone.[11] Another study examining serial biopsy specimens of head and neck premalignant lesions that ultimately progressed to invasive cancer showed a pattern of accumulated microsatellite loss, with the cancer demonstrating losses identical to those found in the previous premalignant lesions.[5,12] Therefore, the theories of field cancerization and the genetic progression model for cancer work hand in hand to describe how the molecular and histopathologic changes occur and lead to malignancy.

The breadth of possible genetic alterations previously discussed as leading to a phenotypic expression of malignancy has grown, although the end targets of genetic alterations almost always involve inactivation of TSGs, activation of proto-oncogenes, or both. TSGs are those genes that are normally present in cells and whose function is to regulate and repress cellular functions that, when left unchecked, would lead to expression of a cancer phenotype. *Proto-oncogenes* are those genes that, when altered either by aberrant, constitutive activation or DNA copy number amplification, result in inappropriate overexpression or increased activity that results in expression of a malignant phenotype. Alterations of both TSGs and proto-oncogenes can be caused by several mechanisms, including endogenous mutation, environmental carcinogens, and the result of the disruption of normal cellular functions by viral, chemical, or other factors. These alterations in the DNA may lead to changes in sequence or quantity of messenger ribonucleic acid (mRNA) intermediates, with subsequent translation into aberrant protein products or an altered level of normal proteins. (This model has been modified with the discovery of noncoding RNAs that regulate translation of mRNA, a topic discussed in another section.) Ultimately, these genetic alterations lead to a malignant phenotype that can include altered cell proliferation, invasion, metastasis, altered immunogenicity, resistance to therapy, and genetic instability, as well as other phenotypic characteristics common to malignancy.

With these principles of malignancy in mind, we proceed to discuss many specific molecular changes that occur in HNSCC and the clinical implications of these advances in knowledge. Although the topics have been separated for the purposes of this chapter, it is important to keep in mind that they are all intimately related.

Environmental Exposures and Risk Factors

The primary risk factors for the development of HNSCC are two environmental toxins, tobacco and alcohol (tobacco exposure being a much higher risk). These two factors combine synergistically to increase the risk of HNSCC. In addition to studying the mechanisms by which these toxins can alter cellular proliferation and death, investigations into the endogenous enzymatic systems dedicated to metabolize these toxins into inert molecules have been performed and are discussed. A third risk factor, which acts independently of the other two, is a history of an oral human papillomavirus (HPV) infection,[13] which is addressed in more detail later in the chapter. D'Souza and coworkers[13] discovered that oral HPV infection increased the risk for oropharyngeal cancer. Oropharyngeal HPV infections were detected by multiplex polymerase-chain-reaction analysis of saline rinses after cytology brushings of patient posterior oropharyngeal walls, as well as ELISA analysis of patient serum with antibodies specific for HPV viral oncoproteins and viral capsid proteins.[13]

Processed tobacco contains at least 30 known carcinogens. Tobacco smoke contains a high concentration of reactive oxygen species and more than 50 known carcinogens and procarcinogens.[14,15] In addition to the direct physical trauma to the upper aerodigestive tract from smoking and drinking, several enzymatic systems are in place to metabolize and deactivate these compounds. It has been proposed that the genetic polymorphisms of these systems to detoxify carcinogens can potentiate putative carcinogens and lead to the development of cancer by either failing to deactivate carcinogens or activating pro-carcinogens.

Cytochrome P-450

The cytochrome P-450 system of enzymes, which is responsible for the oxidative metabolism of most chemicals encountered, consists of more than 20 subfamilies and 60 separate P-450 genes. These enzymes, which are found primarily in the liver tissue, are also found in the aerodigestive tract tissue.[16] Of these, the most studied is CYP1A1, which is present in oral tissue.[17] Several studies into two specific mutations of this enzyme have revealed only a mild risk association between CYP1A1 exon 7 polymorphism and the development of HNSCC.[18] Of particular note, statistical significance was noted only in studies of Asians, whereas results of studies in whites were equivocal. Other systems that have been studied but for which there are insufficient data or inconclusive evidence are CYP1B1, CYP2D6, and CYP2E1.

Glutathione S-Transferase

One of the family of enzymes responsible for the detoxification and processing of such harmful chemicals is known as glutathione S-transferase (GST). There are five separate loci for the production of different GST subtypes that are responsible for detoxifying many different compounds. There also exist several polymorphisms within these subtypes, which may delineate those people more at risk for the development of cancer in the presence of tobacco smoke exposure. In a large meta-analysis, Geisler and Olshan[15] reported inconsistent results among 24 studies looking at the role of GSTM1 and GSTT1. They concluded that there are likely subtle effects of polymorphisms on detoxifying enzyme function and the complexity of detoxification processes in general, and that large population-based studies must be performed before the effects of tobacco smoke in subjects with these alterations can be correctly ascertained. In 2003, Hashibe and associates[19] performed a pooled analysis and a meta-analysis of studies looking at GSTM1, GSTT1, GSTP1, and CYP1A1. They concluded that in the

33 studies reviewed, there is a modest association of GSTM1 and GSTT1 genotypes with head and neck cancer risk. They further concluded that their pooled analysis "supports the notion of greater risk when multiple GST loci are considered."[19]

Other Enzymatic Systems

Variations in other detoxifying enzymes, such as uridine diphosphate–glucuronosyl transferase (UDPGT) have been implicated in an increased risk of head and neck cancer as well.[20] A low-activity UDPGT genotype was associated with 3.7-fold greater odds of development of laryngeal cancer in smokers; the odds ratio increased to 6.1 in heavy smokers and was not increased in those who never smoked. Another interesting study, by Elahi and colleagues,[21] found that human 8-oxoguanine-DNA glycosylase (hOGG1) polymorphism is an important risk factor for the development of orolaryngeal cancer in smokers and alcohol drinkers. The hOGG1 gene encodes a DNA glycosylase that is involved in the excision repair of 8-hydroxy-2′-deoxyguanine (8-OH-dG) from oxidatively damaged DNA. These researchers found that nonsmoking, nondrinking patients with mutant hOGG1 were not at greater risk of orolaryngeal squamous cell cancer. However, smokers and drinkers with this mutation had 4.8 and 6.9 greater odds of development of orolaryngeal cancer, respectively.[21] These two studies suggest that these enzymes are involved in tobacco smoke detoxification and that the genotype can predict the phenotype.

Much study has also been devoted to examining *N*-acetyltransferases, reduced nicotinamide adenine dinucleotide:quinone oxidoreductase 1, aldehyde dehydrogenases, and alcohol dehydrogenases. Some data implicate these substances in the development of cancer. However, larger studies are required to clearly and definitively determine whether they contribute to the development of cancer.[18]

In summary, the molecular mechanisms behind tobacco smoke detoxification are beginning to be elucidated, but further work must be performed to enable accurate prediction as to which people are more susceptible to the development of cancer when subjected to this environmental exposure. Gronau and colleagues[22] have shown that detoxification enzymes are functionally redundant and that only the simultaneous deficiency of several detoxification enzymes increases the risk for oral cancer. Furthermore, a follow-up study by the same group showed that it is probable that the enzymatic activity rather than the actual genotype can influence the risk of cancer.[23] Complicating the issue even more is the influence of ethnicity on the prevalence of polymorphisms; a study in the Netherlands found that two groups of people less than 125 km apart showed statistically significant differences in the prevalence of the GSTT1 genotype.[24]

Other studies have evaluated the enzymes as prognostic markers. Although these detoxifying enzymes play a role in clearing carcinogens, they may also inactivate chemotherapeutic agents delivered in an attempt to kill offending tumor cells. One study examining a different subtype of GST, GST p, found that those patients with high levels of this enzyme had a worsened overall survival when treated with neoadjuvant chemotherapy, likely owing to the clearance of the drug by the GST p.[25] Another study examining GSTT1, a known activator of carcinogens,[26] found that individuals with the functional genotype were two times more likely to die from any cause during the course of HNSCC and three times more likely to die from disease-specific causes after adjustment of data for age, stage, and primary therapy.[27]

Lastly, there has now begun to be some study into the role of saliva and its antioxidative abilities. One group found that the saliva of nonsmoking patients with oral squamous cell carcinoma had highly oxidized DNA and protein, increased levels of reactive nitrogen species, and profoundly reduced levels of antioxidants.[28] Other studies have also examined antioxidant levels after tobacco smoke exposure and shown statistically significant decreases in antioxidants, but as yet no definitive link to the development of HNSCC has been demonstrated.[29]

Human Papillomavirus in Head and Neck Squamous Cell Cancer

Oral HPV infection, like alcohol and tobacco, is now recognized to play an important role in the pathogenesis of a subset of oropharyngeal HNSCCs.[30-36] These lesions are primarily from the lingual and palatine tonsils in the oropharynx and, to a lesser extent, the oral cavity.[31,34,37-42] Furthermore, HPV-related HNSCC has distinguished itself as a separate entity with better prognosis and response to therapy than those of non–HPV-related HNSCC, which is discussed later. It has also been proposed that oral HPV infection is the reason for the rising incidence of oropharyngeal HNSCC relative to all other anatomic sites in the head and neck. We first review in brief what is known about the molecular biology of HPV and how it relates to cancer.

The human papillomavirus is an approximately 7.9-kilobase, nonenveloped, double-stranded, circular DNA virus. It has a specific tropism for squamous epithelium. The virus infects cells in the basal layer of squamous epithelium, and the different types have been traditionally separated on the basis of tropism for cutaneous and mucosal sites as well as of high, intermediate, and low risk, depending on their association with malignancy.[43] The sequences for more than 320 different types of HPV have been identified. Low-risk types, such as HPV-6 and HPV-11, can induce benign hyperproliferations of epithelium such as papillomas and warts. The high-risk types have been implicated in cervical cancer, anogenital cancer, and HNSCC. HPV-16 and HPV-18 are the two types most pertinent to HNSCC and are the focus of this discussion.

The HPV genome typically consists of nine open-reading frame sequences, located on only one of the strands of DNA, and is divided into seven early-phase genes (E) and two late-phase genes (L). The early genes serve to regulate the transcription of DNA, and the late genes encode for proteins involved in viral spread, such as capsid proteins.[44] The E1 and E2 gene products are specifically involved in regulating the transcription and replication of viral proteins. The E6 and E7 oncoproteins are normally under control of E2 and E1 inhibitory genes; these inhibitory genes can be deleted or altered upon integration, leading to unchecked transcription of E6 and E7,[45] which are then able to disrupt the function of Rb and p53, well-known tumor suppressor genes.[46] p53 and Rb are tumor suppressor genes in that they regulate cell-cycle checkpoints at the G1 phase. If these genes are inactivated, cells are more prone to push through division and replication, even in the setting of harmful gene mutations, which can lead to malignancy.

The E6 gene is able to inactivate p53[47] through interaction with the E6-associated protein. This complex then binds with p53 and facilitates ubiquitin-dependent degradation of p53.[48] E7 is able to bind and interact with the Rb gene product.[49] E7 has the ability to phosphorylate the Rb proteins, leading to degradation by ubiquitination.[50] This process subsequently leads to E2F activation, which produces a family of transcription factors resulting in cell proliferation. Many other possible mechanisms have been discovered by which these proteins can induce malignancy so that their role in carcinogenesis is ensured.[51] It has also been shown that p53 sequence alterations are decreased in the setting of HPV infection, because there is an alternative means of p53 silencing with the production of E6, further delineating HPV-related cancers.[31,46,52,53]

The idea that HPV causes HNSCC was first proposed when the cytopathic effects of HPV (koilocytosis) were noted on light microscopy of oral lesions.[54] In situ hybridization later confirmed the presence of HPV DNA in oral pre-malignancies (4/5 leukoplakias) and malignancies (3/6 carcinomas), thereby suggesting a causal association of HPV and carcinogenesis in oral lesions as well.[55] It is now established that histopathologically, HPV-positive tumors tend to have a poorly differentiated and frequently basaloid histology that often lacks keratin.[30,31,36,56] Since then, researchers also discovered that human keratinocytes expressing E6 and E7 genes from HPV-16 become immortal,[57] as do oral epithelial cells.[58-60] It should be noted that the virus must integrate into genomic DNA to have its oncogenic effect.[61,62]

Further study finally confirmed the link between HPV and oropharyngeal HNSCC. In a 2005 meta-analysis, HPV genomic DNA was detected in approximately 26% of all HNSCCs by sensitive polymerase chain reaction–based methods.[63] However, in the majority of studies, 50% or more of oropharyngeal tumors contained the HPV genome.[62] In a multinational study conducted by the International Agency for Research on Cancer (IARC), only 18% of oropharyngeal tumors were HPV positive, indicating that this proportion likely varies by geography.[64] Regardless of the study population, high-risk HPV-16

accounts for the overwhelming majority (90%-95%) of HPV-positive tumors.[63] In addition to the ability to reliably detect HPV in a subset of oropharyngeal cancers, detection of HPV in cervical lymph nodes of patients presenting with an occult primary may be used to establish, with high specificity, the location of the primary within the oropharynx.[65] Tonsillectomy has been shown in retrospective analyses to identify the primary site of cervical metastases as the contralateral or ipsilateral tonsil in approximately 10% or 30% of cases, respectively.[66-69] Therefore, HPV-related cancer is a distinct established entity that can be reliably diagnosed.

The patient population that presents with HPV-positive HNSCC is also distinct. On average, patients with HPV-positive HNSCC are approximately 5 years younger than patients with HPV-negative HNSCC, with equal distribution between the sexes.[41,70-73] HPV-positive HNSCC is more likely than HPV-negative HNSCC to occur in the nonsmoker and nondrinker.[31,32,39,40] In a study restricted to patients with oropharyngeal cancers, nonsmokers were approximately 15-fold more likely than smokers to have a diagnosis of HPV-positive HNSCC.[74] However, whether there is a synergistic, additive, or no relationship between smoking or alcohol use and HPV infection remains to be seen, and research has supported all three possibilities.

Risk factors for HPV-related HNSCC include a high lifetime number of vaginal-sex partners (26 or more), a high lifetime number of oral-sex partners (6 or more),[13] and seropositivity for HPV-16 viral capsid protein antibodies,[33] which carries a 15-fold higher risk for HNSCC.

In the majority of studies, patients with HPV-positive tumors have a better prognosis—as much as 60% to 80% lower risk of dying from the cancer—than patients with HPV-negative tumors, after data are controlled for other risk factors.[31,71,74-77] The reason for their improved survival is unclear; however, better radiation responsiveness, immune surveillance against viral antigens, and the absence of field cancerization in these patients, who tend to be nonsmokers, have been postulated as possibilities. In addition, E6-related degradation of p53 in HPV-positive cancers may not be functionally equivalent to HPV-negative p53 mutations, and therefore, HPV-positive tumors may have an intact apoptotic response to radiation and chemotherapy.

Therapeutic implications of an HPV-positive diagnosis are an active area of investigation. The belief that HPV-positive HNSCC is more responsive to treatment than HPV-negative HNSCC is being considered in the design of future clinical trials. A clinical trial of an HPV-16–specific therapeutic vaccine is also currently being evaluated. The vaccine is administered in the adjuvant setting and is intended to enhance the cytotoxic T-cell response to the HPV-16 oncoproteins.[78] With regard to prevention, a prophylactic vaccine composed of the HPV-16 viral capsid protein has been shown to prevent persistent HPV-16 infection and the development of cervical dysplasia.[79,80] However, the clinical trials have not included an evaluation of the impact of the vaccine on oral HPV infection. The vaccine does have the potential to affect HNSCC incidence, because the current vaccines are targeted to HPV-16 and because animal models demonstrate the vaccine to have a protective effect and a reduction in the development of HPV-related oral lesions.

Possible future diagnostic tests that would likely have high specificity but low sensitivity for a diagnosis of HPV-associated HNSCC include the detection of HPV-16 DNA in plasma,[81] which can be used for surveillance. Other screening tests, such as fluorescence in situ hybridization (FISH) on Papanicolaou smears obtained directly from tumors and HPV-16 E6 and E7 seroreactivity, are currently being tested. And the impact of a positive test result on a patient's risk for the development of cancer is still unclear.

Chemoprevention

As discussed previously, there are well-defined risk factors for the development of HNSCC. In addition to avoiding exposures, there is the possibility of both preventing the development of HNSCC and preventing progression of early disease. Currently, most of the therapy for head and neck cancer is focused on treating the disease after it has already progressed to malignancy. However, because head and neck cancer often manifests initially as premalignant disease and because there is a defined set of high-risk individuals, many researchers have begun the search for agents that can prevent disease from occurring, prevent recurrent disease, or prevent disease progression.[82]

The concept of chemoprevention was first proposed by Sporn and colleagues,[83] who looked at the protective effects of vitamin A and its derivatives on carcinogenesis. The mechanism of action was thought to be via binding of retinoic acid receptor molecules,[84,85] which then function as angiogenic and growth-regulating factors.[86,87] In a landmark study, the utilization of high-dose 13-*cis* retinoic acid in patients with known head and neck cancers proved helpful in preventing the development of second primary tumors[88] and in the treatment of oral leukoplakias,[89] although significant toxicity was associated with this therapy, including skin lesions, conjunctivitis, and cheilitis. Furthermore, when therapy was discontinued, the risk of disease development returned to baseline after about 2 years.[90] A follow-up study looked at use of low-dose fenretinide (a synthetic retinoid) for leukoplakia, and early results were promising for prevention of malignant transformation.[91] Unfortunately, the trial was ended because of low recruitment. In a large trial, 1384 patients were treated with isotretinoin to prevent second primary HNSCC. Treatment showed no benefit, and only smoking cessation correlated with a decreased risk of recurrence.[92] Another large trial by the Italian Head and Neck Chemoprevention Study Group found that treatment with 13-*cis* retinoic acid for 1 year after resection showed no benefit.[93] However, the question is not completely answered; there has been evidence that in cell lines, the combination of 13-*cis* retinoic acid, interferon-alpha-2a, and alpha-tocopherol can cause cell cycle arrest and apoptosis.[94] Another study showed that a synthetic retinoid, MX3350-1, could induce the extrinsic and intrinsic pathways in head and neck squamous carcinoma cells.[95] Whether this combination or any other combination will be beneficial still remains to be seen.

Cyclooxygenase-1 (COX-1) and COX-2 inhibitors have also been studied as possible mediators of prostaglandins and the inflammation that often accompanies many different tumors. Prostaglandin levels have long been known to be raised in head and neck cancers as well, presumably owing to the up-regulation of COX-1 and COX-2.[96,97] Animal models suggested that aspirin or ibuprofen could inhibit the formation of buccal tumors.[98,99] Colon cancer was among the first tumors studied widely in humans, beginning with epidemiologic evidence that aspirin reduced the risk of colon cancer development.[100] Sulindac was shown prospectively to reduce the number and size of colonic polyps in patients afflicted with this disease.[101] Studies of the use of these agents in colorectal, breast, lung, and esophageal carcinomas followed. The mechanism behind the effect of COX-2 inhibitors appears to be multifactorial.[102,103] The overexpression of COX-2 leads to decreased apoptosis, thereby prolonging the life span of abnormal cells. Furthermore, inflammation may be a risk factor for epithelial carcinogenesis because it is often found in these malignancies. Angiogenesis may also be tied into the COX-2 pathway, because vascular endothelial growth factor (VEGF) expression is elevated by high COX-2 levels.[104] Thus, there are several mechanistic reasons why COX-2 inhibitors would be beneficial in preventing recurrence, development, or progression of head and neck lesions, especially in high-risk patients. There have been some promising results in animal models, but study in humans has only begun.[105] In addition, the use of epidermal growth factor receptor (EGFR) inhibitors as chemopreventive agents, both individually and in combination, is also being studied.[105]

Clinical Implications

The ultimate goal of understanding the molecular biology of HNSCC is to use that knowledge to improve patient outcomes. The keys to improving patient care in HNSCC therefore are (1) better diagnostic tests that allow earlier detection of disease, improved surveillance after treatment, and more accurate margin analysis, (2) more accurate prognostic indicators that allow us to tailor therapy to the individual and better predict a patient's course, and (3) additional therapeutic targets. Molecular biomarkers have the potential to improve in all those areas and are specifically discussed later. This section discusses the molecular changes occurring in cancer that form the basis of the biomarkers currently under study.

Genetic Alterations

In this section we address traditional genetic alterations in HNSCC; epigenetic changes are discussed later. The genetic alterations lead to actual sequence or code disruption by deletion, addition, substitution, or translocation of DNA. These alterations may be the result of an inherited defect or of an acquired defect secondary to environmental exposures. With the advent of many new technologies, this area of research has rapidly changed.

Cytogenetics

Cytogenetics is the study of the structure of chromosomal material. The field of cytogenetics has progressed from gross examination of a karyotype to detailed mapping of chromosomal translocations, breakpoints, and areas of loss or gain. Consistent regions of alteration in primary tumors have been correlated with the presence of important genes involved in carcinogenesis. For instance, an area of loss may contain a tumor suppressor gene, whereas an area of amplification may contain an oncogene. Newer techniques allowing for fine mapping of areas of loss or gain combined with the Human Genome Project have greatly increased our ability to focus on the relevant regions or genes involved in HNSCC.

The most basic form of cytogenetics is karyotype analysis, which entails a visual analysis of cells that have undergone short-term culture and have been arrested in the metaphase state to screen for abnormalities in copy number gain or loss and chromosomal breaks or rearrangements. Data have confirmed frequent loss of material on chromosomes 3p, 8p, 11q, 13p, 14p, and 15p with gains on chromosomes 1q, 3q, 8q, and 15q.[106] The limitation of karyotype analysis lies in its resolution. Each region carries numerous genes that could be lost or gained.

Other techniques with different strengths and weaknesses have been employed to evaluate the tumor genome. Spectral karyotyping (SKY) adds the use of chromophores to karyotype analysis; it provides a unique fluorescent background for each of the chromosomes. SKY makes characterizing complex rearrangements or chromosomal aberrations easier. The technique of SKY has been used on HNSCC, and frequent losses were identified at 3p, 8p, 9p, 11q, 14p, and 15p along with gains at 1q, 3q, 8q, and 15q.[107] Comparative genomic hybridization (CGH) is a technique utilized to detect unbalanced chromosomal gains or losses whereby normal DNA and tumor DNA are labeled and hybridized to normal metaphase chromosomes. The relative fluorescence at the different regions is determined, and regions of loss or gain can be detected. The resolution is accurate to about 20 megabases. FISH uses sequence-specific fluorescent probes that are detected through light microscopy after hybridization. It also allows for the specific detection of areas of loss and gain; however, FISH is limited in its genome-wide application.

The use of a combination of SKY, FISH, and CGH on the same samples has the benefit of balancing out the weaknesses and ensuring the consistency of these techniques. Several investigators have used such an approach in evaluating HNSCC.[108,109] As in other studies, common chromosomal losses were found to occur at 1p, 3p, 4p, 8p, 10p, and 18q with gains at 3q, 5p, 8q, 9q, and 14q, and amplification at 3q13, 3q25-26, 5q22-23, 7q21, 8q24, 11q13-14, 12p13, 14q24, and 20q13.1. There was good correlation between SKY and CGH results, and FISH was generally employed to further delineate the nature of aberrations with its sequence specificity. One study identified PIK3CA, a member of the Akt pathway, as a candidate oncogene on chromosome 3q involved in HNSCC.[109]

Cytogenetic alterations may also predict prognosis. CGH analysis of 82 primary head and neck carcinoma samples demonstrated that amplification of 11q13 correlated with a poor outcome.[110] A similar finding was shown in 12 laryngeal cancer cell lines whereby 11q13 amplification was associated with shorter patient survival.[111] Thus, these alterations can be used as markers for prognosis, because they are associated with genetic changes that can influence the development or aggressiveness of HNSCC.

Although these cytogenetic techniques were used as a screen to implicate certain regions of chromosomal losses as harboring tumor suppressor genes or areas of gain with oncogenes, a bit of a disconnect occurs once these assays have been completed. For example, loss of chromosome 3p is one of the most common aberrations identified by cytogenetic applications, but the identification of the specific gene relevant to HNSCC has been difficult. Fine mapping and loss of heterozygosity (LOH) analysis must be performed to identify the significant region of loss. Functional studies then must be performed to pinpoint the gene(s) with tumor-suppressive properties.

With the advent of microarray technology, the application of cytogenetics has begun to take on a new form. CGH-array now hybridizes the normal DNA and tumor DNA to millions of probe sequences, allowing for a much finer map down to 5 to 1010 kilobases. This technique has been shown to have application in HNSCC[112,113] and has been used to identify a novel region of gain on 8q22 and the LRP12 gene.[114]

Single Nucleotide Polymorphisms

Single nucleotide polymorphisms (SNPs) are DNA sequence variations that occur when one nucleotide in the genome sequence is altered. For a variation to be considered an SNP, it must occur in at least 1% of the population. SNPs are scattered throughout the coding and noncoding regions of the genome and account for about 90% of all human genetic variation. Although most SNPs have no effect on cell function, these variations in the DNA sequence can have several uses. Because SNPs are highly conserved, they can be used for profiling cancers and subsequently as clinical biomarkers. In addition, SNPs have been used to reliably map out the locations of genes of interest. For instance, SNP arrays have been created to scan the entire genome, have been used to provide finer mapping of areas of loss or gain, and have identified a region on 6q that is implicated in some cases of HNSCC.[115]

Microsatellites

Microsatellite repeats are tandem repeats of noncoding sequences scattered throughout the genome. Use of these conserved regions as markers in the human genome enabled areas of loss to be found in cancer. Once a microsatellite was found to be deleted or missing in cancer in comparison with normal tissue, the region was identified as having a possible TSG in its proximity. Finer mapping or sequencing could then be performed to identify the gene of interest. Out of this technique came the HNSCC progression model that was discussed in the chapter's introduction. This study by Califano and colleagues[5] demonstrated that TSG deletions occurred early in the precancerous lesions and that there was an accumulation of alterations with progressive disease in HNSCC.

Oncogenes

The genetic amplifications noted in cytogenetic studies are thought to lead to the overexpression of oncogenes. *Oncogenes* encode for products that are normally produced at some time during the life of a cell but that, when aberrantly overexpressed, lead to a selective growth advantage. Thus, they may include anti-apoptotic factors, angiogenic or growth stimulators, or protein stabilizing agents. For technical reasons, the identification of oncogenes can be more challenging than that of their counterparts, TSGs. Because oncogenes are often normally expressed at lower levels, or may not necessarily incorporate any DNA sequence abnormalities, the molecular techniques to detect abnormal oncogenes are more limited. We have largely depended on the cytogenetic work in order to identify these oncogenes by looking at the chromosomal regions that are amplified and then determining which genes are important for function.

One of the best-studied oncogenes in HNSCC is the epidermal growth factor receptor (EGFR). EGFR is a cell surface receptor that is a member of the ErbB family of proteins that has many downstream signaling consequences. The story of EGFR is promising in that its study has led to its use as a therapeutic target. This receptor is discussed in more detail later in the chapter.

Matrix metalloproteinases (MMPs) are genes encoding for a variety of proteins that are thought to be involved in cell adhesion, proliferation, and migration. MMP-2 was one of the first in the family noted to be related to lymph node metastasis in HNSCC,[116] but several other studies have seen other members of MMP overexpression.[35,117] MMP

expression may also be predictive of advanced disease and tumor metastasis in HNSCC.[35,117-119] Interestingly, MMP expression may be influenced by EGFR up-regulation,[120] so there is likely to be overlap between many of the pathways involved in HNSCC. Furthermore, it appears that there are stromal elements that produce MMPs and thus could play a role in the development of metastatic disease.[121]

One of the p53 family members, ΔNp63-α, is known to be amplified and overexpressed in HNSCC cell lines and to have oncogenic properties.[122] It is also known to be created through the alternative splicing of the p63 protein, which encodes for several other putative oncogenes. One possible mechanism of action of ΔNp63-α is through the accumulation of the transcription factor β-catenin.[123] Later data demonstrate that ΔNp63-α functions through the inhibition of p73, and it is through this inhibition that ΔNp63-α is able to repress apoptosis via bcl-2.[124]

Many other oncogenes have been implicated in HNSCC, including VEGF, PIK3c/Akt, and members of the STAT (signal transducer and activator of transcription) family. The exact contributions of these mechanisms to carcinogenesis are constantly being refined. As the basic pathways are further elucidated, they represent possible targets for intervention. The targeting of pathways has the potential for greater specificity and reduced toxicity of therapeutic agents. Compounds designed to inhibit or counteract oncogene expression continue to emerge and to be incorporated into clinical trials.

Tumor Suppressor Genes

Tumor suppressor genes are the counterparts to oncogenes. In general, these genes have a role in growth suppression activities such as apoptosis, cell cycle regulation, DNA repair, and cell adhesion. Thus, when TSGs are deleted or silenced, the cell develops a selective growth advantage and becomes a cancer.

One of the earliest significant TSGs identified in HNSCC was p53. A transcription factor the gene for which has been mapped to chromosome 17p13, p53 is activated in times of cellular stress such as irradiation, hypoxia, and environmental toxin exposure. Interestingly, early reporters of p53 believed that it was an oncogene, because it was found to be overexpressed in cancers. However, it is now known that the p53 gene is inactivated most often by point mutations, although overexpression of the mutant forms still occurs.[125] Activated p53 serves to send cells into apoptotic pathways or can regulate growth through cell cycle control; thus, it plays a critical role in the maintenance and proliferation of cancer cells. Indeed, p53 is the most commonly mutated TSG among all human cancers,[126] and HNSCC is no exception.[127] Premalignant head and neck lesions have also been shown to harbor p53 mutations, suggesting that this mutation can be an early event.[128] Mutations in p53 have been correlated with poorer survival and poorer response to treatment.[129-133] Thus, p53 serves as an excellent marker for disease and has been the target of many therapeutic interventions.

As described previously, cytogenetic data indicated that deletion of 9p21 is a common event in HNSCC, and the LOH data confirmed that it is a common, early event.[134,135] The CDKN2a locus codes for p16 and p14(ARF), which have been accepted as the relevant genes contributing to HNSCC. The p16 gene plays a role in cell cycle regulation at the G1 state through cyclin-dependent kinases 4 and 6, and the p14(ARF) gene is thought to function in the stabilization of p53 through MDM2, a gene that is a negative regulator of p53. Thus, there are two prominent TSGs at this locus that show mechanistic evidence of their function in regulating cell growth and division. Studies suggest that loss of p16 expression may be associated with poorer prognosis in patients with HNSCC.[136,137] Although p16 was frequently found to be down-regulated in HNSCC, there was a surprisingly low incidence of point mutations or homozygous deletions that would explain its contribution to HNSCC.[138] The tumor-suppressive function of p16 was indeed confirmed, although it became evident that there were other mechanisms involved in its silencing (discussed later).

The deleted in colorectal cancer (DCC) gene is located on chromosome 18q21, a region that was shown to have LOH in dysplastic head and neck lesions,[139] in oral cancer cell lines,[140] and in a significant percentage of primary HNSCC.[141] Furthermore, loss of this region was shown to be more common in the metastatic and locally recurrent lesions, suggesting that it played a significant role in more aggressive lesions.[142]

However, there did not appear to be a higher incidence of tumor formation in heterozygous DCC mice than in homozygous deleted DCC mice. Thus, there was some confusion as to its true role in tumorigenesis. One study demonstrated that DCC's function was related to binding with netrin-1 and thus that DCC acts as a conditional TSG. Gene silencing via promoter hypermethylation was confirmed in primary HNSCC and cell lines, and subsequent growth assays showed that transfection of DCC into DCC-cell lines was able to arrest growth, whereas the addition of netrin-1 led to the resumption of cell growth.[143] Thus, the mechanism of the tumor-suppressive effects of DCC is not as simple as that of other models and also suggests that there may be many other ways in which TSGs may function.

The discovery of genetic alterations has been rapidly accelerating with the advent of various microarrays. The importance of understanding the mechanisms of HNSCC carcinogenesis lies in their use as clinical biomarkers and as possible therapeutic targets.

Tumor Suppressor Gene in Fanconi's Anemia

Fanconi's anemia is an autosomal recessive DNA repair disorder that leaves patients uniquely vulnerable to DNA damage and the subsequent development of a multitude of cancers. Thus far, 11 genes have been identified in this disorder that ultimately are involved in the regulation of the BRCA-1 and BRCA-2 pathway (involved in the repair of double-stranded DNA breaks). Previously, patients succumbed to aplastic crises or hematologic malignancies. However, with advances in bone marrow transplantation and longer life spans, patients with Fanconi's anemia have been found to be at profound risk for development of various cancers, in particular HNSCCs. Patients with this disorder are atypically young (<50 years of age) and are usually women who do not smoke tobacco or drink alcohol. The relative risk of HNSCC in patients with Fanconi's anemia is 700 times greater than that in the general population.[144] After bone marrow transplantation, which is performed to prevent a fatal aplastic crisis or hematologic malignancy, the risk is further increased by fourfold.[145] Patients with this disorder should be treated with surgery rather than irradiation or chemotherapy, to prevent further DNA damage and the development of other malignancies.

Epigenetics

The field of epigenetics has greatly furthered our understanding of not only cancer but all of molecular biology. *Epigenetics* is a term used to describe the regulation of gene expression that does not involve DNA sequence alterations but, rather, is a heritable modification of the DNA molecule itself and/or the proteins associated with it. One way in which this modification can occur is through the covalent addition of a methyl group to the 5′ carbon of the cytosine ring, resulting in 5-methylcytosine. However, in order for this methyl group to be added, a cytosine base pair must be followed by a guanine base pair in the DNA sequence, a so-called CpG dinucleotide. Overall, CpG dinucleotides occur at lower than expected frequencies throughout the human genome. However, they are found more frequently in the promoter regions of genes as small stretches of DNA called *CpG islands*.[146] The addition of the methyl group to the cytosine prevents binding of transcriptional activators and RNA polymerase, effectively silencing the gene. Once methylated, the modification is then passed to progenitor cells, making it a heritable or permanent modification to gene expression. DNA methyltransferases (DNMTs) are responsible for maintaining the methylation status of a gene in the progeny. Because CpG islands are most commonly found in promoter regions of the genome, they are believed to be one mechanism of gene expression regulation. In summary, hypermethylation and hypomethylation are epigenetic means of regulating gene expression (Fig. 76-1).

In addition to the methylation of promoters, histones have been shown to play an active role in regulating gene expression. Once thought to be static packaging proteins, histones are now recognized to be dynamic molecules that can physically determine whether transcription factors have access to promoters. Histones may undergo many post-translational chemical modifications, such as acetylation, meth-

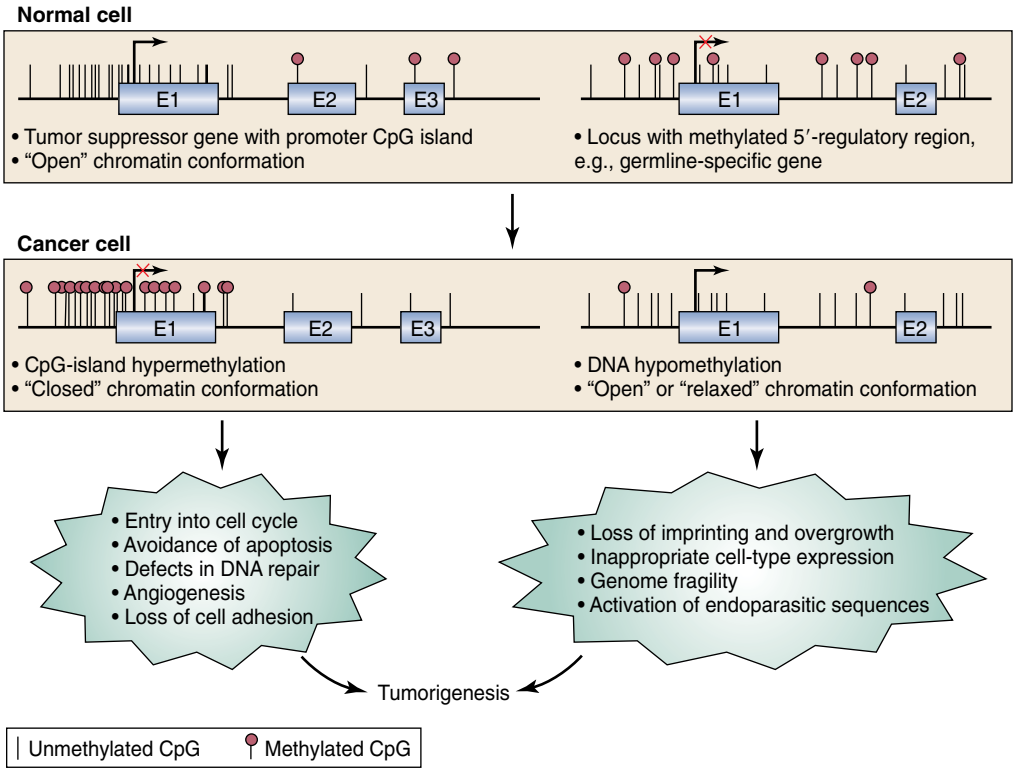

Figure 76-1. Diagram showing the altered DNA methylation patterns in tumorigenesis. The hypermethylation of CpG islands of tumor suppressor genes is a common alteration in cancer cells that leads to the transcriptional inactivation of these genes and the loss of their normal cellular functions. At the same time, the genome of the cancer cell undergoes global hypomethylation at repetitive sequences, and tissue-specific and imprinted genes can also show loss of DNA methylation. In some cases, this hypomethylation is known to contribute to cancer cell phenotypes and contribute to the genomic instability that characterizes tumors. E, exon. *(Redrawn from Esteller M. Cancer epigenomics: DNA methylomes and histone-modification maps.* Nat Rev Genet. *2007;8(4):286-298.)*

ylation, phosphorylation, ubiquitylation, and sumoylation.[147] Histone modifications and DNA methylation play a significant role in the organization of nuclear structure, ultimately influencing what genes may be suppressed or expressed.[148]

The phenomenon of methylation as a regulator of gene expression was first recognized in development, during which the coordinated expression and silencing of genes needs to take place in an organized fashion.[149] It was quickly proposed that epigenetic control of TSGs, as a novel mechanism of gene regulation, could be an important mechanism of carcinogenesis.[150,151] Initially, studies of the global methylation status were performed in animals, and cell culture showed mixed results. Many workers believed that the observed hypomethylation of tumors was simply a marker of an actively dividing cell or the result of malignant transformation rather than the cause. But Feinberg and Vogelstein[150,151] were the first to analyze primary tissue from resected cancers and examine both global methylation and methylation of specific known oncogenes. Interestingly, they found that cancers were globally hypomethylated (10%) and that Ras oncogenes were specifically hypomethylated.

Although hypomethylation was the originally identified epigenetic change in cancer, it was overlooked in preference for hypermethylation for many years and is only now undergoing a renaissance. This situation occurred, in part, because of previous bias in experimental design; if one looks for altered methylation only at sites that are normally unmethylated, then one will observe only hypermethylation.[152] Furthermore, the early success of Baylin and Herman (discussed later) in finding specific regions of hypermethylation prompted many other researchers to search for similar regions with similar techniques.

One of the earliest genes to be characterized as being under epigenetic control is the retinoblastoma gene. Looking in primary tissues of resected retinoblastomas, Sakai and coworkers[153] found that in 10% of the tumors analyzed, the promoter of Rb was hypermethylated in the absence of any other mutations. Since that discovery, many different tumor types have been shown to exhibit various TSG methylation.

Significant promoter hypermethylation has been demonstrated in many of the known TSGs in head and neck cancer. One of the more interesting findings is the high incidence of p16 hypermethylation. It has long been puzzling that p16 expression has been found to be decreased in a majority of HNSCCs, whereas point mutations and homozygous deletion are rare and the incidence of LOH is not. Promoter hypermethylation of p16 has been shown to be quite frequent in HNSCC, explaining the apparent discrepancy between the incidence of deletions or mutations and low expression.[146,153-156] Thus, Knudson's "two-hit" hypothesis could include promoter hypermethylation as one of the hits along with the more traditional sequence mutation or chromosomal deletion.

Many other genes have emerged as putative TSGs in HNSCC based on promoter hypermethylation, including lhx-6 (DIME-6), ATM, p15, TIMP-3, MGMT, RARB-2, DAP-K, E-cadherin, Cyclin A1, RASSF1A, and DCC.[157-167] The list of TSGs that are silenced through promoter hypermethylation continues to grow every year. Furthermore, it has been recognized that many other avenues of research cross paths with epigenetics. For instance, microRNAs (small non-coding RNA molecules; see later) that have tumor-suppressor function have been demonstrated to also undergo DNA methylation–associated silencing in cancer and therefore are under the same epigenetic control[164,168,169] (see Fig. 76-1).

However, one must recall that in general, DNA is hypomethylated in cancer despite local regions of hypermethylation. This apparent paradox was attributed to overall cell activation after carcinogenesis was initiated. Evidence is now emerging on the importance of the hypomethylation of genes. Studies have now shown that the regions of hypometh-

ylation correlate with genes that were important to development and were subsequently "turned off" by methylation. These genes, once reactivated, have proved to be oncogenic. Some of these genes are HOX11, MAGE family, CAGE-1, uPA, MTS1/S100A4, MASPIN/SERPINB5, and BCSG/SNCG.[170] Specific data on genes that are activated in HNSCC are yet to be published, although a 2007 study demonstrated that there is indeed global hypomethylation in HNSCC.[171]

The natural question regarding any of the previously mentioned discoveries regarding epigenetics is how they will ultimately affect clinical practice, if at all. Translational epigenomics has been an exciting area of research that has grown with the field of epigenetics itself. There are several methods to translate epigenetic discoveries into clinical practice. The first is the use of the *epigenetic profile*, which refers to the fact that unique profiles of hypermethylation define each cancer type.[172,173] Once defined, the profile of HNSCC could be used as a marker of prognosis and possibly to predict responsiveness to treatment. Second, the hypermethylated genes themselves are potential therapeutic targets. Promoter hypermethylation is an attractive route for therapeutic intervention because it does not involve loss of DNA or sequence alterations. Selective demethylation is not feasible at this point, but it could eventually become a reasonable means of cancer therapy. Third, detection of methylated DNA in body fluids is a potential marker for screening and surveillance. Studies have already proven the ability of such markers to be detected, but further work is needed to improve their sensitivity and specificity.[165,174] Lastly, it may be possible, with the development of more rapid detection strategies, to perform molecular margin analysis of cancers. These topics are more thoroughly addressed in the molecular diagnostics section of this chapter.

There are still several questions yet to be answered. What is the role of hypomethylation? And why is there global demethylation in cancer? How does DNA become methylated or demethylated? It has been theorized that DNA methylation and histone deacetylation are a means to stabilize chromatin after trauma, but this theory has not been proven. Whether the enzymes that normally maintain methylation are in dysfunction or the DNA is methylated first remains to be seen. It also has become apparent that carcinogenesis is caused not by the activation or deactivation of one or two promoters but, rather, by several hundreds of promoters and histones interacting synergistically.

Epidermal Growth Factor Receptor

One of the best-studied areas of the molecular biology of HNSCC is the role of EGFR and its associated pathways in carcinogenesis. Expression of EGFR is a normal finding in many tissues, including the dermis, gastrointestinal tract, and kidneys. However, dysfunction of this receptor and its associated pathways occurs in most epithelial cancers[175] and in 80% to 90% of HNSCCs specifically.[176,177] What is unique about this area of inquiry is that the research into the biology of EGFR has led directly to clinically beneficial targeted therapies. Before delving into therapies, we examine the basic molecular biology of EGFR.

Biology

A general understanding of the EGFR-related pathways is necessary to comprehension of the therapies directed against it (Fig. 76-2). EGFR is a cell surface receptor that is a member of the larger ErbB family of proteins, which includes the Her2, Her3, and Her4 receptors. EGFR possesses an extracellular ligand-binding domain, a transmembrane region, and an intracellular domain. The intracellular domain includes the tyrosine kinase domain and multiple phosphorylation sites. Once the extracellular portion of the receptor binds a ligand, homodimerization or heterodimerization of EGFR with other ErbBs follows, which then results in the autophosphorylation of the receptor. Currently, 12 ligands of the ErbB family have been identified. Once phosphorylated, the receptor can signal via the MAPK, Akt, ERK, and Jak/STAT pathways. These pathways are related to cellular proliferation, apoptosis, invasion, angiogenesis, and metastasis.[175,177,178] There is also some evidence that the receptor may localize to the nucleus and act as a transcriptional activator. Finally, one study has even linked the effects of tobacco smoke to increased EGFR expression and cellular proliferation.

ERK, extracellular signal-regulated kinase; Gα, g-alpha subunit; GPCR, g-protein coupled receptors; IGF-1R, insulin-like growth factor-1 receptor; MEK, mitogen-activated protein kinase; MMP, matrix metalloproteinase; PKC, protein kinase; Rb, retinoblastoma; STAT, signal transducer and activator of transcription. *(Modified from Kalyankrishna S, Grandis JR. Epidermal growth factor receptor biology in head and neck cancer.* J Clin Oncol. *2006;24(17):2666-2672.)*

Clinical Implications

The pathologic manifestations of EGFR in HNSCC are achieved by at least four major mechanisms, as follows: (1) overexpression of EGFR ligands and establishment of autocrine/paracrine loops, (2) mutational activation of EGFR, (3) amplification of EGFR, and (4) transactivation by other receptor and nonreceptor tyrosine kinases. Although EGFR-driven molecular pathway aberrations are important and are altered in 90% of HNSCCs, they cannot be considered the dominant or sole genetic alteration in the molecular pathogenesis of HNSCC. Initially, EGFR was first found to be up-regulated in HNSCC cell lines[179] as well as in a high percentage of primary HNSCCs.[179-181] Further study showed that histopathologically normal mucosa adjacent to cancer had a high degree of overexpression of EGFR.[182] It was also later found that the up-regulation of EGFR occurs in the transition from dysplasia to HNSCC.[183] All of these revelations, however, should not be surprising, given the field cancerization hypothesis and progression model discussed in "Background".

Furthermore, increased levels of expression were found to predict a worse disease-free and cause-specific survival.[184] Copy number amplification has also been shown to be associated with poorer prognosis in HNSCC.[185] Mutations of the EGFR tyrosine kinase domains have been detected but are infrequent in HNSCCs (1%-7%).[186,187] Further work has demonstrated the association of STAT and Src activation as contributing to the up-regulation of EGFR.[188-190] One study has demonstrated that the overexpression of EGFR is a biomarker for an improved response to therapy that could serve as a predictive marker to distinguish patients for assignment to different arms of therapeutic trials.[191]

In addition, EGFR axis alterations have been intensively researched as markers for response to treatment and as therapeutic targets. General strategies for targeting the EGFR axis are specific tyrosine kinase inhibitors, blocking of dimerization with monoclonal antibodies, and blocking of mRNA expression with antisense oligodeoxynucleotides or small interfering RNA (siRNA). A 2006 clinical trial evaluating EGFR inhibitors as adjuvants to radiotherapy demonstrated both a survival benefit and a lower side effect profile in comparison with radiotherapy alone.[192] This was the first randomized study showing a survival benefit with an EGFR-targeting agent (cetuximab, a monoclonal antibody) in locally advanced HNSCC.[193] Conversely, gefitinib (a tyrosine kinase inhibitor) has shown no survival benefit in recurrent or metastatic HNSCC.[193,194] However, several ongoing trials are looking at various methods of targeting the EGFR axis—one evaluating gefitinib plus docetaxel versus placebo for recurrent or metastatic disease, one examining cetuximab as an adjuvant to cisplatin and 5-fluorouracil therapy for recurrent or metastatic disease, and one studying cetuximab as an adjuvant to radiotherapy and cisplatin treatment for locally advanced disease.[193] A shortcoming of all of these clinical trials is that none incorporates the presence of EGFR-activating mutations, EGFR gene copy number, or both into their primary analyses, even though both factors have emerged as predictors of treatment efficacy.[193] However, retrospective analysis of these factors within the context of prospective therapeutic trials should provide some information.

As alluded to previously, there is evidence that in non–small cell lung cancer (NSCLC), activating somatic mutations in the EGFR tyrosine kinase domain can predict a patient's response to treatment. These mutations, which are present in about 10% of NSCLCs[195,196] and 1% to 7% of HNSCCs,[186,187] correlated with prolonged survival in patients with advanced NSCLCs treated with chemotherapy regardless of EGFR tyrosine kinase inhibition.[197] Moreover, in several studies of NSCLCs, EGFR mutations were predictive of survival in patients treated with EGFR tyrosine kinase inhibitors.[198-200] As a result, multiple clinical trials are evaluating EGFR tyrosine kinase inhibitors in chemotherapy-naïve patients with advanced NSCLC and EGFR-activating mutations.[193,201,202] Both gefitinib and erlotinib have demonstrated response rates of 75% to 82%.[193,201,202] Whether the same correlation and response to therapy will be found in HNSCC for other EGFR alterations has not yet been determined.

Immunotherapy

Immunotherapy, defined broadly as any manipulation of the immune system to achieve a desired treatment effect, is an attractive therapeutic strategy for the treatment of cancer. Theoretically, immune cells can be specifically targeted without the need for potentially toxic foreign chemicals or agents. In addition, immunotherapy can be integrated with and even enhanced by existing therapies such as surgery, chemotherapy, and irradiation. Like vaccination against infectious diseases, tumor vaccines rely on the concept of exploiting antigenic components of target cells. This therapeutic modality is based on the assumptions that (1) the tumors express antigens or neoepitopes that either are not found or are present in low levels on normal cells and (2) the immune system can be appropriately activated to exterminate such cells. However, unlike many microbial organisms, neoplastic cells derived from a patient's own tissues vary only slightly from normal cells. In addition, many potential antigens expressed by these cells have been constitutively present throughout development and therefore are not recognized as foreign. This is because the immune system has evolved a network of sophisticated checkpoints to prevent autoimmunity, collectively known as *tolerance*. This network includes mechanisms such as positive and negative thymic selection as well as peripheral means such as anergy, suppression, and ignorance, all designed to prevent recognition of "self" antigens as "other."

In HNSCC, the presence of tolerance is further confounded by the fact that in T cells of patients with HNSCC, lymphocytes that coordinate recognition of foreign antigens in normal cells are often dysfunctional. A high proportion of both tumor-infiltrating lymphocytes and peripheral blood lymphocytes (in patients with HNSCC) have fragmented DNA and express markers such as annexin V, indicating the occurrence of apoptosis.[203-207] In addition, both tumor-infiltrating lymphocytes and peripheral blood lymphocytes have an impaired ability to proliferate and transduce integral signaling pathways.[205-209] This functional inactivation may be related to a lack of expression of the z portion of the CD3 T-cell receptor complex that is essential for signaling transduction, as well as increased expression of FAS ligand.[206] It is predominantly CD8 T cells that display these dysfunctional attributes, whereas CD4 T cells remain comparatively unaffected.[207,210] The means by which cancer cells escape immunologic detection is still being actively researched. The exact mechanism by which these cells escape detection is still unclear, and much of this realization arose from the poor results of several early-phase clinical trials.[211,212] It has been proposed that the issue lies in a defective HLA class I receptor as well as dysfunctional antigen-presenting cell interactions, but this remains an active area of study.[212,213]

The deficits seen in both tumor-infiltrating lymphocytes and peripheral blood lymphocytes appear to have significant clinical significance in patients with HNSCC. Patients with a high percentage of apoptotic tumor-infiltrating lymphocytes have a significantly lower 5-year survival rate than those with a lower percentage.[208] Patients with HNSCC have significantly lower levels of thymic output of naïve T cells than healthy control subjects.[207] This finding indicates that patients with such deficits do not compensate well for frequent T-cell apoptosis.

Despite the fact that patients with HNSCC display this degree of relative immunosuppression, there has been an increase in the number of translational and clinical immunotherapeutic trials in HNSCC. The types of trials are numerous but are generally categorized into studies of the following: manipulation of cell signaling (such as cytokines), preventive vaccines, and T cell–based, dendritic cell–based, and antibody-based strategies (discussed in the EGFR section).[214]

Early attempts at immunotherapy in patients with HNSCC mainly focused on the administration of nonspecific agents such as the cytokine interleukin-2 (IL-2).[215,216] However, it was found that only a small minority of cases of HNSCC responded to IL-2 and similar agents, and these responses were usually of short duration. Later studies have focused on ways to improve response rates and extend remissions with cytokines through a variety of strategies. Treating peripheral blood mononuclear cells from patients with HNSCC using the combination of IL-2 and IL-12 resulted in higher cytolytic activity than treatment using either alone.[217] In addition, the lack of response to IL-2 may be due to inadequate expression of this cytokine at the tumor site[218]; this hypothesis was reinforced by the demonstration of regression of a significant proportion of implanted murine floor-of-mouth tumors after peritumoral injection of vaccinia virus that had been transduced with

IL-2.[219] Other investigators have hypothesized that the potential reason for lack of efficacy with IL-2 and other cytokines in HNSCC may be a lack of sufficient costimulation, an essential element for T-cell activation.[220]

One phase 2 clinical trial used the natural cytokine mixture IRX-2 in 15 patients with stage II to stage IV HNSCC.[221] Patients were given a 21-day cycle of perilymphatic IRX-2 in combination with cyclophosphamide, indomethacin, and zinc with surgery, irradiation, or both. Although it is difficult to draw substantial conclusions from this study because of the low number of patients enrolled with a variety of clinical presentations, a complete response was seen in 1 patient, and a partial response in several others. The treatment regimen was well tolerated, and all patients enrolled in the trial had evidence of a histologic response. On the basis of these encouraging results, a phase 3 trial involving a larger number of patients is planned for the near future.

In a 2005 study comparing expression of the chemokine CXCL-14 in patients with HNSCC and normal subjects, Shurin and colleagues[222] found a significant difference.[222] CXCL-14 was not expressed in patients with HNSCC or in HNSCC cell lines. In HNSCC cell lines, the researchers were able to demonstrate that re-expression of CXCL-14 would chemoattract dendritic cells. In dendritic cells, the addition of recombinant CXCL-14 caused the cultured cells to display markers of maturation.[222] This was a very promising study that has many therapeutic implications.

Much effort is also being spent to develop immunotherapeutic strategies that induce adaptive (T cell–based) immune responses that are sufficient to eradicate tumor while not affecting normal host tissues. One study examined the efficacy of an autologous whole-cell vaccine and adoptive T-cell immunotherapy in 17 patients with unresectable HNSCC.[223] Patients were first given an injection of irradiated autologous T cells at a single site, followed by three injections of granulocyte-macrophage colony-stimulating factor (GM-CSF) at that site. Approximately 10 days later, the draining lymph nodes were excised and the T cells isolated. The cells were then expanded in culture in the presence of IL-2 and enterotoxin A, and then reinjected into the patients. Overall, the vaccines were well tolerated with minimal adverse effects. Three patients experienced stabilization of disease, and one patient was disease free 4 years after the implementation of therapy. Another success was reported in metastatic melanoma by Dudley and colleagues.[224,225] They demonstrated an objective clinical response in 50% of 35 patients treated. Although these results are promising, it should be noted that autologous tumor vaccines are expensive and labor intensive.

There was also a promising study of the ability of mutant p53 proteins to stimulate T cells in patient serum in comparison with wild-type p53.[226] Furthermore, in a subset of patients with HNSCC (HLA-A*0201-positive patients), it was found that specific missense mutation (Y220C) in p53 not only was immunogenic but also was found in 12% of 50 examined tumors.[227] This may be the first steps in breaking the "tolerance" to cancer cells and identifying patients who may benefit from immunotherapy.

In addition to whole-cell vaccines, dendritic cell–based vaccines are being developed for HNSCC. Dendritic cells are powerful professional antigen-presenting cells that have the ability to phagocytose apoptotic cells and then present peptides to T cells, a process called *cross-priming*.[228] Dendritic cells exposed to the proper antigenic proteins and cytokines can serve as a vehicle for antigen presentation and T-cell priming. This concept was illustrated in a DBA2/J mouse model of HNSCC.[229,230] Mice that were treated with this vaccine regimen demonstrated a greater decrease in tumor burden than did control mice, with little evidence of toxicity.

Despite the fact that using irradiated tumor cells is an efficacious therapeutic technique, targeting antigens known to activate T cells has the potential to lead to a more specific and robust immune response. Although there are no HNSCC-specific antigens as of yet, a variety of immunogenic proteins present in these tumors have been shown in other tissue types to be effective targets of vaccination. HPV-related cancer, the best example of the use of a tumor vaccine for prevention and possibly for treatment, is discussed in the section on HPV. Other examples are the carcinoembryonic antigen (CEA), which has been shown to be a safe and efficacious target in patients with tumors of the digestive tract.[231] In addition, patients can mount CEA-specific T-cell responses that are capable of lysing colorectal carcinoma cells.[232] Kass and associates[233] evaluated the feasibility of targeting CEA with a vaccine in head and neck cancer. This group demonstrated that CEA was expressed in between 50% and 100% of HNSCC tumors, depending on the site. In a slightly different vein, Lee and colleagues[234] found that a high percentage of patients with various head and neck cancers expressed several isoforms of the melanoma antigen E (MAGE) tumor–associated antigen.[234] This protein is an attractive target for immunotherapy because it is expressed in a variety of tumors and is comparatively absent in noncancerous tissues. MAGE proteins have been shown to be effective targets in melanoma and therefore offer a potential target for immunotherapy in HNSCC.[235]

Immunotherapy for HNSCC is a relatively new but promising therapeutic strategy. Difficulties with achieving efficacy with this approach are due mainly to problems with host tolerance and the relative immunosuppression of patients with HNSCC. Despite this fact, both clinical and translational trials with cytokines, monoclonal antibodies, and a variety of other strategies have yielded promising results with little evidence of host toxicity. In HNSCC and other tumor types, immunotherapy has been implemented successfully in patients undergoing a variety of other therapeutic modalities, and often in patients with end-stage disease. It is to be hoped that future efforts find ways to circumvent immune tolerance and overcome malignancy-related immune dysfunction to produce regimens with better efficacy.

Mitochondrial Mutations

The role of mitochondria as the oxidative phosphorylation "power plants" in cellular function has long been known. However, they also have a role in carrying out apoptosis, cellular proliferation, and the processing of reactive oxygen species within a cell. Mitochondria are therefore central to two phenomena of HNSCC, impaired apoptosis, which is a central characteristic of neoplastic and malignant transformation,[236,237] and the Warburg effect, which is the preferential use of the glycolytic pathway rather than oxidative phosphorylation by cancer cells (Fig. 76-3).[238,239] Furthermore, mitochondrial DNA differs from genomic DNA in being uniquely sensitive to oxidative damage because of the lack of protective histones. Smoking exposes the aerodigestive tract to more than 10,000 oxidant molecules, so it is not surprising that mitochondrial dysfunction is evident in HNSCC given its unique susceptibility to oxidative damage.

The body of literature linking mitochondrial function to cancer has been growing steadily although definitive mechanisms of action are yet to be identified. There has been some evidence in cancer cell line studies that mitochondrial dysfunction in cancer involves both the apoptotic and metabolic pathways.[240,241] Mitochondrial mutations also open the door to more sensitive molecular detection techniques. Every cell has several hundred copies of mitochondrial DNA, so the number of cells required for such assays is much lower[242] than with genomic DNA detection.

Studies have demonstrated that there is a progressive increase in mitochondrial DNA content from mild dysplasia to invasive cancer[243] as well as in the saliva of patients with head and neck cancer.[244] Interestingly, the investigators in the second study also found that the salivary mitochondrial DNA content decreased after definitive treatment of patients with head and neck cancer, suggesting that it is at least a marker of disease status.[245] However, how these observations relate mechanistically to the development of cancer is an active area of research.

For instance, a study of a "hot spot" of mitochondrial genome mutation, known as the D-loop, revealed frequent alterations in oral premalignant lesions that rose in incidence with disease severity in oral cavity lesions.[246] Similar D-loop alterations have been detected in lung,[247] gastric,[248] and colorectal cancers.[249] A follow-up study in which the mitochondrial genome was sequenced in 83 HNSCC specimens found that there were mutations in 49% of the samples tested and, furthermore, that these mutations tended to reside in the mitochondrial enzyme complex components.[241] There was a statistical increase in the

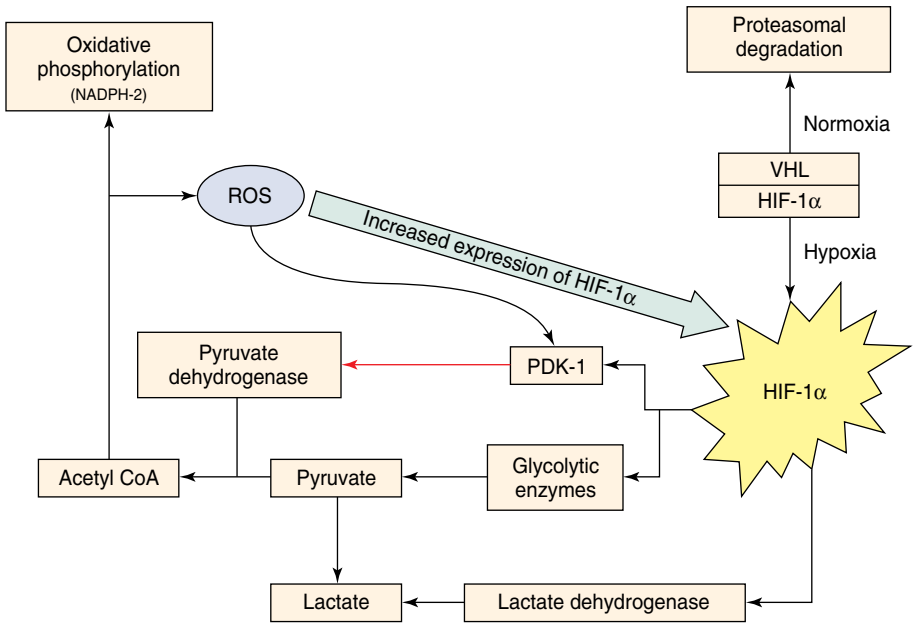

Figure 76-3. Mitochondria and the Warburg effect. During hypoxic conditions, the Von Hippel–Lindau (VHL) protein is associated with hypoxia inducible factor (HIF) and causes the activation of several pathways that lead ultimately to increased lactate production, increased glycolysis, and decreased oxidative phosphorylation. In addition these molecules are shunted toward creating excess reactive oxygen species (ROS). ROS are known to increase HIF-1 expression, to play a role in carcinogenesis, and to further increase genomic instability. CoA, coenzyme A; PDK-1, pyruvate dehydrogenase kinase-1.

number of mutations identified in NADH subunit 2. Mutation of this gene causes increased cellular reactive oxygen species, anchorage-independent growth of tumor cells, preferential glycolytic metabolism (Warburg effect) and hypoxia inducible factor-1α (an oncogene linked to metastasis and angiogenesis in cancer).[241] Another study, in renal carcinoma cell lines, found that the mutation of succinate dehydrogenase (another mitochondrial enzyme in metabolism) leads to the accumulation of succinate which inhibits hypoxia inducible factor-1α degradation enzymes in the cytosol.[250] Subsequently, Mithani and coworkers[251] analyzed HNSCC tumor tissue, adjacent dysplasia, and adjacent normal tissue histologically for mitochondrial mutation. These workers found that the majority of mitochondrial mutations occur during or after the transition of preneoplastic epithelium to cancer in HNSCC, indicating that these are a late event in the head and neck carcinogenesis progression model.[251]

Other cell line studies have revealed several avenues to explore in determining the mechanistic role of mitochondrial dysfunction and cancer. For instance, there is some evidence that mitochondrial DNA repair is hampered in HNSCC cell lines, which might help explain the propensity for mutations.[252] There is also evidence that head and neck cancer cell lines are resistant to mitochondrial depolarization–induced apoptosis.[240] Cisplatin also appears to have direct effects on mitochondria that can trigger the apoptotic pathway independent of nuclear DNA.[253] Mitochondrial mutations are an exciting field of study in HNSCC and in cancer overall. The growing evidence has broad implications in the mechanisms of carcinogenesis and provides for other potential avenues of therapy.

