Although the biologic behavior of tumors involving the skull base may vary, certain general principles should be followed in their extirpation. It is essential, if possible, to determine preoperatively whether the lesion is benign or malignant. Small, benign lesions in the middle ear space whose borders are clearly visible through the tympanic membrane can be removed through the external auditory canal. When removing the tumor, the surgeon should clearly differentiate it from vascular anomaly, because injury to the internal carotid artery in its intratemporal portion is hazardous and may require ligation of the artery for control of bleeding. Benign tumors limited to the mesotympanum whose borders are not visible through the tympanic membrane may be approached through a combined transcanal and facial recess or through an extended facial recess approach. Occasionally, the facial recess is narrow, necessitating removal of all or part of the bony posterior wall of the external auditory canal. Basic surgical approaches to the mastoid and mesotympanum are described in Chapters 127 and 142. Malignancies are best removed en bloc, whereas benign lesions may be extirpated piecemeal, although depending on biology, resection may require establishing a cuff of normal tissue. Surgical approaches to lesions deeper within the temporal bone should be chosen either to provide adequate exposure for complete excision or to allow easy access to an exteriorized cavity, to preserve useful residual hearing if possible, to preserve facial nerve and other cranial nerve functions when possible, to avoid injury to the brainstem and internal carotid artery, and to provide for wound closure without cerebrospinal fluid (CSF) leak.

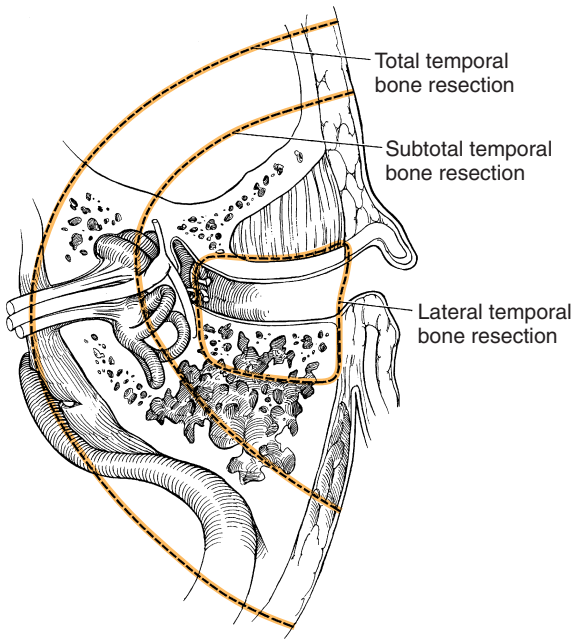

Figure 176-3. Margins of resection for lateral temporal bone, subtotal temporal bone, and total temporal bone resections.

The operative approach and intraoperative technique should maximize safe exposure and minimize morbidity. Surgeons should be well versed in all methods of exposure for various regions of the skull base. Circumferential exposure of tumor margins for benign tumors and en bloc technique for malignant lesions, minimization of blood loss by preoperative selective embolization and intraoperative selective vessel ligation, proximal and distal control of the internal carotid artery around the tumor, and preservation of cranial nerves facilitated with intraoperative monitoring by electromyography (EMG) (see Chapter 178) whenever necessary are essential to a successful outcome.

Sleeve Resection of External Auditory Canal

A sleeve resection of the external auditory canal removes the cartilaginous portion and some or all of the bony canal wall skin circumferentially without bone removal. Split-thickness skin grafts are used in the conchal bowl and external auditory canal. Some surgeons include the tympanic membrane as a medial margin to a sleeve resection, although this type of procedure generally is reserved for malignancies localized to the cartilaginous portion of the canal. Malignancies localized to or involving the osseous portion require at least a lateral temporal bone resection.

Lateral (Partial) Temporal Bone Resection

A lateral temporal bone resection[68-71] removes en bloc the entire osseous and cartilaginous portions of the external auditory canal and tympanic membrane using the extended facial recess approach (Fig. 176-3). This procedure is indicated for patients with malignant neoplasms localized to the osseous canal with no encroachment on the medial mesotympanum. Parotidectomy, neck dissection, and mandibular condylectomy are performed as adjunctive surgical procedures if indicated by preoperative radiologic or intraoperative findings. Intraoperative facial nerve monitoring is useful in this procedure.

Incisions

A soft tissue cylinder is designed to include the tragus and conchal bowl. The incision is taken vertically downward, posterior and superior to the temporal bone. The external auditory canal is sutured shut. A postauricular incision is created approximately a fingerbreadth behind the postauricular sulcus (Fig. 176-4A). It may be extended inferiorly into a neck crease for parotidectomy as required. Retractors then are placed.

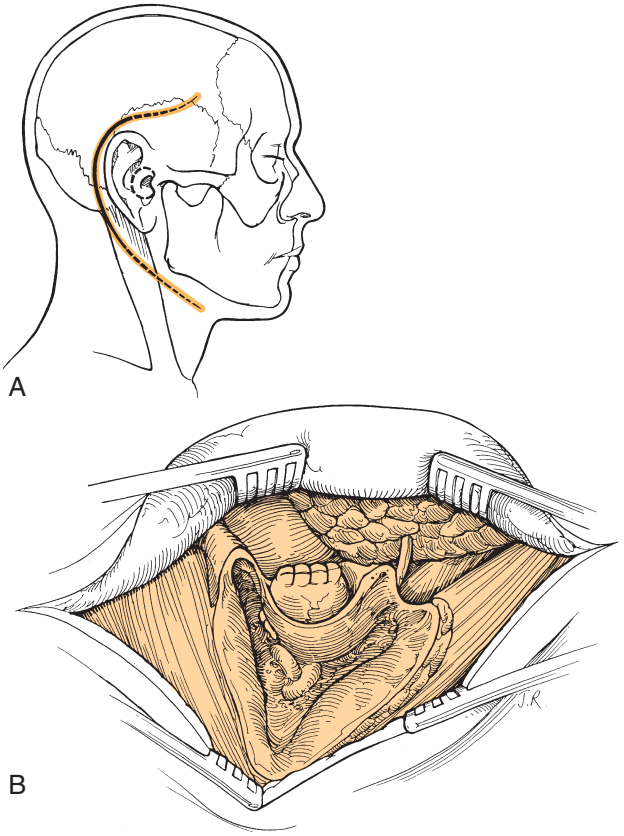

Figure 176-4. Lateral temporal bone resection: incision and initial exposure. **A,** Incisions include a central external auditory canal core, which is sutured closed. Extend incision as needed for neck dissection or temporal muscle rotation flap. Note that the tragus can be preserved for better cosmesis. **B,** Canal closure, mastoidectomy, and epitympanic dissection have been completed.

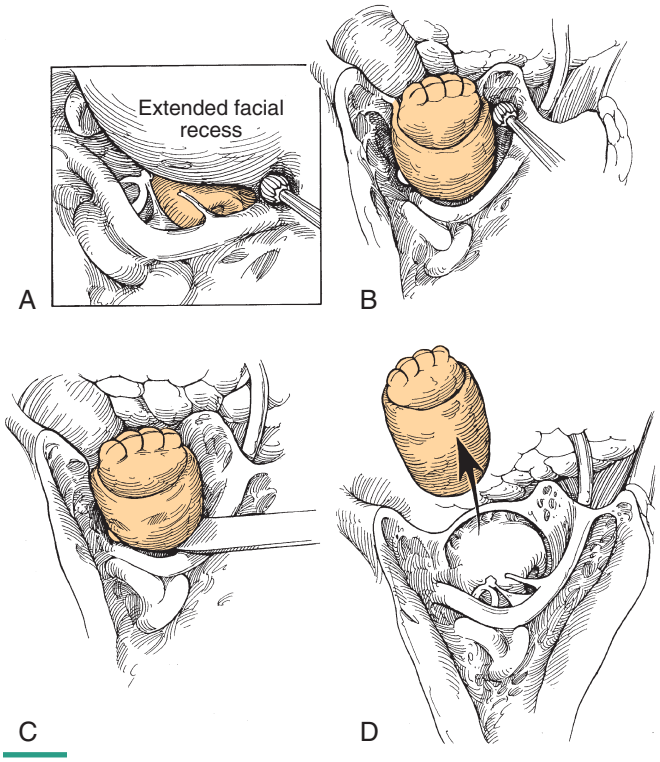

Figure 176-5. Lateral temporal bone resection: specimen delivery. **A,** Extended facial recess dissection. **B,** Hypotympanic dissection. **C,** Specimen fractured with osteotome. **D,** Specimen separated from soft tissue.

A modified neck dissection, total parotidectomy, and partial mandibulectomy may be performed if indicated by perioperative radiologic studies or intraoperative findings.

Mastoidectomy and Facial Recess Approach

A complete mastoidectomy is performed. The superior mastoid dissection is carried to the root of the zygoma, with care taken not to penetrate the osseous portion of the external auditory canal or the tegmen. Epitympanic dissection in an anterior direction should extend into the temporomandibular joint, as depicted in Figure 176-4B. An extended facial recess approach is then performed by "eggshelling" the vertical segment of the facial nerve from the second genu to the stylomastoid foramen (Fig. 176-5A). The incudostapedial joint is separated, and the pillar of bone between the facial recess approach and the fossa incudis also is removed. The tensor tympani tendon is cut with Bellucci scissors. Hypotympanic dissection is performed by extending the facial recess approach through the chorda tympani nerve. Drilling with either a diamond or cutting burr is continued along the inferior aspect of the hypotympanum medial to the annulus and lateral to the jugular bulb and carotid canal until soft tissue is reached, with care taken not to injure the intraparotid facial nerve (see Fig. 176-5B).

Removal of Specimen

Continuity between the hypotympanic dissection and the anterior epitympanic dissection is established by drilling along the anterior mesotympanum into the temporomandibular joint or by fracturing with a curved osteotome (see Fig. 176-5C). Either cautery or sharp dissection is used to separate the bony anterior canal wall from soft tissue of the temporomandibular joint and the superficial lobe of the parotid. The specimen then is sent en bloc for histopathological examination (see Fig. 176-5D).

Closure

If ancillary procedures such as parotidectomy or mandibular resection are not performed and if postoperative radiotherapy is not anticipated, creation of a large mastoid cavity is acceptable. The eustachian tube orifice should be obliterated with temporalis fascia as in a radical mastoidectomy. The mesotympanum and facial ridge may be covered with temporalis fascia graft to facilitate healing. Further conchal bowl cartilage may need to be removed to create a large meatoplasty. A split-thickness skin graft is then sutured to the edges of the conchal bowl and anterior facial skin or tragal skin and allowed to drape into the mastoid cavity and anterior cavity soft tissue. The skin graft then can be tacked into place with absorbable sutures along the soft tissue areas. Use of a graft will minimize postoperative meatal stenosis.[72] Absorbable gelatin then can be placed on the medial aspect of the mastoid cavity, followed by packing with gauze strips.

If postoperative irradiation is anticipated, the mastoid cavity should be obliterated to avoid osteoradionecrosis.[73] This may be achieved with use of abdominal fat and rotation of a temporalis graft to cover the defect. Alternately, a superiorly based sternocleidomastoid muscle flap based on the occipital artery may be rotated by incising the sternocleidomastoid muscle at the clavicle. A skin graft then is sutured to the conchal bowl margins and tacked down to underlying muscle.

Subtotal Temporal Bone and Total Temporal Bone Resections

A subtotal temporal bone resection[70,74-84] essentially allows en bloc resection of the medial surfaces of the mesotympanum, leaving the air cells of the petrous apex and portions of the bony labyrinth (see Fig. 176-3). This type of resection is indicated for patients with malignancies involving the middle ear.

A total temporal bone resection involves an en bloc resection of the temporal bone, including the petrous apex and the sigmoid sinus

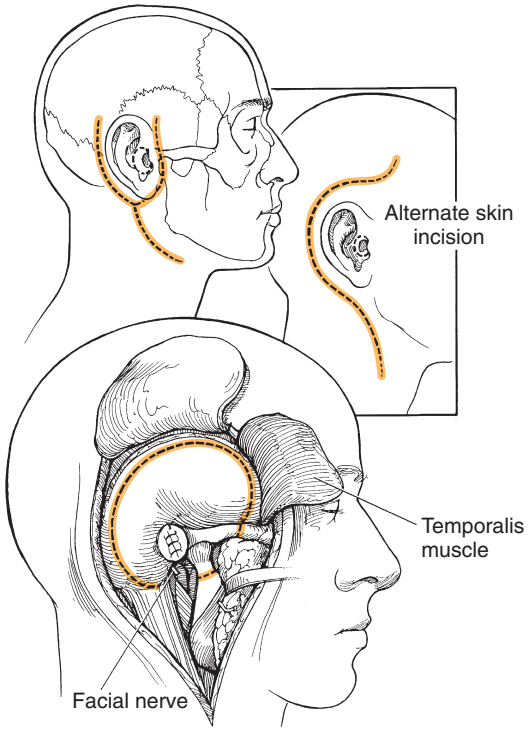

Figure 176-6. Subtotal temporal bone resection. Incisions include a central external auditory canal core, which is sutured closed. Note the tragus can be preserved for better cosmesis. Temporal craniotomy for subtotal temporal bone resection is smaller than for a total temporal bone resection. Parotid gland with main trunk of facial nerve has been elevated from masseter muscle.

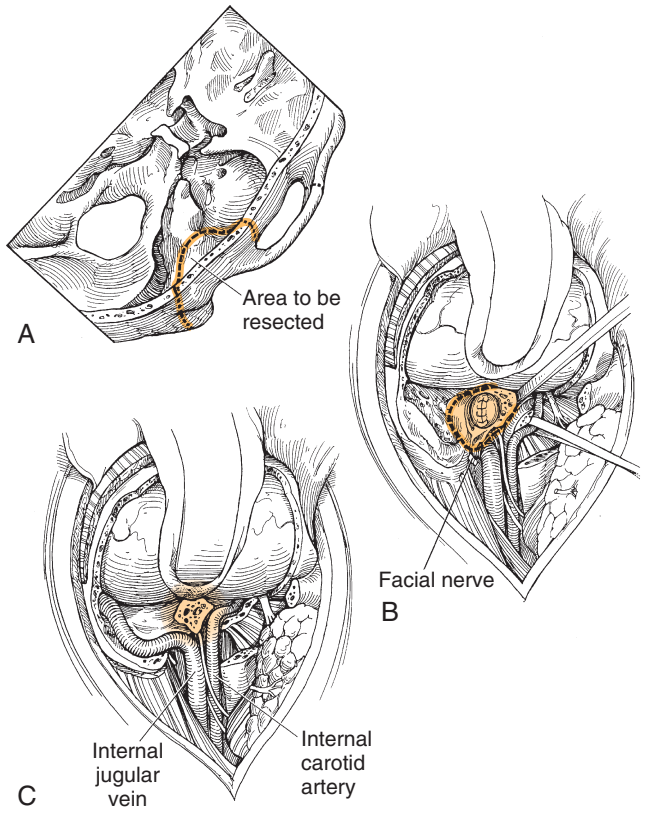

Figure 176-7. Subtotal temporal bone resection. **A,** Bird's-eye view of proposed resection. Note the facial nerve can be exposed for clean sectioning in the labyrinthine segment. **B,** Osteotome at carotid canal first genu directed at internal auditory canal fundus. **C,** Specimen removed showing remaining petrous apex and otic capsule. Roman numerals denote cranial nerves.

(see Fig. 176-3). The petrous internal carotid artery may be included in this resection. Total temporal bone resection is of questionable added benefit if a high-grade tumor involves the petrous apex or internal carotid artery or extends outside of the petrous bone intradurally or toward the cavernous sinus. Total resection may be indicated for low-grade malignancies.[83]

Incision

A large C-shaped postauricular incision or Y-shaped incision can be designed with a central island removed (Fig. 176-6). Alternately, a preauricular incision may be used for cases with involvement of the external auditory canal. In performing the incision, care should be taken to preserve the greater auricular nerve, because this nerve may be used for facial nerve interposition grafting. Also, care should be taken in elevating the flap off the zygoma, so as to not injure the peripheral frontal branch of the facial nerve.

Facial Nerve Management

With parotid involvement or involvement of the facial nerve, the distal branches or main trunks of the facial nerve may be identified and transected and marked for future interposition grafting. If no such involvement is present, the facial nerve is identified at the stylomastoid foramen and transected. The parotid is carefully dissected off the masseter. Proximal facial nerve management is considered later.

Proximal Vascular Control, Neck Dissection

If preoperative imaging indicates lymphadenopathy, a supraomohyoid modified neck dissection can be performed. Regardless of lymph node involvement, proximal vascular control of the carotid artery and internal jugular vein can be obtained, and vascular loops are placed around these vessels. The lower cranial nerve, internal carotid artery, and internal jugular vein can be followed superiorly. The sternocleidomastoid muscle is separated from the mastoid tip, as is the digastric muscle.

Infratemporal Fossa Dissection

The masseter attachment to the zygoma is detached. A mandibular osteotomy is performed from the mandibular notch to the angle of the mandible. The mandibular condyle is separated from the glenoid fossa, detaching the lateral and medial pterygoid musculature, with care taken not to injure the internal maxillary artery. Should the internal maxillary artery be injured, brisk back-bleeding would indicate good blood flow from the pterygoid plexus, presaging a viable temporalis muscle useful for reconstruction. The temporalis muscle is elevated off the skull in a subperiosteal fashion and reflected inferiorly, still attached to the coronoid process. A superior infratemporal fossa dissection should allow identification of the foramen spinosum and foramen ovale.

Temporal Craniotomy

A temporal craniotomy is performed to allow exposure of the superior surface of the petrous bone. A larger craniotomy is performed for a total temporal bone resection. The dura is elevated off the petrous bone, proceeding from posterior to anterior.

Subtotal Temporal Bone Resection

The vertical petrous portion of the internal carotid artery is identified (Fig. 176-7). This resection is performed by drilling with diamond burrs through the glenoid fossa and across the eustachian tube orifice. Mobilization of the carotid is just distal to the first genu. The distal eustachian tube orifice should be either sutured or closed with autologous tissue.

Delineation of the Sigmoid Sinus and Jugular Bulb

Presumably, if a subtotal temporal bone resection has been selected, the mastoid air system is not involved in patients with carcinoma. A mas-

toidectomy is performed, removing the mastoid cortex with cutting burrs. The sigmoid sinus and jugular bulb are carefully delineated with diamond burrs, and the jugular bulb is carefully dissected from the temporal bone, with recognition that the inferior petrosal veins enter it inferomedially. The sigmoid sinus may require ligation or extradural packing for vascular control later in the procedure.

Proximal Facial Nerve Management

Although an osteotomy may be performed at this point, with sectioning of the proximal facial nerve during an often bloody dissection, it probably would cause further stretch injury to the facial nerve. If grafting of the facial nerve is desired, further stretch injury is best avoided. The facial nerve may be delineated from the labyrinthine segment to the internal auditory canal as with routine middle cranial fossa nerve decompression or may be identified by a translabyrinthine approach (see Fig. 176-7A). Nonetheless, clean sectioning of the facial nerve facilitates interposition grafting and later facial nerve function.

Osteotomy

A groove may be drilled along the floor of the middle fossa connecting the glenoid fossa area, lateral internal auditory canal, and posterosuperior mastoid. An osteotome is inserted into the carotid canal just distal to the first genu and pointed toward the internal auditory canal (see Fig. 176-7B). The temporal bone specimen is brought out (see Fig. 176-7C), which often will result in inferior petrosal sinus bleeding, requiring intraluminal packing of the inferior petrosal sinus with oxidized cellulose or control of the jugular bulb and sigmoid sinus.

Total Temporal Bone Resection

The internal carotid artery is dissected to the foramen lacerum (Fig. 176-8). The vessel may have been permanently occluded perioperatively in accordance with the surgical plan. The internal jugular vein is ligated and cut. A suboccipital craniotomy is performed, extending over the transverse sinus and lateral posterior fossa. The dura is divided over the cerebellum, and the transverse sinus is ligated between the vein of Labbé and the superior petrosal sinus. The tentorium is divided from the lateral sinus across the superior petrosal sinus to the inferior edge of V_3 with continued dural incision along the floor of the middle cranial fossa laterally. Cranial nerves VII and VIII and the labyrinthine artery are divided at the internal carotid artery. Cranial nerves IX, X, and XI are divided intradurally. The inferior dural incision along the clivus extends from Meckel's cave caudal to the lower cranial nerve to the postsigmoid dural edge. An osteotome is inserted just posterior to the foramen ovale and directed slightly posteriorly to avoid entering the foramen lacerum. This will release the temporal bone specimen, with the occasional need for osteotomy just above the jugular bulb to separate the petro-occipital synchondrosis.[84,85] Alternatively, a groove is drilled under direct vision through the posterior fossa to connect to an externally drilled groove posterior to the petrous internal carotid artery.[83]

Reconstruction

The facial nerve and other appropriate cranial nerves can be cable grafted. Dural defects are closed as needed with fascia or pericranium. The temporalis muscle can be rotated and sutured to surrounding soft tissue. Alternately, regional or free flaps are used. Craniotomy bone and zygoma are secured with wire or miniplates. A closed suction drain then is placed before skin closure.

Infratemporal Fossa Approaches

Attacking various problems of the skull base through a lateral approach transgresses the temporal bone and infratemporal fossa. The postauricular infratemporal fossa approaches as described by Fisch[61,86-88] and the preauricular[89-92] approaches offer the best access to the jugular bulb, internal carotid artery, petrous apex, clivus, pterygomaxillary fossa, and nasopharynx. Proponents of these approaches have written extensively on the subject, and the techniques described here have been adapted from their work. Anatomic maneuvers may be added as needed to facilitate tumor exposure and extirpation.[93,94]

Postauricular Approaches to the Infratemporal Fossa

Fisch[61] has been the primary innovator of these techniques and should be credited for his work. He has divided these techniques into three basic approaches: *Type A* dissection entails radical mastoidectomy, anterior transposition of the facial nerve, exploration of the posterior infratemporal fossa, and cervical dissection permitting access to the jugular bulb, vertical petrous carotid, and posterior infratemporal fossa. *Type B* dissection explores the petrous apex, clivus, and superior infratemporal fossa. *Type C* allows exposure of the nasopharynx, peritubal space, rostral clivus, parasellar area, pterygopalatine fossa, and anterosuperior infratemporal fossa.

Incisions and Skin Flaps

The planned incision should allow for further extensions without devascularization of the elevated skin flap (Fig. 176-9A). Cervical exposure to a variable extent and anterior extension for dissection toward the clivus and parasellar area should be permitted. Keeping the inferior limb of the incision in a posterior location over the mastoid tip allows extension into the cervical area for dissection while protecting the marginal mandibular nerve. Similarly, extending the incision anterosuperiorly into the frontal area permits elevation over the zygoma to the orbital rim.

The flap should be elevated superficially to the temporalis and postauricular muscles, leaving a periosteal flap based on the external auditory canal (see Fig. 176-9B). The canal is transected with care to protect the branches of facial nerve anterior to the canal.

The plane of dissection in an anterior direction is in the subcuticular tissue over the temporal, parotid, and cervical areas. In the type A approach, the tertiary branches of the facial nerve are identified and protected, whereas in the type B and type C approaches, the frontal branch is exposed and protected near the lateral orbital rim.

Closure of the External Auditory Canal

The external auditory canal is closed in a watertight blind sac. The cartilaginous canal skin is undermined to approximately the level of the conchal bowl with tenotomy scissors. The cartilaginous canal skin then is everted and sutured with absorbable sutures and reinforced medially with the periosteal flap elevated off the mastoid cortex (see Fig. 176-9C to F).[96]

Removal of External Auditory Canal Wall Skin and Tympanic Membrane

The skin of the osseous portion of the external auditory canal wall is elevated circumferentially down to the annulus. With an operating microscope, the tympanic annulus is elevated, the incudostapedial joint is separated, the tensor tympani tendon is cut, and the neck of the malleus is nipped, allowing total removal of the canal wall skin, tympanic membrane, and attached manubrium (Fig. 176-10).

Cervical Dissection

Cervical dissection is done as needed to expose the inferior margins of the tumor. This part of the procedure is not required in most type B and type C approaches, except to gain cervical control of the vascular structures if needed. The greater auricular nerve should be sectioned as distally as possible in the parotid for potential use as an interposition graft if needed. Major structures, including the common, external, and internal carotid arteries, the internal jugular vein, and cranial nerves IX to XII, are identified (Fig. 176-11). Division of the posterior belly of the digastric near the mastoid facilitates identification of these structures up to their entrance in the skull base. Ligation of the occipital artery and ascending pharyngeal artery is indicated when these vessels prove to be the vascular supply to the tumor on arteriography. Transection of the glossopharyngeal nerve often is necessary to follow the carotid artery into the skull base. Vascular loops are placed around the internal carotid artery and jugular vein for quick identification and control in the event of bleeding (see Fig. 176-11).

Extratemporal Facial Nerve Dissection

The extratemporal facial nerve may be located deep to the midpoint of a line between the tragal pointer cartilage and the mastoid tip. After

release of parotid tissue from the sternocleidomastoid muscle, the tragal cartilage is dissected medially, identifying the facial nerve just inferior to the pointer. The facial nerve is dissected out to tertiary branches by cutting overlying the parotid gland and freeing it from the underlying parotid tissues. This exposure is required for anterior transposition in the type A approach (see Fig. 176-11). In the type B and type C approaches, facial nerve transposition is not required; only the frontal branch is followed distally to allow its preservation when the zygoma is transected. The parotid gland is bluntly dissected off the masseteric fascia to reduce traction on the facial nerve when the mandible is retracted.

Radical Mastoidectomy

The radical mastoidectomy removes the air cell tracts lateral and adjacent to the otic capsule (Fig. 176-12A). Exenteration of all tracts is important to prevent long-term complications after cavity obliteration.[96] The stapes suprastructure is removed to prevent inner ear trauma. The facial nerve is skeletonized in preparation for transposition. The eustachian tube is obliterated with bone wax impregnated with bone dust and a muscle plug. Removal of the external auditory canal, tympanic membrane, ossicles, and air cells of the temporal bone lateral to the otic capsule constitute the radical mastoidectomy.

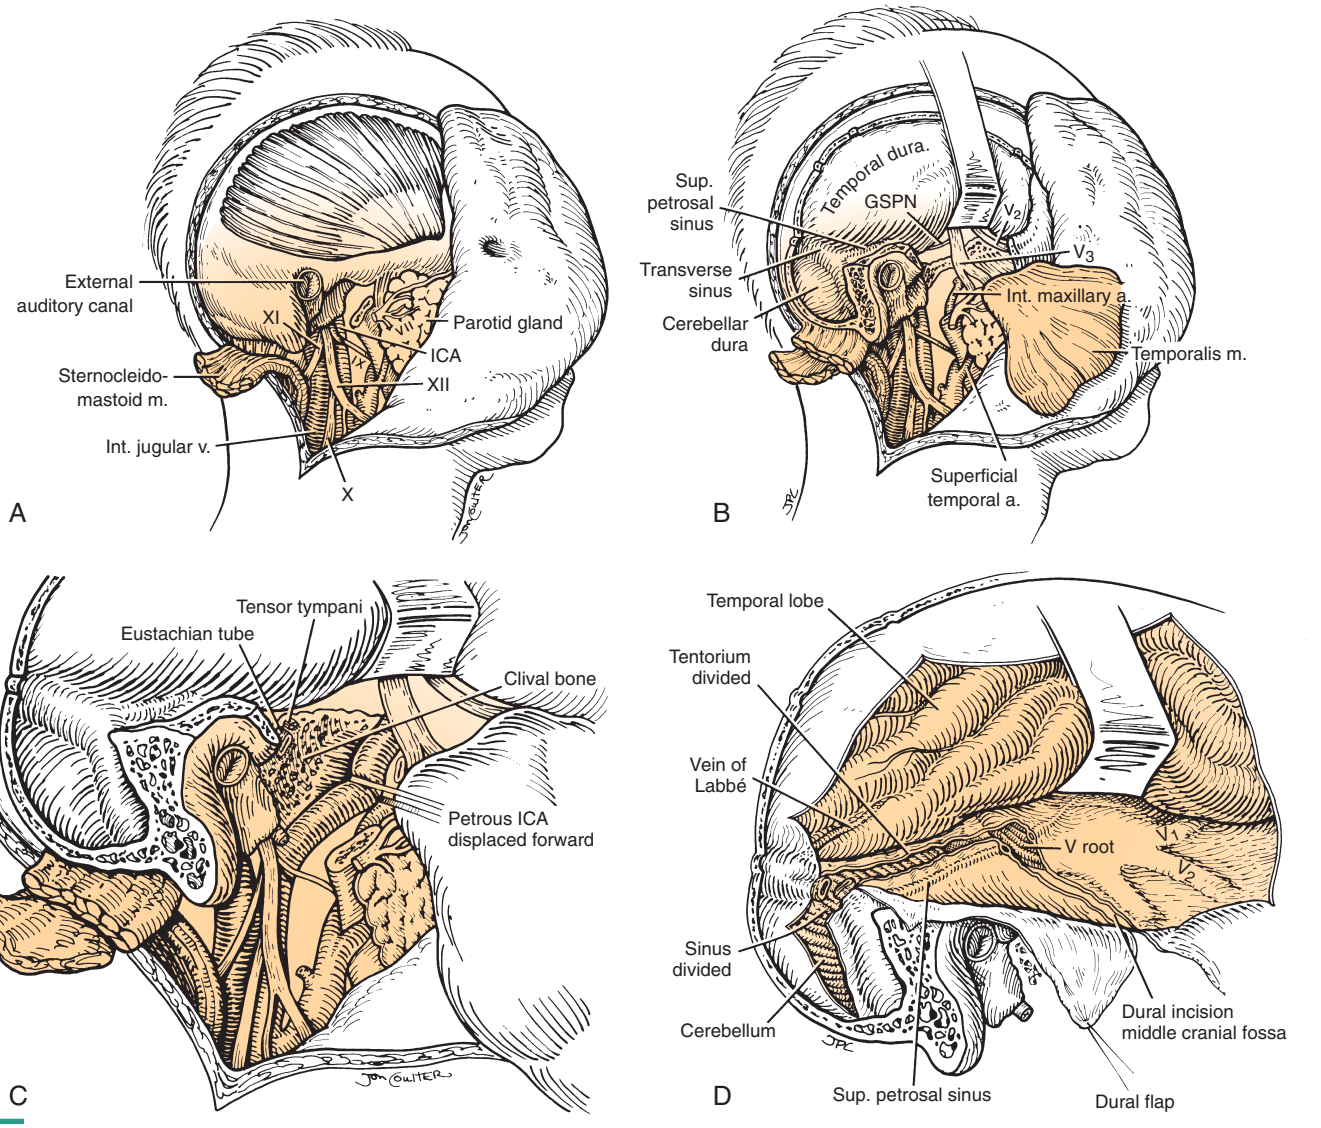

Figure 176-8. Schematic depiction of total temporal bone resection. Roman numerals denote cranial nerves. **A,** The frontotemporal-retroauricular-cervical skin flap is rotated forward. The external ear canal has been transected. The facial nerve has been transected just beyond the stylomastoid foramen. The temporomandibular joint has been opened and the mandibular ramus resected. Cranial nerves IX through XII and the jugular and carotid vessels are exposed to the neck. **B,** A temporal and suboccipital craniotomy has been extended over the transverse sinus and lateral posterior fossa. A zygomatic osteotomy and a partial mastoidectomy have been performed. The osseous middle fossa floor has been partially resected to expose second (V_2) and third (V_3) divisions of the cranial nerve V and the greater superficial petrosal nerve (GSPN). The middle meningeal artery has been transected. **C,** Continuing resection of the osseous middle fossa floor; the eustachian tube and the tensor tympani muscle have been transected. The ascending and transverse segments of the petrous ICA have been unroofed, and the ICA has become mobilized anteriorly. **D,** The temporal and retrosigmoid portions of the dura have been opened. The lateral sinus has been ligated at its junction with the sigmoid; the tentorium has been opened along the inferior edge of the mandibular nerve, trigeminal ganglion, and roof, with the interruption of the superior petrosal sinus. If the superior petrosal sinus is uninvolved, its drainage into the transverse sinus may be preserved by changing the dural incision lines. The dura has been cut over the cerebellum; the transverse sinus has been ligated and transected, and a dural flap has been brought down from over the temporal lobe. The tentorium has been divided from the transverse sinus transection, alongside and behind the petrous ridge, and anteromedially across the sinus. This cut has been connected to an incision in the dura on the middle cranial fossa floor anterior to the petrous base. The outline of the trigeminal ganglion and roots can be seen through the middle fossa dura.

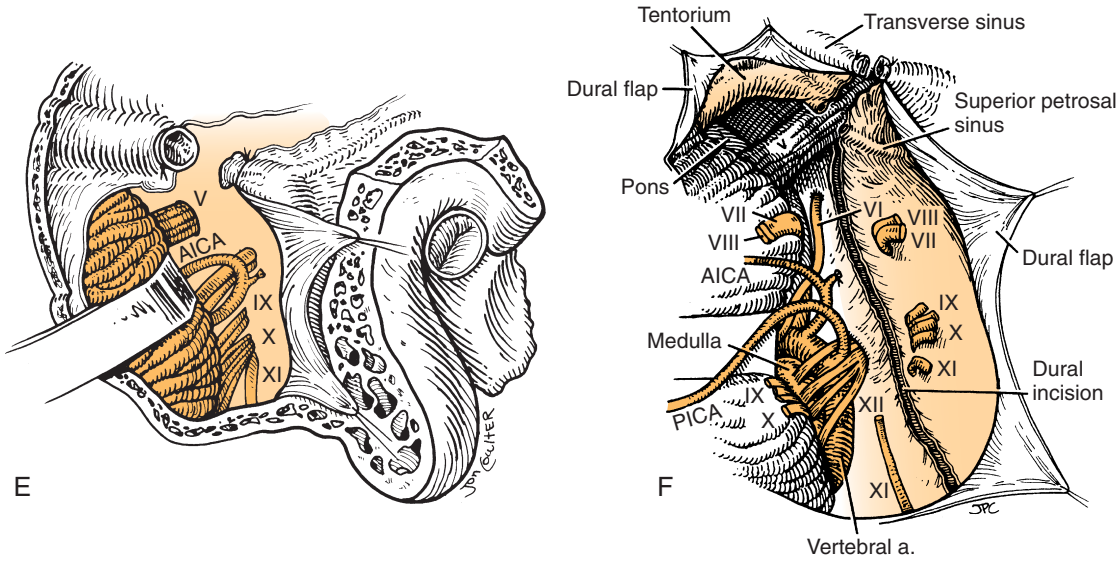

Figure 176-8, cont'd. **E,** With the cerebellum retracted medially, cranial nerves V and VII through XI can be seen. The labyrinthine (internal auditory) artery has been transected at its origin from the anterior inferior cerebellar artery (AICA). **F,** Cranial nerves VII through XI have been transected, and the underlying dura has been incised as the posterior border of the en bloc resection of the petrous bone. The petrous bone specimen then is disconnected from any remaining attachments and removed. ICA, internal carotid artery; PICA, posterior inferior cerebellar artery. *(Used with permission from Sekhar LN, Pomeranz S, Janecka IP, Hirsch B, Ramasastry S. Temporal bone neoplasms: a report on 20 surgically treated cases.* J Neurosurg. *1992;76:578-587.)*

Type A Approach

FACIAL NERVE TRANSPOSITION. The facial nerve should be skeletonized and freed of its bony canal 180 degrees circumferentially from the geniculate ganglion distal to the stylomastoid foramen. The horizontal semicircular canal is in jeopardy at the second genu, and bone should be removed only on the tympanic side of the facial nerve. The air cells of the mastoid tip are exenterated lateral to the digastric ridge; the cortical shell is removed with a rongeur after incising the attached digastric muscle. At the stylomastoid foramen, the facial nerve is densely adherent to the surrounding fibrous tissue, and these tissues are elevated as a unit to prevent devascularization and stretch injury to the nerve. A new bony canal is drilled in the anterior wall of the epitympanum to receive the nerve. The facial nerve is elevated carefully from the geniculate ganglion to the pes anserinus and is transposed into the new groove and secured within the parotid soft tissue (see Fig. 176-12B).

Meticulous handling of the facial nerve decreases the risk of permanent facial nerve dysfunction after transposition. Use of the operating microscope, diamond burr, and constant irrigation minimizes direct trauma. The epineurium is kept intact. The stapedius nerve, the soft tissue of the stylomastoid foramen including periosteum and enclosed facial nerve, and all medial attachments to the nerve should be sharply dissected to prevent stretch injury.

Intraoperative facial nerve monitoring with EMG is of great benefit during transposition in preventing injury (see Chapter 178).[80]

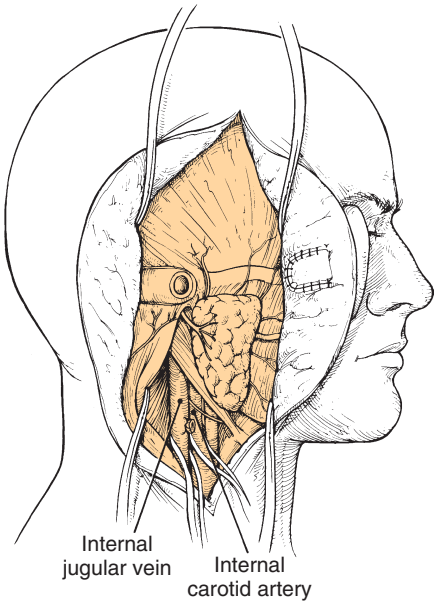

Figure 176-11. Preparatory dissection with flap elevation and proximal vascular control.

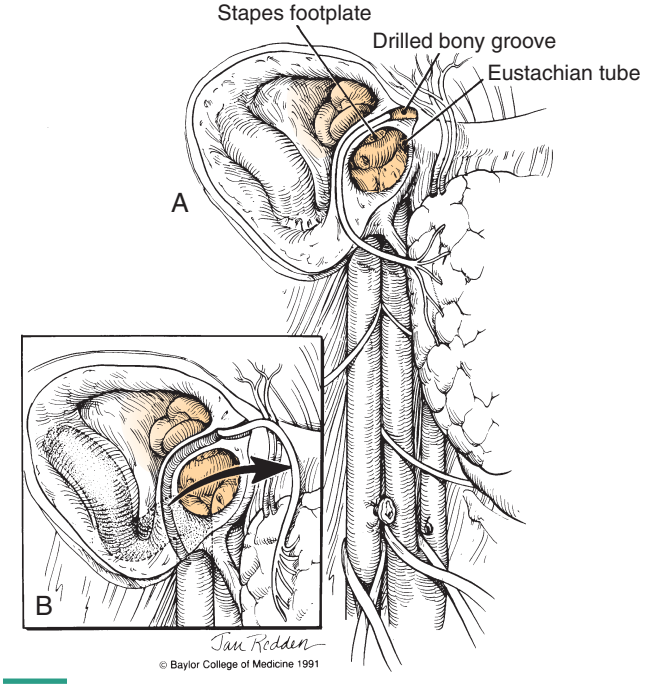

Figure 176-12. **A,** Radical mastoidectomy with facial nerve skeletonization. **B,** Anterior transposition of the facial nerve.

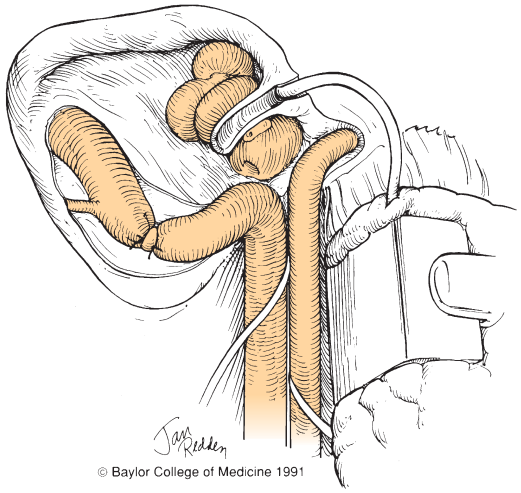

Figure 176-14. Fisch type A infratemporal fossa exposure and vascular control completed by removal of bone over carotid artery and jugular bulb.

Immediate feedback is available to the surgeon during manual manipulations, helping prevent direct trauma and stretch injury, the latter being the most common reason for postoperative dysfunction. With feedback monitoring, the surgeon can remove bone over the facial nerve more aggressively.