Expression Microarrays and Integrative Genomics

Expression microarrays examine the level of expression of mRNA of thousands of genes in a single assay, thus determining the translational makeup of any sample. In its simplest form, this powerful technology allows us to simultaneously determine which genes are over-expressed or under-expressed in cancer in comparison with normal tissue. One of the first studies did so in head and neck cancer, identifying 91 statistically significantly up-regulated genes (putative oncogenes) and 122 down-regulated genes (putative TSGs).[254] Thus from a list of thousands of genes, the number of differentially expressed genes has been greatly reduced. Through other screening methods, this list can be further reduced to a more manageable number, as discussed later.

The global expression pattern can accurately distinguish HNSCC samples from normal mucosa to delineate those genes that are characteristic of each population.[255,256] Another study identified expression patterns for premalignant disease, frank malignancy, and normal mucosa.[6] Most interesting was the finding that the majority of expression differences occurred between the normal and premalignant cohorts rather than between the premalignant and malignant cohorts. This finding confirms that significant expression alterations have already occurred in the premalignant lesions, as referred to in the progression model of cancer discussed in "Background". Further subset analysis has allowed for the detection of expression differences that might help explain cisplatin resistance,[257] recurrent disease,[258,259] metastatic disease,[260] and human papillomavirus–associated cancers.[261] Once the targets are identified by expression array to be statistically significantly differentially expressed, these genes require further study by more traditional approaches to confirm their significance.

The next step is then to find a high-throughput method to confirm the findings of these expression arrays. One method that has been used to identify the best candidates from the list of hundreds of genes is to combine techniques such as CGH and SNP arrays (which identify areas of loss and gain, respectively) with expression arrays. For example, one would anticipate there to be chromosomal amplification as well as increased expression at the locus of an oncogene. With array technology, one could search for putative oncogenes and TSGs throughout the entire genome with minimal time expenditure. Combining array data might increase the yield and likelihood of finding significant targets. This strategy has been successfully utilized in lung cancer[262] and bladder cancer.[263] This integration of data from multiple approaches further increases the likelihood of finding a TSG or oncogene. Using multiple high-throughput approaches to determine significant genes in cancer is known as *integrative genomics*. This process is an extremely powerful approach to studying the molecular biology of HNSCC. Integrative approaches to HNSCC are currently being utilized to identify novel targets.

Molecular Biomarkers

Having reviewed the molecular changes in HNSCC, we now discuss their role as biomarkers. A biologic marker, or *biomarker,* is any characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.[264] Ultimately, a biomarker must be studied in a randomized clinical trial to prove that there is a reliable clinical endpoint (a characteristic or variable that reflects how a patient feels, functions, or survives), in which case it would be referred to as a *surrogate endpoint*.[264] A molecular biomarker for HNSCC can be derived from many sources that can be classified into three general categories—primary tissue, surgical margin tissue, and bodily fluid markers. Three basic types of molecules can be extracted from these sources—DNA, RNA, and protein, respectively.

Practitioners rely heavily on the histopathologic and radiographic assessments of tumors and their margins to make decisions about treatment and prognosis. The current system can fail to adequately stratify specific risk of metastasis, locoregional recurrence, or second primaries. Furthermore, though it is well known that early detection is the key to improving patient survival in HNSCC,[265] two thirds of patients present with advanced disease.[266] Biomarker research ultimately strives to fulfill one (or more) of the three inter-related categories—diagnosis, prognosis, and therapy. Success of this research would be defined as identification of a biomarker of interest that is statistically significant and independent of currently used parameters. An ideal biomarker would fulfill the requirements of all three categories, as follows: (1) the biomarker could be used to accurately diagnose cancer and recurrence, as well as screen asymptomatic populations for the presence of disease (diagnosis); (2) the biomarker could accurately stratify the risks of a patient's course or predict response to therapies (prognosis); and (3) the biomarker itself could be a therapeutic target (therapy). The final hurdle for any biomarker is logistical. Is the biomarker cost effective and practical for everyday use? The following discussion describes three biomarkers that have been extensively studied and the clinical utility of which has been established.

Human Papillomavirus Infection

As a biomarker, HPV infection and the subsequent genomic integration in HNSCC offers diagnostic, prognostic, and possibly therapeutic opportunities. Multiple studies have shown that HPV-associated oropharyngeal cancers are a distinct subset of head and neck cancers. These tumors can be reliably diagnosed and distinguished from other HNSCC tumors by several molecular biologic methods. HPV-associated tumors appear to have a better prognosis than other HNSCC tumors. In addition, because these tumors respond well to chemotherapy and radiation, HPV infection and integration appear to be good markers for responsiveness to nonsurgical treatment. Please refer to the previous HPV section for a more complete discussion of HPV-related head and neck cancers.[30-80]

Epidermal Growth Factor Receptor

Another well-studied biomarker of HNSCC is the EGF receptor. EGFR's role in HNSCC has continued to expand rapidly, and with this expansion its use as a biomarker has developed. It has been proven to be reliable from a diagnostic standpoint. There are several methods by which EGFR dysfunction leads to HNSCC, and for each dysfunction there is a reliable molecular diagnostic technique.[179-181] From a prognostic standpoint, EGFR over-expression and amplification have been demonstrated in retrospective studies to be reliable markers for poor prognosis.[184] Furthermore, there is suggestive evidence that a specific EGFR tyrosine kinase mutation may be a marker for response to chemotherapy.[197] The EGF receptor is an attractive target for chemotherapy because EGFR is a cell-surface marker, which allows it to be readily targeted, and EGFR activation corresponds to an entire pathway that is dysfunctional in cancer, which allows for the simultaneous targeting of multiple portions of the pathway. Preliminary studies have demonstrated some benefit from targeting the EGFR pathway, but further study into its ability to define a clear subset of tumors that is responsive to targeted therapy is needed. For a complete discussion of EGFR, please refer to the previous EGFR section.[175-202]

Loss of Heterozygosity

As discussed previously, the inactivation of TSGs can lead to the development of cancer. If one allele is already inactivated by DNA damage or by hereditary mechanisms, LOH can lead to inactivation of TSG through the physical loss of chromosomal material that contains the remaining allele of that particular TSG. Several regions of chromosomal loss are commonly found in cancer. For instance, the loss of chromosome region 9p21-22 is the most common of all genetic changes in HNSCC, at a frequency of 70%, and it occurs early in the progression of head-and-neck tumors.[267] Another example is the loss of chromosome region 3p.[268] Thirty percent of benign hyperplastic lesions, the earliest of precancerous lesions, have been found to exhibit loss at either 9p21 or 3p.[268] These studies indicate that LOH is commonly found in both malignant and premalignant lesions.

In a retrospective study, premalignant lesions demonstrating loss of chromosomes 9p21 and 3p14 were determined to be more common in patients whose premalignant disease eventually developed into HNSCC.[269] In another study, investigators showed that patients whose premalignant or benign leukoplakic lesions exhibited losses of only 3p and 9p had a 3.8-fold higher risk of progression to cancer, whereas those whose lesions showed the additional losses of 4q, 8p, 11q, or 17p had a 33-fold higher risk.[270] Another research group screened premalignant lesions for LOH for several markers, including 3p21, 8p21-23, 9p21, 13ql4.2, 17p13.1, and 18q21.1, and showed that having LOH in two more of these regions carried a 73% probability of development of cancer in 5 years.[271] Lastly, some smaller studies looking at tumor margins that are histologically normal have also shown that LOH of the field of cancerization may lead to cancer and that these cells originated from the same clonal lineage.[272,273]

Other Biomarkers

This section evaluates the latest research on other biomarkers of disease, organized by the source of biologic material. Although there is evidence that tumor DNA can be detected in serum or salivary rinses, as will be discussed, some issues make population screening with these tests impractical. First, no one common panel of tests or genetic alterations can encompass all patients with HNSCC. Because HNSCC is a relatively rare cancer, the sensitivity and specificity of a screening test would need to be very close to 100% for it to be useful. Second, genetic alterations arise in patients who smoke or have premalignant lesions that are indicative of DNA damage, but not necessarily the presence of malignancy. However, surveillance after treatment is a feasible application of these molecular tests, in the form of either oral rinses or serum analysis.

Oral Rinses and Saliva

Oral rinses have been shown either to harbor naked DNA or to shed cells that might harbor cancer DNA that could be used for detection or surveillance. Studies have been performed demonstrating that one can detect common mutations in saliva that are shared with the primary tumor. For example, p53 mutations detected in primary tumors were detected in five of seven salivary rinse specimens.[274] Microsatellite alterations in the primary tumor were detected in a significant majority of salivary rinse samples as well.[275] Promoter methylation has also been studied in salivary DNA and found to have a 65% concordance rate with primary tumor methylation status.[276] The detection of methylation in oral rinses has also been shown to be a good surrogate marker for the presence of disease.[277] Furthermore, mitochondrial DNA content has been shown to be higher in the salivary rinses of patients with HNSCC.[244] Patients with HNSCC also exhibited a statistically significant decrease in content after treatment.[245]

Serum

Serum analysis has also been studied as a possible way to detect circulating DNA that might harbor mutations specific to HNSCC. Microsatellite alterations in the primary tumor have been shown to shed DNA such that detectable levels of the common mutations were detected in 6 of 21 patients in one of the early studies[268] and in 68 of 152 patients in a subsequent study.[278] Serum analysis of promoter hypermethylation patterns in HNSCC showed a 42% concordance

between primary tumor and serum methylation pattern,[279] and a later study looking at p16 methylation found a 64.7% correlation in HNSCC patients.[280] In addition, serum analysis frequently detected LOH or allelic imbalance in patients preoperatively, but as patients progressed beyond treatment, the percentage of positive markers in their serum decreased. Furthermore, the patients in whom persistently high levels of serum markers were detected after surgery eventually developed disease recurrence.[281]

Molecular Margins

Margin analysis has also been studied to determine whether the molecular detection of genetic alterations is predictive of disease recurrence. There is evidence that patients whose surgical margin specimens were found by molecular analysis to be positive for p53[282] or the proto-oncogene eIF4E[283] but that histopathology classified as negative for pathology may have an increased risk of recurrence. A prospective study looking at p53 mutations in the histologically clear margins of 76 patients showed that the presence of p53 mutations led to a relative risk of 7.1 for locoregional recurrence.[284] Another use of molecular margin analysis is to determine whether real-time information could be provided to the surgeon in the intraoperative setting to help determine the extent of resection. In a pilot feasibility study, investigators were able to provide molecular margin assessment, using methylation-specific polymerase chain reaction analysis, within a timeframe that could be used in a clinical setting.[285]

Primary Tissue

Polymorphisms detected in DNA repair enzymes have been shown to correlate with the response of HNSCC responses to cisplatin and with patients' overall prognosis.[286] MMP3 polymorphisms have also been shown to be associated with sensitivity to 5-fluorouracil and cisplatin.[287] Amplification of CCND1 and c-myc along with p16 deletion has been shown to lead to a statistically higher chance of disease recurrence or metastasis.[288] Interestingly, even stromal genetic alterations have been shown to be associated with tumor aggressiveness, which might be a precursor to the progression of HNSCC.[289]

Summary

Biomarker research ultimately strives to achieve success in one (or more) of three inter-related categories, diagnosis, prognosis, and therapy. A successful biomarker is defined as being statistically significant and independent of current parameters. HPV and EGFR have been able to fulfill several of these criteria, and LOH markers have been validated in premalignant disease. HPV has proved to be a good diagnostic and prognostic tool, and attempts to exploit this marker for therapeutic purposes are ongoing. With the advent of widespread use of a polyvalent HPV vaccine in young girls in the United States, it is possible that the incidence of HPV-related oropharyngeal cancers will decrease, and its role as a biomarker may be useful only in regions without access to vaccination.

EGFR has similarly fulfilled several of the criteria but has shown more promise in the therapeutic realm as a target. However, better studies that account for EGFR amplification and mutations are needed. LOH has shown great promise in defining the risk of progression for premalignant lesions. However, prospective studies would be helpful in defining the utility of LOH as a risk factor in larger populations, so that guidelines regarding surveillance and testing can be implemented. Furthermore, there has been little progress in treating histologically normal but molecularly premalignant regions with chemoprevention or gene therapy.

Currently studies are under way to determine the unique signature of HNSCC via high-throughput techniques, examining DNA methylation, genomic copy number, microRNA, and protein or mRNA expression. Therefore, it will likely be possible to classify tumors beyond simply TNM staging and HPV, p53, and EGFR status. In addition, future therapies will depend on characterization of individual tumors for specific molecular pathway alterations for specifically tailored therapy. These alterations will also likely be useful for surveillance and detection of disease in a variety of settings. However, the ultimate utility of these biomarkers will be in their ability to add information independent of previously known clinical and biomarker parameters.

Novel Fields in Cancer Research

In addition to the study of established biomarkers, whole new fields of research have been revealed that may provide more opportunities for better biomarkers and improved targeted and tailored therapy. As our understanding of cancer biology has become refined, it is evident that the mechanisms of carcinogenesis go beyond genetic alterations and the simplified notion of TSGs and oncogenes. These alternative pathways regulating cellular function can also be used as biomarkers and novel therapeutic targets. This section discusses a few of the exciting developing fields in cancer research. In particular, we discuss the role of microRNA in HNSCC, the cancer stem cell hypothesis, biomarker profiling, and bioinformatics. Although these novel fields of research extend our understanding of the molecular biology of HNSCC, it is necessary to keep in mind that there is still much to be investigated in the current fields of study. Proper study of current biomarkers and therapeutic agents (individually and in combination) still have yet to be undertaken.

MicroRNAs

MicroRNA (miRNA or miR) molecules were discovered in *Caenorhabditis elegans* in 1993.[290] MiRs are small noncoding RNA molecules often found in introns (≈22 nucleotides) that regulate post-transcriptional gene expression.[291] With this discovery, a novel method of gene expression regulation was revealed (Fig. 76-4).[290] However, because of their short sequence, miRs have relatively nonspecific binding; a single miR may regulate the expression of several genes, making their study difficult. Various prediction algorithms identify several thousand targets per miR. It has been proposed that miRs may potentially regulate more than one third of all protein-coding genes.[292] As a result, they are involved in a variety of cellular processes, including the regulation of cellular differentiation, proliferation, and apoptosis.[293] Once miRs were discovered in the human genome, there was intense interest in their role in human diseases. It has been shown that these molecules play a role in cancer, and many studies have established that increased or decreased miR expression plays an important role in cancer biology.[294] Other studies have demonstrated that there is a unique expression profile or miR signature for certain cancer types.[294]

Results of some preliminary studies suggest that there is dysregulation of microRNA in HNSCC. A study comparing microRNA expression levels of 27 tumors and 8 normal tissue specimens revealed eight differentially expressed miRs. Of these, miR-494 (under-expressed in cancer) and miR-21 (over-expressed in cancer) were shown to be able to modulate cellular proliferation.[295] Mir-21 has been examined in several areas of molecular biology in addition to cancer biology.[296-298] Mir-21 has been implicated in chronic lymphocytic leukemia, lung adenocarcinoma, breast carcinoma, pancreatic cancer, hepatocellular carcinoma, papillary thyroid carcinoma, glioblastoma, T-cell differentiation, ovarian cancer, resistance to 5-fluorouracil, cervical carcinoma, multiple myeloma, B-cell lymphoma, uterine leiomyomas, chromosomal instability, and even hypertrophic heart muscles and vascular formation.[297,299-313] Mir-494 appears to be a marker unique to HNSCC.

Other studies have also attempted to study miR-21 as an antiapoptotic agent. Zhu and colleagues[314] proposed that miR-21 exerts some of its oncogenic effects through regulation of the tumor suppressor gene tropomyosin-1. Si and associates[298] proposed that miR-21 is able to decrease cell death through association with bcl-2. In addition, Chan and coworkers[297] proposed that caspase activation occurred with knockdown of miR-21. Interestingly, studies have shown that there is no association with other apoptosis-related proteins, such as p53, PUMA, FasL, and CDC25A. Other studies have shown that miR-21 is involved in invasion and metastasis. Meng and associates[309] proposed that miR-21 works through PTEN signaling in hepatocellular cancer to modulate matrix metalloproteases-2 and matrix metalloproteases-9.[309] Lastly, Loffler and coworkers proposed that in multiple myeloma, miR-21 is in the control of IL-6 via a Stat3 mediated pathway.[307]

There also has been some study showing miR-21 as a marker for response to therapy[310] and as a target for therapy. A study in a xenograft

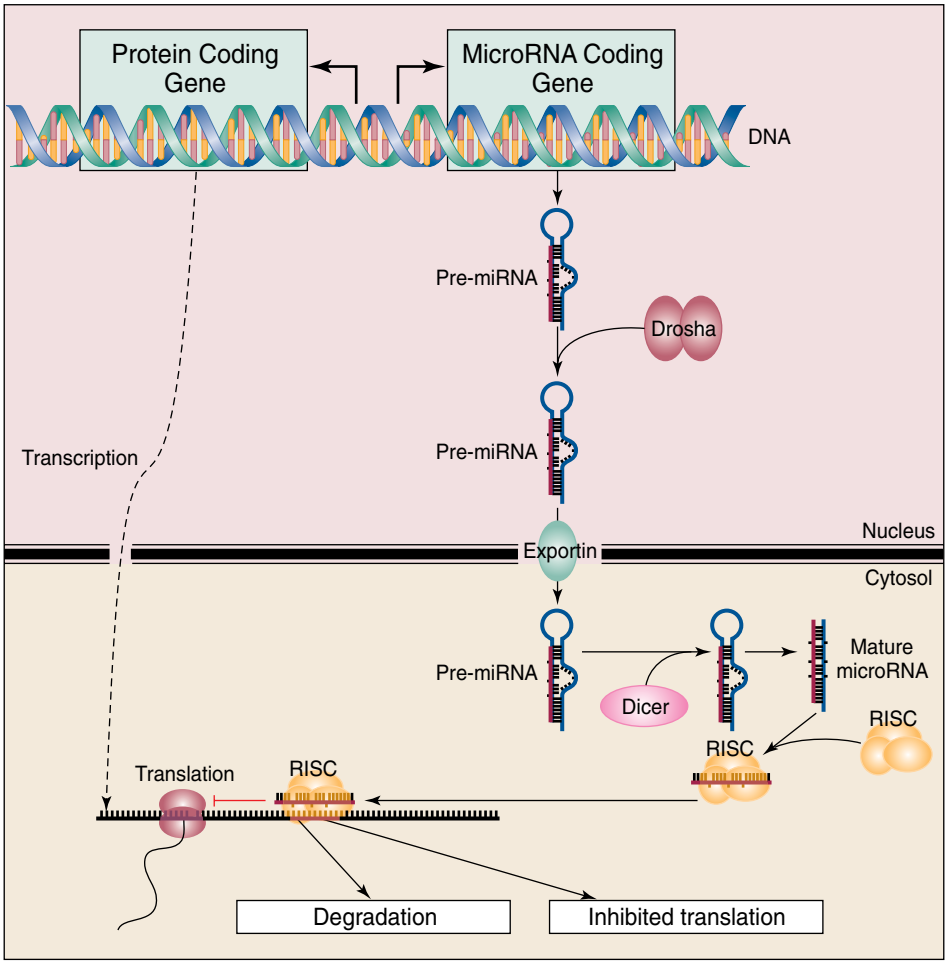

Figure 76-4. MicroRNA pathway and mechanism of action. Mature functional microRNAs (miRNAs) of approximately 22 nucleotides are generated from long primary microRNA (pre-miRNA) transcripts. First, the pre-miRNAs, which usually contain a few hundred to a few thousand base pairs, are processed in the nucleus into stem-loop precursors (pre-miRNA) of approximately 70 nucleotides by the RNase III endonuclease Drosha and its partner Pasha. The pre-miRNAs are then actively transported into the cytoplasm by exportin 5 and further processed into small RNA duplexes of approximately 22 nucleotides by the Dicer RNase III enzyme. The functional strand of the miRNA duplex is then loaded into the RNA-induced silencing complex (RISC). Finally, the miRNA guides the RISC to the cognate messenger RNA (mRNA) target for translational repression or degradation of mRNA. *(Modified from Chen CZ. MicroRNAs as oncogenes and tumor suppressors.* N Engl J Med. *2005;353(17):1768-1771.)*

mouse model showed that inhibiting miRs can reduce tumor growth by intravenous therapy.[311] This is a blossoming field in both cancer biology and molecular biology in general, and we are sure to see many more future studies of this interesting topic.

Cancer Stem Cell Hypothesis

The cancer stem cell hypothesis is the theory that a tumor is an aberrant organ that is sustained by a progenitor stem cell that drives tumorigenesis. These cells are the basis for the differentiated cells that make up the bulk of a tumor. This finding is based on the clinical observation that epithelial tumors, HNSCC included, contain cellular heterogeneity.[315-317] It is also based on the laboratory observation that only certain cells are able to recreate tumors in immunodeficient mice. For instance, tumorigenic and nontumorigenic populations of breast cancer and central nervous system cancer cells can be isolated on the basis of their expression of cell surface markers. Furthermore, these isolated tumorigenic cells, but not the nontumorigenic ones, have been shown to have the unique ability to form new tumors.[318-323]

Using methods similar to those employed in breast cancer, several groups of researchers have found a distinct population of cancer cells in HNSCC tissues that could produce not only tumors in mice (NOD/SCID mice and Rag2γDKO mice) but also the supporting stromal microdomains associated with cancer. These researchers used the cell surface expression of CD44, nuclear expression of BMI1 (a gene previously implicated in self-renewal and tumorigenesis),[324-328] positive staining for cytokeratin 5/14, and negative staining for involucrin to select out putative cancer stem cells. These cells, which were a small percentage of CD44-positive cells (<10% of cells are typically CD44-positive in a tumor), had the ability in culture to be serially passaged and to differentiate, two hallmarks of stem cells.

These findings elucidate the possible molecular mechanisms mediating the self-renewal of cancer cells and the ability of cancers to recur. In addition, this finding supports the need for research into targeted therapy against cancer stem cells. However, it must be first conclusively established that cancer stem cells indeed drive tumorigenesis. As this notion is still a theory, it cannot fully explain several clinical observations of HNSCC behavior. First, there is no explanation as to how these stem cells are able to escape surgical excision. Presumably these cells reside within the bulk of tumors, and for them to be the source of a local recurrence would imply that they are not within the surgical resection zone. Second, there has been no evidence that these cells are uniquely insensitive to chemotherapy. Furthermore, presuming that these cells have a high rate of replication, one would expect that they would be uniquely susceptible to our current chemotherapeutic regimens.

Bioinformatics

Bioinformatics and data mining have revolutionized our approach to both cancer detection and treatment. Many of the techniques and

experiments described in this chapter were based on the findings determined by genome-wide array-based approaches. As these results become publicly available as databases of the cancer genome, the efficiency of cancer research should improve exponentially. For instance, if a microarray is run on a tumor set by one institution and put in a publicly available database, any other institution will have access to this data set for research without having to recapitulate the experiment. The ability to manage and glean relevant information from these large data sets has become a field of study unto its own. The National Cancer Institute Center for Bioinformatics is currently working on this issue.

Proteomics

Another field that is still in its clinical research infancy but is well established in the basic science community is the field of *proteomics*, the study of protein structure and function. Whereas there are approximately 25,000 human genes, there are estimated to be more than 500,000 proteins in humans. This higher number is due to alternative splicing and post-translational modifications. This area of study is still new, but with the advent of high-throughput techniques, its progress has greatly increased. Two-dimensional gel electrophoresis and antibody arrays have been utilized as well as newer matrix-assisted laser desorption-ionization–time-of-flight (MALDI-TOF) and surface-enhanced laser desorption ionization–time of flight (SELDI-TOF) techniques, which have allowed for rapid identification of protein peaks involved in HNSCC. However, the greatest challenge is in identifying not the differentially expressed proteins but rather the in vivo functions of proteins and how they contribute to cancer.

Several proteins have been identified as being significantly upregulated in HNSCC on the basis of proteomic approaches.[329-332] However, although several proteins correspond to genes known to play a role in carcinogenesis, it is often difficult to identify the protein merely on the basis of its peak. Interestingly, the signature pattern of peaks can be used as a biomarker of disease that is able to classify normal mucosa and HNSCC with a high degree of accuracy.[330,333] More time is needed to determine whether there is any clinical significance to these findings. However, another study found that factors such as tobacco and alcohol use as well as gender could confound the data and lead to only moderate success in differentiating the cancer and normal test groups.[334] Serum biomarkers have also been studied as a means of early detection in a cohort of patients with hypopharyngeal carcinoma, with a sensitivity of 92% and a specificity of 82% in a training set.[335] Another similar study in HNSCC patients looked at plasma protein levels with SELDI-TOF and found that the pattern of peaks was more important than the actual identification of the corresponding proteins.

As mentioned previously, the field of proteomics is at its relative infancy. The next steps in this field will be to identify which proteins are reliable biomarkers of disease and to elucidate their functional role in carcinogenesis. Both aims are lofty goals, although they are essential to our understanding of HNSCC.

Conclusion

In this chapter, we have reviewed the current understanding of the molecular biology of HNSCC, introduced the future directions of research in this field, and discussed the clinical implications. With the accelerating pace of research discovery using high-throughput technology coupled with growing use of bioinformatics, advances in clinical care should also improve significantly. We should expect to see advances in all aspects of patient care but specifically in the fields of molecular biomarkers and targeted therapy. Better screening and surveillance tests, improved prognostic markers, and tailored and targeted therapies for patients are all on the horizon. There are several challenges to bringing these improvements to clinical reality. First, it is necessary to study any prospective biomarker and therapy in properly run clinical trials. Poorly run trials are both a waste of resources and provide no worthwhile clinical conclusions. Second, it is imperative that the right treatments and markers are chosen for study, either individually or in combination. Currently, many potential markers and therapies are available. Choosing the right dose, combination, and patient population is essential to optimizing the chances for a successful trial and maximizing efficient use of research resources.

CHAPTER SEVENTY-SEVEN

Radiotherapy for Head and Neck Cancer: Radiation Physics, Radiobiology, and Clinical Principles

Aron Popovtzer

Avraham Eisbruch

Key Points

Basic Radiation Physics

- The unit of measure for radiation is the gray (Gy), which corresponds to 1 joule being deposited per kilogram of material.
- The two main energy sources in use are electrons and photons.
- Electrons differ from photons in that electrons travel only a certain (short) distance within tissue. The deposition of the majority of their dose is in superficial tissues, so they are mainly used for treating superficial tumors.
- Radiation treatment includes the following processes: simulation, treatment planning, verification, dose delivery, and quality assurance.
- Planning targets includes gross tumor volume; clinical target volume, which includes areas at risk for spread, such as adjacent tissues or draining lymphatic regions; and planning target volume, which includes margin to correct for possible variability in daily positioning and patient motion during treatment.

Radiation Biology

- The main radiation biology principles are the four Rs of radiotherapy, as follows: (1) repair (of sublethal damage); (2) redistribution (across the cell cycle); (3) repopulation; and (4) reoxygenation.
- Rapidly dividing tissues, such as the skin, mucous membranes, bone marrow, and tumor cells, are responsible for the acute toxicity. Acute toxicity correlates with the total treatment time, while late-responding tissues such as the spinal cord, brain cells, and connective tissue are responsible for the late toxicity from radiation therapy. The level of this toxicity depends mainly on total dose and dose per fraction.

Clinical Principles of Radiotherapy

- Altered fractionation (accelerated or hyperfractionation) achieves better local control and higher overall survival than conventionally fractionated radiation but has not yet been compared with conventional chemoradiation.
- The concurrent addition of chemotherapy to radiation in advanced head and neck cancer improves organ preservation and survival.
- In the postoperative setting, the addition of concurrent chemotherapy to radiation improves survival in cases with extracapsular extension and/or microscopically involved surgical margins.
- The use of intensity-modulated radiation therapy in advanced head and neck cancer may offer sparing of vital organs, including major salivary glands, minor salivary glands dispersed within the oral cavity, mandible pharyngeal musculature, inner and middle ears, temporomandibular joints, temporal brain lobes, and optic pathways.
- Intensity-modulated radiation therapy offers a potential for better tumor control by reducing the constraints on the tumor dose that are due to critical organs that occasionally limit the tumor boost doses in conventional radiation therapy.
- Acute side effects occur during radiation therapy and in the following weeks. They include mucositis, odynophagia, dysphagia, hoarseness, xerostomia, dermatitis, and weight loss. Late toxicity includes xerostomia, osteoradionecrosis, fibrosis, thyroid dysfunction, carotid artery rupture, and radiation-induced myelitis. These toxicities may become apparent many months or even years after treatment.

The aim of this chapter is to provide an outline of the basic principles of physics and biophysiology that lie behind modern radiotherapy. This overview is intended to enable the clinician to understand the physics background of the various radiation treatments, with a special focus on head and neck treatment technologies.

Toward the closing years of the nineteenth century, many investigations into electricity characteristics were conducted, one of them demonstrating that electric potential placed across two separated platinum electrodes produces a spark.[1] British physicist William Crookes demonstrated that if the two electrodes were placed within an evacuated glass tube, the vacuum would eventually cause the walls of the vessel to fluoresce.[2] On November 8, 1895, Wilhelm Roentgen, while performing an experiment with the Crookes tube, accidentally left a piece of paper painted with barium platinocyanide nearby; he noted that the paper fluoresced and realized that this fluorescence of the paper could have been caused by a new, invisible type of ray that the tube was now emitting. Thus, the x-ray was discovered.

Radioactivity was discovered shortly after by Henri Becquerel, who investigated the capability of different substances to produce x-rays. He observed the darkening of photographic plates by uranium salts and concluded that the same x-rays were emitted spontaneously and continuously from the uranium.[3] Pierre and Marie Curie, who read his results, coined the term *radioactivity* to describe this phenomenon. In 1898 they isolated a material with radioactivity 60 times higher than uranium and called it radium.[4]

These discoveries led to radiation biology experiments. The first documented experiment was performed unintentionally at about the same time, when Antoine Becquerel developed a "burn" on his chest from carrying a vial of radium salt in his vest pocket. It soon became apparent that radiation had the ability to produce profound biologic changes. In the beginning it was believed to be a magical cure for almost every known illness. The first documented success was reported in 1899 in Stockholm[5] by Thor Stenbeck, who treated a 49-year-old woman's nasal basal-cell carcinoma. He delivered 100 treatments in the course of 9 months, and the patient was alive and well 30 years after the treatment. In 1901, Dr. Frand Williams in Boston reported on the successful treatment of a lip cancer.[5] The early treatments often involved very large single exposures that resulted in extensive skin toxicities and other complications. Therefore, only superficial sites were originally treated by the direct application of radium.[6] Eventually, physicians started to insert radium directly into deep-seated tumors, effectively beginning the field of brachytherapy.[7]

The use of external beam treatments made its leap in 1922 when Coutard and Hautant reported a new concept of fractionated treatments: advanced laryngeal cancer could be cured without severe toxicities using fractionated treatments.[8] Advances in measurements were also achieved when the skin erythema dose (the dose of x-rays required to give a light skin reaction) was replaced by the roentgen in 1928,[9] which was later replaced by the rad. The *rad* is the unit of absorbed dose and is a measure of the energy deposition per unit mass by all types of ionizing radiation. The next step was achieved with the development of higher-energy machines capable of depositing dose at depth.

As technology has progressed, radiation therapy (RT) has become increasingly sophisticated, with computer controls to deliver exact and modulated doses to depths and specific areas within the treatment field. The advances in energy technologies led to the routine use of high-energy and accurate deep-penetrating radiation produced by linear accelerators. Nuclear physics innovations produced many artificial radioisotopes, enabling the use of high-dose brachytherapy, which shortens treatment time and simplifies the radioprotection procedures.

Aside from the technology advances, radiation treatment has a special role in head and neck cancer (HNC), in which it has in many cases a major advantage over traditional surgery in its ability to preserve organs, improving quality of life without compromising the survival rate.

Basic Physics

Characteristics of Radiation

Radiation refers to the propagation of energy through space or a medium (Fig. 77-1). Radiation can be broadly classified as either particulate or electromagnetic. If the radiant energy is carried off by a particle that has rest mass, the radiation is called "corpuscular" or "particulate" radiation. Examples of particulate radiations are electrons, beta particles, protons, neutrons, and heavy charged particles.

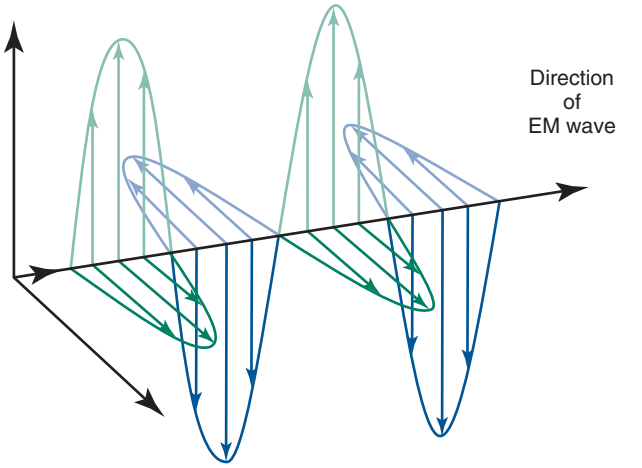

Figure 77-1. Propagation of electromagnetic (EM) radiation with oscillating electric and magnetic fields. *(From Saw CB. Foundation of Radiological Physics. Omaha, NE: C. B. Saw Publishing; 2004:10, with permission.)*

Electron beams, which are produced in a linear accelerator, are widely available for the treatment of superficial lesions in clinical radiation oncology practice. In addition, mixed beams consisting of electron beams and photon beams are used to treat lesions that require higher surface doses. Negatrons from strontium Sr-90 are used in the treatment of restenosis in intravascular coronary brachytherapy. Although other forms of particulate radiation have been used experimentally in the past, their use has been limited to a few centers. The use of protons is gaining popularity in many centers specifically for pediatric tumors.

Electromagnetic radiation is a packet of energy (a photon) that propagates through space. It has no rest mass and propagates at the speed of light. This discrete energy (E) is related to its associated frequency (ν) as follows:

$$E = h\nu \qquad \text{(Eq. 77-1)}$$

where h is Planck's constant, having a value of 6.626×10^{-34} joule-second (J.s). The energy of a photon is often expressed in electron volts (eV). One eV represents the amount of energy required to accelerate an electron through a potential of one volt. The frequency (v) of a photon is related to its wavelength (λ) as follows:

$$\nu = c/\lambda \quad 2 \qquad \text{(Eq. 77-2)}$$

where $c = 3.0 \times 108$ m/sec, the speed of light in a vacuum. The waves of electromagnetic radiation are composed of oscillating electric and magnetic fields that are orthogonal to each other and to the direction of propagation, as shown in Figure 77-1. The electromagnetic spectrum spans a broad and continuous range from radiowaves to x-rays with wavelengths from 106 to 10^{-13} m. Radiation with wavelengths shorter than visible light is classified as ultraviolet rays, x-rays, and gamma rays. The boundaries between these regions are not sharply defined. For example, x-rays and gamma rays are indistinguishable except for their origins, one from the orbital electrons and the other from the nucleus, respectively. Different types of electromagnetic radiation interact differently with the same material (see Fig. 77-1).

Radiation Production by Radioactive Decay

As previously discussed, radioactivity is the phenomenon in which radioactive materials disintegrate by emitting radiation to achieve

nuclear stability. The amount of radioactivity is measured in units of curie (ci), named after the Polish-born French scientist, Madame Curie. A curie is equal to 3.7×10^{10} disintegrations per second. A smaller unit, the millicurie (mci), is routinely used in the field of radiologic physics. The SI unit of radioactivity is the *becquerel*. It is equal to 1 disintegration/sec, typically denoted as the reciprocal of 1 second (s-1).Unstable nuclei decay by emitting alpha particles, beta particles, or gamma rays. An alpha particle (denoted by the symbol α) is actually stripped helium consisting of two protons and two neutrons. A negative beta particle (β^-) carrying a unit negative charge (−1e) is called a negatron; a positive beta particle (β^+) carrying a unit positive charge (+1e) is called a positron.

Unstable atoms de-excite by emitting x-rays. An atom is said to be in an excited state if any orbital electron is not in its lowest energy state. When an atom is in an excited state, an electron from the higher energy shell jumps into the vacant position. As a consequence of this transition, an x-ray is emitted. A cascade of x-rays can be emitted after a tightly bound electron is ejected. The process of ejecting an orbital electron is called *ionization radiation*.

Radiation Production from Linear Accelerators

Another type of radiation is termed bremsstrahlung[11] (German for "braking radiation"), electromagnetic radiation produced by a sudden slowing down or deflection of charged particles (especially electrons) passing through matter near the strong electric fields of atomic nuclei.

Internal bremsstrahlung arises in the radioactive process of *beta decay*, which consists of the production and emission of electrons by unstable atomic nuclei or the capture by nuclei of one of their own orbiting electrons. These electrons, deflected from their own associated nuclei, emit internal bremsstrahlung. During the deceleration process, the electrons interact with the atomic nuclei, resulting in the emission of bremsstrahlung radiation. Before 1950, external beam RT was accomplished in this way, with a maximum energy of about 300 keV. As just stated, these x-rays are low in energy compared to what is used today, with the disadvantages of poor penetration and maximal deposition of dose at the skin.

Today, other types of radiation are produced in nuclear reactors, cyclotrons, and linear accelerators.

Interaction of X-Rays with Matter

After these high-energy x-rays are produced successfully, they can interact with matter via several different processes. Each interaction type has a probability, based on the composition of the matter and the energy of the x-rays. These interactions cause some photons (x-rays) to be removed from the forward-moving x-ray beam, an effect called *attenuation*, which is basically the loss of intensity and subsequent decrease in the deposition of dose as the beam reaches greater depths. The five possible interactions of x-rays with matter are as follows:

- Coherent scattering
- The photoelectric effect
- The Compton effect
- Pair production
- Photodisintegration

The most important of these interactions in RT are represented in Figure 77-2.

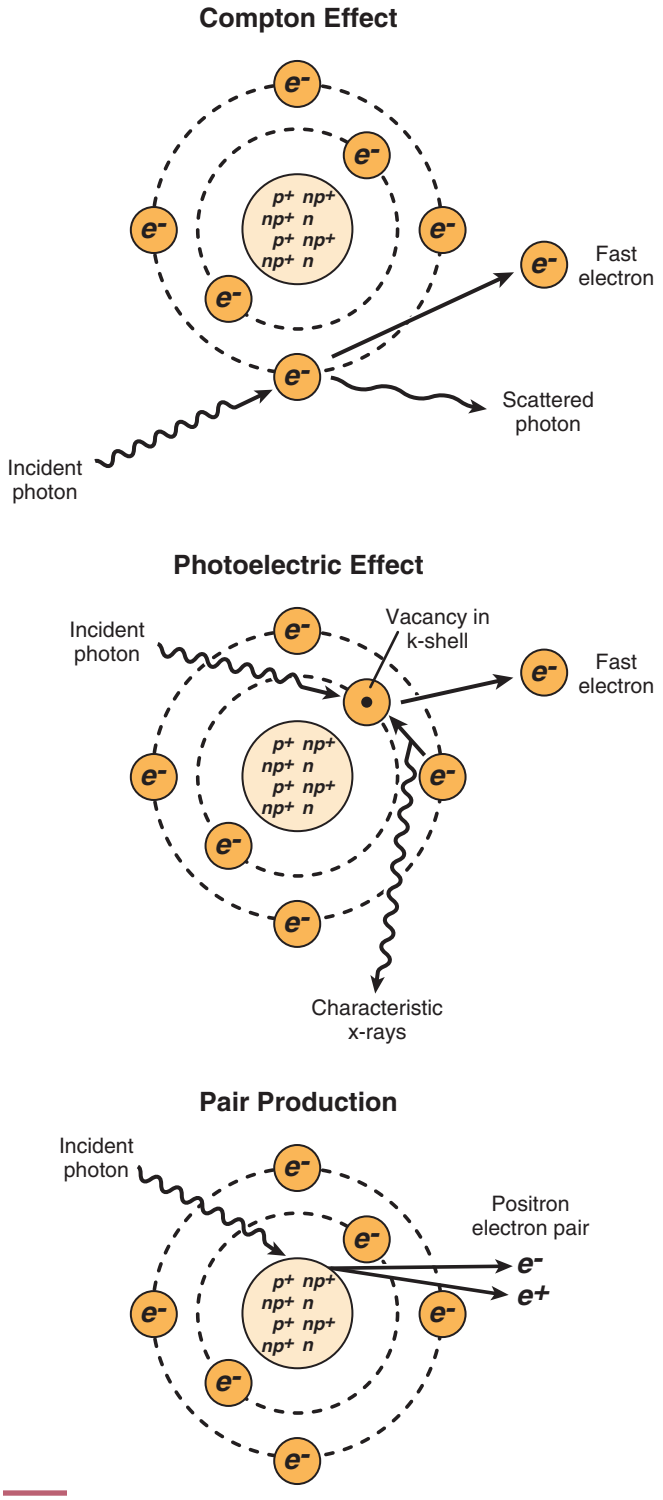

Figure 77-2. The major radiation interactions. e, electron; n, neutron; p, proton. *(Redrawn from Cox JD, Ang KK, eds.* Radiation Oncology: Rationale, Technique, Results. *8th ed. St. Louis: Mosby; 2003:5.)*

Coherent Scattering

Also called classic scattering, coherent scattering occurs when x-rays are of low energy. In coherent scattering, a photon is separated from an electron with a resultant change in direction but no change in energy. The amount of coherent scattering that occurs in therapeutic (and even diagnostic) radiation is negligible. Coherent scattering is important in processes such as x-ray crystallography. It is a dominant process at low photon energies (below 10 keV) and in material with a high atomic number. Because of its low photon energy, coherent scattering does not contribute to either diagnostic radiology or RT.

Photoelectric Effect

The photoelectric effect was first described by Albert Einstein, and it was this contribution to physics, not his discoveries regarding relativity, that led to his being awarded the Nobel Prize in 1921. In the

photoelectric effect, a photon interacts with a tightly bound inner-shell electron of the target tissue. Complete absorption of the photon's energy occurs, with the ejection of the electron from the orbit. The probability of a photoelectric interaction is highly dependent on the atomic number (Z) of the material through which the photon is passing, and thus the photoelectric effect is very important in diagnostic radiology. It is the process that is the basis for the radiographic contrast between tissues (e.g., between bone [calcium and phosphorus] and fat [carbon and hydrogen]). The photoelectric effect is in most instances undesirable in RT. Typically, we do not want bony structures to be shielding underlying tumors. With higher-energy x-rays such as are used in radiotherapy, however, the contribution of the photoelectric effect is relatively small. In comparison this effect is high in low-energy radiation used for diagnostic radiology, in which the difference between bone and tissue absorption provides the necessary tissue contrast.

Compton Effect

Compton scattering is the most important interaction in energies within the range used for RT. In Compton scattering, a photon transfers energy to an electron of the target tissue, causing the ejection of this electron. In contrast to the photoelectric effect, however, the energy of the photon is not completely absorbed, and is scattered at an angle relative to the forward direction of the original photon. This secondary photon interacts with tissue again and again, ionizing and depositing dose with each interaction. These interactions and subsequent ionizations are responsible for the biologic effects on tissues during RT.

In contrast to the photoelectric effect, Compton interactions are independent of the atomic number of the tissue because the interactions tend to be with the loosely bound outer electrons in atoms, where the energy binding an electron to the atom is much less dependent on the atomic number (Z). This results in a fairly even probability of interaction and, hence, in fairly even deposition of dose throughout the different biologic tissues with which the x-rays would interact in a patient.

Pair Production

Pair production occurs at high energies as a result of interaction of a photon with a nucleus, with the spontaneous disappearance of the photon and the production of an electron and a positron. Pair production occurs at higher energies and becomes dominant at ranges above standard treatment, at about 25 megaelectron volts (MeV); thus it rarely has a role in treatment.

Photodisintegration

At very high energies, x-rays can deposit so much dosage into the nucleus of the target tissue that partial disintegration of the nucleus occurs, with emission of neutrons from the nucleus. Although this process has little importance in the clinical interactions used in RT, the production of neutrons is important in the planning of shielding around high-energy linear accelerators for the sake of protecting patients and personnel from potentially carcinogenic low-dose radiation.

Deposition of Dose

The absorbed dose from an x-ray beam is the measure of the energy deposited by the beam and absorbed by the target. Radiation doses were historically measured by roentgen, which was a unit of exposure but did not quantify the dose the patient absorbs. In the late 1950s the *rad*, an abbreviation for "radiation-absorbed dose," was introduced. The rad is equivalent to the deposition of 100 ergs (10^{-7} joules) per gram of material.

More recently, an international commission has agreed that radiation doses should be specified in terms of gray (Gy), which corresponds to the deposition of 1 joule per kilogram of material. Numerically, doses in rad can be converted to equivalent doses in Gy by dividing by 100 (i.e., 100 rad = 1 Gy). This is closely related to the observed biologic effects, how and where the dose is deposited is obviously very important. Because the amount of radiation absorbed by the target is assumed to be as stated previously, x-rays in the megavoltage energy range, such as those used in RT, exhibit the phenomenon of skin sparing, whereby the dose deposited in tissue is relatively low at the surface but increases rapidly over the first few millimeters. The region of rapidly increasing dose is known as the *buildup region*. This rapid increase occurs because of the forward-moving photons interacting with electrons of the target tissue via the interactions described previously. Because these electrons are also propelled forward but have a shorter course than the photons, there becomes an area at depth at which the number of electrons entering the plane of interaction from superficial interactions is exactly equal to the amount leaving the plane from interactions in that plane. This plane is termed the D_{max}, as it represents the maximum number of ionization events past this point; as more interactions between the photon beam and tissue occur, fewer photons are available to travel forward and deposit dose at greater depths. This process, as previously described, is called *attenuation*. How quickly a photon beam is attenuated (i.e., how much dose it deposits at depth) depends on qualities both within the beam and within the target tissue. The most substantial effect on depth dose from the photon beam itself is the beam's energy.

Deposition of Energy

As a high-energy photon beam traverses through a medium, the atoms are excited and ionized. Of the two interacting processes, ionization is disruptive to atoms, changing the molecular integrity and leading to cell death in tissue. The ejected electrons undergo further interactions and deposit their energies to the medium through excitation and ionization. The amount of energy transferred to the electrons at the initial point of interaction is called *kerma*. The second stage of the energy-transfer process is called the *absorbed dose*. Not all the energy transferred to the medium at the initial point of interaction is absorbed. Some of the energy is radiated away as bremsstrahlung, and the remaining is called *collision kerma.* The absorbed dose is the energy retained in the medium along the path of the electrons. If the electron track has an appreciable length, the transfer of energy (kerma) and the absorption of energy (absorbed dose) take place at separate locations.

When a photon beam enters a medium, the initial ionization of atoms takes place at the surface. The energy is directly transferred to the ejected electrons, and therefore kerma has a maximum value at the surface. As the beam proceeds farther, the photon intensity decreases as a result of absorption and scatter. Hence kerma decreases as a function of depth into the medium. On the other hand, absorbed dose is initially low at the medium surface, increases to a maximum, and thereafter decreases as a function of depth. The region from the surface to depth of maximum dose is called the *buildup region*. The position of maximum absorbed dose is called the *point of equilibrium*, and the region beyond the maximum dose is the region of *transient electronic equilibrium*.

Radiation in Conventional Medicine

External beam radiotherapy is the most frequently used form of radiotherapy. With this technique, the patient lies on a bed and an external source of radiation is pointed at a particular part of the body. Kilovoltage (which may be either superficial or deep) x-rays are used for treating skin cancer and superficial structures. Megavoltage x-rays are used to treat deep-seated tumors (e.g., bladder, bowel, prostate, lung, brain). Megavoltage electrons are used mainly for treating superficial tumors.

The energy of diagnostic and therapeutic gamma rays and x-rays is expressed in kilovolts (kV)or megavolts (MV), whereas the energy of therapeutic electrons is expressed in terms of megaelectron volts (MeV). In diagnostic and therapeutic situations, this voltage is the maximum electric potential used by a linear accelerator to produce the photon beam. The beam is made up of a spectrum of energies: the maximum energy is approximately equal to the beam's maximum electric potential times the electron charge. Thus, a 1-MV beam will produce photons of no more than about 1 MeV. The mean x-ray energy is only about a third of the maximum energy. Beam quality and hardness may be improved by special filters, which improve the homogeneity of the x-ray spectrum.

In the medical field, useful x-rays are produced when electrons are accelerated to a high energy. Some examples of x-ray energies used in medicine are as follows:

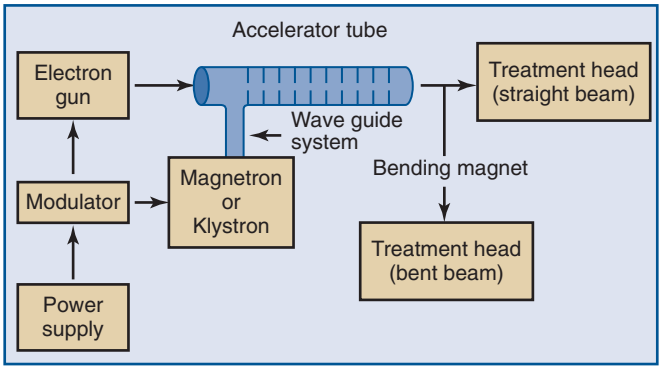

Figure 77-3. Block diagram of a typical medical linear accelerator. *(From Leibel SA, Phillips TL, eds.* Textbook of Radiation Oncology. *Philadelphia: WB Saunders; 1998:110.)*

Diagnostic x-rays: 20 to 50 kV

Superficial x-rays: 50 to 200 kV

Orthovoltage x-rays: 200 to 500 kV

Supervoltage x-rays: 500 to 1000 kV

Megavoltage x-rays: 1 to 25 MV

Of these energy ranges, megavoltage x-rays are by far the most common in radiotherapy. Orthovoltage x-rays do have limited applications, and the other energy ranges are not typically used clinically.

Medically useful photon beams can also be derived from a radioactive source such as cobalt Co-60, iridium Ir-192, cesium Cs-137 and radium Ra-226 (which is no longer used clinically). Such photon beams, derived from radioactive decay, are more or less monochromatic and are properly termed gamma rays.

Orthovoltage x-rays are produced by linear accelerators operating at 200 to 500 kV. These are also known as "deep" or "superficial" machines, depending on their energy range. Orthovoltage units have essentially the same design as diagnostic x-ray machines. These machines are generally limited to less than 600 kV.

Linear accelerators (linacs) produce megavoltage x-rays. Commercially available medical linear accelerators produce x-rays and electrons with an energy range from 4 MeV up to around 25 MeV.[11] The x-rays themselves are produced by the rapid deceleration of electrons in a target material, typically a tungsten alloy, which produces an x-ray spectrum via bremsstrahlung radiation. The shape and intensity of the beam produced by a linear accelerator may be modified or collimated by a variety of means. Thus, conventional, conformal, intensity-modulated, tomographic, and stereotactic radiotherapy are all produced by specially modified linear accelerators (Fig. 77-3).

As the particle bundle passes through the tube it is unaffected, and the frequency of the driving signal and the spacing of the gaps between electrodes is designed so that the maximum voltage differential appears as the particle crosses the gap. This accelerates the particle, imparting energy to it in the form of increased velocity. At speeds near the speed of light the incremental velocity increase will be small, with the energy appearing as an increase in the mass of the particles

Additional magnetic or electrostatic lens elements may be included to ensure that the beam remains in the center of the tube and its electrodes (see Fig. 77-3).

Linear Accelerators

Linear accelerators typically produce beam energies ranging from 6 to 18 MeV, and the dose at depth increases with beam energy. Therefore, an 18-MeV photon beam would deliver more dose to a given depth in a patient than would a 6-MeV photon beam. An 18-MeV beam would also have more skin sparing (i.e., it would have a greater D_{max}). Another aspect that affects the depth dose is the size of the field of radiation used to treat the patient. With a larger field size, there is greater scattering of photons within the field during the interactions with electrons. This scatter effect leads to more interactions, which translate into a higher deposition of dose at depth. In other words, the dose at 10-cm depth within a patient from a photon beam that has a field size of 20 cm × 20 cm would be higher than the same photon beam with a field size of 5 cm × 5 cm. Many other factors go into the calculation of dose delivered at varying depths in a patient, including scatter from the collimators in the machine, blocks to shield normal tissue, and wedges and compensators (which are used to shape the photon beam). Another main modifier in the target tissue that affects dose at depth is the density of the tissue being treated. Lung, for example, being less dense than soft tissue, allows more photon transmission. Additionally, the inverse square effect, first noted by Roentgen, must be taken into account. All of these factors must be taken into consideration in the determination of the dose being delivered to structures within the patient. Calculation of the dose given to a tumor or other volumes within a patient is thus complex, requiring much more knowledge than simply how much x-ray dose the machine is putting out.

As an energy source, electrons differ from photons in that electrons travel only a certain (short) distance within tissue. They are very light particles compared with the nuclei of the target tissue with which they interact. Hence, the electrons lose a large fraction of their energy in a single process. This leads to much less skin sparing and the deposition of the majority of the dose in superficial tissues. Consequently, however, they are very useful for treatments in which the target of the radiation lies close to the surface of the patient, such as skin tumors (Fig. 77-4).

Particle Beams

High-energy charged particle beams interact with tissues in a unique way. At first, the charged particles lose energy gradually, but there is an intense release of energy at the end of the range. This intense energy deposition is called the *Bragg peak*. This feature provides a means of delivering the maximum dose to a target at a specified depth. Often in clinical practice, the particle beams are modulated to change the energy, and hence the depth, to widen the dose deposition to cover the target, and this change is in addition to allowing optimized dose delivery.

In the strictest sense, the electron beams used in conventional radiotherapy facilities are a type of particle radiation, but this section is devoted to the heavier charged particles (e.g., protons, α-particles, heavy ions, π-mesons, and fast neutrons) used experimentally at a small number of radiotherapy centers throughout the world. These particles are of special interest because of their different radiobiologic properties or their better depth-dose characteristics, which allow for higher tumor doses without causing a commensurate increase in the dose to the surrounding healthy tissues.

One particle for which there has been a great amount of clinical work is the *fast neutron*.[12,13] Fast neutrons are of clinical interest because of their radiobiologic properties, which occur because of the much greater amount of energy they deposit when they go through tissue. Neutrons are neutral particles and interact with the atomic nuclei, producing "heavy" charged particles such as protons, α-particles, or nuclear fragments that in turn create a dense chain of ionization events as they go through tissue. The distribution of these secondary particles depends on the energy spectrum of the neutron beam, so the biologic properties of the beam depend strongly on its energy spectrum. Neutrons used in therapy generally are produced by accelerating charged particles, such as protons or deuterons, and impacting them on a beryllium target.

There is considerable interest in using charged particle beams directly for therapeutic purposes, which generally requires beams of much higher energy than those used to produce neutrons. The lighter particles, such as protons[14] and α-particles, are of interest because of their extremely favorable depth-dose characteristics. The radiobiologic properties of these beams are similar to those of conventional photon or electron beams. Heavy charged particles combine the favorable depth-dose properties of the proton and α-particle beams with the

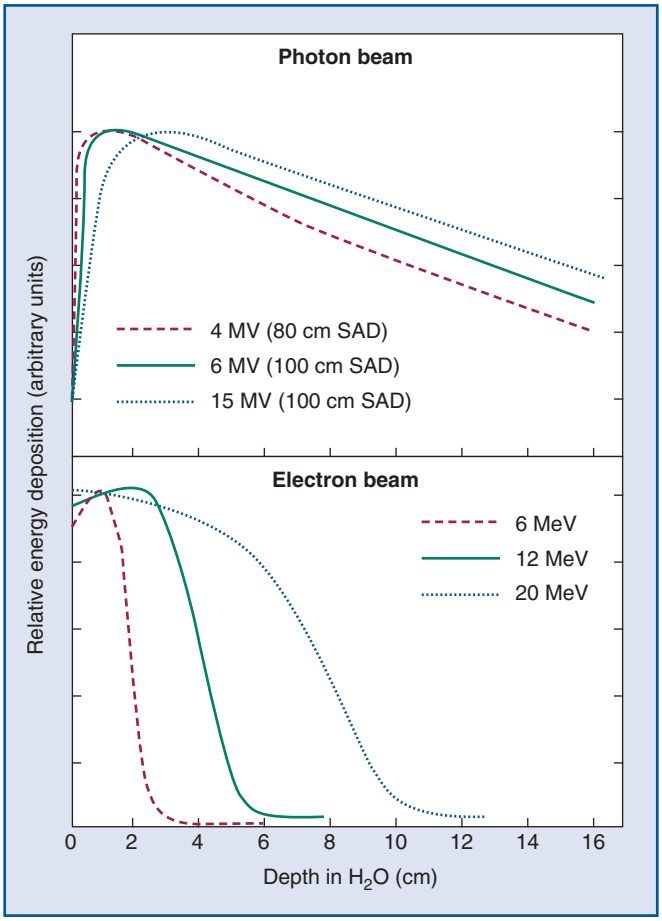

Figure 77-4. Typical depth-dose curves for megavoltage photon and electron beams commonly used in the therapy of head and neck cancers. The *upper panel* shows curves for 10 cm × 10 cm fields for a 4-megavolt (MV) (80-cm source axis distance [SAD]) linear accelerator *(dashed line),* a 6-MV (100-cm SAD) linear accelerator *(solid line),* and a 15-MV (100-cm SAD) linear accelerator *(dotted line)*. The *lower panel* shows depth-dose curves for 10 cm × 10 cm fields for 6–megaelectron volt (MeV) *(dashed line),* 12-MeV *(solid line),* and 20-MeV *(dotted line)* electron energies.

favorable biologic properties of the neutron beams. Energies are on the order of several hundred MeV per nucleon, rather than the few MeV per nucleon for the recoil fragments produced by neutrons. These highly energetic particles do not deposit much energy in tissue until they reach the end of their path, where they are moving slowly. Hence, they do not produce much radiation damage in the intervening tissues. Because of their extremely high cost and general unavailability, however, these beams are not widely in use. Interest in proton beams has grown, and the number of radiotherapy facilities using protons in the United States is expected to rise.

Treatment Aspects of External Beam Radiation

A series of technical tasks must be performed to prepare a patient to undergo external beam RT. The purpose of these tasks—simulation, treatment planning, verification, dose delivery, and quality assurance—is to ensure that high radiation doses are delivered to the patient in an accurate and controlled manner. Usually the processes of simulation, treatment planning, and verification take 1 to 3 days. The setup and treatment planning must be individualized to maximize the dose delivered to the target while minimizing the irradiation of surrounding normal tissue. Any inaccuracy in this process could cause further delay in the initiation of the radiation treatment.

During simulation, the patient setup is assessed for ease of positioning and daily reproducibility. This process involves the use of

Figure 77-5. Photograph of a linear accelerator.

immobilization devices (anything that can hold a patient in position during treatment) and treatment aids (any kind of support to make patient comfortable). In most HNC cases, a mask that immobilizes the head and neck is used.

After the patient is immobilized, at least two reference points are marked on the patient with x-ray markers to define a reference plane close to the internal tumor target. The marking of the reference points is aided by the use of lasers. Next, the region of interest on the patient is scanned using computed tomography (CT), often using a dedicated CT-simulator scanner to obtain CT images for image-based treatment planning. The images are scanned to a treatment planning station. The radiation oncologist then outlines the tumor target region and critical surrounding normal structures on the axial images on the basis of the CT scan, and a prescribed dose with appropriate normal tissue margin is provided. On the basis of this information, a medical physicist or a medical dosimetrist designs an individualized treatment plan. The challenge in the plan is to deliver the prescribed dose uniformly to the tumor or tumor bed target while maintaining a very low dose to the critical normal structures. Although these goals are achievable, it takes time to arrive at an optimized individualized plan.

Aside from delivering the prescribed dose to the target and minimal dose to the surrounding critical structures, the individualized plan must be evaluated for *deliverability*—that is, the selected beam orientation must be such that the linear accelerator does not collide with the patient or the table, and the technical parameters of the patient's plan must comply with the technical requirements of the delivery machine. Next, the individualized machine-delivery parameters are downloaded into a record verification system database. Patient *verification* is the process of ascertaining that the individualized plan is correct and deliverable. *Correct* here means that the patient is easily placed into treatment position, relatively comfortable, and immobile, the setup is reproducible, and the target is at the appropriate position relative to the isocenter according to the plan. Finally, there is clearance to avoid patient-equipment collision. During verification, orthogonal radiographs or individualized field radiographs are taken, with films or a portal imager, for assessment and for documentation of the setup. In addition, machine parameters are captured into the database. These images can be used to assist in repositioning the patient as necessary.

Typically, the radiation dose is delivered to the patient using a linear accelerator (Fig. 77-5). The radiation beam as produced is a forward peak; that is, it has extremely high intensity along the beam axis. It must pass through a conical metallic flattening filter to create a uniform field beam for clinical use. As the clinical beam exits the linear accelerator, it is collimated by a pair of jaws or a multileaf collimation

(MLC) system (see Fig. 77-5). The multileaf collimation system is used to shield and protect normal structures (replacing the antiquated and cumbersome lead blocks). In addition, the system is used to modulate beam intensity in intensity-modulated RT. The linear accelerator has a gantry that allows the rotation of the treatment head around the patient. Hence, the radiation beam can be directed at the target from multiple positions to reduce dose to the normal tissues. Because of the high voltage, moving parts, and high dose, the linear accelerator must be properly calibrated and properly maintained for its safe use (see Fig. 77-5).

In addition to external beam therapy, radiation oncology departments offer brachytherapy services. In brachytherapy (*brachy* is derived from the Greek word for "short"), sealed radioactive sources are implanted near or directly into tumors. The principal advantage of brachytherapy has been its rapid dose fall-off away from the source. Brachytherapy is generally invasive. When the implant requires short-lived radioactive sources, preimplant dosimetry is performed to determine the number of sources required. After the number of sources has been determined, they are ordered from the vendors. When the sources arrive, they must be assayed and prepared for implantation. On the day of implantation, a final dosimetry plan is created and the sources (often in the form of seeds, as used in prostate brachytherapy) are implanted according to the new treatment plan. For cases involving sources with long half-lives, catheters are provided to the radiation oncologist for implantation. After the implantation, the patient must undergo simulation, and a final treatment plan is generated, similar to the process already described for external beam RT. With advances in computer technology, remote afterloading brachytherapy is now being practiced, in which radioactive sources are remotely loaded into a patient and can be retracted at any time if necessary.

Treatment Planning

Successful treatment planning is imperative to the success of a radiation treatment course. The goal is to identify the full extent of the tumor and areas of possible spread. Several considerations must be taken into account. They include the tumor histology, the extent of the gross disease, regions of microscopic spread but no gross disease, whether the treatment is being given postoperatively or in an undisturbed tumor bed, and the tolerances of adjacent structures. A plan must then be devised to treat this entire region to the dose desired for each region while keeping the volume of each normal tissue below its tolerance. After the image data sets are obtained in any type of simulation, careful review of the clinical data must be made to delineate the tissue in need of treatment. This volume to be treated is defined as the target volume and is created by adding three components together. First, the gross tumor volume (GTV) is noted. This volume is expanded to create the clinical target volume (CTV) by accounting for the areas at risk for spread, such as adjacent tissues or draining lymphatic regions. The planning target volume (PTV) is calculated by adding margin to correct for possible variability in daily positioning and patient motion during treatment.

The remainder of the planning process involves choosing the number of radiation beams required, the energy of these beams, and the angles and weighting of the beams needed to deliver the required radiation dose to the tumor with optimal sparing of normal tissues. After these beams are designed, digitally reconstructed radiographs are produced to reflect the designed treatment fields. The availability of three-dimensional treatment planning has allowed for greater complexity of plans in the attempt to increase the therapeutic ratio via the designing of radiation fields, because the doses to the tumor and normal organs can be evaluated accurately and three dimensionally. This evaluation process allows assessment of the possible toxicity that could result from the radiation treatment via the evaluation of a dose volume histogram, which shows the dose delivered throughout the volume of the organ.

Once treatment planning is completed, the patient begins the course of RT. The first step is to set up the patient to verify the simulation fields on the actual treatment machine. Each day, the patient is repositioned into the exact position in which the simulation and subsequent treatment planning were done. To aid in the repositioning, immobilization devices are often used, consisting of foam body casts or plastic head masks, as previously described. These are made prior to simulation and are kept for use throughout the entire radiation course. Laser lights that converge on the exact isocenter (the point around which the treatment machine rotates) of the treatment machine are available within the treatment room and are used to assist in this repositioning. As three-dimensional techniques allow for greater refinement of treatment volumes and of the increasing complexity of plans, exact daily repositioning is absolutely imperative.

When planning radiation treatment, one must keep in mind the dosages needed to control gross tumor-positive margins and microscopic disease. The probability of tumor control correlates with both the dose of radiation and the volume of the cancer. Radiation cell kill is basically an exponential function of dosage. As a result, the necessary dosage of radiation is roughly proportional to the number of cells in the tumor (tumor volume). Control of microscopic disease in HNC usually requires a dosage of approximately 50 Gy, whereas positive margins require 60 Gy, and adequate control of large (stages T3 and T4) tumors requires dosages in the range of 70 Gy.

Radiobiology

Radiation biology is the study of the effect of radiation on biologic systems. It includes everything from DNA strand breaks to genetic mutations to cellular nongenetic events such as apoptosis.

Radiation cell killing occurs when critical targets within the cell are damaged by radiation.[15] A number of biologic molecules or structures are potential targets for radiation damage. According to most studies DNA is the most critical target for the biologic effects of radiation. On a molecular level, this effect requires the production of ionizations, which is why we refer to the process as *ionizing radiation*. The damage can occur directly when the radiation is absorbed by the DNA itself, because the atoms of the DNA become ionized and damaged. More commonly, however, it occurs indirectly through the following three modes of action[15,16]:

- The effect of x-rays or gamma rays requires the generation of an intermediate ion. (By contrast, particulate types of ionizing radiation, such as α-particles, are directly ionizing and do not require an intermediate ion for effect.)
- The intermediate ion in most cases produces intermediate free radicals, which affect the DNA by breaking chemical bonds (the intermediate ion can also generate DNA damage directly: a less common event for photon ionizing radiation).
- Water molecules surrounding the DNA are ionized by the radiation, creating hydroxyl radicals, peroxide, hydrated electrons, and oxygen radicals.[17]

All of these species are highly reactive free radicals that, in turn, interact with the DNA and cause damage. Both ways eventually cause broken bonds in the DNA backbone, which can cause double-strand breaks, ultimately resulting in mitotic death (Fig. 77-6).

These broken bonds can result in the loss of a base or of the entire nucleotide, or in complete breaking of one or both of the strands of DNA. Single-strand breaks are easily repaired with use of the opposite strand as a template. Therefore, single-strand breaks show little relation to cell killing, although they might result in mutation if the repair is incorrect. Double-strand breaks, on the other hand, are thought to be the most important lesion in DNA produced by radiation.[18] Double-strand breaks, as the name implies, results in snapping of the chromatin into two pieces. These double-strand breaks can result in mutations or, most important, in cell killing.

A growing body of experimental data suggests that radiation damage to DNA is not the only mechanism by which ionizing radiation damages cells. Other mechanisms are apoptosis, cell cycle arrest, and mitotic death. One study has suggested that apoptosis can be triggered by radiation energy deposition in cell membranes.[19] It has also been reported that direct radiation damage to mitochondria can trigger apoptosis.[20]

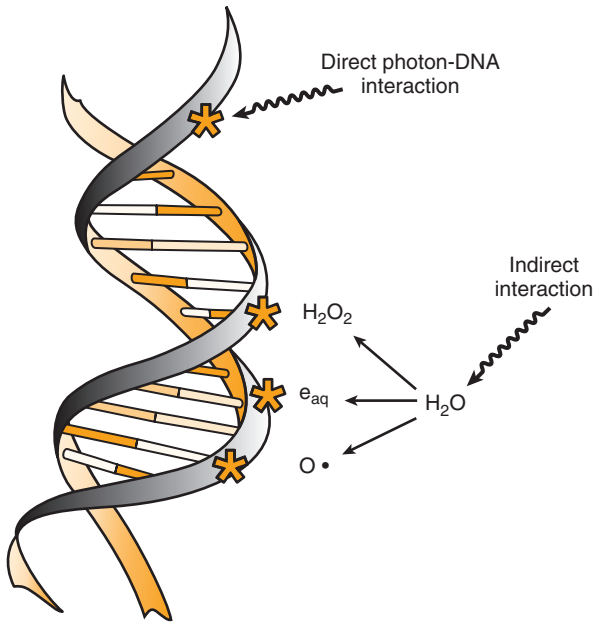

Figure 77-6. Two types of interactions are possible between x-rays and DNA: Direct interaction, in which x-ray interacts with the DNA molecule itself (this interaction is relatively rare); and indirect interaction, in which x-rays ionize water and the reactive species that are created interact secondarily with DNA, causing damage and DNA strand breakage. *(Redrawn from Lichter AS. Radiation therapy. In: Abeloff M, ed.* Clinical Oncology. *2nd ed. London: Churchill Livingstone; 2000:423-470.)*

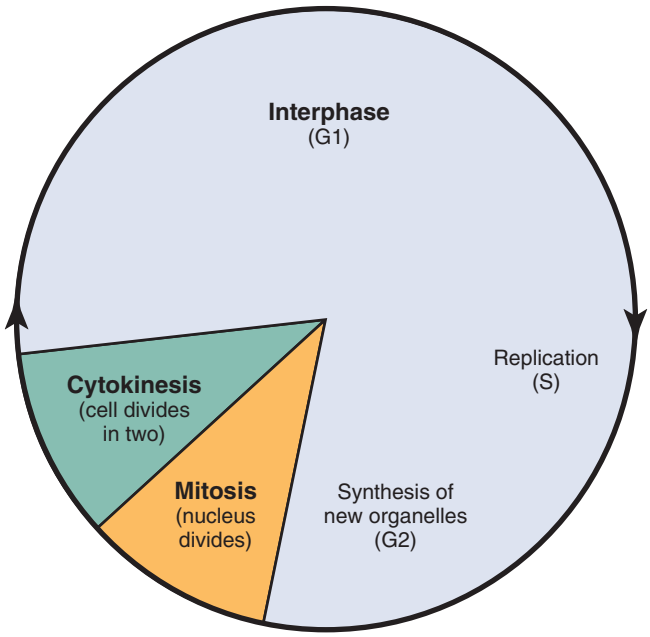

Figure 77-7. Cell cycle.

Cell Cycle Arrest

Radiation triggers signaling cascades leading to arrest, usually at the G1 and G2 checkpoints in the cell cycle.[21] Cell cycle perturbations (Fig. 77-7) are seen characteristically after radiation exposure and were among the earliest observed biologic effects of radiation. Cells can show checkpoints or arrest in any phase of the cell cycle, although the best-described checkpoints with respect to radiation damage are the G1 and G2 checkpoints. Normal cells and those cancer cells that retain p53 function are blocked in the G1 phase of the cell cycle. This is a p53-mediated event.

Mitotic Death

Many cancer cells (typically those with loss or mutation in the p53 protein pathway) have lost the ability to stop in G1. These cells retain the ability to arrest in the G2 phase of the cell cycle. Even in cells that re-enter the cycle after the G2 checkpoint, however, cell death can still be seen and can take several forms. Some cells fail in cytokinesis and form multinucleated giant cells. Some undergo mitotic catastrophe as they attempt to undergo mitosis.

Radiosensitivity

Our main interest in radiobiology is in figuring out ways to improve the treatment toxicity ratio. One of the main concepts is *radiation sensitivity*, which refers to the relative susceptibility of cells, tissues, tumors, or organisms to radiation. However, tumor regression is not solely a function of tumor cell death, but is influenced by many factors, including the amount of extracellular stroma, the propensity of the tumor cells to undergo rapid rather than delayed death, and the resorption of radiation-inactivated cells (depopulation). A frequent misconception is that tumors should be more radiosensitive than normal tissues because they proliferate more rapidly. This misconception may go back 100 years. In 1906, only 11 years after the discovery of x-rays, Bergonie and Tribondeau formulated a "law" for the relationship between cellular radiosensitivity and reproductive capacity.[22] They postulated that cells that have a higher proliferation rate are more radiosensitive than slowly proliferating cells. On a purely cellular basis, it is correct that cells in mitosis at the time of irradiation are more radiosensitive than cells in other phases of the cell cycle. However, many other factors, such as tissue- and host-specific factors, have important influence. In 1906, there was no appreciation of late-occurring normal tissue complications. Nowadays, we know that many slowly proliferating or nonproliferating normal tissues, such as the kidney, are highly radiosensitive; they just express radiation injury much later than rapidly proliferating tissues. Similarly, the proliferation rate of tumors does not predict their radio-curability. For example, rapidly proliferating tumors such as glioblastoma multiforme can be highly radioresistant.

Cell Survival

Loss of reproductive integrity in long-term survival assays is important to our understanding of the response of either a tumor or a normal tissue to radiation. When cells are exposed to lethal doses of radiation, they may not die immediately or within a few hours of treatment, or even sometimes within a single division of radiation. When cells have been observed by time-lapse cinematography after irradiation, some cells survive and go on to form colonies, and some die quickly. Others go through up to several rounds of abortive cell division before finally ceasing to divide. Radiation biologists have demonstrated that it is the proportion of cells capable of forming a colony by sustained cell division that most fully predicts the effects of a dose of radiation.[23] In order to eradicate or control a tumor; one must inactivate all clonogenic tumor cells. In other words, the treatment may fail if only one clonogen survives, because that cell can give rise to a regrowing tumor. In order to understand tumor control better, plots of the surviving fraction of cells as a function of the radiation dose have been performed. An example is shown in Figure 77-8.

By convention, the surviving cell fraction is plotted on a logarithmic scale, and the radiation dose is plotted on a linear scale. This curve is representative of most mammalian cells. Consider the solid curve in Figure 77-8, which represents the survival data. Note that there are two distinct regions to the curve. There is an initial region for low radiation doses, where the slope of the curve is shallow. In this region, small incremental changes in the amount of radiation are not very effective at increasing the number of cells killed. This is called the *shoulder region*, and its width is characterized by the parameter D_q. It is the distance along the dose axis at a surviving fraction of unity between the abscissa and the point where the extrapolated linear portion of the curve is intersected. It is a measure of the ability of the cells to repair small amounts of radiation damage. At higher doses of radiation, the curve

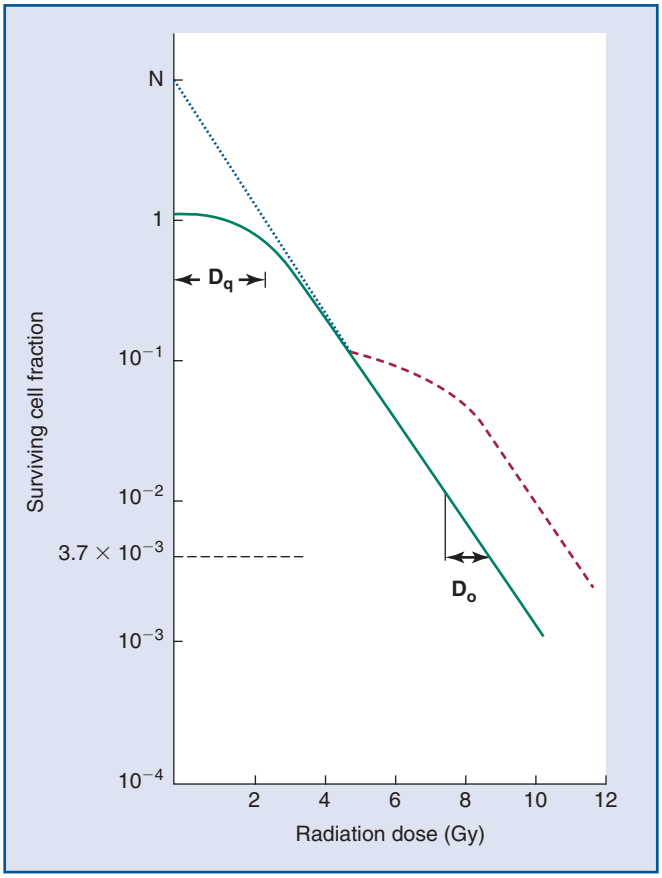

Figure 77-8. A representative cell survival curve *(solid line)* for mammalian cells exposed to single doses of radiation. The surviving cell fraction is plotted on a logarithmic scale, and the radiation dose is plotted on a linear scale. D_q characterizes the width of the shoulder region, which in target theory also may be characterized by the extrapolation number, N. D_o characterizes the slope of the "straight line" portion of the curve. The *dotted line* shows the extrapolation of the linear portion of the curve back to the abscissa. The *dashed line* shows the regeneration of the cell survival curve if, after a certain amount of radiation is given, 6 to 8 hours are allowed to pass before additional radiation is given. *(Redrawn from Hall EJ.* Radiobiology for the Radiologist. *Philadelphia: JB Lippincott; 1994.)*

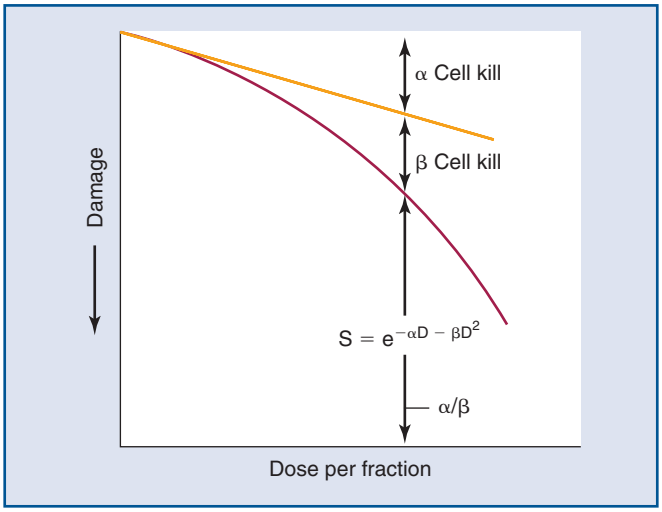

Figure 77-9. Dose-response curves for mammalian cells are adequately fitted by the linear-quadratic relationship, at least over the range of doses of concern in radiation therapy. The form of the equation is where S is the fraction of cells surviving a dose (D), and α and β are constants. Cell killing by the linear and quadratic term are equal when $D = \alpha/\beta$. *(From Cox JD, Ang KK, eds.* Radiation Oncology: Rationale, Technique, Results. *8th ed. St. Louis: Mosby; 2003:14.)*

becomes a straight line on a semilog plot. Its slope is characterized by D_o, which is the incremental dose change required to reduce the surviving cell fraction to 1/e of its value. The steeper the slope in this region, the smaller is the value of D_o and the more radiosensitive is the cell line. When extrapolated back to a zero radiation dose, it intersects the abscissa at a value N. A curve of this type can be modeled using the following equation:

$$S = 1 - [1 - \exp(-D/D_o)]^N \qquad \text{(Eq. 77-3)}$$

where *S* is the surviving fraction, *D* is the radiation dose, and *N* and D_o are as indicated in Figure 77-8. In target theory, *N* can be thought of as the number of distinct targets in the cell that should receive one radiation "hit" before the cell is inactivated.

A number of mathematical models have been devised to attempt to describe the shape of the cell survival curves that are observed experimentally, with an initial shallower slope, an eventual bending (the "shoulder"), and a final, steeper slope. These include target models, lethal and potentially lethal damage models, and repair saturation models. Some of these have been based on simple mathematical modeling without any real attempt to model known molecular events involved in cell killing, whereas others have been based on attempts to model some of the known molecular events (e.g., chromosome breaks or DNA repair) that are involved in cell killing. All of the models can describe the shape of the survival curve to a first approximation. None does so perfectly, and none takes into account all the events and all of the possible mechanisms involved in cell death. A model that has been most influential on clinical practice is the linear quadratic model,[24] because it is one of the models that best fits the behavior of cells after exposure to radiation doses within the range used in the clinic. The linear-quadratic model was devised by Keller and Rossi,[25] who proposed that radiation-induced cell killing resulted from two potential events, one with a linear relation to dose ($\exp[-\alpha D]$), the other having a quadratic relation to dose ($\exp[-\beta D^2]$). This was expressed mathematically by the "alpha-beta" equation, as follows:

$$S = e^{-(\alpha D + \beta D^2)} \qquad \text{(Eq. 77-4)}$$

where *S* represents survival of a cell population after a dose, *D* (Fig. 77-9). It has been hypothesized that this equation actually represents a molecular reality.[26] Double-strand breaks in the DNA are lethal lesions that are produced by either one energy deposition, an event termed (αD), or by two separate events, each involving a single strand of DNA (βD^2), which then interact. This hypothesis is now thought to be unlikely because of the low probability of two tracks interacting within a single double helix.

The α/β ratio, which is derived from Equation 77-4, represents a point on the survival curve at which the components of cell killing are equal to each other—that is, $\alpha D = \beta D^2$, or $D = \alpha/\beta$. In other words, for each cell population there is a dose of radiation in which the linear (α) and quadratic (β) contributions to cell killing are equal. The α/β ratio is specific to each cellular population and reflects the sensitivity of the cell to the two types of damage. Tissues that have an early response to radiation (skin, mucosa, and tumor cells) have a high α/β ratio. In other words, their survival curves stay straight for a longer period before the bend occurs, in which there is a higher contribution of single-event or α killing. Late-responding tissues, such as spinal cord, kidney, and muscle, have survival curves that bend earlier, with resultant lower α/β ratios. These late-responding tissues have shoulders on their survival curves within the range of doses commonly used in RT. This understanding led to the concept that altered fractionation sched-

ules could be used to treat tumor populations more effectively with respect to damage to late-responding tissues.

Tissue-Radiation Characterizations

The main intent in clinical radiotherapy is to irradiate tumoral tissues while minimizing the damage to the surrounding healthy tissues. The four main concepts of clinical radiotherapy are known as "the four Rs of radiotherapy": repair (of sublethal damage), redistribution (across the cell cycle), repopulation, and reoxygenation. Radiotherapy basically works not because tumors are more radiosensitive than normal tissue but because normal tissues are better at repair and repopulation. These four Rs also account for different response rates of tumors.[27-29]

Dividing the total dose into a number of smaller fractions allows for normal tissue sparing because of the *repair* of sublethal damage between fractions; however, doing so may also influence tumor cells. Cells show increased survival with split-dose radiation because the shoulder of the survival curve must be repeated with every fraction. In other words, the shoulder of the survival curve represents the accumulation and repair of sublethal damage.

Fractionating the therapy also allows for reassortment or *redistribution* of tumor cells into radiosensitive phases of the cell cycle, according to several studies. The cells are radiosensitive early in the M phase but become more resistant toward the end of this phase. They are resistant in the early G_1 phase but then become more sensitive in the late G_1 and early S phases. They then become more resistant again in the late S and early G_2 phases. The exact mechanisms underlying this change in radiosensitivity are not clear, but it is interesting to note that at the beginning of mitosis, the DNA in the chromosomes aggregates into a discrete state; in the late S phase, the DNA content of the cell has doubled. These points in the cycle correspond, respectively, to the points of maximum and minimum radiosensitivity.

Reoxygenation of the tumor cells causes the cells to be more radiosensitive. The response of cells to ionizing radiation is strongly oxygen dependent, with well-oxygenated cells showing up to threefold greater sensitivity to the killing effects of ionizing radiation than the same cells under hypoxic conditions (Fig. 77-10).[30] Tumors tend to have a much higher proportion of hypoxic cells than normal tissues do. Therefore it is important to allow tumor cells to reoxygenate. However, if too much time occurs between fractions, *repopulation* or proliferation of the tumor cells could occur. Therefore the main issue is creating a balance between reoxygenation of the tumor and its repopulation and repair, and at the same time minimizing the damage to the surrounding tissue.

Rapidly dividing tissues, including tissues such as the skin, mucous membranes, bone marrow, and tumor cells, are responsible for the acute toxicity following RT. The severity of acute toxicity correlates with the relationship between the rates of cell killing of early-responding tissues counteracted by regeneration by those tissues' surviving stem cells. This balance is based mainly on total treatment time. Prolonging overall treatment time spares the patient from the severe acute toxicity caused by shorter, intense treatment courses. If the therapy is so intense and does not allow a sufficient number of stem cells to survive, the acute toxicity can progress to consequential late effects. Late-responding tissues are responsible for the late toxicity from RT. These tissues, such as the spinal cord, brain cells and connective tissue, are composed mostly of terminally differentiated cells with no reproducible cell population. Thus, there is usually no turnover of such cells within a radiation treatment course, and no opportunity or need for regeneration to occur during treatment. Therefore, unlike in early-responding tissues, the overall treatment time has little importance in determining toxicity in late-responding tissues. Instead, late toxicity depends mainly on total dose and dose per fraction.

Provided that full recovery occurs after each fraction, most late radiation effects show no dependence on the duration of treatment. In contrast, overall treatment time has a large effect on both acute toxicity in early-responding tissues and the cure of tumors. This implies that the tumors that show a decrease in curability with longer treatment times have a rapid regeneration in response to the cell killing that occurs with radiation.

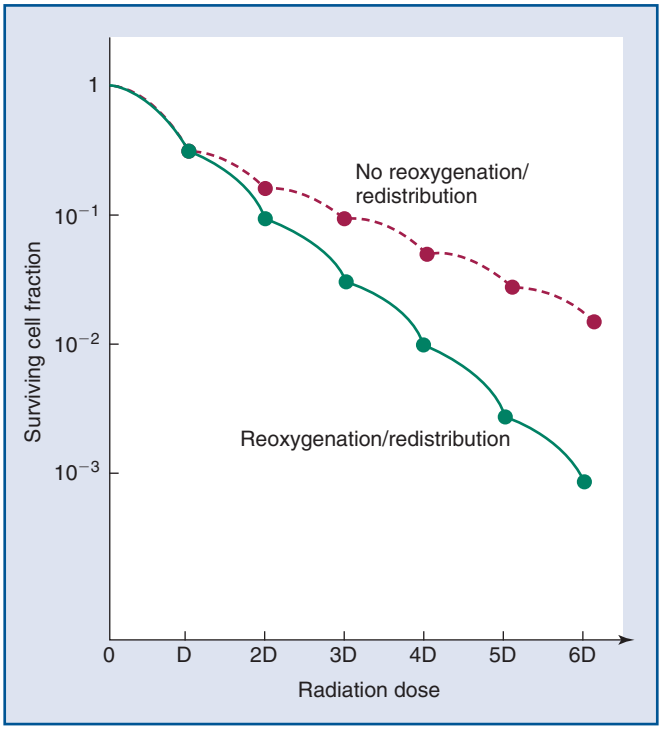

Figure 77-10. Illustration of the effects of fractionated radiotherapy on a heterogeneous cell population. Surviving cell fraction is plotted along the abscissa as a function of the radiation dose. The dose is given in increments, D, with the time interval between successive doses being long enough to allow for sublethal damage repair. The initial dose increment kills a greater fraction of well-oxygenated cells than it does their hypoxic counterparts. It also preferentially kills those cells in the radiosensitive phases of the cell cycle. The *solid curve* indicates when the remaining cells reoxygenate and redistribute along the cell cycle before the next radiation dose is given. The *dashed curve* indicates when there is no reoxygenation or redistribution, and successive radiation doses are delivered to a more radioresistant cell population. The figure is schematic and is not meant to represent any particular cell line.

In order to evaluate the impact of a radiation treatment, time-dose considerations are important in estimating the effect of a given total radiation dose.[31] If the dose were given in a single fraction, then the healthy tissues would experience more cell killing than if it were given in a fractionated manner. This difference occurs because single fractions allow no opportunity for repair of sublethal damage. In general, smaller total radiation doses given over shorter total treatment times can produce the same normal tissue effects as larger total radiation doses given over longer intervals.

The classic measurements that illustrate this point are the isoeffect measurements on skin that were made by Strandquist.[32] He showed that the isoeffect lines for various degrees of skin damage and for curing skin cancer were straight when plotted on a log-log scale of total dose versus time. Moreover, the lines appeared to have the same slope (i.e., were parallel). The required dose to produce a given effect was proportional to time to the 0.33 power. Ellis[33] extended this concept to clinical radiotherapy by allocating a portion of the exponent 0.33 to the overall treatment time, *T*, and a portion to the number of fractions, *N*. He defined the nominal standard dose (NSD) with the following equation:

$$NSD = D^t / T^{0.11} N^{0.24} \qquad \text{(Eq. 77-5)}$$

where D^x is the total radiation dose. The exponents in this expression are for skin and no doubt vary for other tissues.

Clinical Applications

Radiation Fractionation

Altered Fractionation Schedules

The highly fractionated radiotherapy protocols used today are based on the notions just discussed. They are a result of many years of clinical experience, and are extremely crucial for patients with HNC, in whom the radiation in most cases is a curative treatment. Side effects of treatment may have an impact on treatment and therefore may influence survival. In order to further improve the outcome, many studies have suggested different types of dosage prescriptions. The two main treatment methods that have been explored are hyperfractionation and accelerated fractionation treatment.

Several trials suggested the use of *hyperfractionation*, which involves the administration of multiple daily doses of radiation of such a size that the overall treatment time is about the same as for a conventionally fractionated course of once-a-day radiotherapy. The decreased size of each radiation fraction should permit utilization of a higher total dose without increasing late morbidity. Because normal tissues that show delayed toxicity (and hence long-term morbidity) are more dependent on the size of the individual dose than are tumors, decreasing the size of each radiation fraction should permit utilization of a higher total dose without increasing late morbidity. In practice, multiple daily treatments with smaller than conventional fraction sizes are given over approximately the same treatment duration. Typically, 1.1 to 1.2 Gy/fraction, two fractions per day, to total doses of 74 to 80 Gy have been employed.

Four prospective randomized trials comparing hyperfractionation with standard irradiation alone (without chemotherapy) have been performed.[34-37] In all studies locoregional control was significantly better for those patients treated with hyperfractionation and accelerated fractionation with a concomitant boost than for those treated with standard fractionation. The advantage ranged from an 8% to a 20% 2-year locoregional control rate. There was also a trend toward better disease-free survival with hyperfractionation. In one of the studies, which dealt specifically with oropharynx tumors, there was an improvement in overall survival: Overall survival rate at 42 months was 27% for the hyperfractionation arm and 8% for the conventional treatment arm ($P = .03$).[36] Survival rates were 40% for the hyperfractionated arm and 18% for the conventional RT arm ($P = .06$). All groups treated with altered fractionation RT had significantly greater late side effects than those undergoing conventional fractionation. The acute side effects of hyperfractionation were slightly more intense and common than with standard fractionation, but the long-term effects appear to be very similar.

Accelerated fractionation is the administration of multiple daily radiation doses of larger size to reduce the overall treatment time. The goal of accelerated fractionation is to prevent tumor repopulation during a course of radiation therapy. Clinical support for tumor cell proliferation during therapy is found in numerous studies that have shown a loss in tumor control with prolongation of overall treatment time in HNC. In general, accelerated treatments that employ continuous (rather than split-course) RT schedules without compromise in the total dose result in better local control. However, whether the added mucosal toxicity from this approach is justified by meaningful gains in survival remains an open question. The studies present a trend toward better primary tumor control in the hyperfractionation arm but no significant difference in overall survival. Comparison of accelerated RT with conventional RT for locoregionally advanced HNC has been tested in a considerable number of randomized trials.[34-41] All of these trials used somewhat different dose fractionation schedules, and the results (in terms of both locoregional control and survival) are inconsistent. The only trial suggesting a survival benefit for this approach was the smallest.[39]

The reasons for these inconsistent findings may be the differences in treatment regimens used. In some studies overall treatment time was decreased by more than 50%, necessitating a decrease in total dose by approximately 10% to 20%.[38,40,41] This approach resulted in significantly better locoregional control in only one trial,[38] and none showed gains in overall survival. Another approach involved moderate reduction in the overall treatment time without a relevant compromise in total dose, with the use of split-course RT regimens.[34,35,38] With this strategy, no benefit in local control or survival has been observed, except for a significant improvement in local control in one of the trials.[35] This improvement did not translate into an improvement in overall survival, however. This lack of survival benefit has been attributed, at least in part, to the significantly higher rate of severe late toxicities in the accelerated treatment arm, which resulted in an increase in the non–cancer-related death rate.

Moderate reduction of the overall treatment time without a relevant compromise in total dose has also been achieved in two studies, with the use of six or seven fractions per week (compared with the usual five fractions weekly) without a split course.[39,42] Both of these studies showed a significantly improved local control rate in the accelerated treatment arm, and one demonstrated a trend for an improvement in overall survival.[39] Both studies demonstrated a significant increase in acute side effects. Whether late toxicity is also worse with the accelerated treatment approach is unclear. The available data are conflicting, with some trials suggesting no increase in late toxicity,[38] and others suggesting the opposite.[35]

The benefit of altered fractionation RT for squamous cell HNC was addressed in a meta-analysis of 6515 patients enrolled in 15 selected trials comparing hyperfractionated or accelerated fractionation RT with conventional fractionation RT.[43] The majority were treated for stage III or IV disease. Compared with conventional fractionation RT, altered fractionation RT resulted in a statistically significant 18% reduction in rate of local failure at the primary site, corresponding to a 6.4% absolute reduction in rate of locoregional failure at 5 years. The improvement in locoregional control was more pronounced in patients undergoing hyperfractionated RT and in those treated with accelerated RT without dose reduction. A significant benefit in overall survival was also found; altered fractionation regimens reduced the risk of dying by 8%, which translated into an absolute survival benefit of 3.3% and 3.4% at 2 and 5 years, respectively. The magnitude of benefit was statistically significant in patients treated with hyperfractionated RT, but not for those undergoing accelerated fractionation RT, with or without a dose reduction. Although this meta-analysis demonstrates the advantage of hyperfractionation versus conventionally fractionated radiation, the standard of care today is chemoradiation, and these studies do not demonstrate superiority of any RT regimens over chemoradiation.

The benefit of combining radiosensitizing chemotherapy with hyperfractionated RT (CRT) schedules was shown in one study in which 116 patients with HNCs (approximately 53% of which were unresectable) were randomly allocated to undergo hyperfractionated RT either alone or with 5-fluorouracil (5-FU) and cisplatin.[44] At 3 years, CRT was associated with significantly higher rates of locoregional control (70% vs. 44%), a trend toward better relapse-free survival (61% vs. 41%, $P = .08$), and better overall survival (55% vs. 34%, $P = .07$). Toxicity, although high, was equivalent in the two groups. However, no trial has compared a regimen using hyperfractionated RT with or without chemotherapy directly with a regimen using concomitant CRT and conventional fractionation RT, the widely accepted standard of care, at least in the United States, for locoregionally advanced laryngeal and oropharyngeal cancers. These twice-daily treatments place greater time demands on the patient as well as on the treatment facility and may create problems with compliance. As a result, hyperfractionated regimens have not been widely adopted, at least in the United States.

Radiosensitizers

The two main options for improving radiation treatment outcome are modulation of the radiation itself, as already discussed, and helping the radiation to become more effective, known as *radiosensitizing*. A number of mechanisms have been proposed to explain radiation resistance or failure. These can be divided into mechanisms based on radiation dose and schedule, and genetic and epigenetic factors that affect

the tumor and its response to radiation therapy. In this section the following existing strategies are discussed: (1) reducing hypoxia, (2) concomitant chemotherapy, and (3) targeted therapy.

Reducing Hypoxia

Within the tumor cell microenvironment, radiation therapy effectiveness is closely dependent on oxygen availability at the time of treatment. Hypoxic cells are 2.5 to 3 times less radiosensitive than well-oxygenated cells.[45,46] The hypoxic cell fraction in solid tumors ranges from less than 1% to more than 50%.[47] Hypoxia in the tumor microenvironment may be a result of increased interstitial pressure, which leads to vascular collapse with resulting areas of transient or persistent hypoperfusion, local hypoxia, and acidosis.[48] Many patients with cancer are anemic, a factor that may also contribute to localized hypoxia and that has an adverse effect on curability of a tumor by radiation therapy.[49] In order to overcome the hypoxia, specific trials addressing this issue were performed. These explored the concept of increasing the delivery of oxygen, also known as hyperbaric oxygen therapy (HBO), which increases the amount of oxygen in the blood. The use of carbogen, also raises the local oxygen level. Although the use of HBO was associated with significant increases in response rate (clinical complete response rate 84% with HBO vs. 52% without it),[50] there were no significant differences in 5-year rates of local control or survival. Inhalation of carbogen (95% oxygen–5% carbon dioxide) during radiation therapy, often combined with accelerated radiation and oral nicotinamide (ARCON treatment)[6,7] has been suggested in several trials, and its benefit has not been confirmed.

A second approach to decreasing the impact of hypoxia is the use of hypoxic cell sensitizers, some of which have been used in concomitant chemotherapy regimens, including nimorazole and tirapazamine. Although results of initial clinical trials have been promising, so far there is no proven evidence for survival benefit.[51-53]

Several trials have evaluated the hypothesis that outcomes might be improved through correction of preexisting anemia using recombinant human erythropoietin (epoetin or darbepoetin); this hypothesis was supported by the results of uncontrolled studies.[52] However, subsequent randomized trials directly testing this hypothesis did not confirm benefit and, in fact, suggested significantly worse locoregional control and overall survival outcomes, or both, in patients who received epoetin during therapy for HNC.[54,55]

Concomitant Chemotherapy

In general, there may be a synergistic effect between radiotherapy and chemotherapy that alters the radiobiologic parameters (α and β) or there may be an additive effect.

The *additive effect* may occur in two different ways, as follows:

1. The chemotherapy may be effective at eradicating micrometastases, thus reducing the incidence of distant metastases.

2. Spatial cooperation, meaning independent activity of each treatment modality (i.e., radiation within the treatment field and chemotherapy inside and outside the field) may occur. Toxicity independence (i.e., non-overlapping toxicity) allows for administration of each treatment modality at near full dose without a significant increase in normal tissue damage, although almost all chemoradiotherapy regimens are associated with higher rates of mucositis and other regional toxicities than radiation alone.

Alternatively, a *synergistic effect* may occur, through increased cytotoxic activity within the radiation field as a direct result of the interaction of chemotherapy with radiation. In this case, the drug is acting as a sensitizer, enhancer, or potentiator of radiation. A number of chemotherapy drugs act as direct cellular radiosensitizers in vitro. They include cisplatin, mitomycin C, 5-FU, hydroxyurea, bleomycin, paclitaxel, docetaxel, and cetuximab, a monoclonal antibody that is directed against the epidermal growth factor receptor, which is over-expressed in the majority of HNCs.

Synergistic or additive effects are thought to be due to the following mechanisms[56-58]:

- The drug may interfere with cellular DNA repair after sublethal or potentially lethal damage. This may be part of the mechanism of action of cisplatin.[56]

- The drug may reduce tumor cell repopulation by enhancing the cytotoxic effect, particularly following fractionated RT.[57]

- The drug may reduce the population of hypoxic tumor cells. Tumor cell oxygenation can be improved by reduction of interstitial pressure that follows successful cytoreduction.[56-58] Alternatively, hypoxic cells can be sensitized to radiation (or chemotherapy). Hypoxic cells can be killed with a hypoxic cell toxin; for example, mitomycin is preferentially activated in hypoxic cells,[58] and tirapazamine is another hypoxic cell toxin.

- The drug may kill radioresistant cells in the S phase of the cell cycle and increase cell cycle synchronization.[59] Hydroxyurea is an S phase–specific agent that inhibits ribonucleotide reductase. Therefore, it may have additive effects with radiation because it is toxic to S-phase cells that are considered radioresistant. It has also been shown to synchronize cells by inhibiting the entry of cells from the radiosensitive S phase. Paclitaxel works similarly as a cell cycle modifier: It causes accumulation of cells at the G2/mitosis phase of the cell cycle, at which both it and radiation are most effective.[60]

Concomitant chemoradiation has been tested in several settings, for example as up-front curative treatment in resectable and unresectable tumors, postoperatively.

UNRESECTABLE TUMORS. Several meta-analyses have been performed to analyze the use of chemoradiotherapy in unresectable tumors. One meta-analysis of trials evaluating locoregional treatment with or without chemotherapy suggested that the magnitude of the absolute survival benefit with chemotherapy (given in any fashion with RT) was 4% at five years.[61] The hazard ratio (HR) for death was 0.81 (95% confidence interval [CI] 0.76 to 0.88) with concomitant chemoradiotherapy compared with locoregional therapy alone, and the benefit was more pronounced with multiple-agent chemotherapy regimens (hazard ratio 0.69).

A second meta-analysis of randomized trials testing curative intent RT alone or with concurrent or alternating chemotherapy concluded that the addition of concurrent (but not induction) chemotherapy to conventional or altered fractionation RT prolonged survival by an average of 12 months.[62] Benefit was most pronounced in those trials that used 5-FU or cisplatin-based chemotherapy (average survival prolongation 24 months and 16 months, respectively).

INDUCTION CHEMOTHERAPY. Some writers have suggested that the optimal regimen should include induction chemotherapy prior to chemoradiation. The rationale for using induction chemotherapy is that a reduction in the overall tumor burden will permit more effective local therapy: Radiotherapy can be directed against a smaller number of tumor cells, and early treatment of micrometastases may diminish the chance of developing gross metastatic disease. The reduction in tumor size and healing prior to definitive RT may improve functional outcomes. The response to chemotherapy may be an important predictor of survival, because various studies have shown that patients with a good response to induction chemotherapy have a better overall survival.

The majority of studies suggest that there is no obvious role for induction chemotherapy. Tumor cells that remain after chemotherapy are likely to be chemoresistant and to show cross-resistance to radiation therapy as well.[63] Delaying radiation treatment can lead to accelerated repopulation of surviving tumor clonogens, which occurs during an extended total treatment time. There are also practical issues. Induction chemotherapy is associated with increases in toxicity (compared with local therapy without chemotherapy), cost, and overall duration of treatment. Some patients receiving induction chemotherapy do not go on to receive definitive therapy because of the toxicities.

Several trials have compared different regimens of induction chemotherapy.[64,65] The triple regimen of docetaxel or paclitaxel plus cisplatin and 5-FU has been compared with a regimen using cisplatin

plus 5-FU in the setting of induction chemotherapy. The studies demonstrated that the taxane-containing regimen (with docetaxel or paclitaxel) provided superior outcomes, reporting a 14% improvement of overall survival at 3 years and improvement in median survival from 30 to 71 months.[65] However, neither of these studies compared induction chemotherapy with direct chemoradiation. In the study by Hitt and associates,[64] 13% of the patients assigned for the better-tolerated PCF induction regimen dropped out and did not receive the definitive treatment, a situation that might lead to worse survival than that with standard treatment. In order to answer this question, three large randomized trials have been initiated to test the benefit of adding induction chemotherapy to chemoradiotherapy. Until these trials are completed, this approach should be considered investigational.

ORGAN PRESERVATION. One of the main goals in chemoradiation treatment in HNC is the ability to preserve organs that would have been destroyed by surgery. Many studies have dealt with producing the optimal combination in order to preserve function.

The U.S. Department of Veterans Affairs (VA) Laryngeal Cancer Study was the first published randomized trial using neoadjuvant chemotherapy with the major endpoint of organ preservation.[66] In this study, 332 patients with advanced laryngeal cancer, either stage III (53%) or stage IV (47%), were randomly assigned in equal numbers to one of the following two regimens:

Arm 1—Induction chemotherapy followed by RT, with surgery reserved for salvage. Chemotherapy was given on a 21-day cycle. Clinical tumor responses were reassessed by physical examination and indirect laryngoscopy 18 to 21 days after the start of the second cycle of chemotherapy. The patients undergoing definitive RT received 66 to 76 Gy to the primary tumor site. The doses to the nodes varied according to initial nodal size, ranging from 50 Gy to 75 Gy. Patients with persistent disease in the larynx after RT underwent salvage laryngectomy, and patients with persistent disease in the neck underwent neck dissection alone. In addition, patients with late relapses underwent salvage laryngectomy.

Arm 2—Standard surgery and RT. These patients underwent total laryngectomy and most also underwent neck dissection. This surgery was followed by postoperative RT (PORT) (50 to 74 Gy). The results were as follows: 15% of patients had less than a PR and received standard laryngectomy, 31% had a clinical CR at the primary site, and 85% had a complete response (CR) or partial response (PR) of the primary and involved regional lymph nodes.

Outcome was reported at 33 months' follow-up, and outcome measures of both survival and organ preservation were clearly delineated. Two-year survival was equivalent at 68% in the two treatment arms.

A second publication from the same study reported long-term survival in the chemoradiation group only.[67] At the time of that report, 53% survival was noted at 3 years. Patients who had a histologic CR had better survival than patients with persistence of tumor after chemotherapy.

The most significant findings in the VA studies were those related to organ preservation. In the patients randomly assigned to neoadjuvant chemotherapy followed by definitive radiotherapy, 66% of the survivors had a preserved larynx at 2-year follow-up, and 39% of the overall group were alive at 2 years with a functional larynx. A major conclusion of this study was that a significant number of patients could remain alive with a functional larynx after neoadjuvant chemotherapy with definitive RT. However, no survival advantage was seen.

Subsequently, Forastiere and colleagues[68] compared RT alone with either induction chemotherapy followed by RT or concomitant CRT, with larynx preservation as the primary end point. In their initial report, 2-year laryngectomy-free survival rates significantly favored the concomitant chemoradiotherapy group (88% vs. 75% for neoadjuvant chemotherapy and 70% for RT alone), and the rates of local control were also significantly better (80%, 64%, and 58%, respectively).[68] There were no significant differences when induction chemotherapy followed by RT was compared with RT alone, and overall survival was nearly identical in all three groups (2-year and 5-year survival rates 74% to 76%, and 54% to 56%, respectively).

In a later report that this group presented at the 2006 meeting of the American Society of Clinical Oncology, there were no longer any differences in laryngectomy-free survival between the groups receiving concomitant chemoradiotherapy and induction chemotherapy followed by RT (47% versus 45% at 5 years, respectively, compared with 35% for RT alone).[69] However, the overall laryngeal preservation rate still favored concomitant therapy (84% versus 71% respectively, compared with 66% with RT alone), as did locoregional control rates. This study has established concomitant CRT as a standard of therapy in this setting.

POSTOPERATIVE TREATMENT. The treatment goals for patients with resectable locally advanced HNC are to maximize cure and to maintain functional status through organ preservation. Historically, surgery with postoperative radiotherapy (PORT) has been used for most patients with potentially resectable stage III or IV HNC. Indications for PORT include involved surgical margins, perineural involvement, bone or cartilage invasion, and advanced primary (T3 or T4) or nodal (N2 or N3) disease.

Two large trials have reported a survival benefit for combined chemotherapy and conventional fractionation over radiation alone after surgical resection among patients with locally advanced but resectable disease.[70,71] These benefits came at the cost of enhanced acute mucosal toxicity, although late toxicities were not more common.

In a multi-institutional trial sponsored by the European Organization Research and Treatment of Cancer (EORTC), 334 patients with high-risk resected squamous cell cancer (SCC) of the oral cavity, oropharynx, larynx, or hypopharynx were randomly assigned to RT alone or the same dose of RT with concomitant cisplatin.[62] High-risk disease was defined as a T3 or T4 primary with any nodal stage (excepting T3N0 laryngeal cancer), involved surgical margins, extracapsular extension, perineural invasion, vascular invasion, or oral cavity/oropharyngeal primary sites with involvement of level IV or V lymph nodes.

At a median follow-up of 60 months, concomitant chemoradiotherapy was associated with significantly better 5-year rates of progression-free survival (47% vs. 36%) and overall survival (53% vs. 40%), fewer locoregional relapses (18% vs. 31%), and a significantly longer time to progression (55 versus 23 months) than those for PORT alone. In a similarly designed Radiation Therapy Oncology Group (RTOG) trial, 459 patients with resectable high-risk SCC of the oral cavity, oropharynx, larynx, or hypopharynx were randomly assigned to RT alone or the same doses of RT with concomitant cisplatin on days 1, 22, and 43.[70] The definition of "high-risk" differed somewhat from that used in the EORTC trial, consisting of positive resection margins, involvement of two or more lymph nodes, or extracapsular nodal extension. At a median follow-up of 46 months, chemoradiotherapy was associated with a significantly better 4-year disease-free survival (40% vs. 30%) and fewer locoregional relapses (19% vs. 30%) than those for PORT alone. The difference in overall survival was not statistically significant (hazard ratio 0.84, $P = .19$). As in the EORTC trial, the incidence of acute severe mucosal toxicity was significantly greater in the chemoradiotherapy group (77% vs. 34%). Long-term toxicity rates were comparable in the two groups, although data derived from larger numbers of patients undergoing definitive treatment suggest that the rate of long-term toxicity is higher in patients receiving chemoradiotherapy than in those undergoing RT alone.

In order to suggest treatment guidelines, risk stratification was addressed in a pooled analysis comparing the selection criteria, clinical and pathologic risk factors, and treatment outcomes of the EORTC and RTOG studies.[71] The findings can be summarized as follows: Extracapsular extension and/or microscopically involved surgical margins were the only risk factors for which the effect on survival of adding chemotherapy to RT was statistically significant in both trials. There was a trend toward better survival in favor of chemoradiotherapy in the group of patients who had stage III or IV disease, perineural infiltration, vascular embolisms, and/or clinically enlarged level IV or V lymph nodes secondary to tumors arising in the oral cavity or oropharynx, but the differences were not statistically significant.

Patients in whom two or more histopathologically involved lymph nodes without extracapsular extension was the only risk factor that did not seem to benefit from the addition of chemotherapy.

Targeted Therapy

In order to reduce side effects and optimize treatment, several studies have substituted chemotherapy with molecular targeting antibodies. The most prominent molecule thus far investigated has been cetuximab (Erbitux, IMC225), which is a monoclonal antibody that is directed against the epidermal growth factor receptor and often over-expressed in the majority of HNCs. Cetuximab inhibits receptor activity by blocking the ligand binding site. The benefit of cetuximab as a radiation sensitizer was tested in a multicenter trial[72] in which 424 patients with locoregionally advanced SCC of the oropharynx, hypopharynx, or larynx were randomly assigned to RT (once daily, twice daily, or with a concomitant boost, with the specific approach selected by each participating institution) with or without weekly concurrent cetuximab. The majority of patients underwent concomitant boost RT (56%), whereas once daily and twice daily fractionation schedules were used in 26% and 18% of patients, respectively. Cetuximab was administered at a dose of 400 mg/m^2 over 2 hours 1 week prior to RT, then at 250 mg/m^2 over 1 hour for subsequent weekly doses during the RT weeks. At a median follow-up of 54 months, the cetuximab-treated group had significantly better median (49 vs. 29 months) and 3-year survival rates (55% vs. 45%) than the group receiving RT alone. Locoregional control rates were also significantly better (50% vs. 41%, respectively), and there was also a suggestion of a higher laryngeal preservation rate in the cetuximab group (88% versus 80% at 3 years, respectively).[72] The cumulative rates of distant metastases at 2 years were similar (16% versus 17%, respectively).[72] Although cetuximab did not appear to exacerbate the toxic effects commonly associated with RT (i.e., mucositis, xerostomia, dysphagia, and weight loss), patients receiving combined therapy had a greater incidence of grade 3 or 4 skin toxicity (17% vs. 1% rate of acneiform rash, respectively).

These results are encouraging; however, cetuximab has not been directly compared with other agents as a radiosensitizer. Thus, its role, particularly in comparison with the current standard cisplatin-based chemoradiotherapy, remains uncertain. Nevertheless, it is approved in the United States in combination with RT for the treatment of locally or regionally advanced head and neck SCC. It could be considered in older patients with a borderline performance status (PS2) whose ability to tolerate cisplatin-based chemoradiotherapy is questionable.

The next generation of clinical trials is focusing on combinations of RT, cetuximab, and conventional cytotoxic chemotherapy agents. Although early reports using this approach are promising, it may result in greater toxicity, and incorporation of this strategy into clinical practice would be premature.[73]

Advanced Radiation Technologies

In traditional irradiation of HNC, the placement of the radiation fields and their shapes were based on the bony anatomy acquired by the simulator diagnostic-quality films. During the late 1980s, advancements in computer technology and imaging introduced methods to identify the targets on CT scans and display the radiation beams in three dimensions relative to the anatomy. In addition, calculation and display of the radiation dose distributions and methods to evaluate and compare rival plans with dose-volume histograms (DVHs) became available. The introduction of multileaf collimators facilitated an increase in the number of beams that could be delivered without a large extension of treatment time. The result was the emergence of three-dimensional conformal radiotherapy (3DCRT), which allowed better precision of irradiation delivery to image-based targets and some improvements in the sparing of noninvolved critical tissue. Early studies of the utility of 3DCRT in HNC examined larynx,[73] nasopharynx,[74] hypopharynx,[75] and paranasal sinuses cancers.[76] These studies demonstrated a significant benefit for 3DCRT—better coverage of the tumors and reduced doses to critical tissue—over standard techniques.

Another step forward in the mid-1990s was the development of intensity-modulated radiotherapy (IMRT), which facilitated a higher degree of dose conformality and offered opportunities for additional clinical gains. More recently, imaging-guided radiotherapy (IGRT) has emerged, providing opportunities for better precision of patient setup and for tracking of tumor regression and anatomical changes in the noninvolved tissue during the course of radiation therapy. Other emerging technologies are new imaging modalities that enable study of the customization of the radiation dose according to the expected tumor biology, and the use of heavy particles like protons and carbon ions, which offer additional advantages in dose conformality.

Intensity-Modulated Radiotherapy

IMRT implies the use of radiation fields whose intensity varies across the field, depending on the thickness of the target and the existence of critical organs or critical noninvolved tissue in their path. Treating the targets with multiple beams of varying intensity allows a relatively uniform dose in an irregularly shaped target while avoiding a high dose to the surrounding structures. Two technologic developments made IMRT possible: the introduction of computer-controlled multileaf collimators, and the development of computerized optimization, or "inverse planning," which determines the intensity of the beams required to satisfy a specified set of dose distributions. Inverse planning demands the planner to state the treatment goals, usually in terms of the dose and/or dose/volume goals for the targets, and the constraints for the critical normal tissue (the objective, or cost function). The computer attempts to achieve the desired outcome by iteration through numerous possible beam intensities. The desired solution is the dose distribution that minimizes the variance of the delivered dose relative to the objective function. For each target and noninvolved organ or tissue, an importance factor or weight is assigned, and the objective function is the sum of the variance terms representing each structure of interest, multiplied by the importance factor.

Intensity-Modulated Radiotherapy in Head and Neck Cancer

The anatomy of the neck is complex, with many critical and radiation-sensitive organs in close proximity to the targets. Tight dose gradients around the targets that limit the doses to the noninvolved tissue, features characteristic of IMRT, are desirable and offer the potential for therapeutic gains (Fig. 77-11). Noninvolved tissues, the sparing of which may offer tangible gains, include the major salivary glands, minor salivary glands dispersed within the oral cavity, the mandible, and the pharyngeal musculature. In the cases of nasopharyngeal and paranasal sinus cancers, critical normal tissues that may be partly spared using IMRT are the inner and middle ears, the temporomandibular joints, temporal brain lobes, and the optic pathways.

In addition to sparing of noninvolved tissues, IMRT offers a potential for improved tumor control by reducing the constraints on the tumor dose due to critical organs. Examples include the spinal cord, brainstem, and optic pathways that occasionally limit the tumor boost doses in conventional RT. This goal is achieved by specifying a maximal dose to the critical organs and a high penalty in the optimization process if that dose is exceeded. In addition, IMRT eliminates the need for posterior neck electron fields, commonly used in conventional RT, and their associated dose deficiencies. Although IMRT in the head and neck is more feasible than in other sites because breathing-related organ motion is practically absent, other factors must to be taken into account, such as patient setup uncertainties, swallowing-related organ movements, and changes in target and organ positions related to tumor shrinkage and patient weight loss during therapy; these are discussed later.

Not every patient is expected to benefit from IMRT. Those who would benefit most are patients with paranasal sinus cancer in whom the targets are near the optic pathways, patients with oropharyngeal or nasopharyngeal cancer in whom standard RT fields would encompass most of the salivary glands, and patients in whom standard techniques would require a compromise in the tumor dose because of proximity of the tumor to the spinal cord or brainstem. For patients with laryngeal cancer and clinically noninvolved neck, who are receiving treatment to the larynx alone or who require irradiation of the neck encompassing the jugulodigastric nodes but not extending to the base of skull, IMRT may not be better than simpler techniques. The same applies to patients requiring irradiation to the ipsilateral neck alone.

Defining the Target: Imaging

The simulation contrast-enhanced CT is in most cases the only imaging modality required for the delineation of the targets. Magnetic resonance imaging (MRI) is a necessary adjunct to CT for tumors close to the base of skull, such as nasopharyngeal and paranasal sinus cancer, where it provides better details of tumor extension and of the parapharyngeal and retropharyngeal spaces than CT.[77,78] Another potential imaging modality for this purpose is fluorodeoxyglucose-positron emission tomography (FDG-PET). However, in a series of HNCs in which CT, MRI, and FDG-PET were obtained, and surgery was then performed to validate the primary tumor extent and lymph node involvement, a rather limited benefit of FDG-PET over CT and MRI was found.[79] PET-derived gross tumor volumes were smaller than those derived from CT and MRI, and surgical specimens were even smaller. However, when examined in detail, despite overestimation in most dimensions, all three imaging modalities actually underestimated the mucosal extent of disease.[79] Therefore, physical examination and laryngoscopy findings should be part of the definition in addition to image modalities such as CT and PET.

Selection and Outlining of the Targets

Target Definitions in the Head and Neck

As described previously, the gross tumor volume (GTV) consists of the primary tumor and of lymph nodes with apparent or suspected metastasis. The clinical target volume (CTV) surrounding the primary tumor consists of tissue perceived to contain microscopic, subclinical tumor extension. In addition to the primary tumor CTV, the lymphatic CTVs consist of nodal areas that are at risk for metastatic disease but that do not match the radiologic criteria for involved nodes.

Selection and Delineation of the Lymphatic Clinical Target Volumes

Our knowledge of the pattern and risk of lymphatic drainage from different head and neck sites is based on the classic anatomical work of Rouviere,[80] which has been reviewed,[81] the assessment of the location and prevalence of clinical neck metastasis by Lindberg[82]; and the large experience with elective neck dissections providing information about microscopic metastases, which was reported by Byers and colleagues[83] and Shah.[84] A division of the neck into six levels has been developed by surgeons from Memorial Hospital and revised by Robbins and associates.[85,86] The retropharyngeal nodes, which are not routinely dissected surgically, are not considered in the surgical neck levels classification but are important targets in the irradiation of nasopharyngeal and other advanced HNCs.[87]

The Planning Target Volumes

Once the GTVs and CTVs are outlined on the axial CT scans, a uniform expansion of these targets is performed to obtain the PTVs that accommodate setup uncertainties. Typically the magnitude of the margin is 3 to 5 mm, which means that an extra 5-mm ring of normal tissue around the target receives full dose. In a region with targets and organs at risk in close proximity, reducing this margin can potentially reduce treatment-related toxicity. Indeed, it has been estimated that each 1 mm of margin adds 1.3 Gy of dose to the parotid gland, which is particularly sensitive to low doses of radiation.[88] In order to reduce setup uncertainty, many groups have advocated daily imaging, with a position correction if the displacement from the original plan exceeds a threshold value. An example of the delineation of the targets and noninvolved structures in a case of oropharyngeal cancer is provided in Figure 77-12. The delivery of a single IMRT plan throughout the course of treatment provides better dose conformality than the use of several consecutive plans common in conventional radiotherapy, which consist of initial fields encompassing all targets followed with a boost to the gross tumor.[89] When a single plan is prescribed, the gross tumor PTV receives both a higher total dose and a higher dose per fraction than the PTVs of the subclinical disease. Owing to the differences in the daily fraction doses, a correction of the total dose to yield the normalized total dose for a 2-Gy fraction regimen is required. Therefore a standard IMRT plan would include 70 Gy over 35 fractions to the GTV, and lower fraction doses to the subclinical disease PTVs: 63 Gy to the high-risk and 56 to 59 Gy to lesser-risk elective targets, over 35 fractions (1.8 Gy and 1.6-1.7 Gy).

Dose and dose/volume specifications are made to impose constraints on the dose-volume histograms of the targets, noninvolved tissue of interest, and nonspecified tissue outside the targets. Radiation Therapy Oncology Group protocol H-0022 specified the prescription dose as the dose that encompasses at least 95% of the PTV. No more

than 20% of the PTV can receive more than 110%, and no more than 1% of the PTV can receive less than 93%, of the prescribed dose.

Dose constraints regarding critical organs are usually stated in terms of the maximal dose. Commonly applied constraints in the head and neck are maximal doses of 45 Gy to the spinal cord, 54 Gy to the brainstem, 70 Gy to the mandible, and 50 to 55 Gy to the optic pathway.

The Optimization Process: The Number and Directions of the Beams

Although tomotherapy uses arcs around the patient, IMRT using multileaf collimators requires decisions regarding the number and orientation of the beams. It was suggested early on that if the number of segments (or beamlets) is large enough, the direction of the beams is not important, and coplanar beams arranged at equal distances around the patient's head and neck would achieve satisfactory results. Most investigations of IMRT of the head and neck with multileaf collimators use this approach. The beam number should be odd, to prevent opposed beams, which would increase hot spots near their entrances to the neck. Nine beams arranged equidistantly (40 degrees apart) were found to be optimal: They provided better dose distributions than five or seven beams, whereas fifteen beams did not seem to improve the plans.[90]

Clinical Results

Most studies comparing IMRT with conventional treatments are retrospective and therefore have a potential selection bias. IMRT is far more complex and time consuming than conventional radiotherapy. It is likely that different selection factors play a role in each institution: In patients who cannot tolerate lengthy treatment, those judged to be too sick to benefit from complex therapy, those requiring urgent start of therapy, more simple, conventional treatment may be selected. Therefore the comparison of IMRT with conventional RT in such situations would be futile. With this in mind, we would like to briefly summarize the existing results for specific sites.