OCCLUSION OF THE SIGMOID SINUS. Bone is removed over the posterior fossa dura anterior and posterior to the sigmoid sinus to allow ligation. The mastoid emissary vein is left undisturbed, and ligation is performed below it if possible. Dural vessels are coagulated; the dura is elevated with dural hooks, incised in front of and behind the sigmoid sinus, and a blunt-tipped aneurysm needle is used to pass a double 2-0 silk ligature (Fig. 176-13A to C). A small CSF leak may occur and is easily controlled with a sutured muscle plug. Other methods of sigmoid sinus interruption, involving intraluminal absorbable packing (see Fig. 176-13D), are used by Jackson[97] and Holliday[98] and their coworkers.

EXPOSURE OF JUGULAR BULB AND INTERNAL CAROTID ARTERY. A clamp is passed medial to the styloid process to protect the internal carotid artery while the process is fractured and removed with the attached muscles. The parotid gland is dissected from the tympanic bone, and a modified self-retaining laminectomy retractor (Karl Storz, D-7200, Tuttlingen, Germany) is placed behind the ramus of the mandible to effect anterior subluxation. The facial nerve EMG activity is monitored to avoid stretch injury or compression of branches in the parotid gland. Exposure of the posterior infratemporal fossa now permits isolation of the vertical intrapetrous segment of the internal carotid artery. With removal of bone over the carotid artery and beneath the otic capsule, the jugular fossa is exposed for tumor removal (Figs. 176-14 and 176-15).

TUMOR REMOVAL. After exposure and distal control of the internal carotid artery are accomplished, the tumor may be carefully

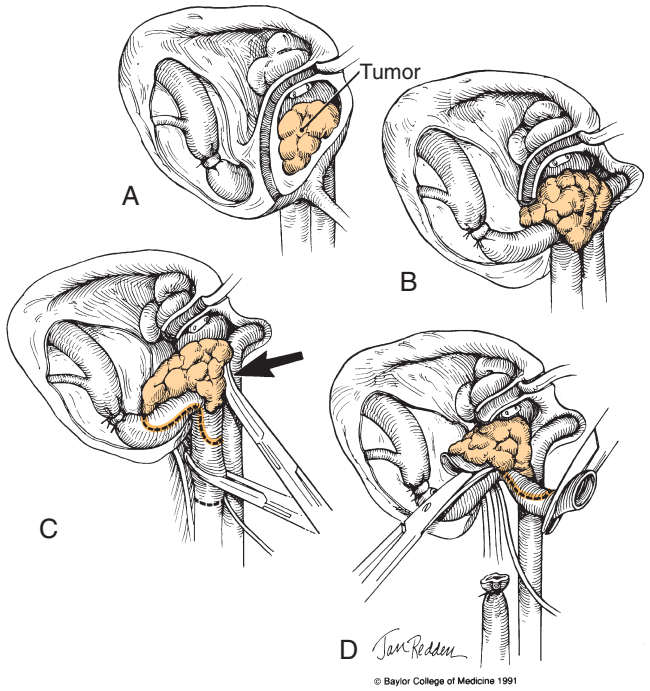

Figure 176-15. **A** to **D,** Removal of paraganglioma of the jugular bulb using the Fisch type A infratemporal fossa approach.

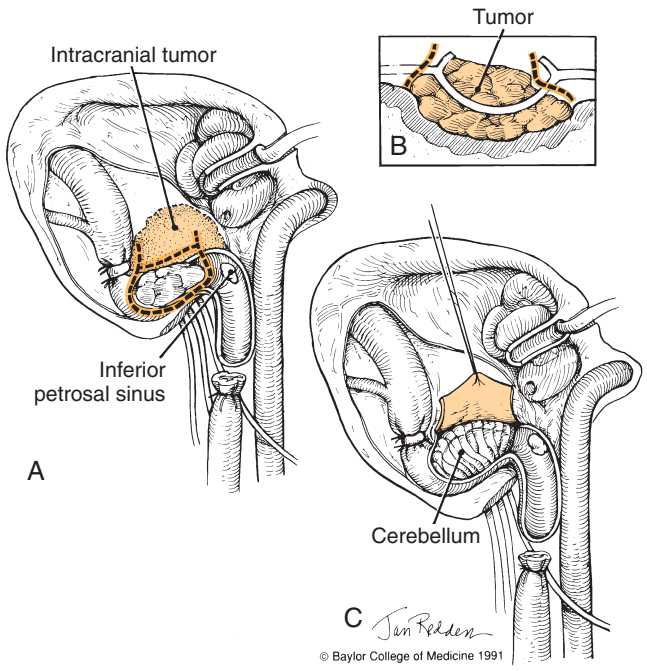

Figure 176-16. **A** and **B,** Intracranial paraganglioma extension into posterior fossa. **C,** Intracranial paraganglioma removed.

removed.[95,99] The jugular vein is ligated to prevent tumor and air embolism. Dissection begins by freeing the internal carotid artery and rotating the tumor posteriorly (see Fig. 176-15C). The lateral wall of the sigmoid sinus is removed along with intraluminal tumor (see Fig. 176-15D). The medial wall forms the barrier to the CSF. The inferior margin of the tumor is elevated, and the extracranial tumor is removed (see Fig. 176-15D). If the tumor extends intracranially, it is amputated sharply at this point. Profuse bleeding may occur from the entrances of the inferior petrosal sinus into the jugular bulb. Control is achieved by surgical packing.

After hemostasis is obtained, the posterior fossa dura is opened, and the intracranial portion of the tumor is excised (Fig. 176-16) at the same setting for intracranial tumors smaller than 2 cm. Larger tumors may be staged and removed at a later time.[100,101] Care should be taken to preserve the blood supply to the brainstem.

CLOSURE OF WOUND. The dura usually is left with a defect too large for primary closure. Fascia lata provides the best material for reconstruction, although lyophilized dura can be used to seal the defect. Abdominal fat is used to obliterate the dead space of the temporal bone, and the temporalis muscle is rotated inferiorly for reinforcement of the wound (Fig. 176-17). The skin is closed routinely, and a bulky pressure dressing is applied for a minimum of 5 days to prevent leakage of CSF.

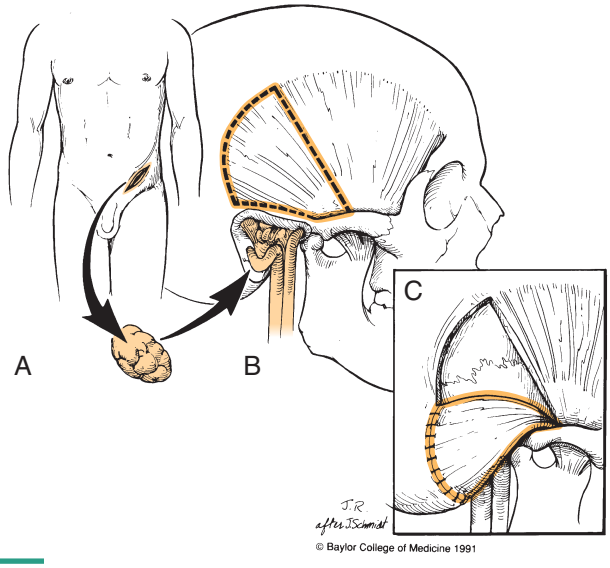

Figure 176-17. **A** to **C,** Obliteration of wound defect with abdominal fat and rotated temporalis muscle.

Type B Approach

The type B approach differs from the type A approach with respect to the facial nerve in that transposition of the nerve usually is not required. The steps up to transposition are identical to those for the type A approach. Reflection of the temporalis muscle still attached to the coronoid process and the zygoma allows the retractor to expose the superior infratemporal fossa (Fig. 176-18, A to C). Monitoring of facial nerve EMG activity during mandibular displacement helps prevent stretch injury. The limits of operative exposure in the type B approach are defined by the middle cranial fossa floor, mandibular condyle, and reflected temporalis muscle (see Fig. 176-18D).

Thinning bone under the MCF dura improves exposure. The middle meningeal artery and V_3 branch of the trigeminal nerve require bipolar cauterization and transection, respectively, thereby giving exposure to the superior 4 cm of the infratemporal fossa. The carotid artery may be uncovered from its vertical segment to its anterior limit at the foramen lacerum after separation from the soft tissues around the eustachian tube (Fig. 176-19A). The geniculate ganglion of the facial nerve and cochlea may be prone to injury if not properly recognized.

Petrous apex lesions, such as cholesteatoma or low-grade chondrosarcomas, may be removed at this point with careful anterolateral retraction of the internal carotid artery. The artery can be elevated from the foramen lacerum to the canalis caroticus to permit temporary transposition of the vessel (Fig. 176-20B). This maneuver may easily result in hemorrhage and should be performed with care. Extensive benign lesions involving the petrous apex and perilabyrinthine area may require a transotic approach combined with posterior facial nerve transposition, accomplished by cutting the greater superficial petrosal nerve and by liberating the facial nerve from the porus acusticus to the stylomastoid foramen (see Fig. 176-20).[102,103] In addition, the middle fossa

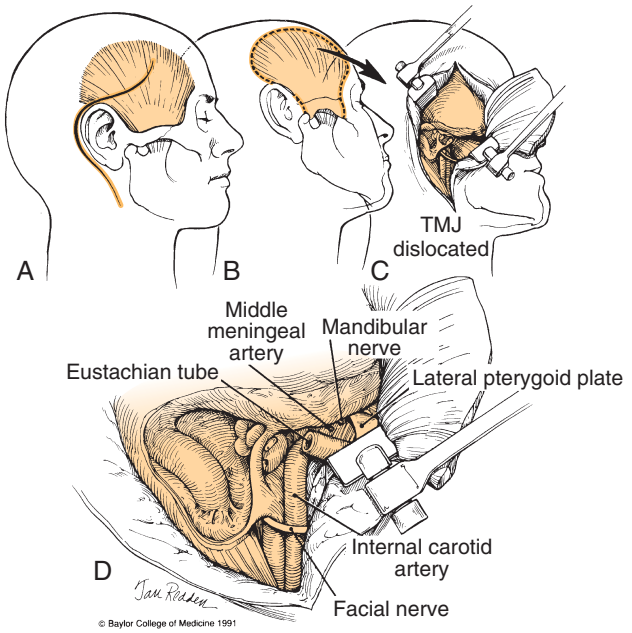

Figure 176-18. Fisch type B or C approach, incorporating the steps of the type A approach, as shown in Figures 176-9 through 176-12A. Note, however, that the intratemporal facial nerve is *not* skeletonized.) **A** to **C,** Dissection also includes transection of zygoma, elevation of the temporalis muscle and periosteum of skull base, and self-retaining retractor dislocation of the mandible inferiorly. **D,** Bone is removed to identify the middle meningeal artery and V_3 (transected here). TMJ, temporomandibular joint.

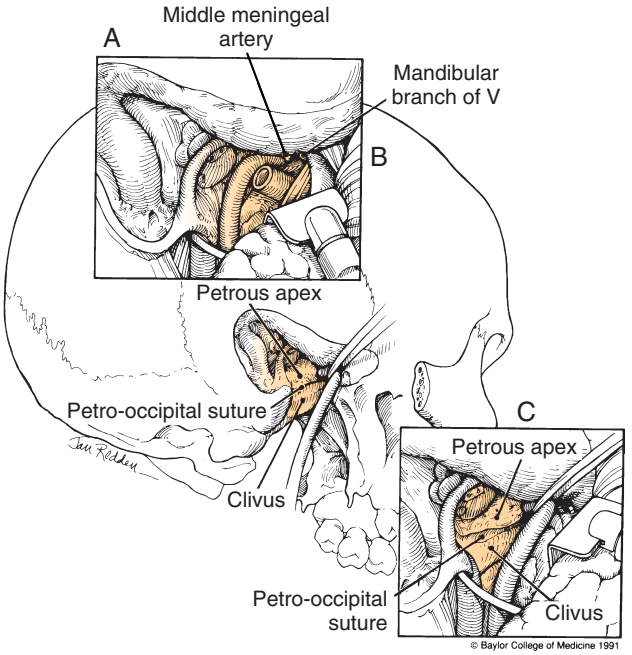

Figure 176-19. **A,** Removal of the eustachian tube permits access to the internal carotid artery up to the foramen lacerum. **B** and **C,** Elevation of the carotid artery permits additional access to the petrous apex and clivus.

may easily be accessed through a temporal craniotomy (see Chapter 174). Exposure of the clivus can be obtained by sharp incision of the fibrous attachments at the petro-occipital fissure. Tumors of the clivus, such as chordomas, up to the parasellar area may be removed through the type B approach (see Fig. 176-19C). Removal of the mandibular

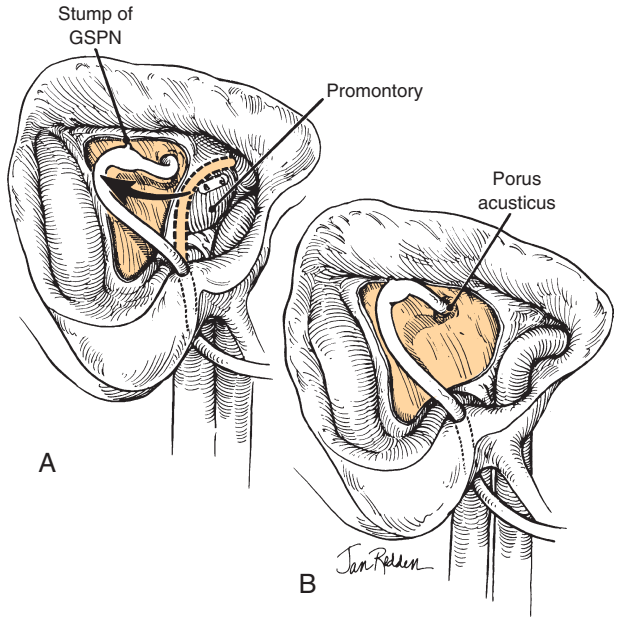

Figure 176-20. Transcochlear approach to the petrous apex. **A,** Posterior translocation of the facial nerve. GSPN, greater superficial petrosal nerve. **B,** Subtotal petrosectomy with removal of the otitic capsule.

condyle may give better exposure to the inferior clivus and upper cervical vertebrae. With inferior extension of the tumor, the facial nerve may be transposed as in a type A approach. Tumors located superior or medial to the horizontal portion of the internal carotid artery may require further mobilization of the cervical and vertical petrous carotid or the addition of a middle cranial fossa craniotomy. The superior and inferior petrosal sinuses may require removal in these extended dissections.

Type C Approach

The type C approach is an anterior extension of the type B approach. The type C infratemporal fossa approach permits posterolateral access to the rostral clivus, cavernous sinus, sphenoid sinus, peritubal space, pterygopalatine fossa, and nasopharynx and to the areas exposed by the type B approach. The type C infratemporal fossa approach, in essence, permits access anterior to the foramen lacerum up to the posterior aspect of the maxillary sinus and nasopharynx.

The base of the pterygoid process is removed to approach the sphenoid sinus and cavernous sinus (Fig. 176-21). Removal of the pterygoid base uncovers V_2 in the foramen rotundum and the inferior orbital fissure. Removal of bone from the pterygoid base permits better visualization of the sphenoid sinus; with the sinus exposed, the floor of the sella turcica can be visualized. The cavernous sinus is exposed by thinning the bone of the middle cranial fossa floor anterior to the V_2 stump. The middle cranial fossa dura may be retracted, giving an inferolateral view of the cavernous sinus.

To enter the lateral nasopharyngeal cavity, the lateral and medial pterygoid processes are removed, and the buccopharyngeal fascia and nasopharyngeal mucosa are incised. Separation of the pterygoid muscles from the mandible allows en bloc removal of the lateral nasopharyngeal wall, peritubal space, and superior infratemporal contents when needed for tumor extirpation (Fig. 176-22).

Tumors involving the pterygopalatine space require resection of the pterygoid process and a portion of the greater wing of the sphenoid with sacrifice of the maxillary branch of the trigeminal nerve. A portion of the posterior maxillary wall may be removed for further access.

Preauricular Infratemporal Approach

The preauricular approaches to the skull base described by various investigators, including Sen and Sekhar and colleagues,[90-92,104] can

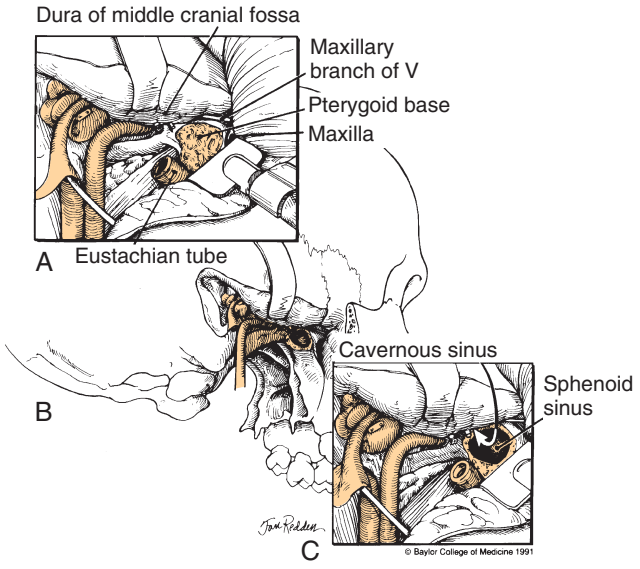

Figure 176-21. Fisch type C approach. **A,** Pterygoid base dissected with exposure of V_2. **B** and **C,** Sphenoid sinus entered.

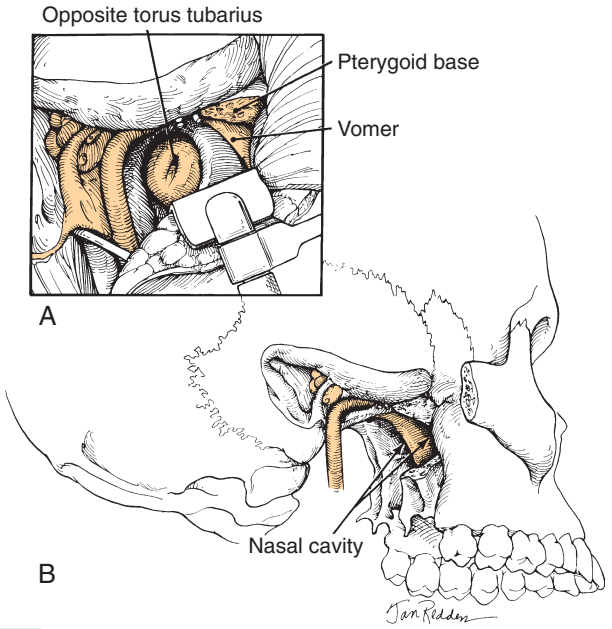

Figure 176-22. Fisch type C approach to nasopharyngeal exposure. **A** and **B,** Removal of pterygoid process and lateral wall of the nasopharynx exposing the opposite torus tubarius.

expose the upper cervical segment (without facial nerve transposition) and the intrapetrous segment of the internal carotid artery. These infratemporal dissections expose virtually the same areas as in the Fisch type B and type C approaches, albeit from a purely lateral vector of exposure. The preauricular approach permits access to the petrous apex, clivus, and superior infratemporal fossa and may be extended to include the nasopharynx, parasellar area, pterygopalatine fossa, and anterior infratemporal fossa. A frontotemporal craniotomy may be included for intracranial extension.[105] The petrous bone may be entered for access to the internal carotid artery, but the external auditory canal is not removed, and the tympanic cavity is not obliterated; therefore, the middle ear function is preserved, although the eustachian tube may be sacrificed, resulting in permanent serous otitis media. Although resecting the mandibular condyle in the preauricular approach facilitates the exposure of the internal carotid artery, such resection usually is not required in the postauricular approaches, because a posterior vector of orientation improves access.

The preauricular incision may be extended into the frontoparietal and upper cervical areas to expand exposure into the anterior infratemporal fossa (Fig. 176-23A). Identification and control of vascular structures in the neck are similar to those with the postauricular approaches. The superior cervical dissection is hindered by the facial nerve exiting the stylomastoid foramen to enter the parotid gland. Retraction of the mandible anteroinferiorly permits exposure of the upper cervical segment of the internal carotid artery (see Fig. 176-23B). Constant EMG monitoring during application of retractors greatly reduces the risk of facial nerve injury. Reflection of the temporalis muscles and zygoma as previously described for Fisch type B and type C approaches permits dissection of the anterior infratemporal fossa (see Fig. 176-23C).

The added time required for performance of a subtotal petrosectomy followed by obliteration is a disadvantage of the Fisch approach. Conductive hearing loss is inevitable, although transposition of the facial nerve, required in the type A approach, provides better access to the jugular fossa and the internal carotid artery at the skull base. The primary disadvantage of the preauricular approach is the inability to resect lesions extending into the temporal bone or posterior fossa.

Selected Problems

Rhabdomyosarcoma

A rhabdomyosarcoma is the most common childhood middle ear and mastoid malignancy. The recent spectacular improvement in 5-year

survival rates in patients with this disease has been achieved by several continued refinements of combined therapy: more accurate staging of parameningeal disease, adjustments of chemotherapeutic agents and dosage schedules, and advances in radiotherapy techniques.[95,106,107] Although total tumor removal is the surgical goal when possible, surgical debulking is an important concept in this disease. Gross total removal with preservation of the dura, otic capsule, and neurologic and vascular structures is performed, followed by postoperative chemotherapy and radiotherapy.

Carcinomas of the External Auditory Canal and Temporal Bone

Carcinomas and benign tumors of the external auditory canal and temporal bone are uncommon. Squamous cell carcinoma is by far the most common malignant tumor of the external auditory canal, followed by basal cell carcinoma and adenoid cystic carcinoma.[35,108-123] Carcinomas of the external auditory canal usually occur in persons 40 to 60 years of age, with some reports of carcinomas originating from cerumen glands somewhat earlier.

Pertinent Anatomy

The outer third of the cartilaginous portion of the external auditory canal contains all cerumen glands, which are modified sweat glands and sebaceous glands. The cartilage of the cartilaginous canal is J-shaped, being absent posteriorly. Anteriorly, the cartilage has small dehiscences known as the fissures of Santorini. The junction of the cartilaginous and osseous canal also permits radial spread.[124] The cartilaginous canal thus facilitates radial tumor extension. The osseous or medial two thirds of the external auditory canal for the most part is devoid of glandular tissue. The epithelium has no underlying subcuticular tissue and is closely adherent to the periosteum. The bone provides resistance to radial spread, so longitudinal spread toward the tympanic membrane is an early phenomenon. Radial spread through Huschke's foramen, a developmental defect in the tympanic ring, may permit anterior extension into the parotid. The tympanic membrane is thought to act as a barrier to longitudinal spread, although McCabe[125] has warned that microscopic extension around the annulus into the mesotympanum may occur even when the tympanic membrane is intact or grossly uninvolved. Entry of tumor into the middle ear space permits a myriad of paths of least resistance through air cell tracts and the eustachian tube.[126]

Symptoms and Signs

Carcinoma of the external auditory canal and temporal bone often will masquerade as chronic external otitis or chronic otitis. The frequency of these complaints in "routine" clinic patients has led to an average 6-month delay in diagnosis. Persistence of external otitis, despite adequate management by routine treatment measures, should increase suspicion for carcinoma and inflammatory processes as potential etiologic disorders, leading to biopsy. Persistent pain that is inordinately severe for the abnormality or a change in pain pattern with a chronically painful ear should precipitate further investigation. Some adenoid cystic carcinomas have been preceded by ear pain for several months before any abnormality is noted; therefore, serial examinations are important.

Squamous cell carcinoma may appear as a meaty or polypoid lesion in the external auditory canal. Adenoid cystic carcinoma usually is epithelium-covered and may appear as a small pimple, accompanied by complaints of significant pain. Basal cell carcinoma may exhibit serpiginous ulceration, with absence of the typically pearly edges because of characteristics of the thin, adherent canal epithelium. Hearing loss usually is conductive, from obstruction of the canal. Cochlear hearing loss and vertigo indicate labyrinthine involvement and an aggressive, advanced lesion. A parotid mass, cranial nerve paresis, and cervical lymphadenopathy also are late signs portending a grave prognosis. It is important to assess the nasopharynx to ascertain that a tumor does not originate from this area. Carcinomas of the external auditory canal should prompt close evaluation of the parotid gland, because the tumor may have originated from the parotid gland.

Figure 176-24. Squamous cell carcinoma of the right external acoustic canal in a 73-year-old woman: Axial view, computed tomography (CT) with bone algorithm. Only a focused bone algorithm CT scan would reveal the subtle bone erosion *(arrows)* associated with this carcinoma.

Staging

Planning management depends critically on preoperative evaluation. Thin-slice temporal bone CT, with soft tissue and bone protocols with intravenous contrast, will delineate the medial extent of disease and provide evidence of osseous erosion and some soft tissue detail[127] (Fig. 176-24). With extensive lesions or CT evidence of osseous erosions or soft tissue extension, MRI with gadolinium enhancement of the temporal bone, parotid gland, and upper neck will provide further soft tissue detail around the canal and intracranial involvement. Four-vessel carotid angiography and functional CBF assessment may be useful if extensive resections are indicated. An appropriate workup for metastatic disease also should be performed.

A system for staging carcinoma of the external auditory canal has been described by investigators from the University of Pittsburgh. Arriaga and Janecka[124] proposed a primary tumor–regional nodes–metastasis (TNM) staging system based on clinical examination, preoperative imaging studies, and intraoperative findings (Box 176-2). Of note, imaging may understage soft tissue extension seen intraoperatively. Other investigators have supported the clinical usefulness of this staging system.[128,129]

Management

In treating these carcinomas, the clinician should heed the admonition of Jesse and colleagues[130]: "One factor becomes painfully obvious, that the first treatment is the only one that has a chance of curing the patient, while subsequent treatment is simply palliative." For this reason, initial treatment by whatever modality chosen should be radical enough to eliminate the cancer. Consensus regarding management of carcinomas of the external auditory canal and temporal bone is not easily found in the literature, mainly because of the rarity of these lesions. Most series have one or two cases per year, extending over 2 decades or longer. Some of the larger series represent evolution of management philosophy, making critical analysis difficult. Authors often lump together all malignancies of the external auditory canal, regardless of histology, involvement of the middle ear, or other signs of advanced disease.

En bloc surgical resection of external auditory canal malignancies is considered by almost all investigators to be the primary therapy, with an adjunctive role for radiotherapy. Most recurrences are local. Positive

Box 176-2

University of Pittsburgh Tumor–Lymph Node–Metastasis Staging System Proposed for Neoplasms of the External Auditory Canal

T Status

- T_1 Tumor limited to the external auditory canal without bony erosion or evidence of soft tissue extension
- T_2 Tumor with limited external auditory canal bony erosion (not full-thickness) or radiographic finding consistent with limited (less than 0.5 cm) soft tissue involvement
- T_3 Tumor eroding the osseous external auditory canal (full-thickness) with limited (less than 0.5 cm) soft tissue involvement, or tumor involving middle ear or mastoid, or patients presenting with facial paralysis
- T_4 Tumor eroding the cochlea, petrous apex, medial wall of middle ear, carotid canal, jugular foramen or dura, or with extensive (greater than 0.5 cm) soft tissue involvement

N Status

Involvement of lymph nodes is a poor prognostic finding and automatically places the patient in an advanced stage (i.e., stage III [T_1, N_1] or stage IV [T_2, T_3, and T_4, N_1] disease).

M Status

Distant metastasis indicates a poor prognosis and immediately places the patient in the stage IV category.

margins, despite postoperative radiotherapy, have an almost uniform fatal result.[131] Advanced lesions involving the middle ear and medial structures can be handled with combined therapy or palliatively, depending on clinical factors.

An algorithm for the management of high-grade carcinomas of the external auditory canal and temporal bone is presented in Figure 176-25.

"Local" resections in rare circumstances may be appropriate but in general are to be condemned. T_1 tumors localized to the cartilaginous canal can be appropriately managed with sleeve resection of the external auditory canal with frozen section sampling of medial margins. Such cases are rare. Lateral temporal bone resection (or en bloc removal of the canal and tympanic membrane) is the minimum operation for patients with carcinoma of the osseous portion of the canal (T_1 and T_2 tumors) and with carcinomas abutting the chondro-osseous junction. Moore and coworkers[132] argue that "canal wall down" mastoidectomy technique with anterior canal drillout (i.e., not en bloc) is equal in efficacy to an en bloc lateral temporal bone resection. Spector[133] suggests that all patients should receive postoperative radiotherapy after en bloc resections. Other workers believe that postoperative radiotherapy should not be used unless aggressive clinical or pathologic features are noted, such as soft tissue extension, metastatic lymphadenopathy, or any osseous or cartilaginous invasion on pathologic examination. If postoperative radiotherapy is likely, the mastoid cavity should be obliterated at the time of the operation to prevent osteoradionecrosis.[73]

These operations yield complex surgical specimens, and it is incumbent on the surgeon to orient the pathologist and request information regarding osseous or soft tissue invasion to gain maximum benefit for the patient. Temporal bone laboratory techniques have been advocated.[134] However, temporal bone laboratory techniques may not provide clinically pertinent information in a timely manner.

Extension into the mesotympanum, stage T_3 disease, gives rise to several other therapeutic options. The least aggressive option includes a lateral temporal bone resection plus subtotal petrosectomy followed by postoperative radiotherapy (for a 28.6% 5-year survival rate),

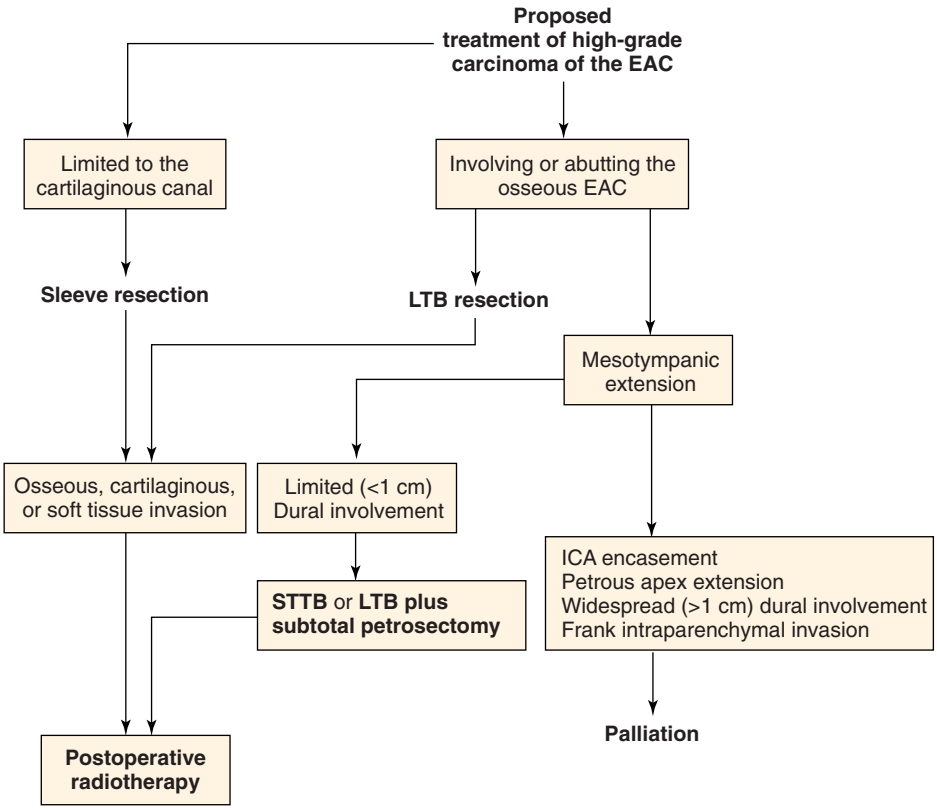

Figure 176-25. Algorithm for management of high-grade malignancies of the external auditory canal (EAC) and temporal bone. ICA, internal auditory canal; LTB, lateral temporal bone; STTB, subtotal temporal bone.

although this modality has been shown on literature analysis to be inferior to subtotal temporal bone resection (associated with a 41.7% 5-year survival rate).[84,85] Although it is uncertain whether postoperative radiotherapy provides added benefit after subtotal temporal bone resection,[84,85] we recommend subtotal temporal bone resection followed by postoperative radiotherapy. T_4 lesions with transdural extension generally have been thought to be inoperable. However, Moffat and associates[135] have successfully treated well to moderately differentiated T_4 tumors with limited temporal lobe involvement. A study by Ducic and colleagues,[136] supported by the International Study of Cranial Facial Surgery,[137] involving high-grade carcinomas of the anterior cranial fossa addressed issues of dural and intraparenchymal involvement. If dural involvement is limited (less than or equal to 1 cm) and frank intraparenchymal involvement is not apparent intraoperatively, the disease-free survivial or locoregional control shows no statistical difference with respect to dural involvement, but a dramatic decline in survival is associated with parenchymal invasion. Preoperative MRI may show dural or parenchymal involvement when none is found at surgery, possibly due to edema or inflammation. However, if overt intraparenchymal involvement is noted on frozen section, the procedure is abandoned, because as noted by Ganly and coworkers, "resection margin can still be achieved when either bone or dura is involved, but less likely when brain parechyma is involved."[137] The morbidity associated with subtotal temporal bone resection includes stroke, meningitis, and that due to sacrifice of the audiovestibular nerve and facial nerve, with a 5% perioperative mortality rate.

Total temporal bone resection also results in further morbidity from additional sacrifice of cranial nerves IX, X, and XI. Total temporal bone resection extends a subtotal resection by including the petrous apex and the entire mastoid air cell system. High-grade malignancies of the temporal bone with extension outside the petrous bone or to the petrous apex, extensive dural involvement, frank parenchymal involvement, gasserian ganglion involvement, or invasion along the skull base portend a poor outcome in nearly all cases. Palliation should be carefully and strongly considered. Patients with low- to medium-grade malignancies or extensive benign tumors, T_3 or T_4, may benefit from total temporal bone resection.[138]

Aneurysms of the Upper Cervical and Petrous Internal Carotid Artery

Primary lesions of the upper cervical and petrous segments of the internal carotid artery are decidedly rare. They include those lesions with a congenital aberrant course,[139,140] aneurysms, spontaneous and traumatic dissections, and lacerations. Aneurysm types include congenital, infectious (mycotic), pseudoaneurysms (traumatic), atherosclerotic, luetic, and fibromuscular dysplasia. Although upper cervical carotid aneurysms are associated with a high incidence of ischemic attacks and strokes, reports of rupture are unusual.[141-146] Petrous internal carotid artery aneurysms are associated with a high risk for cranial nerve dysfunction and aural hemorrhage.[147] In light of the natural history, observation is undesirable in most patients with internal carotid artery aneurysms unless other medical exigencies take precedence. Cervical carotid occlusion carries a high risk of cerebrovascular complications.

BTO aids in management decision-making (see Fig. 176-1).[148] CBF greater than 30 mL/100 g per minute carries a low risk for postocclusion infarction, thereby permitting surgical or endovascular trapping or occlusion. Surgical or permanent balloon trapping or occlusion, consisting of proximal cervical ligation or occlusion and supraclinoid internal carotid artery clipping or occlusion proximal to the ophthalmic artery, avoids late thromboembolic phenomena. Neurologic change observed on BTO or CBF less than 30 mL/100 g per minute necessitates some form of revascularization if the internal carotid artery is to be trapped or occluded. Transarterial detachable balloon trapping and cervical internal carotid artery occlusion preceded by extracranial-intracranial arterial bypass have been used.[29,149]

Preservation of internal carotid artery patency is desirable. Endovascular stenting has been performed for a petrous carotid pseudoaneurysm, preserving patency of the vessel and occluding the pseudoaneurysm with detachable coils,[150] as well as for extracranial aneurysms and dissections of the artery.[151,152] When surgical intervention is feasible or necessary, internal carotid artery reconstitution with direct reanastomosis or saphenous vein interposition grafting is preferable. A preauricular approach as described by several investigators[89,142,143,145,153] may be used to expose upper cervical carotid aneurysms, although these approaches are hindered by the facial nerve, mandible, styloid process, and tympanic bone. Lateral mandibulotomy may give access to upper cervical lesions.[154] For extension of the aneurysm to the skull base or vertical petrous internal carotid artery, the postauricular (Fisch type A or B) approach gives maximal vascular control with good distal exposure of the vessel[100,155] (Figs. 176-26 and 176-27) or routing a saphenous graft from the external carotid artery to the horizontal petrous internal carotid through a retroauricular groove.[153] Aneurysms involving the horizontal petrous segment may be approached through a Fisch type B or preauricular approach as described by Sekhar and coworkers.[91] Inadequate exposure and distal control of the horizontal petrous segment may lead to uncontrolled entry into these aneurysms. Some form of trapping with or without extracranial-intracranial bypass should be considered in patients with poorly accessible lesions.

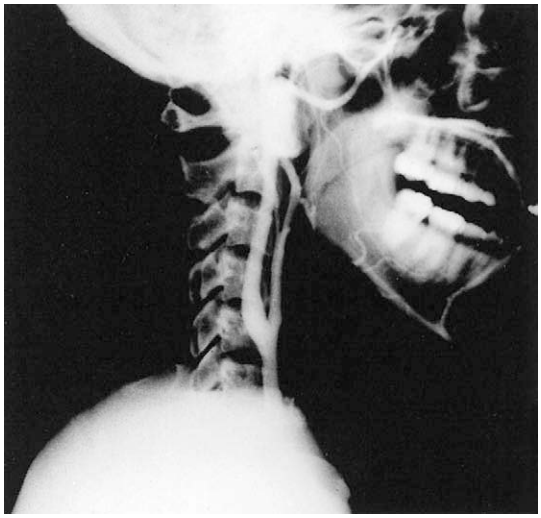

Figure 176-26. Preoperative angiogram of an upper cervical internal carotid aneurysm at the skull base.

Jugular Foramen Tumors

Tumors of the jugular foramen primarily include glomus jugulare (paraganglioma) and schwannomas of cranial nerves IX, X, and XI. The Fisch type A approach with transposition of the facial nerve and the Farrior approach[156] with limited mobilization of the vertical segment of the facial nerve both allow adequate exposure of the jugular bulb area. Donald and Chole[76] advocate a transcervical-transmastoid technique to gain access to the jugular fossa without transposing the facial nerve. This procedure, although technically feasible, provides less exposure and more limited vascular control but has the advantage of absence of facial nerve morbidity. Use of this technique is more desirable in cases in which extensive retrofacial air cells are present.

Schwannomas of the Jugular Foramen

Schwannomas originating from cranial nerves IX, X, and XI at the jugular foramen are decidedly uncommon, with only slightly more than 100 cases reported in the world's literature.[157] These tumors may be intracranial, intraforaminal, or cervical, or a combination thereof.[158] For removal of intracranial tumors, the suboccipital approach clearly is the most direct and effective route. Intraforaminal and combination tumors are removed in the safest manner through the infratemporal fossa approaches described by Fisch. These tumors originate anatomically from the pars nervosa of the jugular foramen and are situated anteromedial to the jugular bulb and internal jugular vein and posterior to the upper cervical and petrous internal carotid artery. Transposition of the facial nerve, as in the Fisch type A approach,[159] is helpful for

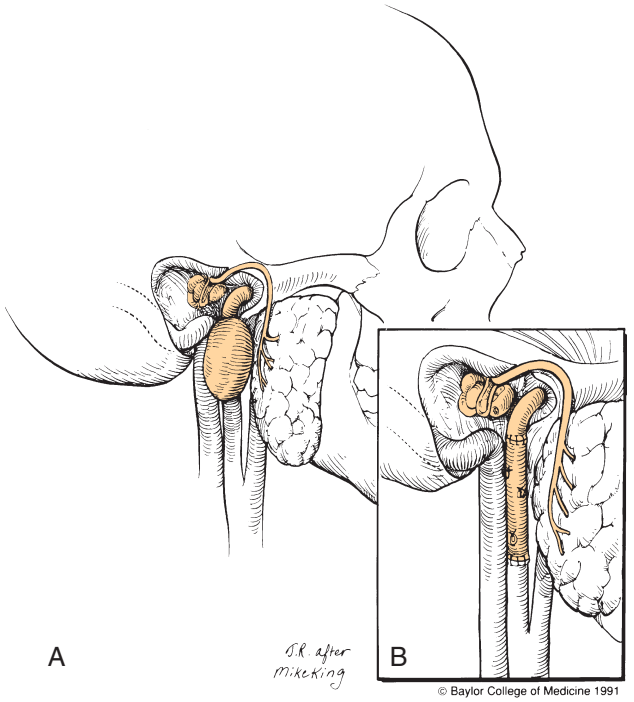

Figure 176-27. **A** and **B,** Saphenous vein repair of the aneurysm shown in Figure 176-26 with a Fisch type A infratemporal fossa approach.