Nasopharynx

The use of IMRT for the nasopharynx represents opportunities to spare many critical noninvolved structures and to improve tumor coverage, as detailed previously. These improvements have been demonstrated in several treatment planning exercises in nasopharyngeal and oropharyngeal tumors, in which IMRT plans were compared with "standard 3D" plans in the same patients.[91,92]

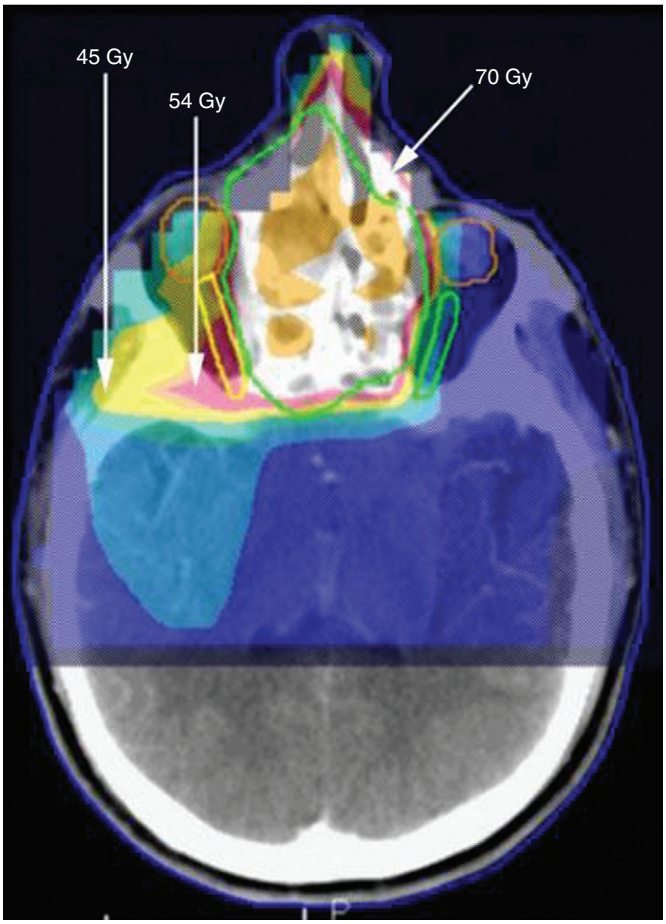

Figure 77-13. Radiation of sinuses with sparing of the optic nerves. *Green* represents GTV, to Gy dose; *yellow* is US Gy; and *pink* is SU Gy.

Two randomized prospective studies compared IMRT treatment with conventional treatment in early stage nasopharyngeal cancer.[93,94] Both showed similar high rates of tumor control and a benefit for IMRT for sparing of salivary flow. One of these studies demonstrated a benefit for IMRT in patient-related xerostomia.[93]

A large clinical series of IMRT of nasopharyngeal cancer has been reported by investigators at the University of California in San Francisco.[95] They studied 67 patients treated in the years 1995 to 2000. The GTV dose was 1.12 to 2.25 Gy/fraction to a total of 65 to 70 Gy, and the CTV dose was 1.8 to 2.0 Gy/fraction to a total of 50 to 60 Gy. In order to prevent under-dosing of the targets, the prescribed doses were typically the minimal doses encompassing the targets. The resulting delivered mean GTV dose was 74.5 Gy, at mean GTV fraction doses of 2.24 to 2.4 Gy. The resulting normalized total dose (calculated for late-responding tissue) was 80 Gy. This regimen yielded excellent locoregional tumor control: The rate was 97% at median follow-up of 31 months, with reasonable rates of acute toxicity. For re-irradiation of nasopharyngeal cancer, IMRT offers dose distribution advantages because it significantly reduces the extent of irradiation of the previously irradiated tissue volume. Lu and coworkers[96] described their experience with re-irradiation using IMRT for recurrent nasopharyngeal cancer. The rate of acute toxicity was acceptable, and at a median follow-up of 9 months, the locoregional control rate was 100%. Although longer follow-up is necessary, the preliminary toxicity and local control data for these recurrent cases are promising.[96]

Paranasal Sinuses

The main obstacle to adequate irradiation of tumors of the paranasal sinuses is the proximity of the optic pathways to the target in advanced cases. In these cases, IMRT can provide adequate target coverage while sparing the optic pathways (Fig. 77-13).

The group from the Royal Marsden Hospital found that compared with 3DCRT using the same beam arrangement, IMRT significantly reduced the dose to the optic nerves and improved PTV coverage.[97] Tsien and colleagues[98] at the University of Michigan found that IMRT planning in patients with nonresectable maxillary sinus cancer revealed no substantial difference between plans using an anterior field and two lateral fields and plans using nine equidistant beams arranged around the patient. Optimization using normal tissue complication probability (NTCP) of the optic nerves as an objective function was found to facilitate planning and to provide a basis for the assessment of the clinical trade-off between PTV coverage and ipsilateral optic nerve sparing.[98]

A large clinical series of IMRT for paranasal sinuses was reported from Ghent University in Belgium.[99] 39 patients were treated postoperatively, and the 4-year actuarial local control after surgery and IMRT was more than 80% for patients with T1-4aN0M0 disease. In the group undergoing IMRT, there was significantly lower incidence of severe dry-eye syndrome than in the historical cohort.

Oropharynx

In general, all series investigating IMRT for oropharyngeal cancer have reported outstanding locoregional control rates.[92,100] These series reported 2-year locoregional tumor control rates of 90% to 98% for patient populations who mainly had stage III or IV tumors. However, these results should be evaluated in the context of a likely selection bias and, importantly, with consideration of the emergence of human papillomavirus–related oropharyngeal cancer, which is associated with better prognosis.[101]

Some of the most reliable information gained from clinical series of IMRT for HNC in general, and oropharyngeal cancer in particular, relates to the pattern of tumor recurrences relative to the targets and the locally delivered doses. These data allow an assessment of the adequacy of target selection and delineation. In all reported cases, it seems that careful selection and delineation of the targets resulted in very few or no marginal or out-of-field recurrences. De Arruda and colleagues[100] reported that all recurrences in their series were in-field. In the series by Chao and coworkers,[102] most marginal recurrences were in the lower neck, which was treated with an anterior field that was matched to the IMRT-treated upper neck. In the series reported by Eisbruch and associates,[87] in which the majority of patients had oropharyngeal cancer, almost all recurrences were in-field, in high-risk volumes that had received the full prescribed doses.

Larynx and Hypopharynx

IMRT can improve target dose homogeneity for laryngeal and hypopharyngeal SCC while reducing the dose to the normal tissues at risk.[103-105] Clinical data on IMRT for laryngeal and hypopharyngeal SCC are scarce, however, and include limited numbers of patients within large heterogeneous series of multiple HN tumor sites.[87,95,105] In general, these series showed lower tumor control rates than those reported for oropharyngeal sites. Potential reasons could be patient selection factors. For example, at the University of Michigan, only patients with laryngeal cancer and advanced nodal disease receive IMRT. The reason is that for patients with nodal stage 0 to 1, the uppermost nodes at level II are the subdigastric nodes, which can be treated with conventional techniques while sparing the majority of the parotid glands and avoiding the oral cavity; the retropharyngeal nodes or level II near the base of skull are not at risk in these patients. Another small study has suggested a benefit in xerostomia without a compromise in local control (94% at 2 years) in advanced node-negative laryngeal cancer.[106]

In general the main intent in IMRT planning is preservation of function. One of the main issues is reducing xerostomia via the sparing of the parotid salivary glands and submandibular glands. According to one study, the mean dose of 26 Gy is the threshold for parotid gland sparing (see Fig. 77-12),[107] and patients in whom at least one functioning parotid gland was spared enjoyed significant preservation of salivary flow and reduced xerostomia.

Other potential functional gains from IMRT compared with conventional RT include reduced long-term dysphagia. Sparing of pharyngeal constrictors and the glottic and supraglottic larynx may be beneficial in this regard.[108]

Proton Therapy

Currently, all centers utilize photons, or high-energy x-rays, for their IMRT treatments. However, because of their inherent physical characteristics, protons are better able to concentrate dose inside targets and minimize dose to surrounding normal tissues. Most of the energy of a proton beam is deposited near the end of the beam path (Bragg peak), the location of which is determined by the energy of the beam. Thus, the target can be included in the tissue volume receiving the high dose while little is delivered before or after the beam passes through the target, and the integral dose delivered outside the targets is lower than the dose delivered using IMRT. Use of proton beams would be expected to reduce the risk of secondary malignancies, which is especially important in pediatric cancer patients.[109] With the use of inverse planning, intensity-modulated proton therapy (IMPT) can further improve the therapeutic index of radiotherapy. Several groups have published treatment planning comparisons of (photon) IMRT with IMPT.[110-112] Using IMPT, mean doses to the organs at risk—the parotid glands, in particular—have been reduced by as much as 50%. However, because IMPT has been used for only a few years, long-term clinical treatment results are not yet available. The areas in the head and neck that could benefit from the added conformality achievable with protons are the paranasal sinuses and nasopharynx, which are often in close proximity to the optic nerves and chiasm, as well as the brain. Retrospective reviews of 3D conformal proton therapy suggest high local control rates with minimal toxicity, including preservation of vision in patients with advanced sphenoid sinus cancers.[113]

Neutron and Carbon Ion Therapy

In addition to protons, other particles have been used to treat HNCs. Neutrons have found a niche in treatment of salivary gland tumors, after a small trial randomly assigning patients to photon or neutron radiotherapy demonstrated a survival benefit for neutron therapy.[114] Other ions, including helium, neon, and carbon, have been investigated over the past 50 years. Currently, carbon ion therapy shows the most promise. Compared with photons, carbon ions have the conformality advantage of protons, with the additional advantage of a greater relative biologic efficacy (RBE): A smaller dose of carbon ions is required to achieve the same biologic effect as a reference dose of photons. This difference is due to a higher linear energy transfer with carbon ions, which theoretically causes more irreparable DNA damage, is more effective in hypoxic cells, and is less subject to variation in radiosensitivity with cell cycle. Currently, few centers worldwide are able to treat with this modality. Initial results in adenoid cystic carcinoma and locally advanced SCC of the head and neck, which demonstrate excellent local control rates with low toxicities, are promising.[115] However, long-term results are not yet available.

Imaging-Guided Radiotherapy

The term *imaging-guided radiotherapy* relates to the performance of patient and tumor imaging with electronic portal imaging devices (EPIDs) or CT before each fraction or every few fractions of therapy in order to ensure tracking of the tumor by the treatment beams. In cancer of the head and neck, where breathing-related motion is inconsequential, imaging-guided radiotherapy has two main goals, minimizing setup uncertainties, thereby enabling reduction of the PTV margins, and assessing anatomic changes in tumor and critical tissue during the course of therapy.

Tracking Anatomic Changes during Therapy

During the 6- to 7-week course of radiotherapy, many anatomic changes can occur. Because dose distributions achieved using IMRT have steep gradients, and PTV "safety" margins are becoming smaller, it is especially important to understand the consequences of anatomic changes during therapy for the dose to both targets and normal tissues. In definitive cases, the primary tumor, nodes, or both can shrink, whereas in postoperative cases, inflammation and edema can resolve. Additionally, weight loss, a common consequence of acute treatment toxicity, can lead to muscle wasting and shifting of both normal tissue and tumor positions. Barker and associates[116] conducted a detailed study of such anatomic changes during radiotherapy for HNC.[116] The

primary tumors and nodes were noted to shrink at a median rate of 1.8% of the initial volume per treatment day, so that on the last day of treatment, the median overall volume loss was close to 70%. The parotid glands moved medially during treatment, the median displacement at the end of therapy being 3.1 mm. These changes were highly correlated with patient weight loss. After publication of these findings, several investigators suggested replanning during treatment to minimize parotid gland dosage while maximizing tumor dosage. This issue is subject to ongoing studies.

Brachytherapy

As described previously, brachytherapy is localized radiotherapy that uses many radioactive isotopes, such as radium Ra-226 and cesium Cs-137 needles for implants in certain cases or afterloading techniques using iridium Ir-192 sources.[117] These sources produce a lower-energy gamma ray, thus simplifying the radiation protection requirements associated with routine patient care. The sources are left in place for a specified time and then are removed. Alternatively, permanent implants using gold Au-198 and iodine I-125 can be used. These implants deliver their total radiation dose over the effective lifetime of the radioactive material. The obvious advantages of implants are better dose localization, which results in less radiation damage to the healthy tissue surrounding the tumor, and the relatively prolonged time over which the radiation is delivered. The disadvantages include lack of addressing subclinical disease and the requirement for general anesthesia in many cases.

External-beam radiation is given at the rate of 1.5 to 2.0 Gy per minute.[118] A typical Ir-192 implant delivers its dose at the rate of 0.4 to 0.8 Gy per hour. High-dose-rate (HDR) remote afterloading devices have also been developed. These devices push a single, high-activity Ir-192 source through a set of interstitial catheters, and a computer program controls the source dwell time at various points throughout the implant. Typically, about 3.0 to 3.5 Gy is given to a distance of about 1 cm from the periphery of the catheters each treatment, and up to two daily treatments are given about 6 hours apart. Each treatment takes about 15 to 30 minutes, depending on the strength of the radioactive source and the complexity of the implant.

Radiation Side Effects

Acute Side Effects

Acute reactions that can occur during irradiation with or without chemotherapy are predictable toxicities, and depend on the dose and schedule of radiation therapy used and the accompanying chemotherapy. Such effects include mucositis, odynophagia, dysphagia, hoarseness, xerostomia, dermatitis, and weight loss. These effects occur to some degree in the majority of patients, but they are self-limited in duration.

Acute complications can interfere with and delay treatment. Even short delays can be deleterious, interfering with local tumor control.[119,120] In one study, for example, a 5-day delay in completing RT was associated with a 3.5% to 8% reduction in local control for laryngeal cancers.[120] The effect was greater in tumors with a higher probability of local failure. In addition to treatment-related factors, the nature, frequency, and severity of complications are heavily influenced by tumor-related factors (e.g., location, invasion of vital structures) and patient-related factors (e.g., oral hygiene, nutritional status, continued tobacco use, and history of diabetes, collagen vascular disease or human immunodeficiency virus).

The following sections discuss the most common acute side effects:

Dermatitis

Radiation damage to stem cells in basal layers of the skin can give rise to a sunburn-like desquamation. This can be aggravated by chemotherapeutic agents such as 5-FU. These effects can occur as early as 2 weeks after the start of radiotherapy.

This side effect can be minimized through appropriate skin care, avoidance of exposure to potential chemical irritants, limitation of direct sun exposure, and avoiding application of lotions, ointments, or fragrances to the head and neck region to minimize the bolus effect that might alter the depth at which the maximum RT dose is delivered. IMRT typically worsens skin reaction because of the multiple target beams, but this effect can be reduced by specifying the skin as an avoidance structure and by treating the lower neck with an anterior beam rather than including it in the IMRT plan.

Xerostomia

The severity of xerostomia resulting from RT for HNC depends on the volume of salivary tissue irradiated. Temporary loss of saliva is significant after about 10 Gy is delivered to the salivary glands, whereas administration of doses significantly higher than 26 Gy can cause permanent loss of function. Alteration in taste can also occur, and decreased oral intake may contribute to reduced saliva production.

Prevention of this side effect can be performed by reducing salivary gland dosage in formal planning. Some suggested that the use of amifostine may reduce xerostomia. The benefit of amifostine was shown in a landmark trial of 315 patients receiving RT alone (60 to 70 Gy in 1.8- to 2.0-Gy daily fractions), who were randomly assigned to receive either amifostine or no amifostine.[121] Amifostine reduced the incidence of significant acute xerostomia from 78% to 51% and the incidence of significant chronic xerostomia at 12 months from 57% to 34%. This agent had no impact on rates of mucositis or on tumor control at 2 years.[121] However, data on the effect of amifostine in the chemoradiation setup are conflicting,[122,123] other than that it has severe side effects and is expensive and therefore has not been widely used.

Mucositis

Radiation-induced loss of stem cells in the basal layer interferes with the replacement of cells in the superficial mucosal layers when they are lost through normal physiologic sloughing. The subsequent denuding of the epithelium results in mucositis, which can be painful and can interfere with food intake and nutrition. Mucositis usually develops 2 to 3 weeks after the start of RT. The incidence of mucositis is variable, depending on the field, the total dose and duration of RT, and the concomitant administration of chemotherapy.[124] In one series, clinically significant mucositis occurred in 64% of patients receiving RT to the head or neck for any malignancy.[125] Both incidence and severity are higher in patients receiving chemoradiotherapy than in those undergoing RT alone. Chemotherapy can have a similar effect on the mucosa, and the combination of chemotherapy with RT increases the rate of mucositis especially when the modalities are delivered concurrently. Mucositis is managed symptomatically with scrupulous oral hygiene, dietary modification, and topical anesthetics. A variety of agents have been evaluated for use either prophylactically or after the onset of symptoms; their role in the treatment of radiation-induced mucositis is uncertain (Fig. 77-14).

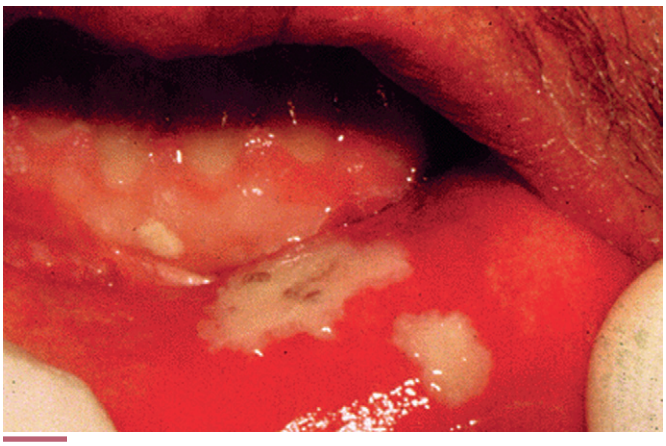

Figure 77-14. Acute mucositis.

Late Toxicities

Xerostomia

Xerostomia is a frustrating side effect that may lead to many other effects. It often improves with time,[126] but it can be long-lasting or even permanent. Regarding treatment, several strategies may minimize the incidence of xerostomia. When possible, sparing one parotid gland and, if possible, the submandibular glands can greatly diminish the incidence of xerostomia.[127] Commercially available salivary substitutes or artificial saliva (oral rinses containing hyetellose, hyprolose, or carmellose) relieve the discomfort of xerostomia by temporarily wetting the oral mucosa. Although they can provide temporary relief, especially prior to eating, many patients must take frequent sips of water to remain comfortable. In addition to being inconvenient, this can lead to secondary problems such as nocturia from late night fluid intake in men with prostatic hypertrophy and in men and in women with small bladder capacity. In patients in whom untreated or unaffected residual salivary tissues are intact, sialagogues that stimulate salivary production may be used. Sialagogues can be characterized as gustatory, tactile, or pharmacologic. Gustatory stimuli such as acidic or bitter substances are most effective at stimulating salivary flow.[128] Sweet substances such as sugar-free hard candy also stimulate the flow of saliva, but to a lesser extent. Pharmacologic sialagogues, which are typically agonists of the muscarinic (M3) receptor, include pilocarpine and cevimeline. Of these, pilocarpine has been the most extensively investigated. Pilocarpine may improve or prevent xerostomia when given after completing radiotherapy. Improvement in symptoms may occur only after many weeks of treatment, and cholinergic side effects, in particular sweating, may stop a significant number of patients from continuing to use the drug.[128]

Osteoradionecrosis

Osteoradionecrosis (ORN) of the jaw is a severe complication of RT for HNC. The presentation of post-RT ORN ranges from small asymptomatic bone exposures that remain stable for months to years and heal with conservative management, to severe necrosis necessitating surgical intervention and reconstruction. Depending on the location and extent of the lesion, symptoms can include pain, bad breath, dysgeusia, dysesthesia or anesthesia, trismus, difficulty with mastication, deglutition, and/or speech, fistula formation, pathologic fracture, and local, spreading, or systemic infection. The mandible is the most commonly affected bone, because in the majority of patients undergoing treatment for HNC, a large part of it is inevitably exposed to high RT doses. Another reason is the blood supply of the mandible, which is unilateral; the maxilla has bilateral blood supply. Maxillary ORN is reported infrequently, usually in the setting of irradiation for nasopharyngeal cancer (in which both jaws are at risk).

Mandibular ORN occurs in 5% to 10% of patients treated with conventional RT or high-dose-rate brachytherapy, and is severe in about 2%.[129,130] The incidence of this complication appears to be higher with hyperfractionated regimens, especially with a short inter-fraction interval. In one study of 168 patients with oral cancer treated with hyperfractionated or conventional RT, the incidence of ORN was higher with hyperfractionated therapy (23% vs. 9%, respectively).[130] Tooth extraction and dental disease in irradiated regions are major factors in the development of both mandibular and maxillary ORN.[129,130] Although opinion differs as to whether extraction of diseased and nonrestorable teeth should be performed before or after irradiation, many writers report that postirradiation extraction of such teeth produces a higher rate of mandibular ORN.[131] Furthermore, at least some data suggest that mandibular ORN associated with postirradiation tooth extraction more often requires radical resection than does ORN that develops after pre-irradiation extraction (45% vs. 12%, respectively).[132] Repair of nonrestorable and diseased teeth prior to RT may reduce the risk of this complication. However, most authorities do not recommend the pre-irradiation extraction of healthy or restorable teeth.

Ben-David and colleagues[133] demonstrated that rates of ORN could be significantly lower if the following rules were observed: reducing the mandibular volumes receiving high doses, improved salivary flow rates and associated improved oral health, and uniform prophylactic dental care. For mild ORN, treatment with conservative débridement, antibiotics, and occasionally ultrasound is usually successful.[134] However, when bone and soft tissue necrosis are extensive, radical resection of the mandible with immediate microvascular reconstruction may provide better results.[135] Persistence of ORN despite aggressive treatment should raise the suspicion of recurrent cancer.[135]

Hyperbaric oxygen therapy (HBO) has been suggested as a beneficial therapeutic maneuver in patients in whom ORN of the jaw develops after RT. ORN may be triggered by a predominantly fibroatrophic mechanism.[136] At least in theory; HBO simulates the function of monocytes and fibroblasts, increasing collagen synthesis and vascular density. Despite this theoretical rationale, the available data are conflicting, as to clinical benefit, of HBO for both prevention and therapy of ORN. The benefit from HBO was called into question by results of a randomized multicenter trial in which 68 patients with overt mandibular ORN were randomly assigned to receive either 30 to 40 exposures to HBO or a placebo at 2.4 absolute atmospheres for 90 minutes.[137] Healing rates were equivalent in the two groups and in fact trended toward worse in the HBO group (19%, compared with 32% for placebo; $P = .23$). Although this was only a single study and did not include patients receiving HBO prior to dental extraction, its results raise doubt about the efficacy of HBO for ORN.

Fibrosis

A serious complication of RT in the treatment of cancer patients is the late-onset of fibrosis in normal tissues, including the neck, pharynx, esophagus, and temporomandibular joint. Radiation-induced fibrosis (RIF) is similar to inflammation, wound healing, and fibrosis of any origin. Typical histologic features include the presence of inflammatory infiltrates (particularly macrophages in the earlier stages of fibrosis), differentiation of fibroblasts into postmitotic fibrocytes, and changes in the vascular connective tissue with excessive production and deposition of extracellular matrix proteins and collagen. RIF can cause a wide range of clinical manifestations, including cutaneous induration, lymphedema, restrictions in joint motion, strictures and stenoses in hollow organs, and ulcerations. Specifically in the head and neck region it may cause trismus, which can progress over time. RIF in the esophagus and hypopharynx may lead to strictures, ulcerations, and fistula formation. Radiation fibrosis to the constrictor muscles may lead to chronic dysphagia. The best way to prevent this side effect is conformal planning to spare unnecessary radiation.

Thyroid Dysfunction

Irradiation of the low neck is associated with hypothyroidism. The incidence varies widely and is dose-dependent as well as time dependent, increasing with time elapsed since treatment. RT-induced hypothyroidism develops at a median of 1.4 to 1.8 years (range 0.3 to 7.2 years) after RT.[138] It is more common in patients undergoing both neck surgery and RT but is not higher in patients who undergo chemotherapy in addition to RT than in those who have RT alone.

Vascular Complications

Carotid artery rupture (also called carotid blowout syndrome) and oropharyngocutaneous fistula are major complications associated with RT to the neck. These sequelae occur almost exclusively in patients who have received combined surgery and RT. As an example, in one series of 46 patients with carotid artery rupture, 43 had undergone extensive primary and salvage radical surgery with intraoperative brachytherapy, external beam irradiation, or both.[119] Both retrospective and prospective studies show that both carotid artery rupture and oropharyngocutaneous fistula occur more often with preoperative than postoperative irradiation.

Carotid rupture and fistula are rarely observed after definitive RT with or without concomitant chemotherapy but may be more common when tumor is invading the carotid sheath or extending into and occupying a large volume of the soft tissue of the neck.[139] Patients with ORN of the temporal bone after definitive treatment for nasopharyngeal cancer are also at risk for carotid artery rupture.

The most common angiographic abnormality seen in one study was one or more pseudoaneurysms.[140] Although this devastating complication can sometimes be managed with endovascular therapy, it recurs in up to 25% of patients, often as a manifestation of recurrent tumor or of multifocal iatrogenic arteriopathy and occasionally wound complications.

Neurologic Complications

Radiation therapy can cause toxicity to either the central or peripheral nervous system when these structures are included in the treatment field. Nervous system toxicity is usually subdivided into acute (during the course of radiation), early delayed (weeks to three months after radiation), and delayed reaction (after more than 3 months). Late toxicity is the most common.

A transient myelopathy may develop 2 to 6 months following spinal irradiation. This condition is widely believed to be due to temporary demyelination of the posterior columns of the spinal cord. Self limiting, it is generally not a precursor of chronic progressive myelitis. The characteristic manifestation is the development of Lhermitte's sign, a nonpainful but unpleasant electric shock–like sensation that shoots down the spine during neck flexion. Increased spinal cord metabolic activity and PET imaging have been described in association with Lhermitte's sign.

Radiation myelopathy may begin acutely, but more often the onset is insidious. Paresis, numbness, and sphincter dysfunction developing 6 to 12 months after irradiation are the typical manifestations of progressive radiation-induced myelitis. However, the initial signs can be subtle, such as decreased temperature sensation and decreased proprioception. These signs may stabilize or slowly progress inexorably to lower extremity weakness, footdrop, the Brown-Séquard syndrome, incontinence, hyperreflexia, loss of bowel and bladder function, and complete paresis below the irradiated section of the spinal cord. The risk of chronic radiation myelopathy rises progressively with the dose of radiation.[141] Evidence derived from several large series suggests that the incidence of myelopathy is less than 0.5% after 50 Gy with conventional fractionation.[141] The best estimate of the dose expected to cause a 5% risk of myelopathy within 5 years (sometimes called the TD 5/5) is approximately 60 Gy if the radiation is given in 1.8- to 2.0-Gy daily fractions. This dose value appears to be independent of the region or length of spinal cord treated. The risk of myelopathy increases rapidly with doses above 60 Gy, with one series reporting an incidence of 50% in patients receiving between 68 and 73 Gy to the spinal cord.[141]

CHAPTER SEVENTY-EIGHT

Chemotherapy and Targeted Biologic Agents for Head and Neck Cancer

William N. William, Jr.

Merrill S. Kies

Key Points

- Combined-modality therapy is an acceptable treatment option for patients with locally advanced squamous cell carcinoma of the head and neck in three clinical scenarios: (1) chemoradiation delivered concurrently for organ preservation, (2) chemoradiation as adjuvant therapy after definitive surgical resection, and (3) induction chemotherapy, also termed neoadjuvant chemotherapy, delivered before definitive treatment with surgery or irradiation.
- In the setting of organ preservation for cancers of the larynx and hypopharynx, chemotherapy followed by radiation therapy has been shown to produce similar survival, but higher larynx preservation rates, in comparison with surgery followed by postoperative irradiation. Chemotherapy delivered concomitantly with radiation therapy has better laryngeal preservation rates than single-modality radiation therapy.
- In the setting of adjuvant therapy after definitive surgical resection, cisplatin delivered concomitantly with radiation therapy results in higher overall survival than single-modality radiotherapy, especially in patients with high-risk features in the surgical specimen (i.e., positive margins, extracapsular nodal extension).
- Induction chemotherapy is not yet considered standard of care for patients with locally advanced head and neck cancers. However, when induction chemotherapy is used, regimens containing docetaxel, cisplatin, and 5-fluorouracil are associated with longer survival time than cisplatin–5-fluorouracil doublets.
- In the setting of recurrent/metastatic disease, regimens containing two cytotoxic drugs produce a higher response rate than single-agent regimens; however, this rate does not translate into an increase in survival.
- Molecular targeted agents directed at the epidermal growth factor have emerged as important strategies for the treatment of head and neck cancers. Cetuximab has been shown to improve survival, when added to radiation therapy, for patients with locally advanced disease. Cetuximab added to platinum/5-fluorouracil doublet chemotherapy achieves better survival than platinum/5-fluorouracil in patients with recurrent/metastatic disease. In this setting, cetuximab is also active as monotherapy in patients in whom a platinum-based regimen has failed.

The otolaryngologist frequently cares for patients with head and neck cancer who will receive chemotherapy as a component of treatment. Often, these patients have locally advanced squamous cell cancer or metastatic disease not amenable to curative therapy with surgery or irradiation. Chemotherapy may be administered concomitantly with radiotherapy (concurrent therapy), before definitive radiotherapy or surgery (induction/neoadjuvant therapy) or as a single-modality treatment for patients with recurrent or metastatic disease not amenable for cure (palliative approach). Biologic agents targeted at specific molecular pathways involved in carcinogenesis (e.g., the epidermal growth factor receptor [EGFR] pathway) have been increasingly used in these settings as well. This chapter focuses on chemotherapy and targeted biologic therapy for squamous cell carcinoma of the head and neck (SCCHN).

Surgeons treating SCCHN should be familiar with (1) the basic principles of integrating systemic therapy as a component of combined-modality programs, (2) the design and results of the key clinical trials that support the use of chemotherapy and/or biologic agents in the concomitant, induction, and palliative therapy settings, and (3) promising experimental approaches of chemotherapy and targeted agents under study for the treatment of these tumors.

Squamous Cell Carcinoma

Before 1970, chemotherapy had a limited role in the management of squamous cell cancer of the head and neck in community practice and at academic centers. Part of the reason was the paucity of available drugs with documented antitumor activity for this disease. The only drug

with clearly established activity, used worldwide, was the folic acid analogue methotrexate. Many other drugs have since been tested, although the assessment criteria used to define response years ago were not uniform. Hence, the reported response rates tended to be unreliable, representing an accumulation of observations of any degree of tumor regression. In contrast, during the past decade, more rigid criteria have been applied to the testing of potentially useful drugs. There are now clearly defined parameters for the objective evaluation of response and survival time as well as statistical guidelines for the design of clinical research trials to establish efficacy or to show improvement in comparison with standard therapies.

The serendipitous identification of the metal compound cisdiamine-dichloroplatinum (II) (cisplatin) as a potential anticancer agent by Rosenberg[1] in 1968 spurred clinical research efforts to test new agents and to develop combination chemotherapy regimens for the palliative benefit of patients with locally recurrent and metastatic cancers. After highly active chemotherapy regimens were identified, drug therapy was incorporated into combined-modality approaches for treating the newly diagnosed patient. The objectives then changed, with more focus on increasing tumor eradication in order to improve survival time. It became clear that if administered as the initial treatment, chemotherapy could result in rapid regression of tumor in the majority of patients without substantially increasing the morbidity of subsequent surgery or irradiation. Moreover, in a proportion of patients with responding tumors, there is no histologic evidence of tumor in resected specimens. This observation led to consideration of altering standard surgical approaches to some primary tumors with the objective of organ preservation. In addition to investigational trials using chemotherapy before definitive local therapy, adjuvant radiation and chemotherapy administered after surgical resection and chemotherapy used as a radiosensitizer concomitant with radiotherapy have been under active study.

A new class of drugs (i.e., targeted biologic agents or molecular targeted agents) has become available for the treatment of cancer. These compounds have a distinct mechanism of action, blocking specific molecular pathways key to the carcinogenic process. As a result, molecularly targeted drugs exhibit antiproliferative, proapoptotic, antiangiogenic and chemotherapy/radiotherapy-sensitizing properties that contribute to antineoplastic effects. Adverse events associated with these drugs are very distinct from the classic side effects observed with cytotoxic agents and are largely determined by the target pathway inhibited. Bonner and colleagues[2] demonstrated that cetuximab (a biologic agent targeted at EGFR), given concomitantly with radiotherapy, improves survival of patients with head and neck cancer, with no increased incidence of severe radiotherapy-induced side effects. This study can be accepted as proof of principle that biologic agents may become substantial therapeutic agents for this disease. Moreover, the report inaugurates an exciting era for both research and clinical management of SCCHN.

In the next sections, the roles of chemotherapy and biologic therapy in the treatment of locally advanced and recurrent or metastatic squamous cell carcinomas are discussed. Systemic therapy as a single-modality treatment has a limited or no role as a curative treatment option. However, the addition of chemotherapy given concomitantly with radiotherapy has been demonstrated to improve local control and survival, both as definitive treatment with organ preservation and after surgical resection. For locally advanced disease, chemotherapy given as an induction strategy before definitive irradiation or chemoradiation (induction) may also affect survival, especially with combination regimens utilizing a taxane, cisplatin, and 5-fluorouracil (5-FU).

A role for human papillomavirus (especially subtype 16) has now been recognized in the pathogenesis of a substantial percentage of oropharyngeal squamous cell carcinomas.[3] Transmission is sexual. The E6 and E7 viral oncogenes are overexpressed and associated with degradation of wild type p53. Indeed, molecular studies[4] suggest that human papillomavirus–positive tumors have relatively minimal genomic alterations and that, stage for stage, prognosis is better than that for human papillomavirus-negative tumors, which tend to have multiple cytogenetic changes, p53 mutations, loss of p16, cyclin D1 overexpression, and increased surface expression of EGFR.

Combined-Modality Therapy

Although surgery and radiotherapy achieves cure in a high percentage of patients with early-stage SCCHNs, conventional treatment does not achieve cure for the majority of those with locally advanced disease, and treatment for recurrent disease with chemotherapy is far from satisfactory. Thus, much effort has been directed toward improvements in primary treatment programs with advances in combined-modality therapy. To this end, the following three general approaches have been established:

- Chemoradiation for organ preservation, in which chemotherapy is given simultaneously with radiotherapy to enhance its effect as a definitive, potentially curative treatment
- Chemoradiation as adjuvant therapy, in which chemotherapy and radiotherapy are simultaneously administered after surgery in high-risk patients in an effort to improve local control and to decrease the metastatic disease burden, thus improving survival
- Induction chemotherapy, also known as neoadjuvant therapy, in which chemotherapy is given before surgery or radiotherapy in a sequential format

Concomitant Chemoradiation

For early-stage cancers of the larynx, definitive radiotherapy or conservation laryngeal surgery produces excellent tumor control with preservation of speech and swallowing functions. These approaches are discussed in Chapter 112. A majority of patients with SCCHN present with stage III to IV M0 disease and may require extensive or radical surgery, with potential deleterious effects on speech or swallow function, depending upon the primary tumor site. Of course, general appearance may also be altered. In the 1990s, the dual objectives of improving survival and preserving organs represented a major challenge and became a focus for clinical trial development. This led to the Department of Veterans Affairs (VA) Laryngeal Cancer Study,[5] which tested a nonsurgical alternative for locally advanced squamous cancer of the larynx, matching induction chemotherapy followed by definitive radiation against laryngectomy with postoperative radiotherapy. Thus, initial drug treatment as a component of primary treatment in sequence before definitive radiotherapy was tested in a prospective, phase III randomized trial.

Induction chemotherapy with cisplatin-based regimens is highly active, with clinical partial and complete responses observed in 80% to 90% of previously untreated patients. It was postulated that a substantial response to initial treatment with chemotherapy would lead to an improvement of therapeutic efficacy for surgery or radiotherapy. If so, radiotherapy might then become an acceptable alternative to laryngectomy with preservation of prospects for tumor control and organ function. In the VA Study, 332 patients with stage III or IV squamous cell carcinoma of the larynx were randomly assigned to receive either induction chemotherapy consisting of cisplatin and 5-FU followed by radiotherapy or surgery with postoperative radiotherapy.[5] Patients who experienced no tumor response to chemotherapy or those who had locally persistent or recurrent cancer underwent salvage laryngectomy. Two-year survival for both treatment groups was 68%, and 41% of patients randomly assigned to the experimental arm were alive with a functional larynx at 2 years. Thus, the efficacy of chemotherapy followed by radiotherapy (with surgical salvage) was similar to that of surgery followed by radiotherapy, establishing organ preservation as a realistic goal of nonsurgical treatment administered with curative intent. Lefebvre and colleagues[6] later reported data from a European trial involving patients with cancers of the hypopharynx. In this randomized study, comparing induction chemotherapy followed by irradiation in subjects who had complete response with surgical resection and postoperative radiotherapy, overall survival rates in the two arms were considered equivalent, again demonstrating that larynx preservation could be achieved in some patients without jeopardizing their survival. Calais and associates[7] presented data from GORTEC (Groupe d'Oncologie Radiotherapie Tête et Cou) 2000-01, which compared induction chemotherapy using cisplatin and 5-FU with 5-5-FU (TPF)

Data from Forastiere A, Maor M, Weber RS, et al. Long-term results of intergroup RTOG 91-11: a phase III trial to preserve the larynx—induction cisplatin/5FU and radiation therapy versus concurrent cisplatin and radiation therapy versus therapy. *Proc Am Soc Clin Oncol.* 2006:24(No 18S); 5517.

or without docetaxel for organ preservation in hypopharynx and larynx cancer. In 220 patients, preliminary results show a superior overall response rate of 83% with TPF, versus 61% for cisplatin and 5-FU. The rate of larynx preservation was also better, offered in 80% of patients in the TPF arm, versus 58% in the cisplatin and 5-FU arm. Neutropenia was greater in the experimental arm (57% vs. 35%). On balance, TPF demonstrated a significantly superior tumor response rate, was tolerated with acceptable toxicity, and appeared to be associated with better larynx preservation.

In the VA study,[5] there were observed trends in patterns of tumor relapse, with 20% of patients in the chemotherapy arm having locoregional recurrence, compared with 7% in the surgery arm. Distant disease recurrence was more likely in the surgical arm, affecting 17% of patients in that group, but only 11% in the chemotherapy/radiotherapy arm. Salvage laryngectomy was required more often in patients with glottic cancers than in those with supraglottic primary sites (43% vs. 31%, respectively), in patients with fixed vocal cords than in those with mobile vocal cords (45% vs. 29%), and in patients with gross invasion of thyroid cartilage than in patients without (41% vs. 35%). Notably, salvage laryngectomy was required in 56% of patients with T4 cancers but in only 29% of patients with smaller primary tumors (P = .001).

The VA study has prompted further investigations of chemotherapy and radiotherapy in the treatment of intermediate-stage laryngeal cancer using the sequential administration of induction chemotherapy, consisting of cisplatin and 5-FU, followed by radiotherapy as the control arm.[8] In a study reported in 2003 by Forastiere and colleagues,[8] called the Intergroup Radiation Therapy Oncology Group (RTOG) 91-11 trial, this modality was compared with concomitant cisplatin and radiotherapy and with radiotherapy administered as a single treatment modality. For all groups, totaling 547 patients, surgical salvage was reserved for patients with persistent or locally recurrent disease. Eligible patients had stage III or IV disease, but all of those with T1 and most of those with T4 disease were excluded. The rate of preservation of the larynx was greatest in patients receiving concomitant chemoradiotherapy, and the difference between it and the preservation rate in patients receiving radiotherapy as a single modality reached statistical significance. Survival was not affected by treatment assignment. Acute mucocutaneous toxic effects of treatment were greatest in the patients who received radiotherapy with concomitant cisplatin.

In 2006, Forastiere and colleagues[9] provided a 5-year analysis of Intergroup RTOG 91-11 data (Table 78-1). Most notably, laryngeal preservation was greatest in those patients randomly assigned to concomitant radiotherapy with cisplatin (84% vs. 66% with radiotherapy alone; P = .0002). Data for patients living with preservation of the larynx was similar when contrasted with the cisplatin and 5-FU induction arm with concomitant chemoradiation. Moreover, overall survival was 59% in the induction arm compared with 55% in the concomitant chemoradiation arm, not a statistically significant difference. Disease-free survival was similar for the sequential and concomitant chemoradiation strategies.

These trials indicate that for patients with intermediate-stage squamous cell carcinoma of the larynx, a combined treatment program with the objectives of tumor eradication and laryngeal preservation is feasible. It should be emphasized that patients with destructive T4 primary laryngeal cancers were not included in the RTOG 91-11 trial. These patients may require total laryngectomy for optimal tumor control and to preserve swallow without aspiration. Treatment planning should be multidisciplinary for accuracy in staging and most effective decision-making. Moreover, to optimize long-term function, patients should also be followed up by qualified speech pathologists, further emphasizing the value of multispecialty care in managing complex cancers of the head and neck.

Within the past decade, concomitant chemoradiotherapy has become the standard-of-care treatment option for patients with locally advanced squamous cell carcinomas of the larynx, oropharynx, and hypopharynx (Table 78-2). The theoretical rationale of and mechanism for the interaction between cytotoxic drugs and irradiation that results in additive or synergistic enhancement have been reviewed in detail.[10] This biologic phenomenon rests on several mechanisms, as follows: (1) inhibition of DNA repair, (2) redistribution of cells in sensitive phases of the cell cycle, and (3) promotion of oxygenation of anoxic tissues. The net effect is to improve cellular cytotoxicity.[11] The benefits of adding chemotherapy delivered during irradiation are notably demonstrated in two meta-analyses.[12,13] Concomitant administration of chemotherapy and irradiation was reported to achieve better local control and an 8% survival advantage at 5 years over radiotherapy administered as a single modality. Notably, however, this approach to improved tumor control appears to be associated with increased acute and chronic toxicities, inanition, esophageal stenosis with gastrostomy tube dependence, and recurrent infection related to aspiration.

The choice of the best chemotherapy regimen to be used in conjunction with irradiation has not been well addressed in randomized trials, but cisplatin 100 mg/m^2 administered on days 1, 22, and 43 of a daily radiation treatment plan is widely accepted as a standard. The major drugs with efficacy for SCCHN and in vitro evidence of radiation enhancement capability have been tested as single agents since the 1960s. Most of the single agents used to treat patients with head and neck cancer have been combined with irradiation. Multiagent chemotherapy given concomitantly with radiotherapy has also been evaluated in several studies. Data from selected randomized trials of combined therapy are shown in Table 78-2. In general, to date, there is no convincing evidence to suggest that multiagent chemotherapy is superior to single-agent chemotherapy when given concomitantly with radiotherapy. Additionally, nearly all reported trials of concomitant chemotherapy (single-agent or multi-agent) and radiotherapy have noted enhanced acute radiation-induced toxicity, primarily mucosal, which may result in dose reductions and interruptions in the radiation fractionation schedule. This result violates a guiding principle of radiation therapeutics. Thus, in combining these two treatment modalities, especially when multi-agent chemotherapy regimens are used, it is essential that sensitizing drug-related toxicity not compromise an optimal radiation dose and volume plan. As a result, single-agent cisplatin therapy has evolved as a predictable and effective regimen and is commonly accepted as a standard in the United States in chemoradiation programs

for head and neck cancers of any site. In part, this development has been due to favorable results observed in the Intergroup 0099 trial for nasopharyngeal carcinomas.[14] In this study, patients were to receive either radiotherapy alone or cisplatin (100 mg/m^2 on days 1, 22, and 43) during radiotherapy, followed by adjuvant chemotherapy with cisplatin and 5-FU (three cycles). An analysis of 147 randomly assigned patients revealed significant differences in 3-year survival time (78% vs. 47%) and progression-free survival time (69% vs. 24%) favoring the chemotherapy group.

An alternative approach to combined drug therapy and radiotherapy has been developed by Robbins and Homma,[15] with rapid infusion of high-dose intra-arterial cisplatin followed by the systemic neutralizing agent sodium thiosulfate and administered with concomitant irradiation, a technique known as RADPLAT. Drug is infused selectively into the tumor bed after technically demanding placement of microcatheters with the intent of concentrating the cytotoxic compound within the tumor and minimizing systemic exposure, in order to gain a marked therapeutic effect with modest toxicity. In a 2008 report on a series of 240 patients with T3 or T4 squamous cell cancers of the oral cavity, oropharynx, and hypopharynx, in whom RADPLAT was used, local disease control ranged from 69% to 89% and was most favorable for oropharyngeal lesions.[16] These control data approximate what may be achieved with concomitant intravenous chemotherapy. Severe mucositis was observed in 31% of patients. The precise risk of long-term complications, such as osteonecrosis and neurologic deficits, is under scrutiny. Continued research is anticipated.

Biologic agents have been studied in combination with radiotherapy as well, with EGFR-targeted agents representing the class of drugs in the most advanced stages of clinical development. See Figure 78-1 for a depiction of signaling pathways that are considered potential targets for new drugs in development. In an important study, Bonner and associates[2] conducted a prospectively randomized phase III trial in 424 treatment-naïve patients with stage III and IV SCC of the oropharynx, hypopharynx, and larynx. Patients were randomly assigned to radiotherapy as a single modality or radiotherapy with cetuximab administered in a weekly schedule at 250 mg/m^2 after an initial loading dose of 400 mg/m^2. The experimental regimen was generally well tolerated. Three per cent of patients receiving the targeted agent demonstrated severe hypersensitivity reactions, but notably, severe "in-field" mucocutaneous toxicity was not increased in the combined-modality treatment arm. Moreover, locoregional tumor control (median 24.4 months vs. 14.9 months for radiotherapy only) and overall survival (hazard ratio for death 0.74; $P = .03$) were higher in the combined-modality arm. In a retrospective subset analysis, the survival advantage was most favorable for patients with oropharyngeal primary cancers, although the study was not sufficiently powered for a survival analysis according to primary site. This is a landmark study, the first to demonstrate a survival advantage for targeted therapy in the primary treatment of SCCHN.

In summary, organ preservation strategies are feasible for the treatment of squamous cell carcinomas of the head and neck. For adequately selected patients, combined-modality treatment confers survival that is similar to if not greater than that with surgical approaches while avoiding extensive resections and maintaining anatomic organ preservation. Of concern in patients receiving chemoradiotherapy is the level of long-term organ function and quality of life. For selected patients with oropharyngeal and hypopharyngeal squamous cell cancers, concomitant chemotherapy and radiotherapy have been demonstrated to be superior to radiotherapy alone and are considered a standard of care for the treatment of locally advanced disease that is not judged amenable to surgical resection. Oral cavity and locally advanced laryngeal cancers are more often treated with surgical resection as the optimal definitive local therapy. Single-agent cisplatin therapy administered every 3 weeks with radiotherapy administered once daily is the most widely accepted regimen in the United States. Biologic agents, such as cetuximab, are currently being studied for the treatment of this disease as well. Their optimal application has not been well defined to date, but the combination of cetuximab and radiotherapy may be a suitable treatment

alternative for older patients who have intermediate-stage head and neck cancers or who are not good medical candidates for chemotherapy.

Concomitant Chemoradiation as Adjuvant Therapy

Adjuvant chemotherapy after definitive surgery is a treatment strategy used in many types of cancer with the goal of eradicating residual micrometastatic disease and thus ultimately improving long-term survival. In head and neck cancer, adjuvant chemotherapy as a single-modality treatment is still not widely accepted because previous trials have shown difficulty with completing the treatment plan and efficacy has not been demonstrated. Through the Head and Neck Intergroup organization, a large multi-institutional trial was conducted to test whether the addition of chemotherapy to surgery and radiotherapy prolonged survival time or altered the pattern of recurrence.[17] Patients with stage III or IV squamous cell carcinoma of the oral cavity, oropharynx, or larynx and patients with stage II, III, or IV of the hypopharynx in whom resection margins were pathologically negative were eligible. Randomization was to either immediate postoperative radiotherapy or three cycles of cisplatin plus 5-FU chemotherapy followed by radiotherapy. An analysis of the 503 patients in the study showed no significant difference in disease-free survival time, overall survival time, or locoregional control between the two treatment groups. However, there was a significantly lower rate of distant metastases as a site of failure ($P = .016$) at any time for patients treated with adjuvant chemotherapy. Perhaps more important was the finding that a high-risk subset of patients (those with extracapsular extension, carcinoma in situ, or narrow surgical margins) appears to benefit from adjuvant chemotherapy, with increases in survival time and local control that approached statistical confidence in comparison with those receiving radiotherapy alone.

Two trials testing induction chemotherapy added maintenance chemotherapy to one treatment group and observed differences in outcome. The Head and Neck Contracts Program[18] trial of one course of cisplatin and bleomycin induction chemotherapy before surgery and irradiation also planned for 6 months of maintenance chemotherapy in one of the three treatment arms. A significant decrease in the distant metastatic rate was observed for patients in that arm. Ervin and associates[19] randomly assigned patients showing a response to cisplatin, bleomycin, and methotrexate induction chemotherapy to receive either three additional cycles or observation after definitive surgery and radiotherapy. The 3-year disease-free survival time for patients receiving maintenance chemotherapy was 88%, compared with 57% for the control subjects ($P = .03$). In a phase II pilot study, Johnson and colleagues[20] treated 42 patients who had extracapsular spread of tumor in cervical lymph node metastases with 6 months of methotrexate and 5-FU after resection and radiotherapy. The 2-year disease-free survival rate was 66%, which was better than the control rate of 38% that was expected on the basis of historical experience.

Considered together, the results of these trials indicated that adjuvant chemotherapy can affect micrometastatic disease and decrease the rate of distant recurrence. The data also suggested that disease-free survival time might be improved. However, impediments to successfully conducting adjuvant or maintenance chemotherapy in patients with head and neck cancer are patient noncompliance and physician fatigue. The morbidity of the primary treatment, combined with the medical and social situations of many patients, makes classic adjuvant chemotherapy difficult or sometimes not feasible. In addition, there appears to be no role for adjuvant chemotherapy in low-risk patients, although high-risk patients may benefit. Certainly, improved patient selection remains to be clarified in definitive randomized phase III trials.

More recently, prospective phase III studies conducted in the United States[21] and Europe[22] testing the value of concomitant cisplatin and radiotherapy in patients considered at high risk for recurrence after surgery because of tumor margin involvement of the resected specimen, nodal extracapsular spread, or both have demonstrated better local tumor control and overall survival.[23] Although the entry criteria were slightly different in the two studies, patients were randomly assigned to either radiotherapy alone or combined treatment. The rate of acute mucocutaneous side effects was higher in the combined-modality arm, but the chronic toxicity was not reported to be elevated. There was an overall 42% reduced risk of locoregional treatment failure. Thus, for patients who have undergone surgery and have the selection factors previously indicated, postoperative drug therapy with concomitant radiotherapy is now considered the standard of care.

Induction Chemotherapy

Theoretically, treatment with chemotherapy before surgery or irradiation—known as induction chemotherapy—has several advantages. Initial treatment with chemotherapy is feasible. Patients are not debilitated because of surgery or radiotherapy. Clearly the drug activity is optimal in the previously untreated patient, probably because there had been no disruption of normal vascularity. Effective systemic therapy induces primary and nodal disease response in a high percentage of patients, and further, there may be a systemic effect with a reduction in risk of distant disease recurrence.[24]

With the introduction of cisplatin into clinical trials in the mid-1970s, Hong and coworkers[25] combined cisplatin with a 5- to 7-day continuous infusion of bleomycin and observed an overall response rate of 75%, with a 20% complete response rate. Other investigators added vinblastine, vincristine, or methotrexate to the two-drug combination and had similar results. An alternative and probably more effective regimen tested in the 1980s at Wayne State University was cisplatin (100 mg/m^2) followed by a 5-day infusion of 5-FU (1 g/m^2 per day by continuous infusion). In phase II trials, this regimen produced an overall response rate as high as 93% and a 54% complete response rate when three cycles were administered.[26] Although the toxicity from cisplatin is the same, 5-FU appeared to be better tolerated than bleomycin, without the associated allergic phenomena or lung toxicity.

Ensley and colleagues[27] from Wayne State University have reported a high complete response rate with the use of five or six courses of cisplatin and 5-FU alternating with methotrexate, leucovorin, and 5-FU. In one study, the complete response rate was 65% in 31 patients completing the protocol, although toxicity was formidable and approximately one third of patients withdrew from the study early. Despite the potential for improvement in response rate, the applicability of alternating regimens has yet to be demonstrated. This group of investigators and others showed that a response to induction chemotherapy correlated with a response to subsequent radiotherapy.[28-30] Thus, patients whose tumors are resistant to cisplatin-based induction chemotherapy had a high likelihood of not having a response to radiotherapy.

Most authorities agree that randomized trials incorporating appropriate stratification factors and prognostic variables, and with adequate follow-up periods, are necessary to draw conclusions about the effects of induction chemotherapy on disease-free survival and overall survival.[24,31] The results of numerous randomized controlled trials of induction chemotherapy before surgery, radiotherapy, or both, have been published.

The previously mentioned Head and Neck Contracts program,[18] a Southwest Oncology Group trial,[32] and the VA Laryngeal Cancer Study Group trial[5] were large multi-institutional randomized studies. The patients in all studies had advanced resectable head and neck cancer, and the treatment arms were well balanced as to TN stage and primary site. The Head and Neck Contracts program randomly assigned patients to receive one of the following three treatments: (1) surgery followed by irradiation, (2) induction chemotherapy with one cycle of cisplatin plus bleomycin followed by surgery and irradiation, and (3) induction chemotherapy, surgery, irradiation, and maintenance chemotherapy with cisplatin for 6 months. The 5-year survival rates for the three regimens were 35%, 37%, and 45%, respectively; the differences were not statistically significant. However, the time to development of distant metastases and the frequency of distant metastases as a site of first recurrence were significantly lower in patients in the maintenance chemotherapy arm than in the other two groups.[18] Subgroup analysis also found a significant difference in disease-free survival time for patients receiving maintenance chemotherapy for oral cavity primary tumors and for N1 or N2 disease.[33] In retrospect, it is not surprising that this trial did not show improvement in overall survival time because only one cycle of cisplatin and bleomycin was administered before surgery, resulting in a low response rate of 37%.

In the Southwest Oncology Group trial, patients were randomly assigned to receive either three cycles of cisplatin, bleomycin, methotrexate, and vincristine before surgery and radiotherapy or standard treatment with surgery and radiotherapy. The median survival time was 30 months for patients in the standard treatment arm and 18 months for those in the induction chemotherapy arm. The distant metastatic rate was 49% with standard treatment and 28% with induction chemotherapy. Although differences in survival time and pattern of recurrence are striking, they did not reach statistical significance. This trial fell short of its accrual goals and had a high rate of noncompliance, with only 56% of patients assigned to induction chemotherapy completing the treatment per protocol.[32]

Domenge and associates[34] have reported a phase III trial in which 318 patients with locally advanced oropharyngeal squamous cancers were randomly assigned to receive either induction chemotherapy with cisplatin and 5-FU followed by locoregional treatment or locoregional therapy alone. Overall survival was better in the chemotherapy group (median, 5.1 vs. 3.3 years; $P = .03$).

Encouraging data emerge from induction chemotherapy trials and in the area of organ preservation concurrent chemoradiotherapy. The VA Laryngeal Cancer Study Group[5] completed a randomized trial in patients with resectable stage III and IV squamous cell cancer of the larynx. Patients were randomly assigned to receive either standard therapy with total laryngectomy and postoperative radiotherapy or a maximum of three cycles of cisplatin and 5-FU chemotherapy followed by radiotherapy. Surgery was reserved for salvage in patients with persistent or recurrent disease. If patients did not have at least a partial response at the primary site after two cycles of chemotherapy, they underwent immediate surgery. The complete and partial response rate after two cycles of chemotherapy was 85%, and after three cycles it was 98%. The pathologically confirmed complete response rate at the primary site was 64%. At a median follow-up period of 33 months, there was no significant difference in survival time. However, the patterns of relapse differed: recurrence at the primary site was 2% for the surgery group compared with 12% for the chemotherapy group ($P = .0005$); regional node recurrence rates were similar ($P = .305$); rates of distant metastases were 17% and 11%, respectively ($P = .016$); and the rates of second primary malignancies were 6% and 2%, respectively ($P = .029$). After 3 years of follow-up, 66% of surviving patients in the induction chemotherapy treatment group had a preserved, functional larynx. Similar results were reported by a European Organisation for Research and Treatment of Cancer study comparing cisplatin and 5-FU induction chemotherapy followed by radiotherapy with laryngopharyngectomy and irradiation in patients with locally advanced cancer of the hypopharynx. There was no survival difference between the arms, and 28% of patients receiving sequential chemotherapy and radiation were alive with a functional larynx at 3 years. The larynx preservation rate was 42% at 3 years, only deaths from local disease being regarded as treatment failure.[6]

In the follow-up to the VA study, the Head and Neck Intergroup conducted a prospective three-arm study comparing (1) induction chemotherapy with cisplatin and 5-FU followed by radiotherapy, (2) radiotherapy alone, and (3) radiotherapy with concomitant cisplatin.[9] Entry criteria involved stage III or IV disease, but T1 and advanced T4 lesions conferred ineligibility. Tumors infiltrating more than 1 cm into the tongue base or demonstrating thyroid cartilage destruction were also barred from the study. Five hundred forty-seven patients were entered, 65% of whom had stage III disease. Two thirds of patients had supraglottic primary tumor sites. No unexpected toxicity was observed. With no difference in overall survival, the concomitant treatment arm resulted in superior larynx preservation; the rate for that group was 88%, compared with 74% for sequential chemotherapy and irradiation and 69% for radiotherapy alone. Notably, patients with destructive T4 primary tumors were excluded from this study. Long-term outcomes, including quality of life and functional data, are awaited.

Two trials showed an improvement in survival time for chemotherapy-treated patients after subset analysis. In a large Italian study, Paccagnella and others[35] observed an improvement in local control, metastatic rate, and survival time for patients with inoperable tumors. In a follow-up study to the Head and Neck Contracts Program study, Jacobs and others[33] reported an improvement in survival time for the subgroup with oral cavity primary tumors and limited nodal disease. Multiple trials have shown a decrease in the rate of distant metastasis.[6,24,32,33,35]

These trials have helped clarify many issues. First, the overall response rates to cisplatin-based chemotherapy range from 60% to 90% with clinical complete response rates of 20% to 50%. Survival time is better in patients with a complete response than in patients with no response, and complete pathologic responses can be seen in about 30% of patients with complete clinical responses. Second, a response to chemotherapy predicts for a response to radiotherapy. Tumors that show no response to chemotherapy do not respond well to irradiation. Third, neoadjuvant or induction chemotherapy increases neither surgical nor radiotherapy complication rates. Fourth, the most critical prognostic factors for response have been TN stage and type of chemotherapy. Biologic behavior appears to differ per site. Fifth, although no benefit in overall survival time has yet been shown, a significant reduction in the rate of distant metastases has been observed with induction chemotherapy. Finally, this modality can achieve organ preservation and improved quality of life. For patients with advanced laryngeal cancer who would require a total laryngectomy, the available data indicate that laryngeal function can be maintained in two thirds without jeopardizing survival time. However, much more work in this area as well as longitudinal follow-up are needed, especially with respect to preservation of functional swallow in the setting of induction chemotherapy followed by chemoradiotherapy, particularly in patients with cancers of the oropharynx and hypopharynx.

There has been increased interest in the study of induction chemotherapy, with the development of potentially more effective three-drug combinations (Fig. 78-2). These trials reflect attempts to improve on the cisplatin and infusional 5-FU regimen. Hitt and coworkers[36] compared cisplatin and 5-FU with a three-drug combination of paclitaxel, cisplatin, and modified dose of 5-FU (PCF). Responses were significantly better in the experimental program (33% complete response vs. 14% for the two-drug group), without an overall increase in the rate of acute toxicity. Indeed, rates of mucositis seemed reduced with the modified 5-FU dosage. Grades 2 to 4 mucositis affected 16% of patients who received PCF compared with 53% of patients treated with cisplatin and 5-FU. Significant peripheral neuropathy occurred in 8% of patients who received PPF. Following induction chemotherapy, patients received concomitant chemoradiation with cisplatin (100 mg/m^2) administered on days 1, 22, and 43. Patients who received the three-drug combination showed a trend to longer overall survival ($P = .06$); however, the subset of patients whose disease was defined as "unresectable" experienced a clearer benefit ($P = .004$).

Later studies[37,38] have generated considerable excitement. A 358-patient phase III European Organisation for Research and Treatment of Cancer study compared cisplatin and 5-FU with docetaxel, cisplatin, and 5-5-FU (TPF). After induction chemotherapy administered for four cycles, all patients received radiotherapy as a single modality. With a median follow-up of 32 months, TPF produced superior tumor responses, with a significant progression-free survival advantage hazard ratio of 0.72 and an overall survival hazard ratio of 0.73. Also, more toxic deaths (5.5% vs. 2.3%) were observed in the cisplatin and 5-FU arm. In the TAX 324 phase III trial,[38] 501 patients were randomly assigned to receive either induction chemotherapy with docetaxel (75 mg/m^2), cisplatin (100 mg/m^2), and continuously infused 5-FU (1000 mg/m^2/day) for 4 days or the standard cisplatin and 5-FU schedule. Three treatment cycles were administered before patients underwent an examination under anesthesia followed by chemoradiation, with weekly carboplatin area under the curve 1.5. Next, a fraction of patients underwent surgery either for residual disease or for advanced node involvement at diagnosis. There was a significant disease-free and overall survival advantage for patients receiving TPF. With a hazard ratio of 0.70, 62% of patients who received TPF were alive at 36 months, compared with 48% of patients who received standard cisplatin and 5-FU. Analysis of the sites of treatment failure also is of note. There was an unexpected, but statistically significant difference with respect to locoregional disease control favoring the TPF group as well

as a more modest reduction in the distant metastasis rate with the addition of the third drug (Table 78-3).

Previous experience with induction chemotherapy has not led to a consensus regarding overall benefit. There is the potential for added chemotherapy toxicity and a delay of or compromise in definitive local therapy. However, the data of the recent randomized trials are promising, and we strongly support ongoing randomized studies designed to more precisely define the value of induction chemotherapy in patients with locally advanced disease who are then to proceed to concomitant chemoradiation. Treatment planning for induction chemotherapy is likely to be most applicable in patients with advanced or lower neck nodal metastases, at diagnosis—patients at greatest risk for development of distant metastases after effective local therapy. Two such trials are currently accruing patients in North America, both testing docetaxel, cisplatin and 5-FU followed by concomitant chemoradiotherapy. Survival is the primary end point. These studies are summarized in Table 78-4. We anticipate that future phase I and II studies will evaluate innovative and novel systemic therapy programs with integration of molecularly targeted agents. We look forward to a day when individual patient characteristics, tumor site and stage, and tumor biologic markers will prompt individualized therapy based on validated selection factors.

Induction chemotherapy is highly active, with tumor responses observed in a large percentage of patients. TPF is the current model for further testing; the induction strategy has been demonstrated to reduce risk of distant metastases but also represents a vehicle for the evaluation of other clinical and molecular end points. The development of increasingly effective induction chemotherapy may eventually result in better local local disease control after radiotherapy. However, we must await the results of ongoing randomized trials, as well as better identification of the subgroups of patients who may be most likely to benefit from this approach, before we accept induction chemotherapy as a standard treatment.

Systemic Chemotherapy for Recurrent or Metastatic Disease

Systemic management of recurrent head and neck cancer is a major concern, because 30% to 50% of patients with locally advanced SCCHN at diagnosis eventually die of recurrent local or regional disease within 5 years. Distant metastases may be clinically present in about one third of patients with recurrent disease, but autopsy may determine the presence of disease in up to 60%.[39] The primary goal of conventional chemotherapy used for palliation should be to ease discomfort and prolong survival time. Patients with locally advanced or disseminated recurrent SCCHNs have a median survival time of 6 to 9 months, and 20% survive 1 year. Patients with tumors showing a substantial response to chemotherapy have better symptom control and overall survival.

Prognostic Factors

Many chemotherapy trials have been analyzed to determine factors that would predict a favorable response to chemotherapy and prolonged survival time. Most single-institution trials have only modest numbers of patients, so firm conclusions about their results cannot be drawn with statistical confidence. For patients with recurrent disease, poor prognostic factors are a low performance status, poor nutrition, a large tumor burden, and extensive previous radiotherapy and surgery.[40] Tumor progression during or shortly after surgery or radiotherapy is also an

Table 78-4

Ongoing Randomized Induction Chemotherapy Trials in Squamous Cell Carcinoma of the Head and Neck

ominous sign. In these circumstances, any response to chemotherapy is likely to be marginal and brief, without an impact on overall survival time. However, it seems clear that survival time may be prolonged in patients who demonstrate a complete response to chemotherapy. These patients, in general, have good performance status, they are not malnourished, and they have not received previous chemotherapy for recurrent disease.

In the next sections, we discuss the use of single agents and combination chemotherapy for the palliative treatment of recurrent or mestastatic SCCHN. Last, we describe the promising results obtained with selected molecularly targeted agents, which are currently being evaluated in both locally advanced disease and metastatic disease.

Single Agents

The response rate (complete and partial) of recurrent or metastatic squamous cell cancer to commonly used agents is 20% to 40%, and the drugs most commonly used are the platin compounds (cisplatin and carboplatin), taxanes (docetaxel and paclitaxel), 5-FU, methotrexate, and ifosfamide. In general, the older literature indicates that about one third of patients have response to treatment. Response criteria previously were somewhat less stringent than today. According to the Response Evaluation Criteria in Solid Tumors (RECIST), a partial response is defined as a reduction in the largest tumor dimension by 30%. The majority of responses to single agents are partial, as indicated by clinical and imaging criteria, with less than 5% of patients having a complete response to chemotherapy alone. Response duration tends to be brief, on the order of 2 to 4 months, and median survival time is 6 to 9 months. Methotrexate and cisplatin are the most extensively studied single agents for this disease, and they may still be considered to be of standard use, but most practitioners recommend a platin and taxane drug combination regimen for patients medically able to tolerate it.

Methotrexate was previously widely used for management of SCCHN. Therapy with this drug is relatively nontoxic, inexpensive, and convenient. Response rates to conventional doses vary between 10% and 50%, averaging 30%.[41] Weekly treatment with doses in the range of 40 to 60 mg/m^2, if tolerable, is superior to twice monthly or monthly treatments. Levitt and associates[42] have shown in vitro that when moderate to high doses of methotrexate are used with leucovorin rescue, an enhanced therapeutic index results from the high intracellular levels of drug associated with selective rescue of healthy tissue. The initial results of pilot trials of moderate- or high-dose methotrexate suggested improvement in response rates for patients with head and neck cancers. However, there has been no clear benefit to the higher dose levels (e.g., as much as 5000 mg) from prospective randomized trials comparing conventional-dose with moderate- or high-dose methotrexate, with or without leucovorin rescue,[43,44] and the approach has fallen out of use.

Cisplatin is associated with response rates ranging from 10% to approximately 30%, with some reported complete responses and a duration of response of approximately 2 to 4 months.[45,46] Two controlled trials comparing methotrexate with cisplatin found no difference in response rate or survival time between the two, but noted quite different toxicities.[47,48] Advantages of cisplatin over methotrexate are a relatively rapid response rate and the need for less frequent administration, every 3 or 4 weeks. Cisplatin has been studied at different doses to determine whether a dose-response effect exists. In a comparison of 60 mg/m^2 and 120 mg/m^2, Veronesi and coworkers[49] found no difference in response rates. Forastiere and colleagues[50] conducted a pilot trial evaluating 200 mg/m^2 and observed a 73% response rate, or double that expected with conventional dosing. Although these findings suggested a benefit from the higher dose, ototoxicity and neurotoxicity occurred frequently, limiting the feasibility of this approach.

Combination Chemotherapy

In an effort to improve response rates and, hopefully, survival time, combination chemotherapy was developed. Many combination chemotherapy regimens have been evaluated in phase II trials involving a few patients with recurrent head and neck cancer. Often, the results indicate a high response rate that suggests improvement over that expected from single-agent therapy with methotrexate or cisplatin. However, the median duration of response ranges from 2 to 4 months, and there has not been a clear demonstration of a median survival advantage for conventional cytotoxic chemotherapy combinations. Moreover, these regimens may be complex to administer and have greater toxic effects than single-agent therapy.

Most often, prospective comparative trials with patients randomly assigned and stratified for prognostic variables are needed to best determine therapeutic benefits of new or innovative drug regimens. Large multi-institutional trials well designed with respect to prognostic factors tend to show a significant difference in response rates between the combination treatment and single-agent control arms.[51-55] The Eastern Cooperative Oncology Group (ECOG) compared an outpatient regimen of cisplatin, bleomycin, and methotrexate with weekly methotrexate.[55] The rate of response to single-agent therapy with methotrexate was 35%, and that to the combination 48%—a significant improvement ($P = .04$). However, toxicity was greater for the combination, with no difference in survival time.

The Southwest Oncology Group reported a comparison of cisplatin with 5-FU, carboplatin with 5-FU, and weekly methotrexate.[52,53] The response rates for the three arms were 32%, 21%, and 10%, respectively. There was a significant difference in response rates between the cisplatin combination and methotrexate ($P < .001$); the difference between the response to the carboplatin combination and the response to methotrexate approached statistical significance ($P = .05$). Cisplatin with 5-FU was associated with significantly more toxicity than methotrexate; carboplatin with 5-FU was intermediate in toxicity. Despite these findings, the median survival times were no different, varying between 5.6 and 6.6 months. The third study to show a difference in response rates compared the combination of cisplatin and 5-FU with each drug used alone.[54] The response rate to the combination was 40%, compared with 18% for cisplatin and 15% for

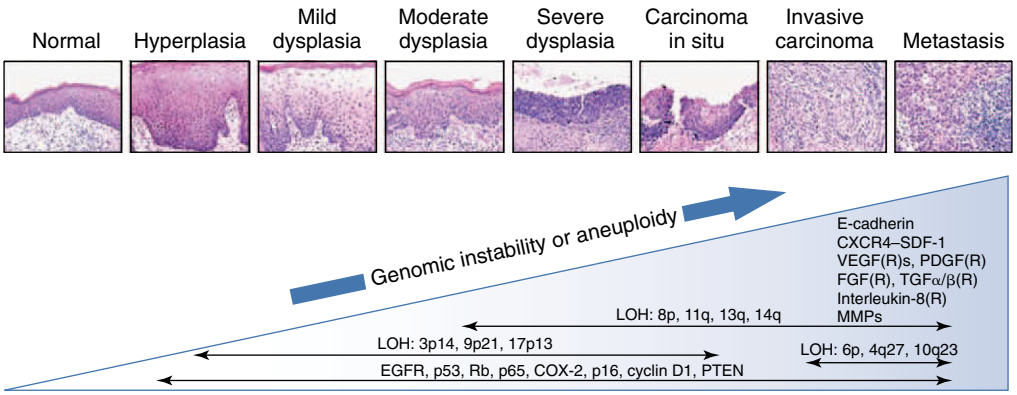

Figure 78-3. Head and neck cancer is considered to progress through a multistep process from normal histologic features to hyperplasia through mild dysplasia, moderate dysplasia, severe dysplasia, carcinoma in situ, invasive carcinoma, and metastasis. Underlying genetic instabilities, including the loss of heterozygosity (LOH) of certain chromosomes (3p14, 9p21, 17p13, 8p, 11q, 13q, 14q, 6p, 4q27, and 10q23) and amplification or deletion or up-regulation or down-regulation of certain oncogenes or tumor suppressor genes, including epidermal growth factor receptor (EGFR), p53, Rb, p65, cyclooxygenase 2 (COX-2), p16, cyclin D1, and phosphatase and tensin homologue (PTEN), have been identified as genetic alterations in each of the pathologic stages of this disease. Several genes—including those encoding E-cadherin (CDH1), chemokine (C-X-C motif) receptor-stromal-cell-derived factor (CXCR4-SDF-1), vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factors α and β (TGF-α and TGF-β), interleukin-8, and the respective receptors, along with matrix metalloproteinase (MMP)—are involved mainly in the progression of metastasis and in early stages of tumor progression. (R), randomization. *(From Haddad RI, Shin DM. Recent advances in head and neck cancer.* N Engl J Med. *2008:359:1143-1154.)*

continuous-infusion 5-FU ($P < .01$). Although the median survival times were not different, an analysis of patients surviving longer than 9 months showed a 40% survival rate for the combination treatment group, compared with 27% for cisplatin and 24% for 5-FU ($P < .05$). The latter two trials are also of interest because of the similar response rates observed for cisplatin and 5-FU, which were administered with the same dose and schedule. Cisplatin with 5-FU is a commonly used drug regimen for the treatment of patients with head and neck cancer both for palliation and in combined-modality programs. The results of these large trials have served to establish that a response rate of 30% can be expected from the cisplatin and 5-FU combination in patients with recurrent head and neck cancer. Clavel and associatess[51] also observed differences between combination chemotherapy and single agents. They found higher response rates for two cisplatin-based combinations than for single-agent methotrexate therapy—34%, 31%, and 15%, respectively.

From these randomized trials, it appears that higher response rates can be achieved with some combination chemotherapy regimens. Toxicity is more severe, and overall median survival time is not notably improved.

In an attempt to compare the efficacy of cisplatin with 5-FU with that of cisplatin with paclitaxel, the Eastern Cooperative Oncology Group conducted a prospective phase III trial on 218 patients with locally advanced, recurrent metastatic disease. Patients were randomly assigned to cisplatin 100 mg/m^2 on day 1 followed by 5-FU infusion 1000 mg/m^2 per day for 4 days or cisplatin 75 mg/m^2 and paclitaxel 175 mg/m^2 on day 1. Tumor responses were observed in 27% of the cisplatin–5-FU group and 26% of the cisplatin-paclitaxel group, with similar toxicity. There was no survival difference.[56]

Targeted Therapy

The histologic prognostic factors for head and neck cancer are the presence of locoregional metastases, perineural invasion, vascular or lymphatic invasion, positive surgical margins, and extracapsular spread of tumor cells from involved lymph nodes into soft tissues of the neck. There is a major effort[4] to identify molecular signatures and to better understand mechanisms of tumor progression as this may facilitate the identification of more precise biomarkers and vulnerable therapeutic targets.

Metastatic progression of tumor cells is a multistep and complicated process.[57] Each step appears to involve interdependent molecular interactions among tumor cells and between tumor cells and the surrounding microenvironment. Multilayered systems are under study with genomic and proteomic techniques. See Figure 78-1 for a conceptualization of potential molecular targets. DNA microarray and other techniques posit multiple potential factors affecting metastases:[58-60] keratins, cell-surface proteases, mesenchymal-cell markers, cell-matrix adhesion molecules, chemokines, and modulating elements for the extracullular matrix and epithelial-to-mesenchymal transition.[61] Chemokine (C-X-C motif) receptor (CXCR4), and its ligand, stromal-cell-derived factor (SDF-1), may combine to direct primary tumor cells to metastatic sites.[60] This activity may be crucial in the evolution of metastatic patterns and relate to enhanced secretion of angiogenic factors, such as vascular endothelial growth factors (VEGFs), and surface receptor concentration. Figure 78-3 provides a model of genetic instability and tumor progression in SCCHN.

Antiangiogenic compounds target VEGF, platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), transforming growth factors α and β (TGF-α and TGF-β), and interleukin-8, along with the receptors of these proteins.[4] Phase I and II trials are examining VEGF inhibitors, single agents or in combination with chemotherapeutic agents, in SCCHN. We have observed tumor responses in 25% of patients receiving cetuximab and bevacizumab in a phase II inter SPORE project with no significant hemorrhagic toxicity as yet.[62]

EGFR is overexpressed in SCCHN.[63,64] The development of monoclonal antibodies and small-molecule tyrosine kinase inhibitors has led to "inhibition" of EGFR signaling and associated molecular networks. EGFR consists of four family members. EGFR-1 (HER1) and EGFR-2 (HER2/neu) are the best characterized.[65] Ligands for EGFR are epidermal growth factor (EGF), TGF-α, amphiregulin, epiregulin, betacellulin, and heparin-binding EGF-like growth factor (HB-EGF). HER2 has no known natural ligands. After binding receptor, dimerization obtains and activates subsequent phosphorylation of tyrosine kinases, downstream signaling mediators and ultimately cellular proliferation. Nuclear translocation of EGFR and other growth factor receptors is important for signaling in rapidly growing cells, and the activity is largely abrogated by treatment with cetuximab, which also strongly inhibits phosphorylation of EGFR. EGFR and the ligands, EGF and TGF-α, are overexpressed in SCCHN, and linked to a poor prognosis after treatment. For these reasons, EGFR is a target for experimental therapeutics.[4,66]

Chimeric and humanized IgG antibodies target the extracellular domain of EGFR epitopes and have been shown to prevent EGFR signaling.[65] Antibodies have been shown to have single agent antitumor

activity. Small molecule EGFR tyrosine kinase inhibitors, such as gefitinib and erlotinib, bind within the intracellular domain to inhibit kinase activity, thus modulating transcription, cell-cycle progression, cell survival, and motility, all of which facilitate invasiveness and metastasis. In early clinical trials, these agents have independent activity, with response rates from 5% to 15% depending upon dose and schedule.[24]

Most recently, there have been efforts to identify targeting agents which would exploit tumor cell vulnerabilities. Cetuximab is a chimeric monoclonal antibody directed against the epidermal growth factor receptor (EGFR), and has been found to be quite an active agent in SCCHN, when used as a single compound,[67] or in combination with cisplatin or radiotherapy. In a important phase III trial,[68] 117 patients with metastatic or recurrent SCCHN were randomized to receive cisplatin as a single agent or in combination with cetuximab. The addition of cetuximab improved the overall response rate from 10% to 26% ($p = 0.03$) and median survival from 2.7 to 4.2 months. These data suggested benefit associated with the combination, over single agent cisplatin.

In a landmark study, Vermorken and colleagues[69] randomly assigned 442 eligible patients with untreated recurrent or metastatic squamous cell carcinoma to receive a platin/fluorouracil regimen with or without cetuximab, in a prospective phase III trial. This led to significant prolongation of overall survival from 7.4 months to 10.1 months in the group of patients receiving cetuximab, $P = 0.04$. The addition of cetuximab prolonged median progression free survival from 3.3 to 5.6 months ($P < 0.001$) and increased the response rate from 20% to 36%. There was no crossover treatment. This study marks the potential for targeted systemic drug therapy to have an impact on survival, as a component of treatment for patients with metastatic disease.

Chemoprevention of Head and Neck Cancer

Chemoprevention is defined as the administration of pharmacologic agents to inhibit the events occurring during the multistep process of carcinogenesis or the reversal of a premalignant condition[70,71] The key concepts underlying chemoprevention are that carcinogenesis is multistep (i.e., it results from accumulated genetic and epigenetic alterations), multipath (i.e., multiple functional pathways are involved, such as self-sufficiency in growth signals, insensitivity to anti-growth signals, apoptosis evasion, limitless replicative potential, tissue invasion and metastasis and sustained angiogenesis), and multifocal (both multiclonal, i.e., "field cancerization," and clonal, i.e., cloning expansion leading to intraepithelial spread).[72]

Drug development for chemoprevention purposes is challenging, given that the cancer risk for the overall population is relatively low, especially for head and neck cancers. Chemoprevention interventions usually have to be administered over extended periods of time and long-term follow-up is necessary to ascertain the true benefits (i.e., reduced incidence of invasive cancer) of any given treatment. In an effort to expedite advances in the field, in 2002, the American Association for Cancer Research recommended the development of chemoprevention strategies focused on carcinogenesis, not necessarily invasive cancer, as a measure of clinical benefit. This recommendation specified the prevention and regression of clinical/histopathologic intraepithelial neoplasia (i.e., pre-malignant lesions).[70] A 2006 update of these recommendations highlighted the importance of molecular intra-epithelial neoplasia (i.e., molecular alterations detected early in the target histopathologic intra-epithelial neoplasia) as a potential surrogate marker for invasive cancer and an end point for chemoprevention studies.[71]

The setting of head and neck pre-malignant lesions provides an excellent model for chemoprevention studies, given that these lesions can be easily followed by physical examination, and are readily assessable for biopsies, both for histopathologic evaluation and biomarker discovery. Furthermore, there has been increasing knowledge on the carcinogenic pathways leading to transformation of head and neck premalignant lesions into invasive cancer, thus providing strong rationales for developing strategies for cancer risk assessment, treatment and prevention, as well as identification of surrogate markers of invasive cancer that could serve as intermediary end points in chemoprevention studies.

As a result, many head and neck cancer prevention trials have focused on patients with pre-malignant lesions (i.e., leukoplakia and erythroplakia) to test a variety of pharmacologic compounds (e.g., retinoids[73-79] and non-steroidal anti-inflammatory agents[80,81]). The majority of these trials relied on histopathologic or clinical response of the oral pre-malignant lesions as the primary end point (as opposed to invasive cancer incidence), and none resulted in the development of chemopreventive agents that could be used routinely in the clinic (either due to toxicity or lack of long-term efficacy). A second set of trials focused on the prevention of second primary tumors/tumor recurrence after definitive treatment of a head and neck cancer.[82-86] So far, these trials also failed to identify drugs that could be routinely used in the clinic for this indication.

In the next paragraphs, we will summarize the seminal head and neck chemoprevention studies with retinoids (the most widely investigated class of drugs in this setting). Subsequently, we will briefly discuss how the molecular knowledge gained from the translational component of these and other trials is now shaping the design of the next generation of molecular-targeted, chemoprevention clinical studies in head and neck cancer.

Retinoids are the synthetic and natural analogues of vitamin A. β-carotene is a precursor and the major source of vitamin A in the diet. Although the exact mechanism by which retinoids inhibit carcinogenesis is not known, retinoids have been shown to modify genomic expression at the level of messenger RNA synthesis and to regulate transcription of specific genes.[87,88]

The major limitation in the use of retinoids is associated toxicity. Acute toxicity includes dryness of conjunctival and oral mucous membranes, cheilitis, skin desquamation, hypertriglyceridemia, bone tenderness, arthralgias, and myalgias. Chronic toxicities include hepatotoxicity and bone remodeling.[89] The most commonly used retinoids in the clinic are vitamin A (retinol); β-all-transretinoic acid; 13-cis retinoic acid (isotretinoin); and an aromatic ethyl ester derivative, etretinate. In contrast to the retinoids, the major toxicity of the carotenoids is yellowing of the skin.

In patients with pre-malignant lesions, Stich and others[76,90] reported two trials conducted in India and the Philippines in betel nut chewers. In one placebo-controlled trial, β-carotene was compared with β-carotene plus vitamin A. Complete response was observed in 3% of the patients taking placebo, in 15% of β-carotene-treated patients, and in 28% of those taking the combination. These patients demonstrated significant suppression of micronuclei expression and index of DNA damage on serial cytologic examinations. In a subsequent study, patients were randomly assigned to receive placebo or twice the dose of vitamin A (200,000 IU/wk) received in the first trial. A 57% complete response rate was observed with total suppression of the development of new leukoplakic lesions. In the placebo group, the complete response rate was 3%, and there was a 21% rate of new lesion formation.[76] In a small pilot study, Garewal and others[91] observed a 71% complete and partial response rate in 24 patients treated with β-carotene. There was no significant toxicity. Other investigators reported complete and partial response rates ranging from 60% to 100% with 13-cis retinoic acid.[92,93]

These results led Hong and others[73] to conduct a randomized placebo-controlled trial of 13-cis retinoic acid (1 or 2 mg/kg per day) in oral leukoplakia with dysplastic change. All patients were assessed with pretreatment and post treatment biopsies. Patients were treated for 3 months and observed for 6 months. There was a highly significant difference in response rate, 67% vs. 10%, comparing the treated group with those taking placebo. Histologic reversal of dysplastic change was documented in 54%. Unfortunately, after stopping treatment, the relapse rate was high within 2 or 3 months, and the regimen was associated with considerable toxicity. In a follow-up trial,[74] 56 patients received 13-cis retinoic acid (1.5 mg/kg per day) for 3 months, followed by randomization to low-dose 13-cis retinoic acid (0.5 mg/kg per day) or β-carotene maintenance therapy for 9 months. 13-cis-retinoic acid proved superior in maintaining remissions and had an acceptable level of toxicity in this low dosage. Nonetheless, the beneficial effects of therapy diminished over time (23% and 25% of patients in the low-dose isotretinoin and beta carotene arms, respectively, developed either

in situ or invasive carcinoma after a median follow-up of 66 months).[75] Three other placebo-controlled trials reported increased response rates or decreased recurrence rates of oral leukoplakia in patients treated with retinoids (vitamin A[76] or fenretinide[77,78]). Recently, Papadimitrakopoulou and colleagues published the final results of the longest-term study of retinoids in patients with oral pre-malignant lesions.[79] This trial randomized 162 patients with oral pre-malignant lesions to receive low-dose 13-cis-retinoic acid or beta-carotene plus retinyl palmitate for 3 years. After other randomized trials established an adverse effect of beta-carotene on lung cancer incidence/mortality, beta-carotene was dropped and patients were randomized to 13-cis-retinoic acid alone or retinyl palmitate alone. There was a higher incidence of adverse events in the 13-cis retinoic acid group. The clinical response rate of retinyl-palmitate alone was significantly lower than the other experimental treatments. However, the oral cancer-free survival in all arms was similar. Most importantly, there was no correlation between clinical response rate of the oral pre-malignant lesions and subsequent cancer incidence. This study illustrates many of the difficulties with the use of retinoids for head and neck oral pre-malignancies: 13-cis-retinoic acid is not well tolerated for long-term use, even at low doses. Moreover, even though short-term clinical response might be demonstrated following retinoid administration (particularly 13-cis-retinoic acid), evidence that clinical response correlates with long-term cancer development is still lacking, and this may not be considered a validated intermediary end point (despite its widespread use as a primary end point in many clinical trials).

Chemoprevention is also particularly relevant to patients who are curatively treated for an early stage head and neck squamous cell cancer. It is recognized that second primary malignancies develop at a rate of 3% to 4% per year in these patients.[94,95] The explanation for this risk is based on the concept of field cancerization first formulated in the 1950s.[96,97] Repeated exposure of the entire epithelial surface to carcinogens, such as tobacco and alcohol, can lead to the development of multiple sites of premalignant and malignant change.

The pioneer randomized placebo-controlled trial by Hong and coworkers demonstrated fewer second primary tumors in curatively treated head and neck cancer patients receiving high-dose 13-cis-retinoic acid for one year versus placebo (4 and 24%, respectively, $P = 0.005$) at a median follow-up of 32 months. This preventive effect persisted after 54.5 months of follow-up (14 versus 31% for the retinoid and placebo arms, respectively, $P = 0.042$). However, overall survival was not statistically different between the groups (57 and 52%, $P = 0.39$), nor was the annual second primary tumor rate. Again, the patients in the high-dose retinoid arm experienced increased toxicity with roughly 48% of the cohort requiring dose reductions or therapy discontinuation, thus limiting the clinical applicability of this strategy.[82,83] In an attempt to reduce the side-effects profile, a large randomized trial with 1218 patients (with prior stage I or II squamous cell carcinoma of the head and neck) evaluated the effects of low-dose 13-cis-retinoic acid versus placebo for three years in the incidence of second primary tumors. There were no statistically significant differences in the primary end point, disease recurrence, nor overall survival between the two groups after 7 years of follow-up.[84] Two other large trials enrolling patients with previous lung or head and neck cancer (EUROSCAN—2592 patients)[85] or oral cavity/oropharynx cancer (316 patients)[86] also failed to demonstrate a beneficial effect of retinoids (retinyl palmitate[85] or etretinate[86] in the second primary tumor rates or overall survival.

The lack of consistent benefit from retinoids for head and neck cancer prevention, as well as the advances of molecular-targeted approaches for the treatment of invasive/advanced disease have prompted a shift in the research focus of the chemoprevention field. This has been driven by two major aspects evolving from basic and translational studies of head and neck cancer biology: refining of assessment of invasive cancer risk (using molecular tests), and development of molecular-targeted agents for both cancer treatment and prevention.

The ability to identify individuals at increased risk for developing invasive cancer allows for the design of clinical trials enriched with a population likely to experience a high number of events, thus maximizing the chances for successful and accelerated development of chemoprevention strategies. This might ultimately translate into potentially meaningful benefits in the clinic. Perhaps the most promising risk assessment tool currently being incorporated in clinical trials of chemoprevention is the evaluation of allelic imbalances in patients with oral pre-malignant lesions: loss of heterozygosity of specific loci in chromosome 3p and/or 9p have been demonstrated to be associated with increased cancer risk, both in patients with and without a history of prior oral cancer.[98-100] As an example, in a Canadian series of curatively treated oral cancer patients who subsequently developed an oral pre-malignant lesion adjacent to the cancer site, the 5-year cancer risk was 72% in patients with loss of heterozygosity at 3p and/or 9p versus 6% in patients without the allelic imbalance.[100] These findings are currently being evaluated prospectively in the erlotinib prevention of oral cancer (EPOC) study.[101] One of the entry criteria of this ongoing U. S. multi-institutional clinical trial is presence of loss of heterozygosity at specific loci in the oral pre-malignant lesions of patients with or without a prior oral cancer. Eligible patients (who are considered to be at highest risk for cancer, based on the aforementioned molecular assessment) are then randomized to receive placebo or erlotinib for one year. Unlike the previous retinoid studies discussed above, the primary end point of the trial is cancer development, thus allowing for a definitive assessment of erlotinib's preventive activity in this enriched, at-risk population.

EPOC also highlights the second hallmark of the newer generation of chemoprevention trials: use of molecular-targeted agents directed at pathways relevant to the carcinogenic process. Erlotinib, the oral investigational drug used in EPOC, inhibits EGFR, a key molecule in head and neck cancer development.[102,103] Moreover, cetuximab (an anti-EGFR monoclonal antibody) has been shown to increase survival when used in combination with radiation therapy[2] or chemotherapy[69] in patients with intermediate and advanced stage head and neck cancer. This further supports the development of pharmacologic strategies inhibiting this pathway earlier on in the course of the disease.

In summary, abundant trials using retinoids have failed to demonstrate a consistent benefit from this class of agents in the treatment of oral pre-malignant lesions and/or prevention of recurrent/second primary tumors. Nonetheless, they have set the stage for the development of newer generations of clinical trials based on improved risk assessment and use of molecular-targeted drugs directed at relevant pathways of carcinogenesis. Hopefully this will advance the field of chemoprevention research, leading to the design of effective preventive strategies, ultimately resulting in decreased cancer incidence and mortality.

Summary

Tumors of various histologic types occur in the head and neck. Excluding thyroid malignancies, approximately 80% are squamous cell carcinomas. Data evaluating the impact of chemotherapy on survival time, particularly for combined-modality treatments, are limited to this common histologic type for which patient numbers are available for randomized comparative trials. Phase I, II, and III studies in patients with locally recurrent or metastatic disease have shown that chemotherapy can produce response rates of 30% to 40%, and combination chemotherapy is more effective than single agents. However, responses historically have tended to be brief, 2 to 4 months, and may not be associated with longer survival time. The addition of cetuximab to cytotoxic chemotherapy may augment efficacy. Nonetheless, chemotherapy for these patients is palliative. An exception to this is patients with tumors of the nasopharynx in whom higher response rates and a small proportion of long-term disease-free survivors are observed. Prognostic factors have been identified that should be used by the physician to select patients most likely to benefit from palliative treatment.

In newly diagnosed patients with locally advanced disease, high response rates have been achieved with induction chemotherapy; and this approach remains under study. An important role for chemotherapy may be to preserve organ anatomy and function at selected sites. Three large multicenter randomized trials have been conducted showing preservation of the larynx in a substantial fraction of patients. Chemotherapy administered concomitantly with radiotherapy has

improved local control and survival in selected series, particularly in the setting of oropharyngeal cancers. The potential for increased acute mucocutaneous toxicity associated with these regimens should be carefully considered when selecting patients for combined treatment. Moreover, long-term follow-up is needed to best assess tumor control, risk of metachronous cancers, and functional outcomes after intensive combined-modality regimens. The concomitant administration of cetuximab and radiotherapy shows promise for advancing non-surgical therapy without an apparent increase in severe grade toxicity.

Patients with earlier-stage disease (i.e., stage I or II) should receive conventional therapy with either surgery, radiotherapy, or both. Negative prognostic factors such as an endophytic growth pattern may be an indication for chemoradiotherapy either as definitive or postoperative treatment. Patients with stage III or IV disease can be divided into those for whom surgical resection is indicated or not. Those with disease not to be resected should often be treated with chemotherapy and radiation or entered into a combined chemoradiation treatment protocol. Those with stage III disease may also benefit from combination treatment as part of a clinical trial. Patients with metastatic disease should receive chemotherapy with palliative intent if performance status is favorable.

Patients with resectable disease can be further divided by site. Those with primary oral cavity tumors would most likely be best served by surgery followed by radiotherapy, whereas patients with oropharyngeal, hypopharyngeal, or laryngeal tumors are often treated with radiation, with or without chemotherapy depending on the precise site and stage. Many patients with hypopharyngeal cancers and T4 cancers of the larynx should be considered for possible laryngectomy.

Chemoprevention will continue to be an important area of research in the coming decade. Multiple new strategies are to be considered for further testing.

The management of head and neck cancer is a multidisciplinary activity. The identification of effective targeted and chemotherapeutic agents and their integration into the initial curative therapy of head and neck cancer has the potential to improve survival time and preserve organ function. Systemic therapy has become an accepted component of primary therapy. The increasing appreciation of human papillomavirus as an etiologic and favorable prognostic factor can be expected to affect patient management and the conduct of future studies. Through well-designed and well-executed clinical trials, coupled with basic research of the biology of upper aerodigestive tract tumors, further advances in the management and prevention of these cancers can be achieved.

CHAPTER SEVENTY-NINE

Skin Flap Physiology and Wound Healing

Eugene A. Chu

Patrick J. Byrne

Rick M. Odland

George S. Goding, Jr.

Key Points

- Flap survival depends on adequate perfusion to meet the metabolic demands of the mobilized tissue.
- The primary insult affecting flap survival is impaired vascular supply and the resultant ischemia.
- Current research for improving flap survival has focused on modulating the cascade of cytokines and intercellular signaling molecules involved in wound healing.
- Wound healing is a dynamic process involving soluble mediators, blood cells, extracellular matrix, and parenchymal cells.
- At present there are no data to support the routine use of growth factors or other wound mediators to aid wound healing. However, continued research and development of substances that stimulate wound healing are under way.

A comprehensive discussion of the physiology of the skin as it applies to surgery is essentially one of vascular supply. Local skin flaps, like pedicled flaps and free tissue transfer, depend on the maintenance of adequate perfusion to meet the metabolic demands of mobilized tissue. An understanding of this physiology allows the surgeon to plan flaps intelligently to ensure a favorable outcome. In addition, an understanding of flap physiology provides a conceptual basis with which to optimize the management of the challenging defect or the tenuous flap.

The vascular supply to the skin serves two purposes, thermoregulation and nutritional support. Nutritional support is regulated largely by the capillary network, which is under the control of the precapillary sphincters. Local hypoxemia causes vasodilation of the precapillary sphincters. Thermoregulation is controlled by arteriovenous shunts, which are located more superficially in the skin. The sphincters of the arteriovenous shunts are under sympathetic control. When body temperature increases, the resulting decrease of norepinephrine leads to lesser sphincteric contraction, thus allowing greater blood flow to the skin; the opposite occurs with decreased body temperature.

The creation of a flap applies specific stresses to healthy skin. These stresses include local tissue trauma and reduced neurovascular supply to the affected tissue. The extent to which skin can survive these injuries is a reflection of the anatomy and physiology of skin and of the cutaneous response to injury. Knowledge of these principles has led to improved skin flap survival rate by means of better flap design. Increasing cutaneous flap survival rate by minimizing the deleterious physiologic effects of flap transposition is an area of active research that has yet to produce techniques that have widespread clinical application.

An important concept in skin vascular physiology as it applies to flaps is that of the *angiosome.* In 1987, Taylor and Palmer[1] coined the term *angiosome* to refer to the tissue supplied by a named artery. The head and neck region has several such angiosomes, including the important thyroid, facial, buccal, ophthalmic, superficial temporal, and occipital.[1] Adjacent angiosomes are in communication with each other via choke vessels. This relationship becomes important in the design of various flaps. It has been demonstrated that axial pattern flaps (to be discussed in this chapter) are capable of supplying adequate blood flow to an adjacent angiosome. The incorporation of tissue on an additional angiosome beyond this adjacent angiosome, however, invites vascular compromise and likely flap failure. Techniques to extend this vascular supply, such as delay, may be necessary.

Zones of Perfusion

Maintenance of cell function and viability is the objective of the circulatory system at macrocirculatory, capillary, interstitial, and cellular levels. The importance of tissue vascularity is well recognized, but the complexity and diversity of tissue perfusion mechanisms require that the process be divided into components. Each level of perfusion has unique physiologic characteristics, and optimal management is possible only if these differences are recognized. Johnson and Barker[2] described two levels of risk zones for flap failure, making a distinction between thrombosis at the arterial and capillary levels. By extension of this concept, four zones of the circulatory system can be considered for all hazards (Fig. 79-1). Proper function of each zone is crucial to tissue viability.

Zone I consists of the cardiopulmonary system, the conduits for blood flow (arteries and veins), neural control of those conduits, and the lymphatic system. Zone I has historically been recognized as essential for flap survival. The delay phenomenon is primarily a zone I effect.

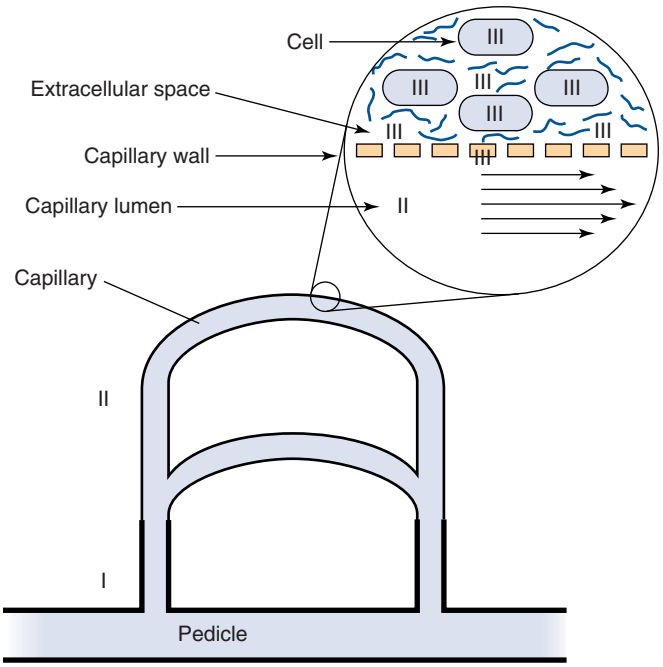

Figure 79-1. Zones of perfusion. Zone I is the macrocirculatory system consisting of cardiopulmonary, neurovascular, and lymphatic function. Zone II is the capillary circulatory systems composed of arterioles, capillaries, venules, and arteriovenous shunts. The interstitial system is zone III and entails the capillary membranes and interstitial ground substance. The cell membrane, organelles, and intracellular space constitute zone IV, the cellular system.

The development of the pedicled flap[3] underscores the importance of zone I in extending flap survival time. Free microvascular tissue transfer is also a zone I manipulation.

Zone II comprises the capillary circulation. The importance of the capillary circulation is shown by the "no-reflow phenomenon," wherein a loss of nutritive blood flow occurs in the presence of an adequate vascular supply.[4]

Zone III is the interstitial space and its mechanisms of nutrient delivery. The capillary wall is included in zone III because capillary permeability is a main determinant of interstitial space properties. Failure of metabolites to enter and traverse the interstitial space can result in loss of cell viability, even though there is adequate zone I and even zone II function. Interstitial systems are an important link in skin flap survival rate.[5]

The cell and its membranes constitute *zone IV*. Maintaining viable cells is the ultimate determinant of flap survival. Prolongation of cell survival through selective changes in cell permeability and uptake is a potential intervention that may improve flap survival rate.

Anatomy and Physiology of Skin

The skin serves as a sensory organ and a protective organ. The thick epidermal layers are largely impermeable to gases and most liquids. Therefore many agents that could have beneficial effects on skin flaps are ineffective when applied topically to intact skin.

The epidermis of the skin is derived from ectoderm in the early embryo. The glandular appendages of the skin (i.e., sebaceous glands and hair follicles) develop from tubes and solid cords that invaginate from the covering ectoderm.[6,7] The epidermis is a metabolically active, but avascular, stratified squamous epithelium. The average epidermal thickness for most of the body is 0.1 mm. The majority of cells undergo keratinization and form the various epithelial layers.[8] The superficial keratinized cells of the skin are continuously replaced by cells originating from the mitotic activity in the basal layer of the epidermis. Melanocytes derived from neural crest cells also are found in the epithelium of skin and constitute a second cell type.

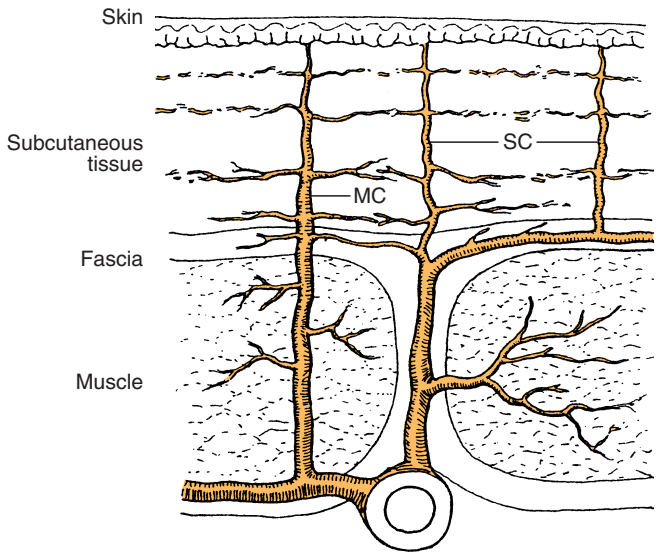

Figure 79-2. Varying pathways to skin define musculocutaneous (MC) and septocutaneous (SC) arteries.

The dermis, derived from embryonic mesoderm, consists primarily of noncellular connective tissue. This relatively noncellular layer has metabolic requirements far less than those of the epidermis. Nerves, blood vessels, lymph vessels, and the base of the epidermal glandular appendages are found within the dermis.[8] The dermis is 15 to 40 times thicker than the epidermis, with a maximum width of 4 mm on the back.[9] The outer surface of the dermis has an uneven border contacting the epidermis that is known as the papillary layer. The papillary dermis is characterized by an abundant ground substance, irregularly arranged collagen bundles, and a highly developed microcirculation. The reticular dermis is composed of thick bundles of collagen and coarse elastic fibers, and fibrocytes and blood vessels are proportionally less numerous.

Deep to the reticular layer of the dermis, the subcutaneous layer consists of loose connective tissue and a varying amount of fat cells. It is a deeper continuation of the dermis and collagenous fibers continuous with those in the dermis. The density of the collagenous fibers is related to the degree of cutaneous mobility over the underlying structures. In the palms and soles, for example, these fibers are particularly numerous. The deep surface of the subcutaneous layer is attached to the superficial fascia of underlying muscle where it is present.

Zone I: Macrocirculatory System

Blood vessels travel by one of two main routes to terminate in the cutaneous circulation. Musculocutaneous arteries pass through the overlying muscle to which they provide nutrition; septocutaneous arteries[10] (also referred to as direct cutaneous arteries) travel through fascial septa that divide the muscular segments (Fig. 79-2).

The cutaneous portion of a septocutaneous artery typically runs parallel to the skin surface, providing nutrition to a large area of skin. Septocutaneous arteries are usually accompanied by pairs of veins and run above the superficial muscular fascia.[11] The more common musculocutaneous arteries leave the muscle and enter the subcutaneous tissue to supply a smaller region of skin.

Septocutaneous and musculocutaneous arteries empty into a diffuse interconnecting vascular network of dermal and subdermal plexuses. This network provides a redundancy in the vascular supply to the skin. A collateral blood supply supports the vascular territory of each artery. Lymphatic vessels form a plexus running parallel and deep to the network of blood capillaries. The lymphatic capillaries, which end in blind sacs, conduct extracellular fluid back into the blood stream. Lymphatic function is affected by inflammation and loss of blood vessel pulsations.[8]

The neural supply to the skin originates from sensory nerves and sympathetic nerves. The sensory nerves are distributed in segmental fashion, forming dermatomes, and participate in the skin's protective function. The postganglionic terminals of cutaneous sympathetic nerves contain the neurotransmitter norepinephrine and are found in the area of cutaneous arterioles.[12]

Zone II: Capillary System

The cutaneous capillary system, along with the arteriovenous shunts, serves the two important functions of nutritional support and thermoregulation. Primarily because of its thermoregulatory function, the rate of blood flow through the skin is one of the most variable in the body. During ordinary skin temperatures, the amount of blood flowing through the skin (approximately 9 mL/min per 100 g of tissue) is greater than the flow required for nutritional support.[13,14] Blood flow can increase to 20 times this value with maximal vasodilation. When the body is exposed to extreme cold, blood flow can be reduced to levels that are marginal for cutaneous nutrition.

Before entering the capillary bed, the arterioles branch into small vessels (e.g., terminal arterioles or metarterioles) that are surrounded by a discontinuous layer of smooth muscle. A simple ring of smooth muscle forms a sphincter at the point where the capillaries originate from the metarteriole. This sphincter can completely stop blood flow within the capillary. The capillary bed can be bypassed by arteriovenous shunts that allow the arterioles to empty directly into venules. During conditions of adequate systemic vascular pressure, preshunt and precapillary sphincters regulate the distribution of cutaneous blood flow.[16]

The preshunt sphincters are involved in regulating the changes in blood flow that affect thermoregulation and systemic blood pressure.[16,17] Release of norepinephrine by the postganglionic sympathetic fibers results in contraction of the preshunt sphincters. This contraction diverts blood away from the skin surface, where heat loss could occur. With increased body temperature, the sympathetic vasoconstrictor impulses decrease, allowing for greater blood flow to the skin.

Local production of bradykinin may play a role in regulating skin blood flow by causing vasodilation.[15] The cutaneous circulation also is extremely sensitive to circulating norepinephrine and epinephrine. Even in areas of skin that have lost their sympathetic innervation, a mass discharge of the sympathetic system still results in intense vasoconstriction in the skin.

The precapillary sphincter, which controls the amount of nutritive blood flow to the skin, responds to local hypoxemia and increased metabolic byproducts by dilating.[16-18] Capillary blood flow is also affected by elevated interstitial pressure, which can compress the capillary and decrease transcapillary flow. Conversely, as pressure decreases in the interstitium, the capillary expands and flow increases.[19] Acute rises in systemic blood pressure cause an immediate increase in local blood flow followed by return of flow to near normal levels in less than 1 minute. This normalization of capillary blood flow is called *autoregulation*.[20] The metabolic theory for autoregulation proposes that an excess of oxygen and nutrients results in arteriolar constriction. This process is believed to be the primary functional mechanism of autoregulation. The myogenic theory suggests that stretching of the arteriolar muscle results in reflex contraction and may be a mechanism to protect capillaries from excessively high blood pressures. Reduction of blood flow may also occur as a result of increased interstitial pressure.

Zone III: Interstitial System

The interstitial space is filled with proteoglycans and collagen.[13] In many tissues, hyaluronic acid filaments make up the interstitial ground substance. These filaments are normally woven through the interstitium, producing a medium that exhibits high resistance to fluid movement unless the tissue is well hydrated. In tissues with excess edema, the filaments do not overlap, producing shear planes of free fluid within the interstitium.[5]

Two processes by which substances can move across the interstitial space are diffusion and convection.[21,22] Diffusion is the process wherein a molecule passively moves to a lower concentration. Molecular movement by diffusion is affected by many factors. An important characteristic is lipid solubility. Lipid-soluble molecules tend to traverse cell membranes more easily and quickly than non–lipid-soluble agents. Large molecules diffuse more slowly than small ones. As molecules diffuse away from the capillary, the concentration of that molecule decreases by the inverse square law. As edema occurs, diffusion distances increase.[23]

Convective flow, or bulk flow, is another way for molecules to move across the interstitium. Rather than diffusing to a lower concentration, an agent is swept along with the current of plasma that flows across the interstitial space in microchannels. The agent then diffuses the short distance from the microchannels to the cells.

The relative importance of diffusion and convective flow is controversial. Some writers believe that diffusion is primarily responsible for cell nutrition. Convection becomes relatively more important for certain tissues, molecules, or pathologic states.

Convective flow of nutrient-laden plasma out of the capillaries and across the interstitial space is produced by a combination of hydrostatic and osmotic pressures as described by Starling in 1896.[24] The equation is as follows:

$$Jv/A = L_p[(P_c - P_i) - \pi_s(\pi_c - \pi_i)]$$

In descriptive terms, flow of plasma out of the capillary per unit area (Jv/A) is related to the product of the water permeability of the membrane (Lp) multiplied by the difference between hydrostatic pressure in the capillary (P_c) and interstitial space (P_i) minus the difference between osmotic pressure in the capillary (π_c) and the osmotic pressure in the interstitial space (π_i). The osmotic pressures are adjusted by the osmotic coefficient, (π_s), a measure of the "leakiness" of a semipermeable membrane.

In functional terms, over the length of the capillary, hydrostatic pressure decreases as fluid exits the capillary and hydraulic resistance is overcome. At the same time, oncotic pressure within the capillary increases as fluid exits the capillary and plasma proteins are retained. These changes in gradients favor return of fluid at the venular end of the capillary and in the immediately postcapillary venule. Pressure gradients also are responsible for bulk flow of fluid across the interstitial space in fluid microchannels.

A net change of 2 mOsm is sufficient to increase interstitial pressure beyond transmural capillary pressure, thereby compressing the capillary. Increased venous pressure limits interstitial resorption of fluid and contributes to formation of an interstitial transudate.[25] Inflammation in a flap is probably a result of nociceptor pathway stimulation by handling of the flap. Even the relatively minor trauma of inserting a fine needle causes a "very large" increase in capillary permeability within minutes after insertion, as evidenced by rapid influx of proteins into the interstitium.[26] Ischemia also produces inflammation. Capillary hyperpermeability has been found throughout ischemic flaps.[27,28] The lymphatic system has two functions that affect zone III, to remove excess fluid and to remove interstitial protein. There is some controversy in the physiology literature regarding the magnitude of the latter function.[21] If the lymphatic system is malfunctioning, interstitial fluid and interstitial protein accumulate.[29,30]

Zone IV: Cellular Systems

The intracellular space is the endpoint for nutrient transport and the origin of metabolic waste. The cell wall is a fluid lipid bilayer 7.5 to 10.0 nm thick. The lipid bilayer is a major barrier to movement of solutes across the membrane. The primary function of the cell membrane is to maintain or to vary in a controlled fashion the separation of the extracellular and intracellular environments. This separation is achieved by specific membrane proteins, which act as solute pumps and solute and solvent leaks. The osmotic pressure between the two environments also should be maintained to preserve normal cell volume. The sodium-potassium pump is important in maintaining osmotic equilibrium across the cell membrane and has a requirement for energy in the form of adenosine triphosphate (ATP).[31] A loss of energy substrate (oxygen and consequently ATP) produces an intracellular movement of sodium and an increase in intracellular osmotic pressure.[25] These changes occur quickly,[32] within 10 minutes after arterial occlu-

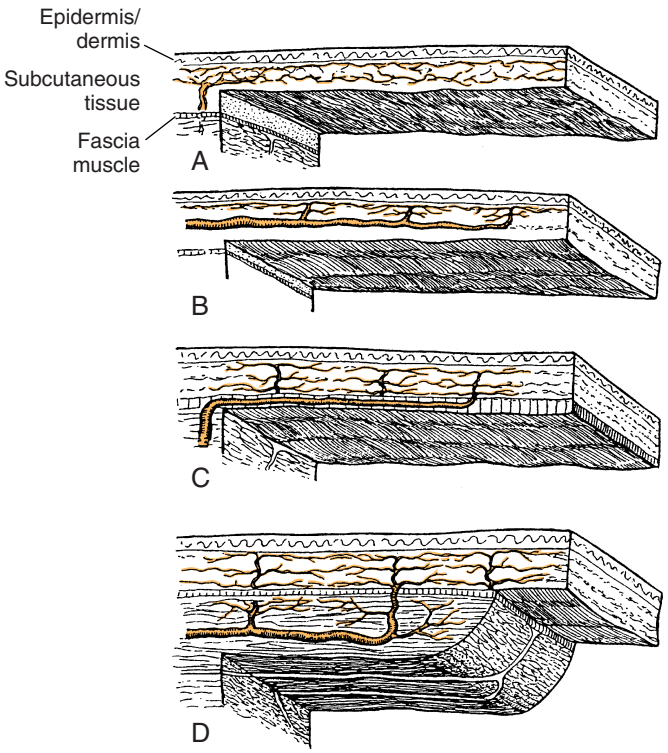

Figure 79-3. Classification of skin flaps based on vascular supply. **A,** Random. **B,** Arterial cutaneous. **C,** Fasciocutaneous. **D,** Musculocutaneous.

sion. Within seconds of hypoxia, levels of ATP begin to decrease, and cells begin to swell.[29] Relatively brief periods of ischemia result in a reversible swelling of the cell and organelles. If the ischemic insult is severe and prolonged, cell lysis and flap necrosis occur.

Classification of Flaps

Flaps are commonly classified according to their principal blood supply. They include random, arterial cutaneous (i.e., axial), fasciocutaneous, musculocutaneous, and venous flaps (Fig. 79-3). Venous flaps to this point have had no application in head and neck reconstruction. Flaps may also be described according to site of origin relative to the area to be reconstructed. Thus, flaps utilized in the head and neck are local, regional, or distant. Distant flaps may be pedicled or free flaps (microvascular free tissue transfer).

Random Cutaneous Flaps

The vascular supply to a random flap is from the subdermal plexus. The subdermal vascular plexus is supplied by unnamed musculocutaneous artery perforators near the base of the flap. The random cutaneous flap is commonly used in local flap reconstruction. The plane of dissection is through the subcutaneous fat. Examples of local random flaps are advancement, rotation, a combination of rotation-advancement, transposition, and tubed flaps. The survival of such flaps is determined by the perfusion pressure supplying the flap, and is not necessarily related to simple length-to-width ratios.

Arterial Cutaneous (Axial) Flaps

Arterial cutaneous flaps (also called axial pattern flaps) are supplied by a defined septocutaneous artery that runs beneath the longitudinal axis of the flap. These flaps typically have a better survival length than random cutaneous flaps. The plane of dissection must include the septocutaneous vessel within the subcutaneous fat. The axial flap may be designed to include tissue distal to that supplied directly by the artery. In such a case, the more distal portion of the flap is essentially a random flap, and caution must be exercised to avoid overextending the design beyond viability.

Use of arterial cutaneous flaps is limited by the availability of direct cutaneous arteries. Examples of arterial cutaneous flaps used in head and neck reconstruction are the deltopectoral flap, based on the anterior perforators of the internal mammary artery, and the paramedian forehead flap, based on the supratrochlear vessels.

Myocutaneous and Fasciocutaneous Flaps

Myocutaneous flaps represent an additional modification to improve flap survival. They are based on distal segmental vessels, leaving the local vasculature (perforators and cutaneous vessels) intact, which requires incorporation of muscle with the flap. Myocutaneous flaps are typically named for the donor muscle. Examples are the pectoralis myocutaneous flap, based on the pectoral branch of the thoracoacromial artery, and the latissimus dorsi myocutaneous flap, based on the thoracodorsal artery.

The greater blood flow and higher tissue oxygen tensions available with myocutaneous flaps[33] make this design superior in the management of contaminated or infected defects.[34,35] Improved phagocytotic and bactericidal activity of leukocytes is seen in myocutaneous flaps in comparison with random pattern flaps in the canine model.[36] These physiologic benefits contribute to the ability of myocutaneous flaps to resist bacterial inoculation more effectively than random pattern flaps.

As for arterial flaps, it often is desirable to extend the surface area of the flap in clinical situations. A random portion of the flap based on the subdermal plexus can be incorporated. This random extension is usually the portion of the flap most at risk for ischemic necrosis.

Fasciocutaneous flaps use direct arterial (septocutaneous) vessels with the cutaneous branches at the level of the deep fascia forming a plexus, which supplies the subdermal plexus.[37] The appropriate size of fasciocutaneous flaps is less well defined than axial pattern flaps with their obvious arterial supply.[38] Fasciocutaneous flaps appear to rely more on potential skin vascular territories. Four types of fasciocutaneous flaps have been described on the basis of the pattern of blood supply incorporated into the fascial component of the flap. Examples are the parascapular flap and the radial forearm flap.[39,40]

Free Microvascular Flaps

Free flaps have become the standard of care for many types of reconstruction and hold several advantages over regional flaps. Free flaps may be fasciocutaneous, musculocutaneous, myofascial, osseous, or osteocutaneous, or a combination of these. Tissue from a distant site can be harvested according to the characteristics of the donor site and the needs of the defect. Vascularity of the flap is maintained by microvascular anastomosis of the artery and vein. The flap can be harvested and customized to the defect in terms of absolute size and relative amounts of bone, muscle, skin, and nerve needed. Careful design of a free flap can eliminate the risk of partial necrosis associated with a random extension.

Physiology of Acutely Raised Flaps

A number of changes detrimental to skin survival occur when a cutaneous flap is created. That flaps survive at all is a testimony to the minimal nutritional requirements of skin. The primary insult affecting flap survival is impaired vascular supply and the resultant ischemia. In the presence of adequate blood flow, complete flap survival occurs. Nerve section and inflammation influence flap survival primarily by affecting blood flow. Recovery from ischemia also can occur through the timely formation of new vascular channels between the transposed flap and the recipient bed.

Impairment of Vascular Supply

Partial interruption of the vascular supply (zone I) to the skin is the most obvious and critical change that occurs with elevation of a cutaneous flap. Flap survival depends on the severity of ischemia and the amount of time before recovery of nutrient blood flow. Flaps can tolerate and survive an average of 13 hours of complete avascularity.[41] Limitation of the vascular supply results in a local decrease in perfusion pressure to the skin. In arterial or myocutaneous flaps, the blood supply to the skin overlying the vascular pedicle is usually adequate.[42] In random flaps or random extensions of flaps, the decrease in perfusion

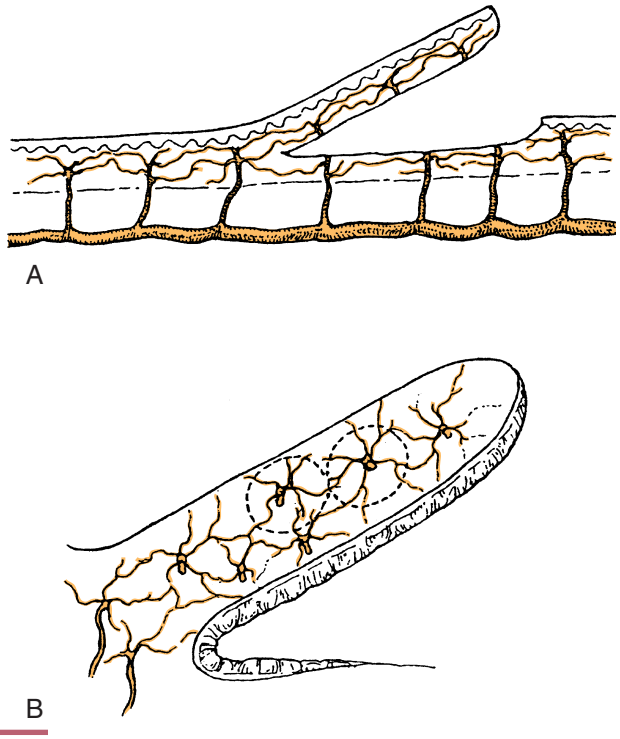

Figure 79-4. **A** and **B,** Vascular territories in skin flaps. Multiple perforating vessels exist and are interconnected at the periphery of their vascular territory. When some of these vessels are cut, blood supply can be replaced from nearby perforating vessels, and then tissue necrosis does not occur.

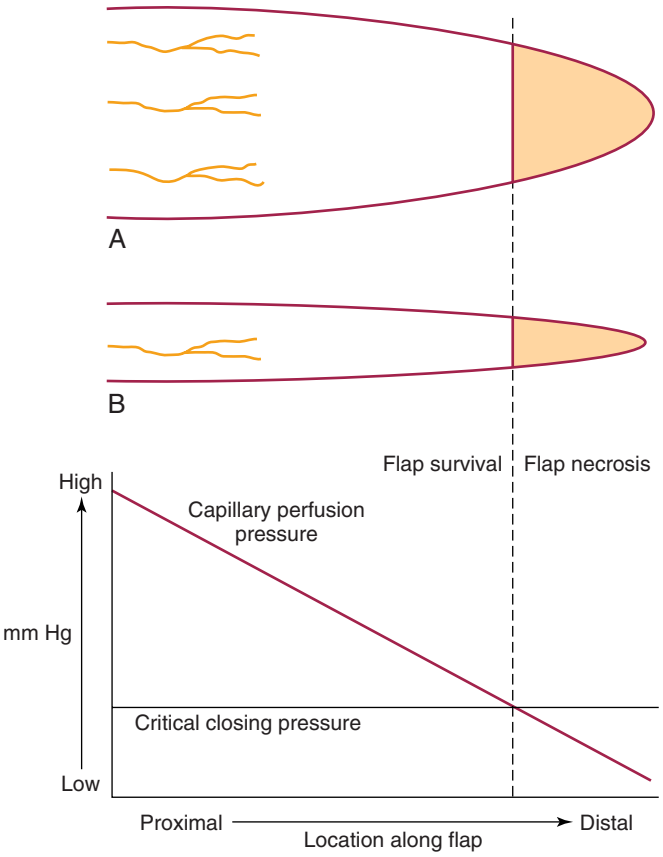

Figure 79-5. Fallacy of the length-to-width ratio. The slope of decreasing perfusion pressure versus flap length does not change with incorporation of additional vessels (flap *A* versus flap *B*) with the same perfusion pressure. Flap necrosis occurs when perfusion pressure decreases below critical closing pressure of the capillary bed.

pressure becomes more pronounced with increasing distance from the base of the flap.[43,44] When perfusion is reduced in one area of a random flap, the adjacent vascular territories supplied by a separate perforating vessel can provide a low-pressure blood supply through the subdermal plexus (Fig. 79-4). Because the nutritional requirements of skin are relatively low, a number of vascular territories can be compromised before necrosis results.

The surviving length of the random portion of the flap depends on the physical properties of the supplying vessels (intravascular resistance) and the perfusion pressure.[45,46] When the perfusion pressure drops below the pressure in the interstitial space, capillary blood flow ceases. The pressure at which there is no longer enough intravascular blood pressure to maintain capillary blood flow is called the *critical closing pressure*.

In the past, random cutaneous flaps often were designed according to a desired length-to-width ratio, a wider base being needed to successfully transfer a longer flap. The wider random flap includes only additional vessels with the same perfusion pressure. The relationship between perfusion pressure and critical closing pressure is not altered, and there is no change in survival length (Fig. 79-5).[9,47]

In free flaps, a secondary ischemia can occur when thrombus forms at the anastomosis. Anastomosis failure is related to exposure of the vascular intima to platelets.[48] Platelet activation is caused by superficially exposed subendothelium or, with deeper vessel injury, exposure to collagen types I and III. The geometry of the vascular arrangement is often a critical factor when experienced surgeons lose a free flap., Measurements of transcutaneous oxygen pressure ($TcPo_2$) and transcutaneous carbon dioxide pressure ($TcPco_2$) have been investigated for monitoring of compromised flaps. In experimental studies $TcPo_2$ was found to be more sensitive to flap ischemia; however, in clinical studies it was difficult to distinguish between flap ischemia and congestion on the basis of $TcPo_2$ alone. Instead, a $TcPco_2$ greater than 90 mm Hg in a congested flap proved a more useful guideline for warranting further treatment.[49]

The venous outflow from the skin also is impaired with flap elevation. Venous flow can occur through the subdermal plexus or via venous channels that accompany the feeding artery in the pedicle. Complete venous occlusion in the early postelevation period may be more damaging to flap survival than inadequate arterial supply.[48] Fortunately, the subdermal plexus alone is often able to provide adequate venous outflow. Care should be taken to preserve venous outflow in flaps pedicled solely on the feeding vessels.

Impairment of lymphatic drainage with flap elevation also occurs. Reduction of the cutaneous lymphatic drainage results in a rise in interstitial fluid pressure that is compounded by increased leakage of intravascular protein associated with inflammation. The resulting edema leads to increased interstitial pressure, which decreases capillary perfusion by raising the critical closing pressure (Fig. 79-6).[24,45] Alterations in the Starling forces result in further ischemic swelling of cells and the interstitial space, setting a positive feedback circle in motion.