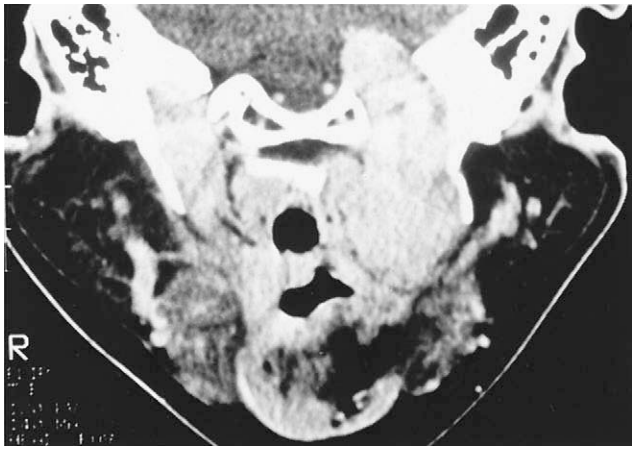

Figure 176-28. Coronal computed tomography scan revealing a jugular foramen schwannoma with a small intracranial extension removed by way of a Fisch type A infratemporal fossa approach.

control of these vascular structures and tumor exposure (Fig. 176-28). Farrior's limited approach also may have a role in small tumors.[160] Pellet[161] gave consideration to the use of an extended transcochlear route, in which a Fisch type A dissection is performed followed by sacrifice of the labyrinth to gain access to large tumors extending into the cerebellopontine angle. Oghalai and colleagues[162] describe a "transjugular craniotomy" whereby the facial nerve is not mobilized but left in a bridge of bone between an extended facial recess approach and a presigmoid craniotomy. These workers have used this technique for removal of intracranial glomus jugulare tumors.

Paragangliomas of the Temporal Bone

The glomus tumor of the temporal bone is the most frequently encountered neoplasm after the acoustic neuroma. Glomus tumors are divided into two broad categories on the basis of their site of origin: glomus tympanicum and glomus jugulare. Several classification systems have described paragangliomas of the temporal bone.[61,97,163,164] The classifications are similar and allow clinicians to communicate and compare findings and results.

Symptoms

Alford and Guilford[163] thoroughly described the signs, symptoms, and classification of glomus tumors of the temporal bone. The glomus tympanicum most frequently manifests with pulsatile tinnitus of insidious onset and a conductive hearing loss, although it also may be an incidental finding on routine physical examination.[165,166] The glomus jugulare tumor originates within the dome of the jugulare bulb and commonly appears late, after considerable growth and bony destruction. It may cause dysfunction of cranial nerves passing through the jugular bulb (cranial nerves IX to XII), facial nerve paresis caused by tumor extension into the mastoid, or sensorineural hearing loss caused by bony erosion of the labyrinth. Occasionally, either a glomus tympanicum or a glomus jugulare tumor may erode the tympanic membrane and appear as a bleeding mass in the external auditory canal.

Diagnostic Evaluation

Accurate diagnosis and evaluation of the extent of a glomus tumor of the temporal bone require appropriate physical examination and radiologic assessment.[167] The physical examination infrequently differentiates between the two kinds of glomus tumors. Only if all borders of the tumor are visible through the tympanic membrane can it be assumed that it is a glomus tympanicum tumor. If all of the borders are not visible behind the tympanic membrane, the tumor may be either a large glomus tympanicum tumor or a much larger glomus jugulare tumor that extends from the jugular bulb into the hypotympanum. If cranial nerve abnormalities are associated with a lesion, it is more likely to be a glomus jugulare tumor.

Although physical examination helps deduce the extent of a paraganglioma, radiologic evaluation is required to precisely define the lesion. CT and MRI usually are used for this evaluation (Fig. 176-29; see also Fig. 176-2). Glomus jugulare tumors require four-vessel angiography, for reasons previously discussed. Paragangliomas are vascular neoplasms. Arteriography is required if preoperative embolization of the lesions is desired. Such embolization takes place through specialized intra-arterial catheters and can lead to a marked reduction in vascularity of these masses, which reduces intraoperative blood loss and hemorrhage-related complications. The glomus jugulare paraganglioma, the most common of these tumors, causes somewhat selective erosion of the pars vasculosa portion of the jugular foramen. It also frequently destroys the bony septum between the internal carotid artery and the internal jugular vein. This bony septum is a distinctive structure whose absence is easily seen. Confounding lesions include schwannomas of cranial nerve IX, X, or XI, because these lesions also destroy the jugular foramen (Fig. 176-30). These lesions, however, usually destroy the more medial portion of the pars vasculosa or, if originating from cranial nerve IX, the pars nervosa.

At times, the paraganglioma manifest only after becoming large and eroding nearly all of the jugular foramen. Simple differentiation by the localization of bone erosion is not possible in such cases. MRI is helpful in defining these lesions, but results should be interpreted carefully. The complex flow characteristics of venous blood result in the presence of many signal artifacts in and about the jugular vein. Although experienced practitioners have become used to these artifacts, errors can still be made, and careful attention to the precontrast and postcontrast-enhanced MRI or fMRI is necessary so that the flow-related signal artifacts are not interpreted as a vascular lesion. Vasoactive peptides are produced by 1% to 3% of these tumors; therefore, patients should be screened with quantitative urine vanillylmandelic acid and hydroxyindoleacetic acid assays.

Surgical Approach

Only small glomus tympanicum tumors whose borders are clearly visible through the tympanic membrane can be removed through the external auditory canal. In radiologically proven glomus tympanicum tumors whose borders are not entirely visible through the tympanic

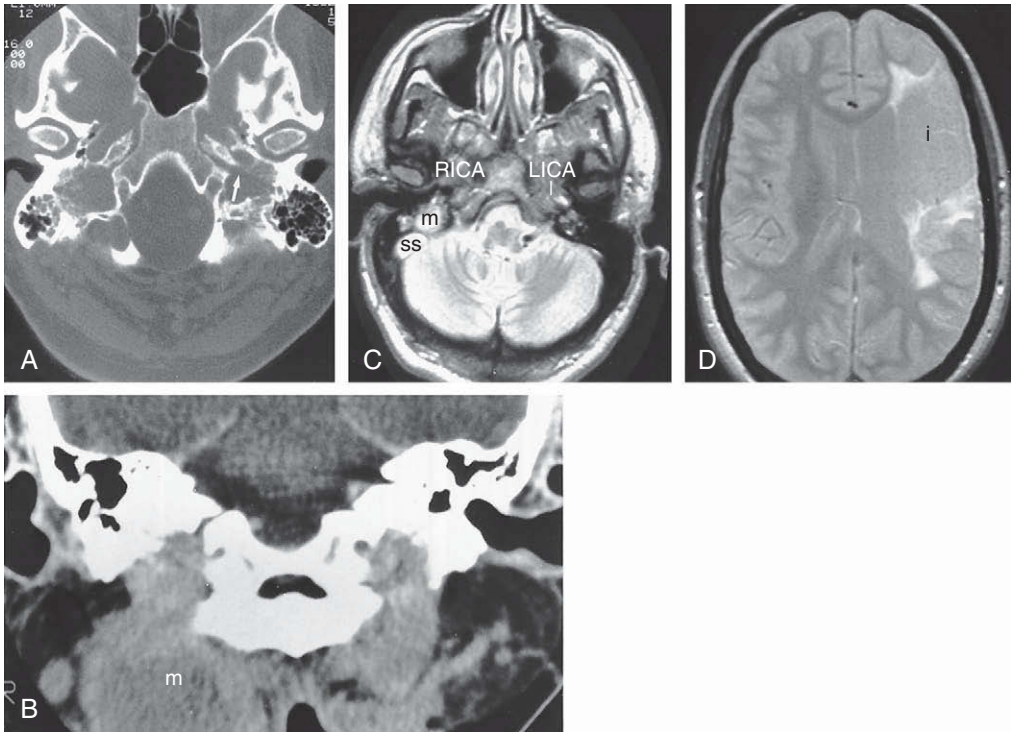

Figure 176-29. Familial paragangliomas in a 53-year-old woman.The tumors included bilateral glomus jugulare paragangliomas, a right-sided glomus vagale paraganglioma, and bilateral carotid body paragangliomas. **A,** Axial view, computed tomography (CT), bone algorithm. This CT study is performed with a small field of view and a bone algorithm to increase the resolution of bone edges. The bilateral glomus jugulare paragangliomas are destroying bone from the pars vasculosa laterally. On the left side, the lesion is destroying the septum between the internal carotid artery and the internal jugular vein. These are common findings in a glomus jugulare paraganglioma *(arrow)*. **B,** Coronal view, CT with intravenous contrast. Both glomus jugulare paragangliomas extend into the neck. However, another large mass can be seen on the right, a glomus vagale paraganglioma (m). **C,** Axial view, T2-weighted magnetic resonance imaging (MRI). The high-signal-intensity lesion, a glomus jugulare paraganglioma (m), has occluded the sigmoid sinus, which shows high-intensity signal (ss). The left internal carotid artery (LICA) shows signal of pathologic high intensity. This vessel has been occluded by a large paraganglioma in the neck *(not shown)*. Compare the signal intensity of this vessel with the normal dark black appearance of internal carotid artery flow on the right (RICA). Although MRI cannot provide the fine bony resolution of CT (see **B**), it gives more information about vascular patency. **D,** The LICA occlusion has resulted in a middle cerebral arterial distribution infarct (i).

membrane, the extended facial recess approach is recommended.[166] Occasionally, the facial recess is narrow, requiring removal of all or part of the bony posterior external auditory canal.

Glomus jugulare tumors are best approached by the Fisch type A route. Alternatively, Oghalai and colleagues[162] advocate a "transjugular craniotomy," which does not involve facial nerve transposition and its attendant morbidity. Staging may be necessary with those large tumors with extensive intracranial extension (Fig. 176-31). Bleeding intraoperatively remains a major problem in removal of glomus tumors. The efficacy of preoperative embolization of glomus tumors in reducing intraoperative blood loss is debated.[97] Some studies suggest major reduction in intraoperative blood loss and operative time after embolization.[50,67,168,169] Intraoperative ligation of the feeding vessels, such as the ascending pharyngeal, stylomastoid, caroticotympanic, internal maxillary, and superior tympanic arteries, before extirpation may lessen bleeding, although ancillary blood supply from various other sources may mitigate this result.[50] Piecemeal tumor removal, as in acoustic neuroma surgery, is impractical for management of these vascular tumors and often will result in hemorrhage, obscuring anatomic landmarks.

Lack of cranial nerve dysfunction is not a reliable indicator of intraoperative nerve integrity in patients with these tumors.[170] Cranial nerves VII and IX to XII may be involved at the skull base. In superficial involvement, segmental removal of involved epineurium may clear the tumor. Neural invasion requires segmental neurectomy. Paragangliomas often invade the periosteum of the carotid canal but rarely involve the adventitia itself.[60] Good preoperative angiographic assessment is of absolute necessity. A subperiosteal plane of dissection is developed intraoperatively. If the adventitia is involved, surgical manipulation may result in a large laceration of the carotid artery. Preoperative transarterial permanent balloon occlusion of the internal carotid artery should be considered in those tumors with infiltration of the wall of the horizontal petrous segment of the artery or with intracranial extension receiving significant blood supply from the artery and for reasons identified in Figure 176-1. If the status of the internal carotid artery is not appreciated preoperatively, several options are possible. Lacerations may be sutured directly. Saphenous vein interposition grafting may be performed with or without shunt placement.[48] The internal carotid artery may be transarterially balloon-occluded intraoperatively with or without angiographic confirmation, depending on the urgency of the situation.[60,61,169]

Radiotherapy

Although radiotherapy is not the modality of choice for treatment of surgically resectable glomus tumors of the temporal bone, tumor reductions after radiotherapy have been recorded.[171-173] Glomus tumors have been shown to have nonuniform responses, and tumor sterilization by radiotherapy is infrequent. Radiotherapy is useful for management of recurrences and unresectable lesions.

Facial Nerve Schwannomas

Schwannomas may involve the facial nerve along its intracranial, intratemporal, or extratemporal course. Altmann[174] presented the first comprehensive description of a facial nerve schwannoma and believed that its symptoms were sufficiently pathognomonic for the facial nerve schwannoma to be diagnosed clinically. These reported cases generally

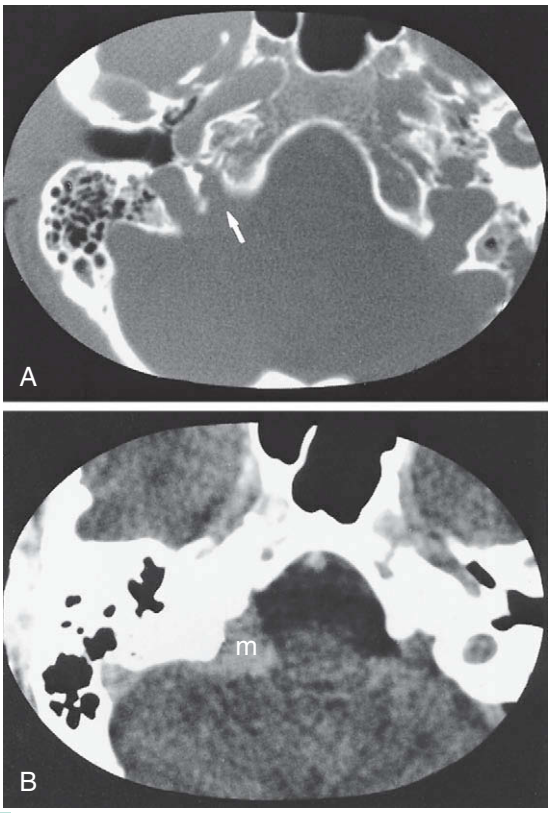

Figure 176-30. Right glossopharyngeal schwannoma in a 50-year-old woman **A,** Axial view, computed tomography bone algorithm. The neoplasm has focally expanded and destroyed the pars nervosa portion of the jugular foramen *(arrow)*. This is a helpful finding in this type of schwannoma. **B,** Axial view, computed tomography brain algorithm. This patient's neoplasm is large. It has ascended past the cochlear aqueduct toward the internal acoustic canal. If only this level were viewed, the mass (m) could simulate a vestibular schwannoma.

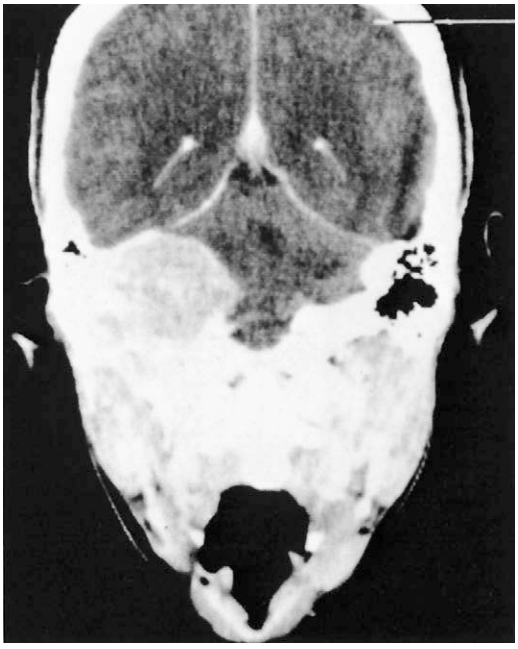

Figure 176-31. Paraganglioma of the jugular bulb with intracranial extension. The tumor was removed in one stage using a Fisch type A infratemporal fossa approach.

were diagnosed late; the patients presented with long-standing facial nerve paralysis and obstruction of the external auditory canal with tumor. More recently, with the increased awareness of this clinical entity and improved neurotologic diagnostic methods, earlier diagnosis is possible.

Diagnostic Evaluation

Facial weakness has been the most common presenting symptom in a number of series.[175,176] The classic history is one of slowly progressive facial paralysis over months to years, not days to weeks, although sudden onset of paralysis, fluctuating paresis, and facial tic may occur.[177] Hearing loss is the second most common presenting manifestation.[178] Conductive hearing loss may occur with middle ear involvement caused by tumor expansion and pressure on or disruption of the ossicular chain. In such cases, a gray-white polypoid mass frequently can be seen behind the posterosuperior tympanic membrane. Sensorineural hearing loss may result from erosion into the labyrinth or tumor compression on the cochlear nerve.

An intratemporal facial nerve schwannoma generally extends along the course of the facial nerve for a greater distance than that anticipated from the clinical or radiologic findings. The schwannoma visualized in the middle ear may extend intracranially into the internal auditory canal and cerebellopontine angle or extratemporally into the parotid gland. Preoperative radiologic assessment addresses this potential spread, but the surgeon should be prepared for more extensive nerve involvement than that suggested by clinical or radiologic testing. Topographic testing of facial nerve function, including tearing, stapedius reflex, taste, and salivation, may be helpful, but it is not definitive in the evaluation of the extent of facial nerve neuroma. Definitive assessment of facial canal alterations is made with axial and coronal temporal bone CT. The entire bony path of the facial nerve can be traced with certainty. In the normal structure, seldom is much variation observed in this path from side to side. Hence, it is simple to compare right and left to determine abnormality. The most common abnormality seen in patients with facial schwannomas is simple enlargement of the fallopian canal by a soft tissue mass. These lesions usually follow the exact path of the facial nerve. One great mimic of facial schwannomas is the facial nerve hemangioma. This uncommon lesion probably originates from arteriovenous plexus around the geniculate ganglion, internal auditory canal, or vertical segment of the facial nerve near the chorda tympani takeoff.[179] Differential diagnostic imaging characteristics include calcification-based higher CT attenuation in a hemangioma compared with a schwannoma. MRI is superior to CT in delineating a soft tissue mass along the facial nerve, especially when MRI contrast material is used. This material provides such sensitivity that the arteriovenous plexus along the fallopian portion of the facial nerve is visualized. This plexus normally can enhance in a spotty fashion, making it possible for inexperienced practitioners to identify this abnormality. In addition, inflammatory lesions of the facial nerve also will result in contrast enhancement. Accordingly, facial nerve enhancement on MRI should not be considered to be indicative of neoplasm unless a soft tissue mass is present. The clinical, CT, or MRI findings should be correlated before diagnosis of a facial nerve neoplasm. If this correlation is not definite, later follow-up imaging evaluation after a clinically appropriate amount of time has passed should resolve the issue.

In some patients with facial paralysis, radiologic evidence for tumor is lacking. Surgical exploration of all progressive facial palsies that occur over an extended period of time or facial palsies that show no return of tone or function after 6 to 12 months has been recommended, and facial schwannomas occasionally are discovered.

Management and Surgical Approach

Timing of intervention requires extensive discussion with the patient, especially if facial function is intact. McMonagle and coworkers advocate observation with serial scans until facial function deteriorates to House-Brackmann grade IV.[180] The management goals of facial nerve neuroma surgery are complete removal of the tumor with preservation of hearing and restoration of facial nerve function.[181,182] Most commonly, the transmastoid and middle cranial fossa approaches are

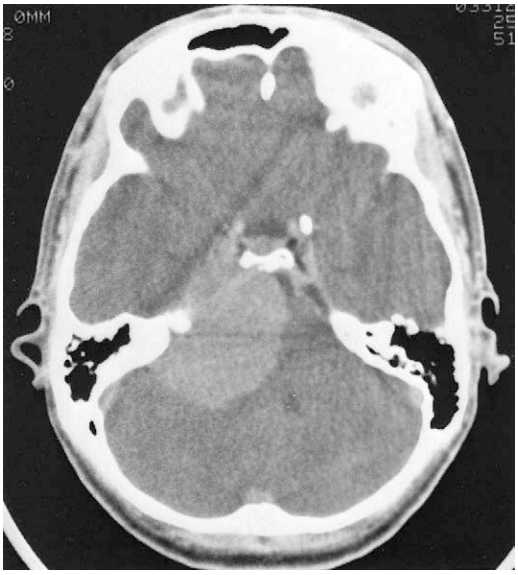

Figure 176-32. Computed tomography scan of a large posterior fossa meningioma with petrous apex involvement. The tumor was removed through a retrosigmoid craniotomy with petrosectomy, with posterior facial nerve transposition.

adequate for exposure of neuromas of the intralabyrinthine facial nerve segments. In patients with no serviceable hearing, a translabyrinthine exposure of the facial nerve may be indicated. Surgical removal and cable grafting of the facial nerve with frozen section histologic control is indicated in most patients. The nerve graft usually is placed in the fallopian canal, and its ends are approximated and stabilized with packing. Approximation of the cable graft to the facial nerve stump in the internal auditory canal is difficult. When the involved segment of nerve is limited to less than 1 cm, a facial nerve transposition and primary anastomosis sometimes can be performed. If primary anastomosis or cable grafting fail, hypoglossofacial anastomosis may be necessary (see Chapters 171 and 172).

Petrous Apex Lesions

Primary tumors of the petrous apex, either benign or low-grade neoplasms, such as cholesteatoma, schwannoma, chondroma, meningioma, chordoma, and low-grade sarcomas, are best removed totally to prevent recurrence.[183-185] The infratemporal fossa approaches to the petrous apex (i.e., Fisch type B or perhaps type A approach) give better exposure and control of the internal carotid artery and may be combined with the middle cranial fossa, retrosigmoid, transcochlear, or translabyrinthine routes as needed (Fig. 176-32). In patients with serviceable hearing, the petrous internal carotid artery may be temporarily transposed to gain access to the petrous apex with major risk of hemorrhage. The combination of the transcochlear or translabyrinthine route with posterior translocation of the facial nerve offers the best access to the petrous apex (see Figs. 176-20 and 176-32). Total temporal bone resection also is an option for low grade maligancies.

Benign cystic lesions such as cholesterol granulomas or cephaloceles are generally not extirpated. Drainage of cholesterol granulomas can be performed through the perilabyrinthine pathways[186] (see also Chapters 139 and 140) or transsphenoidally using endoscopic imaging guidance.[187-189] Symptomatic petrous apex cephaloceles can be either marsupialized intracranially using a posterior fossa approach or obliterated through a middle cranial foassa approach.[190]

Congenital Cholesteatoma

Congenital cholesteatomas of the temporal bone may be divided into four anatomic groups: middle ear, perigeniculate area, petrous apex, and cerebellopontine angle. These cholesteatomas originate from epithelial rests and should be distinguished from acquired cholesteatomas and from congenital auditory canal cholesteatomas associated with congenital atresia of the external auditory canal.

Diagnostic Evaluation

The clinical presentation of a congenital cholesteatoma varies, depending on its location. Middle ear cholesteatomas originally were described by House,[191] and clinical series have been reviewed by House and Sheehy[59] and Curtis.[192] Conductive hearing loss and a bulging whitish mass behind an intact tympanic membrane are common findings in patients with middle ear congenital cholesteatomas.[193] One half of all patients present with recurrent otitis media, and the lesions may fistulize through the tympanic membrane. The lesions also may be discovered incidentally at the time of a myringotomy or routine physical examination in children. Perigeniculate and petrous apex cholesteatomas usually present with insidious or rapidly progressive facial nerve paralysis.[194,195] Sensorineural hearing loss from labyrinthine or internal auditory canal erosion is common, but a conductive hearing loss also may result from cholesteatoma extension into the middle ear or blockage of the eustachian tube. Facial twitching may occur in the presence of congenital cholesteatomas and with facial nerve neuromas. Vestibular dysfunction may complete the symptom complex. On occasion, the cholesteatoma may erode into the middle or posterior fossa and expand markedly before producing symptoms. Preservation of hearing despite extensive destruction of the labyrinth has been reported.[45,74]

Radiologic evaluation of the temporal bone is essential in the evaluation of a congenital cholesteatoma (Fig. 176-33). Only the largest lesions will show on plain radiographs. High-resolution, focused CT of the temporal bone is ideal in this evaluation, because any alteration in normal bony structure can be seen. At times, the normal asymmetry in aeration, inflammatory, or passive effusion and bone marrow deposition in the petrous apices can cause diagnostic difficulties. These difficulties usually are resolved by clinical correlation; if the findings are problematic, MRI will provide further definition, because congenital cholesteatomas almost always will have a slightly higher signal intensity than that of spinal fluid on T1-weighted images, with moderately high signal intensity on T2-weighted images. By contrast, bone marrow fat will have a high signal intensity on T1-weighted images and then go on to fade dramatically on T2-weighted images. Typical effusions will have a low signal intensity on T1-weighted sequences, with high signal intensity on T2-weighted sequences. Giant cholesterol granulomas can be difficult to separate from congenital cholesteatomas of the petrous apex (Fig. 176-34), although giant cholesterol granulomas, but not congenital cholesteatomas, tend to show capsular enhancement.

Surgical Approach

Surgical management of a congenital cholesteatoma requires either complete removal of the cholesteatoma matrix or permanent exteriorization. The isolated middle ear cholesteatoma may be removed transtympanically. At surgery, it is essential to visualize clearly the complete extent of the cholesteatoma in the middle ear, particularly on the medial aspect of the tympanic membrane. Routine middle ear reconstructive techniques may be used if ossicles are eroded or removed or if the tympanic membrane is sacrificed. Removal of congenital cholesteatomas of the perigeniculate area or petrous apex may be accomplished by the transmastoid, middle cranial fossa approach,[196] the transsphenoidal approach,[197] or by a combination of these procedures.[94] Frequently, a cholesteatoma must be dissected from the facial nerve, and occasionally, the intralabyrinthine portion of the nerve must be mobilized to allow complete removal of a perigeniculate cholesteatoma. This maneuver may require sectioning of the greater superficial petrosal nerve and transposition of the facial nerve posteriorly at the geniculate ganglion. The cholesteatoma also may insinuate itself between the dura and the middle fossa floor and may extend for a considerable distance along this plane. Petrous apex cholesteatomas may act similarly and erode the bony labyrinth or internal auditory canal. Only by careful and often tedious dissection can injury to these structures be prevented. Cholesteatomas of the petrous apex may be exteriorized into the mastoid cavity or the sphenoid sinus, although frequent cleansing of debris from

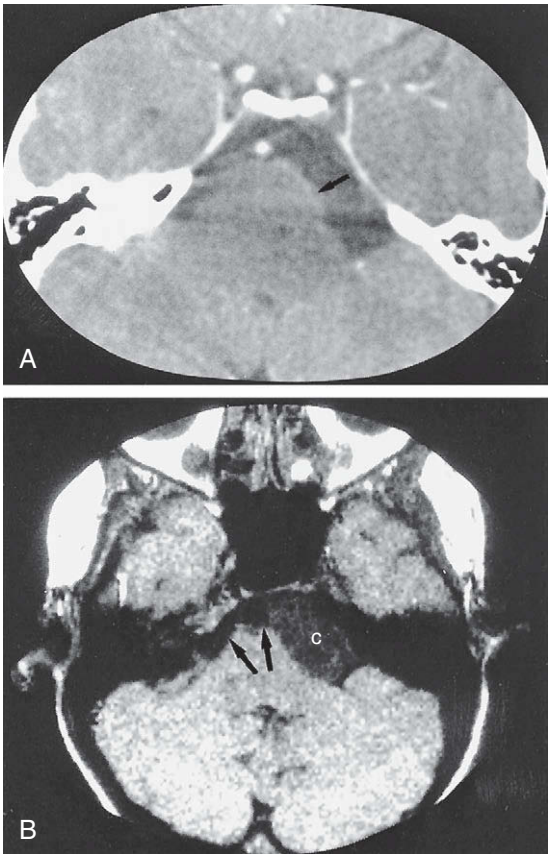

Figure 176-33. Left cerebellopontine cistern congenital epidermoid cyst in a 36-year-old man. **A,** Axial view, computed tomography (CT). Displacement of the pons to the right *(arrow)*. This displacement seems to be caused by cerebrospinal fluid (CSF) attenuation material. Accordingly, this could be an arachnoid cyst. **B,** Axial view, T1-weighted noncontrast magnetic resonance imaging. The cystic lesion (c) is now clearly seen to have higher-intensity signal than the CSF in the right cerebellopontine angle cistern *(arrows)*. This slightly higher signal intensity on T1-weighted images is helpful in separating epidermoid cysts from arachnoid cysts. This relative hyperintensity is caused by lipid, mostly cholesterin. The lipid is not seen on the CT scan as low attenuation because higher-attenuation keratin is mixed with the cholesterin. The sum of these two components balances out to nearly CSF attenuation.

the cholesteatoma cavity is required to prevent inspissations and subsequent infection.[198]

Encephalocele and Cerebrospinal Fluid Leaks

Postsurgical and postinfectious encephaloceles herniating through the tegmen tympani and tegmen mastoideum are well-recognized complications in otology.[199-201] Temporal bone herniation of the mastoid cavity is a result of loss of bony and dural support. Subsequent management should deal with CSF leakage, herniation of the brain into the mastoid cavity, and skin and cholesteatoma matrix in the middle ear and mastoid. Less frequently recognized is a spontaneous congenital encephalocele associated with CSF otorrhea or rhinorrhea.[202-207]

Diagnostic Evaluation

The appearance of postsurgical encephaloceles may occur early or late in the postoperative course. Early occurrences generally are associated with maceration of exposed brain and CSF leakage. Late occurrences are associated with pulsatile tinnitus and/or progressive prolapse of skin-covered brain into the mastoid cavity. Spontaneous congenital encephalocele may manifest as serous otitis media, CSF rhinorrhea, or CSF otorrhea through a tympanic membrane perforation or pressure-equalizing tube. Occasionally, prolapsed brain can be present as a mass behind the tympanic membrane. Because small and often multiple bony defects can be involved, carefully focused CT in the axial and coronal planes is needed to find these fenestrations. If necessary, the subarachnoid space can be opacified with myelographic contrast material, and the actual flow of the contrast-opacified spinal fluid through the fenestrations can be observed. Occasionally, encephaloceles also may be discovered as an intraoperative surprise.

Surgical Approach

Temporal bone encephaloceles and CSF leaks may be surgically approached either transmastoidally or through the middle cranial fossa intradurally or extradurally. Although transmastoid repair of the defect frequently is successful, repair through the middle cranial fossa allows greater visualization. Techniques for repair of the tegmen defect through the mastoid approach have included intracranial placement of reconstructive material (i.e., fascia, cartilage, or prosthetics) from the mastoid combined with obliteration of the mastoid with flaps or free tissue.[200,204,205,207,208] A fascia (banked)-bone-fascia technique incorporating use of a modified radical cavity, with neurosurgical consultation, followed by postoperative lumbar drainage, has been used successfully on several occasions by one of us (MM). A middle cranial fossa approach for repair provides greater visualization and can be either extradural or intradural.[209,210] A variety of closure techniques, including primary dural repair and fascia-bone-fascia, bone, cartilage, or synthetic supports, have been used. The bony and dural defects in spontaneous encephaloceles are routinely small and multiple.[211] Frequently, an encephalocele exists in the anterior epitympanum, where visualization may be inadequate and surgical repair through the transmastoid approach is difficult without ossicular disruption. Although transmastoid exposure defines the defect, repair may be better accomplished through the middle cranial fossa. The bony defects usually are small and do not require repair. The dural defects can be sealed by wide coverage of the middle cranial fossa with temporalis fascia and bone or cartilage as necessary.

Approaches to the Clivus

Clival tumor extirpation, both planning and execution, is perhaps the most difficult of skull base surgical procedures. Surrounding neurovascular structures of the brainstem and both internal carotid arteries are at risk during surgery. House and Hitselberger[103] reported use of a transcochlear route to the petrous tip and midclivus, sacrificing ipsilateral cochlear and vestibular function. This approach may be useful in removing tumors that are not intrinsic (primary) neoplasms of the clival bone itself, such as cholesteatoma and meningioma, because only the dorsal midclivus is exposed. The Fisch type B approach is useful for removal of tumors involving the midclivus with extension to the petrous apex.[61] Tumor extension medial and superior to the horizontal segment of the internal carotid artery in the petrous apex requires temporary transposition of the artery. Adding a middle cranial fossa subdural dissection may circumvent this problem.

A transcochlear dissection added to a Fisch type B approach also may improve access to the clivus. Tumor of the posterior clinoid (retrosellar) is not accessible through this route, but an intradural middle cranial fossa approach may be of benefit.[212]

With the preauricular approaches,[92,105] limitations are similar to those for techniques already discussed, but the transcochlear route cannot be used for further exposure in combination with the preauricular approach. Numerous anterior approaches to the clivus also have been described (see also Chapter 173).[124,213-217] Transnasal endoscopically assisted approaches also may result in complete extirpation with greatly reduced morbidity compared with lateral skull base or facial translocation anterior techniques (see also Chapter 174).[218] Hanna and colleagues have begun exploring robotic endoscopic surgery of the anterior and central skull base.[219]

Lesions Involving the Cavernous Sinus

The cavernous sinus is a small plexus of veins enclosed by leaves of dura on either side of the sella turcica.[220] In the cavernous sinus lie the internal carotid artery, sympathetic nerves, and cranial nerves III, IV,

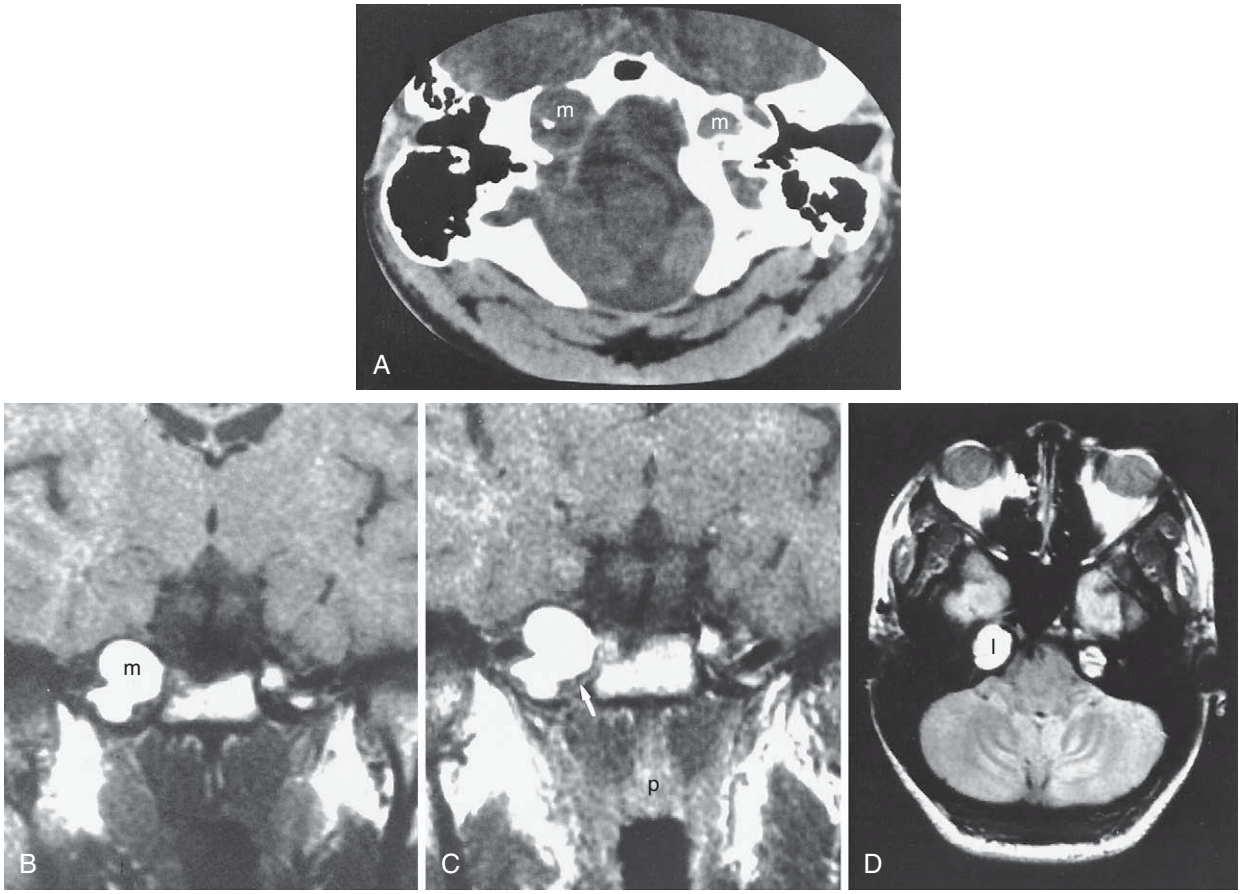

Figure 176-34. Cholesterol cysts in a 21-year-old woman. **A,** Axial view, computed tomography (CT) with intravenous contrast. Expansile, slightly low-attenuation masses (m) are seen in both petrous apices. **B,** Coronal view, T1-weighted sequence on noncontrast magnetic resonance imaging (MRI). High signal intensity is evident within both petrous apices, more pronounced in the larger, right-sided mass (m). **C,** Coronal view, T1-weighted sequence on MRI after administration of intravenous gadolinium contrast material. The edges of the lesion show enhancement *(arrow)*. The larger high-signal-intensity portion does not change. Notice the increased signal intensity in the pharyngeal mucosa (p). This is a normal finding after gadolinium administration. **D,** Axial view, T2-weighted MRI. The right-sided lesion (l) shows extremely high signal intensity. The left-sided lesion is similar but intensty increase is less marked. There is only slight inhomogeneity in this signal reflected by small patches of lower signal intensity. The combination of the CT appearance with extremely high signal intensity on T1- and T2-weighted sequences is distinctive for a cholesterol cyst. The slight inhomogeneity in the lesions is due to bone fragments, calcification, and small hemorrhages of varying ages.

VI, V_1, and sometimes V_2. Primary tumors of the cavernous sinus commonly include meningiomas or schwannomas,[89] but this region usually is invaded secondarily. Operations involving the cavernous sinus are fraught with potential complications, including bleeding, cranial nerve deficits, and carotid injury. Palliative therapy such as with conventional irradiation or gamma knife techniques may be warranted for patients with lesions in this location.

Chordoma

Cranial chordomas originate from the clivus and progressively destroy the skull base[202,204,206] (Figs. 176-35 and 176-36). They may extend ventrally into the nasopharynx, nose, or sinuses and cause obstruction. Headache, loss of vision, and cranial nerve deficits with involvement of the abducens, trigeminal, facial, and acoustic nerves are common presenting complaints. Because of the inaccessibility of the tumor site, surgical exposure and tumor removal may be difficult. Surgical debulking of the tumor followed by high-dose radiotherapy is historically the treatment of choice and may afford good palliative results. More recently, skull base surgeons have become more aggressive, tailoring surgical approaches to individual lesions to ensure complete removal. Because of the difficult accessibility, surgical control of chordoma is a unique challenge to the skull base surgeon and lends itself to creative surgical approaches (see Chapter 173). Anterior, endoscopic approaches rather than lateral skull base approaches are being pioneered to resect these difficult tumors, with great promise (see also Chapter 174).[218]

Tumors of the Parapharyngeal Space

Tumors involving the infratemporal fossa or parapharyngeal space at the skull base and extending into the temporal bone or middle cranial fossa require lateral skull base techniques. For tumors confined to the parapharyngeal space, a cervical approach, often with mandibular transection, may be indicated. Radical en bloc procedures for malignancy may require removal of the mandibular ramus and condyle.[221,222] A labiomandibulotomy[223,224] or extraoral mandibulotomy will give improved access to the tumor within the middle to upper infratemporal fossa. Reflection of the temporalis muscle and zygoma provides improved access to the superior infratemporal fossa. Retracting the mandibular condyle or resecting it may obtain further exposure. Middle cranial fossa approach may be added for superior extension (Fig. 176-37).

Approaches to the Nasopharynx

In patients with extensive benign tumors of the nasopharynx (e.g., juvenile angiofibromas), a lateral approach may be indicated. These approaches may be combined with any of the anterior approaches as the situation warrants. The Fisch type C (see Fig. 176-22) and Sekhar lateral approaches to the nasopharynx provide similar exposures, and either approach may be extended to include removal of tumor from the sphenoid sinus or pericavernous sinus area. Transmaxillary endoscopic approaches also may provide adequate exposure while minimizing operative morbidity (see Chapter 175).