Microcirculatory Changes

Necrosis in flaps is caused by prolonged loss of nutritional blood flow.[50,51] There are several proposed mechanisms for loss of nutritional flow, each of which may play a role. Erythrocyte sludging has frequently been noted in capillaries undergoing ischemia, often without thrombus formation. Therefore, sludging is not necessarily caused by platelet activation unless a microvascular anastomosis or other vessel injury is involved, such as tearing, stretching, laceration, or crushing. Microemboli are commonly generated from a microvascular anastomosis.[52]

The reason for the erythrocyte sludging is multifactorial. Erythrocytes become turgid and lose their flaccid, biconcave disk shape in the acidic environment of ischemia. Narrowing of the capillaries,[9,53] presumably a result of external compression, also contributes to

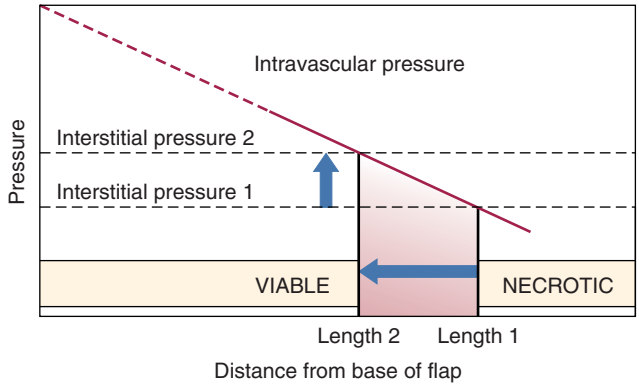

Figure 79-6. The relationship between increased interstitial pressure and decreased surviving flap length. Intravascular perfusion pressure decreases along the length of the flap. At the distal end of the flap, intravascular perfusion pressure becomes less than interstitial pressure, causing the capillaries to collapse (critical closing pressure). As edema is generated by ischemia and inflammation, interstitial pressure increases, resulting in a decrease in surviving length from length 1 to length 2.

stacking of erythrocytes within the lumen of ischemic tissue capillaries. Sludging is seen less often if the hematocrit value is kept below 30%.[54]

Capillary blood flow is further hindered by leukocyte adherence to the capillary wall.[55] The leukocytes are probably responding to cytokines released from the cells in response to initial injury. The leukocytes first roll along the capillary wall and then begin to stick. As time progresses, the leukocytes flatten onto the endothelial cell and eventually pass into the interstitium. Each step of the process has biochemical mediators. In patients undergoing heart transplantation, leukocyte depletion decreases ultrastructural evidence of reperfusion injury.[56] Ischemic cells of all tissues swell because of the loss of energy substrate needed to continue maintaining the osmotic gradient. Swelling of extravascular cells causes compression of the vascular lumen,[57] but endothelial cell swelling has a greater effect on capillary blood flow.[58] Histologic evidence of edema can be used to grade the severity of free flap injury.[59] Nitric oxide synthase, an endothelium-derived vasodilator, has been studied for its effect in skin flaps.[60-64]

Neovascularization

In surviving flaps, blood flow gradually increases. If the flap is in a favorable recipient site, a fibrin layer forms within the first 2 days. Neovascularization of the flap begins 3 or 4 days after flap transposition.[65,66] Revascularization adequate for division of the flap pedicle has been found as early as 7 days in animal models and humans.[67]

During revascularization, vascular endothelial cells play a major role in the formation of new vessels. Normally, endothelial cells are in a quiescent state, although when stimulated by angiogenic growth factors, they can dramatically proliferate. This proliferation normally occurs only during certain conditions, such as wound healing and ovulation.

Beginning with an angiogenic stimulus, the angiogenic process involves a number of discrete yet overlying steps (Fig. 79-7). Initially, the vessels become dilated and permeable with retraction of the endothelial cells and a decrease in endothelial junctions. The basement membrane is then dissolved by proteases, and the endothelial cells migrate from the vascular wall toward the angiogenic stimulus. Behind the leading front of migrating endothelial cells, endothelial cell replication begins, forming a capillary sprout that elongates toward the angiogenic source. The nearby capillary sprouts then anastomose to each other, forming capillary loops. As capillary loops and sprouts continue, the loops become patent, developing newly formed blood vessels. These blood vessels differentiate and lay down basement membrane consisting of type IV collagen, laminin, and proteoglycans. Pericytes and fibroblasts then migrate to the capillary loop sites.[68]

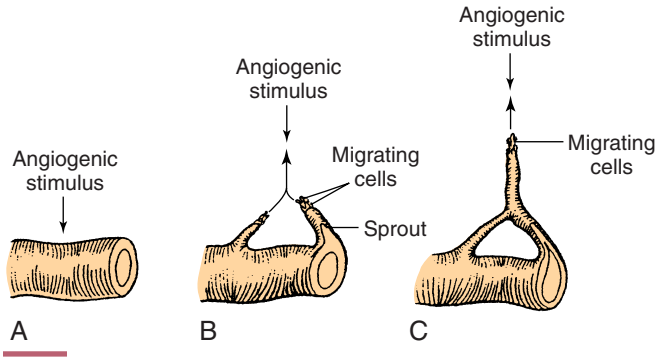

Figure 79-7. Steps in angiogenesis. **A,** Initial stimulus with retraction of endothelial cells and thinning of basement membrane. **B,** Migration of endothelial cells and formation of capillary sprout. **C,** Formation of capillary loops, which become patent to form new blood vessels.

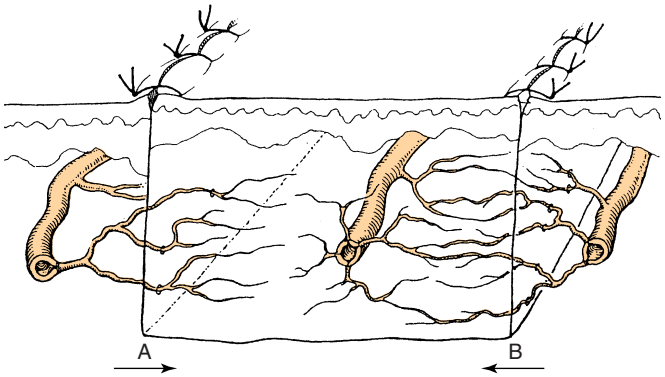

Figure 79-8. Ingrowth of angiosomes. Cross section of the flap showing direct ingrowth (*A*) versus inosculation (*B*).

With the continued presence or absence of the angiogenic stimulus, substantial remodeling, regression, and rearrangement of the new capillaries occur.[69] Some capillaries join preexisting flap vessels (*inosculation*), but the majority of revascularization appears to involve direct ingrowth of recipient vessels into the flap (Fig. 79-8). New capillaries can grow toward an angiogenic source at a mean rate of 0.2 mm/day. When the angiogenic stimulus is discontinued, the capillary vessels regress and eventually disappear over a period of weeks. Angiogenic growth factors can stimulate capillary growth over distances of 2 to 5 mm.[70] It is believed that mechanisms to inhibit angiogenesis exist to prevent an uncontrollable cascade of neovascularization. Evidence suggests that pericytes can suppress endothelial growth by direct contact.[66] Thus, the physiologic response of angiogenesis may be analogous to the blood coagulation pathway that should be maintained at a steady state of control. In soft-tissue wound repair, macrophages, lymphocytes, mast cells, and platelets are involved in releasing various factors that modulate angiogenesis.[71,72]

Nerve Section

Sensory and sympathetic nerves are severed in the process of flap elevation. Although loss of sensation may limit the usefulness of the flap after transfer, adrenergic denervation has implications for flap survival. When a sympathetic nerve is divided, catecholamines are released from the nerve terminal, and the mechanism for catecholamine reuptake is eliminated.[73-75] A local "hyperadrenergic state" exists, which produces vasoconstriction mediated by α-adrenergic receptors in the cutaneous vasculature.[73]

The vasoconstricting effect of sympathectomy further reduces total flap blood flow.[76,77] which has already been decreased by division of supplying vessels. This further reduction negatively affects the ratio of perfusion pressure to the critical closing pressure of the arterioles in

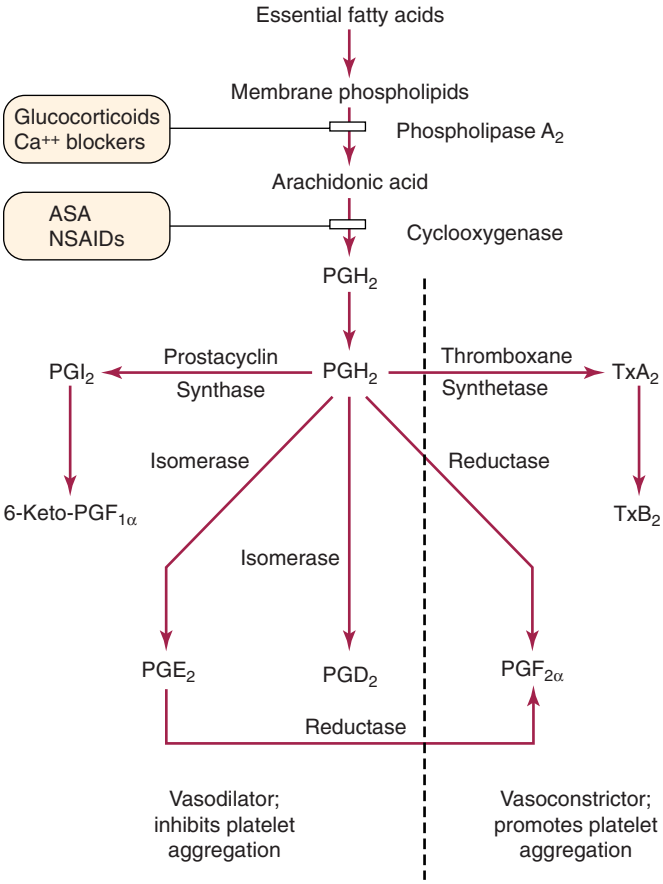

Figure 79-9. Synthesis of prostaglandins (PG) and thromboxanes (Tx) and their general effects in the cutaneous circulation. ASA, acetylsalicylic acid; NSAIDs, nonsteroidal anti-inflammatory drugs.

the subdermal plexus. A greater proportion of the distal flap is excluded from the blood supply, and necrosis becomes more likely. The stored transmitter is depleted within 24 to 48 hours,[73] and blood flow increases as the concentration of norepinephrine declines.[77] In critical areas of the flap, the time to recovery of nutrient blood flow may be delayed sufficiently to produce additional necrosis.

Inflammation and Prostaglandins

The surgical trauma and ischemia associated with an acutely raised flap result in an inflammatory response. Histamine, serotonin, and kinins are released into the extracellular compartment after flap elevation, increasing the permeability of the microcirculation. The result is a rise in the concentration of proteins and cells within the extracellular space. The presence of nonbacterial inflammation beginning a few days before flap elevation has been shown to improve flap survival,[78-80] presumably as a result of an increase in local blood flow.

The inflammation created during flap elevation may have deleterious effects because of the resultant edema formation. In addition to compromising capillary blood flow and altering the relationships of the Starling equation, interstitial edema increases the diffusion distances between cells. The effect is enhanced because of the inverse square law for diffusion. Edema also can constitute a direct barrier to diffusion.[23,29]

The action of the primary mediators of the inflammatory response (histamine, serotonin, and kinins) is short-lived. After kinin formation and in the presence of complement, prostaglandins are synthesized by injured cells. Prostaglandins play an important role in the later stages of the inflammatory reaction while simultaneously initiating the early phases of injury repair.

Prostaglandins are derived from essential fatty acids that are incorporated in membrane phospholipids (Fig. 79-9). Activation of phospholipases results in the production of prostaglandin (PG) H_2 by cyclooxygenase. Prostaglandins E_1 and E_2 can be synthesized from PGH_2 by isomerases in the vascular endothelium. PGE_1 and PGE_2 produce vasodilation. PGD_2 also is formed by an isomerase reaction and is the principal cyclooxygenase product of the mast cell. Its effects on the cutaneous microvasculature are similar to those of PGE_1. Prostacyclin (PGI_2) is a vasodilating agent and inhibitor of platelet aggregation that is derived from PGH_2 through the action of prostacyclin synthase. In the skin, PGI_2 is produced primarily in the endothelial cells of blood vessels.[81,82]

Thromboxane synthetase, which converts PGH_2 into thromboxane (Tx) A_2, is located primarily in the platelets. Its effects include vessel constriction and promotion of platelet aggregation.[83] TxA_2 is unstable and is rapidly converted into TxB_2. $PGF_{2\alpha}$ is derived from PGH_2 by a reductase reaction. A marked increase in resistance is seen in cutaneous arteries, arterioles, and venules in the presence of $PGF_{2\alpha}$.[84] The synthesis of prostaglandins and thromboxane can be altered by pharmacologic manipulation. The action of phospholipase A_2 can be inhibited by drugs that reduce the availability of calcium. Glucocorticoids also affect phospholipase A_2 activity by inducing the synthesis of a protein that inhibits the enzyme.[85] Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) interfere with the cyclooxygenase enzyme, inhibiting the synthesis of PGH_2.

Prostaglandins clearly play a role in the inflammatory response after flap surgery. Prostacyclin levels increase after flap elevation, with a peak concentration around 7 days, and then decrease to postoperative day 21.[81] PGE_2, $PGF_{2\alpha}$, and TxB_2 levels also rise after the creation of a flap.[86] The increase in PGE_2, $PGF_{2\alpha}$, and TxB_2 can be blunted by creation of a bipedicled flap. Conversion to a single-pedicle flap ("delay") results in decreased levels of thromboxane and a higher level of PGE_2, which remain elevated for at least 7 days.[87] Whether these changes in prostaglandin levels represent a cause or a side effect of the observed phenomenon remains to be seen.

Reperfusion Injury

Controversy and, often, confusion surround the terms no-reflow and reperfusion injury. *No-reflow phenomenon* connotes the condition in which zone I perfusion has been reestablished but zone II or III failure prevails.[76,80,83,86,88-90] *Reperfusion injury* describes the observation that tissues tolerate short periods of total ischemia fairly well but exhibit histologic injury after return of perfusion—thus, injury apparently caused by reperfusion.[91,92] Both terms imply a period of ischemia, and both conditions result in microcirculatory failure.

All flaps experience some ischemia, and return of blood flow may result in microcirculatory impairment.[53,93] Free radicals form during reperfusion and cause tissue injury, but other factors, such as hyperosmosis from lactic acid accumulation,[94] have also been implicated.[95,96]

Free Radical Formation

When oxygen becomes available with reperfusion, an additional menace to flap survival is produced—the free radical. This byproduct of reperfusion can cause damage at the cellular and subcellular levels,[97,98] contributing to postischemic tissue necrosis. The neutrophil appears to play a major role in the mediation of reperfusion injury.[99]

Free radicals are extremely reactive compounds because of an unpaired electron in their outer orbits. Oxygen free radicals are formed by the sequential univalent reduction of molecular oxygen. The superoxide anion radical (O_2^-) is formed by the addition of a single electron to molecular oxygen. Superoxide is a byproduct of ATP production in the mitochondria and other oxidation-reduction reactions.[98] Polymorphonuclear cells, a second source of superoxide radicals, are released in response to bacterial inflammation.[97]

A major source of free radicals in ischemic tissue is the enzyme xanthine oxidase (Fig. 79-10).[100] With ischemia, high-energy phosphate compounds are converted to hypoxanthine, which accumulates in the tissues. When oxygen becomes available with reperfusion, xanthine oxidase catalyzes the conversion of hypoxanthine into uric acid, producing superoxide in the process. This reaction is believed to be an important mechanism in ischemic tissue injury in skin flaps.[50] The role of xanthine oxidase has been brought into question by the fact that some investigators have found xanthine oxidase activity in ischemic

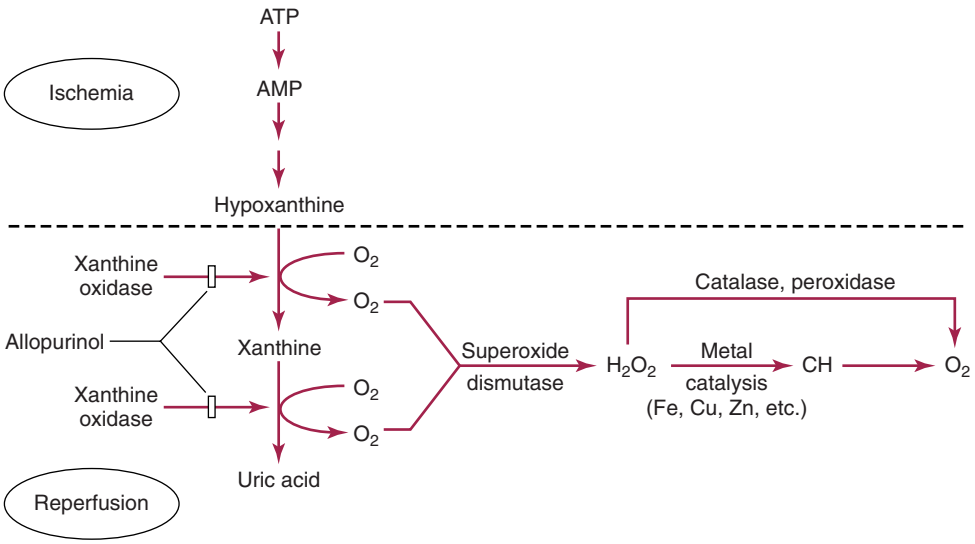

Figure 79-10. Xanthine oxidase. Possible mechanism for formation of oxygen-derived free radicals during reperfusion after ischemia and the subsequent reduction of the superoxide. AMP, adenosine monophosphate; ATP, adenosine triphosphate.

skin[27,101] but others have not.[102] Xanthine oxidase activity has been found in normal rat skin and increases its activity after venous occlusion, reperfusion,[27] and flap elevation, with the highest levels present distally.[43] Tissue damage resulting from production of free radicals can occur through lipid peroxidation of the cellular membrane and denaturation of the intracellular matrix.[98] Delayed neovascularization has been proposed as another consequence of free radical damage affecting proliferating endothelial cells.[103]

Capillary Obstruction (No-Reflow Phenomenon)

Arterial and random flaps can tolerate several hours of total avascularity and remain viable.[104] When the critical ischemia time for a flap is exceeded, an ischemia-related obstruction to blood flow, known as the *no-reflow phenomenon*, develops. Even though large vessels (zone I) have adequate flow, there is no perfusion in zone II or III. The no-reflow phenomenon was described in skin flaps by May and colleagues.[105] Swelling of the endothelial and parenchymal cells, coupled with intravascular stasis and eventual thrombosis, leads to loss of nutritive flow. Interactions between polymorphonuclear cells and endothelial cells appear to play a fundamental role in the generation of a reperfusion injury.[96] Both cell groups produce cytokine and proadhesive molecules that affect the inflammatory response.[93] Polymorphonuclear cells adhere to the vascular wall and generate proteases and oxygen free radicals that injure the endothelial cells.[106]

Flap Biomechanics

Skin flap biomechanics are governed principally by collagen and elastin.[107,108] The interplay of these components has a direct influence on the results of flap wound closure. Collagens I and II constitute the principal structural framework of the extracellular matrix.[109] Elastic fibers, meanwhile, are responsible primarily for the elasticity and compliance of the skin. When skin is stretched, the fine elastin network initially allows easy deformation. This is demonstrated on the stress-strain curve (Fig. 79-11).[110] As the force (stress) applied to the skin increases, randomly arranged collagen fibers begin to lengthen in the direction of the force and deformation becomes more difficult (section II). Further lengthening becomes difficult. Once the collagen fibers have all become oriented longitudinally with the force, little further deformation is possible with increasing stress (section III). Skin in section III of the curve behaves like elderly skin, suggestive of the maintenance of collagen biomechanics with aging. As patients age, there is a progressive decrease in elastic fibers.[111] Thus, less force is necessary to produce lengthening. Older patients can therefore be expected to have less wound tension.

Figure 79-11. Perfusion types. Zones of circulatory impairment. The relationship of microcirculatory impairment and anomalous readings of common measurements of flap perfusion is shown. All zones should be functioning for cell viability, and zone III is the first to fail. Zone III failure is shown as a loss of interstitial flow, even though capillary blood flow is potentially still present. Zone II failure occurs with loss of capillary blood flow; arteriovenous shunt flow may still be present, but it is not nutritive. Finally, with zone I failure, the flap is ischemic. See text for a discussion of the monitors of perfusion. Doppler, laser Doppler velocimetry; Fluoro, fluorometry; $TcPo_2$, transcutaneous oxygen tension; Temp, temperature measurement.

Wound tension is an important factor in flap survival as well as scar formation. Excessive tension in skin flaps is associated with greater flap necrosis.[112,113] This is probably secondary to a drop in blood flow with increasing wound tension.

Creep refers to the increase in strain (change in length relative to original length) seen when a constant stress (force) is applied to the skin. *Stress relaxation*, on the other hand, refers to the decrease in stress that occurs when skin is held under tension at a constant strain.[3,114] Thus, the physiology of skin is altered over time by the application of a constant stress. These properties are responsible for the effects seen with tissue expansion and serial excisions of lesions.

Flap undermining is routinely performed during flap elevation and wound closure. It is the release of the attachments of the skin to

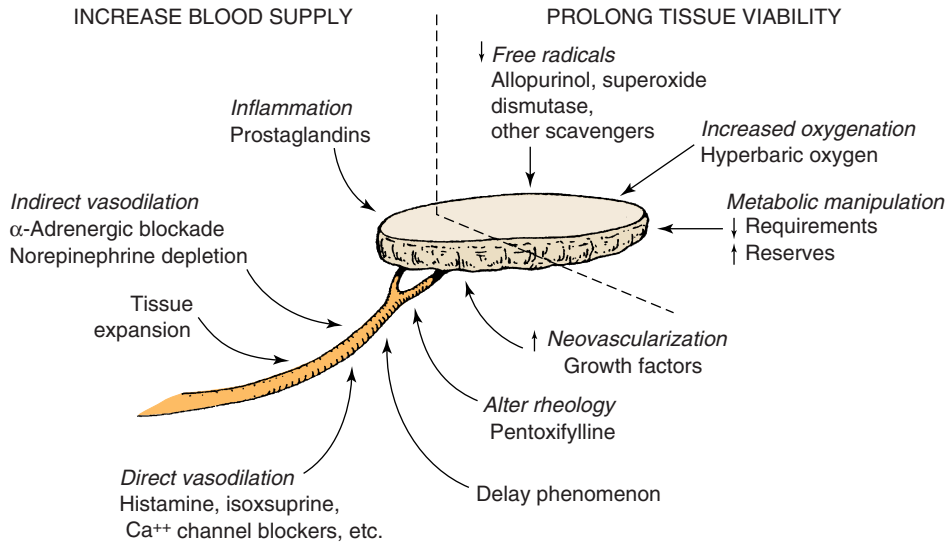

Figure 79-12. Experimental attempts to affect flap survival.

the underlying tissue that results in a decreased wound tension when undermining is performed.[115] The force required to counteract the resistance between the dermis and underlying tissue is the shearing force. In an animal model, the reduction in the shearing force, and thus wound tension, was found to decrease with undermining up to 4 cm. Further undermining did not produce more improvement in wound tension.[114]

Attempts to Alter Skin Flap Viability

Increased Blood Supply

Skin flap failure can occur from extrinsic and intrinsic causes.[116] Extrinsic reasons for flap necrosis are reasons not resulting from the design of the raised flap. Examples are systemic hypotension, infection, and pedicle compression. These factors often can be overcome in the clinical situation. The primary intrinsic factor affecting flap survival is inadequate blood flow. Numerous experimental attempts have been made to influence flap microcirculation or decrease the deleterious effects of inadequate flap blood flow (Fig. 79-12). The most successful has been flap delay. Table 79-1 shows the zones of perfusion affected by various interventions to increase flap survival.

Delay

Four things are accepted about the delay phenomenon. First, surgical trauma is required to cause it. Second, a large percentage of the neurovascular supply to the flap should be eliminated. Third, delay results in increased flap survival at the time of tissue transfer. Fourth, the beneficial effects can last up to 6 weeks in humans.[117] To explain this phenomenon, three theories regarding the mechanism of delay have been developed: (1) delay improves the blood flow, (2) delay conditions the tissue to ischemia, and (3) delay closes arteriovenous shunts.[118] Most later studies support a mechanism resulting in increased circulation to the flap; how this occurs remains to be proven.[117]

The percentage of arteriovenous shunt flow to total blood flow is similar in delayed flaps and acute flaps.[77] Delayed flaps simply have an increase in total blood flow. The addition of systemic norepinephrine decreases the blood flow in delayed flaps to the level seen in acute flaps. Thus, one effect of delay is a decrease in vasoconstriction in the distal portion of the flap.

Flaps delayed as few as 24 hours survive to a greater length and can tolerate longer periods of ischemia.[119,120] Distal perfusion in the pig flank flap increases with a bipedicled flap delay up to 4 days. No further increase in perfusion occurs, extending delay up to 14 days.[121,122] Pang and colleagues[77,93] theorized that after a delay, reduced vasoactivity of the small arteries allows delivery of more blood to the distal portion of the flap. This modulation could occur by release of vasoconstrictive substances (i.e., norepinephrine, thromboxane, and serotonin) during elevation of the bipedicled flap. Degeneration release of norepinephrine occurs soon after flap elevation, with norepinephrine stores largely depleted in the first 24 to 48 hours.[82,123] In bipedicled flaps, Cutting and associates[121,124] found the catecholamine level beginning to rise 4 days after flap construction; other researchers have found the catecholamine levels to be depressed over a greater period. Necrosis is not seen with the first stage of delay because the bipedicled flap has an adequate blood supply. After depletion of the catecholamines, a relative state of sympathectomy develops. Because of the catecholamine depletion, conversion of the delayed flap to a single pedicle is not accompanied by the same degree of vasoconstriction.[75]

Early after elevation, the vasculature to the flap has a greater sensitivity to the effects of adrenergic drugs. Intravenous norepinephrine decreases blood flow to a myocutaneous flap, even in the presence of increased blood flow to control skin.[125] This hypersensitivity to exogenous norepinephrine can be partially blocked by management with phenoxybenzamine, an α-adrenergic blocking agent. The period of hypersensitivity to norepinephrine lasts slightly less than 1 week[73]

Table 79-1

Zones of Perfusion Affected by Various Interventions to Increase Flap Survival

Intervention	Affected Zone(s)
Flap design	I
Delay	I, II
Vasodilators	II
Neovascularization	II
Rheology	II
Inflammation	II, III
Antioxidants	II, III, IV
Metabolic manipulation	II, IV
Increased oxygenation	IV

and correlates with the period of decreased tissue norepinephrine found after flap elevation.[121] Recovery from the hyperadrenergic state also appears to play a role in the delay phenomenon.

Vasodilators

Indirect Vasodilators

The intense vasoconstriction associated with the release of norepinephrine after flap elevation should hinder flap survival. One of the benefits of flap delay seems to be depletion of norepinephrine before creation of the flap to be transferred. If this vasoconstriction could be blocked or reversed, the duration and severity of distal flap ischemia should be lessened. The result would be increased flap survival without the need for delay.

α-Adrenergic blocking agents are directed against the catecholamine-induced vasoconstriction seen after flap elevation. In some studies using the rat model, phenoxybenzamine resulted in improved flap survival.[51,126,127] Phenoxybenzamine and phentolamine ointments applied topically were also found to be effective in increasing flap survival in the rat model.[127] Other investigators have been unable to reproduce beneficial effects in the rabbit or pig.[37,128] Depletion of norepinephrine stores through the use of reserpine[129] and guanethidine[130] before flap elevation has also met with mixed results and systemic toxicity.

Several anesthetic agents have vasoactive properties and may influence flap survival. Because general anesthetics are often used during the creation of larger flaps, their potential effects on flap survival are important. Use of isoflurane (a sympatholytic vasodilator) was found to be associated with significantly better flap survival than nitrous oxide, which induces vasoconstriction.[131] Verapamil and lidocaine have also been found to decrease skin flap necrosis when used locally in the vicinity of the pedicles of axial pattern flaps.[132]

Direct Vasodilators

Multiple topical anti-ischemic agents have been found to have beneficial effect on skin flaps in experimental models.[133-135] This finding has not yet translated into widespread clinical use of these agents, however, because the experimental and clinical results have been mixed. Direct vasodilators such as histamine, hydralazine, nitroglycerin, pentoxifylline, and topical dimethylsulfoxide have been found to have both a beneficial result and no effect on skin flap survival.[43] Isoxsuprine is a phenylethylamine derivative of epinephrine having α-adrenergic receptor antagonistic and β-adrenergic receptor agonistic properties, resulting in relaxation of vascular smooth muscle. In high doses, isoxsuprine can decrease viscosity and inhibit platelet aggregation. Isoxsuprine was found to increase blood flow in the area of the dominant artery in porcine myocutaneous and arterial flaps. Unfortunately, no improvement in blood flow was seen in the distal random portion of the flaps or in flap survival.[136,137] The smaller vessels in the distal random portion of a flap were theorized to differ in sensitivity from muscular or axial arteries to vasodilator drugs. Manipulation of these distal vascular channels appears to be critical in increasing flap survival.

Calcitonin gene–related peptide is a bioactive neuropeptide found in primary sensory neurons. A potent vasodilator, it is thought to stimulate smooth muscle relaxation by an endothelial-dependent mechanism. Administration of this neuropeptide improves blood flow and survival in ischemic skin flaps and delays the onset of the no-reflow phenomenon.[138,139] Pretreatment with capsaicin, which depletes neuropeptides from primary sensory neurons, results in a decreased flap survival.[140] These findings suggest a potential role for primary sensory neurons in cutaneous vascular control and flap survival.

Prostaglandins have multiple effects on healing wounds and the vasculature to the skin, including vasodilation and decreased platelet aggregation. Prostaglandins E_1 and E_2 have been found to decrease skin necrosis in random skin flaps.[141] PGE_1 also effects leukocyte-endothelial cell adhesion, a factor in ischemia-reperfusion injury. Administration of prostaglandin E_1 may increase flap survival by decreasing the expression of anti–intercellular adhesion molecule-1, thus limiting leukocyte-endothelial cell adhesion.[86] The mechanism of delivery for these substances has been by topical application, with absorption through the skin, or by subcutaneous or intravenous injection. Attempts to improve delivery have shown promise in the laboratory. The vasoactive drug buflomedil has been delivered bound to liposomes and found to have a measured therapeutic effect on ischemic skin flaps.[142] Topical application of nitroglycerin was shown to increase flap survival in some studies but not in all.[143-145] Nitroglycerin acts as a vasodilator with more potent venodilator than arteriodilator effects. Its action on the veins was believed to contribute to the increased flap survival. The ability to reduce platelet aggregation may be the main therapeutic benefit of nitroglycerin and other direct vasodilators that affect platelet function. Nitroglycerin and nifedipine have been found effective in improving random-pattern skin flaps in laboratory animals exposed to cigarette smoke.[146]

Neovascularization

The identification of a host of biologically active growth factors and the continued development of methods of delivery of these agents into target sites have generated enthusiasm for the application of these technologies to aid in flap outcomes. The stimulation of angiogenesis through gene transfer techniques offers hope for the treatment of ischemic tissues of various types, including flaps. Vascular endothelial growth factor (VEGF) is a potent angiogenic molecule, as is basic fibroblast growth factor (FGF-2). VEGF has shown promise, having been demonstrated in the laboratory to improve flap survival in random flaps, axial flaps, and flaps treated preoperatively.[70,117,147] In a rat model, injected VEGF-transduced mesenchymal stem cells survived in vivo and were incorporated into the capillary networks in the ischemic flaps. Compared with controls, the VEGF group demonstrated better flap viability and increased ischemic flap neovascularization, as evidenced by increased capillary density and blood perfusion of the flaps.[148] Similarly, adipose-derived stem cells, which have been found to demonstrate angiogenic potential, injected into flaps in a mouse model demonstrated a statistically significant increase in flap viability and capillary density in comparison with the control group.[149] Nitric oxide synthase inhibitors may raise VEGF levels and improve ischemic flap survival.[63] Application of growth factor can generate functional blood vessels and nonsurgically anastomose divided vessels within 2 or 3 weeks.[150] The greater neovascularization also allows earlier ligation of the original vascular pedicle with complete tissue survival.[65,151] The delay phenomenon does not work by an angiogenic mechanism, however, and attempts to improve survival of the random portion of a pedicled flap with fibroblast growth factors have had mixed results.[142,152-155]

Rheology

In a homogeneous fluid that exhibits equal shear stress at different rates of shear, flow (Q) in a vessel can be approximated by Poiseuille's equation:

$$Q = \frac{\pi r^4 (\Delta P)}{8nl}$$

where ΔP equals pressure gradient; r^4 equals the fourth power of the vessel radius; l equals vessel length; and n equals viscosity.[13] Although blood is a non-newtonian fluid, the qualitative relationships in the equation remain. In larger vessels, the radius is a dominant factor, but in the capillary microcirculation, viscosity becomes more important. Decreasing the viscosity of blood may make it possible to increase flow to the distal random portion of the acutely raised flap and beneficially affect flap survival. Viscosity is influenced by the hematocrit, serum proteins, temperature, erythrocyte deformability, aggregation, and other factors.[156] Each of these factors can be potentially manipulated with a resultant change in viscosity.

Hemodilution has been shown to decrease viscosity and to have a beneficial effect on flap survival.[157,158] Reducing blood viscosity by protein depletion also results in increased flap survival in rats.[159]

Pentoxifylline and low-viscosity whole blood substitutes (Fluosol-DA) also lower viscosity. Pentoxifylline is a hemorheologic agent that increases erythrocyte deformability and decreases platelet aggregability.[156] When given 7 to 10 days before flap elevation, pentoxifylline improves flap survival.[156] Beneficial effects of limited preoperative

dosing with pentoxifylline have not been uniform, however.[81,160-163] Administration of Fluosol-DA also has failed to increase flap survival in a consistent manner.[164]

Inflammation

The surgical trauma associated with an acutely raised or a delayed flap engenders an inflammatory response. This response results in a local increase in blood flow that could benefit flap survival. Improved flap blood flow and survival can occur with different methods of creating an inflammatory response before flap creation.[78,165] The beneficial effects of inflammation on flap survival also can be seen on a flap raised adjacent to a previously delayed flap.[166] Attempts to increase flap blood flow and survival with 5 days of low-power laser burns have had mixed results.[167,168] These studies show that the inflammatory response has the potential to improve survival without sympathectomy or vascular division.

The mechanism by which inflammation produces a beneficial effect appears to involve the products of cyclooxygenase metabolism of arachidonic acid. Administration of PGI_2 leads to dilation of the arterial pedicle and increased flap blood flow.[169] The result is increased flap survival.[86,141,170] Systemic administration of PGE_1 increases flap survival at low doses but can hinder flap survival at higher doses, which cause hypotension.[171] Topical administration of PGE_1 also improves flap survival but should be applied to the area of critical ischemia to be effective.[43,172,173] Additional prostaglandin effects, such as increased erythrocyte deformity and decreased platelet aggregation, have been proposed as the mechanism of better survival with prostaglandin administration.[171,174,175]

Cyclooxygenase inhibitors, such as indomethacin and ibuprofen, have been shown to increase skin flap viability and prolong tolerance of ischemia.[141,176] Glucocorticoids, which inhibit phospholipase activity, also have improved flap survival in some studies[128,177,178] but not in others.[179] Blocking TxA_2 synthesis has had mixed results.[180,181]

Tissue Expansion

Tissue expansion has been shown to increase the size of the transferred flap in experimental animals and humans. Examination of expanded skin in the guinea pig has shown an increase in the thickness[182] and mitotic activity[115] of the epidermal layer, indicating epidermal proliferation. Blood flow in expanded tissue is greater than that in skin overlying a noninflated expander 1 hour after creation of a pedicled flap.[44] The increase in blood flow to expanded skin seems to be short-lived.[183] Apart from the acute changes seen with expander manipulation, flap viability and blood flow in expanded skin appear to be similar to those seen in delayed flaps.[184]

Prolonged Viability

Protection against Harmful Agents

The formation of free radicals with reperfusion and the return of molecular oxygen to ischemic tissue place an increased burden on flap survival. Research has focused on reducing the production of free radicals and using agents that remove free radicals (free radical scavengers) from the immediate environment.

Nitric oxide is a radical with vasodilating properties that protects tissues from neutrophil-mediated ischemia-reperfusion injury.[185] L-Arginine, a nitric oxide precursor, is converted into nitric oxide by the enzyme nitric oxide synthase. This precursor has been found to have a protective effect on myocutaneous island flaps as well as random-pattern skin flaps.[186,187] Nitric oxide inhibition decreases skin flap survival.[188]

Ischemia-reperfusion injury occurs in zones II and III, where a cascade of events may lead to flap failure upon the reestablishment of blood flow after prolonged ischemia. Platelets play a role in this cascade of events. Inhibition of platelet activation by a platelet glycoprotein IIb/IIIa inhibitor has shown promise in the enhancement of skin flap survival after a long period of ischemia.[189,190]

Preoperative administration of allopurinol (a xanthine oxidase inhibitor) prevents the increased xanthine oxidase activity seen with acute flap elevation.[191] Improved survival of dorsal rat flaps has been accomplished with allopurinol given at high doses,[27,192,193] lower doses having no effect.[192] The high doses required to obtain a beneficial effect have led to concern about the use of allopurinol to increase flap survival in the clinical setting.

A number of free radical scavengers are available to protect the tissues from destruction by free radicals. Superoxide dismutase (SOD), an intracellular free radical scavenger, catalyzes the conversion of superoxide to hydrogen peroxide (H_2O_2) and molecular oxygen. When given systemically, SOD is an effective scavenger of the superoxide radical regardless of its source.[94] SOD treatment has resulted in improved flap survival[193,194] and increased tolerance of flaps to ischemia.[95,195] Improved flap survival also has been shown with a number of other naturally occurring compounds with free radical scavenging properties. They include deferoxamine,[50] vitamin E, vitamin A, vitamin C, glutathione,[196] various amino acids,[197] and amino acid derivatives.[198]

Hyperbaric Oxygen

Improvement in flap survival with hyperbaric oxygen treatment has been documented,[12] but it has not been a consistent finding.[161,199] Hyperbaric oxygen treatment increases blood oxygen-carrying capacity by 20%.[200] This relative increase is greater with a low hematocrit because the additional oxygen is dissolved in the plasma rather than carried by hemoglobin. A greater effect of hyperbaric oxygen treatment may be increasing oxygen diffusion from surrounding perfused tissue to the ischemic portion of the flap.[3] Improved flap survival also occurs with treatments using hyperbaric air, showing that increased oxygen can be delivered with a rise in ambient pressure alone.[201]

The beneficial effect of hyperbaric oxygen in pedicled flaps includes decreased leukocyte adherence, reduction of edema caused by vasoconstriction, and neovascularization in irradiated tissue.[200,202,203] Animal studies have confirmed that the treatment should be given early, and one study suggested that it should be used often.[161,204] There is little benefit from hyperbaric oxygen if the treatment is given 24 hours or more after flap elevation.[200]

In a retrospective study of 65 patients with pedicled flaps that were determined by the surgeons to be in a high-risk group, hyperbaric oxygen was beneficial.[202] Although there is evidence that hyperbaric oxygen is effective for impaired flaps, it is not cost effective to treat every flap.[205] Determining which flaps need treatment and which flaps will benefit is key. French investigators found that a hyperbaric oxygen challenge test (test dive) was predictive of successful outcome if the transcutaneous oxygen measurement rose 50 mm Hg or more. Still, the researchers noted the need for further studies to determine indications for hyperbaric oxygen.[19]

Metabolic Manipulation

Additional strategies for increasing flap survival include reducing the metabolic requirements and enlarging the metabolic reserves of skin. These approaches are based on the idea that flap necrosis occurs when tissue metabolic demand is greater than what the blood supply can deliver. Decreasing temperature is an effective way to reduce metabolic activity and delay necrotic changes, but improvement in flap survival is not seen with this maneuver.[206]

Administration of ATP–magnesium chloride complex increased survival in the rat abdominal flap.[43] The metabolic support provided by this compound was believed to delay the onset of irreversible cell damage. Difluoromethylornithine (DFMO) was found to increase survival of abdominal flaps in rats.[207] It appears to decrease metabolic demand by inhibiting the synthesis of polyamines, which are required for protein synthesis and cellular proliferation.

The use of a vacuum-assisted closure (VAC) device was first described in 1997 for the stabilization of skin grafts.[208] Shear stresses, hematoma, and seroma collection can contribute to flap failure or poor skin-graft take. Immobilization of the flap with the device limits shear stresses, eliminates fluid collections, and decreases bacterial contamination. Traditionally vacuum-assisted closure devices have been used in abdominal wounds and chronic leg ulcers,[209] but their use has expanded to the treatment of complicated head and neck wounds[210] and in securing skin grafts to microvascular free flaps as well as to the donor sites.[211] The negative pressure provided by the vacuum-assisted closure device

has circumvented the limitations of conventional tie-over bolster dressing and has allowed successful graft take in complex three-dimensional flaps.[210,211] Even irradiated wounds, previously thought to be a contraindication to split-thickness skin graft reconstruction, have been successfully managed with split-thickness skin grafts and vacuum-assisted closure.[212]

Impaired Flaps

In the majority of flaps carefully designed and accomplished in healthy patients, flap survival is the rule, and methods to improve survival and extensive monitoring or treatment of the flap are not warranted. The exceptions to the rule should be identified so extra efforts to ensure survival are reasonable and cost effective. Several factors place the patient in a higher risk category.

Smoking tobacco is associated with an increased chance of flap necrosis in facelift operations.[213] Exposure to tobacco smoke resulted in greater flap necrosis of dorsal flaps in rats[146] and hamsters.[214] The deleterious effects of nicotine appear to increase with prolonged exposure. The mechanism by which tobacco or nicotine decreases flap survival is unknown but may involve direct endothelial damage, vasoconstriction caused by catecholamine release, or local concentrations of prostaglandins.[215,216] Long-term, low-dose nicotine (comparable with human smoking exposure) was used in a rat model to document decreased capillary blood flow and survival; these effects could be avoided if the nicotine was withdrawn 2 weeks before the flap was raised.[215]

Irradiation has been shown to be deleterious to flap survival in some studies[2] but not in others.[161,217-219] The reason for this discrepancy is probably differences in the radiation regimen administered (i.e., radiation dosage, fractionation, and surgical timing in respect to the irradiation). Radiation treatment results in endarteritis obliterans and altered wound healing. Even in previously irradiated tissue, the delay phenomenon continues to improve flap survival.[217,220,221] Flap neovascularization is delayed but not eliminated after irradiation. The use of angiogenic growth factors has the potential to increase the viability of irradiated skin flaps by means of accelerated revascularization.[151]

The ischemia time during the transfer of free flaps (called primary ischemia) appears to hinder the flap's ability to tolerate a second ischemic insult. The longer the period of perfusion after the microvascular anastomosis (called the reperfusion period), the better a flap will tolerate secondary ischemia. Porcine ventral arterial island flaps initially exposed to 2 hours of ischemia followed by 12 hours of blood flow had a 50% survival rate after a subsequent 7.2 hours of "secondary ischemia,"[222] The same researchers found that 13 hours was required for the initial ischemic event to produce a 50% survival rate.[223]

Vascularity of the recipient bed is an important factor in free flaps. Experimentally, a pedicle can be divided 6 days after flap creation.[65,67] Typically in clinical situations, the pedicle is no longer monitored after 1 week, although there are cases of late flap failure.[224,225] If the flap is placed into a bed with poor vascularity, dependence on the pedicle may be prolonged. If late pedicle failure occurs in a flap with a poor vascular bed in which neovascularization has not occurred, the chance of late complications could be greater.

Diabetes may be considered a risk factor because of the small vessel disease in diabetes, although investigators did not find decreased flap survival in streptozotocin-induced diabetic rats. They did find slower endothelial growth at the anastomosis but concluded that diabetes is not a contraindication to the use of a free flap.[226] In a study on rats, older rats were found to have less tolerance to muscle ischemia than young rats, and this difference was assumed to be related to decreased mitochondrial function.[227] Fluid management also can have an impact on flap survival. Fluid overload increases flap edema, and at the other extreme, intraoperative systemic hypotension has been shown to be detrimental.[228] Central venous pressure monitoring was not found to be helpful.[229,230]

Flap Salvage

Once a flap is identified as being at risk for necrosis, action can be taken to improve survival. Zone I manipulations are the most effective. In pedicled flaps, efforts to enhance zone I perfusion are limited to preoperative planning, flap execution and design, and surgical delay. If a pedicled flap is effectively executed, its loss results from failure of zones II and III, which will develop slowly and involve the distal or random portion of the flap. Clinical efforts to improve zone II or III failure are limited to methods such as hyperbaric oxygen and leeching. Of the hundreds of pharmacologic agents that have been tested for this application, none has gained widespread clinical use.

In contrast, the global ischemia of free flap failure often relates to a zone I failure—thrombosis or compression of the pedicle. This failure often is acute and relatively easy to detect and repair. If the zone I failure is not quickly resolved, the injury progresses to zones II and III.

Free flaps need intensive postoperative monitoring. There are several different methods of monitoring free flaps, but none is foolproof, and frequent observation by experienced personnel is still the gold standard. Pedicle failure can be determined early, and the flap can be salvaged in many cases by exploration of the anastomosis and clearing of the thrombus.

Because of the accessibility of the vessels and a short period of nonperfusion (primary ischemia), the question was raised whether washing out flap vessels could potentially improve survival in the event of secondary ischemia,[224] analogous to organ transplantation. University of Wisconsin solution has been used to effectively decrease perivascular swelling in the microvasculature of organ systems.[169] Babajanian and and colleagues[231] used it as a washout solution to improve survival in free flaps.

An intriguing application of perfusion washout technology is extracorporeal circulation,[232] which investigators theorize could be used if there were no suitable donor site vessels. Extracorporeal circulation was studied in a flow-through venous free flap. Only a plasma solution was able to maintain viability over 3 days of extracorporeal infusion, although three other test perfusates caused massive edema and total obstruction to perfusion.

Perfusion washout also has been studied for its ability to improve survival after the thrombosis is cleared from the anastomotic site. University of Wisconsin solution caused greater improvement when used during secondary ischemia than during primary ischemia, indicating that it may be better for flap salvage than for prophylaxis.[232] Urokinase has been used for the antithrombotic effects at the anastomosis and, because of microemboli, at the capillaries (zone II).[233,234] Intravascular heparin was not useful after thrombus formation.[235] Medicinal leeches have been used clinically.[236] The leeches are thought to relieve microcirculatory congestion during active feeding and for several hours afterwards because of the antithrombotic effect of the leeches' salivary fluid. There is a risk of *Aeromonas* infection with their use, however. The "chemical leech" and mechanical leeches have been described.[237] Relief of vascular congestion and edema may also be possible with microdialysis techniques, which have been used to reduce skin flap edema in a rat model.[238]

Hyperbaric oxygen has been used for free flap salvage. In a study of a rat epigastric free flap after 8 hours of global ischemia, hyperbaric oxygen increased survival and increased distal blood flow as shown by laser Doppler velocimetry.[203] In a similar model, hyperbaric oxygen inhibited the xanthine oxidase system and improved free flap survival after 18 hours of nonperfused storage.[239] Hyperbaric oxygen therapy will not be effective treatment unless the thrombosis has been cleared, but it may prolong viability and increase neovascularization.

Wound Healing

The creation of a surgical flap results in a cutaneous wound that requires repair. A series of overlapping and closely coordinated events is initiated with disruption of the skin surface. The events associated with wound repair are relatively consistent regardless of the causative agent. Multiple cell types participate in wound repair (Table 79-2).

Disruption of the protective layer of skin results in exposure of the subepithelial layers and vascular endothelium along with extravasation of blood products. A blood clot is formed that both provides a wound matrix for cell migration and initiates the inflammatory response. This is the beginning of tissue repair. After establishment of an inflammatory phase, a phase of tissue proliferation occurs that

Table 79-2

Cell Types Shown to Be Involved with Wound Repair

Tissue	Cell Types
Vascular	Platelets, macrophages, neutrophils, endothelial cells, smooth muscle
Epidermis	Keratinocytes, melanocytes, Langerhans cells
Adnexal structures	Outer root sheath cells, hair dermal papilla cells
Dermis	Fibroblasts, myofibroblasts
Nervous system	Neurons
Subcutaneous fatty layer	Adipocytes

involves the formation of granulation tissue, reepithelialization, and wound contraction. Finally, a prolonged phase of tissue remodeling completes the healing process. All three phases of wound healing overlap in time and appear to be tightly coordinated. Much of the later work in wound repair has involved the regulation of and communication between the involved cell types that result in a well-healed wound.

Inflammatory Phase

The initial injury to the skin results in disruption of blood vessels and extravasation of blood constituents. The vascular response to injury begins with a brief period of vasoconstriction that aids in hemostasis.[106] Platelets respond by aggregating at the injury site; along with fibrinogen, fibrin, and fibronectin, they form a blood clot that reestablishes hemostasis. The clot covers the wound and provides an initial matrix for cell attachment and migration.[240] The clot contains a variety of cytokines and growth factors. Platelets release three substances[241]: (1) Platelet-derived growth factor (PDGF) plays roles in chemotaxis for macrophages and fibroblasts, macrophage activation, fibroblast proliferation, matrix production, and angiogenesis.[242,243] (2) Transforming growth factor-β (TGF-β) is involved in keratinocyte migration, chemotaxis for macrophages and fibroblasts, and fibroblast matrix synthesis and remodeling.[107,244-246] (3) Epidermal growth factor (EGF) is active in keratinocyte migration and replication.[244,247]

Tissue injury is associated with the onset of acute inflammation and the arrival of polymorphonuclear granulocytes (neutrophils). One day after tissue injury, neutrophils constitute nearly 50% of all cells at the wound site.[248] Neutrophils help remove foreign material and bacteria from the wound. They are subsequently extruded with the eschar or cleared by macrophages. Neutrophils also release interleukin (IL)-1α and IL-1β and tissue necrosis factor-α (TNF-α),[99] all of which are early activators of growth factor expression in macrophages, keratinocytes, and fibroblasts.

Neutrophils are highly abundant in the circulation, and quite a number are collected passively along with platelets at the wound site in the blood clot. Neutrophils also appear to be specifically attracted by a subset of cytokines referred to as *chemokines*. Along with growth factors, platelets release the chemokine connective tissue–activating peptide-III (CTAP-III), which is converted into neutrophil-activating peptide-2 (NAP-2) by proteases released from neutrophils already attached to the thrombus.[249] Neutrophil-activating peptide-2 stimulates migration and extravasation of neutrophils via the chemokine receptor 2 (CXCR2). In addition, vascular endothelial cells and pericytes secrete growth-related oncogene-α (GRO-α),[99] which supports movement of neutrophils to the wound. An additional method of attracting neutrophils involves the strong and selective expression of IL-8 under the wound surface that stimulates the CXCR2 and CXCR1 (not targeted by growth-related oncogene-α) receptors. IL-8 is expressed by neutrophils and macrophages immediately below the denuded wound surface. The expression of IL-8 is induced by pro-inflammatory cytokines such as IL-1, tissue necrosis factor-α (expressed initially by neutrophils and later by macrophages), bacterial products (lipopolysaccharides), and hypoxia.[250]

Monocytes infiltrate the wound early after injury and become activated macrophages. On the third day following an injury, with wound closure and the decline of neutrophils, monocytes represent the largest blood cell population.[251] Monocytes/macrophages are attracted to the wound by the chemokine monocyte chemoattractant protein-1 (MCP-1). This chemokine is produced by resident and infiltrating mononuclear cells, keratinocytes at the wound edge, and endothelial cells. Macrophages play a central role in the inflammatory phase of wound healing. In addition to their immunologic functions as antigen-presenting cells and phagocytes, macrophages are an important source of growth factors. Macrophages release TGF-α. TGF-β, insulin-like growth factor I (IGF-I), heparin-binding epidermal growth factor (HB-EGF), FGF, PDGF, and VEGF.[70,252] TGF-α, like EGF, has a stimulatory effect on keratinocyte migration and replication.[245,253] IGF-I—also produced by keratinocytes, fibroblasts, and platelets—promotes reepithelialization and granulation tissue formation. Heparin-binding EGF, basic FGF (bFGF, or FGF-2), PDGF, and VEGF promote angiogenesis.[147,241,254,255] As its name implies, FGF also enhances fibroblast growth.[142,153]

Lymphocytes are attracted to the wound site and after 14 days are the dominating leukocyte subset. Lymphocytes interact with Langerhans cells in the epidermis and nerve endings in the dermis to play an antimicrobial role. Leukocytes also produce growth factors (e.g., heparin-binding EGF and basic FGF).[250] Lymphocytes are attracted to wound sites initially by MCP-1. After day 4, lymphocytes are attracted to wound sites by interferon-γ–inducible protein-10 (IP-10) and monokines induced by interferon-γ (Mig). The presence of these two chemokines after day 4 reflects a shift in the cytokine profile from TNF-α/IL-1 to interferon-γ.[250]

Nitric oxide (NO) is a short-lived free radical that exerts its effects at many levels.[256] Nitric oxide synthase is frequently produced in response to acute inflammatory stimuli such as wounding. NO may have a capacity for selective regulation of gene expression.[63] This would be important during the inflammatory phase of wound healing, when NO production is greatest. Production of NO is catalyzed by nitric oxide synthases (NOSs), a group of three isoenzymes, neuronal (nNOS), endothelial (eNOS), and inducible (iNOS).[64,257] NOS catalyses the oxidation of the amino acid L-arginine to release citrulline and NO.[258] NO appears to participate in the regulation of skin homeostatic functions such as circulation, ultraviolet B–mediated melanogenesis, sunburn erythema, and the maintenance of the protective barrier against microorganisms.[185] During the inflammatory phase, iNOS is elevated, with infiltrating macrophages being a major source of its expression.[257,259]

Proliferation Phase

The successful development of an inflammatory phase results in the recruitment of keratinocytes, fibroblasts, and endothelial cells. The arrival of these cells marks the transition from a process of clearing and stabilizing the wound to one of proliferation and repair. The proliferation phase consists of reepithelialization, formation of granulation tissue, and wound contraction. Like the three major phases of wound healing, these three aspects of the proliferation phase overlap in time and are closely interrelated.

Reepithelialization

Reepithelialization attempts to restore the protective barrier of the skin. It begins within hours of injury and is the result of keratinocyte migration and proliferation.

Keratinocyte Migration

Changes leading to keratinocyte migration begin early after wounding. Growth factors that enhance keratinocyte migration are EGF, TGF-α, FGF-7 (keratinocyte growth factor), TGF-β1, hepatocyte growth

factor, IGF-I, and insulin.[244,260] IL-8 is also capable of stimulating keratinocyte migration and proliferation.[250] IL-8 is highly expressed along the denuded wound surface. Keratinocytes express the receptor for IL-8 and growth-related oncogene-α. These findings suggest that the interaction of the keratinocyte with its ligand plays a role in reepithelialization.

Under the influence of these growth factors and cytokines, epithelial cells at the wound margin undergo changes that set the stage for cell movement. These changes include filament reorganization, reduction of the number of intercellular attachments, and the expression of members of the integrin superfamily of cell surface receptors.[261]

Integrin receptors are transmembrane, heterodimeric glycoproteins consisting of one α chain and one β chain. Keratinocytes, at the leading edge of the wound, express integrins that allow them to interact with fibronectin (αvβ6, α5β1), vitronectin (αvβ5), and collagen (α2β1) present at the wound margin and interwoven with the fibrin clot.[240,262] The keratinocytes are guided into the wound, migrating between the fibrin clot and the collagenous dermis through the interaction of the integrin receptors and the extracellular matrix proteins. Keratinocytes produce plasminogen activators,[263] which activate plasmin and collagenase-1 (matrix metalloproteinase-1 [MMP-1]).[189] Plasmin and MMP-1 must dissolve fibrin and collagen type I, respectively, in order for migration to occur. In partial-thickness wounds, keratinocyte migration also occurs from skin appendages, including the hair follicle.[260]

The relationship between the enzyme production of MMPs, extracellular matrix proteins, integrins, and keratinocyte migration has been nicely summarized by Parks.[189] Plasmin and collagenase-1 break down matrix barriers that impede cell migration. Keratinocytes migrate along a path of least resistance driven and oriented by collagenase-1.[109] Collagenase-1, acting on its principal substrate in the dermis (i.e., type I collagen), provides migrating keratinocytes with a mechanism to maintain their course and directionality in the wound environment during reepithelialization. In wounds, basal keratinocytes dislodge from the basement membrane and contact dermal collagen type I. The integrin α2β1 becomes concentrated at the forward-basal tip of the migrating keratinocyte. α2β1 binds dermal collagen with high affinity, and this interaction induces collagenase-1 expression. Collagenase-1 cleaves type I collagen and converts it to a gelatin, allowing the cell to migrate. The high affinity of α2β1 with dermal collagen, but not with gelatin, favors establishment of attachment to native, uncleaved, and exposed dermal collagen in the open wound surface. When continually repeated, this process provides the migrating cells with a mechanism to control their direction and to remain superficial to the dermis but deep to the fibrin clot during reepithelialization.

Keratinocyte Proliferation

Migrating keratinocytes are found on the advancing epithelial margin. Proliferating keratinocytes are found within the epithelial margin and the nearby hypertrophic epithelium behind the actively migrating cells. Keratinocyte proliferation begins 1 to 2 days after injury. The growth factors known to enhance keratinocyte replication are EGF, TGF-α, FGF-7, IGF-I, IL-1, IL-6, hepatocyte growth factor, nerve growth factor,[247,260-262] and IL-8.[250] Neuropeptides are also thought to have growth-stimulatory effects on keratinocytes through the activation of cyclic adenosine-5-monophosphate. Examples are calcitonin gene–related peptide, vasoactive intestinal polypeptide, peptide histidine-methionine, and growth hormone–releasing factor.[264] Leptin, produced in the subcutaneous layer, is reported to have growth-stimulatory effects on keratinocytes as well.[265]

Keratinocytes can express all three forms of NOS.[258] NO serves as a mediator that regulates gene expression and proliferation in keratinocytes. Proliferating keratinocytes at the wound margin and, to a lesser extent, fibroblasts express iNOS. Wound closure in iNOS-deficient mice[259] and inhibition of iNOS in normal mice[256] are delayed. These findings suggest an important role for iNOS in the regulation of epithelial movements and the reepithelialization process.

With the reestablishment of an epithelial layer, basement membrane proteins reemerge, progressing inward from the wound margin. Keratinocyte behavior returns to normal with adhesion of basal keratinocytes to the basal lamina and restoration of intercellular attachments.[251]

Formation of Granulation Tissue

At approximately 3 to 4 days following injury, a new stromal framework, known as granulation tissue, begins to enter the wound and replace the fibrin clot. Granulation tissue consists of a dermal matrix that provides a framework for cell migration, which is enhanced by new vessels migrating into the wound (i.e., angiogenesis).

Dermal Matrix

The cell that is most important in the production of the dermal matrix is the fibroblast.[266] Fibroblasts enter the wound by 2 to 3 days, and within the first week, they become the dominant cell population in the wound. As fibroblasts invade, the fibrin clot is lysed and fibronectin and hyaluronic acid are deposited, forming early granulation tissue. These molecules serve as scaffolding to which the fibroblasts can migrate and adhere.

To facilitate migration into a wound filled with cross-linked fibrin or later with a tightly woven extracellular matrix (ECM), migratory fibroblasts secrete a range of proteolytic enzymes (i.e., collagenase-1, gelatinase-A, and stromelysin-1, or MMP-1, MMP-2, and MMP-3, respectively).[267] This process occurs initially in the periphery of the clot and later more centrally as the granulation tissue grows into the wound space. At any given time, the ECM of the wound margin differs from the ECM located centrally.

The fibroblast is critical to the production of the dermal matrix producing type I and III collagens, fibronectin, elastin, and proteoglycans. Fibroblasts also contribute to growth factor production, providing connective tissue growth factor (CTGF). Connective tissue growth factor stimulates migration and proliferation of fibroblasts. Keratinocyte growth factor stimulates epidermal cell motility and proliferation. VEGF stimulates angiogenesis.[147] MCP-1, involved in neutrophil recruitment early in the inflammatory process, also attracts mast cells. The mast cells produce high levels of IL-4, which in turn stimulate proliferation of fibroblasts and decrease the expression of MCP-1 and IL-8,[268] limiting the inflammatory reaction.

NO in granulomas seems to exert an organizing influence,[269] allowing the host to assemble macrophages, directing vascular ingrowth, and compartmentalizing the inflammatory nidus.[61,270] Peak NOS activity is noted 24 hours after wounding and then declines but remains subsequently elevated for at least 14 days.[271] The macrophage is the primary cell type implicated in iNOS activity and NO production during inflammation.[272] Fibroblasts may also participate during the time coincidental with active collagen synthesis. Fibroblasts are able to produce NO linked either to endothelial NOS or, after stimulation with interferon-γ or bacterial lipopolysaccharide (LPS), to iNOS.[64,186]

When NO is inhibited experimentally, granulomas tend to become larger and have a higher bacterial load.[269] NO-deficient states (diabetes and protein-calorie malnutrition) are associated with decreased wound extracellular matrix deposition and impaired wound healing.[273,274] Excessive delivery of NO can also inhibit wound healing.[275] NO also affects wound collagen accumulation and the acquisition of wound mechanical strength. Inhibition of wound NO synthesis is accompanied by a lowered wound-breaking strength and decreased collagen deposition.[188,259,275] NO likely mediates an antiproliferative effect on skin fibroblasts in addition to its effects on collagen synthesis.[276]

Angiogenesis

The process of angiogenesis is closely related to the formation of granulation tissue. The newly formed granulation tissue requires a vascular supply to provide for its metabolic needs. The process of angiogenesis begins at the time of injury. Cell disruption and hypoxia, hallmarks of tissue injury, are strong inducers of angiogenesis factors. Acidic fibroblast growth factor (aFGF or FGF-1) and FGF-2 are released from disrupted cells and have potent angiogenic activity.[254,277] Hypoxia stimulates macrophages and keratinocytes to produce the angiogenic growth factor VEGF.[70,242] FGF-2 may set the stage for angiogenesis during the first 3 days of wound repair, whereas VEGF may be critical for angiogenesis during granulation tissue formation from day 4 through 7.[147]

Endothelial NOS appears to contribute to granulation tissue formation by triggering endothelial migration, proliferation, and differentiation, thus participating in capillary ingrowth into the wound site during repair.[64,258] NO stimulates VEGF production and VEGF-mediated endothelial cell migration and helps redistribute microvascular blood flow.[147] Increased VEGF production also encourages vasodilation and angiogenesis. Other growth factors known to enhance angiogenesis are PDGF, heparin-binding EGF, IGF-I, and hepatocyte growth factor.[254]

Mast cells are commonly found near capillary sprouting sites, suggesting an association between mast cells and angiogenesis. Mast cells may act at sites of new vessel formation by secreting tryptase, which also functions as an angiogenesis factor.[277] Heparin, leptin, and fibronectin also enhance angiogenesis.[254]

The process of angiogenesis has been reviewed by Tonnesen and colleagues.[255] Following stimulation by growth factors and other angiogenic agents, vessels adjacent to the wound transiently (3-5 days after injury) deposit fibronectin within their walls. Endothelial cells release plasminogen activator and procollagenase, resulting in the digestion of the basement membrane by plasmin and collagenase. On the fourth day after injury, with disruption of the confining basement membrane, the endothelial cells are able to enter the ECM as capillary sprouts.[252] The fibrin and fibronectin surrounding the tips of capillary sprouts are released from the plasma rather than being derived from wound fibroblasts.