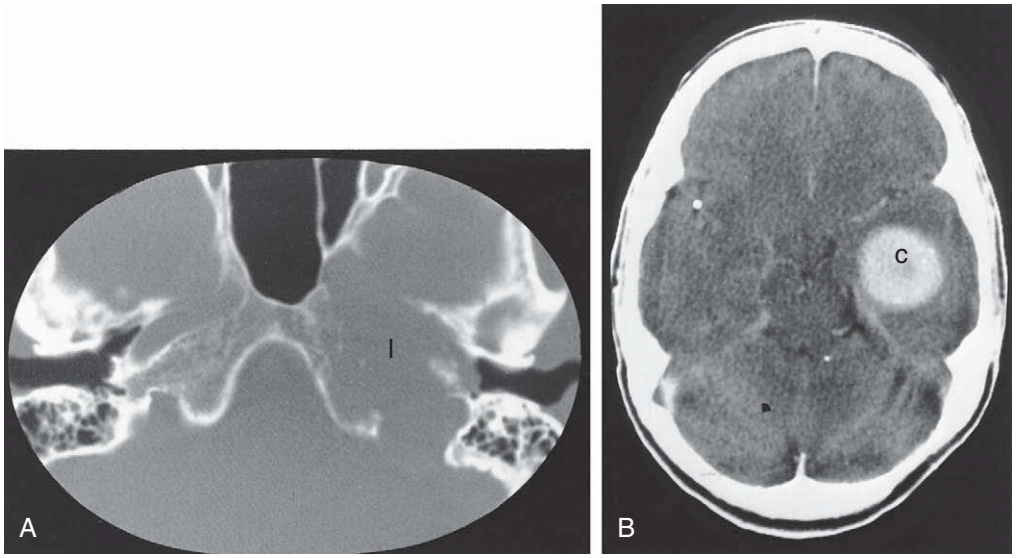

Figure 176-35. Massive petrous apex chordoma on the left in a 57-year-old man. **A,** Axial view, bone algorithm computed tomography (CT). Off-midline destructive changes characteristic of this lesion (I). Whereas most chordomas are midline, some can be quite far lateral. **B,** Axial view, brain CT with intravenous contrast. The chordoma (c) was so large that it extended up into the left temporal lobe.

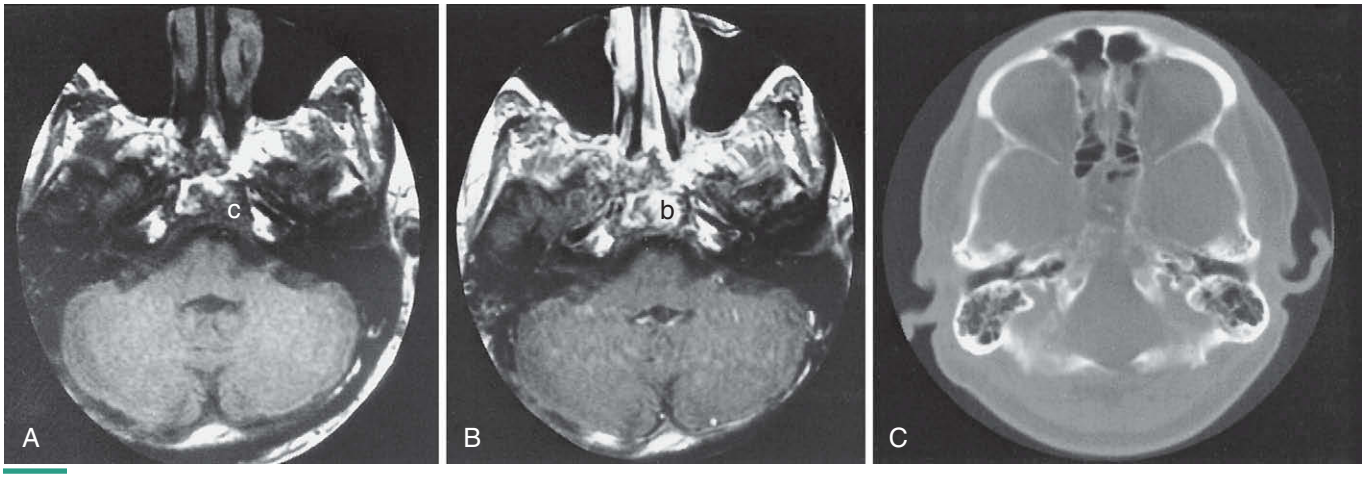

Figure 176-36. Clivus chordoma in a 59-year-old man. **A,** Axial view, T1-weighted magnetic resonance imaging (MRI). Subtle permeative changes can be seen extending into the clival bone marrow. The chordoma (c) is the darker area (of lower signal intensity) invading the brighter area (high-signal intensity) normal bone marrow fat. **B,** Axial view, T1-weighted MRI, after administration of intravenous gadolinium contrast material. The area of low signal intensity on the previous scan demonstrates markedly increased intensity (b). However, it is difficult to assess the degree of bone destruction with MRI. **C,** Standard computed tomography (CT), bone windows. Even on this nonfocused CT scan, the gross destructive changes associated with this clivus chordoma are visible. MRI is less sensitive than CT in showing bone destruction.

Excision of malignant lesions of the nasopharynx is fraught with controversy. Wang[225] has shown that patients with recurrent squamous cell carcinoma of the nasopharynx staged T_1 to T_3 may have improved survival rates if the lesions are excised. Fisch type C approach and Sekhar's approach permit en bloc removal of the lateral nasopharyngeal wall with the pterygoid and tubal musculature for persistent or recurrent tumor postradiation.

Complications

Intraoperative Complications

Intraoperative complications result mostly from lack of vascular control or coagulopathy. Management of unexpected blood loss from an internal carotid artery laceration is facilitated by proximal and distal control before repair. A lack of exposure may result in the need for emergency intraoperative balloon occlusion and ligation when hemorrhage occurs. Bleeding from the cavernous sinus can be massive, and an air embolus may occur, although this bleeding can be stopped with patient application of oxidized cellulose hemostatic strips (Surgicel). Carotid spasm may require termination of the procedure.[97]

Coagulopathy may occur as a result of massive transfusions of packed erythrocytes from citrate-induced hypocalcemia, depletion of clotting cascade proteins, hypothermia, thrombocytopenia, disseminated intravascular coagulopathy, or incompatible blood. When massive transfusion is necessary, 2 units of fresh frozen plasma and platelets should be given for every 10 units of packed erythrocytes.[226] Vasoactive glomus tumors or concomitant pheochromocytomas may lead to unexpected hypertension intraoperatively. For this reason, patients with glomus should be screened preoperatively with urine vanillylmandelic acid and hydroxyindoleacetic acid assays to rule out vasoactive tumors.

Figure 176-37. Intracranial-extracranial trigeminal schwannoma: Coronal view, magnetic resonance imaging. Excision through a preauricular approach with extraoral transection of mandible and temporal craniotomy.

Postoperative Complications

CSF leakage is one of the more common postoperative complications from infratemporal fossa surgery when the dural space must be entered. The risk of meningitis with high attendant morbidity rate is increased, as is length of hospital stay. Postoperative lower cranial nerve deficits leading to aspiration and subsequent coughing increases CSF pressure, adding another adverse variable to the management equation. Most CSF collections beneath flaps may be managed with compressive dressings, head elevation, and repeated aspirations. A lumbar subarachnoid drain best manages leakage of CSF through the wound or persistent otorhinorrhea.

In patients with large tumors and intracranial extension, the subarachnoid space should be entered for tumor exposure and extirpation. Jackson and associates[97] secured autogenous fascia to existing bone or dural margins for small to medium dural defects with temporalis muscle rotations for reinforcement. Obliteration with fat is not used. For larger defects, Gulya and coworkers[227] have used an infant-size ventriculocardiac shunt from the wound bed to the jugular stump to the right atrium, to allow continuous drainage. Lumbar subarachnoid drains combined with pressure dressings usually suffice to control leakage for large dural defects.

Cranial Nerve Deficits

The invasive nature of glomus tumors, especially those extending into the posterior fossa, has led historically to rather high rates of postoperative paralysis. Aside from intraoperative electrophysiologic monitoring,[80] the proximal identification of cranial nerves IX, X, XI, and XII in the posterior fossa and distal identification at the skull base should improve preservation of these nerves.[101] Unfortunately, these cranial nerves often are encased in tumor extending transdurally into the posterior fossa toward the root entry zones, making their preservation extremely difficult.

Most preoperative cranial nerve deficits persist postoperatively if they result from tumor invasion rather than compression. Creation of new cranial deficits, although necessary for complete tumor removal, can result in a prolonged rehabilitative phase and substantially reduce the quality of life. The patient's age and cardiopulmonary status should be carefully weighed against the tumor pathology, extent of disease, and natural course of the disease. Responses to other forms of therapy, such as radiotherapy or chemotherapy, should be considered before extensive skull base surgery is attempted. Younger, healthier patients, in general, tolerate new cranial deficits better than older patients do. Patients with marginal cardiac output are at high risk for myocardial infarction or congestive heart failure when subjected to prolonged surgery and recovery; those with compromised pulmonary function have poor tolerance for the problems created by lower cranial nerve deficiency (i.e., aspiration and decreased cough).

The oculomotor nerve can potentially be injured in cavernous sinus surgery or orbital apex. Neurapraxia or axonotmesis usually leads to a good functional recovery in 2 to 8 months, respectively. Functional recovery with reanastomosis after transection has been reported.[228] Loss of the trochlear nerve is reported to be associated with minimal functional disability. Good recovery with reanastomosis has been reported.[175] The abducens nerve has the longest intracranial course and is most prone to injury, especially in surgery for tumors of the clivus, petrous apex, or cavernous sinus. Good functional return should be expected with stretch injury, because this is a purely motor nerve.[228]

Prevention of facial nerve paresis already has been mentioned. If transection is required and the site optional, it is best to section the nerve at tertiary branches to limit synkinesis. In order of reconstructive preference for the facial nerve, options include direct reanastomosis, interposition grafting, and cranial nerve XII to VII crossover. Ocular care, with prevention of exposure keratitis, especially if the V_2 branch has been sacrificed, is of paramount importance postoperatively if the facial nerve has been injured. A lateral tarsorrhaphy affords the best protection to the eye for a combination deficit involving cranial nerves V and VII.

The approaches by Fisch to the infratemporal fossa by definition preserve cochleovestibular function. Inadvertent stapes subluxation or tumor invasion of the otic capsule may lead to sensorineural hearing loss. Exposure of the upper cervical internal carotid commonly entails loss of the glossopharyngeal nerve. Sequelae from its loss are infrequent, except when such loss is combined with other lower cranial nerve defects involving X and XII. Intraoperative reanastomosis of a vagal nerve is not indicated because of an association with paradoxic vocal cord motion. High vagal injuries can lead to a prolonged rehabilitative period. Not only are the quality of voice and protective sphincter function breached, but deglutition also is impaired through disruption of the pharyngeal plexus; when combined with losses of cranial nerves IX and XII, its loss may be debilitating. Persistent aspiration will lead to pneumonia. Tracheostomy is indicated if paresis of this combination of nerves is expected. Vocal cord medialization with endoscopic polytetrafluorethylene (Teflon) or surgical gel (Gelfoam) injection may be considered to protect the airway. Modified barium swallow may help in the decision regarding the need for a temporary feeding gastrostomy when aspiration persists.

Injury to the spinal accessory nerve usually is well tolerated in skull base procedures, because C2 and C3 ventral roots supply some motor innervation to the trapezius muscle. The suprascapular muscle also has a role in shoulder girdle stabilization. Nevertheless, reanastomosis or interposition grafting should be performed, if possible. Physical therapy and exercise instruction often are helpful in preventing persistent shoulder dysfunction.

The hypoglossal nerve often is involved with tumors of the clivus or jugular foramen. Because use of the hypoglossal nerve is an important reanimation option in facial nerve injury, its preservation is of added importance. Unilateral hypoglossal nerve loss usually is well tolerated unless combined with cranial nerve IX and X paralysis. Reconstruction of a transected hypoglossal nerve can lead to good functional recovery.[228]

Cerebrovascular Complications

The extensive manipulation of the internal carotid artery required by lateral skull base techniques understandably may lead to stroke. Preoperative angiographic evaluation and collateral circulation studies are mandatory. Anesthetic techniques such as increasing blood pressure, hypervolemia, pharmacologic vasodilation, calcium channel inhibitors, hemodilution, hyperosmolarity, and anticoagulation (when the carotid is occluded) theoretically reduce the risk.[229]

Cerebral edema or venous stroke is a concern, especially if a connection at the torcular Herophili is absent or if the vein of Labbé is interrupted.[7,8] Ligation of the sigmoid sinus is potentially more hazardous than extracranial jugular vein ligation. Collateral drainage through the superior and inferior petrosal sinuses may not be present. Presumably, the vertebral venous system compensates for posterior fossa outflow, and cerebral edema from venous occlusion is uncommon. At present, no good preoperative tests to predict this risk are available. Therefore, anastomotic veins, such as the superior petrosal sinus, inferior petrosal sinus, and mastoid emissary vein, should not be indiscriminately sacrificed.

CHAPTER ONE HUNDRED AND SEVENTY-SEVEN

Neoplasms of the Posterior Fossa

Derald E. Brackmann

Moisés A. Arriaga

Key Points

- Extra-axial neoplasms of the posterior cranial fossa have distinguishing imaging characteristics.
- Vestibular schwannomas and meningiomas are the most common lesions. Although both enhance with gadolinium on T1-weighted MRI, meningiomas tend to be eccentric to the porus acusticus, have enhancing dural "tails," and often demonstrate adjacent hyperostosis or intralesional calcifications on CT.
- Epidermoids and arachnoid cysts both are nonenhancing lesions hypointense to brain on T1-weighted and hyperintense on T2-weighted MRI studies. They are distinguished from one another on intermediate spin sequences and diffusion-weighted imaging (DWI) sequences, with arachnoid cysts exhibiting CSF characteristics and epidermoids demonstrating restricted diffusion (bright) on DWI.
- Vascular imaging studies including traditional angiography, magnetic resonance angiography (MRA), magnetic resonance venography (MRV), and CT angiography (CTA) are useful for demonstrating the proximity of these lesions to important vascular structures.
- Treatment of extra-axial neoplasms is individualized, with consideration of patient factors, tumor size, and tumor type. The treatment objectives are patient safety and functional preservation of cranial nerves.
- Treatment strategies include observation with serial imaging, stereotactic radiosurgery or radiotherapy, and surgical removal. Total surgical removal of these lesions usually is curative.
- Neuro-otologic surgical approaches are team therapies including the translabyrinthine approach, retrosigmoid approach, middle fossa approach, extended middle fossa approach, petrosal approach, and a series of petrous apex drainage approaches. Each strategy must be considered in the context of tumor size and location, patient symptoms and overall health, and short- and long-term outcomes.

With the evolution of advanced audiovestibular testing, sensitive imaging technologies, and modern skull base surgical teams, diagnosis and management of extra-axial posterior fossa neoplasms constitute a consideration in the daily practice of otolaryngology. This chapter reviews diagnostic issues and surgical management.

Approach to Diagnosis of Neoplasms of the Posterior Fossa

Cerebellopontine angle (CPA) lesions are the predominant skull base neoplasms that affect the posterior fossa. Although acoustic neuromas account for most primary neoplasms in this category, many other lesions should be considered in the differential diagnosis.

The diagnostic evaluation begins with a thorough neuro-otologic history and physical examination. Any suspicious neuro-otologic finding should be evaluated thoroughly, because these lesions produce minimal signs and symptoms until they are far advanced. As noted, acoustic neuromas are the most common posterior fossa skull base tumors; less common lesions usually can be diagnosed accurately with the application of modern audiologic and imaging modalities and a systematic approach to evaluation of their differing characteristics. Today's improved diagnostic capabilities facilitate routine detection of tumors smaller than those detectable previously.

Posterior fossa skull base neoplasms may be grouped into common CPA lesions, including lesions of the internal auditory canal; petrous apex lesions; rare CPA lesions; and intra-axial lesions. The signs, symptoms, and diagnostic procedures for tumors within the designated categories (Box 177-1) are described next.

Common Cerebellopontine Angle Neoplasms

In published series of CPA neoplasms, acoustic neuromas are the most common tumors, accounting for more than 90%. The remaining primary tumors were meningiomas (3%), primary cholesteatomas (2.5%), and facial nerve schwannomas (1%), with less common tumors composing the remaining lesions.[1] When secondary tumors also are considered, paragangliomas constitute up to 10% of CPA neoplasms.[2]

Acoustic Neuroma

Acoustic neuroma refers to a benign schwannoma of the eighth cranial nerve. These lesions are relatively common and account for 8% to 10% of all intracranial tumors. Acoustic neuromas arise principally from the vestibular division of the nerve. The superior and inferior divisions are equally affected; intraoperatively, the nerve of origin usually is difficult to determine. The 1992 National Institutes of Health Consensus Conference made *vestibular schwannoma* the official nomenclature term for these lesions. Acoustic neuromas are slowly growing neoplasms that

originate in the nerve sheath and consist of schwannoma cells in a collagenous matrix. They typically are circumscribed, grossly encroaching on and displacing neural structures without direct invasion. Consistency varies, ranging from firm and dense to soft with large cystic spaces.

In the past it was taught that acoustic neuromas usually arise near the myelin-glia junction near the porus acusticus. However, no published histopathologic study has confirmed this assertion. These lesions usually arise within the internal auditory canal; however, they occasionally develop in the CPA medial to the porus. Because acoustic neuromas produce symptoms by exerting pressure on surrounding neurovascular structures, auditory and vestibular symptoms develop earlier with tumors of the internal auditory canal than with tumors of the CPA.

Of the 2000 to 3000 acoustic neuromas diagnosed annually in the United States, more than 95% occur as unilateral and nonhereditary lesions. The remaining acoustic neuromas are manifestations of the neurofibromatoses, which consist of at least two distinct genetic disorders.

Neurofibromatosis type 1 (NF1), or von Recklinghausen's disease, is a relatively common disorder of autosomal dominant inheritance with variable penetrance and an incidence of 1 in 4000 live births. The gene responsible for NF1 has been localized to chromosome 17. NF1 neuromas occur throughout the body, arising both intracranially and extracranially from the Schwann cells of any nerve; however, acoustic neuromas develop in less than 5% of patients, and bilateral acoustic neuroma is not a part of the syndrome.

Type 2 neurofibromatosis, NF2, is the central form of the disease, characterized by bilateral acoustic neuromas in up to 96% of patients. Schwannomas of the other cranial nerves, meningiomas, and ependymomas also are observed much more commonly in patients with NF2.[3]

Figure 177-1. On T2-weighted fast spin echo magnetic resonance imaging, this axial reconstruction shows a 5-mm intracanalicular tumor on the *left*.

The precise frequency of NF2 is unknown, but it is far less frequent than NF1. The gene responsible for the condition encodes a membrane protein (merlin or schwannomin) and is located on chromosome 22. Acoustic neuromas in NF2 are characterized by an onset early in life, often before the age of 21 years, as opposed to unilateral lesions, most of which are diagnosed between the ages of 40 and 60 years. Thus, acoustic neuromas appearing before the age of 30 years mandate particularly close evaluation of the contralateral ear. Although the acoustic neuromas in NF1 and NF2 resemble the lesions in nonhereditary acoustic neuromas, they are technically more challenging to remove because of a tendency to adhere to nearby structures. The clinical presentation of acoustic neuroma in neurofibromatosis is identical to that of unilateral acoustic neuroma.

Malignant schwannomas may rarely occur. They often are associated with neurofibromatosis, but they also may occur with solitary schwannomas. Another very uncommon variant is a pigmented schwannoma.[4]

Natural History

The growth rate of acoustic neuromas is extremely variable. These tumors generally are slow-growing, with average reported growth rates of 0.2 cm per year; however, growth rates in excess of 2 cm per year have been documented. Acoustic neuromas that are not treated are potentially lethal. Gradual enlargement can lead to indentation of the brainstem, increased intracranial pressure, and death during a course of 5 to 15 years.[5]

Growth of acoustic neuromas generally occurs in three phases: internal auditory canal, cisternal, and brainstem compression (Figs. 177-1, 177-2, and 177-3). Growth within the internal auditory canal results in acoustic and facial nerve compression and attenuation. Displacement of the seventh cranial nerve, the acoustic (eighth) nerve, and the anterior inferior cerebellar artery occurs just medial to the porus acusticus (cisternal portion). Medial tumor growth augments the blood supply of the tumor with bridging vessels from the brainstem surface. Fourth ventricle shift often occurs when the CPA component reaches 2 to 3 cm and total ventricle obstruction with resulting hydrocephalus occurs with continued tumor growth. Trigeminal compression occurs at approximately the 3-cm stage, which permits the superior portion of the tumor to abut the fifth cranial nerve. Massive tumor growth with hydrocephalus, brainstem compression, and cerebellar tonsil herniation may occur even with modern imaging. The otolaryngologist should remain vigilant for signs and symptoms suggestive of retrocochlear pathology.

Signs and Symptoms

Sensorineural hearing loss (SNHL), tinnitus, dysequilibrium, and facial hypesthesia are, in descending order, the most common symptoms of

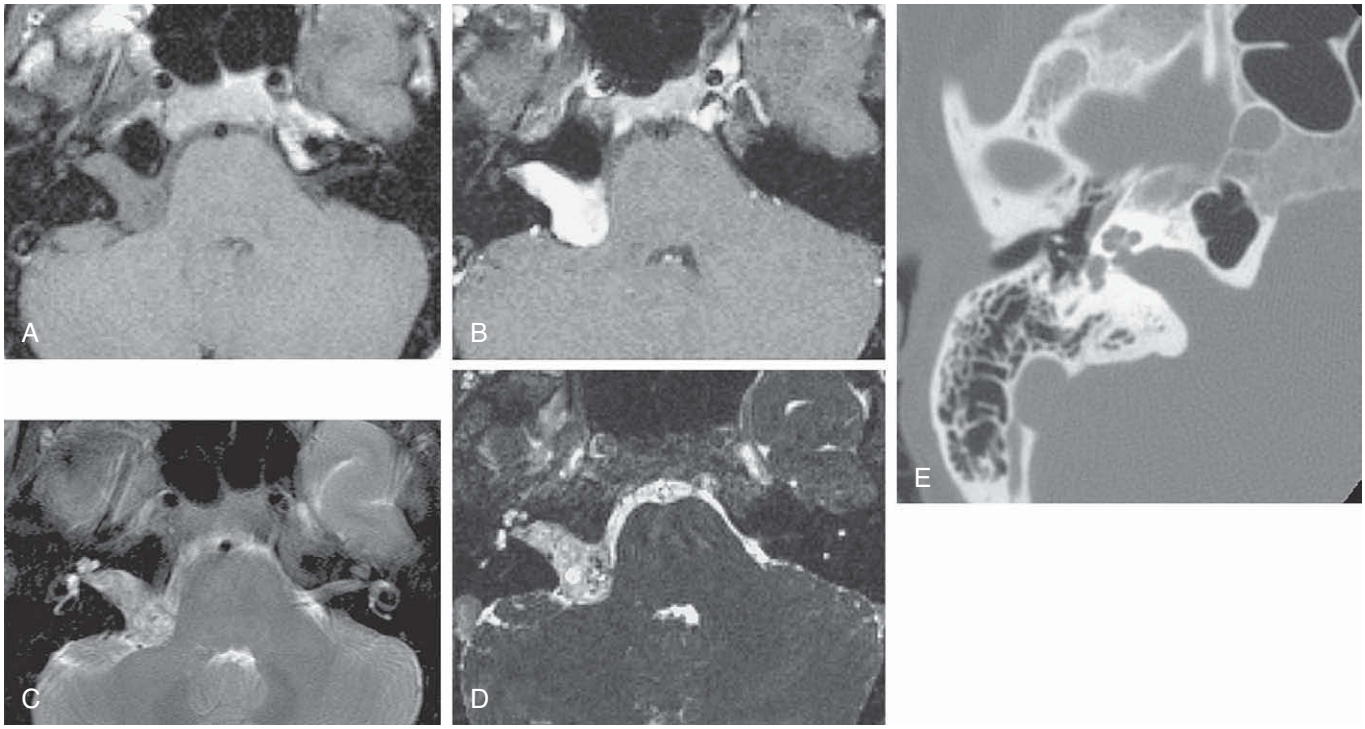

Figure 177-2. A medium-sized vestibular schwannoma, demonstrated by magnetic resonance imaging **(A** to **D)** and computed tomography **(E)**. **A** and **B,** T1-weighted images before and after intravenous administration of gadolinium contrast The tumor in the right internal auditory canal (IAC), which is mushrooming into the cerebellopontine angle and enlarging the canal, is isointense to mildly hypointense to the cerebellum and enhances markedly with contrast. **C** and **D,** T2-weighted and constructive interference in steady-state (CISS) images. The tumor is moderately hyperintense on the T2-weighted images. CISS images precisely demonstrate the cochlea, cystic, and calcified components of the tumor and surrounding vascular structures. **E,** CT bone windows. Note the enlargement of the IAC. *(Adapted from Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003:245.)*

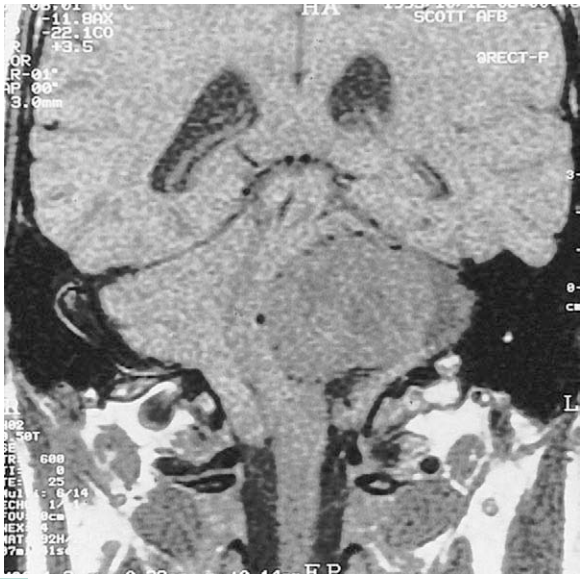

Figure 177-3. Noncontrast coronal T1 magnetic resonance image of a large acoustic neuroma with hydrocephalus, brainstem shift, and cerebellar tonsil herniation.

acoustic neuroma. Although progressive unilateral SNHL is the most common symptom, loss of speech discrimination is characteristic of retrocochlear dysfunction of the cochlear nerve presumably from pressure on the auditory nerve. The symptoms usually are slowly progressive, with a median duration of 2 years in one series.[6,7] However, up to 20% of affected patients experience sudden SNHL, although complete recovery of hearing has been reported.[8] Overall, only 1% of patients with sudden SNHL are found to have acoustic neuroma, whereas up to 5% of patients with acoustic neuroma have normal hearing.[9] Thus, any patient with asymmetric or sudden hearing loss (even after total recovery) should be considered for further evaluation for a possible retrocochlear lesion.

The dysequilibrium associated with acoustic nerve tumors usually is a mild balance disturbance, which often is so minor that the patient does not mention it and only careful questioning elicits it. Rotatory vertigo is far less common.

Diminished facial sensation or corneal reflex results from compression of the fifth cranial nerve, which is more likely with medium-sized and large tumors. As large acoustic neuromas compress the fourth ventricle and brainstem, long tract signs, ataxia, and findings of increased intracranial pressure (e.g., headaches, nausea) are produced.

Diagnostic Studies

Two categories of studies are performed in the diagnosis of acoustic neuroma. Auditory and vestibular studies assess the functional integrity of the audiovestibular system, whereas imaging studies are performed for the definitive anatomic diagnosis.

Audiometry

Routine air, bone, and speech discrimination studies may suggest the possibility of an acoustic neuroma. Asymmetric SNHL or impairment of speech discrimination disproportionate to the pure tone loss requires specific investigation for a retrocochlear lesion. In the past, an extensive audiometric test battery was necessary for timely tumor diagnosis.[6,10] In the magnetic resonance imaging (MRI) era, specialized audiometric tests are not sensitive or specific enough to detect small acoustic neuromas consistently.[11]

Auditory Brainstem Response Testing

Until recently, auditory brainstem (evoked) response (ABR) testing was considered the most sensitive modality for the detection of even small tumors, with detection rates of 95% to 100%.[12] The brainstem response to an 83-dB broadband click is recorded while the contralateral ear is masked by 78-dB white noise.[13] The latency for detection of wave V for the two ears is compared, and an adjusted interaural latency for wave V greater than 0.2 msec is considered abnormal. An approximately 10% false-positive rate has been reported for patients with SNHL who do not have a CPA tumor. Since the advent of gadolinium-enhanced MRI, however, the ABR false-negative rate (missing tumor diagnosis) has been 18% to 30% for intracanalicular tumors.[14] The possibility of false-negative results with intracanalicular acoustic neuromas has lessened the role of ABR testing for routine screening.[15] Stacked ABR testing is a modified ABR technique that offers improved sensitivity for detection of intracanalicular acoustic neuromas. It consists of testing the audiometric spectrum in a frequency-specific fashion followed by temporal alignment of the results; amplitude changes thus detected are much more sensitive for diagnosing small acoustic tumors than with routine ABR.[16,17] Nonetheless, the technique has not yet been verified in widespread clinical practice.

Vestibular Tests

Vestibular testing is not a useful screening test for acoustic neuroma. Electronystagmography (ENG) and infrared video caloric testing are helpful in defining whether the tumor arises from the superior or the inferior vestibular nerve.[18] Such information is valuable when hearing preservation surgery for acoustic neuromas is under consideration, because theoretically better results may be obtained with resection of tumors of the superior vestibular nerve.

Imaging

Computed tomography (CT) and MRI with the paramagnetic intravenous contrast agent gadopentetate (gadolinium-DTPA) are the principal imaging modalities for CPA lesions. Lo[19] proposed a scheme for the CT or MRI differential diagnosis of CPA lesions by anatomic location (extra-axial, extradural, or intra-axial) and by incidence (rare or common) (Table 177-1). In adults and teenagers acoustic neuromas, meningiomas, and epidermoids are the three most common lesions. Acoustic neuromas are very rare in children. Instead, brainstem gliomas (which can enlarge the internal auditory canal) are the most common CPA lesion in younger children.[20] Distinguishing among the three most common CPA lesions is based on specific imaging characteristics on CT and MRI (Table 177-2).

Although CT revolutionized the diagnosis of CPA tumors, gadolinium contrast MRI is sensitive and specific for detection of acoustic neuroma and is the diagnostic imaging technique of choice for the evaluation of acoustic neuroma and other CPA lesions (see Fig. 177-2).[21,22] Acoustic neuroma images on MRI are isointense or mildly hypointense to brain on T1-weighted images and mildly hyperintense to brain on T2-weighted images.[19] MRI for investigation of possible acoustic neuroma should be performed with intravenous contrast. Gadolinium increases the diagnostic sensitivity of MRI on T1-weighted images, and detection of lesions as small as 3 mm has been reported.[21] In addition to improving sensitivity in diagnosing acoustic neuromas, MRI is noninvasive, and the patient incurs no radiation exposure.

Before MRI, CT was the principal study for CPA lesions. Now the role of CT is to provide adjunctive information regarding the osseous structures surrounding a CPA lesion. It also can be the primary imaging modality in patients who cannot undergo MRI because of medical reasons (e.g., cardiac pacemaker or cochlear implant) or unmanageable phobic reactions. The CT finding characteristic of an acoustic tumor is an ovoid lesion centered on the internal auditory canal with moderate enhancing qualities. The tumor often is not homogeneous, exhibiting areas of lesser and greater enhancement. Approximately 85% of acoustic neuromas show acute angles at the bone-tumor interface, in contrast with meningiomas, in which the interface is obtuse in 75% of tumors.[19]

Intravenous contrast CT can fail to detect acoustic neuromas smaller than 1.5 cm in greatest dimension. Oxygen cisternography has been used to diagnose small, mainly intracanalicular lesions. In this technique, 4 mL of oxygen was introduced into the subarachnoid space through the opening afforded by a lumbar puncture, to highlight the structures of the internal auditory canal. This technique was very sensitive for detection of small lesions; however, it was limited by a false-positive rate of 5% and the need for a lumbar puncture.[23]

The improved availability of MRI has led to the development of MRI-based internal auditory canal screening protocols, which in many centers are comparable in cost to ABR-based internal auditory canal screening.[11] Special T2-weighted fast-spin echo sequences may achieve the accuracy of T1-weighted sequences with gadolinium without the need for contrast (see Fig. 177-1).[24] Although the software for these special sequences is not generally available, initial findings with this technique are very encouraging.

Table 177-1

Differential Diagnosis of Cerebellopontine Lesions by Imaging Location* and Incidence

Location	Incidence	Type
Extra-axial	Most common	Acoustic neuroma
	Common	Meningioma
	Common	Epidermoid (and other cysts: arachnoid, cysticercal, dermoid)
	Rare	Nonacoustic neuromas (cranial nerves V, VII, IX, X, XI, XII)
	Rare	Vascular lesions (loops, aneurysms, malformations)
Extradural	Common	Paraganglioma (glomus jugulare, glomus vagale)
	Rare	Bone lesions (benign or malignant; primary or metastatic)
Intra-axial	Rare	Astrocytoma, ependymoma, papilloma, hemangioblastoma, metastasis

Meningiomas

Meningiomas represent up to 18% of all intracranial tumors and approximately 3% of CPA tumors.[25] The cells lining the arachnoid villi are the cells of origin. These cells are distributed throughout the intracranial space predominantly in relation to veins and dural sinuses. Meningiomas are benign but locally aggressive tumors, which occur at different anatomic sites in the following order of frequency: parasagittal region, falx, convexity, olfactory groove, tuberculum sellae, sphenoid ridge, petrous face (CPA), tentorium, lateral ventricle, clivus, and others.[26]

The gross appearance typically is that of a globular mass firmly adherent to the dura mater, with characteristic speckles scattered throughout the tumor that correspond to the microscopic psammoma bodies. The tumor displaces but does not invade adjacent neural tissue and has a thin investing capsule. Meningiomas can invade bone without destruction by extension along haversion canals. Adjacent bone is hyperostotic in 25% of cases.[26]

Many histopathologic classifications have been proposed, but a single, widely used system distinguishes among syncytial, transitional, fibrous, angioblastic, and sarcomatous types.[27] The specific histopathologic subtypes and growth characteristics are reviewed elsewhere.[28] In

Table 177-2

Imaging Features of the Three Most Common Cerebellopontine Angle Lesions

Feature	Acoustic Neuromas	Meningiomas	Epidermoids
Location	Centered on the internal auditory canal	Eccentric to the internal auditory canal	Anterolateral or posterolateral to brainstem
Bone changes	Most enlarge the internal auditory canal	Occasional hyperostosis	Occasional erosion
Shape	Spherical or ovoid, acute bone-tumor angle	Hemispherical, rarely plaquelike; may herniate through tentorium; obtuse bone-tumor angle	Variable—tends to dumbbell into middle fossa or contralateral cerebellopontine angle
Computed tomography density	Mostly isodense	Slightly hypodense; some calcified	Mostly hypodense; occasional peripheral calcium
Computed tomography enhancement	Moderate to marked; often inhomogeneous	Marked and homogeneous	Nonenhancing
T1-weighted magnetic resonance imaging	Isointense or hypointense	Isointense or hypointense	Hypointense
Gadolinium enhancement	Marked	Moderate	Nonenhancing
T2-weighted magnetic resonance imaging	Isointense or hypointense	Variable	Hyperintense

Adapted from Lo WM: Tumors of the temporal bone and cerebellopontine angle. In: Som PM, Bergeron RT, eds. *Head and Neck Imaging*. St Louis: Mosby; 1991:420-445.

the posterior fossa, meningiomas usually arise on the posterior surface of the petrous bone, away from or at the edge of the internal auditory canal, or along the sigmoid sinus. Because they usually arise outside of the canal, these tumors may become large before producing signs and symptoms of cranial nerve VIII compression. Most meningiomas eventually involve cranial nerve VIII.

Signs and Symptoms

Audiovestibular symptoms usually are the first indication of a posterior fossa meningioma. Among patients presenting to neurosurgeons, a higher proportion first experienced symptoms referable to the trigeminal nerve.[29] The signs and symptoms of meningiomas are similar to those of acoustic neuromas. Small tumors produce hearing loss, tinnitus, and imbalance. Larger tumors also produce signs and symptoms of involvement of other cranial nerves and hydrocephalus.

Diagnostic Studies

Audiovestibular Testing

It is impossible to distinguish acoustic neuromas from meningiomas on the basis of audiovestibular testing. Because meningiomas cause cranial nerve VIII compression, auditory and vestibular test findings become abnormal in a pattern similar to that with acoustic neuromas. Because meningiomas usually do not arise within the internal auditory canal, the sensitivity of audiometric and vestibular testing is lower with meningiomas than with acoustic neuromas. For instance, only 75% of patients with meningiomas exhibit an abnormal ABR.

Imaging

Table 177-2 summarizes features of meningiomas that assist in differentiating them from acoustic neuromas. Unlike acoustic neuromas, meningiomas usually are eccentric to the porus. Whereas acoustic neuromas seldom herniate into the middle fossa, approximately 60% of meningiomas extend to the middle fossa.[19] Meningiomas usually are hemispheric because of their broad-based attachment to the posterior petrous wall, accounting for the obtuse bone-tumor angles in 75% of meningiomas. Unlike the site of origin of acoustic neuromas, that of posterior fossa meningiomas is varied (Figs. 177-4 and 177-5).

On CT, approximately two thirds of meningiomas are hyperintense relative to the brain. Unlike acoustic neuromas, meningiomas are homogeneous and occasionally calcified. They show homogeneous enhancement with iodine infusion, which usually permits differentiation from acoustic neuromas. Hyperostosis of adjacent bone is infrequent but characteristic of meningiomas when present.

On MRI, meningiomas are of extremely variable intensity on T2-weighted images and isointense or slightly hypointense to brain on T1-weighted images. The different signal intensities among meningiomas correspond to different histopathologic subtypes.[27] Surface flow voids on MRI correspond to marginal pial blood vessels, and arborizing flow voids represent active feeders to the tumor. Calcification and cystic foci cause heterogeneity on MRI images of meningiomas.

Primary Cholesteatomas

Primary cholesteatomas (epidermoids) consist of a stratified squamous epithelial lining surrounding desquamated keratin, which originates from epithelial rests within the temporal bone or CPA. These lesions usually are slow-growing, and symptoms often do not become apparent until the second to fourth decades of life. As the lesions expand, compression and irritation of surrounding structures produce the signs and symptoms.

Primary cholesteatomas arise adjacent to the brainstem. Because they expand into the area of least resistance, primary cholesteatomas have variable shapes with irregular surfaces. They may burrow into crevices on the surface of the brain or extend in a dumbbell pattern into the middle fossa.

Signs and Symptoms

Although primary cholesteatomas produce pressure on cranial nerves VII and VIII with continued growth, these lesions can become quite large without producing any symptoms. Facial twitching is a distinguishing clinical manifestation of primary cholesteatomas. Progressive

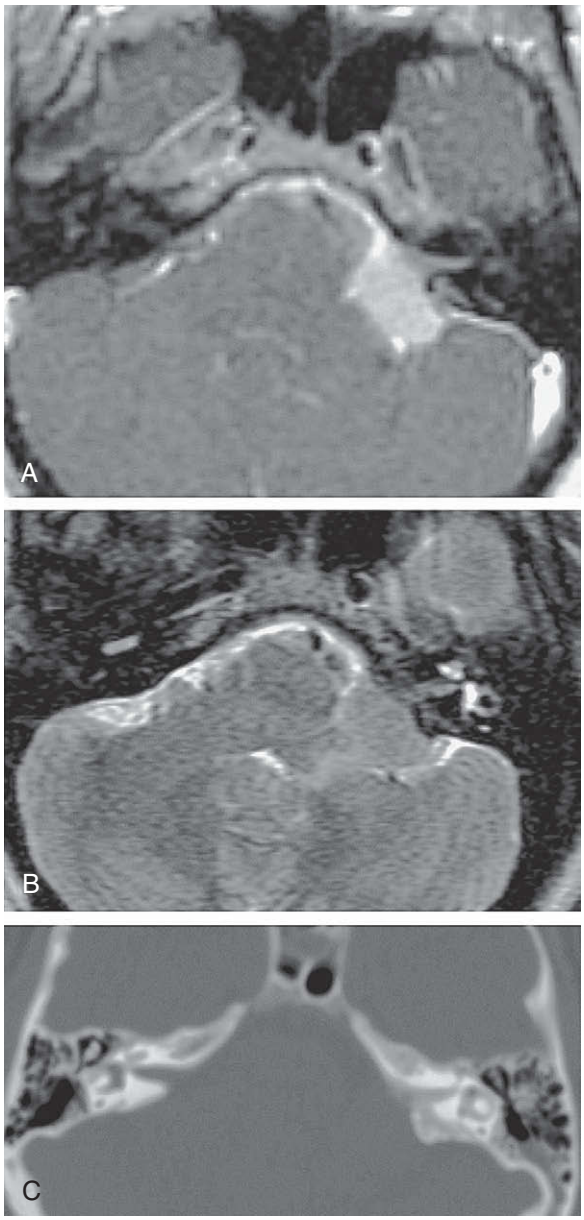

Figure 177-4. Cerebellopontine angle meningioma with classic features on magnetic resonance imaging (MRI) and computed tomography (CT). **A,** Post-gadolinium T1-weighted MRI: The tumor is eccentric to the internal auditory canal (IAC) and broadly dura-based, with obtuse angles at the bone-tumor interface. This hemispherical tumor shows uniform enhancement. Note the lack of IAC involvement. **B,** T2-weighted MRI: The tumor is homogeneously isointense to gray matter. **C,** CT bone windows. The tumor shows extensive hyperostosis underlying the dural base. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003:245-250.)*

facial paralysis is more common with these lesions than with schwannomas.

Diagnostic Studies

Auditory Testing

Auditory testing does not show any distinguishing features. As with other retrocochlear lesions, speech discrimination is poorer than would be expected from the degree of pure-tone loss. ABR also is frequently abnormal in primary cholesteatomas.[30]

Imaging

CT and MRI are useful to differentiate primary cholesteatomas from other lesions. Epidermoids originating in the CPA should be distinguished from arachnoid cysts, and epidermoids in the petrous apex should be distinguished from the much more common cholesterol granulomas. This distinction affects therapy because adequate management for primary cholesteatoma requires excision, whereas drainage is sufficient for cholesterol granulomas and arachnoid cysts.

On CT, primary cholesteatomas are less dense than brain (having a density approximating that of cerebrospinal fluid [CSF]) and exhibit no enhancement with intravenous contrast. These lesions have irregular margins and are eccentric to the porus acusticus. Enhancing components suggest an associated malignancy.[31] With MRI, primary cholesteatomas are inhomogeneous and hypointense to brain on T1-weighted images, and homogeneous and isointense or hyperintense to brain on T2-weighted images (Fig. 177-6). Schwannomas, meningiomas, and chondromas are similar to primary cholesteatomas by intensity criteria; however, epidermoids are differentiated because they are nonenhancing.

Arachnoid cysts of the CPA are difficult to distinguish from epidermoids on CT and MRI. Both lesions are of CSF density and nonenhancing; compared with primary cholesteatomas, however, arachnoid cysts have smoother surfaces, and special MRI sequences such as diffusion-weighted images (DWIs) may differentiate the intensity of the epidermoid from the CSF intensity of the arachnoid cyst (Fig. 177-7).

Facial Nerve Neuroma

Facial nerve neuromas (schwannomas) are uncommon benign neoplasms of Schwann cells that may arise anywhere along the course of the facial nerve.

Signs and Symptoms

Symptoms associated with these tumors depend on the portion of the nerve affected by the neoplasm. Peripheral involvement can manifest as a parotid mass, middle ear involvement can produce conductive hearing losses, and internal auditory canal or CPA involvement may result in SNHL. Unlike hemangiomas of the facial nerve, schwannomas do not produce facial weakness until they become very large. Sometimes a facial nerve tic is evident, which helps distinguish facial neuromas from acoustic neuromas but not from primary cholesteatomas. Of note, intratemporal lesions, with the possibility of neural entrapment, are more likely than CPA lesions to result in facial paralysis.[32]

Diagnostic Studies

Auditory Testing

The mechanisms for conductive hearing impairment and SNHL have already been described earlier in this chapter. Impedance testing may reflect motor fiber impairment on ipsilateral reflex testing or cranial nerve VIII involvement on contralateral reflex testing. ABR testing of tumors arising in the internal auditory canal shows abnormalities similar to those seen with acoustic neuroma.[13]

Electroneurography

Electroneurography, also known as electroneuronography (ENoG), measures the muscle response to a maximal bipolar stimulation of the facial nerve near the stylomastoid foramen. ENoG potentials may be reduced in facial nerve neuroma even when no facial weakness or tic is present, whereas ENoG findings remain normal in acoustic neuroma until the tumor becomes very large. Some reports suggest that the value of preoperative ENoG in patients with acoustic neuroma lies in predicting whether the lesion actually represents a facial nerve tumor.[33,34]

Imaging

Intratemporal facial nerve lesions may produce bone destruction. Because the clinical presentation and audiometric study findings in facial neuroma are not distinct, CT and MRI constitute the mainstays of diagnosis.

Because facial nerve neuromas are histologically identical to acoustic neuromas, they have the same enhancement characteristics. It

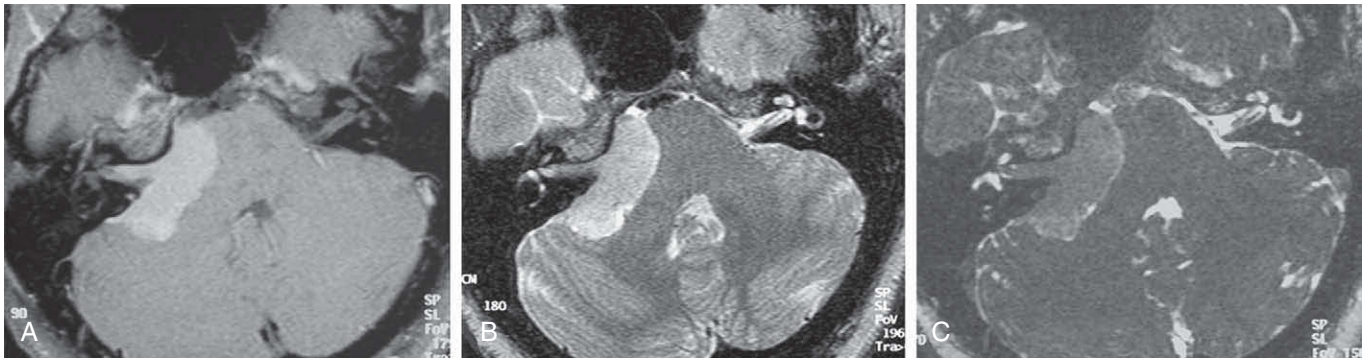

Figure 177-5. Cerebellopontine angle meningioma with intracanalicular extension, demonstrated by magnetic resonance imaging. **A,** Post-gadolinium T1-weighted image. Typical hemispherical tumor with intracanalicular extension. The dural tail of the tumor extending posteriorly is best seen on post-gadolinium images. **B,** T2-weighted image demonstrates the cerebrospinal fluid spaces and clefts surrounding the tumor. **C,** Constructive interference in steady-state (CISS) image. The internal auditory canal extension and margins of the tumor are better delineated on CISS images than on T2-weighted images. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003:245-250.)*

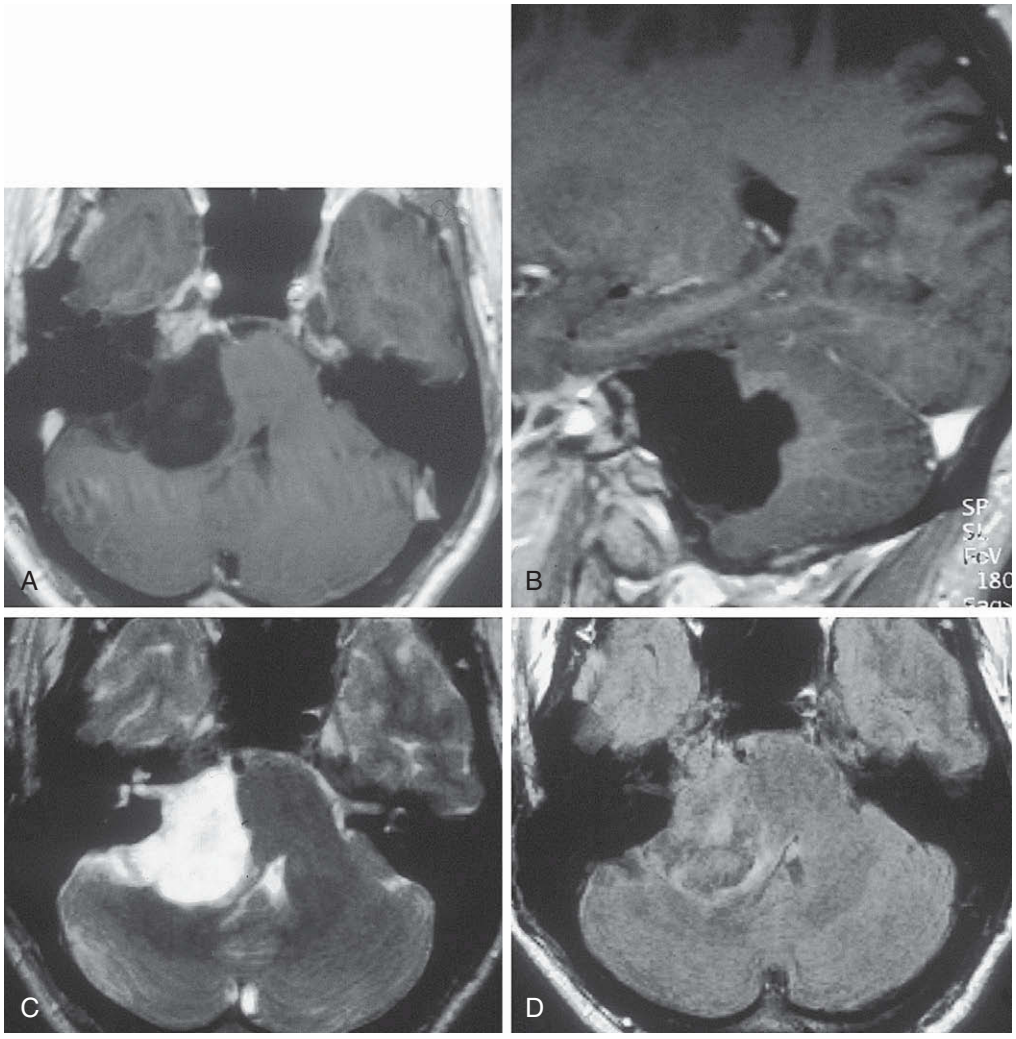

Figure 177-6. Cerebellopontine angle (CPA) epidermoid, demonstrated by magnetic resonance imaging. **A** and **B,** T1-weighted axial and sagittal images after gadolinium administration. The CPA mass extending to the prepontine cistern is isointense to cerebrospinal fluid (CSF) and shows no enhancement. **C,** T2-weighted image. The tumor, with irregular, cauliflower-like margins, is isointense to CSF, as in T1-weighted images, and is compressing the fourth ventricle. The internal auditory canal is normal. **D,** On this fluid-attenuated inversion recovery (FLAIR) sequence image, the epidermoid has heterogeneous hyperintense foci, enabling differentiation of an epidermoid from an arachnoid cyst in this case. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003:245-250.)*

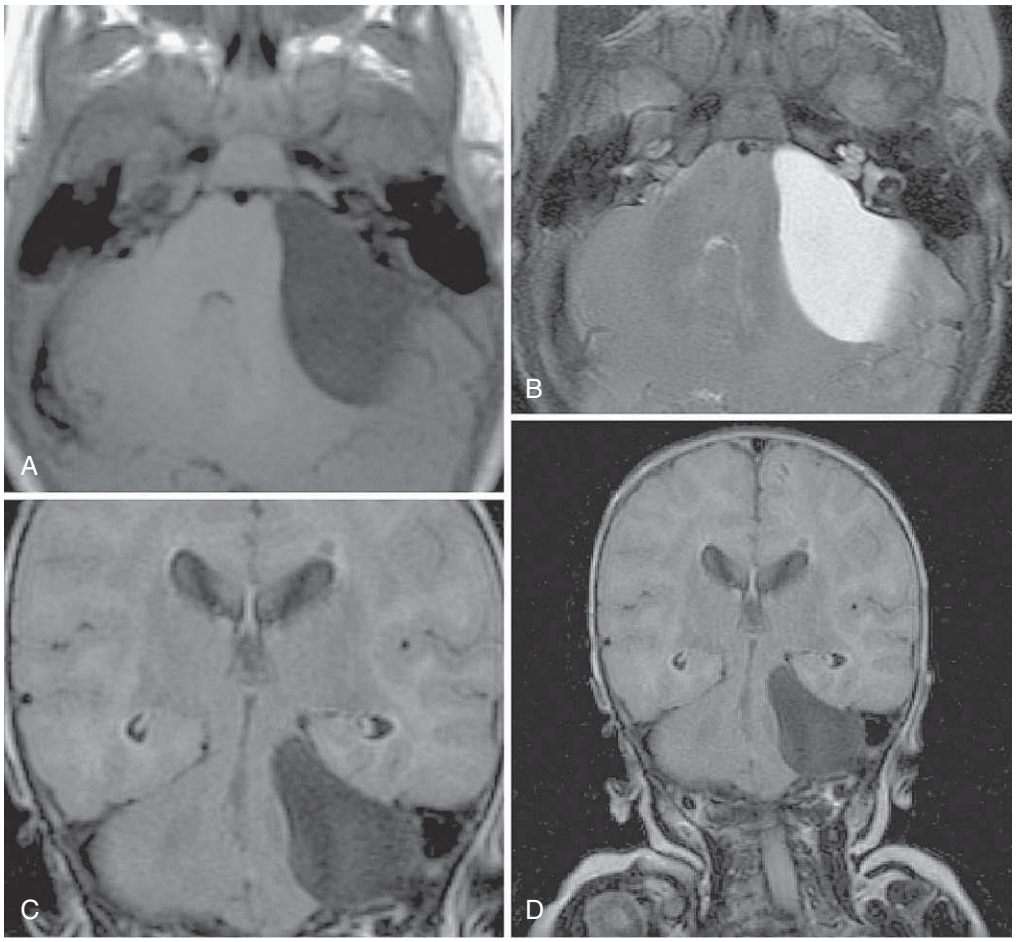

Figure 177-7. Cerebellopontine angle arachnoid cyst, demonstrated by magnetic resonance imaging. **A,** T1-weighted image. **B,** T2-weighted image. **C** and **D,** T1-weighted coronal and axial images, respectively. The cyst is isointense to CSF on all sequences. It is homogeneous, with a smooth surface, which can be helpful in differentiating it from an epidermoid. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003:245-250.)*

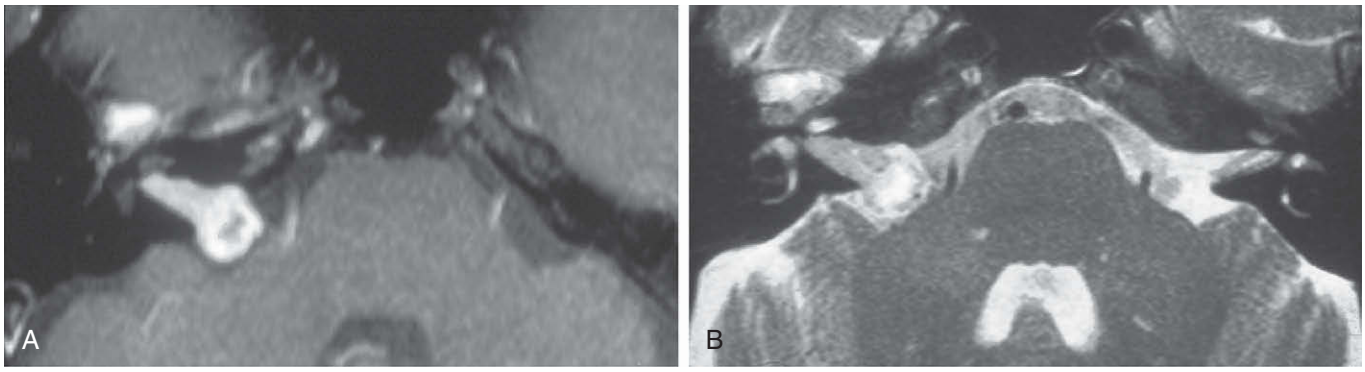

Figure 177-8. Facial schwannoma of internal auditory canal, demonstrated by magnetic resonance imaging. **A** and **B,** Post-gadolinium T1-weighted and T2-weighted images. The patient presented with progressive sensorineural hearing loss, with later development of facial palsy. The enhancing intracanalicular tumor is indistinguishable from an acoustic schwannoma. Note also the extension of the tumor to the geniculate ganglion. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003:245-250.)*

usually is impossible to identify these lesions using CT. Anterosuperior erosion of the internal auditory canal or erosion of the labyrinthine facial nerve canal if present may be the only diagnostic clue.[19] More distal tumors enlarge the geniculate ganglion and fallopian canal.

As with CT, MRI of facial neuroma produces imaging characteristics identical to those of acoustic neuromas (Fig. 177-8). The preoperative diagnosis of intracranial facial neuroma is difficult. Early facial nerve symptoms are an obvious warning that a CPA lesion may rarely be a facial nerve neuroma. Patients diagnosed with CPA neuromas should be warned preoperatively of a 1% risk of facial nerve neuroma. This possibility is emphasized if findings on preoperative ENoG are abnormal on the tumor side. In some tumors, the lesion may extend

Figure 177-9. Cystic trigeminal schwannoma, demonstrated by magnetic resonance imaging. **A,** T1-weighted image. **B,** Gadolinium T1-weighted image. **C,** T2-weighted image. The bulk of the tumor lies in the posterior fossa, with a small middle cranial fossa component enlarging the left Meckel's cave *(arrow)*. Note the similarity of the tumor to an arachnoid cyst (see Figure 177-7) on the noncontrast images (**A** and **C**). The tumor is nearly of CSF intensity because of the predominance of the intratumoral cystic components. *(From Jackler RK, Brackmann DE, eds.* Neurotology. *St Louis: Mosby; 1994.)*

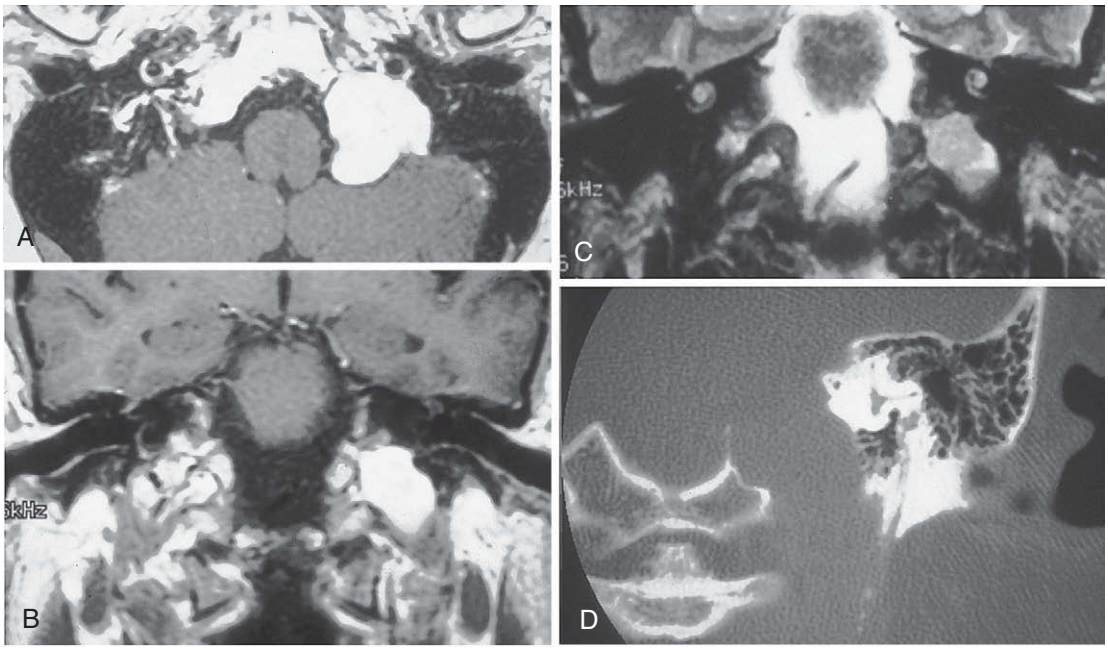

Figure 177-10. Jugular foramen schwannoma, demonstrated by magnetic resonance imaging (MRI) and computed tomography (CT). **A** and **B**, Axial and coronal T1-weighted post-gadolinium images. The large tumor in the left jugular fossa is extending inferiorly. It shows avid enhancement. **C,** Coronal T2-weighted image depicts the extracranial portion of the tumor, which is hyperintense to gray matter. **D,** CT bone windows, coronal image. Expansion of the jugular foramen is symmetric, and the margins are well defined. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003:245-250.)*

from the CPA through the temporal bone course of the nerve to the extratemporal nerve in the parotid gland.

Other Cranial Nerve Neuromas

Neuromas may arise on any other cranial nerve in the posterior fossa. On imaging studies, nonacoustic neuromas have the same characteristics as those of acoustic neuromas except for their location. Overall, acoustic neuromas represent 95% of intracranial schwannomas, and trigeminal neuromas are the next most common; however, schwannomas also have been reported on cranial nerves IX, X, XI, and XII. These lesions are distinguished by their different location and by symptoms of dysfunction of the cranial nerve of origin.

Trigeminal neuromas arise intradurally, from the nerve root in the CPA and Meckel's cave, and extradurally, from the gasserian ganglion in the middle cranial fossa.[35] Typically these lesions enlarge Meckel's cave and produce hypesthesia of the face (Fig. 177-9).

Neuromas of cranial nerves IX, X, and XI produce smooth enlargement of the jugular foramen and classically cause hypesthesia and weakness of the palate, vocal cord, and shoulder, respectively (Fig. 177-10). If they arise in the posterior fossa, these tumors may grow to a large size before producing predominantly acoustic or cerebellar signs. Accurate preoperative differentiation of these tumors from acoustic neuromas is important because residual hearing is more likely to be preserved with lower cranial nerve neuromas. Hypoglossal neuromas produce motor hemiatrophy of the tongue and enlargement of the hypoglossal canal on radiography.

Glomus Tumors

Glomus tumors (paragangliomas) are discussed in detail in Chapter 176. Because glomus jugulare tumors and glomus vagale tumors may extend into the posterior fossa, they constitute an important consideration in the differential diagnosis of skull base neoplasms.

The first symptom often is pulsatile tinnitus, after which a conductive hearing loss develops. Involvement of the nerves of the jugular foramen and the hypoglossal nerve causes progressive neurologic deficits related to those nerves.

The characteristic appearance on CT with bone windows is irregular destruction of the jugular foramen, as compared with jugular

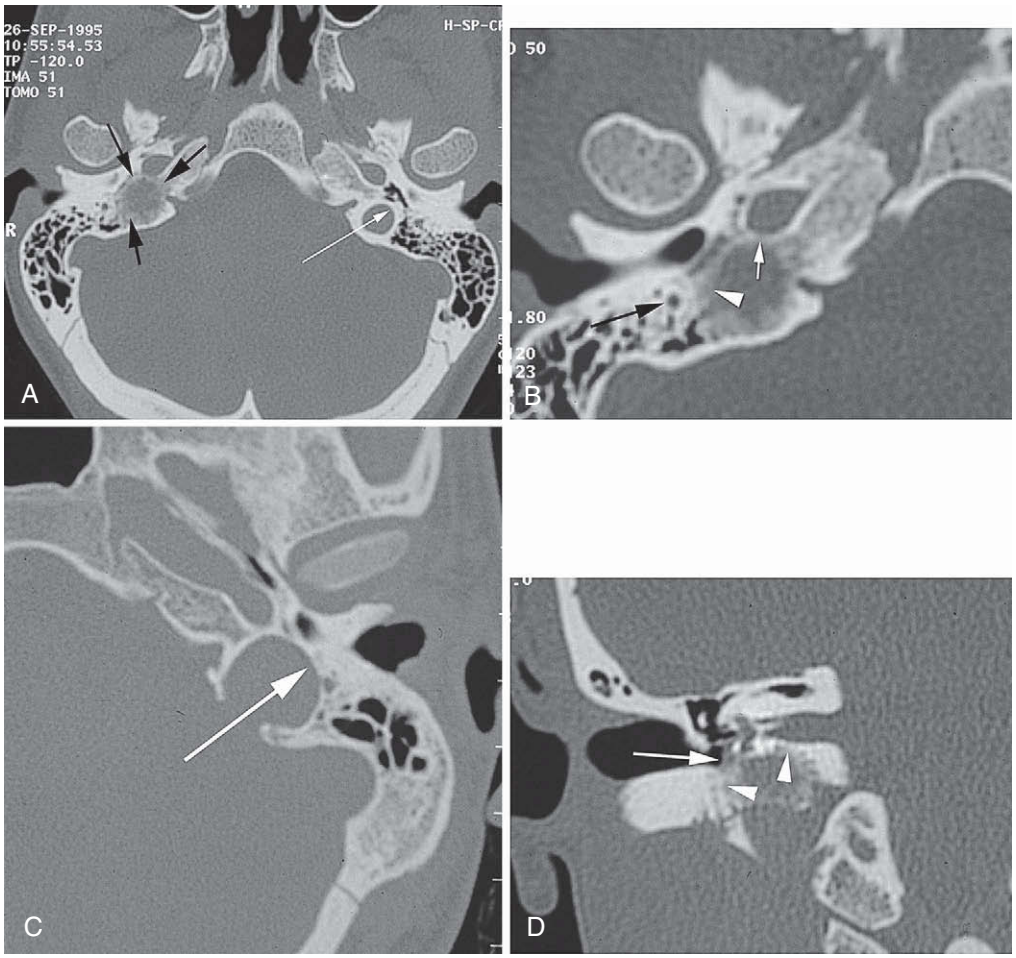

Figure 177-11. Glomus jugulare tumor, demonstrated by computed tomography. **A,** Axial image shows demineralization of the bony margins of the jugular foramen on the right side *(black arrows)*. There is demineralization of the fine cortical line usually demonstrated along the lateral aspect of the vascular portion of the jugular foramen. Compare with intact cortical plate on the opposite side *(white arrow)*. Note the demineralization of the bony wall separating the carotid canal from the jugular foramen. **B,** Enlarged axial image shows the demineralization of the lateral cortical plate *(arrowhead)*, as well as slight demineralization of the bony plate between the carotid canal and the jugular foramen *(white arrow)*. Note the proximity of the demineralized bone to the vertical section of the facial nerve canal *(black arrow)*. **C,** Axial image enlarged through the normal side shows the intact white cortical line *(arrow)* along the lateral aspect of the jugular foramen. The integrity of this line essentially excludes a glomus jugulotympanic tumor. **D,** Coronal image shows demineralization of the margins *(arrowheads)*, as well as the soft tissue of the intratympanic portion of the tumor *(arrow)*. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

foramen schwannomas, which produce smooth enlargement (Fig. 177-11). The vascular pattern of paragangliomas on angiography is characteristic (Fig. 177-12), and biopsy of these lesions is not indicated.[36] Diagnostic angiography should be performed concomitantly with preoperative embolization when surgical resection is planned.

MRI produces a unique salt-and-pepper mixture of intensities on T1- and T2-weighted images. Arborizing flow voids reveal the prominent tumor vessels of this lesion. Lo[19] described two limitations of MRI in evaluating paragangliomas: (1) bone changes and the relation of tumor to bone landmarks are not visualized; and (2) distinguishing tumor from bone marrow is difficult, especially on gadolinium-enhanced T1-weighted images. Thus, MRI may provide complementary information about infralabyrinthine and intracranial tumor extensions, but bone algorithm CT is the cornerstone of imaging evaluation in paragangliomas.

The combination of CT, MRI, and angiography can provide extensive information about involvement of the internal carotid artery. Magnetic resonance angiography (MRA) is an adjunct to intra-arterial catheterization and formal angiography (see Fig. 177-12). Angiography is a necessary step in preoperative embolization of glomus tumors; however, it is unlikely that MRA can replace direct intravascular angiography in glomus tumor management. For resection of skull base neoplasms involving the posterior fossa, if surgical resection requires manipulation of the artery, preoperative assessment of the adequacy of collateral flow by way of the circle of Willis is necessary. Temporary balloon occlusion of the carotid artery in combination with radioisotope imaging or xenon-enhanced CT can accurately quantify collateral blood flow.[37]

Arachnoid Cysts

Arachnoid cysts are thin-walled sacs that contain yellow, entrapped CSF. The current theory is that these lesions represent congenital developmental anomalies.[38] Symptoms are produced by the mass effect of the cyst on surrounding structures and may be similar to the symptoms of acoustic neuromas. These patients may experience mild to profound hearing loss with a retrocochlear pattern.[39]

These lesions have CT and MRI characteristics similar to those of epidermoids. Enlargement of the internal auditory canal often is noted but is not characteristic of these lesions. The typical appearance is that of a smooth-surfaced lesion, which on CT approximates CSF and is nonenhancing and on MRI exhibits isointensity or hypointensity to brain on T1-weighted images and hyperintensity to brain on T2-weighted images (see Fig. 177-7). In most patients, no direct inter-

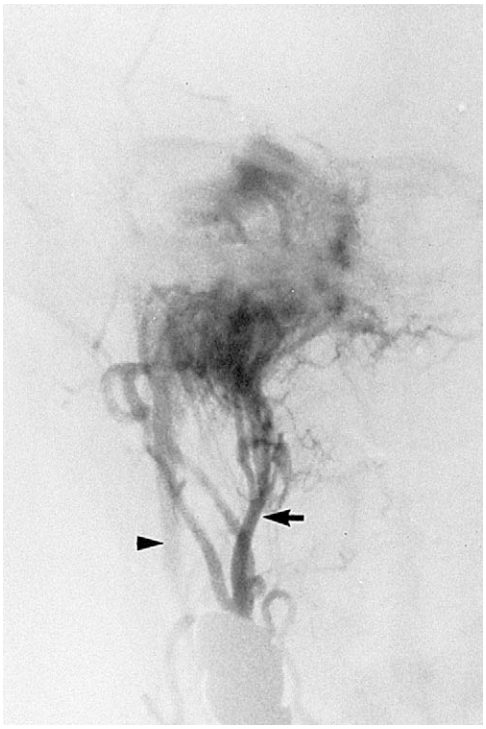

Figure 177-12. Glomus jugulare tumor. As seen on this selective external carotid angiogram, the characteristically hypervascular tumor is supplied by the hypertrophic ascending pharyngeal artery *(arrow)*. Note the early draining vein *(arrowhead)* seen during the midarterial phase. Considerations in the differential diagnosis include other hypervascular tumors such as metastatic hypernephroma, metastatic pheochromocytoma, and myeloma. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

vention is necessary. When treatment is necessary to control symptoms, management of these lesions is not total resection. Instead, surgical drainage by way of retrolabyrinthine exposure is the usual recommended therapy; however, diuretic therapy provides symptomatic relief in a few patients.

Hemangiomas

Hemangiomas are hamartomatous neoplasms originating from blood vessels. Although benign, they produce symptoms by compression of adjacent structures. Hemangiomas are capillary or cavernous.

Capillary hemangiomas typically arise in the area of the geniculate ganglion in association with a perigeniculate capillary plexus.[40] The lesion is characterized by a progressive facial weakness despite being much smaller than facial nerve neuromas. The expanding lesion with the production of pulsatile tinnitus may expose the upper basal turn of the cochlea. CT shows a smooth enlargement of the geniculate ganglion and enlargement of the labyrinthine portion of the fallopian canal by a soft tissue mass. Although capillary hemangiomas are enhancing, they produce facial weakness at such an early stage that only subtle findings may be apparent on CT, and a very small enhancement in the area of the labyrinthine segment may be the only finding. Other CT findings include honeycomb bone, irregular and indistinct bone margins, and intratumoral bone spicules (Fig. 177-13). These findings contrast with those in facial nerve neuromas, which are larger, more obvious lesions with sharp bone margins.

Cavernous hemangiomas are the second type of hemangioma. These lesions arise in the internal auditory canal and produce symptoms typical for an acoustic neuroma. Although they tend to produce symptoms more rapidly than do acoustic neuromas, these two tumor types are identical on CT. However, on MRI, cavernous hemangiomas tend to be slightly more hyperintense than the typical acoustic neuroma.

Table 177-3

Imaging Features of Petrous Apex Cystic Lesions

Features	Cholesterol Granuloma	Epidermoid	Mucocele
Computed tomography density	Isodense	Hypodense	Hypodense
T1-weighted MRI appearance	Hyperintense	Hypointense	Hypointense
Gadolinium contrast MRI appearance	Nonenhancing	Nonenhancing	Rim enhances; mass is nonenhancing
T2-weighted MRI appearance	Hyperintense	Hyperintense	Hyperintense
Borders of lesion	Smooth	Scalloped	Smooth

MRI, magnetic resonance imaging.

Petrous Apex Lesions

Petrous apex lesions constitute an important category of skull base neoplasms that may involve the posterior fossa. Some of the specific lesions have been described earlier under "Common Cerebellopontine Angle Neoplasms." The critical distinction in diagnosis of petrous apex lesions is between cholesterol granulomas, which require drainage procedures, and mass lesions, which generally require complete excision.

Cholesterol Granulomas

A cholesterol granuloma arises in the pneumatized spaces of the temporal bone presumably as a result of occlusion of the air cell system. Hemorrhage into the air cells results in a foreign body reaction and progressive granuloma formation. An expansile lesion of the temporal bone results, with extension into the CPA and resultant signs and symptoms of cranial nerve VIII dysfunction. A recent theory suggests that exposed bone marrow may hemorrhage into the pneumatized petrous apex air cells, producing the foreign body reaction and granuloma formation.[41] This newer concept more adequately explains the presence of cholesterol granuloma in well-pneumatized temporal bones.

The CT and MRI findings with this lesion are distinguishable from those with the other common lesions of the petrous apex (Table 177-3). On CT, the lesions result in a punched-out appearance of the temporal bone with an isodense mass of the petrous apex that does not enhance; however, rim enhancement is evident with intravenous contrast. On MRI, T1- and T2-weighted images are hyperintense with respect to brain (Fig. 177-14). Primary cholesteatomas are the main lesions from which cholesterol granulomas should be distinguished. Cholesterol granulomas are much more common and occur 20 times more frequently than epidermoids. Overall, cholesterol granulomas are relatively uncommon compared with acoustic neuromas. Only 1 cholesterol granuloma is identified for every 35 acoustic neuromas diagnosed. Imaging distinguishes petrous apex epidermoids from petrous apex cholesterol granulomas. On CT, epidermoids show rim enhancement. With MRI, cholesterol granulomas are hyperintense on T1- and T2-weighted images, whereas epidermoids are hyperintense only on T2-weighted images.

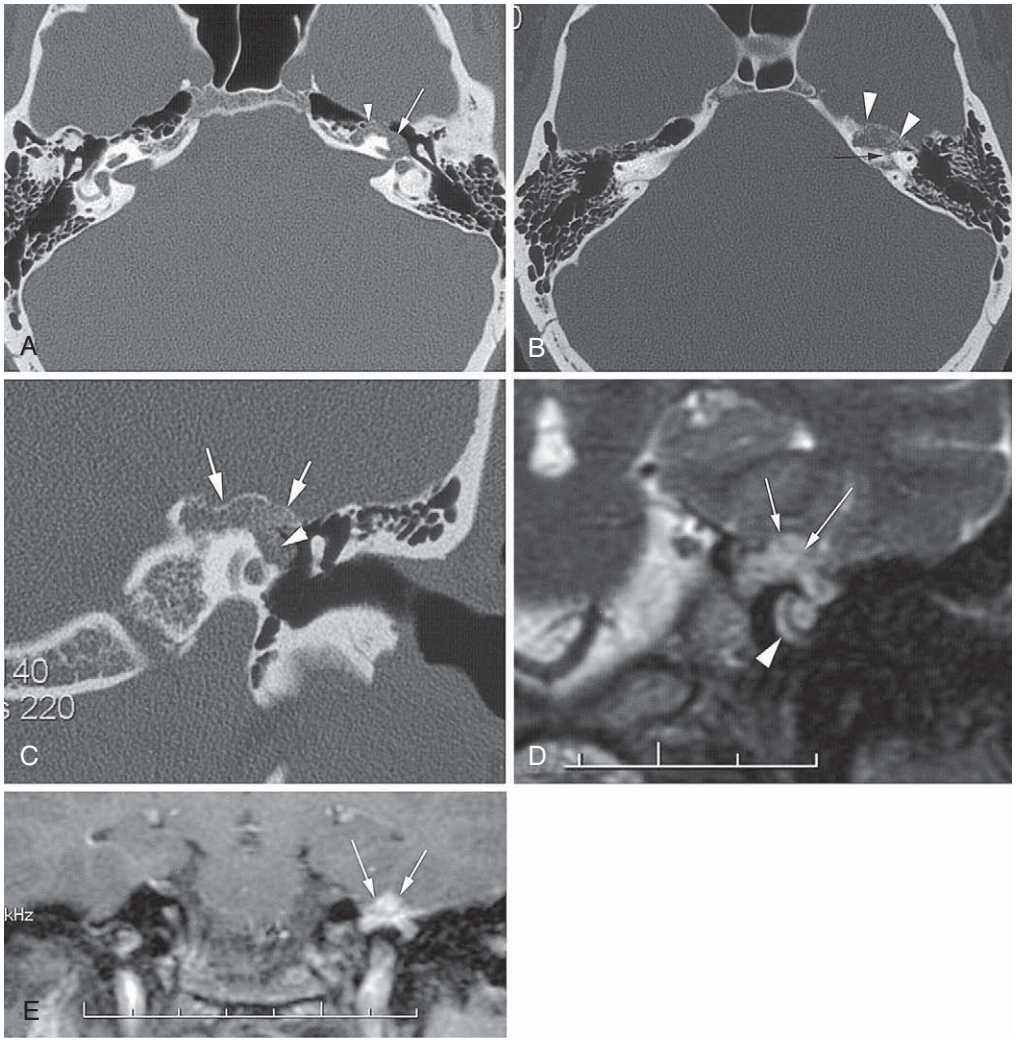

Figure 177-13. Intratemporal vascular tumor in the region of the geniculate ganglion, demonstrated by computed tomography (CT) and magnetic resonance imaging. **A,** CT image through the region of the geniculate ganglion shows expansion of the facial nerve *(arrow)*. Irregular bone is seen extending medially toward the petrous apex *(arrowhead)*. **B,** In this CT image, at a level slightly superior to **A,** demineralization is evident in the region of the labyrinthine segment of the canal *(black arrow)*. Note that the lesion *(arrowheads)* contains small spicules of bone. **C,** Coronal CT image shows the demineralized bone *(arrows)*. The abnormality extends inferiorly to enlarge the FNC *(arrowhead)* and involve the facial nerve. **D,** Coronal T2-weighted image shows the relatively high signal *(arrows)* of the vascular lesion. The fluid within the cochlea *(arrowhead)* is noted for comparison and orientation. **E,** Coronal postcontrast gadolinium T1-weighted magnetic resonance image shows the enhancement *(arrows)* of the lesion. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

Total excision of cholesterol granulomas usually is unnecessary. Drainage may be achieved by a transmastoid or transcanal infralabyrinthine approach with preservation of cranial nerve function. The transcanal, infracochlear, hypotympanotomy approach is preferred because it affords dependent drainage and the possibility of revision, if necessary, through a myringotomy.[42] In cases with unfavorable anatomy for infracochlear or infralabyrinthine drainage, middle fossa drainage is an option. Suprisingly, long-term follow-up imaging has demonstrated that middle fossa catheter drainage to the mastoid remains patent.[43]

Asymmetric Petrous Apex Pneumatization

Although asymmetric pneumatization of the petrous apex does not represent a true neoplasm, this condition can be confused with and should be distinguished from true neoplasms. The fat content of bone marrow in a nonpneumatized petrous apex can produce a hyperintense appearance on T1-weighted noncontrast MRI (Fig. 177-15). The lack of bone destruction or expansion on CT, absence of contrast enhancement with gadolinium, and hypointensity on T2-weighted images distinguish this condition from a neoplasm.