The fibrin- and fibronectin-rich provisional ECM induces capillary sprouts to express αvβ3 integrin with the most pronounced expression at the capillary tips. Appearing to have a functional role in wound angiogenesis,[240] αvβ3 allows the capillary sprouts to migrate through the basement membrane (infiltrated with fibronectin) and into the fibrin- and fibronectin-rich wound clot.

The endothelial sprouts extend, branch, and create networks, pushed by cell proliferation (stimulated by FGF and VEGF) from the rear and pulled by chemotaxis from the front. These events require an interaction among endothelial cells, angiogenesis factors, and surrounding ECM proteins. At first, the developing blood vessels are surrounded by a provisional matrix containing fibronectin and proteoglycans, but eventually a mature basement membrane is formed. Blood flow begins with the formation of capillary arcades. VEGF, FGF, and mast cell tryptase induce new sprouts to extend from these loops, further extending into the dermal matrix. With maturation of wound granulation tissue and accumulation of collagen, most of the new vessels degenerate, and the density of blood vessels declines.[260] The coverage of endothelial cells by periendothelial cells (smooth muscle cells) is necessary for vascular maturation.[242] This coverage appears to be regulated by PDGF and VEGF. The mature vessels no longer express αvβ3.[242]

Wound Contraction

During the second week of healing, fibroblasts acquire smooth muscle cell features by presenting cytoplasmic microfilament bundles.[251] These fibroblasts are called myofibroblasts. Myofibroblasts contain α-smooth muscle (αSM) actin and provide the contractile forces produced in wound granulation tissue.[278-280] During wound healing, α-smooth muscle actin is transiently expressed by fibroblasts (myofibroblasts). In a mouse model, the staining intensity of α-smooth muscle actin increased from the 6th to the 15th day of injury, decreased thereafter, and disappeared at the 30th day.[281] TGF-β1 is thought to induce expression of α-smooth muscle actin in fibroblasts.[278]

Fibronectin plays a role in wound contraction by binding to fibrin in the provisional and forming a scaffold for fibroblast and keratinocyte migration and tissue support.[282] Fibronectin binds to cell surface integrin receptors to form fibrils, allowing interaction between the cell and ECM. The fibroblasts, having already migrated into the wound, begin to interact with each other and the matrix, resulting in wound contraction.

Remodeling Phase

By the third week after an uncomplicated injury, wound closure has been completed, and local infections overcome. Collagen synthesis and degradation are in balance, and the remodeling phase begins. Myofibroblasts and vascular cells undergo apoptosis (programmed cell death) and are removed.[278] Granulation tissue is transformed into a scar. Lymphocytes constitute the most common leukocyte subset in human skin wounds during this phase,[252] but it is unknown whether lymphocytes are associated intimately with tissue remodeling. Tissue collagenases (MMPs) degrade and digest the excess collagen fibers. Other enzymes (hyaluronidase, bacterial collagenase, and lysosomal proteases) also function to remodel granulation tissue. A more ordered pattern of collagen arrangement is achieved under the influence of local mechanical forces.

The wound gradually gains in strength, ultimately attaining 80% of the tensile strength of normal skin.[248] Type III collagen, synthesized early in the repair process, is replaced by type I collagen until the normal skin ratio of 4:1 (type I to III collagen) is realized.[283]

CHAPTER EIGHTY

Free Tissue Transfer

Douglas A. Girod

Terance T. Tsue

Yelizaveta Shnayder

Key Points

- Free tissue transfer involves autotransplantation of skin, soft tissue, muscle, or bone isolated on a supporting vascular supply. Although more than 40 donor sites for free tissue transfer have been described, forearm, fibula, rectus, and jejunum flaps account for 92% of all the free flaps used for head and neck reconstruction.
- A multidisciplinary team approach, especially for patients with head and neck cancer, is necessary to maximize both the oncologic and reconstructive efforts. Some situations in which free tissue transfer has become the standard of care include: oromandibular defects, especially those involving the anterior mandible, circumferential pharyngoesophageal defects, and salvage surgical resections of recurrent/persistent head and neck carcinomas following organ preservation chemotherapy or radiotherapy.
- Aspirin, heparin, and dextran have all been extensively used in the management of patients undergoing microvascular surgery. Many microvascular surgeons use some form of postoperative antithrombotic therapy on a routine basis, despite a paucity of prospective clinical trial data to guide it.
- Most ischemic complications in free flap anastomoses occur within the first 48 to 72 hours. After approximately 12 hours of ischemia, even with reestablishment of anastomotic flow, the free flap is usually not salvageable.
- Systemic medical complications are common in patients with head and neck cancer and should be recognized and treated aggressively. Local complications, such as hematoma, salivary fistula, and infections, are especially common in previously irradiated patients and may lead to late flap compromise.
- In addition to expertise, free flap reconstruction requires significant health care resources, including time, equipment, and personnel. However, the actual costs of microvascular reconstruction are either equivalent to or even lower than the costs of pedicled flap reconstruction, owing to the shorter length of hospitalization for patients receiving free flaps.

The expansion of knowledge, expertise, and training in the techniques of free tissue transfer since the early 1970s has redefined the standard of care in head and neck reconstructive surgery. *Free tissue transfer* refers to the isolation of tissues (fascia, skin, fat, muscle, nerve, and bone—individually or in combination) on a supporting vascular supply with transfer to a new location in the body, with the use of microvascular surgical techniques to revascularize the tissues in a permanent fashion. This autotransplantation of tissues relies entirely on the anastomosis of the feeding artery and draining vein to blood vessels in the head and neck for tissue survival. Upon revascularization, the transferred tissues can then be utilized to reconstruct various complex defects of the head and neck from any cause. Since the first reports of free tissue transfer for reconstruction in the head and neck in the early 1970s, the technique has gained widespread acceptance and growing availability. Advances in the understanding of surgical anatomy, operative microscopes, instrumentation, microsuture manufacture technology, and formalized training opportunities as well as unparalleled success rates have been largely responsible for this rapid growth. Because of the additional required training (e.g., microvascular reconstructive surgery fellowships) and resources, the majority of these complex procedures have been completed in larger, academic medical centers.

A multidisciplinary team approach, especially for patients with neoplastic disease, is commonly employed to maximize both the oncologic and reconstructive efforts. Postoperative management is often labor intensive and requires additional team members to achieve maximal rehabilitative potential. Although significant additional training and resources are required to perform free tissue transfer for head and neck reconstruction, the diversity of available tissues for harvest allows for the replacement of "like tissue with like tissue" in most instances, with a focus on functional and cosmetic issues. Currently, more than 40 identified sites in the human body are candidates for the harvest of tissue for transfer, with new sites being added regularly.[1] It becomes the reconstructive surgeon's mandate to determine the optimal flap for free tissue transfer for each patient and the anticipated defect. The advantages of free tissue transfer in the reconstruction of these complex defects include the following:

- Immediate reconstruction at the time of tumor resection (avoiding multiple, staged procedures)
- The transfer of well-vascularized tissue into a bed that often has salivary contamination and underlying tissue damage from earlier radiotherapy

- Significantly improved wound healing
- Immediate separation of critical compartments, including the aerodigestive tract and intracranial contents
- Improved ability to manage massive defects that might otherwise preclude surgical resection of tumors
- Better prospects for functional and cosmetic rehabilitation

Specific circumstances exist in which reconstruction using free tissue transfer has become the standard of care in most communities. These include oromandibular composite defects (particularly defects involving the anterior mandibular arch),[2,3] subtotal or total pharyngoesophageal defects,[4,5] and defects resulting from resection of recurrent carcinoma failing organ preservation nonsurgical therapy (combined chemotherapy and radiation therapy).[6] These situations have traditionally been the most challenging in head and neck reconstructive surgery and have been associated with high complication and failure rates. The introduction of free tissue transfer for reconstruction of these defects has dramatically improved the overall course for these difficult patients.

In this chapter we review the indications, patient selection, and preparation for free tissue transfer as well as the dominant "free flaps" in use today for head and neck reconstruction. We also discuss perioperative issues, management of complications, and future directions.

Historical Perspectives

The first clinical application of free tissue transfer was a 1959 case report by Seidenberg and colleagues,[7] as a transfer of a free jejunal segment for cervical esophageal reconstruction. In 1961, Hiebert and Cummings[8] transferred and revascularized a portion of the gastric antrum for pharyngoesophageal reconstruction. Other reports of the clinical application of free tissue transfer techniques began to appear in the literature in the early 1960s. The first reports of oral cavity reconstruction were made in the early 1970s by Kaplan and associates,[10] who utilized a free groin flap, and Harii and coworkers,[9] who described the microvascular distant transfer of a deltopectoral flap. Panje and associates[11] at the University of Iowa are credited with being the first otolaryngologists to report the use of free tissue transfer for the reconstruction of the oral cavity, in 1976. Subsequent years saw rapid implementation of free tissue transfer in head and neck reconstruction by both plastic surgeons and otolaryngologists. Pioneers such as Panje, Urken, Hayden, and Sullivan worked to establish head and neck microvascular reconstructive surgery as an important part of the specialty of Otolaryngology—Head and Neck Surgery.

With the recognition of the endless possibilities afforded by free tissue transfer came the progressive study and identification of vascular supply patterns and territories that could be potential donor sites. Vascular injection studies identified axial vessels and the presence of perforating vessels passing through muscles to supply the overlying subcutaneous tissues and skin. Identification of axial vessels supplying fasciocutaneous tissues without muscular perforators followed.

Taylor and associates[12] reported the first vascularized bone graft using a fibula for reconstruction of long bone injuries in 1975, and Hidalgo[13] adapted the osteocutaneous fibula flap for mandibular reconstruction in 1989. Dye-injection studies proved a reliable vascular supply to the ilium from the deep circumflex iliac artery for vascularized bone transfer.[14,15] Cadaver dissections identified the vascular branch of the circumflex scapular artery to scapula, allowing vascularized scapula transfer.[16] Throughout the 1980s, there was a progressive development and refinement of these and other vascularized bone flaps for oromandibular reconstruction, significantly expanding the availability of this technique.

Indications for Free Tissue Transfer

Free tissue transfer is just one of many options available to the reconstructive surgeon. Well-established methods of primary closure, skin grafting, local flaps, and pedicled fasciocutaneous or musculocutaneous flaps all remain viable and necessary tools in the surgeon's armamentarium. The indications for free tissue transfer continue to evolve with experience and as additional donor site options have emerged. The etiologies of defects that may require free tissue transfer are listed in Box 80-1. The advantages of free tissue transfer over less sophisticated techniques have likewise become more apparent with greater experience; they are listed, along with the method's disadvantages, in Box 80-2. The tremendous versatility offered by multiple potential donor sites can test the surgeons' imagination for new reconstructive methods. The result has been a progressive evolution of new ways to tackle old problems. Certainly, the driving force behind the expansion of free tissue transfer has been the potential for dramatically improved functional outcomes and a remarkable success rate in the head and neck of more than 90%.[17-19] For some situations, such as reconstruction of the oral cavity, free tissue transfer offers a significant improvement from a functional and cosmetic standpoint over previously available techniques, particularly for composite defects. In other situations for which no reconstructive options had been available, such as large skull base and scalp defects, free tissue transfer offers excellent reconstructive possibilities. Clinical situations commonly requiring free tissue transfer for reconstruction in the head and neck are listed in Box 80-3.

As with any new surgical procedure or technique, a significant learning curve exists.[20] As a result, these procedures have been available primarily in major academic medical centers, and multiple fellowship training programs have been developed to safely convey the necessary

Box 80-1

Etiology of Head and Neck Defects

Neoplasia
Trauma
Congenital defects
Infection, osteoradionecrosis
Secondary reconstructions

Box 80-2

Free Tissue Transfer in Head and Neck Reconstruction

Advantages

Versatility in tissue (skin, muscle, bone, nerves)
Versatility in orientation (no limitations on flap "reach" as with pedicled flaps)
Restoration of shape, function, and sensation
Single operation for complex reconstructions
Multiple potential donor sites available
Simultaneous resection and flap harvest possible
Donor sites out of field of prior treatment
Extensive amounts of tissue available for large or massive defects
Postoperative irradiation tolerance
Independent blood supply for compromised tissue beds
Improved function and cosmesis
Dental rehabilitation possible
High success rates (>90%), including for bony reconstruction
Only available option for some patients

Disadvantages

Increased technical difficulty (additional training required)
Two surgical teams required (surgeons and nurses)
Expensive instrumentation
Longer operation times
More intensive postoperative management
Donor site morbidity

knowledge and experience through advanced training. From a medical center perspective, a high level of investment in personnel and equipment is necessary. Anesthesia support is critical, and additional training and experience for dedicated microsurgical operating room nurses are advised as well. The postoperative management of patients undergoing free tissue transfer is certainly more complex, and the demands on personnel are more intensive, in comparison with those for most patients undergoing head and neck surgery. The overall cost of free tissue transfer has been examined and compared with the cost of more conventional (pedicled flap) techniques. The higher operative costs for free tissue transfer resulting from longer operating room times and instrumentation are offset by the significantly shorter lengths of hospitalization. The resulting overall cost of free tissue transfer is either comparable to[21] or less than[22] the cost of pedicled flap reconstruction.

Box 80-3

Defects or Situations Commonly Requiring Free Tissue Transfer

- Composite defects of the oral cavity
- Three-layer (through-and-through) defects of the oral cavity
- Total or near-total pharyngoesophageal defects
- Extensive skull base defects
- Extensive scalp defects
- Massive defects not readily addressed with other techniques
- Lack of other reconstructive options (failures or patient limitations)
- Salvage surgery for chemoradiation failures

Donor Site Options

Although more than 40 donor sites for free tissue transfer have been described,[1] only a handful have been found to be consistently useful in the routine reconstruction of head and neck defects. The dominant free tissue transfer flaps in use today are shown in Table 80-1. In fact, we have found that the radial forearm fasciocutaneous, radial forearm osteocutaneous, and fibula osteocutaneous free flaps are utilized in more than 80% of cases of head and neck reconstruction. Disa and colleagues[23] reported that forearm, fibula, rectus, and jejunum flaps accounted for 92% of free flaps they used for head and neck reconstruction.[23] This distribution will certainly vary according to the makeup of the surgeon's practice as well as the surgeon's preferences and experiences. Nonetheless, it is important for the reconstructive surgeon to be

Table 80-1

Free Tissue Transfer Flaps Commonly Used in Head and Neck Reconstruction

Flap	Artery	Vein	Nerve	Reconstruction Uses
Fasciocutaneous Flaps				
Radial forearm	Radial	Venae comitantes or cephalic vein	Medial and lateral antebrachial cutaneous	Oral cavity, tongue, palate, nose, face, scalp, lip, pharynx, larynx
Ulnar forearm	Ulnar	Venae comitantes or cephalic vein	Medial and lateral antebrachial cutaneous	Oral cavity, tongue, palate, nose, face, scalp, lip, pharynx, larynx, cervical esophagus
Lateral arm	Posterior radial collateral	Posterior radial collateral	Posterior cutaneous nerve of the forearm	Oral cavity, tongue, palate, pharynx
Lateral thigh	Deep femoral	Venae comitantes	Lateral femoral cutaneous	Oral cavity, tongue, palate, pharynx
Anterolateral thigh	Descending branch, lateral circumflex femoral	Venae comitantes	Lateral femoral cutaneous	Oral cavity, tongue, palate, pharynx, larynx, cervical esophagus
Scapular-parascapular	Subscapular	Subscapular	None	Oral cavity, tongue, palate, pharynx, face, lip
Muscle or Myocutaneous Flaps				
Rectus abdominis	Deep inferior epigastric	Deep inferior epigastric	Intercostals (mixed motor and sensory)	Skull base, total glossectomy
Latissimus	Subscapular	Subscapular	Thoracodorsal	Skull base, scalp
Osteocutaneous Flaps				
Fibula	Peroneal	Peroneal	Lateral sural cutaneous	Mandible reconstruction
Radius	Radial	Venae comitantes or cephalic vein	Medial or lateral antebrachial cutaneous	Mandible and midface
Scapula	Subscapular	Subscapular	None	Mandible and midface
Iliac crest	Deep circumflex iliac	Deep circumflex iliac	None	Mandible and midface
Other Flaps				
Jejunum	Superior mesenteric branch	Superior mesenteric branch	None	Pharyngoesophageal reconstruction
Omentum	Gastroepiploic	Gastroepiploic	None	Scalp coverage
Temporal-parietal	Superficial temporal	Superficial temporal	None	Bone and cartilage coverage

Box 80-4

Important Considerations Influencing Flap Selection

Skin and soft tissue volume, bulk, and color
Pedicle length and vessel caliber
Innervation capacity (sensory-motor)
Bone quality, quantity, and availability
Donor site location to allow concurrent resection and harvest
Donor site morbidity (dysfunction, cosmetic deformity)

familiar with a full array of flaps to manage the more difficult or unusual situations. Although several flap options are available for most defects, the surgeon must choose one on the basis of critical characteristics such as those listed in Box 80-4. Additionally, a thorough donor site evaluation and assessment of long-term donor site morbidity must be considered. A complete discussion of each of these flaps is beyond the scope of this chapter; however, some general comments are warranted.

Soft Tissue Flaps

For many cutaneous, mucosal, and soft tissue defects in the head and neck, the radial forearm fasciocutaneous free flap has proved to be the most versatile and reliable. Forearm skin is available in large quantities, is thin and pliable, and has excellent sensory capability that is ideal for oral cavity reconstruction (Fig. 80-1). The vascular pedicle (1) is long, (2) has a favorable vessel caliber, (3) can easily be harvested concurrently, and (4) exhibits acceptable functional morbidity at the donor site. However, as many as 12% of people have an incomplete superficial palmar arch and poor communication between the deep and superficial arches, precluding the safe harvest of the radial artery without causing hand ischemia.

The lateral arm flap is similarly thin and pliable with sensory capability but is limited in skin quantity, has a much shorter pedicle, and has vessels of small caliber.[24-29] There is no risk of vascular compromise to the hand, and the donor site can usually be closed primarily. The scapular and parascapular fasciocutaneous flaps produce the largest volume of skin but are quite bulky, have no sensory capability, and have intermediate pedicle length with large vessel caliber.[30-34] Although the donor site may be closed primarily, the donor site location (back) for these two flaps requires intraoperative patient repositioning, which precludes simultaneous resection and harvest.

In order to maximize color match, eliminate tissue bulk, and streamline the process of simultaneous flap harvest, other donor site choices, such as the anterolateral thigh flap, have been popularized.[35] The anterolateral thigh flap, based on the perforators from the descending branch of the lateral circumflex femoral artery, has been used extensively, mostly in Japanese and Taiwanese centers, as a flap of choice for defects requiring more soft tissue bulk than a radial forearm free flap can provide (see Table 80-1). Peripheral vascular disease is not a contraindication to the use of the anterolateral thigh flap, because the profundus femoris arterial system is not usually affected by atherosclerotic changes. A pedicle length up to 14 cm could be obtained by ligation of the transverse branch of the lateral circumflex femoral artery and the branch to the rectus femoris muscle. This may allow access to the neck vessels contralateral to the defect, if the ipsilateral neck has no suitable vessels. A skin paddle as wide as 12 cm may be harvested, while still allowing primary closure of the donor site. Overall, this flap may allow harvesting of a skin surface area up to 25 cm wide and up to 40 cm long as a single paddle or as multiple skin paddles.[36]

The two main reasons that the anterolateral thigh flap has been slow in gaining popularity in the United States are the thickness of the subcutaneous tissue of the thigh in the Western population and the highly variable vascular anatomy of the flap. However, the negligible donor site morbidity, primary closure of the donor site, and significant experience gained by microvascular surgeons in harvesting and thinning the flap have led to popularization of the anterolateral thigh flap in many U.S. centers.[35-39] Some writers describe using a handheld Doppler probe to identify perforators preoperatively, before designing the skin paddle.[37]

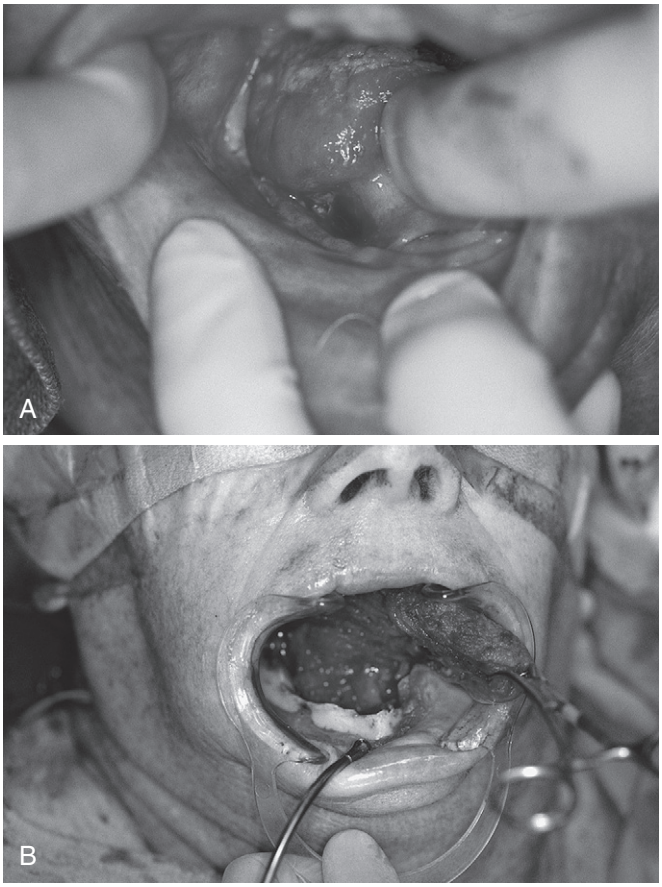

Figure 80-1. Fasciocutaneous radial forearm free flap for oral cavity reconstruction. **A,** Carcinoma involving the anterior floor of the mouth and ventral oral tongue. **B,** Extensive soft tissue defect after resection of the carcinoma.

Muscle and Myocutaneous Flaps

Muscle and myocutaneous flaps have found a niche in the reconstruction of very large defects that require significant bulk. The most common of these defects are found at the skull base, where large portions of the facial skeleton, paranasal sinuses, facial skin, and palate may be missing. The rectus abdominis flap may be harvested as a muscle or myocutaneous flap with the patient in a supine position, a long vascularized pedicle of large caliber vessels providing adequate reach to the defect site in most instances.[40-44] The skin of the rectus myocutaneous flap is useful for lining the nasal and oral cavities of the defect, and the muscle provides the needed bulk to replace the missing facial skeleton. Donor site morbidity is minimal, although abdominal hernias may occur as a result of a weakening of the abdominal wall due to the partial harvest of the anterior rectus sheath.

The latissimus flap may be harvested as a muscle or myocutaneous flap based on the subscapular vascular system.[45,46] Originally described as a pedicled flap, the latissimus flap has been found to be much more versatile as a single-stage, free tissue transfer. The large amount of muscle available for harvest is very useful for very large soft tissue defects, including the skull base and scalp. The subscapular system has additional versatility, with the option for vascularized bone (scapula bone or rib). The vascular pedicle has large vessel caliber and a length of 6 to 10 cm, and the donor site is repaired primarily without the need for a skin graft. The major disadvantage of the latissimus flap is patient positioning for harvest. As for scapula flaps, the patient must be placed in the lateral decubitus position, making harvest concurrent with the

head and neck procedure difficult or impossible. The donor site morbidity from the loss of latissimus function is well tolerated in most people. The latissimus flap has been most useful in skull base defects and larger scalp defects requiring cranial coverage (Fig. 80-2).[43,47,48]

Vascularized Bone Flaps

One of the primary indications for free tissue transfer is for the reconstruction of oromandibular defects. In this setting, no other reconstructive option offers a single-stage procedure with a greater than 90% success rate. The choices for vascularized bone flaps also dictate the need for careful evaluation and selection. Most bone reconstructions also require some soft tissue and/or mucosal reconstruction. The anticipation of the length of bone required, plans for future dental implantation, soft tissue and innervation requirements, and donor site suitability and morbidity must all be considered.

Osteocutaneous Fibula Flap

The osteocutaneous fibula free flap has become the mainstay for mandibular reconstruction at most institutions (Fig. 80-3).[49-51] The fibula is touted as "the most donateable bone in the body," with up to 25 cm of bone available for harvest and adequate bone stock to support dental implantation.[52,53] With such lengths of bone available, the entire mandible may be reconstructed with vascularized bone if required. Multiple osteotomies may be performed to shape the fibula to reconstruct the anterior arch, body, angle, or ramus of the mandible, as long as the fibular periosteum is not disrupted. The septocutaneous or musculocutaneous perforating vessels of the lower leg can be quite variable in location and quantity, affecting the placement and reliability of the skin paddle.[54-56] The skin of the lower lateral leg is thin and pliable, with fairly large amounts of skin available, and may be transferred in a sensate fashion. With smaller skin paddles, the donor defect may be closed primarily. With larger defects, a split-thickness skin graft is utilized. The fibula flap harvest can easily be performed simultaneously with the head and neck procedure.

Confirmation of three-vessel flow to the distal lower extremity should be determined preoperatively to avoid vascular compromise of the foot after harvest of the peroneal artery.[57,58] The primary disadvantage of the fibula flap is the limitations of the skin paddle. The skin is inadequate for larger soft tissue defects and most three-layer defects, requiring a second flap for soft tissue repair. The somewhat unreliable nature of the presence and location of the cutaneous perforator vascular supply can usually be minimized by inclusion of a cuff of soleus

Figure 80-2. muscle with the flap, to include musculocutaneous perforators. If dental implants are not planned, use of the fibula bone results in a very broad and rounded neomandible, which is quite difficult to fit for a tissue-borne prosthesis. The donor site morbidity of the fibula flap involves prolonged pain on ambulation for some patients.[59-63]

Osteocutaneous Radial Forearm Flap

The radial forearm free flap (RFFF) has also been described as an osteocutaneous radial forearm free flap (OCRFFF), with harvest of a portion of the radius bone based on perforators in the intermuscular septum passing to the periosteum.[64-66] This addition significantly broadened the applicability of the already widely used forearm flap in reconstructive surgery. Although the OCRFFF is seemingly the best of options, with tremendous soft tissue characteristics and an option for bone harvest, its widespread acceptance has been limited by concerns about the bone quality and possible pathologic fracture of the radius bone postoperatively.

The length of radius bone that can be safely harvested without unacceptable forearm dysfunction is limited to 10 to 12 cm (Fig. 80-4). To avoid pathologic fracture, most surgeons recommend that the thickness of the bone harvested be limited to 40% of the circumference of the radius.[67,68] This thickness generally does not provide adequate bone stock to support endosseous dental implants.[52,53] When a segment of bone is removed from the radius, the bone is significantly weakened, especially to torsional forces; the weakening previously resulted in a postoperative pathologic radius fracture rate of up to 66%, with an average of 23%.[68-71] The prophylactic internal fixation of the radius bone after OCRFFF harvest has been shown to successfully eliminate this risk (Fig. 80-5).[72,73]

Despite the limitations of bone availability with the OCRFFF, it has been used successfully for oromandibular reconstruction, with fewer complications than those associated with the fasciocutaneous RFFF with plate reconstruction.[68,74-76] For limited mandibular defects, the radius bone is quite adequate and can easily bear a tissue-borne prosthesis (denture). This characteristic has proved beneficial, because many patients do not have the financial means for dental implantation, which is frequently not covered by many third-party payers. In this setting, the radius bone provides a better contour for the support of a tissue-borne prosthesis than either the fibula or scapula bone.

Reconstruction of maxillofacial defects is a challenging problem, owing to the complex three-dimensional, esthetic, and functional roles of the midfacial structures. Cordeiro and Santamaria[77] presented a classification of maxillofacial defects and suggested an algorithm for their reconstruction. The combination of a large skin paddle to line the palatal mucosal surface, small volume of the soft tissue, and moderate vascularized bone stock are the requirements fulfilled very well by a reconstruction with OCRFFF. The radial forearm free flap is ideal to solve one of the most problematic aspects of choosing the flap for a midfacial reconstruction: a need for a long (10-13 cm) pedicle to span the distance between the midface and cervical vessels. Using an OCRFFF eliminates the need for vein grafts, shortening operative time and improving the success of the reconstruction. Chepeha and colleagues[78] expanded the use of the OCRFFF for maxillectomy defects with infraorbital rim involvement in ten patients. They advocate the choice of OCRFFF for total maxillectomy defects, with or without the orbital exenteration, that involve less than 40% of the orbital floor. Rather than using the vascularized bone to reconstruct the malar alve-

Figure 80-4. olar ridge, these researchers employed osteotomized radial bone to recontour the infraorbital rim and to provide support for the orbital contents when preserved. Dental rehabilitation was achieved through the use of palatal obturator and dentures.[78]

Osteocutaneous Scapula Free Flap

The osteocutaneous scapula free flap remains one of the most versatile flaps available for harvest in the human body.[30-32,34,79,80] The subscapular arterial system offers tremendous amounts of skin as well as the latissimus dorsi and serratus anterior muscles and scapular bone for harvest, all supplied by one major vascular pedicle, which is favorable in both length and caliber. Each of these different tissue components has a separate vascular branching supply, allowing for almost limitless degrees of orientation in relation to one another and to the recipient bed. The skin of the upper lateral back is usually quite thick, with considerable subcutaneous fat, resulting in significant soft tissue bulk, which can be advantageous in some reconstructive situations. This bulk reliably remains on a long-term basis, without atrophy. The skin can also be separated into scapular and parascapular skin paddles based on the transverse and descending branches of the circumflex scapular artery, respectively.[31,32,34] Inclusion of the dorsal cutaneous rami of the T1 or T2 spinal nerves into the flap, which may allow for sensate transfer of scapular cutaneous paddles, has been described.[81] A total of 10 to 14 cm of bone is available for harvest from the lateral border of the scapula, supplied by the periosteal branch of the circumflex scapular artery. The separation of the bony and fasciocutaneous components of the flap resulting from unique vascular supplies can be as much as 4 cm, allowing for significant versatility in hard and soft tissue orientation during reconstruction. Osteotomies may be safely performed for mandibular contouring, as long as the periosteum is preserved. The harvested scapular bone has a thick border along its free edge but transitions quickly to thin (1 to 2 cm) bone medial to the edge. The resulting limited bone stock may not be adequate for the support of endosteal dental implants.[52,53]

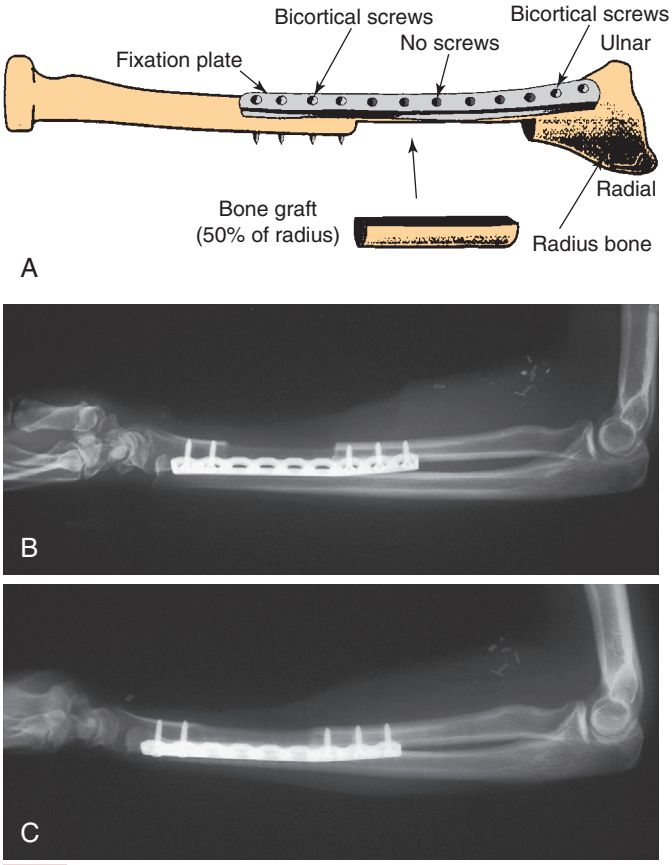

Figure 80-5. Prophylactic fixation of the radius bone after bone graft harvest. **A,** Diagram showing the harvest of the bone graft and placement of a plate spanning the defect. **B,** Postoperative radiograph of the forearm demonstrating plate fixation. **C,** One-year follow-up radiograph showing significant bone formation and remodeling in the area of the defect.

The scapular osteocutaneous flap remains an optimal choice for the reconstruction of the oromandibular complex when the surgeon is faced with large complex defects, especially those involving a large surface area, or with three-layer composite defects involving both the oral cavity and external soft tissues (Fig. 80-6).

For extremely large defects, some surgeons have employed the scapular "mega-flap," which includes not only the scapular bone and extensive skin as described earlier but also the latissimus dorsi muscle or the serratus anterior muscle for additional bulk and coverage.[82,83] The muscles are based on the thoracodorsal artery and vein that branch off the subscapular vessels, and therefore can be harvested on the same vascular pedicle, requiring only one arterial anastomosis and one venous anastomosis. The mega-flap offers significant mobilization of the various tissue components relative to one another as a result of the branching vascular supply, providing great reconstructive versatility for the largest of defects.

The major disadvantages of the scapula flap include the bulky and insensate nature of the skin paddles and the necessity to reposition the patient several times during the operation, which adds significant time to the procedure. Long-term shoulder dysfunction can result from the harvest of the scapular osteocutaneous flap, with winging of the scapula, decreased range of motion, and chronic pain. These problems can usually be minimized with careful technique and aggressive physical therapy.

Iliac Crest Flap

The iliac crest has long been a source of free bone grafts for mandibular reconstruction. A vascularized iliac crest flap harvested off the deep circumflex iliac artery may provide 14 to 16 cm of bone, which has a natural curvature for mandibular reconstruction. Studies have found that, of the available osteocutaneous flaps, the iliac crest provides the highest quality bone for the support of osseointegration for dental implantation.[52,53]

The cutaneous portion of the flap is both bulky and limited in mobility, restricting its usefulness for large composite defects. Urken and colleagues[84-87] described the addition of the internal oblique muscle based on the ascending branch of the deep circumflex iliac artery for mandibular reconstruction, which significantly increased the versatility of the flap and provided excellent results.[84-87]

Despite the high quality of the iliac bone for mandibular reconstruction, the soft tissue limitations, overall bulk, and donor site morbidity have limited the popularity of the iliac crest flap. Most surgeons utilize this flap when the other options are precluded because of peripheral vascular disease, earlier surgery or trauma, or other factors.

Dental Rehabilitation

Significant dental rehabilitation of the oral cavity after composite resection for malignancy can be achieved only with microvascular free tissue transfer of bone and soft tissue (Fig. 80-7). The placement of enosseous dental implants into the replaced bone allows for the optimal rehabilitative outcome that approaches function in the patient with normal dentition.[84,88] Appropriate contouring of the reconstructed oral cavity may allow the fitting of tissue-borne dentures. Although this reconstruction is generally cosmetically acceptable for most patients, the diet remains significantly affected.

Other Flaps

Unique situations that require the employment of less frequently utilized flaps often arise. Pharyngoesophageal defects have long presented one of the more challenging reconstructions in head and neck surgery. This is reflected by the first reported free tissue transfer in the head and neck, described by Seidenberg and colleagues[7] in 1959 as a transfer of a free jejunal segment for cervical esophageal reconstruction. The jejunal flap may be harvested off a segmental arcade of the superior mesenteric artery, for free transfer to the head and neck. As a mucus-producing tubular structure of similar size, the jejunum seems a natural replacement for the cervical esophagus. On transfer, the jejunum retains some intrinsic contractile motility, which is beneficial for swallowing (and detrimental if the jejunum is inverted on the inset or placement into the defect) (Fig. 80-8).[89-92] Through the years, experience has found the jejunum to be a fairly fragile flap that does not tolerate episodes of ischemia. The donor site morbidity of a bowel resection can be considerable. The reconstructed pharynx can successfully undergo tracheoesophageal puncture[89,93]; however, this maneuver often results in a very "wet" vocal quality. As a result, most surgeons now routinely use a radial forearm fasciocutaneous free flap, which is "tubed" to recreate the cervical esophagus (Fig. 80-9). This flap results in less donor site morbidity, provides a very functional adynamic "funnel" into the thoracic esophagus, and produces a better tracheoesophageal puncture vocal quality.[94]

Patient Evaluation and Preparation

Despite technologic advances and new options in head and neck microvascular reconstruction, the best treatment plan still depends initially on general patient factors. Multiple factors, other than the stage of cancer or surgical defect (i.e., comorbid conditions, overall performance status, occupational and recreational activities, and personal preferences) also play significant roles not only in establishing whether a patient is a safe, suitable candidate for free tissue transfer but also in dictating the possible free flap donor sites available. The reconstructive surgeon, in consultation with the patient's other health care providers, needs to expeditiously address issues such as airway status, nutritional status, and uncontrolled medical conditions. Treatment of acute issues can occur in parallel with the reconstructive surgeon's careful evaluation and often requires the input of multiple medical disciplines.

History and Current Illness

An extensive history of symptoms gathered by the reconstructive surgeon not only helps determine the size and character of the anticipated extirpative defect that needs reconstruction but also can yield

Figure 80-6. hints about the possibility of a synchronous primary or metastatic disease. Complaints of unilateral conductive hearing loss, hyponasal speech, breathy voice, ptosis, diplopia, trismus, chin numbness, otalgia, and contralateral symptoms are frequently indicators of deep or extensive disease beyond that immediately apparent.

The extent of premorbid and current oral cavity function is important. The reconstructive functional result, in terms of deglutition, taste, mastication, voice, breathing, and cosmesis, generally cannot be improved beyond the premorbid state. In patients with compromised premorbid function due to neurologic disability or earlier treatments, preoperative counseling about the potential reconstructive outcome is even more crucial to providing realistic expectations.

Unfortunately, smoking and chewing tobacco are prevalent among patients with head and neck cancer. Beyond its ill effects on anesthesia and cardiopulmonary function, nicotine also has adverse vasoconstrictive effects that can compromise flap perfusion and wound healing.[95,96] A history of regular alcohol use requires aggressive perioperative withdrawal prophylaxis and nutritional supplementation. Acute withdrawal after surgery is associated with a higher rate of complications and flap loss.[97,98]

A history of previous radical neck dissections may limit the current reconstructive options at both recipient and donor sites. Careful review of old surgical reports, review of current radiographs, and discussions with previous surgeons is often necessary to supplement the patient's memory. Similarly, extensive radiotherapy can compromise recipient site vascularity and healing and cause premature vascular wall changes, but may or may not affect free flap viability.[99-101] Post-irradiation hypothyroidism should be detected and reversed to help maximize postoperative recovery and healing. Both previous surgery and prior radiotherapy can cause extensive fibrosis in the surgical bed, making safe isolation of needed recipient vessels and nerves very difficult, if not impossible.

Donor site–specific history must also be obtained. A patient's hand and foot dominances, occupation, hobbies, and recreational activities can dictate the side or site of a free flap harvest. Previous abdominal and pelvic surgery can obviate the use of some potential free flap vascular pedicles (i.e., rectus abdominis, iliac crest). Claudication or extremity rest pain is indicative of significant peripheral vascular disease and warrants aggressive assessment of extremity vascular pedicle adequacy. History of previous surgery or trauma to the donor site prompts in-depth evaluation of the donor site anatomy.

Physical Examination

The microvascular surgeon should also perform a complete head and neck examination. Direct visualization of the neoplasm or traumatic defect, along with bimanual palpation, should complement the tumor mapping anticipated by the symptom history. This step allows a discussion with the extirpative surgeon, in terms of the anticipated surgical defect size and potential structures to be removed (mucosa, skin—with

or without bone) or exposed (brain, orbit, bone, carotid artery). A secondary survey can then focus on the anticipated fine-tuning reconstructive procedures necessary during either the primary or secondary setting, to maximize both functional and aesthetic outcome. This survey involves status and integrity of the parotid and submandibular ducts, nasal airway, lip vermilion, oral commissure, dental occlusion, maxillary sinus, soft and hard palate, eustachian tube, facial sensation, and motor nerve function. A superinfected area of cutaneous involvement should be treated with antibiotics to help delineate infected from neoplastically involved tissue; this treatment can lead to a more efficient resection and also possibly improve pain, hygiene, and healing. The extent of neck disease determines not only prognosis but also the type of neck dissection. It influences changes in neck volume, contour, and potential available recipient vessels for microvascular anastomosis. Previous facial and neck incisions and traumatic scars must be recognized, because they will limit placement of future incisions.

Microvascular free tissue transfer has been used with success in the elderly. Chronologic age itself does not seem to contraindicate surgery, although the incidence of medical complications is higher after treatment.[18,102,103] Mental impairment, such as dementia or mental illness, is a very difficult situation to control in the debilitated postoperative patient. Serious consideration should be given to more tolerant alternative reconstructive techniques if surgery is still considered an option in a mentally impaired patient. Morbid obesity not only may influence perioperative recovery and healing but also may require alteration in available useful donor sites because of flap thickness and bulk.[104] Morbidly obese patients may also have undetected significant obstructive sleep apnea, which heavily influences perioperative airway management and can also be seriously exacerbated postoperatively by large, bulky, and swollen reconstructions. Potential airway compromise due to the bulky or edematous flap should be anticipated and should be prevented by the intraoperative tracheotomy.

Examination of the potential free flap donor site for scars, asymmetries, or bony deformities can often prompt a patient's memory of an old injury or operation. Objective evaluation of the mobility, strength, and function of an extremity should confirm the patient's history. Preoperative disabilities, from previous strokes, spinal injury, or trauma, may either prompt or discourage the use of certain free flap donor sites. Nonhealing sores, cold digits, loss of sensation, as well as significant distal extremity swelling are also indicators of inadequate vascularity and commonly contraindicate the use of the involved extremity as a donor site. Palpation of distal extremity pulses (i.e., radial, ulnar, dorsalis pedis, and posterior tibial arteries) as well as the performance of subjective Allen's tests and determination of the ankle-

arm index can be reassuring, but adequacy determinations should be supplemented by formal vascular assessments in equivocal cases.[105-107]

Past Medical History

In all patients, special attention should be paid to optimization of any known medical conditions. Certain comorbid conditions can also affect free tissue transfer specifically, although absolutely contraindicating conditions are uncommon.[108] Certain extremity vessels are known for a tendency toward advanced atherosclerotic disease in patients with peripheral vascular disease. Radial and peroneal arteries tend to be affected frequently, but the scapular arterial system remains relatively unaffected. Poor digit perfusion can be further exacerbated by donor vessel sacrifice, yielding cold intolerance or even digit necrosis. Patients with severe extremity venous or lymphatic insufficiency should also be considered for other donor sites to prevent postoperative extremity complications. Patients with arterial vascular disease due to atherosclerosis or hypertension must also be evaluated for significant concomitant cerebrovascular and cardiovascular disease. In the patient with significant carotid disease, availability of adequate recipient external carotid artery branches may be reduced; also, intraoperative hypotension or neck extension positioning may cause perioperative strokes. Adequate cardiopulmonary reserve must be present to tolerate the often prolonged anesthesia time and intravascular fluid shifts associated with free tissue transfer operations.[109] Such comorbid disease can significantly lower the limits of resectability and reconstructability, because such procedures often require more prolonged general anesthesia and possibly even multiple trips to the operating room.

Patients who have connective tissue disorders with vasculitis are at a relatively high risk for microvascular pedicle compromise, which therefore should be a relative contraindication to microvascular reconstruction. Unfortunately, patients with well-controlled disease who have been aggressively treated with steroids or other immunosuppressive agents can experience poor healing or increased infectious complications.[110] Similarly, patients with hematologic disorders (i.e., von Willebrand's disease, hemophilia, lupus anticoagulant abnormality, thrombocytopenia, polycythemia vera, sickle cell disease, protein C deficiency) should also be strongly considered for nonmicrovascular reconstructions because of the difficulties in maintaining healthy patent anastomoses associated with prothrombotic and coagulopathy states.[111,112] Paraneoplastic hypercoagulability or extensive inadvertent preoperative use of anticoagulating medicines (i.e., aspirin, nonsteroidal anti-inflammatory drugs, vitamin E) can also compromise microvascular success. Patients who require perioperative anticoagulation because of concurrent conditions (i.e., prosthetic heart valves, deep venous thrombosis) are predisposed to compressive neck hematomas that can lead to significant blood loss, airway compromise, or flap pedicle compression.

Diabetic wounds are known to heal more slowly, so uncontrolled or previously undiagnosed diabetes should be aggressively treated. Necessary adjustments must be made in terms of incision line suturing and monitoring. The immunosuppressive effects of diabetes can lead to greater postoperative infections, which can cause delayed microvascular pedicle compromise. Untreated profound glucosuria can compound the already large changes in intravascular volume associated with these procedures. Secondary diabetic microvascular disease can cause poor fasciocutaneous paddle perfusion, yielding ischemic areas after harvest. Larger vessel disease not only can cause silent coronary artery disease that may not be detected preoperatively but can also increase both

donor and recipient vessel atherosclerosis. Poor extremity healing after harvest can lead to difficult-to-treat infections and necrosis of donor sites. Further sacrifice of extremity sensory nerves during harvest can exacerbate problems associated with diabetic peripheral neuropathy. Properly evaluated and managed diabetic patients are still suitable candidates for free tissue transfer.[113]

Laboratory and Radiologic Studies

The reconstructive surgeon should review all preoperative laboratory results and radiologic findings. Abnormalities of liver function, platelet count, blood urea nitrogen level, or prothrombin or partial thromboplastin time may lead to significant intraoperative blood loss and postoperative hematomas, with possible compressive flap loss or infection. These abnormalities must be investigated and corrected as much as possible preoperatively. Preoperative albumin, prealbumin, and leukocyte measurements can give an estimate of the level of malnourishment that can affect postoperative healing. Staging computed tomography and magnetic resonance imaging of the head and neck region complement and confirm the history, physical findings, and endoscopic evaluation by the microvascular surgeon and help to further delineate the anticipated reconstruction needs, in terms of size and structures. Magnetic resonance angiography, computed tomography angiography, Doppler ultrasonography, or conventional angiography is used in cases of potential resection for carotid artery involvement, but can also indicate the adequacy of the external carotid branches to support microvascular anastomosis.[114] Sometimes the patency of the transverse cervical arterial system for use as a recipient vessel can be determined. The integrity of potential larger recipient veins in the neck can also be detected radiographically, including predicting the need for sacrifice of the internal or external jugular venous network. Need for venous angiography is rare.

Radiographic evaluation of the determined potential free flap donor sites should help supplement the physical examination in determining safe harvest. A preoperative Allen's test is crucial for maintaining adequate hand perfusion after radial or ulnar forearm free flap harvest. In cases with an equivocal subjective Allen's test result, Doppler plethysmography can objectively document adequate collateral perfusion to the donor hand, allowing its safe use.[107] Additionally, other angiographic techniques have been used adjunctively to study donor site vasculature before harvest of extremity free flaps.[57,58,115,116] These studies can detect anatomic abnormalities, ensure adequate cutaneous flap perforator supply, and document the adequacy of distal collateral arterial flow. In patients with previous trauma or surgery, plain films can document adequate bony integrity and any compromising hardware.

Surgical Treatment Planning

After the initial workup is completed, the patient's case is presented to the institution's multidisciplinary Head and Neck Tumor Board to obtain a consensus on treatment options. Although in general, the oncologic efficacy of any therapy takes preference in the ranking of treatment options, the Tumor Board's recommendations can also be heavily influenced by the expected postoperative functional outcome, which depends somewhat on the reconstructive options available. From the preoperative clinical assessment, the microvascular surgeon can generally determine which tissue types will be required to reconstruct the anticipated surgical defect. This determination, of course, is much easier in post-traumatic defects, in which loss of further tissue is unlikely. Soft tissue considerations include volume and surface area of tissue needed, need for sensory innervation, availability of and mobility from adjoining vascularized bone graft, and other characteristics, such as motor, secretory, or peristaltic activity. The need to provide protected coverage of bone, large vessels, and brain parenchyma adds to the soft tissue volume needed. Bone considerations in choosing the appropriate free flap include length and caliber of bone required and character and mobility of associated soft tissue.

Unfortunately, there rarely is an ideal free flap that fulfills all the reconstructive requirements perfectly. In addition, the best microvascular reconstructive option may not be possible for every patient because of available expertise, previous therapy, functional or anatomic abnormality, or need for shorter anesthesia time because of medical comorbidity (shorter harvest time). A priority list should be chosen in conversations with the patient, with backup donor sites always available intraoperatively. Also, other reconstructive techniques can be used in combination with free tissue transfer, to maximize the overall reconstructive outcome. Whatever reconstructive technique is implemented, it should not hinder postoperative recovery by requiring multiple operations, possibly delaying or preventing necessary timely adjuvant therapy. Single-stage primary reconstructions are best for meeting this goal. Post-therapeutic expectations should also be discussed in detail. These conversations should include explanation of any staged or delayed procedures anticipated to yield the maximal cosmetic and functional outcome.

The planning stage is also the time to recruit and inform family and friends for the necessary physical and emotional support that complements comprehensive medical therapy. The patient's privacy concerns should, of course, be respected during this process, in accordance with his or her preferences.

Efficient postoperative recovery and early in-patient discharge involve an anticipatory and multidisciplinary approach. Therapy should begin with preoperative consultation and counseling by all involved surgical colleagues (i.e., neurosurgeon, ophthalmologist, vascular surgeon, oral surgeon) and anticipated ancillary personnel (i.e., speech pathologist, physical therapist, social worker, prosthetist). All of these experienced consultants should be familiar with the expected outcome and specific restrictions of microvascular procedures, so that the patient receives consistent information. The myriad preoperative appointments are best arranged for the patient by a patient care coordinator.

Preoperative evaluation by anesthesiologists experienced in microvascular cases is paramount. Such an evaluation ensures not only that the patient's preoperative state is maximized but also that all the necessary personnel and monitoring equipment are available at the time of surgery. An intraoperative plan can then be worked out preoperatively with the surgeon-anesthesiologist team, so that attention can be fully focused on unexpected situations.

In patients expected to undergo a prolonged period of enteral feedings—except in cases in which a gastric pull-up procedure is anticipated—preoperative percutaneous or open gastrostomy tube placement is prudent. This step helps maximize preoperative nutritional status and also removes the postoperative necessity for a nasogastric feeding tube. Postoperative tube placement can be difficult and can risk the suture lines of a free flap paddle. Transabdominal enteral routes are generally more comfortable for the patient and also decrease the incidence of sinusitis, gastroesophageal reflux, and pharyngeal swelling.[117]

Intraoperative Management

An anesthesiologist experienced in microvascular cases is essential. Even before preoperative evaluation of the patient by the anesthesiologist begins, the areas of the body that must be left available for both the extirpative and reconstructive portions of the procedure must be well communicated. Donor extremities should be visibly marked or wrapped to prevent inadvertent blood collections from or placement of intravascular catheters in potential donor vessels. The anesthesiologist should know multiple unconventional and alternate electrode and vascular access sites, in order to leave all potential donor sites available. Necessary preoperative medications, such as prophylactic antibiotics, steroids, and antacids, should be delineated and administered.[118,119] Availability of blood for transfusion should be confirmed.

In the patient undergoing head and neck surgery, airway considerations are frequently challenging. The predetermined approach to the airway is followed in the operating room, and close cooperation between the intubating anesthesiologist and the surgeon is crucial to safe airway access. Complex, lengthy, and risky intubations, including fiberoptic intubations, can be avoided by early placement of a planned tracheostomy with the patient under local anesthesia. The patient is then positioned as the anesthesiologist continues to obtain the desired adequate vascular access, because further access would be difficult once the operation is under way. Availability of lines and electrodes is necessary

during the procedure, and their routes should be planned to avoid contamination of hidden sterile donor sites by the anesthesiologist. All access and monitoring equipment must be adequately fixated to the patient, because changes in patient position are frequently necessary during the procedure. Adequate pressure point padding is confirmed by both surgeon and anesthesiologist. All remaining exposed nonsterile areas of the patient should be covered with a warmer, and unused limbs should be placed in pneumatic compression devices, even if only unilaterally.

The presence of both the extirpative and reconstructive surgeons to guide the povidone-iodine preparation of the operative sites can save a significant amount of later time and trouble. Separate draping of both recipient and donor site operative fields is necessary to prevent not only salivary contamination but also potential tumor seeding of the donor site. Draping of both alternative free and pedicled flap donor sites is also performed (i.e., pectoralis major flap). The maintenance of separate instrument sets for the recipient and donor sites on different operating room tables is necessary. Because most microvascular harvests occur concurrently with the extirpative surgery, two distinct scrub teams are often required. This practice can reduce resource utilization and overall costs.[118] Operating room personnel who are well trained and experienced, especially in microvascular instrumentation and techniques, are crucial to surgical efficiency and success.

Routine good anesthesia management applies to free tissue transfer surgery as well as to other large head and neck procedures.[120-122] Adequate blood pressure must be maintained throughout the operation to provide perfusion of both vital organs and the flap. Hypertension can lead to excess blood loss. Hypotension should be treated initially with a decrease in the inhalation agent, which can be anti-inotropic, a vasodilator, and intravenous hydration. All vasoconstrictors should be avoided, unless the situation is life-threatening, because of their intense vasospastic effect on the hypersensitive free flap pedicle.[123,124] Denervated free flaps are thought to be hypersensitive to catecholamines. Cold patient temperature, which can also cause peripheral vasoconstriction and increased afterload, should be avoided with the use of patient warmers, warm irrigation, and infused fluids.

Experienced anesthesiologists understand how judicious use of intravenous fluids is crucial to operative success. Hemodilution due to minor blood loss and intravenous hydration improves flap perfusion through blood viscosity reduction and can enhance flap ischemia tolerance.[125] Both crystalloid and colloid replacements have been advocated, with some colloids also having an antithrombotic advantage.[126] Fluid overload can cause pulmonary edema but also significant intraoperative and postoperative edema in the head and neck and the free flap. This development can impair insetting the flap or cause pedicle compression. Administration of more than 7 liters of intravenous fluid is also associated with major medical complications.[18] Appropriate hydration can generally be determined by hemodynamic parameters and urine output (0.5 mL/kg/hr), but central venous monitoring may also be necessary in the patient with a history of significant cardiac problems. Too low a hematocrit value can compromise oxygen delivery to vital organs and the flap, and the proper level varies by individual. Transfusion of packed red blood cells may be necessary but can have anticoagulation side effects. The patient should be adequately ventilated and oxygenated to assist with flap perfusion, but positive end-expiratory pressure should be avoided because of its effects on venous return.

Surgical Techniques

Surgical Incisions

Although adequate oncologic resection is paramount in the recipient site, familiarity of the ablative team with the various needs of the anticipated free flap reconstruction is also crucial. Surgical incision planning extends beyond just the purview of the oncologic surgeon. Frequently, multiple-approach options can achieve adequate access and visualization of the surgical field. The chosen surgical approach must also eventually provide sufficient visualization for adequate inset suturing of the free flap into the surgical defect. A needle holder commonly requires more maneuverable exposure than a Bovie cautery, knife, scissor, or laser. Additionally, this problem can be compounded by recipient site edema and initial flap bulk, which can be larger than the extirpated native tissue volume. These needs may require extension of the initial incision or new incisions.

Incision placement also depends on the quality of the native tissue. Previous cervicofacial incisions, traumatic incisions, skin flap elevation, prolonged steroid usage, radiation therapy, and—now more commonly—chemotherapy can all affect skin flap viability. Subplatysmal or thicker skin flap elevations are desirable but are often limited by oncologic considerations. The surgeon should attempt in all cases to use the minimum of incisions necessary for the appropriate exposure. Old incisions are the best initial choice, because the native vascularity is already compromised by them. Incisions perpendicular to or away from large vessels and the planned microvascular pedicle can decrease the exposure risk if there is incisional dehiscence. Incision breakdown often yields a poorer cosmetic result and potential exposure of large vessels, hardware, alloplast, allograft, or bone. Exposure of the microvascular pedicle can result in the rapid loss of the entire reconstruction. If it is detected intraoperatively, the options are (1) providing a vascularized muscular or fascial bed underneath the compromised skin flap area, and (2) including the devascularized area as part of the extirpative defect.

Primary Recipient Site Surgery

Throughout the operation, the extirpative and microvascular surgeons must communicate freely, and often both are working concurrently to minimize anesthesia time. Unanticipated areas of resection of tissue, tissue salvage, and areas of potential re-resection after frozen-section margin analysis should be accurately communicated to the reconstructive surgeon to allow for intraoperative adjustments. This information can affect not only the size but also the shape and orientation of the free flap cutaneous paddle. It is always helpful for the surgeon to mark transected nerve stumps that require subsequent re-anastomosis or cable grafting to innervated free flaps, because finding these areas at the end of the operation can be frustrating. Further recipient preparation includes performing as much primary closure as possible and trimming jagged wound edges to facilitate the necessary even, watertight closure.

In cases of osteocutaneous free flap reconstruction after segmental mandibulectomy, precontouring of the reconstruction plate to the buccal or labial cortex is crucial to maintaining the best postreconstruction occlusion. If there is involvement or distortion of the outer cortex of the mandible, direct plate contouring to the bone is not possible, and use of maxilla-mandibular fixation (MMF) or a mandibular fixbridge system can help maintain preoperative occlusal and joint relationships. Postresection freehand plate contouring and fixation is difficult and suboptimal. Postoperative correction of malocclusion is possible, but difficult.[127] With the currently available low-profile locking reconstruction plates, the contoured plate can closely approximate the natural mandibular projection and contour, without sacrificing durability and strength, when used in conjunction with bone grafts.[128,129] These thinner reconstruction plates are usually not visible or palpable through the external skin flap, even after some subcutaneous tissue resection. The locking plate design affords less accurate contouring of the native mandible contour, because it acts as an internal external-fixator device. Accurate measurement of bicortical screw length is paramount to minimizing readily palpable, and often bothersome, sharp lingual screw tips. The plate should be screw-fixated at the appropriate location along the native mandibular height, so that the bone graft and overlying neoalveolar soft tissue free flap paddle lie even with the remaining native occlusal surface. This fixation facilitates maintenance of the gingivobuccal, gingivolabial, and floor of mouth sulci, to help preserve tongue mobility, oral competence, and an adhesive surface area for dentures. Use of reconstruction plates to span segmental mandibular defects, without the concomitant use of vascularized bone grafts, can have a significant long-term complication rate, depending on mandibular defect location and size and the type of plate used.[130-133] The size and location of the soft tissue defect may necessitate removal of the reconstruction plate before free flap inset by the microvascular surgeon for adequate exposure to perform the paddle inset or microvascular anastomosis. Some microvascular surgeons use miniplate

fixation to attach the osteotomized vascularized bone grafts to the native mandible. Use of maxilla-mandibular fixation or a fix-bridge system is also usually required to maintain proper occlusal relationships. Some miniplate placement on these flaps can occur before pedicle sacrifice at the donor site, to reduce flap ischemia time.

Neck Recipient Site Surgery

Continuous intersurgeon communication during the extirpative neck dissection or neck vessel exploration is also important. Frequently, the range of appropriate recipient vessel size needed can be estimated from the anticipated donor site. Additionally, communication of the anticipated defect location and predicted microvascular pedicle length can guide the extirpative surgeon to save potential recipient vessels in a given area of the neck and allow faster dissection in nonessential areas. Gentle vessel dissection and preservation of lengthy stumps are important for maintaining multiple microvascular anastomosis options. This issue is important, because the best pedicle geometry may not be predictable until the time of anastomosis. Although gentle dissection and stump preservation may take extra effort and time, they usually do not compromise the adequacy of oncologic resection. Saving both the external and internal jugular veins should be attempted, although anastomotic success may be better with use of the internal jugular system.[134] All potential recipient vessels should be kept moist once exposed. Any adventitial or vessel edge dissection should be avoided at this time, until the microscope is used. Similarly, anticipated resection of the proximal external carotid arterial or jugular venous systems because of neoplastic disease must be communicated to the reconstructive surgeon so that alternative recipient vessel networks and vein grafts can be prepared.[135,136] Vein grafting can compromise anastomotic patency. Partial removal of the anterior sternocleidomastoid muscle overlying the pedicle can allow improved microvascular pedicle geometry or decrease venous pedicle compression.

In cases of across-midline resections or previous ipsilateral radical neck dissections, vessels from the contralateral neck may need to be isolated and prepared. This need may prompt the extirpative surgeon to perform a full neck dissection for oncologic reasons in a case with borderline indications for such dissection. In most patients with previous neck dissections, adequate recipient site vessels are still available.[137] Extracervical recipient vessels are sometimes available but may require a longer flap pedicle.[135] Previous anastomoses from established free flaps can also be a source of recipient vessels.[138] Reverse flow through distal ends of certain recipient arteries, such as the facial and superior thyroid arteries, is also a possibility for anastomosis in necks without normally available antegrade-flow recipient arteries.[139] In reconstructions using more than one free flap concurrently, some flaps may be sewn in series (one set of recipient vessels) rather than in parallel (two sets of recipient site vessels). The fibula and radial forearm free flaps can act as flow-through flaps, and their distal pedicles may be used for additional anastomoses.

Free Flap Harvest

An experienced head and neck team can determine the approximate size of each tissue type needed from the preoperative assessment. Communication during the resection is important if these approximations underestimate the actual need. Although many distant donor sites allow harvest of the free flap by the microvascular team to be performed concurrently with the extirpative surgery, scapular-parascapular, latissimus-based flaps require patient repositioning for harvest and so are performed after the resection, significantly increasing the overall procedure time. The separate instrument table should be set up during the extirpation and kept at a distance to remain free of contamination by oral secretions and neoplastic cells.