Mucocele, Mucus Retention Cysts, and Petrous Apex Effusion

Petrous apex air cells may become obstructed, resulting in retained secretions as a mucus retention cyst in the petrous apex (Fig. 177-16) or an expansile mucocele (Fig. 177-17). CT reveals a nonenhancing lesion limited to the petrous apex air cell system. The MRI appearance is consistent with a mucus-filled lesion (hypointense on T1-weighted and hyperintense on T2-weighted images). A symptomatic mucocele behaves like chronic mastoiditis, with pressure symptoms that require drainage for relief. Occasionally, retained petrous apex fluid also can cause symptoms even without mucocele. Medical treatment as for a middle ear effusion or surgical drainage usually is therapeutic.[43]

Petrous Carotid Artery Aneurysms

Although aneurysms of the horizontal carotid artery are rare, they may appear as expansile, well-defined masses (Fig. 177-18). Their preoperative identification is critical for obvious reasons. Carotid aneurysms may be confused with chondrosarcomas on the basis of radiologic appearance.

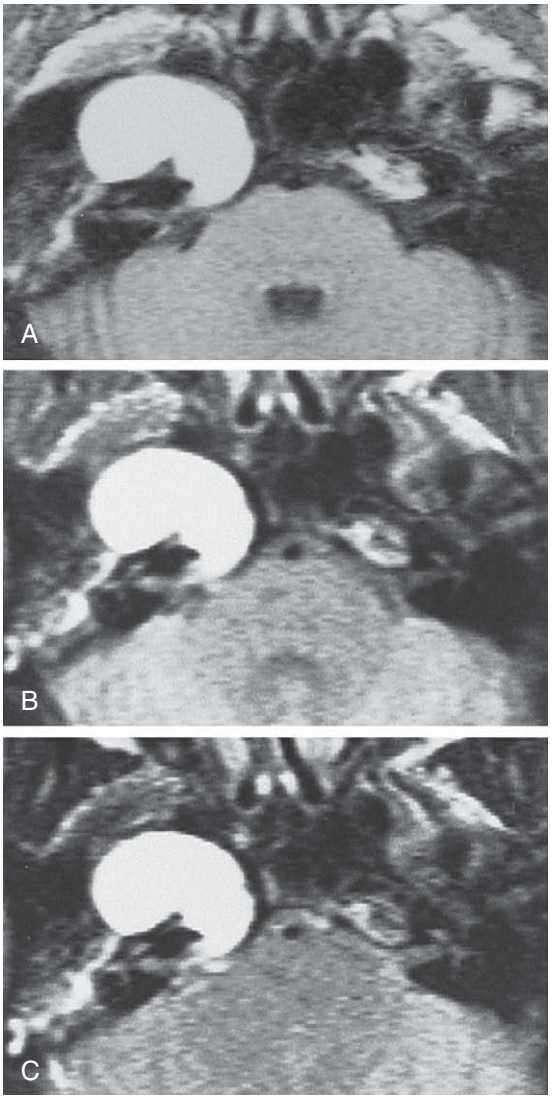

Figure 177-14. Petrous apex cholesterol granuloma, demonstrated by magnetic resonance imaging. **A** to **C,** T1-weighted, proton density, and T2-weighted images, respectively. The lesion is hyperintense on all three images. Note the hypointense rim medial to the lesion accentuated on **B** and **C**, attributable to a hemosiderin deposit or chemical shift artifact. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

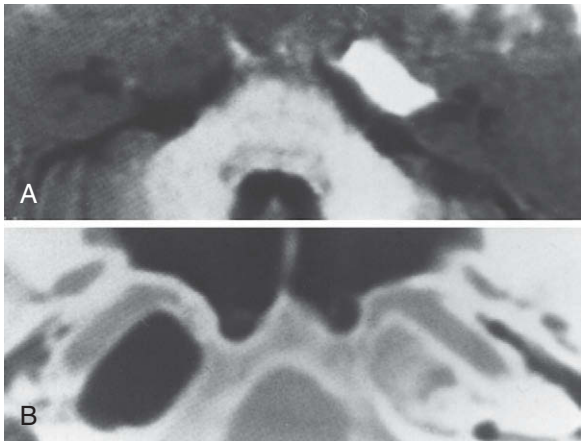

Figure 177-15. Asymmetric pneumatization of the petrous apex, demonstrated on an axial T1-weighted image **(A)** and an axial computed tomography (CT) scan **(B)**. Note that the area of hyperintensity on the T1-weighted image could be confused with a neoplasm. The CT scan reveals extensive pneumatization on the contralateral side and limited pneumatization on the side with hyperintense signal on magnetic resonance imaging.

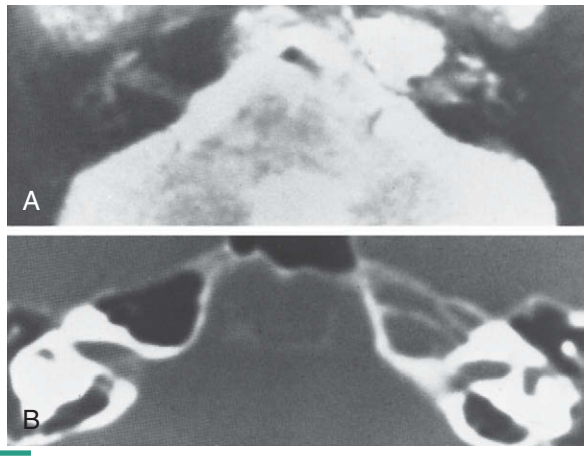

Figure 177-16. Retained mucus in petrous apex air cells, demonstrated on an axial T2-weighted magnetic resonance image **(A)** and an axial computed tomography (CT) scan **(B)**. Note that the mucus is hyperintense on the T2-weighted image, and the CT scan identifies fluid density within the petrous apex air cells.

Giant Cell Tumors

Giant cell tumors are extremely rare primary neoplasms of the temporal bone. They originate from undifferentiated cells of the supporting connective tissue and consist of multinucleated giant cells in a background of spindle-shaped stromal cells. Patients with this unusual condition demonstrate retrocochlear signs and symptoms. CT typically shows a diffuse lesion of the temporal bone compressing the contents of the internal auditory canal.

Miscellaneous Cerebellopontine Angle Lesions

Metastatic Tumors

Tumors may metastasize to the CPA from other sites, including lung, breast, prostate, oropharynx, and skin (i.e., cutaneous melanomas).[44] Tumors from these sites are distinguished by their rapid progression of symptoms and associated neurologic signs, in addition to hearing loss and dizziness. Associated lytic lesions in the petrous apex constitute another distinguishing feature of metastatic tumors. Rapid impairment of hearing, other cranial neuropathies, and brainstem dysfunction suggest malignant neoplasms of the posterior fossa, especially in a patient with a history of another malignancy.

Chordomas

Chordomas are dysontogenetic neoplasms that arise in remnants of the embryonic notochord. Although more than one half of these tumors arise in the sacrococcygeal region, more than one third occur at the skull base in the region of the clivus or, less commonly, the upper cervical vertebrae.[45] The prominent clinical characteristics are extensive bone destruction and progressive cranial nerve palsies. Extension of clivus chordomas to the petrous apex, sphenoid, or CPA is not unusual. Although fronto-orbital headache and vision complaints (e.g., limited visual fields, diplopia, loss of acuity) are more common, occasionally the initial symptoms reflect extension into the CPA. On CT, the bone destruction is readily apparent, and the masses are homogeneous with moderate enhancement and a greater density than that of bone

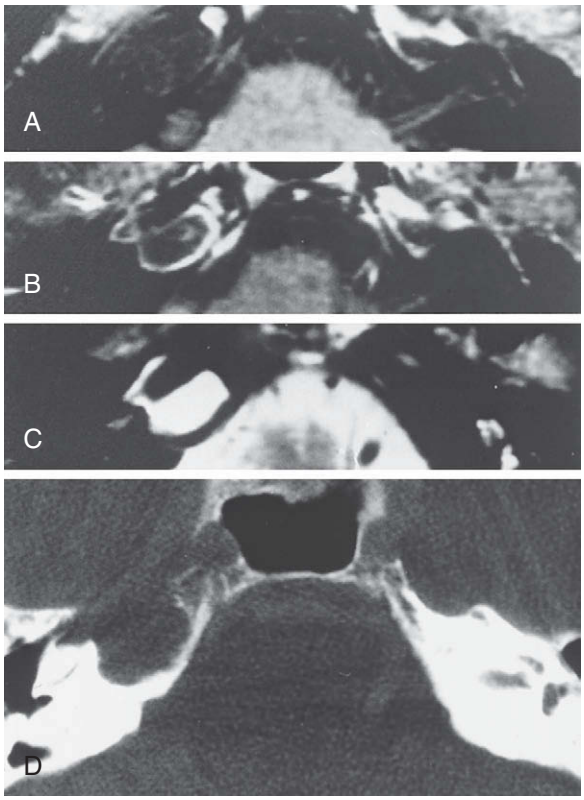

Figure 177-17. **A** to **C,** Axial magnetic resonance images of a petrous apex mucocele: T1-weighted without gadolinium **(A),** T1-weighted with gadolinium **(B),** and T2-weighted **(C).** The lesion is hypointense on the T1-weighted image and shows only rim enhancement with the addition of gadolinium. Note the hyperintensity of the mucocele on the T2-weighted image. **D,** Axial computed tomography scan of the same lesion. Note that the expansile lesion has eroded the petrous apex.

(Fig. 177-19). MRI reveals isointensity on T1-weighted images and hyperintensity on T2-weighted images (Fig. 177-20).

Chondrosarcomas

Chondrosarcomas of the skull base also may arise in the CPA. They are clinically indistinguishable from chordomas except that they are centered more laterally. CT shows characteristic bone destruction and invasiveness. MRI shows this lesion well, which is hyperintense on T2-weighted images in the area of bone destruction in the skull base (Figs. 177-21 and 177-22).

Lipomas

Lipomas are hamartomas that are thinly encapsulated and poorly delineated. They appear as soft, multilobular masses of typical adult adipose tissue. Lipomas within the internal auditory canal can produce symptoms typical of an acoustic neuroma. Although on CT these lesions are less dense than neuromas, MRI is diagnostic. The lesions are hyperintense on T1-weighted images, nonenhancing with gadolinium, and hypointense on T2-weighted images (Fig. 177-23). Fat-suppression techniques with T1-weighted sequences are confirmatory because the previously identified lesion that was hyperintense on nonenhanced T1-weighted images is rendered hypointense with fat suppression (Fig. 177-24).

Dermoid Tumors

A dermoid is a skin-lined cystic tumor containing dermal and adnexal structures. The lining of the cyst is mature, stratified squamous epithelium. A dermoid is a slowly expanding lesion that produces symptoms similar to those of a primary cholesteatoma. It may be differentiated

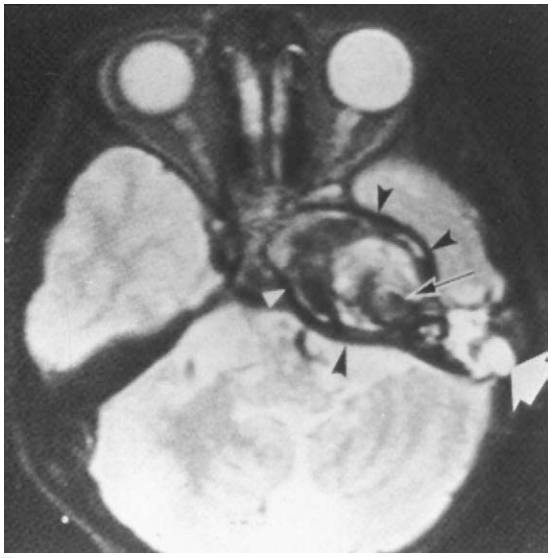

Figure 177-18. Axial T2-weighted magnetic resonance image of a petrous carotid aneurysm. The lesion is heterogeneous and shows decreased signal intensity within the thrombus. The circumscribing areas of low signal intensity *(arrowheads)* probably represents hemosiderin. The lumen *(long thin arrow)* has intermediate signal intensity as a result of slow flow as noted on the arteriogram *(not shown)* and is difficult to distinguish from thrombus. High-signal-intensity fluid is seen in multiple mastoid air cells *(short wide arrow).* *(From Tsuruda JS, Halbach VV, Higashida RT, Mark AS, Hieshima GB, Norman D. MRI evaluation of large intracranial aneurysms using cine low flip angle gradient-refocused imaging.* Am J Neuroradiol. *1988;9:418.)*

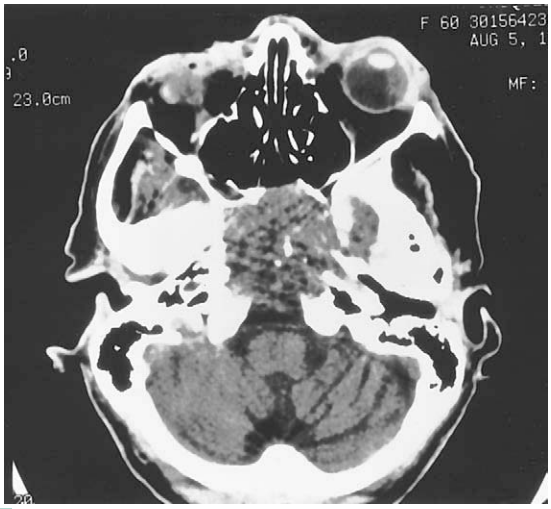

Figure 177-19. Axial computed tomography scan shows a large midline chordoma involving the petrous apex bilaterally.

on CT as a nonhomogeneous cystic mass that contains calcium but that is otherwise less dense than brain.

Teratomas

Teratomas arise from multipotential cells that differentiate into various tissues, representing more than one germ layer. They contain ectodermal, mesodermal, and endodermal tissues. Carcinomatous or sarcomatous changes occur in 10% to 35% of these tumors. When malignant degeneration occurs, symptoms progress rapidly; otherwise, slow progression is the rule, making the lesions indistinguishable from other benign CPA tumors. CT shows a nonhomogeneous lesion of less density than brain without enhancing characteristics.

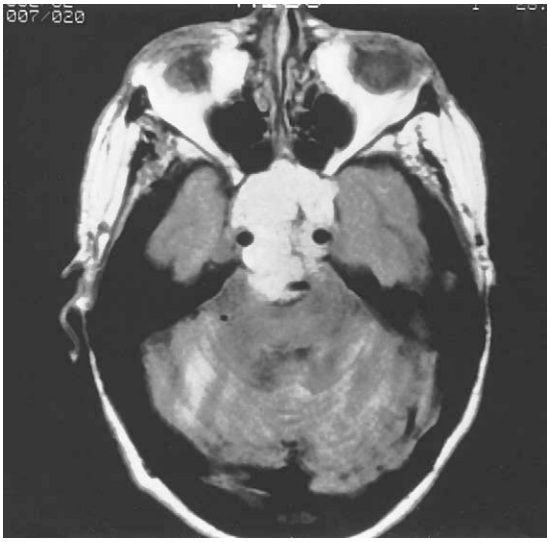

Figure 177-20. Noncontrast T1-weighted axial magnetic resonance image of the same chordoma as in Figure 177-19.

Intra-axial Tumors

Intra-axial tumors may occasionally be confused with CPA tumors as a result of extension to the CPA or compression of CPA structures. Intra-axial tumors may arise from the brainstem (gliomas), the cerebellum (medulloblastomas from the vermis or astrocytomas from the peduncles), or the fourth ventricle (choroid plexus papillomas and ependymomas). Although such lesions are highly unusual, the possibility cannot be ignored. In children, brainstem gliomas are reportedly the most common CPA neoplasms. Intra-axial tumors usually are isointense on T1-weighted MRI and hyperintense on T2-weighted images.[20,21]

Hemangioblastomas

Hemangioblastomas are tumors of blood vessel origin occurring primarily in the cerebellum. They also may occur in the cerebral hemispheres and in association with a similar retinal tumor and may be multicentric. Although histologically benign, hemangioblastomas may produce major neurologic dysfunction by compression of the brainstem.

Rapidly progressive signs and symptoms of cerebellar dysfunction are characteristic of this tumor. Hearing and balance are likely to remain normal. Imaging studies identify a tumor intrinsic to the cerebellum that may extend into the CPA.

Medulloblastomas

Medulloblastomas arise from the cells of the external granular layer of the cerebellar folia. They may appear as exophytic masses on the cerebellum with extension into the CPA. Symptoms are produced by destruction of cerebellar tissue and mass effect of the tumor on the CPA's adjacent structures.

Medulloblastomas are characterized by a rapid development of symptoms. In addition to hearing loss and dizziness, associated neurologic findings include facial weakness, dysmetria of speech and hand motion, perverted nystagmus, and abnormal peripheral reflexes. Temporal bone imaging findings are normal, but CT and MRI show a lesion intrinsic to the cerebellum.

Brainstem Gliomas

Exophytic gliomas may arise on the surface of the pons and grow into the CPA. Gliomas also may be intrinsic to the brainstem. Exophytic gliomas may produce signs and symptoms similar to those of acoustic neuromas, whereas the intrinsic variety produces predominantly long tract signs.

Patients with exophytic lesions may be diagnosed preoperatively to have acoustic neuromas. Long tract signs in association with characteristic brainstem distortion on imaging make preoperative diagnosis possible in the patients with intrinsic lesions.

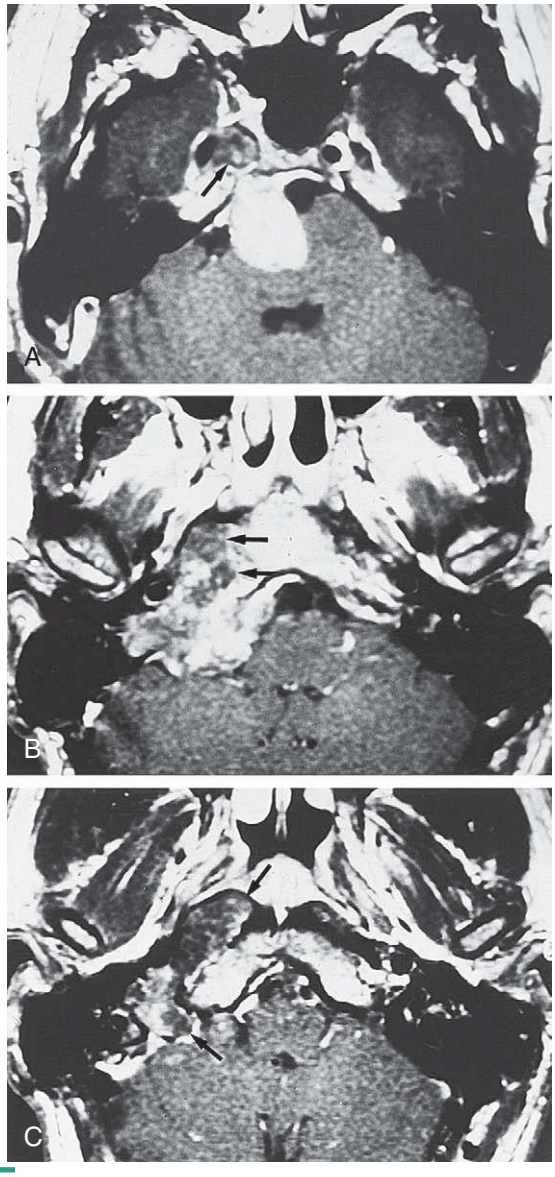

Figure 177-21. Right petrous apex chondrosarcoma. **A** to **C,** On gadolinium T1-weighted magnetic resonance imaging, the mass is markedly but inhomogeneously enhancing, with components containing small, poorly enhancing or nonenhancing foci in Meckel's cave (*arrow* in **A**) and in the petrous apex (*arrows* in **B**), as well as involvement of the longus colli muscle and jugular fossa (*arrows* in **C**). Note the markedly enhancing transdural components in the posterior fossa and the dural "tail" in **A** and **B**. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

Tumors of the Fourth Ventricle

Malignant Choroid Plexus Papillomas and Ependymomas

Choroid plexus papillomas and ependymomas arise from the fourth ventricle and cause CPA symptoms by growing through the foramen of Luschka. In this location, they produce early signs of cranial nerve VIII dysfunction. In malignant choroid plexus papillomas, CT shows a mass with enhancing characteristics of a schwannoma (Fig. 177-25). These tumors are distinguishable from an acoustic schwannoma by being separate from the internal auditory canal. Ependymomas may

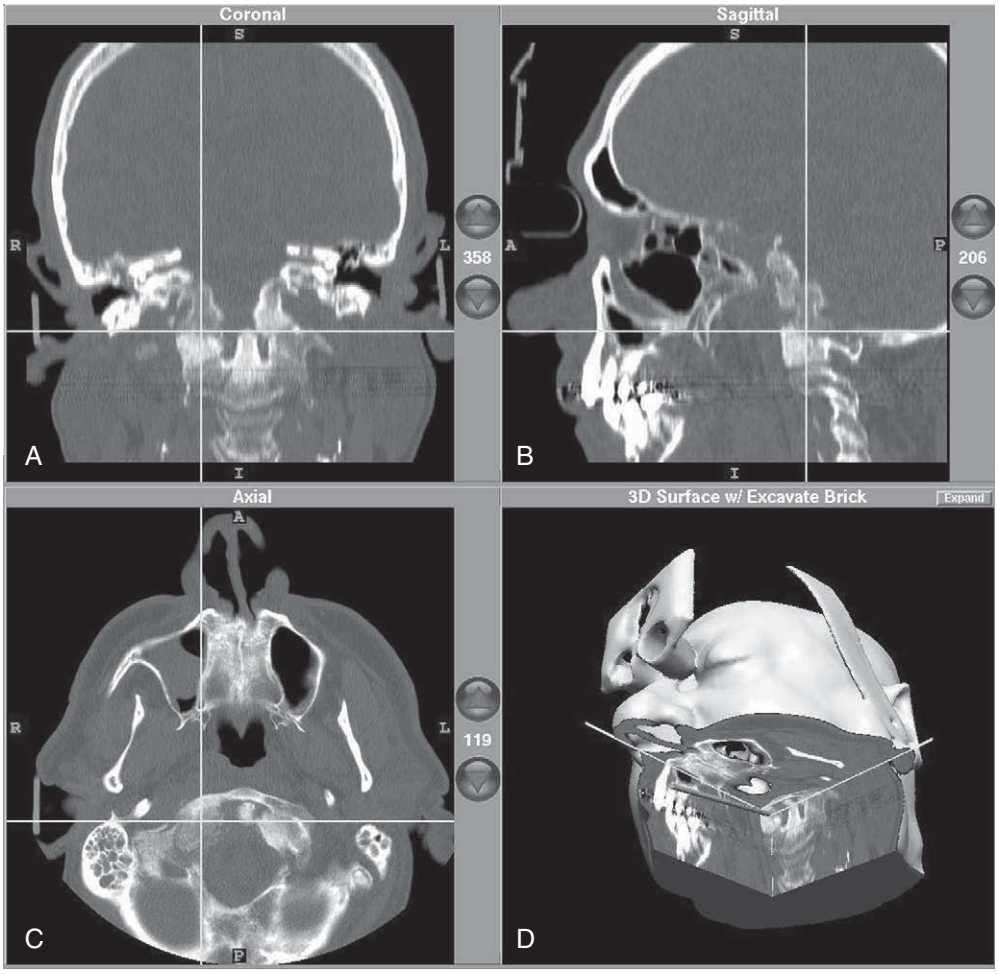

Figure 177-22. Skull base chondrosarcoma, demonstrated by magnetic resonance imaging. **A** and **B,** Axial T1-weighted pre- and postgadolinium images. **C,** Axial T2-weighted images. **D,** Coronal T1-weighted image after gadolinium enhancement. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

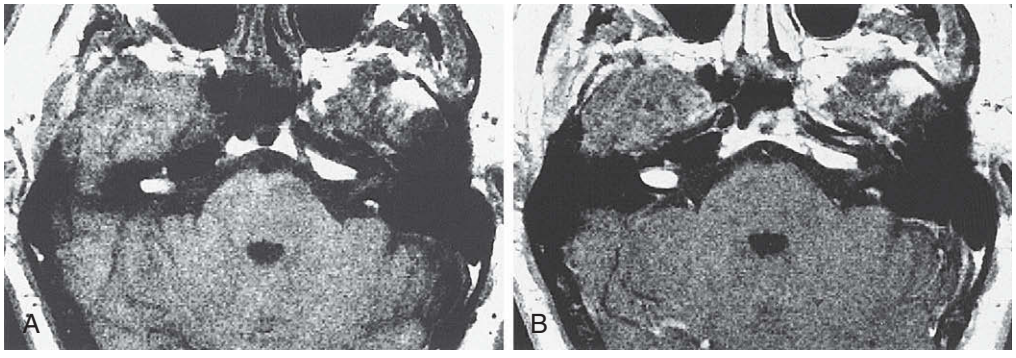

Figure 177-23. Lipoma of the right internal auditory canal, demonstrated by magnetic resonance imaging. **A,** T1-weighted image without gadolinium enhancement. **B,** Postgadolinium T1-weighted image. The lipoma has high signal intensity without gadolinium, which does not change after administration of contrast. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

calcify, and those portions have variable imaging characteristics. At MRI, both lesions are isointense to brain on T1-weighted images and mildly hyperintense to brain on T2-weighted images (Fig. 177-26). Malignant ependymomas require multimodality therapy. The role of surgery is for biopsy, brainstem decompression, and management of hydrocephalus.

Surgery of the Posterior Cranial Fossa

This section addresses surgical management of extra-axial lesions of the posterior cranial fossa and internal auditory canal. Adequate exposure for skull base neoplasms involving the posterior fossa requires precise management of the temporal bone. The modern era for skull base surgery and transtemporal techniques began in 1961, when House

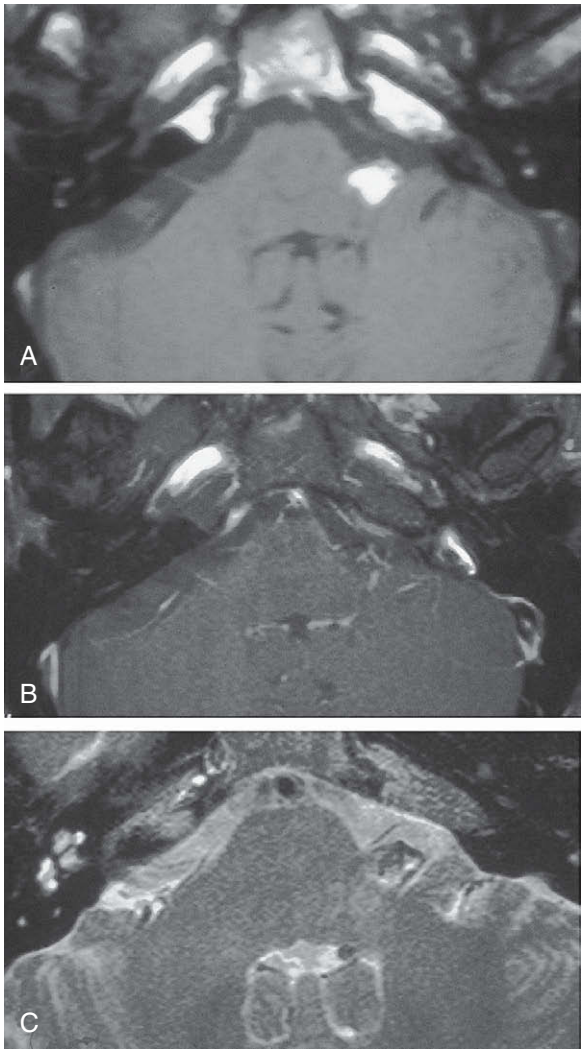

Figure 177-24. Cerebellopontine angle lipoma, demonstrated by magnetic resonance imaging. **A** and **B,** T1-weighted and fat-saturated post-gadolinium images. The signal intensity of the tumor is similar to that of bone marrow. Note the signal loss of the tumor and fatty bone marrow on the fat-saturated images. No enhancement of the lesion is seen. **C,** T2-weighted image. The lipoma typically is moderately hypointense and is seen with surrounding signal void vessels. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

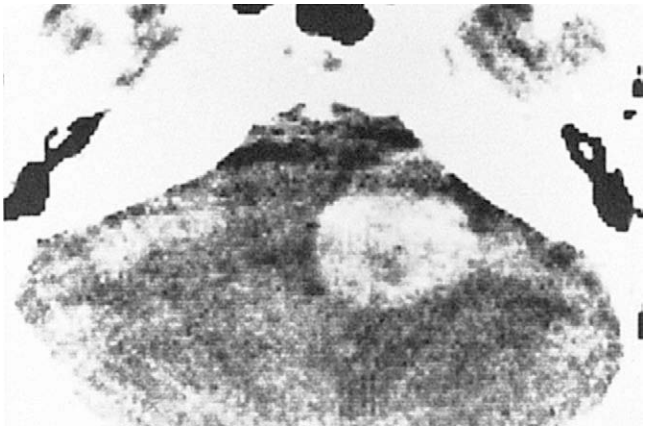

Figure 177-25. CPA choroid plexus papilloma, demonstrated by contrast computed tomography. The tumor is located at the foramen of Luschka. It is more sharply defined than an ependymoma. Like a giant aneurysm, it is detached from the petrous bone, in contrast with schwannomas and meningiomas. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003.)*

introduced the operating microscope and multidisciplinary team surgery for removal of acoustic neuromas. With the vastly reduced mortality and excellent facial nerve preservation rates of the translabyrinthine approach for acoustic neuromas, House established the translabyrinthine approach as the procedure with which all other microsurgical approaches to the CPA are compared.[46] Subsequently, multiple approaches to the CPA have been developed, each with its own advantages and indications.

Thus, the modern skull base surgical team can choose from among various approaches for resection of posterior fossa neoplasms. The procedure should be tailored to the individual patient's pathology and physiologic status. Realistic counseling of patients is critical for informed decisions concerning surgical approaches and possible cranial nerve sequelae. Skull base surgery is a team endeavor, and the full array of experts familiar with the specific needs of these patients is necessary for a successful outcome.

This section details the basic approach, specific indications, techniques, and special features of the translabyrinthine, retrosigmoid, suboccipital, retrolabyrinthine, transcochlear, transotic, middle fossa, extended middle fossa, and petrosal approaches for skull base neoplasms involving the posterior fossa. Table 177-4 summarizes the basic indications for and drawbacks of the various approaches for resection of these tumors.

In addition, the surgical approaches for skull base lesions that are adequately managed by drainage also are reviewed. A method for selecting the surgical approaches for removal of acoustic neuromas suitable for hearing preservation is presented, and general principles of patient management and management of complications of posterior fossa tumor surgery are outlined.

Translabyrinthine Approach

Basic Approach

A transmastoid labyrinthectomy and skeletonization of the sigmoid sinus and posterior fossa dura permit identification of the facial nerve with wide exposure of the internal auditory canal and CPA (Fig. 177-27).

Indications

The translabyrinthine approach is the principal neuro-otologic approach for all lesions of the CPA and internal auditory canal. This technique is ideal for removal of medium-sized and large acoustic neuromas, because hearing preservation is unlikely by any approach in tumors larger than 2 cm and because this approach carries the highest rate of preservation of facial nerve function. Small acoustic neuromas in patients without serviceable hearing also are removed by the translabyrinthine approach.

The approach is suited for removal of any neoplasms requiring exposure of the CPA, including meningiomas, nonacoustic neuromas, gliomas, chordomas, and skull base chondrosarcomas. In addition, if serviceable hearing is not present, the translabyrinthine approach is useful for complete facial nerve decompression and vestibular neurectomy.

Technique

The following discussion details patient positioning, preparation, monitoring, and tumor removal for the translabyrinthine approach. The same techniques are used for the other approaches except when otherwise specified.

The patient is positioned supine with the head turned to the opposite side. Head-holding pins or supports are not used. Electromy-

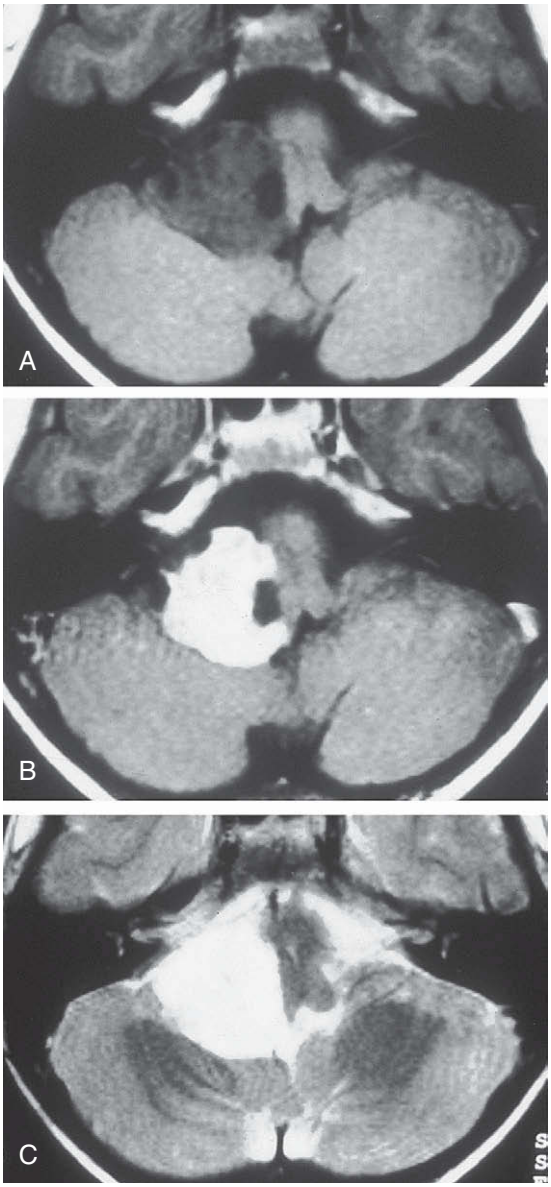

Figure 177-26. CPA ependymoma, demonstrated by magnetic resonance imaging. **A** and **B,** Pre- and postgadolinium images. The mass protruding into the right CPA from the foramen of Luschka shows clear demarcation and strong enhancement. **C,** T2-weighted image. The tumor is hyperintense and does not extend into the IAC. *(From Maya MM, Lo WWM, Kovanlikaya I. Temporal bone tumors and cerebellopontine angle lesions. In: Som PM, Curtin HD, eds.* Head and Neck Imaging. *4th ed. Philadelphia: Mosby; 2003:240-250.)*

ography (EMG) electrodes for intraoperative facial nerve monitoring are inserted into the orbicularis oris and orbicularis oculi. Intravenous antibiotic is administered when the patient arrives in the operating room. Antibiotic also is used in the irrigation solution. Hyperventilation usually is sufficient for brain relaxation.

The curved postauricular incision is made with the apex 3 cm posterior to the postauricular crease. The soft tissue and periosteum are elevated from the mastoid and adjacent occipital bone, and self-retaining retractors are inserted.

The bone removal is accomplished in four stages and is performed using the operating microscope, a high-speed drill, and continuous suction-irrigation.[5] Most of the drilling is performed with cutting burrs; however, diamond burrs are used when drilling is performed on the dura or venous sinuses. The *first stage* is a complete mastoidectomy.

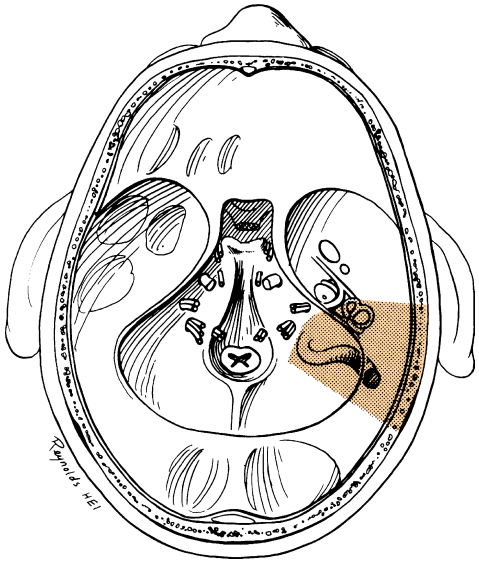

Figure 177-27. Surgical exposure in the translabyrinthine approach to the cerebellopontine angle (CPA). This approach permits direct access to the CPA without retraction of the cerebellum.

Posteriorly, the bone is removed beyond the sigmoid sinus, and the sinus is skeletonized. The extent of bone removal posterior to the sinus and decompression of the posterior fossa depends on the size of the tumor. Greater posterior removal provides greater exposure of the CPA. Superiorly, the middle fossa plate is identified and thinned. Anteriorly, the facial nerve is identified in its vertical segment but left covered with bone for protection against inadvertent burr trauma.

The *second stage* is complete labyrinthectomy. The horizontal, superior, and posterior semicircular canals are systematically removed. Particular care is required in working along the inferior border of the horizontal canal because of the proximity of the facial nerve, and along the ampulated end of the posterior canal because this end lies medial to the facial nerve.

The *third stage* of bone removal consists of actual decompression of the middle and posterior fossa dura and removal of bone around the internal auditory canal. The bone overlying the posterior fossa is removed with cutting and diamond burrs, except for an island of bone over the sigmoid sinus ("Bill's island"). The mastoid emissary vein should be transected to permit retraction of the sinus and posterior fossa dura. Accordingly, bleeding from the emissary should be controlled with sutures, cautery, or bone wax. The petrous ridge, which is the junction between the middle fossa dura and the posterior fossa dura, should be removed. The superior petrosal sinus, which lies under the petrous ridge, is sometimes adherent to the bone. The resulting bleeding is controlled with bipolar cautery or extradural packing with oxidized cellulose strips (Surgicel). The entire middle fossa dura and posterior fossa dura adjacent to the mastoid are exposed.

The *final stage* of bone removal consists of skeletonization of the internal auditory canal. The orientation of this structure is roughly parallel to the external auditory canal. Thus, the fundus of the canal is just medial to the floor of the vestibule, which was exposed during the labyrinthectomy. By contrast, identification of the porus requires extensive bone removal as the internal auditory canal is dissected medially. The basic principle of exposing the internal auditory canal is that all bone removal should be accomplished before the dura is opened, and complete bone removal requires decompression of 270 degrees around the circumference of the canal to avoid obscuring any ledges of bone. By completing bone removal before opening the dura, the risk of accidental injury to the nerves of the internal auditory canal is minimized. The inferior border of the canal is skeletonized first. This edge of the canal is identified by gradually enlarging a trough between the inferior edge of the vestibule and the jugular bulb. The cochlear aqueduct

Table 177-4

Surgical Approaches for Resection of Posterior Fossa Skull Base Neoplasms: Indications, Advantages, and Disadvantages

Approach	Indications	Advantages	Disadvantages
Translabyrinthine	Large, medium-sized, or small cerebellopontine angle tumor	Wide exposure not limited by tumor size; facial nerve identified at the cerebellopontine angle and fundus of the internal auditory canal; immediate repair of facial nerve is possible; bone removal is extradural; limited cerebellar retraction	Total hearing loss
Retrosigmoid (suboccipital)	Cerebellopontine angle tumors without extensive internal auditory canal involvement	Hearing preservation possible; wide exposure; familiarity to most neurosurgeons	Internal auditory canal fundus not exposed in hearing preservation cases; cerebellar retraction may produce hydrocephalus; intradural drilling may result in severe headaches
Retrolabyrinthine	Selected cerebellopontine angle lesions without internal auditory canal involvement, biopsy of cerebellopontine angle lesions	Hearing preservation possible; bone removal is extradural; no cerebellar retraction	Limited exposure
Transcochlear	Extensive lesions of petrous apex and clivus	Wide exposure of skull base with access to clivus and vertebral and basilar arteries and full exposure of petrous carotid artery	Temporary facial nerve paralysis; total hearing loss
Transotic	Same as for transcochlear; some advocate use in acoustic neuromas with unfavorable venous anatomy	Same as for transcochlear; no facial nerve transposition	Facial nerve in the internal auditory canal and mastoid segments limits exposure; total hearing loss
Middle fossa	Intracanalicular tumors with minimal cerebellopontine angle involvement and good hearing	Hearing preservation possible	Small tumors only; temporal lobe retraction
Extended middle fossa	Petroclival lesions involving posterior and middle fossa with good hearing	Hearing preservation possible	Extensive temporal lobe retraction
Petrosal	Large petroclival lesions with good residual hearing	Widest posterior and middle fossa exposure available	Cerebellar and temporal lobe retraction

usually is identified as the dissection proceeds anteromedially. This structure becomes the inferior limit of the dissection, thereby protecting the lower cranial nerves from injury. After the inferior border of the internal auditory canal has been identified, the bone overlying the porus acusticus is thinned with cutting and diamond burrs. The superior border of the canal is identified last, because the facial nerve is more susceptible to injury in this area. A burr size that will fit between the middle fossa dura and the superior border of the internal auditory canal is used to expose the superior border. The entrance of the facial nerve into the canal can be positively identified just medial to a vertical crest of bone, "Bill's bar," along the superior aspect of the fundus. At this point, the bony exposure has been completed, and tumor removal can begin (Fig. 177-28).

Tumor Removal

With small lesions, opening the dura of the internal auditory canal exposes the tumor. Attention is focused on the fundus of the canal, and an angled hook placed lateral to Bill's bar is used to reflect the superior vestibular nerve inferiorly and then transect it. This maneuver protects the facial nerve and identifies the lateral plane between the facial nerve and the tumor. Sharp and blunt dissection can proceed with scissors and angled hooks from lateral to medial, but without actually placing traction on the facial nerve. With some small tumors, the dissection can be completed entirely without debulking.

With large tumors, CPA exposure is necessary. Intracapsular tumor debulking is completed before the tumor is dissected directly from the facial nerve. In essence, a large tumor is reduced to a small tumor. The dural flaps are developed carefully to avoid injury to the underlying petrosal vein or even branches of the anterior inferior cerebellar artery that can reach the dura. The incision is placed midway between the sigmoid sinus and the porus acusticus. The incision is carried directly to the porus and then continued in a curve around the porus.

Debulking should be accomplished to allow positive identification of the facial nerve medial to the tumor and to complete dissection of the tumor from the brainstem. Vessels that do not actually enter the tumor are reflected away, and the posterior aspect of the tumor is incised. Intracapsular debulking is accomplished with small dissection

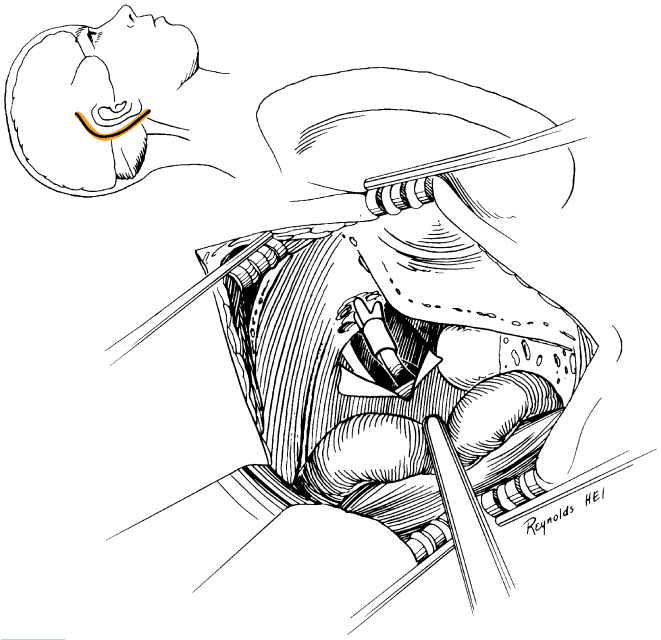

Figure 177-28. Surgical exposure in the translabyrinthine approach to the cerebellopontine angle (CPA). This approach permits positive identification of the facial nerve in its bony canal at the fundus of the internal auditory canal and at the brainstem. *Inset* shows skin incision in relation to the CPA.

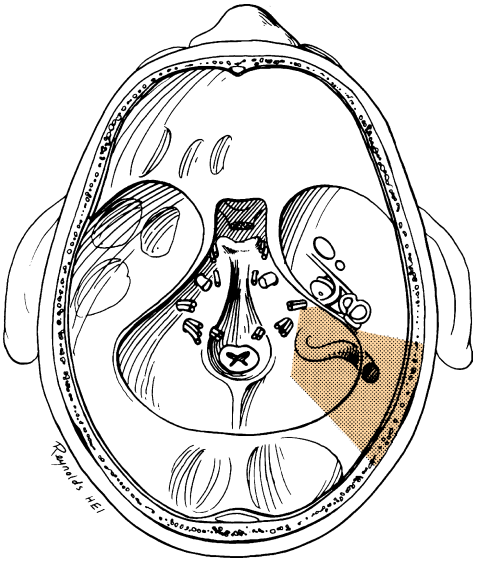

Figure 177-29. Surgical exposure in the retrosigmoid approach to the cerebellopontine angle (CPA). This approach permits wide access to the CPA; however, the cerebellum is between the surgeon and the CPA. Thus, cerebellar support (retraction) is required to permit complete visualization of the CPA.

forceps, scissors, or a rotatory dissector (e.g., House-Urban dissector) or one of the power dissectors used in endoscopic sinus surgery. Some surgeons prefer to use the laser or ultrasonic aspirator for debulking. Such intracapsular debulking permits the tumor to collapse onto itself for easier manipulation during its dissection from the facial nerve. The arachnoid sheath that binds the tumor to the nerve anteriorly is released with small hooks.

In tumor dissection, it is important to avoid pushing the tumor medially into the CPA, because this maneuver stretches the nerve at its lateral fixed bony attachment. The tumor and capsule are removed by separating them completely from the facial nerve. Once tumor debulking is completed and the facial nerve is identified medially, attention is focused on the fundus of the internal auditory canal. Final tumor dissection proceeds as for a small tumor. In this manner, most of the tumor has been removed, while the facial nerve has been protected in the dura of the internal auditory canal.

After tumor removal, eustachian tube closure is achieved by removing the incus, transecting the tensor tympani tendon, and filling the eustachian tube with Surgicel. The temporalis muscle closes the eustachian tube. By opening the facial recess during drilling, the surgeon obtains wide exposure for eustachian tube occlusion. The edges of the dura are approximated with sutures, and the mastoidectomy defect is filled with strips of abdominal fat. The ends of the strips are placed through the dural defect to plug the dural opening. Cranioplasty with use of hydroxyapatite cement or titanium mesh is a useful technique to reduce the incidence of CSF fistula postoperatively and to enhance long-term wound healing and the cosmetic result.[47,48] The wound is closed in layers, and a compressive dressing is applied.

Special Features

The translabyrinthine approach provides wide and direct access to CPA tumors with minimal cerebellar retraction. The versatility of this approach for large and small tumors makes it the most common approach for resection of acoustic neuromas.

The fundamental advantage of the translabyrinthine approach, particularly in medium-sized and large tumors, is that it permits positive identification of the facial nerve, laterally at the fundus and medially at the brainstem. Thus, the tumor can be dissected from either direction with optimal control of the facial nerve. Such medial and lateral identification of the nerve has permitted anatomic preservation of the facial nerve in greater than 98.5% of 759 acoustic neuromas removed in one large surgical series.[49] Furthermore, if the facial nerve is transected, as occurs in cases of CPA facial nerve neuroma, the tympanic and mastoid portions of the nerve are available for rerouting and reanastomosis or grafting.

Properly performed, with wide exposure of the middle and posterior fossae, the translabyrinthine approach provides exposure of the CPA as good as with any other neurosurgical approach; however, the direct route of exposure of the CPA eliminates the need for cerebellar support (retraction).

The disadvantage of this approach is that hearing cannot be preserved. In a series of 300 consecutive cases of acoustic neuromas diagnosed before the advent of gadolinium-enhanced MRI, only 5% of patients, using the broadest criteria, could be considered candidates for hearing conservation surgery.[50] The advent of gadolinium-enhanced MRI resulted in an increased percentage of acoustic neuromas among those detected, which are diagnosed at a small size before hearing is affected. Thus, hearing conservation procedures are becoming a more frequent consideration.

Retrosigmoid (Suboccipital) Approach

Basic Approach

Transmastoid decompression of the sigmoid sinus and a retrosigmoid craniotomy permit access to CPA tumors without disturbing the labyrinth. Intradural removal of the posterior wall of the internal auditory canal permits direct access to the medial two thirds of the canal (Fig. 177-29).

Indications

Because the principal advantage of this approach is hearing preservation, this technique is excellent for removal of acoustic neuromas of the CPA in patients with serviceable hearing and limited involvement of the internal auditory canal. Nonacoustic neoplasms of the CPA that do not involve the internal auditory canal, such as meningiomas, can be approached in this fashion with an opportunity for hearing preservation.

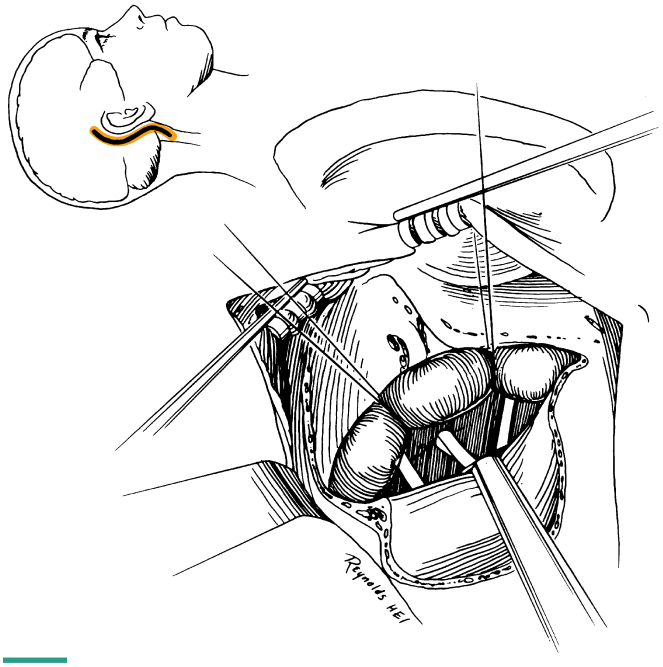

Figure 177-30. Surgical exposure in the retrosigmoid approach to the cerebellopontine angle (CPA). The mastoidectomy in conjunction with the retrosigmoid exposure permits anterior retraction of the sigmoid sinus, which improves anterior exposure. The mastoidectomy also allows positive identification of the posterior semicircular canal, which facilitates removal of the posterior lip of the internal auditory canal. *Inset* shows skin incision in relation to the CPA.

Technique

The soft tissues of the ear are reflected anteriorly and the muscles are widely reflected from the retromastoid region. Complete mastoidectomy is performed, and the sigmoid sinus is skeletonized and decompressed. The posterior semicircular canal also is skeletonized, and the posterior fossa dura up to the posterior semicircular canal is exposed. This area of exposed dura identifies the location of the posterior semicircular canal if the posterior lip of the internal auditory canal needs to be removed later in the procedure. A bone flap is removed posterior to the sigmoid sinus with the otologic drill. This flap can be preserved for replacement at the conclusion of the procedure. Alternatively, in cases with favorable venous anatomy, a craniectomy with skeletonization of the dura and sinus can be performed without entering the presigmoid mastoid air cells.

The dura is incised posterior to the sigmoid sinus, with care taken to avoid injury to the underlying vessels that may be adherent to the dura. Adequate drainage of CSF is necessary to minimize the need for cerebellar retraction. The cerebellum is exposed and supported with retractors to allow visualization of the tumor in the CPA. The neurosurgical techniques for tumor removal at the brainstem are the same regardless of the approach chosen. If the tumor is too large to permit proximal identification of the facial nerve, debulking of the tumor is performed. Once the debulking has been accomplished, the tumor is dissected from the facial nerve toward the porus acusticus (Fig. 177-30).

If the tumor extends into the internal auditory canal, the posterior lip of the canal is removed with diamond burrs. A dural flap is created lateral to the porus and reflected medially. Drilling of the posterior lip of the canal is continued until the lateral extent of the tumor is visualized. The anatomic limit for exposure of this posterior lip that will preserve hearing is the posterior semicircular canal. Attention to the area of dura previously exposed just posterior to the posterior semicircular canal will direct the surgeon to the precise location of the posterior canal when the posterior lip of the internal auditory canal is removed. Once the lateral limit of the tumor has been identified, tumor removal is accomplished in the same manner as with the translabyrinthine approach.

Unlike in the translabyrinthine approach, in which Bill's bar permits definitive identification of the facial nerve at the fundus, in the retrosigmoid approach the surgeon relies primarily on the facial nerve monitor for identifying the nerve laterally in the internal auditory canal. Once the location of the nerves is known medially and laterally, the tumor usually can be removed with preservation of the facial nerve. With surgery attempting hearing preservation, the cochlear nerve also should be preserved. Particular care is taken to preserve the blood supply to the internal auditory canal, because hearing preservation depends on an intact blood supply.

After tumor removal, the edges of the dura are reapproximated, and the mastoid and the internal auditory canal are obliterated with abdominal fat. The bone flap is replaced and the wound is closed in separate layers. A compressive dressing is applied. Alternatively, fat with hydroxyapatite cement or titanium can be used.

Special Features

The retrosigmoid approach, in selected cases, offers an opportunity for hearing preservation, with success rates ranging from 30% to 65%, depending on the selection criteria used for hearing preservation surgery.[51-53] This approach is particularly useful for removal of CPA tumors smaller than 2 cm in patients with good hearing and limited involvement of the internal auditory canal. The principal limitation of this approach is that the fundus of the canal is not directly visualized. This approach is being used more frequently as small tumors of the CPA are diagnosed with enhanced MRI and minimal auditory symptoms.

Extension of tumor to the fundus is a relative contraindication to use of the retrosigmoid approach for hearing preservation. With the retrosigmoid approach, tumor removal in the fundus is accomplished by "feel" with hooks or indirect visualization with mirrors and endoscopes. This approach risks leaving residual tumor.

Bill's bar in the fundus of the internal auditory canal cannot be used to identify the facial nerve laterally in the retrosigmoid approach. Thus, this step is more difficult in the retrosigmoid approach and relies more heavily on the nerve monitor. Although the rates of facial nerve preservation are comparable for the translabyrinthine and the retrosigmoid techniques, in our experience, facial nerve preservation rates are better with the translabyrinthine approach because it allows positive identification of the facial nerve in medial and lateral directions.[52,54,55]

A 10% incidence of severe postoperative headaches has been reported with this approach.[56] This symptom may be related to the intradural spread of bone dust, which occurs as a result of drilling the posterior lip of the internal auditory canal. Unlike in the translabyrinthine approach, drilling should be intradural in the retrosigmoid approach. Replacing the retrosigmoid bone flap with microplates or cranioplasty with synthetic materials has reduced the incidence of headaches with retrosigmoid surgery, suggesting that scar and muscle adherence to the dura also is an important factor.

Another objection to use of this approach has been the need for cerebellar retraction. Skeletonizing the sigmoid sinus and reflecting it anteriorly can minimize cerebellar retraction. However, medium-sized and large lesions require significantly more cerebellar retraction than is necessary with the translabyrinthine approach. Nonetheless, the retrosigmoid approach offers the most panoramic view of the posterior fossa.

Middle Fossa Approach

Basic Approach

A temporal craniotomy permits exposure of the internal auditory canal after identification of the superior semicircular canal and geniculate ganglion (Fig. 177-31).

Indications

The middle fossa approach is ideally suited for resection of intracanalicular acoustic neuromas. It provides limited exposure for surgery of lesions involving the CPA. CPA involvement beyond 1 cm is a relative contraindication to this approach. Decompression of the internal audi-

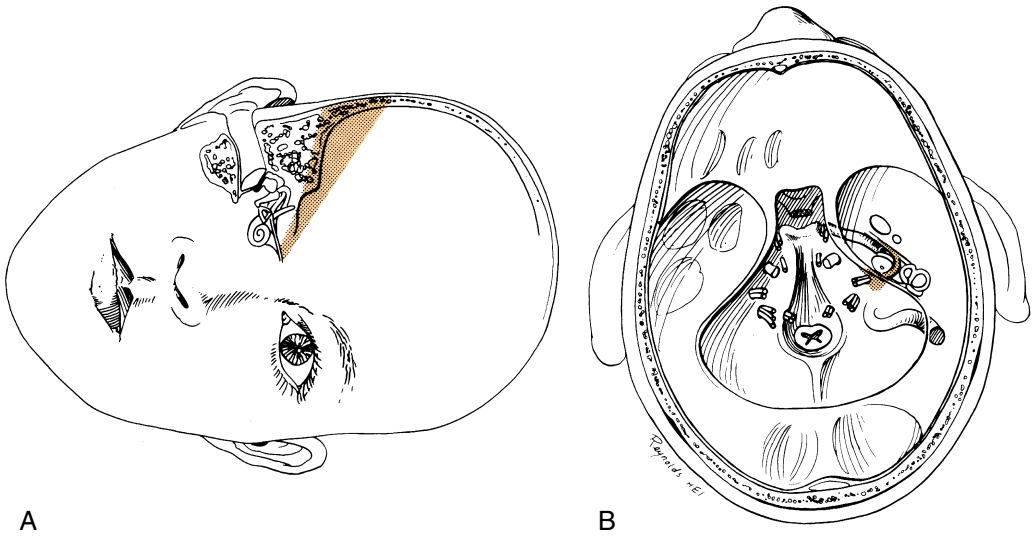

Figure 177-31. **A,** Coronal view: surgical exposure in the middle fossa approach to the cerebellopontine angle (CPA). A temporal craniotomy permits retraction of the temporal lobe and access to the floor of the middle fossa and internal auditory canal (IAC). **B,** Axial view: surgical exposure in the middle fossa approach to the CPA. The *shaded area* indicates the area of bone removal on the floor of the middle fossa. Note that although wider exposure is possible at the porus, limited space is available between the cochlea and the superior semicircular canal as the surgeon approaches the fundus of the IAC.

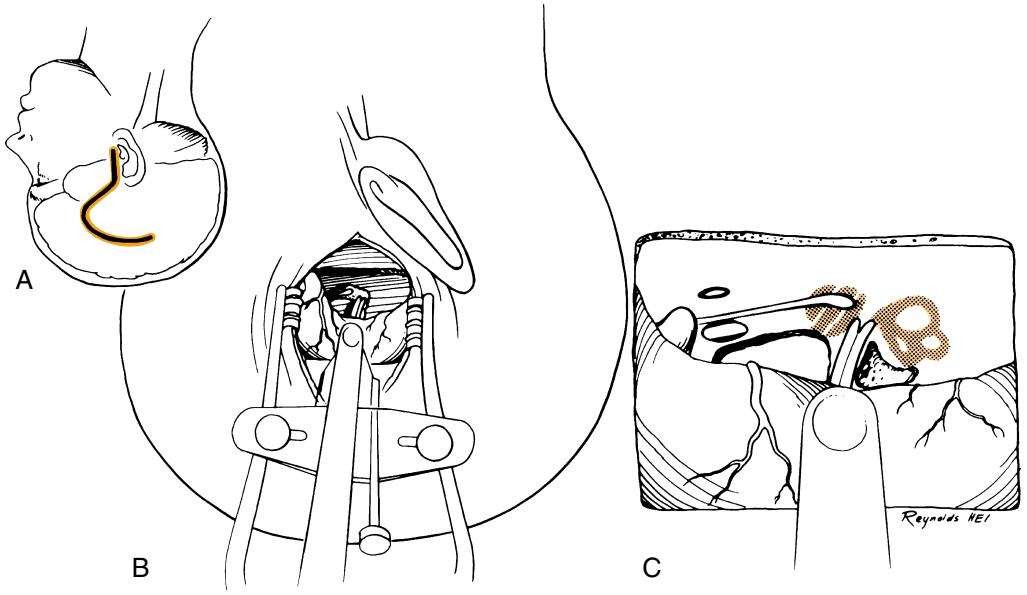

Figure 177-32. **A,** Skin incision for the middle fossa approach. Although the traditional vertical incision is used in middle fossa facial nerve decompression, the larger flap facilitates bony exposure for tumor removal. **B,** Surgeon's view of the internal auditory canal (IAC) via the middle fossa approach. Note the temporal lobe retractor in position. The proximity of the cochlea, labyrinth, and labyrinthine portion of the facial nerve at the fundus of the IAC requires precise identification of anatomic landmarks in this approach. **C,** Surgeon's view of the extended middle fossa approach. The anterior limit of bone removal is the carotid artery and the posterior limit is the labyrinth. In the illustration, the middle meningeal artery at the level of the foramen spinosum has been transected, and the horizontal carotid artery is identified coursing parallel to the greater superficial petrosal nerve and medial to the foramen ovale. Continued dissection anteromedially permits access to the cavernous sinus.

tory canal in cases of acoustic nerve tumors in only hearing ears can be accomplished in this fashion.[57]

Technique

The basic surgical exposure is illustrated in Figure 177-32A and B. Mannitol and furosemide are used in addition to hyperventilation for brain relaxation. A lumbar drain placed at the beginning of the procedure can facilitate dural elevation before open drainage of the cerebrospinal fluid. A preauricular incision is extended along the temporal region. The temporalis muscle may be reflected inferiorly or split and retracted to expose the squamosa of the temporal bone. A 5 cm × 5 cm craniotomy is centered over the zygomatic root.

The floor of the middle fossa is exposed by dissecting and elevating the dura from posterior to anterior to avoid injury to the geniculate ganglion, which can be dehiscent in up to 15% of patients. The principal landmarks for orientation are the greater superficial petrosal nerve

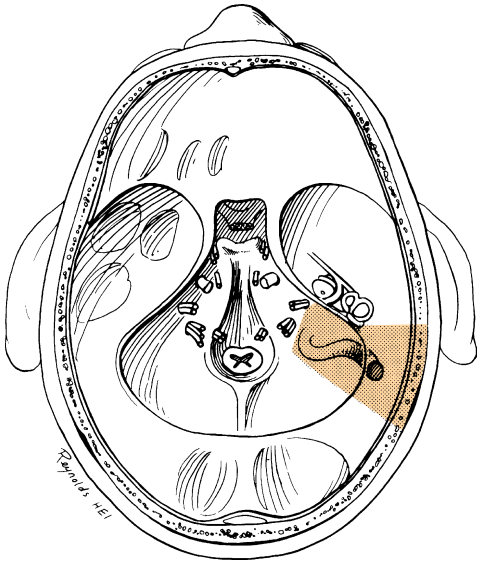

Figure 177-33. The retrolabyrinthine approach to the cerebellopontine angle (CPA). Although the exposure is limited anteriorly, removal of the bone posterior to the sigmoid sinus permits wide access to the CPA.

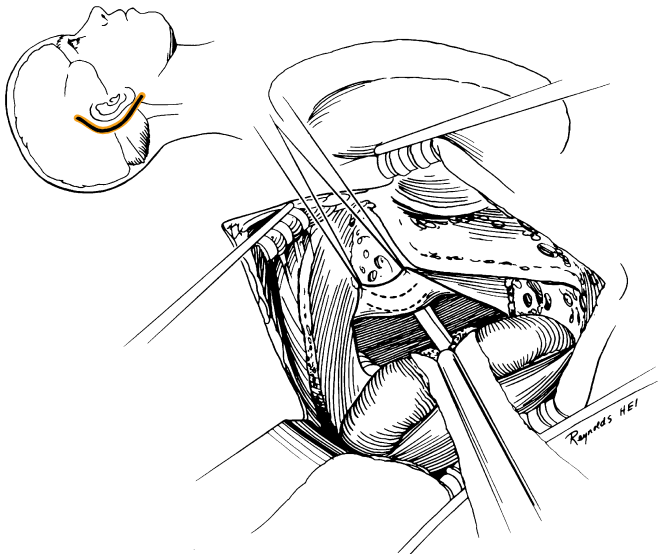

Figure 177-34. Surgeon's view of the cerebellopontine angle (CPA) with the retrolabyrinthine approach to the internal auditory canal. The dura is incised around the endolymphatic sac and reflected anteriorly. Wide posterior bone removal permits access to the CPA without a brain retractor, although suction is used to maintain the exposure. *Inset* shows skin incision in relation to the CPA.

and the arcuate eminence; however, these can be deceptive. Antidromic stimulation of the greater superficial petrosal nerve with the facial nerve stimulator can be helpful for orientation.[58] In addition, preoperative coronal CT can reveal the extent of pneumatization over the internal auditory canal and labyrinth.

Surgeons should be familiar with all techniques for identifying the internal auditory canal in middle fossa surgery, but some prefer to begin drilling medially near the porus acusticus. In this fashion, the cochlea and superior semicircular canal are not approached until the internal auditory canal has been identified. Wide skeletonization of this canal can be performed medially; however, the proximity of the cochlea and superior semicircular canal only permit unroofing the internal auditory canal laterally.

The dura is opened along the posterior aspect of the internal auditory canal. The facial nerve is freed from the tumor, and dissection proceeds in a medial to lateral direction. The canal is sealed with abdominal fat or temporalis muscle and the bone flap is replaced.

Special Features

Intracanalicular tumors, particularly those in the lateral portion of the internal auditory canal, are amenable to removal using the middle fossa approach in cases suitable for attempted hearing preservation. Because use of the approach has been limited to small lesions, the theoretic problem of limited access to the posterior fossa in case of bleeding has not been an issue.

The success of hearing preservation in selected patients is more than 70%; however, the limiting factor is the cochlear blood supply.[59] Just as in retrosigmoid hearing preservation cases, the rate of cochlear nerve preservation is substantially higher than that of actual hearing preservation. The approach is not usually recommended in patients older than 65 years because in this age group, the dura is more adherent and fragile.

Retrolabyrinthine Approach

Basic Approach

A wide mastoidectomy with skeletonization of the posterior semicircular canal permits access to the CPA with preservation of the seventh and eighth cranial nerves (Fig. 177-33).

Indications

The principal indication for the retrolabyrinthine approach is vestibular nerve section for intractable vertigo or for neurotomy in tic douloureux.[60] With posterior fossa neoplasms, the retrolabyrinthine approach affords adequate exposure and hearing preservation in selected cases of arachnoid cysts, meningiomas, and metastatic lesions of the CPA. In situations in which tissue diagnosis is required before proceeding with definitive surgery, the retrolabyrinthine approach permits wide exposure with minimal morbidity for exploration of lesions of the CPA.

Technique

The incision and soft tissue exposure for the retrolabyrinthine approach are identical to those for the translabyrinthine approach. Mannitol and furosemide are used for brain relaxation. A complete mastoidectomy is performed. The fossa incudis and the lateral and posterior semicircular canals are identified. The facial nerve is skeletonized but kept covered with bone.

Because exposure with this approach depends on collapsing the sigmoid sinus posteriorly, bone is completely removed from the sigmoid sinus and the suboccipu posterior to the sinus. Extensive exposure of the retrosigmoid dura is necessary for adequate exposure with this approach. The middle fossa dura is exposed and the petrous ridge is removed to increase the exposure.

The dura is opened as a flap that begins just medial to the sigmoid sinus and preserves the endolymphatic sac. The flap is held anteriorly with sutures and tumor dissection can be performed in the posterior fossa (Fig. 177-34). Once the CPA is entered and CSF is released, the cerebellum falls away. Accordingly, cerebellar retractors are not necessary to expose the cranial nerves in the CPA. Instead, the sigmoid is collapsed posteriorly with fenestrated suction.

When tumor removal is completed, the dura is closed with sutures. The defect is obliterated with abdominal fat with the optional use of hydroxyapatite cement or titanium mesh. Closure is performed in layers, and a compressive dressing is applied.

Special Features

The indications for the retrolabyrinthine approach in tumor removal are limited. If exposure of the internal auditory canal is not needed for a small neoplasm of the CPA, however, this approach can preserve hearing and avoids the greater degree of cerebellar retraction required for the retrosigmoid approach.

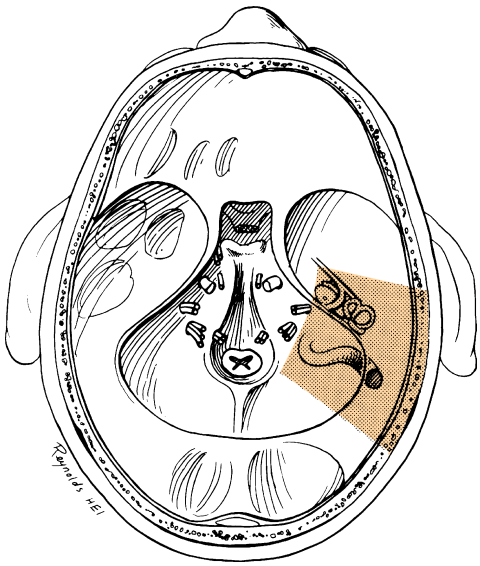

Figure 177-35. The transcochlear approach to the cerebellopontine angle petrous tip and clivus. Removal of the cochlea and anterior portion of the petrous bone permits wide visualization of the clivus and skull base.

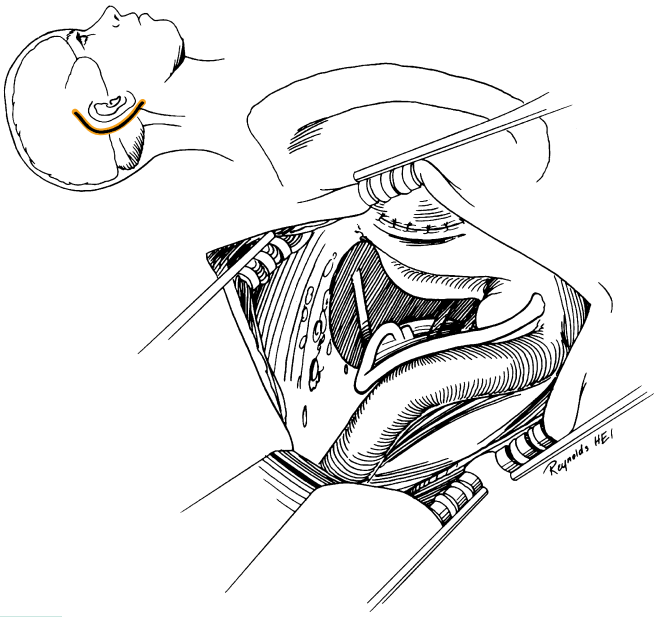

Figure 177-36. Surgeon's view of the skull base with the transcochlear approach. The external auditory canal is transected and sutured closed. Posterior transposition of the facial nerve permits unobstructed visualization from the superior petrosal sinus to the inferior petrosal sinus, anteriorly to the carotid artery, and medially to the clivus. *Inset* shows skin incision in relation to the cerebellopontine angle.

Transcochlear Approach

Basic Approach

As an extension of the translabyrinthine approach, the transcochlear approach affords additional exposure of the skull base. This is obtained by displacement of the facial nerve and removal of the cochlea to provide surgical access to lesions of the petrous tip and clivus (Fig. 177-35).

Indications

Petroclival meningiomas and epidermoids of the petrous tip are the principal lesions for which the transcochlear approach has been applied.[61] However, extensions of this approach have been used with glomus jugulare tumors, temporal bone carcinomas, and extensive nonacoustic neuromas of the CPA.

Technique

The incision, soft tissue exposure, complete mastoidectomy, labyrinthectomy, posterior and middle fossa dura decompression, and skeletonization of the internal auditory canal are performed as in the translabyrinthine approach.

The facial nerve is decompressed from the stylomastoid foramen to the geniculate ganglion. After sectioning of the chorda tympani nerve using an extended facial recess approach and transection of the greater superficial petrosal nerve, the facial nerve can be transposed posteriorly. Transposition of the nerve removes the obstacle to extending the exposure anteriorly. The transcochlear approach has been modified to include transection of the external auditory canal and two-layered closure of the meatus. This modification permits removal of the posterior wall of the external auditory canal, thus allowing wider anterior exposure in the areas of the jugular bulb and internal carotid artery. Next, the incus and stapes are removed. The cochlea is removed, thereby exposing the carotid artery anteriorly, the jugular bulb and inferior petrosal sinus inferiorly, and the superior petrosal sinus superiorly. The bony exposure leaves a dura-covered window extending from the superior petrosal sinus to the inferior petrosal sinus and reaching the clivus medially (Fig. 177-36).

The same principles of tumor removal are used as with the other approaches to the CPA. However, the position of the facial nerve in relation to the tumor and the proximity of the basilar artery make certain aspects of tumor removal with the transcochlear approach different from other approaches to the CPA. Unlike acoustic neuromas, tumors of the petrous apex and clivus often have the facial nerve on their posterior surface. Thus, the nerve should be dissected free of the tumor and protected. The position of the vertebrobasilar arterial system should be considered. As tumor dissection proceeds medially, the basilar artery will be anterosuperior and the vertebral artery will be posteroinferior. Extensive tumors that cross the midline are removed by reflecting the vessels posteriorly from the tumor capsule. Particular care is taken to preseve small perforating vessels that supply the brainstem, because their damage could be fatal. The surgical defect is filled with abdominal fat (often with hydroxyapatite or titanium mesh, or both), the wound is closed in layers, and a compressive dressing is applied.

Special Features

The transcochlear approach provides direct access to the base of implantation and blood supply of tumors arising from the petrous tip and petroclival junction. Temporary facial nerve paralysis occurs uniformly with the posterior transposition of the facial nerve required by this approach. Such paralysis is most likely to be the consequence of devascularization of the perigeniculate segments of the nerve caused by transection of the greater superficial petrosal nerve and its accompanying vessels. Because partial recovery of facial nerve function is the rule (to House-Brackmann grade 3/6 or 4/6), the approach has limited application except for removal of the most extensive life-threatening lateral skull base lesions such as malignancies or vertebrobasilar aneurysms.

Transotic Approach

Basic Approach

The transotic approach is similar to the modified transcochlear approach, in which the external auditory canal is closed and the posterior wall of the external auditory canal is removed. The distinction is that with the transotic approach, the facial nerve is skeletonized but left in its bony canal in the surgical field.

Indications

The transotic approach is indicated for removal of lesions of the CPA extending inferiorly into the jugular foramen or anteriorly into the

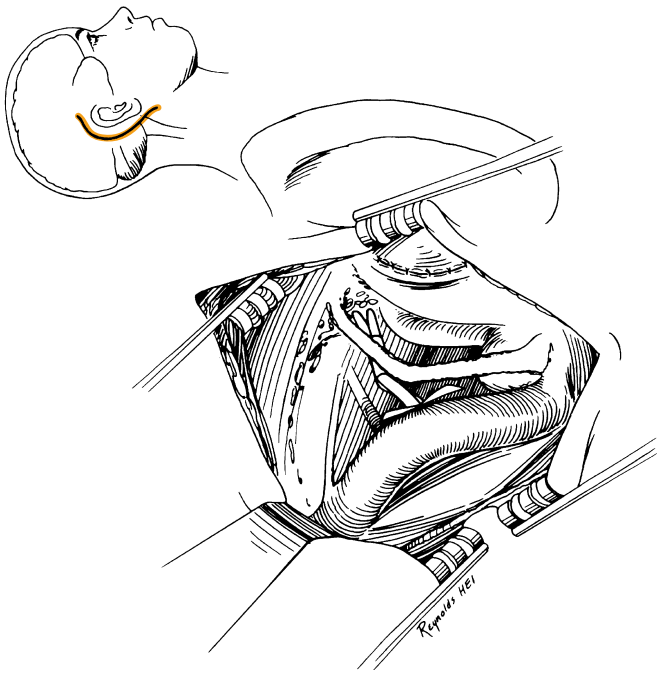

Figure 177-37. Surgeon's view of the transotic approach to the skull base. Note that the approach is identical to the transcochlear approach except that the facial nerve is not transposed. Instead, the nerve is left in its bony canal suspended across the surgical field. The in situ facial nerve limits the exposure in its internal auditory canal and mastoid segments (compare with Fig. 177-36). *Inset* shows skin incision in relation to the cerebellopontine angle.

clivus. Some proponents of this approach use the additional exposure anteriorly in cases of high jugular bulbs or anteriorly placed sigmoid sinuses in small to medium-sized acoustic neuromas.[62] The translabyrinthine approach with wide decompression of the sigmoid sinus and posterior fossa dura provides adequate exposure of the internal auditory canal and CPA, even with large acoustic neuromas with unfavorable venous anatomy.

Technique

Through a postauricular incision, the ear is reflected anteriorly, and the external auditory meatus is transected and closed in two layers. Essentially the same procedure as that described for the transcochlear approach is performed, with the exception that the facial nerve is not completely freed from the fallopian canal. Rather, the nerve is skeletonized and left in its canal. At the conclusion of the exposure, the facial nerve is suspended, traversing the surgical field with a bony cover. The tympanic ring is removed, with systematic exposure of the jugular bulb, jugular foramen, and carotid canal. By working around the facial nerve, the surgeon has access to lesions of the internal auditory canal, CPA, clivus, and jugular foramen (Fig. 177-37). Closure is performed with obliteration of the defect with abdominal fat and optional placement of hydroxyapatite cement or titanium mesh.

Special Features

The transotic approach combines the added exposure provided by removal of the tympanic ring and access medial to the facial nerve with the added safety of the avoidance of transposing the facial nerve. This approach also offers an alternative strategy for management of the anterior sigmoid or high jugular bulb in cases of CPA tumor removal in which hearing preservation will not be attempted. Leaving the facial nerve in situ is an attractive means of avoiding excessive manipulation of the facial nerve; however, leaving the nerve without transposition requires added vigilance by the surgeon as dissection proceeds medial to the plane of the facial nerve. Furthermore, exposure is limited at the brainstem because the labyrinthine segment of the facial nerve and the contents of the internal auditory canal are not transposed.

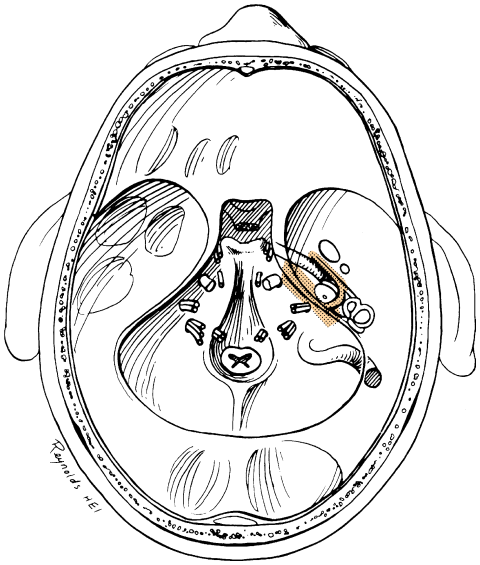

Figure 177-38. Schematic view (axial) of the extended middle fossa approach to the skull base. By removing the bone posterior and medial to the labyrinth and medial to the carotid artery, the exposure of the middle fossa approach is extended to lesions of the cerebellopontine angle that have spread beyond the tentorium or even into the cavernous sinus.

Extended Middle Fossa Approach

Basic Approach

For the extended middle fossa approach, the skull base surrounding the otic capsule is carefully removed through a wide temporal craniotomy. This approach exposes lesions extending from the posterior fossa through the tentorium and incisura and anteriorly up to the region of foramen lacerum and the posterolateral aspect of the cavernous sinus (Fig. 177-38).

Indications

The extended middle fossa approach is indicated in extensive petrous ridge and petroclival lesions involving the temporal bone that have serviceable hearing. Petrous ridge lesions with extension through the tentorium into the middle fossa are especially amenable to removal using this approach.

Technique

The patient is positioned in the supine position with the head turned to the side. Mannitol, furosemide, and hyperventilation are used for brain relaxation. After performing a wide temporal craniotomy, the temporal lobe is progressively retracted to permit identification of the middle meningeal artery anteriorly, the petrous ridge posteriorly, and the petroclival junction medially. The internal auditory canal is uncovered using the standard middle fossa technique as described. The extension in the exposure is accomplished by removing the petrous ridge and posterior aspects of the temporal bone up to the labyrinth. Anteriorly, the temporal bone is removed up to the foramen lacerum and the internal carotid artery (see Fig. 177-32C). The area of Meckel's cave is clearly identified, and the posterolateral portions of the cavernous sinus are accessible.

Special Features

The extended middle fossa approach permits safe removal of extensive lesions (especially meningiomas) of the middle and posterior fossa that have not directly involved the otic capsule or internal auditory canal. Preservation of hearing and the facial nerve is possible with this technique despite wide access to the lesion.