Although tourniquets are certainly not mandatory, many harvests allow their use to minimize blood loss and potentially improve operative site visualization and harvest speed. Use of a tourniquet can hide subtle, but significant bleeders, especially along the pedicle, that should be addressed at the time of tourniquet release and reperfusion. Certainly, any tourniquet time adds to the overall ischemia time of the free flap and should be meticulously monitored. Also, a time alarm should always be set if a tourniquet is used during donor site closure, because inadvertently leaving the tourniquet up under the drapes during the remaining part of the procedure can have disastrous results.

A flap that has been inset to be hidden deep beyond transoral inspection (i.e., pharyngoesophageal and skull base reconstructions) must have an exteriorized monitoring paddle, which is harvested in continuity with the pedicle. At times fiberoptic visualization is possible, but often difficult. Perfusion of the monitoring paddle must reliably mimic that of the main flap paddle, and this issue should be confirmed before final harvest.

The free flap is harvested until it has been isolated on the intact vascular pedicle only. As soon as the arterial and venous donor vessel diameters and pedicle length are known, these facts are communicated to the extirpative surgeon. Gentle dissection along the pedicle with minimal bipolar cautery or hemoclip hemostasis away from the pedicle vessels is important to avoid damage. Monopolar cautery can cause vessel injury well beyond the visible changes. Some microvascular surgeons microscopically separate the artery from the surrounding donor venae comitantes at this point. This conservative dissection should only be long enough to allow good pedicle anastomosis geometry, in order to minimize potential vessel damage. Copious micro-irrigation with saline or heparinized lidocaine (2% lidocaine, 100 U/mL heparin) is used to keep the vessels moist during the harvest.

Once the vessels are sacrificed distally, the tourniquet is released, and the free flap is perfused for as long as possible. This step not only enables confirmation of good flap perfusion to all portions of the free flap but also confirms adequate distal perfusion to the donor extremity. It also allows hemostasis of any bleeding on the free flap. Topical papaverine irrigation (30 mg/mL) is sometimes useful to enhance vasodilation and perfusion. The free flap paddle should be manipulated at this point as much as possible while the flap remains pedicled to its native supply (e.g., tubing, shaping, shortening). Partial closure of the donor site may also be possible at this time, with the remaining closure being done during flap anastomosis or insetting. Harvesting of any necessary vein grafts is also performed before harvest. Only when the neck recipient vessels are ready are the proximal pedicle vessels sacrificed and the free flap brought to the head and neck region. Both surgeon and anesthesiologist should note the time of harvest to indicate the beginning of flap ischemia time.

Free Flap Inset and Microvascular Anastomosis

No hard and fast rule pertains to the order of flap inset versus microvascular anastomosis. Some microvascular surgeons prefer to inset the free flap completely before performing the microvascular anastomosis, to ensure good pedicle geometry and adequate pedicle length while minimizing postanastomotic manipulation. This maneuver does lengthen the potential flap ischemia time but can usually be performed well within tolerance limits of most free flaps. Some reconstructions require this maneuver initially because of the anticipated position of the pedicle, which would otherwise block safe access to perform the flap inset. Wrapping of the finished pedicle in the drill bit during bone graft inset has been described in anecdotal reports. Other surgeons perform the anastomosis first, to minimize ischemia time, maximize exposure for the performance of the anastomoses, and allow close monitoring of the flap during the remaining portion of the procedure. It is often difficult to exactly predict the amount of pedicle compression that can be attributed to flap bulk and defect swelling after flap inset. If the anastomosis is performed first, the free flap is laid in its anticipated position. Some temporary stay sutures should be placed to keep the flap from moving or falling while under the microscope.

Extensive detail of the microvascular technique is beyond the scope of this chapter and available elsewhere.[140,141] The standard microscope used for anastomoses affords 10× to 40× magnification (250 to 300 mm focal-length lens), with opposing binocular heads for simultaneous use by the surgeon and assistant. An attached camera with monitor can help the microvascular scrub nurse anticipate instrument needs. Some surgeons use loupe magnification (3.5× to 5.5×), especially in hospitals without an adequate microscope available.[142] Anastomoses of smaller vessels (less than 1.5 mm), as seen in certain free flaps and in children, may require even more magnification. A dedicated, experienced microvascular nurse is essential for operative efficiency and

instrument maintenance. Meticulous and gentle handling of all instruments is paramount, because the ends are easily bent and broken. Basic microvascular instrumentation consists of straight and curved forceps and scissors, a microneedle holder, vessel dilators, and atraumatic single and double microvascular clamps. Micro-irrigators filled with heparinized lidocaine are useful for irrigating thrombus from open vessel lumens. Papaverine also should be available for arterial vasospasm. Nonabsorbable monofilament nylon suture (8-0 to 10-0), with various atraumatic needle sizes, is used, depending on vessel size and thickness.

Gentle microsurgical technique and good pedicle geometry are the most important factors in performing the microvascular anastomosis. Good technique involves gentle vessel handling, maintenance of smooth vessel approximating edges, and avoidance of suture line tension. Good vessel size match allows linear flow across a straight anastomosis. Good pedicle geometry includes smooth vessel transitions and avoidance of pedicle compression with a minimum of twisting and kinking. These factors also need to be checked, when the head is returned to the neutral position, which can affect pedicle geometry and, especially, venous patency.[143] Adequate recipient arterial flow should be confirmed in the chosen vessel before anastomosis, although flap arterial flow is generally more dependent on the specific flap type.[144] Good recipient vein backflow should also be confirmed before the anastomosis but may be limited by a valve. Although the most common anastomosis is end-to-end, the end-to-side anastomosis and vein grafting techniques should also be in the microvascular surgeon's armamentarium, in order to maximize pedicle geometry. Alternative methods may also be necessary if the appropriate recipient vessel size is not available (i.e., a size mismatch > 3:1) or the pedicle length is inadequate.[145]

When using the microscope, the surgeons can either sit or stand, but they must be comfortable, with good arm support on the table. No jostling of the patient by the anesthesiologists or the concurrent donor site closure team should occur during this time, because such movements are magnified under the microscope. No hard and fast rules exist about whether the arterial or venous anastomosis should be performed first.[146] Some surgeons perform the venous anastomosis initially, because it tends to be the more difficult owing to wall collapse and edge infolding. Others, however, perform the arterial anastomosis first so as to restore flap perfusion as soon as possible.

The end-to-end anastomotic technique is most common and technically the simplest. After the recipient vessel is chosen, both vessel edges are cut sharply and smoothly to provide a clean anastomotic edge, and then the vessel is gently dilated with vessel dilators. The adventitia is then sharply cleaned away from both vessel edges, to beyond where the sutures penetrate the vessel wall. Care must be taken to avoid vessel wall breeches deeper than the adventitia, which are not uncommon in the preparation of the veins. Loose connective tissue should also be trimmed so that it also does not get caught in the anastomosis and act as a thrombotic agent. Both recipient and donor vessels are placed in the sliding, double-approximating vascular clamp, so that the vessel edges approximate without tension. A blue background material provides good contrast for the fine suture.

Multiple anastomotic techniques have been described, including bisecting and trisecting the vessel circumference with simple sutures, to ensure even approximation around the entire vessel. The essence of these techniques includes placement of two or three equally spaced sutures to hold the anastomotic orientation. To minimize intimal damage, penetration of any instrument into the vessel lumen should be avoided. Either the outer vessel wall can be grasped, or a smooth jeweler's forceps can be used intraluminally, to lift the anterior vessel wall away from the posterior wall during suturing to prevent "back walling," or the inadvertant capture of the opposite vessel wall in the suture, which causes vessel closure. The suture needle is inserted perpendicularly to the vessel edge at a distance one to two times the vessel wall thickness from the edge. After the opposing vessel edge is pierced, three half knots are performed, with care taken to make them square. One of the sutures can be cut longer, to be grasped for vessel edge manipulation. Some surgeons tie each anastomotic suture as if it is thrown, but some prefer to leave them untied until half the vessel circumference sutures are placed. This latter technique allows repeated examination of the lumen to make sure no back walling has occurred, but loose sutures can become mixed. Usually, a combination of the two techniques is most successful. After the superficial vessel half wall is sutured, the double-clamp is flipped, and attention is given to closing the deeper wall. Copious micro-irrigation confirms lack of back walling and good superficial wall anastomosis, as well as the cleaning out of any accumulated blood clots. During the venous anastomosis, irrigation can also lift the superficial wall off the deep wall.

The same suture technique is used to complete the anastomosis. The interrupted suture interval can usually be larger in venous anastomosis than with arterial anastomosis, because of the lower flow pressure. A continuous suture technique can also be used but requires more experience and can constrict the vessel lumen. The clamps are then removed, the downstream ones first, and vessel filling across the anastomosis is observed. "Strip testing," which uses two smooth forceps under sliding compression, can confirm flow across the anastomosis, but can damage the endothelium.[147] The best confirmation is slow bright red blood flow from the skin paddle edge. Leaks can usually be repaired, without further interruption of flow, with simple single sutures. A Y-anastomosis has been proposed to improve blood flow across the anastomosis, but this technique is technically more difficult and not widely employed.[148]

The end-to-side anastomotic technique uses similar suturing technique. The recipient vessel is clamped both proximally and distally to the planned anastomotic site. The planned site of the arteriotomy can be grasped with a suture and stably pulled away from the recipient vessel, so that the microscissors can be used to make a clean arteriotomy. This is generally not necessary for making side venotomies. The fashioned arteriotomy or venotomy needs to be slightly larger than the donor vessel, to help keep the anastomosis splayed open in a "fish-mouth" fashion. The donor vessel can be appropriately angled slightly to aid pedicle geometry and minimize turbulence. No particular anastomotic technique is more advantageous in terms of patency.[1] Anastomotic coupling devices have also been described and have been useful for venous anastomosis (Fig. 80-10). They can speed up this portion of the procedure.[149-151]

In some cases, vein grafts are needed, resulting in a higher complication and thrombosis rate as a result of the higher number of anastomoses. Additional vein harvest sites are necessary, and usually the distal saphenous vein provides a good vessel match. Vessel size match is important for vein graft success.[152] The harvested vein graft is always longer than needed, each side branch is clipped or tied carefully, and the native direction of flow is marked, given the potential presence of valves. The flap pedicle is then placed on a sterile back table under the microscope; this location provides a much smoother and controllable

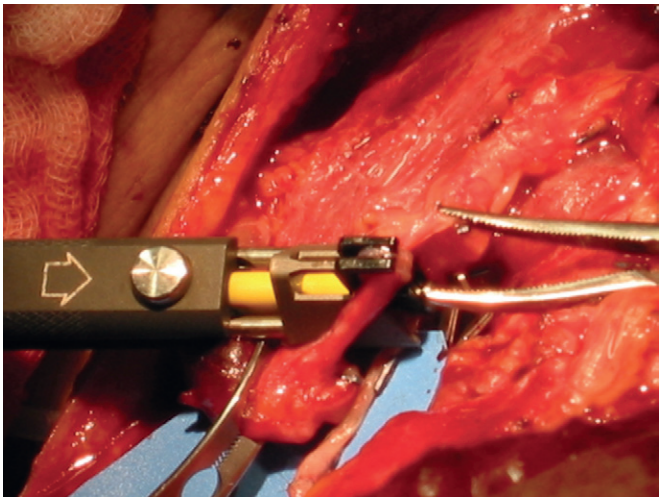

Figure 80-10. The use of a microvascular coupling device for the completion of end-to-end venous anastomosis.

surface for the vein graft anastomoses. The proximal end of the vein graft (direction of flow into vein graft) is anastomosed to the donor vein, while the distal vein graft end (direction of flow out of vein graft) is anastomosed to the donor artery. This yields a U-shaped vein graft from donor artery to vein. The flap is then brought into the head and neck region. The central portion of the vein graft is cut, depending on the needed pedicle length for both donor artery and vein, and the remaining two anastomoses are completed.

The complete inset of the free flap involves both the soft tissue and bony portions of the free flap. It is usually necessary to perform any microscopic neural anastomoses before full inset, which will limit exposure. Reinnervated flaps can adopt sensation in a pattern similar to that of the recipient bed.[153] However, even without direct neurorrhaphy, an adequate level of intraoral flap sensation is possible.[154]

Sufficient hemostasis in the recipient bed is also important, to minimize the risk of the formation of a microvascular compressing hematoma or later infected seroma. The bony inset is most difficult, because of the close proximity of the parallel vascular pedicle, the need for monocortical screw fixation, and the common need for osteotomies. If a locking plate reconstruction is used, either monocortical nonlocking or locking screws can be used; nonlocking screws allow approximation of the bone grafts to the lingual surface of the reconstruction plate. Using the fewest osteotomies as possible is desirable. Necessary osteotomies of the vascularized bone graft should be performed subperiosteally and wedge-shaped, such that bone-to-bone approximation is maximized to facilitate bony union.

Inset of the soft tissue paddle requires the gentle approximation of wound and flap edges with absorbable sutures, to form a watertight seal. Meticulous soft tissue technique is important, and suture lines should be under no tension. Multiple-layer closures are desirable but not always possible. Various techniques have been described to shape and contour the soft tissue paddle so as to mimic the resected tissue, including de-epithelization, fascia rolling, and splitting of the flap. These techniques can help maximize postoperative function and aesthetics.

Drain Placement and Wound Closure

Drain placement at the completion of the procedure is crucial. The best type of postoperative neck drainage remains controversial. A balance between adequate drainage of all potential dead spaces and minimal interruption of any reconstructive flap pedicle must be maintained. Both passive and suction drains have been advocated.[155] A tight neck skin closure can apply significant pressure to the pedicle or a drain tube if it overlies a vascular pedicle. This problem can be compounded by routine postoperative swelling or compression dressings. Drains should typically be placed parallel to flap pedicles and carotid sheath contents. Drain tips should be placed away from mucosal or skin suture lines, to avoid salivary or air leakage. Maintenance of internal drain position with postoperative head and neck movement can be ensured by loose suturing with absorbable sutures. Additionally, the drains should be externally sutured in place to prevent their inadvertent withdrawal with patient movement. Suction drains should be removed from self-suction and withdrawn carefully, according to the reconstructive surgeon's parameters.

Neck incisions are generally closed in layers, but care must be taken to avoid injuring superficial pedicles during the closure. The position of a superficial pedicle should also be marked cutaneously, so that postoperative Doppler monitoring may be employed if needed. This marking also facilitates finding of the pedicle if the neck must be re-explored.

Postoperative Management

Standardized postoperative intensive care unit (ICU) orders, ward transfer orders, and clinical pathways for microvascular cases are crucial for a consistent and efficient hospital recovery.[156] By bringing the patient directly to the ICU themselves, members of the operative team ensure that all drain and monitoring equipment are in proper working order. The operative team can also directly show the ICU nurse the microvascular paddle and monitoring sites. If a warm (80°F) room is required, the proper temperature can be confirmed. The patient is inspected in the ICU for compression by circumferential neck ties from a gown or tracheotomy straps, electrocardiogram wires, intravenous lines tightly overlying the neck, or improperly connected suction drains that may lead to early pedicle compromise. The proper head position to maintain pedicle geometry is also confirmed and maintained with bolsters in the ICU bed. As is the case during the operation, postoperative hypovolemia, hypotension, and hypothermia should be avoided. Some microvascular surgeons prefer that the patient undergo sedation and respiratory paralysis for a time, to help maintain this positioning. This preference must be balanced against the increased risk of pneumonia and deep venous thrombosis associated with prolonged ventilation. Postoperative monitoring of the neck incision is similar to that after any neck dissection. Fluid collections and dehiscences must be aggressively treated, because purulent collections can lead to rapid flap loss from pedicle compression or thrombosis.

Pharmacology

Successful free tissue transfer depends on the maintenance of blood flow through the arterial and venous microvascular anastomoses of flap vessels to the recipient vessels in the head and neck. Surgical technique is the single most important factor in patency; however, various pharmacologic therapies have been proposed in an attempt to improve anastomotic success rates.[157] The majority of these agents have attempted to address one or more of the three common mechanisms for thrombosis—stasis, hypercoagulability, and vessel injury. Of the dozens of agents that have been tried or proposed, only aspirin, heparin, and dextran have found a role in the clinical setting. There remains a paucity of prospective clinical trials on which to base treatment guidelines, with most surgeons relying on anecdotal experience to direct therapy.

Aspirin

Aspirin, or salicylic acid, is an antiplatelet agent that acts by acetylating cyclooxygenase and decreasing the products of arachidonic acid metabolism. These products include thromboxane, a potent platelet aggregator and vasoconstrictor, and prostacyclin, a potent vasodilator and inhibitor of platelet aggregation. The desired therapeutic effect after vascular surgery is a suppression of thromboxane without effect on prostacyclin. The minimal dose to achieve this effect in humans is reported to be 100 mg.[157] Higher doses inhibit both thromboxane and prostacyclin but do so disproportionately, such that some benefit is still seen. Aspirin has been shown to reduce the risk of stroke and myocardial infarction more effectively at lower doses (81 and 325 mg). Although no microvascular surgical trials have been performed, aspirin has been shown to reduce the rate of graft occlusion in a range of vascular procedures if given preoperatively or within 24 hours of surgery. Chewing of the tablet is the most rapid administration method for anticoagulation.

Heparin

Although heparin has multiple mechanisms of action, its anticoagulation effect is largely the result of the inhibition of thrombin and, subsequently, the inhibition of thrombin-induced activation of factor V and factor VIII.[157] Heparin possesses properties to prevent both platelet-induced (arterial) and coagulation-induced (venous) thrombi. In animal models, heparin infusion has been shown to be more effective than antiplatelet agents in preventing vascular occlusion.[158] Unfortunately, systemic heparin can result in significant complications (hematoma and bleeding) in the perioperative patient, largely precluding its routine use in free flap surgery.

Topical heparin irrigation at a dose of 100 U/mL has been suggested as an alternative to systemic therapy to reduce these significant complications. Two studies, however, have not shown a significant benefit of its use for flap outcome.[159,160]

Dextran

Dextran is a heterogeneous polysaccharide that is synthesized by the action of the bacterium *Leuconostoc mesenteroides* on sucrose.[161] Two commercially available forms of dextran are available, dextran 40 (Rheomacrodex) and dextran 70 (Macrodex), which are named according to the average molecular weights of the polysaccharides in the prepara-

tions. Dextrans were initially used as colloids for fluid resuscitation; however, problems with potential anaphylactic reactions and effects on the coagulation system led to a general abandonment of the use of dextrans in this setting. It is their effects on coagulation that have been exploited in microvascular surgery. Dextrans appear to interfere with the formation of fibrin networks, increase the degradation of fibrin, decrease von Willebrand's factor and factor VII, and expand intravascular volume.[161]

Animal studies have shown better immediate postoperative vessel patency with use of dextran infusion. However, Khouri and associates[159] found no improvement in flap outcome with the use of dextran in a prospective trial of pharmacologic agents.

Although a wide variety of regimens for the administration of dextran in the perioperative period have been advocated, two are commonly followed. Johnson and Barker[162] recommend a 40-mL loading dose of dextran 40 before the release of clamps, followed by a 25-mL/hr infusion for 5 days; Buckley and colleagues[163] recommend 500 mL of dextran 40 before anastomosis and then 500 mL per 24-hour period for 3 days. Most surgeons have used dextran in a fashion similar to these protocols.

Anaphylactic reactions to dextran are probably rare, but many surgeons suggest a test dose of 5 mL of dilute dextran before initiation of therapy. More common sequelae of dextran therapy include pulmonary edema from intravascular volume overload, especially in the elderly. Nephrotoxicity and adult respiratory distress syndrome have also been reported.

On the basis of 300 digit replants and 500 free flaps, Conrad and Adams[157] suggest that dextran be used for digit replantation, but not for routine free flap surgery, especially for patients older than 50 years of age. This use also remains anecdotal, and a well-designed prospective trial remains to be performed.

Free Flap Monitoring

Close monitoring of the microvascular reconstruction is paramount, but the exact schedule and method remain controversial, so practices widely vary even within institutions. Care by ICU nurses experienced in the care of the patients who have undergone microvascular surgery is important to the avoidance and early detection of complications. This monitoring is supplemented by physician or electronic monitoring of the free flap. Visible flap inspection and pinprick constitute the most reliable method that must be mastered early by all microvascular surgeons, and should be the end-all test that determines the status of the flap. Digit palpation and Doppler monitoring of a markedly superficial pedicle can supplement direct clinical flap assessment. Both techniques have some subjectivity when there are early changes, and thus, serial monitoring by the same observer is important. Later anastomotic difficulties are not subtle.

Direct flap observation is labor intensive and can be less sensitive to early ischemic changes. Different objective monitoring methods of either pedicle blood flow or flap perfusion, both invasive and noninvasive, are being investigated, with varying success. They include radioisotope scanning, color-flow Doppler ultrasonography, temperature and oxygen tension measurements, perfusion CT scanning, photoplethysmography, and laser Doppler velocimetry.[164-169] Limitations of these methods include the cost of monitoring equipment, a wide variation in normal values with significant artifact, and the need for special expertise.

Complications and Salvage

Systemic medical complications are common in patients undergoing microvascular surgery for head and neck cancer and must be aggressively treated. Local complications to the donor site are specific to each type of free flap. Familiarity with the anatomy of the donor site is paramount to recognition of the complications, which range from pain, bleeding, and infection to more severe complications, such as permanent sensory and motor nerve damage and even loss of the donor limb. Infections under pressure in either natural or surgically created compartments can rapidly lead to compression and thrombosis of the already compromised native vascularity of the extremity. Left undetected and untreated, such developments can rapidly lead to arm or leg loss. Scarring can result in later functional and cosmetic problems that may require physical therapy or further surgery.[60] The donor site must be inspected with the same frequency and vigor as the recipient site.

Recipient site complications are similar to those seen in other patients undergoing head and neck surgery without free flap reconstruction. Hematoma, salivary fistula, infection, and wound dehiscence can occur at any time and require rapid detection and intervention. In the patient who is undergoing radiation therapy, protection of the carotid artery is important. If wound dehiscence or salivary fistula occur close to the free flap pedicle, rapid flap compromise can occur. Presence of healthy nonirradiated vascularized tissue in the heavily irradiated recipient bed can help minimize wound complications.[6]

In the animal model, ingrowth of collateral vessels may keep an inset free flap viable, independent of the pedicle, as soon as 8 days after surgery.[170] Microvascular surgeons do not rely on adequate recipient bed neovascularization until 3 to 4 weeks and probably longer in the previously irradiated patient. The bony portion of some osteocutaneous free flaps may have even longer or permanent dependence on the pedicle blood supply. Postoperative pedicle compromise should be rapidly reversed, because prolonged ischemia leads to at least partial necrosis. After approximately 12 hours of ischemia, even with reestablishment of anastomotic flow, the free flap is usually not salvageable.[171]

The ischemia tolerance of the flap tissues varies with patient and tissue type, with capillary perfusion changes seen as early as 10 minutes after venous pedicle occlusion.[172-174] Arterial insufficiency is less tolerated than venous insufficiency, and most microvascular surgeons keep the ischemia times at less than 2 hours. Ischemic tolerance is generally shortest with bowel mucosa and muscle, intermediate with skin, and longest with bone. Additionally, flap compromise later in the hospital stay tends to be more difficult to reverse. Flap monitoring is usually more relaxed, resulting in a longer undetected ischemia time. Pedicle compromise is also usually caused by localized purulence, which may have a long-term effect on the pedicle and anastomotic patency.

Most free flap anastomotic ischemic complications occur within the first 48 to 72 hours. In multiple large series, the need for pedicle reexploration or revision occurs approximately 8% to 9% of the time, with an overall flap loss rate of 1% to 11%.[174-176] Venous anastomotic thrombosis is more common, but if not remedied, both outflow and inflow will be compromised.[175,176] Early venous congestion may affect the more distal monitoring paddle before the main flap paddle, because of the proximity of the monitoring paddle to the venous anastomosis. Thus, early venous congestion changes in the monitoring paddle should be taken very seriously. Venous anastomotic thrombosis results in an increased flap turgor, rapid capillary refill with brisk bleeding of darker blood, and, finally, darkening and mottling of the skin paddle. Venous congestion may present with any or all of these changes, the color changes usually being a later sign. The arterial pulse can still be felt until the later stages. Arterial insufficiency manifests as a profound paleness and coolness, loss of flap turgor, and absence of any capillary refill or bleeding to pinprick. Usually only a serous bubble, if anything, arises from a pinprick or cut. The superficial pedicle pulse is no longer palpable or obtainable by Doppler testing. Observation of changes in free muscle flaps are more difficult to determine than in fasciocutaneous flaps. Buried flaps require an external monitor paddle for monitoring.[177]

Injury from oxygen free radicals, as well as other etiologies, contributes to flap damage from flap reperfusion after a period of ischemia.[178-180] Despite the injury from reperfusion, rapid intervention is required upon detection of pedicle insufficiency to reestablish flap perfusion if the flap is to be salvaged. This may include bedside maneuvers such as suture release, drain stripping, and opening the neck incision, because it is not always possible to move the patient to the sterile operating theater immediately. Time is of the essence, especially in cases of arterial insufficiency. The patient is urgently returned to the operating room, the neck is reopened, and the anastomoses are explored. Attention is focused on reestablishing blood flow, but the inciting factor must also be corrected to prevent recurrence (e.g., evacuation of hematoma, improvement of pedicle geometry). In the case of isolated venous outflow thrombosis, the venous anastomosis should be investigated, and thrombectomy and thrombolysis performed. When arterial pedicle thrombosis has occurred, both anastomoses must

be taken down and revised after thrombectomy. The arterial anastomosis is then revised, and thrombolysis is performed before the revision of the venous anastomosis. The timing of the release of the recipient artery vascular clamp and reestablishment of blood flow remains controversial.[181] Copious irrigation with heparinized lidocaine is used throughout to help extract gross thrombus from the pedicle. Clots should be atraumatically "milked" or pulled from all arteries and veins. Fogarty catheters may also be useful. The vessels should be trimmed back to fresh clean edges. Alternatively, new recipient vessels or vein grafts should be concurrently prepared if needed to avoid future thrombosis.

Thrombolysis is facilitated with injections of streptokinase (75,000-125,000 U/injection) or urokinase (100,000 U) using a fresh 30-gauge needle while the recipient artery is atraumatically clamped.[182] This is performed near the arterial anastomosis, in case some intimal damage is caused by the penetrating needle, which would require the anastomosis to be revised again. Microcatheterization of a side branch is also possible for instillation. The arterial clamp is then removed, and the effluent from the donor vein collected on a sponge and discarded; this maneuver prevents systemic circulation of the agent and generalized bleeding complications. The procedure is repeated until normal venous outflow from the donor vein is reestablished. Directional massage of the flap paddle can assist this process. Once flow has been reestablished and directly observed for a time exiting from the donor vein, the venous anastomosis is revised. The efficacy of thrombolytic therapy remains controversial, with early detection and treatment being the most important factors in flap salvage.[183] The patient undergoes anticoagulation with heparin, the level depending on the surgeon's preference.[184]

The use of medicinal leeches is indicated for cases of flap venous congestion in which surgical salvage has been attempted but was inadequate in reestablishing full venous outflow.[185] Prolonged use of leeches has resulted in some salvage success but requires an intense protocol. Use of leeches is also indicated as a temporary measure to relieve venous congestion until the patient can be brought to the operating room. This practice requires immediate access to medicinal leeches from the inpatient pharmacy, which may not be available in every institution. Leeches are generally available within 24 hours from a national supplier. Leeches produce both hementin and hirudin, which provide local anesthesia and anticoagulation properties at the leech bite. The leech also harbors a gram-negative beta-lactamase–producing organism (*Aeromonas hydrophila*), requiring antibiotic prophylaxis to prevent soft tissue infection and necrosis. Significant blood loss can require multiple transfusions, and wayward leeches can attach to other body areas or personnel.

Even the best salvage efforts can result in either partial or total loss of a free flap. A partially necrotic flap may be left to demarcate the necrotic from viable portions of the flap, assuming that the pedicle and major vessels are not at risk during this period. Generally, the tissues farthest from the pedicle are at highest risk. These necrotic areas should be eventually débrided down to healthy bleeding tissue. The resulting defect may be left to granulate or may be replaced with other tissue, depending on its size and location. A totally necrotic flap should be resected in a timely fashion, because of the risk of salivary contamination, infection, and disseminated intravascular coagulation. For a time, the flap can act as a nonvascularized biologic dressing, until the patient is medically stabilized and his or her status maximized for the necessary revision surgery. The resultant defect is either reconstructed with an alternative, less optimal pedicled or free flap, depending on the specific patient situation.[186] One alternative that has varying success after composite resection is to leave the fixated nonvascularized bone in place after loss of an osteocutaneous free flap. This then requires coverage with a healthy vascularized flap, separating the bone graft and protecting it from oral contamination (i.e., pedicled pectoralis major myocutaneous flap).

Costs and Outcomes

In addition to the expertise, microvascular reconstructions require significant health care resources, including time, equipment, and personnel.[187] The actual costs of microvascular reconstruction are generally comparable to those of other techniques, with costs being more dependent on comorbidities and extent of disease.[21,22,188,189]

With widespread use, further prospective evidence-based evaluation of current reconstructive techniques is warranted. As new outcome assessment tools become available, function and quality of life after microvascular reconstruction will be increasingly investigated. Focus must be placed on very specific anatomic areas of reconstruction, rather than on a general comparison of all oral cavity, oropharyngeal, and laryngeal areas. Comparisons, mostly retrospective, with alternative forms of reconstruction, including prosthetic rehabilitation and pedicled tissue reconstruction, show mostly better results for microvascular reconstruction.[3,17,18,20,190,191] These investigations should also include long-term outcomes.[192] Further comparison with results of organ preservation protocols or previous reconstruction also requires further study.[193,194]

Future Directions in Free Tissue Transfer

Enhancements to current microvascular techniques are currently being developed. Improvements in the speed of anastomoses, such as the use of mechanical anastomotic devices, must be matched with the equivalency of patency rates. The use of a microvascular anastomotic coupling device has been described in both arterial and venous anastomoses.[149-151] It has been found to be effective in end-to-end as well as end-to-side venous anastomoses, only 3 to 5 minutes being required to complete the end-to-side anastomosis.[195] Similarly, new pharmacologic agents are being investigated to assist in reducing rates of anastomotic thrombosis.[196,197]

Minimally invasive harvest techniques have been developed for some free flap donor sites, including the jejunum, gracilis, omentum, rectus abdominis, temporoparietal, and latissimus dorsi.[198-202] Although less scarring and potentially less donor site morbidity results, the longer harvest times currently required can be detrimental. Multi-institutional experience needs to be studied as these techniques become more commonly attempted, before they can be compared with current harvest techniques.[203] Endoscopic harvest of saphenous vein grafts has gained some acceptance in cardiac surgery and may also be an option for the microvascular surgeon.[204]

Allograft transplantation of whole head and neck organs has gained some media attention. The clinical experience is very small, and the necessary induced immunodeficiency certainly has serious implications for the patient with head and neck cancer. Also, return of adequate native organ function still must be demonstrated experimentally before the clinical applicability of this technique in nononcologic reconstructions can be considered.[205]

New applications and enhancements of current techniques, as well as new donor sites, are needed. Discovering new indications for current free flaps should always be encouraged, including indications such as laryngeal and tracheal reconstruction.[206] The use of prefabricated reconstructions and hybrid alloplast, or bioengineered tissue reconstructions, is slowly gaining momentum.[25,207-211] Prefabricating or prelaminating an intended free flap into a more ideal reconstruction may improve the overall aesthetic and functional result but also may be limited by the preparation time required, especially in oncology patients.[212-215] A combination of free flap reconstructions with current and future alloplastic materials may provide even more expanded indications.[216-218] Improved aesthetic and functional outcome may be possible as new combinations are developed. These techniques should also help minimize the subsequent "fine-tuning" operations that are commonly necessary to maximize overall cosmetic and functional outcomes.

CHAPTER EIGHTY-ONE

Integrating Palliative and Curative Care Strategies in the Practice of Otolaryngology

Rhonda Johnson

Gary Johnson

Key Points

- Palliative care seeks to address symptom management for optimal patient quality of life throughout active head and neck treatment and thereafter.
- Because head and neck cancers compromise critical anatomic structures, both the disease and its treatment can be physically, socially, and emotionally debilitating, rendering palliative care essential in patients with these tumors.
- Pretreatment dental assessment by a practitioner experienced in oral oncology to address oral disease prior to cancer treatment combined with patient education directed toward ongoing good oral hygiene is important to ameliorate the side effects of treatment.
- The complex and clustered nature of symptoms among patients with head and neck cancer requires a multidisciplinary team approach to provide comprehensive palliative treatment.
- Often the behavioral and social habits of patients with head and neck cancer are predisposing factors in the development of the disease. These factors also represent an ongoing risk that influences the efficacy of treatment and therefore must be integrated into the overall treatment plan.
- Oral mucositis is a common side effect of treatment that affects virtually all patients with head and neck cancer receiving multimodality treatment. Later research has provided a model for better understanding the progression of events leading to ulceration. This model provides a framework for the development of targeted strategies to prevent and diminish the effects of treatment.
- Patients with head and neck cancer are at substantial risk for experiencing psychological distress. These patients should be assessed prior to treatment on the basis of high-risk factors, including use of tobacco and alcohol, and should be monitored carefully throughout the treatment process. Patients continue to experience significant disabling effects of their treatment months after its completion and therefore continue to be at risk for psychological distress. Palliative treatment must incorporate long-term monitoring and structured interventions for these patients.
- Approximately 50% of patients with head and neck cancer are nutritionally compromised at initial presentation. The consequences of treatment put such patients at significant risk for treatment-related delays and hospitalization secondary to the effects of nutritional insufficiency. Palliative care treatment includes careful nutritional assessment and specific interventions to alleviate nutritional deficiencies.
- Wherever possible, symptom management should utilize a portmanteau approach to the use of medications to minimize side effects and maximize treatment efficacy.

As of 2006 there were 10.5 million cancer survivors in the United States, with 1 million more anticipated each year.[1] With advances in treatment regimens that allow individuals with cancer to live prolonged periods beyond the time of diagnosis—even for cancers with trajectories that are expected to ultimately end life—symptom management becomes a critical focus of the doctor-patient relationship. Five-year survival rates for patients diagnosed with head and neck cancer (all types and stages) is 59%.[2] Although treatment has improved the disease-free interval, cure rates have not substantially improved over the last 50 years.

Treatment depends on stage of disease. For late-stage disease, treatment most often involves multimodality therapy.[3] Symptom distress that occurs commensurate with treatment and persists long term to influence both function and quality of life provides the impetus for the implementation of prevention and treatment strategies designed to alleviate these difficult conditions.

Palliative care focuses on treating acute and chronic symptoms. As a result this chapter outlines palliative care efforts that are particularly pertinent to patients with head and neck cancers. Because head and neck cancer affects structures that are critical for day-to-day functioning, including such basics as speech and swallowing, and because treatment may lead to deformities that adversely affect psychological functioning as well as debilitating short and long-term side effects, there is a special need for physicians to be attuned to distress that may be reduced by palliative intervention.

Palliative care is a relatively new construct in the epistemology of care for patients with chronic illness. It came about with the realizations that (1) individuals with ongoing illness experience physical, social, physiological, and spiritual issues that influence their quality of life and (2) treatment encompasses a more all-embracing objective than simply attempting to prolong life. The intent behind initiating palliative care, at the time of diagnosis, is to prevent and relieve suffering in order to improve quality of life throughout the disease process. It becomes imperative for the oncologist to be aware of symptoms inherent to the disease process as well as those that are associated with the treatment regimen. Comprehensive cancer care includes palliative care designed to utilize tools that identify distressing symptoms and allow for expeditious intervention.

Broadly speaking, in this chapter, we discuss palliative care strategies by addressing specific domains that include physical symptoms and emotional well-being. Although each of these issues is discussed as a separate domain of individual functioning, it is clear that each construct influences the other; while a patient is experiencing pain, for example, the patient's psychological, social, and spiritual well-being are certainly also affected. Symptoms can be the result of the disease itself or can stem from treatment. For example, malnutrition can be the direct result of the individual's lifestyle prior to the cancer diagnosis but can also result from treatment effects. Addressing one issue, usually the one that is most salient to the patient, therefore may alleviate distress in other domains.

Treatment regimens differ because head and neck cancers are a varied group of diseases comprising malignancies of the oral cavity, oropharynx, larynx, sinuses, and skull base. This difference in treatments coupled with characteristics specific to the patient (e.g. stage, co-morbid medical illness, age) influences treatment outcome and makes it difficult to describe a clearly delineated set of adverse or distressing symptoms.[4] Discussions of treatment options with patients should always include a thoughtful review of possible side effects, late effects, and quality of life consequences as well as best or most likely clinical outcome. Additionally, because both prevention and treatment of distressing symptoms involves complex and time-consuming consultation, palliative care is best delivered through the efforts of a interdisciplinary team[4] including the surgeon, medical oncologist, radiation oncologist, dentist, speech therapist, psychologist, occupational and physical therapists, nurse, and social worker.

Treatment for malignant disease involving the head and neck produces toxicities to normal cells or tissue. By virtue of its rapid cellular turnover rate, the mucosal lining of the gastrointestinal tract including the oral mucosa is a prime target for chemotherapy- and radiation-related toxicities The diverse and complex microflora that exists within the oral cavity renders the oral mucosa vulnerable to infection. Approximately 10% to 15% of patients experience oral complications during adjunctive chemotherapy.[5] This number increases to 40% to 50% when chemotherapy is administered as the primary treatment (palliative).[6] Virtually all patients with head and neck cancer who are undergoing combination chemotherapy and radiotherapy experience oral complications, the majority of whom will experience severe effects.

Treatment for patients with head and neck cancer often involves multimodality therapy. Surgery remains an integral component for most such patients. The adverse effects of surgery are distinctly different from those of chemotherapy and irradiation. Surgical effects often remain life-long and have a significant impact on daily functioning.[7]

In a 2007 Cochrane Review, less than one half of the included studies (39%) reported adverse events with treatment.[8] The writers of this review discuss the perception among oncologists that acceptance of high rates of adverse events is necessary to "tackle the bigger issue of survival." The information presented regarding adverse effects should not be used to argue against specific surgical considerations, because treatment decisions should be weighted primarily toward those that maximize survival. However, studies indicate that more than half the patients treated for head and neck cancer are disabled by their treatment.[9] Specific risk factors include previous treatment with chemotherapy and pain. Pain remains a major predictor of disability and can be disabling for many reasons. Therefore, patient education regarding expected treatment outcomes is critical to the informed consent process.

Among patients receiving treatment for head and neck cancer, the most common complications are mucositis, xerostomia, psychological distress, difficulties with speech and swallowing, taste dysfunction, and pain. These in turn may lead to complications such as dehydration, dysgeusia, and malnutrition. These secondary complications can be quite severe and can potentially cause reductions in treatment doses, delays of treatment, requirements for hospitalization, and even discontinuation of therapy.

Management of these complications consists of screening for and the identification of patients at high risk for them, patient education, initiation of pretreatment interventions, and timely management of lesions when they develop.

Pretreatment Management

Assessment of the oral status and stabilization of oral disease prior to the initiation of therapy is a critical first step to overall patient care. Primary preventive measures include patient counseling for effective oral hygiene practices and early detection of oral lesions. Involvement of a dental team experienced with oral oncology patients can reduce the risk of oral complications.[10] The evaluation itself should occur as early as possible prior to treatment. Ideally, this examination should be performed at least 1 month before initiation of cancer treatment to permit adequate healing from any required invasive oral procedures.[10] Thereafter, a program of oral hygiene can be initiated with emphasis on maximizing patient compliance throughout the course of treatment and after treatment completion.

Data that can be provided by the dental professional to the treatment care team include the presence or absence of dental caries (including amount and severity), the number of teeth requiring restoration, endodontic disease, teeth with pulpal infection, teeth requiring endodontic treatment, periodontal disease status, number of teeth requiring extraction, other urgent care that is required, and the time necessary to complete stabilization of oral disease.[10]

Routine oral hygiene care includes emphasis on tooth brushing with soft nylon–bristled brushes, with the patient instructed to brush two or three times daily and to rinse the mouth frequently. The patient should be also instructed to use a dentifrice with fluoride. The patient should floss once daily, using an atraumatic technique with modifications as needed. The use of bland rinses, either 0.9% saline or sodium bicarbonate solution, every 2 to 4 hours can soothe pain or discomfort.[11] Also, the patient should be instructed to brush a 1.1% neutral sodium fluoride gel or a 0.4% stannous fluoride gel on the teeth daily for 2 to 3 minutes and then to expectorate and rinse the mouth gently.[11]

Mucositis

For years, the development of mucositis was thought to be a direct, nonspecific consequence of the destructive side effects of irradiation and/or chemotherapy on rapidly dividing basal cells of the mucosal epithelium. Over the past several years, however, evidence has increasingly mounted to demonstrate that chemotherapy/radiation-induced mucosal injury (*mucositis*) is actually the result of a complex series of biologic and cellular events that take place predominantly in the submucosa.[12] The process by which these events occur has been modeled into a five-stage sequence as follows: initiation, primary damage response, signal amplification, ulceration, and healing. Clinically, ulceration is the most significant stage of mucositis.[12,13]

The severity of mucositis is usually expressed through the use of one of a number of grading scales. Two of the most commonly used scales are those developed by the World Health Organization (WHO) and the National Cancer Institute (NCI). The NCI's *Common Terminology Criteria for Adverse Events* (Version 3) evaluates the clinical

findings of mucositis (erythema, ulceration) and functional consequences of mucositis on two distinct scales.[12] The WHO incorporates a subjective evaluation of ulceration/erythema, a subjective evaluation of pain, and a functional evaluation (ability to eat) into a single value.[12]

Care for patients with oral mucositis remains essentially palliative. It involves strict maintenance of good oral hygiene practices as outlined previously, a nonirritating diet, and emphasis on maintaining good nutritional intake; use of oral care products such as rinses and topical anesthetics; and appropriate use of opioid analgesics as a mainstay of therapy.

The purpose of maintaining effective oral hygiene is to reduce the effect of the oral microbial flora and prevent soft tissue infections that may have systemic sequelae.[14] Basic oral care also reduces the risk of oral caries and gingivitis.[10]

The prevention and treatment of mucositis have involved the use of a wide variety of agents over many years. For the most part, however, the results of these efforts have been quite disappointing. Only lately have there been any significant advances in mechanistically based intervention, owing primarily to a greater understanding of the underlying pathophysiology of mucositis. The emphasis on quality of life during curative treatment has also engendered recognition of the importance of effectively designed and executed clinical trials that include important quality-of-life information. Comprehensive evidence-based literature reviews of published mucositis interventions by the Cochrane Collaboration and the Mucositis Study Section of the Multinational Association of Supportive Care and Cancer/International Society of Oral Oncology (MASCC/ISOO) have provided clinical recommendations or guidelines.[8,15]

On the basis of the principles of radiation biology and careful treatment planning, a number of strategies have been developed to reduce the cumulative dose of radiation therapy delivered to nontumor mucosal tissues. Midline blocking, mucosa-sparing shields, which are custom fabricated, can effectively decrease the severity of oral mucositis.[16] When metallic dental restorations (e.g. amalgams, gold crowns) exist in direct opposition to the oral mucosa, wetted cotton rolls or a number of other devices such as custom stents can be used to physically separate the tissue (3 mm or greater away from the dental restoration) and reduce mucositis secondary to localized enhanced scatter effect.[17,18] Decreased severity of mucositis has been reported after three-dimensional treatment planning and treatment with intensity-modulated radiation therapy (IMRT).[19] IMRT has come into widespread use over the last several years.[19]

Although palliative treatments do not affect the incidence, severity, or duration of mucositis, they are often indispensable in managing oral symptoms and must be considered a component of supportive care. Topical analgesics such as 2% viscous lidocaine and "magic" or "miracle" mouthwash formulations, which typically are combinations of lidocaine, benzocaine, diphenhydramine, kaolin, milk of magnesia, chlorhexidine, pectin, and/or sucralfate, can provide some relief of symptoms. These agents are swished and expectorated and can be safely used throughout the day as needed for the duration of mucositis symptoms. The lack of compelling evidence to suggest an effectiveness superior to that of normal saline prevented the MASCC/ISOO Mucosa Study Section from recommending any specific mixture for treatment in oral mucositis. The section did, however, recommend that further study of these agents is necessary to define the efficacy and potential toxicity of their use.

Given the presence of opioid receptors in the oral mucosa, topical morphine therapy and fentanyl sublingual spray have been evaluated and shown to be effective in reducing mouth pain.[20] However, it is unclear to what extent the effect is local rather than systemic, via central pathways, especially in the presence of severe ulcerations, in which transmucosal absorption is likely quite high. Systemic management with morphine and other opioid pain medications is effective and considered a standard care of therapy for severe cases, although breakthrough pain and dose-limiting toxicity are frequently encountered.[20]

Several mucosal surface protectants are available that provide relief by physically coating or soothing the oral mucosa. Caphosol (EUSA Pharma, Princeton, NJ), approved by the U.S. Food and Drug Administration (FDA), is a rinse (device) composed of sodium chloride, sodium phosphate, and calcium chloride that has been evaluated in the stem cell transplantation population and has been shown to be effective in decreasing symptoms of pain and xerostomia.[21] Gelclair (EKR Therapeutics, Bedminster, NJ) and Mucotrol (GeoPharma Inc., Largo, FL) are both FDA-approved mucoadhesive agents that coat and adhere to the inside of the mouth, exerting their effects by physically blocking painful exposed nerve endings in the damaged, ulcerated mucosa.[22] Although these agents are safe and generally well tolerated, the relief they provide is variable and additional systemic pain management is typically required.

Although not approved for use in the United States, benzydamine hydrochloride is a unique topical agent with anti-inflammatory, analgesic, and antimicrobial properties used extensively for prevention of radiation-induced mucositis in Europe and other parts of the world.[23] Amifostine, a free radical scavenger, has been found to be effective in reducing acute and long-term salivary gland hyperfunction secondary to head and neck radiation but has not consistently demonstrated efficacy in the prevention of mucositis, although clinical trials are ongoing.[24]

Palifermin, a recombinant keratinocyte growth factor (FGF-7), is approved by the FDA for prevention of oral mucositis in patients undergoing stem cell transplantation for hematologic malignancies. Spielberger and colleagues[25] reported, in a phase I/phase II trial using palifermin for reduction of mucositis in colorectal cancer patients undergoing therapy regimens containing 5-fluorouracil, that the agent demonstrated safety and efficacy.[25] Both industry and cooperative groups are sponsoring trials to evaluate the efficacy of palifermin in preventing mucositis in patients receiving chemoradiation therapy for treatment of head and neck cancers. Valifermin (FGF-20), a member of the same superclass of molecules as palifermin, is also in clinical testing.[26,27]

Several other agents, including several immunomodulators, are currently under investigation to determine their potential role in the prevention or treatment of oral mucositis in patients with head and neck cancers.

Co-morbidity with dental and oral infections may exacerbate mucositis lesions and serve as independent and serious sources of inflammation and pain. Maintaining basic oral hygiene practice during cancer therapy is paramount. Poorly fitting dentures and fractured or sharp-edged dental restorations and orthodontic brackets may all contribute to localized tissue irritation and the development of mucositis lesions. Erythematous and ulcerative lesions that may be mistaken for oral mucositis may actually represent oral candidiasis and recrudescent herpes simplex virus infection; these lesions must be recognized promptly, sampled for culture, and treated with appropriate antifungal or antiviral medications.[28]

Xerostomia

Diminished salivary gland production, induced by exposure of the salivary gland to radiation during treatment of head and neck cancer, can result in xerostomia (dry mouth syndrome).[29] The addition of chemotherapy to the treatment regimen substantially increases the likelihood of development of xerostomia.[30] Salivary gland production is critical to swallowing function, speech, and maintenance of mouth homeostasis, so its loss has a significant effect on a patient's quality of life.

Symptoms and signs of xerostomia include mouth dryness, a burning sensation of the tongue, fissures at lip commissures, atrophy of the dorsal tongue surface, difficulty in wearing dentures, and increased thirst.

Common problems associated with xerostomia also include a constant sore throat, hoarseness, and/or dry nasal passages.[31] If left untreated, xerostomia increases plaque formation, periodontal disease,[21] and the development of dental caries.[31,32] The change in pH and immune function secondary to reduced salivary flow presumably also mediates an increase in the risk of development of oral candidiasis, one of the most common oral infections seen.[32]

Salivary flow decreases within 1 week after the start of radiation treatment, and xerostomia becomes apparent when doses exceed 10 Gy. Doses larger than 54 Gy are generally considered to induce irreversible loss. The degree of dysfunction is related to the radiation dose, the

schedule (fractionation), and the volume of glandular tissue in the radiation field.[33] The parotid glands may be more susceptible to radiation effects than the submandibular, sublingual, and other minor salivary glands. Salivary gland tissues that have been excluded from the radiation portal may become hyperplastic, partially compensating for the nonfunctioning glands at other oral sites. Generally stated, some degree of a salivary gland recovery is seen over the first 6 months after radiation therapy.[34] Maximum recovery is generally reported by 12 months after therapy, but it is usually incomplete and the overall level of dryness can range from mild to severe.[35] One study demonstrated successful surgical submandibular gland transfer to the submental space, resulting in a functioning gland even after irradiation with appropriate shielding.[36] This palliative measure merits further investigation.

Amifostine, an organic thiophosphate whose action as a free radical scavenger is thought to spare normal tissue from radiation and/or chemotherapy-related effects, has been trialed in a number of studies involving patients with head and neck cancer.[37,38] The use of amifostine as a xerostomia-preventive agent has had mixed results and therefore its use remains controversial.

Dosimetric advantages of IMRT over conventional and conformal radiation therapy as it pertains to the prevention of xerostomia have been confirmed by numerous studies.[39-41] However, relatively small numbers of patients enrolled in these individual trials makes it difficult to conclude that IMRT can be recommended without reservation. Common palliation for xerostomia includes drinking water frequently to keep the mouth lubricated, use of ice chips, and artificial saliva, which combines water with lubricants.[42,43] Sucking on sugarless candy or chewing gum can also stimulate salivary flow. Pilocarpine is the only drug approved by the FDA for use as a sialogogue for radiation-related xerostomia.[43] Treatment is generally initiated at 5 mg by mouth 3 times a day; doses are then titrated to achieve optimal clinical response. The adverse effect profile, which includes sweating, rhinorrhea, and urinary frequency, limits its use.

Taste Dysfunction

Taste alterations (dysgeusia) are well described in patients with head and neck cancer who undergo radiotherapy. As the oral and pharyngeal mucosa are exposed to treatment (principally irradiation), taste receptors are damaged and taste discrimination becomes increasingly compromised. After several weeks of irradiation, it is common for patients to complain of no sense of taste. It generally takes upwards of 6 to 8 weeks after the radiation therapy for taste receptors to recover and become functional. Zinc sulfate supplements have been reported to help with recovery of the sense of taste,[44] although a 2007 phase 3 study did not find support for this measure.[45]

New evidence suggests the presence of metallic phantoms, common in patients with head and neck cancer, may be indicative of neural damage after cancer-directed treatment.[46] The presence of metallic phantoms is an independent predictor of long-term pain in this patient population.[46]

Pain

Tumor involvement of head and neck structures, cancer treatment (often multimodal), or preexisting comorbid conditions can cause pain. Pain accompanies oral infections, mucositis, xerostomia, trismus, dental caries, and osteoradionecrosis, all of which are relatively common accompaniments to head and neck cancer treatment.

The general principles of pain management apply to the treatment of patients with head and neck cancer. A careful history must be taken of the nature of the pain, its time course, and any maneuvers that increase or decrease its intensity. The assessment should also include a determination of any pain-related functional interference with activities of daily living and interpersonal relationships. Consistent monitoring of pain management intervention effects[47] is essential to determine efficacy as well to minimize treatment-related side effects. A detailed medical, neurologic, and psychosocial assessment with emphasis on a history of substance use or abuse should be conducted.

The underlying concept of good pain management is that pain is a subjective phenomenon and, therefore, the patient's perception of pain should be the dominant consideration. However, significant under-management of pain continues to persist.[48] Studies that have examined rates of drug addiction in cancer populations indicate that although tolerance and physical dependence are common, addiction (psychological dependence) is rare and almost never occurs in an individual without a history of drug abuse prior to the cancer diagnosis.[49]

Guidelines to help direct analgesic management of cancer pain include those provided by the WHO.[50] These guidelines advocate pairing the analgesic approach with the severity of pain. Under these guidelines, pain of mild to moderate severity would first be addressed with nonopioid analgesics such as nonsteroidal anti-inflammatory drugs (NSAIDs). For pain that is persistent and moderate to severe in intensity, opioid analgesics of increasing potency should be utilized. A common side effect of the use of opioid analgesics is constipation. A bowel regimen should be instituted concomitant with the initiation of opioid analgesics. Psychostimulants may also prove useful in treating sedation, which also commonly accompanies opioid analgesic use.

Importantly, not all pain is somatic in origin. Neuropathic pain is a common source of pain among patients with head and neck cancer and is poorly treated by opioid medications. Neuropathic pain should be treated with the use of effective adjuvant medications that include many of the psychotropic class of medications.

Treatment effects of surgery or that occur during or after radiation treatment include the development of soft tissue fibrosis, mandibular discontinuity, and perifunctional habits associated with emotional distress caused by cancer and its treatment. Mouth pain due to these musculoskeletal conditions can be reduced by early and timely physical therapy interventions such as mandibular stretching exercises as well as the use of prosthetic aids to reduce the severity of fibrosis. Such approaches must be instituted prior to the development of trismus. If clinically significant changes do develop, several approaches, including stabilization of occlusion, trigger point injection, and other pain management strategies, as well as the use of muscle relaxants and/or pain medications, should be considered.

Additional guidance for the appropriate management of pain in patients with head and neck cancers can be found by viewing the American Pain Society (APS) website (http://www.ampainsoc.org). This organization also offers continuing medical education and certification in effective pain management methodology for health care practitioners.

Psychological Distress

Rates of depression and anxiety are particularly high in patients with head and neck cancer. The percentages of such patients who have significant depressive episodes are most often reported at around 30%.[51-53] Such patients also have higher rates of suicide than patients with other cancer.[54-57]

The loss of a normal facial appearance, changes in speech, as well as difficulties with normal communication, are distressing treatment side effects that put the patient with head and neck cancer at risk for significant psychological distress. Symptoms known to be associated with depression, such as disturbed sleep, fatigue, changes in appetite, and difficulty with attention and concentration, are also common side effects of cancer and its treatment. It is not clear whether these symptoms are the result of or the cause of depressed mood. Cytokine and neurohumoral events seemingly mediate the clustering of symptoms commonly experienced by patients with cancer. This would then provide a biologic explanation for the jointly experienced symptoms of depression, pain, and fatigue. The phenomenon of symptom clustering is the impetus for comprehensive symptom assessment and the previously mentioned portmanteau approach to intervention.

Social and economic factors predispose the patient with head and neck cancer to significant mental health–related difficulties. Often the illness causes loss of employment or significant time away from work, resulting in reduced financial resources at a time when the cost of medical care is increased.

Variables that patients with head and neck cancer bring to the treatment process can also contribute to the psychiatric risk profile. Foremost among those are patients who have a history of drug or alcohol abuse, which is common in this patient population.[58]

Because the level of distress experienced by patients changes during the course of the illness and treatment, its manifestation can become extreme, to the point that it prompts delay or discontinuation of therapy, or chronic, resulting in longer-term disability. These variable levels of impairment underlie the need for continued monitoring throughout the treatment trajectory.

The National Comprehensive Cancer Network[58a] has established guidelines for both screening for and treating cancer-related psychological distress. These guidelines suggest that every patient be screened with the distress thermometer, which both evaluates the level of distress and asks patients to identify circumstances in their lives that might be contributing to the distress.

Patients with head and neck cancer most at risk for psychological and social problems are those with the greatest levels of disfigurement, dysfunction, and physical symptoms.[59-61]

Interventions can include emotional support, referral for psychotherapy, and behavior modification specifically targeting smoking cessation and alcohol abuse.

Psychotropic medications can often be used to accomplish more than one objective. For example, mirtazapine, which can be administered as an orally disintegrating tablet, an advantage for individuals with dysphagia, is effective in alleviating anxiety and depression, sleep difficulty, and loss of appetite. Thus, it treats multiple symptoms common to individuals with head and neck cancer.

All antidepressants should be evaluated for possible adverse effects and interactions with other medications. Although anxiolytics are useful for controlling both nausea and anxiety, they can also exacerbate fatigue and can lead to delirium.[62]

Dysphagia and Speech Dysfunction

Treatment options for advanced laryngeal cancer have progressed, with studies demonstrating the efficacy of radiotherapy with concomitant chemotherapy for the purpose of preserving organ function. Unfortunately, organ preservation has been shown to result in swallowing disorders related to the dysmotility of the oropharyngeal and laryngeal structures. Frequent episodes of aspiration[63,64] may also occur as a result of the lack of normal function after organ preservation. Difficulty with swallowing is the basis for gastrostomy tube placement in 54% of patients with head and neck cancer for nutritional assistance during the course of or shortly after concurrent chemotherapy and radiotherapy.[65] Initial screening for nutritional deficiencies among patients with head and neck cancer and ongoing monitoring for the development of nutritional deficiency during therapy are essential to promote timely intervention to avoid treatment-related delays and hospitalization.

Altered speech is a common complication of surgical therapy for head and neck cancers as well as the result of treatment involving irradiation or chemotherapy. The early involvement of speech and language pathologists who specialize in the care of patients with head and neck malignancies should be a part of the comprehensive management of this patient population. Speech and language pathologists provide voice rehabilitation, including acoustic assistive devices, and teach patients modified swallowing techniques.[66]

Nutrition

Nutritional deficiencies are frequently seen in patients with head and neck cancer, approximately 50% of whom have significant weight loss at the time of initial diagnosis. High rates of malnutrition may develop or continue throughout treatment and are secondary to multiple influences, including preexisting lifestyle (smoking and alcohol use/abuse and poor dietary habits), the disease itself, and/or therapies that interfere with eating by mouth.

Options for addressing nutritional needs include parenteral and enteral therapy. Generally it is advantageous to provide enteral feeding rather than parenteral feeding owing to the balance of risks and benefits associated with these two modalities.[67] Enteral nutrition offers the advantage of providing nutrition directly to the gut, thereby reducing the risk of atrophy. Enteral feeding is also associated with fewer complications, such as infection.[68,69]

Malnutrition can progress to cachexia, a complex process of continued weight loss that involves the depletion of host reserves of skeletal muscle and adipose tissue. Importantly, this process can also involve complex and profound metabolic changes, especially in advanced cancer, characterized also by abnormalities in fat and carbohydrate metabolism. Nutritional support alone does not address the underlying catabolic metabolism. Drug treatment to attenuate the tumor-induced catabolic response should be carried out at the same time.[70] Concomitant drug treatments for cancer cachexia may slow down the wasting process by reducing anorexia, attenuating the systemic inflammation and skeletal muscle catabolism, or stimulating the muscle protein anabolism.[71]

End of Life

Although the essential components of assessing and managing symptoms continue to be an important element of palliative care, end-of-life care is differentiated in several ways. The focus of care in this setting becomes facilitation of a "good" death. What constitutes a good death is often defined differently by the individual patient and family. Each person has unique needs for information and support. Understanding of the patient and family's expectations and concerns about the end of life can be best achieved through ongoing discussions.

These discussions begin by helping the patient identify personal goals for the end of life, managing psychological and spiritual needs, assessing the patient's support system, and evaluating and communicating the estimated prognosis. End-of-life discussions between patient and health care provider are associated with less aggressive medical care near death and earlier hospice referral.[72] This issue is important in light of other findings indicating that aggressive care is associated with worse patient quality of life and worse bereavement adjustment for caregivers after the death of the loved one.[72]

Because symptom management at end of life may also involve a more complicated and intensive effort, particularly in terms of management of pain, dyspnea, and ability to urinate or empty bowels, a referral to hospice care before the patient is unable to discuss goals for the end of life is appropriate.

Palliative medicine should be a core clinical skill for all physicians who care for seriously ill patients. Several sources of information are available for physicians to develop and update these clinical skills. The National Consensus Project for Palliative Care has provided comprehensive guidelines for the administration of palliative care services at end of life.[73] These guidelines provide a framework for adoption of palliative care commensurate with diagnosis but also in the context of end-of-life care. The National Quality Forum is now developing specific strategies and guidelines for the implementation of quality palliative care throughout the continuum of a patient's treatment and life.[74]

CHAPTER EIGHTY-TWO

The Management of Head and Neck Melanoma and Advanced Cutaneous Malignancies

Cecelia E. Schmalbach

Timothy M. Johnson

Carol R. Bradford

Key Points

- The incidence of melanoma continues to increase dramatically.
- Warning signs for melanoma are lesion asymmetry, border irregularity, color variation, and diameter more than 6 mm. However, a subset of cancers, such as nodular, amelanotic, and desmoplastic melanoma, lack these features. Any pigmented lesion that meets these criteria, has undergone change, or appears different from surrounding nevi warrants biopsy.
- The biopsy of a potential melanoma is a two-stage process. The first stage entails narrow-margin, excisional, or incisional biopsy to obtain histologic diagnosis. Shave biopsy is discouraged. This prognostic information then serves to guide the second stage, which entails wide local excision using 0.5- to 2-cm margins and, possibly, sentinel lymph node mapping and biopsy.
- The American Joint Committee on Cancer staging system for cutaneous melanoma is founded on the traditional tumor-node-metastasis (TNM) classification. Stage I and stage II represent localized disease, stage III regional disease, and stage IV distant metastasis. Nodal status is the single most important prognostic factor for patients with melanoma.
- The T classification is defined by tumor thickness (measured by even-integer cut points) and ulceration. Ulceration of the primary lesion raises the stage of the patient's disease. Clark's histologic level of invasion is applicable only in staging thin (≤ 1-mm) T1 tumors.
- Significant prognostic factors with stage III regional disease include the number of metastatic lymph nodes, tumor burden as represented by microscopic versus macroscopic disease, and primary tumor ulceration. Satellite and in-transit metastasis are also important prognostic features; they are classified as stage III regional disease regardless of the nodal status.
- The M classification is defined by anatomic site of distant metastasis and elevated serum lactate dehydrogenase value.
- The standard of care for melanoma treatment remains complete surgical excision of the primary lesion.
- Therapeutic lymph node dissection is universally accepted as the treatment for proven regional disease in the neck.