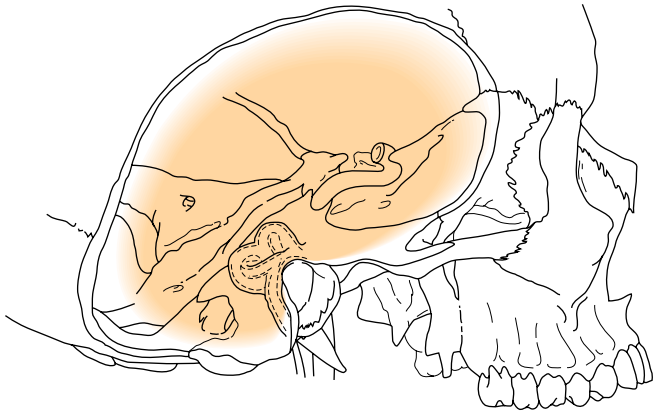

Figure 177-39. Combined petrosal approach uses the extended middle fossa, retrolabyrinthine, and retrosigmoid exposure while preserving the labyrinth.

Combined Techniques (Petrosal Approach)

Basic Technique

The previously described techniques for access to posterior fossa lesions may be combined to provide superior and posterior exposure.

Indications

Lesions involving the posterior and middle fossae or extensive lesions of the clivus are amenable to removal using combined approaches, especially if the patient retains serviceable hearing.

Technique

The usual procedures in the petrosal approach combine extended middle fossa exposure with full retrosigmoid and retrolabyrinthine exposure[63] (Fig. 177-39). The middle cranial fossa, internal auditory canal, posterior fossa, and clivus all are exposed while the otic capsule is preserved. By contrast, the translabyrinthine or transcochlear approach also can be combined with the extended medial fossa approach to provide the widest possible exposure.

Special Features

The petrosal approach provides wide exposure of the skull base from foramen magnum to the cavernous sinus while retaining the possibility for hearing preservation. The wide bone removal maximizes surgical exposure and minimizes the need for brain retraction. If hearing preservation is not a realistic expectation, the addition of otic capsule removal provides even wider surgical exposure.

Experimental Approaches

Attempted hearing preservation with partial or complete labyrinthine resection has been reported. McElveen[64] and Molony[65] and their colleagues reported systematic sealing of the vestibule during labyrinthectomy with successful hearing preservation after translabyrinthine tumor removal. To expose the lateral internal auditory canal with the retrosigmoid approach, Arriaga and Gorum[66] reported posterior semicircular canal resection with successful hearing preservation and total tumor removal in two of three enhanced retrosigmoid procedures. In extensive skull base lesions, labyrinthine procedures can be converted to partial labyrinthine resection procedures with concomitant opportunity for preserved hearing.[67]

Although these findings are promising, such techniques are currently experimental, and further investigation is necessary for such approaches to be offered routinely in clinical practice.

Approaches for Skull Base Lesions Requiring Drainage

As described earlier in this chapter, cholesterol granulomas are nonneoplastic lesions that may expand the petrous apex and produce symptoms related to the nerves of the posterior fossa. Similarly, mucoceles of the petrous apex may produce symptoms by their expansion. Both lesions are adequately managed by surgical drainage.

Translabyrinthine Approach

If hearing and vestibular function are absent, the translabyrinthine approach provides the most direct route for aeration from the mastoid through the surgical defect to the petrous apex.[68] Usually, however, this approach is inappropriate because patients often have excellent hearing despite large cholesterol granulomas.

Middle Cranial Fossa Approach

The middle cranial fossa approach permits hearing preservation but requires temporal lobe retraction for exposure. Placing a catheter from the mastoid tegmen to the apex facilitates drainage, and despite its relatively long course, the catheter remains patent, with radiologic follow-up confirmation of aeration.[43]

Infralabyrinthine Approach

After a complete mastoidectomy, the sigmoid sinus is decompressed, the posterior semicircular canal and jugular bulb are identified, and the infralabyrinthine air cells are followed into the petrous apex. The cyst is incised, drained, and stented open into the mastoid[68] (Fig. 177-40). This approach may be technically impossible in a patient with a high jugular bulb. Furthermore, although reexploration is possible in the face of an occluded stent, revision surgery requires formal reexploration of the transmastoid approach.

Transcanal Infracochlear Approach

The external auditory canal is transected and a superiorly based tympanomeatal flap is elevated. The bony external meatus is widened, and the air cell tract between the jugular bulb and carotid artery is followed into the petrous apex (Fig. 177-41). This approach permits dependent drainage of the petrous apex into the middle ear (see Fig. 177-14). If the drainage tube becomes obstructed, it may be revised through an office myringotomy. The principal disadvantages are the prolonged healing time required for the external auditory canal and the need for direct exposure of the petrous carotid artery.[42]

Selection of Surgical Approach

The rationale for selecting a particular surgical approach for acoustic neuromas is similar to that for other posterior fossa neoplasms. The principal goal is tumor removal with minimal postoperative morbidity. Accordingly, the surgical approach should be tailored to the patient's specific pathology and functional status. The notion that a single approach should be used with all lesions of the posterior fossa is counterintuitive and subjects patients to unnecessary morbidity. In patients without serviceable hearing, the translabyrinthine approach provides wide and direct access to the CPA, with maximal facial nerve safety, minimal cerebellar retraction, and a low incidence of severe postoperative headache.

Patients with small tumors and good hearing have three options for surgical removal: the translabyrinthine approach, which destroys hearing; the middle fossa approach in young patients with small, mainly intracanalicular tumors; and the retrosigmoid approach in small tumors of the CPA that do not extend to the fundus of the internal auditory canal. In general, the best hearing and functional outcomes result from individualizing the surgical approach to patient and tumor characteristics.[69]

Realistic patient counseling is necessary regarding hearing conservation procedures. Gardner and Robertson[51] rigorously reviewed the literature on hearing preservation in acoustic neuroma surgery. Of 621 reported cases of attempted hearing preservation, the success rate was 33%. Reported successful hearing preservation rates often refer only to measurable hearing. The rate is far lower if useful hearing (speech reception threshold [SRT] greater than 30 dB and speech discrimination less than 70%) or serviceable hearing (SRT greater than 50 dB and speech discrimination less than 50%) is considered. Furthermore, long-term follow-up studies reveal that 56% of patients experience significant loss of the preserved hearing over time.[59]

After a discussion of the risks and benefits of the various surgical approaches, many potential candidates for hearing preservation choose

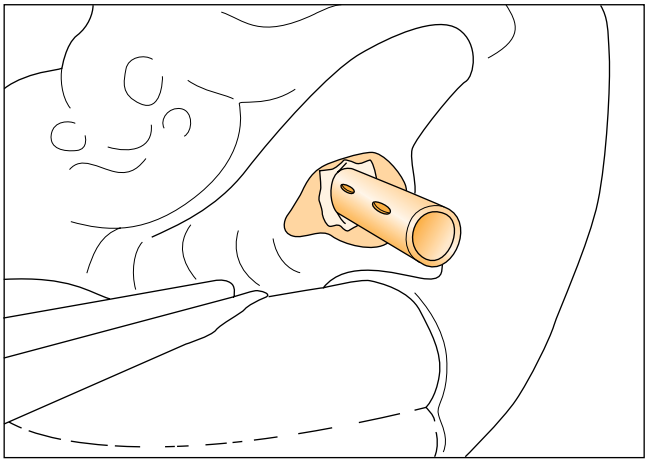

Figure 177-40. Surgeon's view of the completed transmastoid infralabyrinthine drainage of a cholesterol granuloma. The dissection is performed medial to the facial nerve and inferior to the level of the labyrinth. The drainage tube permits aeration of the cholesterol granuloma.

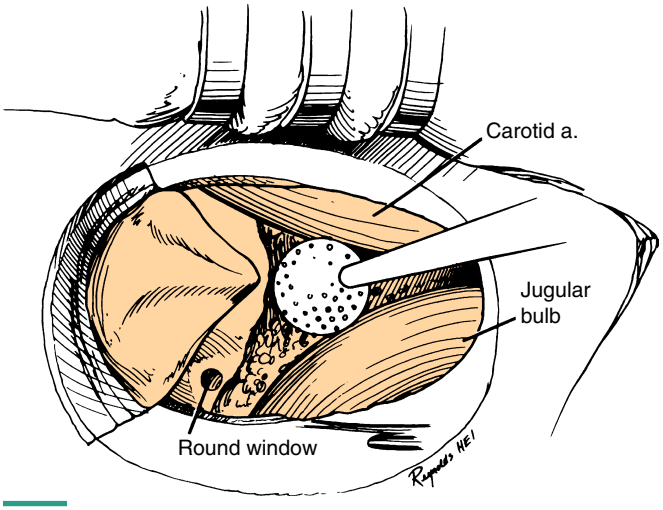

Figure 177-41. Surgeon's view of the transcanal infracochlear approach to the petrous apex. After transection of the ear canal, a superiorly based tympanomeatal flap is elevated. Diamond burrs are used to expose widely the hypotympanum, jugular bulb, and petrous carotid artery. The infracochlear cell tract is followed between the carotid artery and jugular bulb. *(From Giddings NA, Brackmann DE, Kwartler JA. Transcanal infracochlear approach to the petrous apex.* Otolaryngol Head Neck Surg. *1991;104:29.)*

the translabyrinthine approach, with its slightly higher rate of facial nerve preservation, rather than hearing conservation procedures.

With meningiomas and tumors that do not affect the internal auditory canal and have not impaired hearing, the extended middle fossa approach is used if posterior and middle fossa exposure is necessary. The retrolabyrinthine approach is used for removal of limited lesions of the CPA only, whereas the retrosigmoid approach would be applicable for resection of more extensive lesions of the posterior fossa. Extensive anteromedial exposure is needed with lesions of the clivus. Hearing preservation usually is not feasible in treatment of such lesions, and the transcochlear or transotic approach may be used.

Patient Management and Surgical Complications

Comprehensive management of patients with skull base neoplasms of the posterior fossa requires a team of specialists familiar with the particular needs of this patient group. In addition to neuro-otologists and neurosurgeons, designated internists, anesthesiologists, radiologists, ophthalmologists,[70] and critical care nurses are essential members of the team for optimal care of these patients with very specialized needs.

Preoperative Management

Preoperative antibiotics are routinely used even in uncomplicated cases. Osmotic agents and diuretics for brain relaxation usually are not used in the translabyrinthine approach; however, the retrolabyrinthine, retrosigmoid, middle fossa, and extended middle fossa approaches require such techniques to minimize the need for retraction.

Intraoperative Monitoring

Facial nerve monitoring is used routinely in all cases of posterior fossa neoplasm surgery. Continuous monitoring is performed with EMG electrodes and monitoring equipment with instantaneous visual and loudspeaker output. An audiologist assists with interpreting monitoring signals and stimulating the facial nerve when required to identify nerves intraoperatively.

Although ABR monitoring often is used in hearing preservation cases, this modality provides only delayed feedback to the surgeon and cannot affect intraoperative decision-making or tissue manipulation in a meaningful way. The advent of direct eighth nerve recording systems and electrocochleography (ECoG) modifications may make a practical real-time feedback system available to the surgeon in hearing preservation cases.[71]

Postoperative Care

The compression mastoid dressing applied in the operating room is left in place until the fourth postoperative morning if hydroxyapatite or titanium mesh was not employed. The patient is observed in the neurologic intensive care unit for 1 day and then transferred to the general ward. Limited activity is begun on the first postoperative morning, and ambulation usually resumes on the second postoperative day, with discharge home on postoperative day 3 or 4.

Complications

Anteroinferior Cerebellar Artery

Tumor manipulation at the brainstem may result in changes in vital signs. Such changes are related to ischemia, which usually is in the distribution of the anterior inferior cerebellar artery. Manipulation is stopped temporarily until vital sign changes have resolved. Vital sign alterations that do not resolve or that recur with any tumor manipulation constitute an indication to terminate the procedure. Complete interruption of this vessel may result in Atkinson's syndrome, infarction of the lateral tegmental pons, which often is fatal.[72] This complication can occur in a nonfatal form if branches of the anterior inferior cerebellar artery are transected.

Cerebrospinal Fluid Leaks

In the translabyrinthine approach, CSF leakage through the wound is rare with meticulous closure. The incidence of CSF rhinorrhea is less than 5%, and the leak usually responds to replacement of the compression mastoid dressing. The routine obliteration of the eustachian tube has nearly eliminated this problem. In the rare case of persistent leakage, spontaneous sealing of the leak can be expected after 3 days of lumbar CSF drainage. However, surgical closure of the ear canal with direct obliteration of the eustachian tube is promptly effective. Hydroxyapatite cement and titanium mesh cranioplasty techniques have been highly effective in reducing the leakage rate.

In the retrosigmoid approach, the mastoidectomy defect also is obliterated with fat. In some institutions, the mastoid is not routinely entered, and fluid communication is possible through exposed air cells, which ultimately permit fluid leakage through the eustachian tube. Aggressive application of bone wax over mastoid air cells is necessary to avoid leaks. In cases of persistent leakage, additional fat obliteration of the mastoid plus waxing of air cells usually is successful.

Meningitis

Any procedure that exposes the subarachnoid space can be complicated by postoperative meningitis. The diagnosis is suspected in a patient with a toxic appearance including stiff neck, recent headache, and fever. Appropriate CSF studies will confirm the diagnosis. The mean time to onset of meningitis in patients with acoustic neuroma is 8 days postoperatively. Aggressive medical management of this complication successfully avoids any serious complications from meningitis, other than a delayed hospital discharge.[73]

Facial Nerve Injury

Facial nerve transection ideally is managed by immediate repair or with an interposition graft.[74] In the translabyrinthine approach, access to the middle ear and mastoid portions of the nerve can provide a longer distal segment to ensure a tension-free anastomosis.[75] In cases in which direct repair is impossible or in which an intact nerve does not resume function within 1 year, the facial hypoglossal anastomosis provides reliable facial reanimation.[76] Temporalis muscle transfer is an alternative technique for reanimation of the paralyzed face that offers the benefit of immediate effects.

Ophthalmologic Considerations

The combination of facial paralysis and corneal insensitivity, which is more likely with surgery of large tumors, predisposes the cornea to significant trauma. Patients who are expected to have prolonged facial paralysis (6 months) are managed with a brow lift and placement of eyelid springs or gold weights. In cases of partial facial weakness or when the paralysis is expected to be short term, aggressive medical management including a regimen of lubricating drops or ointments, use of contact lenses, moisture chamber protection, and nightly taping of the affected eye is undertaken.[26] In some centers, gold weight implantation in the upper lid is the preferred technique for managing corneal exposure.

CHAPTER ONE HUNDRED AND SEVENTY-EIGHT

Intraoperative Monitoring of Cranial Nerves in Neuro-otologic Surgery

Yasmine A. Ashram

Charles D. Yingling

Key Points

- Effective neurophysiologic recordings to guide the neurotologic surgeon rely on consistent protocols of neural stimulation and arrangement of the recording montage.
- In particular, a well-developed literature now demonstrates the effectiveness of monitoring facial nerve activity during vestibular schwannoma surgery by recording spontaneous and mechanically evoked activity. Recorded electrophysiologic activity reflects both nerve integrity and nerve responsivity.
- Similar methods are applicable to monitoring cranial nerves during other types of procedures, including resection of glomus jugulare tumors and prepontine tumors, microvascular decompression, parotidectomy, and tympanomastoidectomy.
- Other motor nerves—the third, fourth, motor portion of fifth, sixth, tenth, eleventh, and twelfth nerves—also can be monitored by placement of electrodes in appropriate target muscles.
- The cochlear nerve can be monitored by use of auditory brainstem response (ABR) or direct nerve action potential recordings.
- Numerous studies have confirmed that cranial nerve monitoring both reduces the incidence of postoperative deficits and can provide valuable prognostic information.
- Anticipated future developments, including the use of transcranial motor evoked potentials for continuous facial nerve stimulation, are expected to further enhance the utility of monitoring techniques.

The advent of sensitive diagnostic techniques and the refinement of microsurgical procedures have brought about a marked reduction in mortality rates for posterior fossa surgery; accordingly, increasing emphasis has been placed on preservation of cranial nerve function. This goal has in turn stimulated the development of techniques for monitoring cranial nerves during surgery. Seventh nerve monitoring during acoustic neuroma surgery has now become routine at most major medical centers, and anatomic preservation of the facial nerve has been achieved in more than 95% of the cases in some series.[1] Although facial motility often is compromised in the immediate postoperative period, the long-term prognosis is good if the nerve can be electrically stimulated after tumor removal. Preservation of hearing has been more difficult to achieve because of the more intimate relationship of such tumors with the cochleovestibular nerve but is now often achieved in smaller tumors with the aid of eighth nerve monitoring. Furthermore, the techniques developed for facial nerve monitoring are now readily adapted for monitoring other cranial motor nerves. We have reviewed these topics in greater detail elsewhere.[2]

The emphasis in this chapter is on the practical aspects of instrumentation, electrode placement, different neurophysiologic techniques used, artifact identification, types of responses encountered, and the relationship between intraoperative recordings and clinical outcome. Somatosensory evoked potential (SEP) recording[3] is not treated here, although SEP monitoring can be useful in monitoring large posterior fossa tumors with significant brainstem compression; discussions of SEP monitoring can be found in textbooks by Nuwer[4] and Møller.[5] This chapter is based primarily on the experience of the senior author with more than 700 posterior fossa procedures, as well as a review of the literature through 2007; also described are the methods currently available for cranial nerve monitoring, emphasizing facial and cochlear nerve monitoring during acoustic neuroma surgery but also including extension of these techniques to other nerves encountered in a variety of skull base procedures.

Neurophysiology in the Operating Room

Personnel

Successful intraoperative monitoring requires more than simply bringing another piece of equipment into the operating room (OR). The OR, unlike the typical clinical neurophysiology laboratory, presents a time-pressured and electrically hostile environment. Providing technically adequate recordings in the OR requires the services of professional

personnel with specialized skills and experience despite the additional costs incurred. Attempts to monitor without such personnel may result in failure, or, even worse, inadequate monitoring, with inaccurate and misleading feedback to the surgeon. Accordingly, a new specialty field of intraoperative neurophysiologic monitoring has evolved, with its own professional organization, the American Society of Neurophysiological Monitoring (ASNM).

Professional certification for surgical neurophysiologists is now offered by two national organizations in the United States. At the technologist level, the American Board of Registered Electrodiagnostic Technologists (ABRET) offers a Certification in Neuro-physiological Intraoperative Monitoring (CNIM). The American Board of Neurophysiologic Monitoring (ABNM) offers board certification to monitoring professionals holding advanced degrees and with a minimum of 3 years' experience and 300 cases monitored. Because the demand for monitoring services is growing rapidly, there is a growing need for training programs to ensure an adequate supply of qualified personnel.

Technical Considerations

Instrumentation

The basic instrumentation requirements for cranial nerve electromyography (EMG) monitoring are an isolated electrical stimulator that can be precisely controlled at low levels; several low-noise EMG amplifiers; a multichannel display; and an audio monitor with a squelch circuit to mute the output during electrocautery. A system that provides multiple channels is recommended to allow simultaneous monitoring of multiple divisions of the facial nerve independently as well as other cranial nerves.

Auditory brainstem response (ABR) monitoring requires a system that includes high-gain (100 to 500,000 K) differential amplification with multiple band-pass filtering capabilities, acoustic stimulus intensity ranging from threshold to at least 70- to 80-dB hearing level (HL), signal averaging with real-time display of the evolving averages and the input signal, and permanent disk storage with hard copy printout capability.

For complex surgical cases requiring additional EMG monitoring channels or increased ABR averaging capability, or both, several commercial multichannel systems have been developed for intraoperative use. Currently available systems allow multiple independent time bases and functions to operate simultaneously; for example, some channels may be devoted to free-running EMG at slow sweep speeds and others to stimulus-triggered EMG at a faster sweep, and still others can be used for collection of averaged ABRs.

Recording Electrodes: Type and Placement

The most commonly used recording electrodes are the platinum or stainless steel subdermal needles designed for EEG; these have a larger uninsulated surface than that of electrodes designed for single-fiber EMG and thus are more likely to detect activity arising anywhere in the monitored muscle. Disposable, presterilized electrodes are available from several sources, and their use is highly recommended.

Intramuscular hook wire electrodes, which are inserted with a hypodermic needle, also have been used.[6] These are more delicate and have higher impedance, so the simpler needle electrodes are preferred, except in situations in which the electrodes cannot be easily fastened with tape, as in procedures involving the tongue, or when the use of insulated needles is desirable to avoid crosstalk from overlying muscles. An example of the latter case is recording from extraocular muscles, for which the electrodes must pass through the orbicularis oculi muscle and will therefore respond to facial nerve activity as well.

For monitoring the facial nerve, it is desirable to place the electrodes in at least two different muscles supplied by the nerve. Mechanical trauma to the seventh nerve often causes sustained EMG activity that can make identification of the facial nerve with electrical stimulation difficult. With two or more close-spaced bipolar channels, at least one often will be quiet enough to allow responses to stimulation to be identified without signal averaging even with high tonic EMG activity.

For recording the ABR in hearing conservation procedures, one electrode is placed in the ipsilateral ear canal and another on the forehead or vertex. The placement of the second electrode is not critical so long as it is near the midline. The best electrode option for the ear canal is the Nicolet Tiptrode, which is a compressible foam insert covered with gold foil. The acoustic signal is delivered through a tube in the center of the foam, which provides an acoustic seal, and the foil provides the electrical contact for recording.

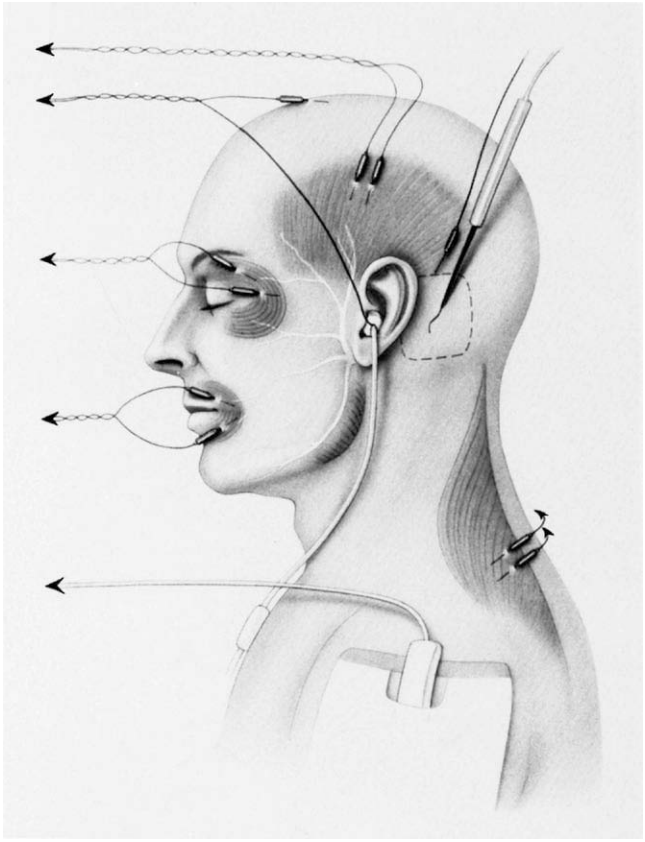

Figure 178-1. Diagrammatic representation of electrode placement for monitoring acoustic neuroma surgery with attempted hearing conservation. Pairs of needle electrodes are placed in the following muscles: temporalis (supplied by V3m), orbicularis oculi and orbicularis oris (supplied by the seventh nerve), and trapezius (by the eleventh nerve). Note that wires are twisted together to reduce 60-Hz pickup. Broadband click stimuli from a small transducer on the chest are fed through plastic tubing into the ipsilateral ear through a foil-covered sponge insert that also serves as a recording electrode and referred to a needle electrode on the forehead or vertex. An electrocautery ground pad is placed on the arm or shoulder as a signal ground. A flexible-tipped probe is used to stimulate cranial motor nerves, with a needle electrode as the stimulator ground placed in the margin of the craniotomy. *(From Yingling CD. Intraoperative monitoring of cranial nerves in skull base surgery. In: Jackler RK, Brackmann DE, eds.* Neurotology. *St Louis: Mosby; 1994:967).*

Figure 178-1 shows the positioning of recording electrodes for a middle fossa or retrosigmoid craniotomy for acoustic neuroma resection with a goal of hearing preservation. For a translabyrinthine approach, the same configuration is used, with the exception of the earphone and electrodes for ABR recording, because hearing conservation is not possible with this approach. Two channels are devoted to the facial nerve itself, with electrode pairs placed in orbicularis oculi and orbicularis oris muscles. One of the electrodes in the orbicularis oculi pair is placed at the lateral canthus, where it also will record volume-conducted activity in the lateral rectus muscle (from the sixth cranial nerve). One channel is used to record from the masseter or temporalis muscle (V3m) using hookwire electrodes, rather than subdermal needles, to reduce crosstalk, and the fourth channel is connected

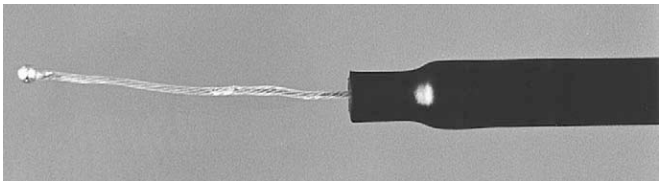

Figure 178-2. Close-up view of flexible-tipped probe used for intracranial stimulation. The entire probe and the flexible wire are insulated, except for the 0.5-mm ball on the end, to achieve localized stimulation.

to electrodes in the ipsilateral trapezius muscle (eleventh nerve). The latter two channels serve two functions: First, larger tumors may expand to involve these nerves, so monitoring may help in their identification and preservation. Second, even with smaller tumors, the extra channels serve as a control for nonsurgical causes of increased EMG activity, particularly light anesthesia.

Stimulating Electrodes

Both monopolar and bipolar stimulating electrodes have been used for intraoperative electrical stimulation. In theory, a bipolar electrode can provide more precise localization, with less current spreading from the electrode to adjacent structures. In practice, however, the threshold for bipolar stimulation depends strongly on the orientation of the two contacts with respect to the axis of the nerve.[7] Maintenance of a specific bipolar orientation is difficult in the close confines of the posterior fossa. Furthermore, if the stimulus intensity is near the threshold level (see later), a spatial resolution of less than a millimeter is easily obtained even with monopolar stimulation. Monopolar electrodes are therefore more commonly used; however, Schekutiev and Schmid[8] and Dankle and Wiegand[9] have described coaxial bipolar electrodes that may eliminate the problem of orientation.

The monopolar electrode should be connected to the cathode of the stimulator; the anodal return usually is a needle inserted into the periphery of the wound, preferably on the posterior margin of the incision to minimize stimulus artifact. This is particularly important in recording from extraocular muscles, which yield small-amplitude and short-latency responses that can easily be swamped by electrical artifacts. Several types of monopolar electrodes are available. Prass and Lüders[10] developed a malleable electrode, with the insulation continuous to a flush-tip that could be bent so that only the central portion of the tip contacted the desired tissue. They showed that this design minimized the spread of current to adjacent structures. Yingling and Gardi[11] developed a probe with a flexible platinum-iridium tip, insulated except for a 0.5-mm ball on the end (Fig. 178-2). This electrode can be used to stimulate within dissection planes or even behind the tumor, out of the surgeon's view, without concern for inadvertently damaging unseen neural or vascular structures (Fig. 178-3). With this probe, the facial nerve frequently can be located electrically even before it can be seen; dissection can then proceed in the most advantageous manner to avoid neural damage. Kartush and coworkers[7] developed a set of Rhoton-type dissecting instruments that are insulated except at the cutting surface, allowing simultaneous dissection with constant stimulation. These "stimulus dissectors" are particularly useful for removing the last portions of tumor capsule that are closely adherent to a nerve.

Stimulation Criteria

Little agreement has been achieved regarding the appropriate stimulation parameters to be used in cranial nerve monitoring, which vary considerably from one center to another. Our preference is to use a monopolar constant-voltage stimulator delivering pulses 0.2 ms in duration at a rate of 5 to 10 per second. In our experience, this is an effective and reliable choice that usually evokes a response from normal nerves at a threshold ranging between 0.05 and 0.2 V and averaging approximately 0.1 V.

Although the issue of whether constant-current or constant-voltage stimulators should be used has been a source of continuing controversy, there is no clear advantage of one method over the other. In many cases, however, the features of available equipment will limit the type of stimulation. Whether constant current or constant voltage is used, the more important issue is what actual level of stimulation is most appropriate. Rather than adhering to a simple "set it and forget it" approach, more useful information can be gained by varying the stimulation intensity in different surgical contexts, such as locating a nerve in relation to a tumor or testing the responsiveness of an already identified nerve.

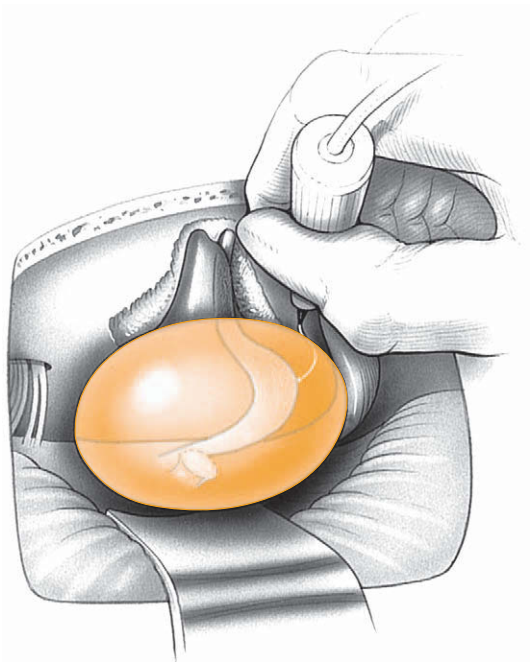

Figure 178-3. Surgical view of large acoustic neuroma (retrosigmoid approach) showing use of flexible-tipped probe to locate the facial nerve on the medial surface of the tumor out of direct view. Early identification of the facial nerve "around the corner" on the ventral surface of the tumor helps speed the procedure by allowing rapid removal of the remaining capsule. Tumor is drawn as if transparent to show details of anatomy on the hidden surface. *(Adapted from Yingling CD, Gardi JG. Intraoperative monitoring of facial and cochlear nerves during acoustic neuroma surgery.* Otolaryngol Clin North Am. *1992;25:413.)*

Anesthesia

Cortical evoked potentials are notoriously sensitive to many anesthetic agents, so careful adjustment of anesthesia levels is necessary in applications such as spinal cord monitoring with SEPs. Fortunately, the ABR and EMG responses that are used for cranial nerve monitoring are essentially unaffected by any commonly used anesthetics. The major anesthetic consideration is a contraindication to the use of muscle relaxants, because blockade of the neuromuscular junction interferes with monitoring of EMG activity. A few reports[12-14] have suggested that partial blockade can be used to prevent patient movement without blocking the ability to elicit EMG responses with facial nerve stimulation. However, in our experience, although electrically evoked EMG is relatively preserved, both spontaneous and mechanically elicited EMG activity tends to be suppressed by these agents. Therefore, *no paralytic agents should be used during surgery with cranial nerve monitoring*, other than short-acting agents such as succinylcholine given to facilitate intubation. Because the ABR and EMG are not significantly affected by routine concentrations of common anesthetics, no other constraints on anesthetic technique generally are necessary.

Finally, if local anesthetic is used at the incision site, care must be taken to avoid injection near the stylomastoid foramen to avoid anesthetizing the facial nerve. Alternatively, epinephrine 1 : 100,000 without any local anesthetic may be used to aid hemostasis.[15]

Facial Nerve (Seventh Nerve) Monitoring

Acoustic Neuroma and Other Cerebellopontine Angle Tumors

Facial nerve (seventh nerve) monitoring is routinely used in procedures to remove acoustic neuromas and other cerebellopontine angle tumors. Several techniques for facial nerve monitoring have been developed, including the use of sensitive detectors mounted on the face to detect facial nerve activity,[16-19] intraoperative EMG, recording of compound nerve action potentials (CNAPs) from the facial nerve,[20-22] intraoperative recording of nasal muscle F-wave,[23,24] and video analysis to detect facial movements.[25,26]

Electromyography

Because of its higher sensitivity[6,7,11,16,27-46] and easy application, EMG has by far overshadowed the other aforementioned methods and has become the most widely used modality for routine facial nerve monitoring. EMG recordings are used for monitoring cranial motor nerve activity in two distinct ways. First, intracranial electrical stimulation is used to identify and map the course of the nerves with evoked EMG activity and to determine the functional integrity of a nerve. Second, spontaneous EMG activity is continuously monitored to detect changes related to mechanical, thermal, or electrical irritation of the nerves by intraoperative maneuvers such as retraction,[47] tumor dissection, use of electrocautery or lasers,[48,49] or ultrasonic aspiration.

Activity Evoked by Electrical Stimulation

Use of Stimulation to Identify and Map Nerves in Relation to Tumor

Electrical stimulation is used in two main ways: (1) to rule out the presence of a nerve in a region to be dissected (using suprathreshold stimulation levels, i.e., 1 V) and (2) to map the precise locations of cranial nerves and determine their functional integrity, using stimulation levels at or just above threshold (i.e., 0.05 to 0.3 V).

Before electrical stimulation begins, correct functioning of the stimulating and recording system must be confirmed as soon as possible to avoid potentially catastrophic false-negative results. The presence of a stimulus artifact is not an unequivocal test; it is possible to have a stimulus artifact with only one lead (either the anodal return or the cathodal stimulator) connected. However, the absence of any artifact usually indicates an open circuit somewhere in the system. To avoid any ambiguity, it is preferable to confirm the operation of the entire system before beginning tumor dissection. In a retrosigmoid approach, the eleventh nerve usually can be stimulated at the jugular foramen as soon as the dura has been opened and the cerebellum retracted; an EMG response in the trapezius muscle confirms that the system is operating correctly. This confirmatory maneuver usually is possible before tumor resection begins, except in operations involving very large acoustic tumors. If the eleventh nerve is not visible at the outset, the stimulating electrode can be placed directly on a muscle and a direct muscular response obtained, although muscle requires higher stimulation levels than those effective in nerve. In translabyrinthine procedures, the facial nerve can be stimulated within the mastoid bone in the course of the labyrinthine dissection (before the tumor is exposed), although the threshold will be higher (usually 0.6 to 1.0 V, although up to 2 V may be needed), depending on the thickness of the overlying bone.

Once system function has been verified, an attempt is made to locate and stimulate the facial nerve. In smaller tumors (cerebellopontine angle component of 1 cm or less), the nerve usually can be located at its brainstem entry and an electrical response confirmed before dissection begins. Once a threshold has been established, the voltage is increased to at least three times the threshold value, and the stimulator is swept across the exposed surface of the tumor to confirm the absence of facial nerve fibers before dissection is begun. With larger tumors, the location of the facial nerve may not be immediately apparent. In such cases, we start with 0.3 V and map the accessible region, and if no response is obtained, we repeat the search at 0.5 and 1.0 V. If no response is obtained at 1.0 V, it can be safely assumed that the facial nerve is not on the exposed surface, and dissection can proceed.

During dissection, the stimulator is used repeatedly to scan the operative field for the presence of facial nerve fibers as the tumor is mobilized, using suprathreshold stimulus intensities as described previously. Once a response is obtained, stimulus intensity is reduced to 0.1 to 0.2 V, and the responsive region is narrowed. When the nerve is in sight, the electrode is placed directly on the nerve, and a threshold is obtained by slowly increasing the stimulus level from zero until a response is obtained. Further stimulation for mapping the location of the nerve is carried out at approximately three to five times this threshold, which should be periodically rechecked as dissection proceeds.

The spatial resolution of electrical mapping with monopolar stimulation is determined by stimulus intensity. For the most accurate localization, the stimulus is kept at a low level. At just suprathreshold levels, the spatial resolution is less than 1 mm, allowing the facial nerve to be easily distinguished from the adjacent vestibulocochlear complex. Conversely, to confirm that the nerve is not in an area about to be cut or cauterized, higher levels of stimulation (up to 1.0 V) are used to reduce the likelihood of false-negative results. As more and more tumor is removed, the course of the facial nerve can be mapped from brainstem to internal auditory canal. Although the nerve may be relatively cylindrical at each end, it frequently is compressed by the tumor in the cerebellopontine angle and may be seen as a broad, flat expanse of fibers splayed across the surface of the tumor. Frequently, the only way to identify the nerve and distinguish it from arachnoid tissue is with electrical stimulation; the nerve may be literally invisible to photons and visible only with electrons!

Assessment of Functional Status of Nerves after Tumor Removal

The primary use of intraoperative stimulation is in localizing and mapping the course of cranial nerves in relation to cerebellopontine angle tumors. However, electrical stimulation also is used to determine changes in the functional status of these nerves and is a useful predictor of postoperative function. In general, facial EMG responses elicited by low-threshold stimulation of the seventh nerve at the brainstem after total tumor resection constitute a good but not infallible predictor of postoperative function, because transient or delayed-onset facial palsies may be seen even when a low threshold is obtained at the end of the operation.[50-53] Conversely, a substantially elevated threshold or the inability to elicit a response with stimulation up to 1 V carries a significant likelihood of postoperative facial dysfunction, particularly in the short run.[51]

Methods based on measurement of the compound muscle action potential (CMAP) amplitude after tumor removal also have been used to quantify the functional status of the seventh nerve.[32,54] Absolute amplitude is quite variable between patients, however, and may be partially determined by nonspecific factors such as precise electrode placement, amount of subcutaneous fat,[29] facial nerve dimensions, and muscle mass.[55] These variations have led some investigators to use ratios rather than absolute values for assessment of postoperative facial nerve function. Taha and associates[56] measured the ratio of CMAP amplitudes to stimulation at the brainstem proximally and at the internal auditory meatus distally after tumor excision and found that proximal-to-distal amplitude ratios greater than 2:3 were associated with excellent outcome. Similarly, Isaacson and colleagues[57] analyzed proximal-to-distal amplitude ratios and reported that a higher ratio reflected good immediate postoperative facial nerve function. Lin and coworkers[55] used the ratio between proximal amplitude measurement after tumor dissection and supramaximal amplitude measurement in response to transcutaneous facial nerve stimulation and found that a CMAP ratio greater than 50% of maximum had a 93% positive predictive value when measured at 0.3 mA.

Prediction of long-term rather than short-term facial nerve function is the surgeon's major concern, because this would allow for better patient counseling and planning of rehabilitative treatment.[58] It has been suggested that low threshold recorded at the brainstem after tumor resection is a good predictor of long-term facial nerve function[50,59-61]; however, the ability of threshold to accurately predict long-term function has been questioned by some.[62,63] Neff and colleagues[64] evaluated a combination of threshold and amplitude and found that a minimum threshold of 0.05 mA together with a CMAP amplitude greater than

240 μV predicts a good postoperative outcome 1 year postoperatively. Fenton and associates[65] concluded that a more reliable predictor of long-term facial nerve is the clinical grade of early postoperative facial function. They also demonstrated that all patients with a recordable EMG response to proximal stimulation after tumor dissection, irrespective of the threshold or amplitude, recovered to a follow-up grade III or better facial nerve function. Although this correlation has been previously reported,[53,54,61,66,67] its importance has gone unnoticed. Therefore, it is now accepted that whenever a recordable response to electrical stimulation of whatever amplitude or threshold can be demonstrated, the facial nerve is most likely to show signs of improvement with follow-up, and intervention is therefore not recommended within the first year.[65] On the other hand, the absence of response to stimulation at the end of surgery does not doom the patient to a bad outcome. If the nerve is anatomically preserved, even with an immediate postoperative palsy, there is still a good possibility of eventual return of function as functional nerve fibers regenerate. Partial recovery of function in patients with unrecordable responses after surgery has been previously reported.[68] The earlier the onset of recovery, the better its quality; however, ifevidence of recovery is lacking at 12 months, then it is unlikely to occur.[69]

Intraoperative Identification of the Nervus Intermedius

Anatomic identification of the nervus intermedius during cerebellopontine angle surgery is important in order to prevent confusing this nerve with the facial nerve itself. Electrical stimulation of the nervus intermedius during cerebellopontine angle surgery was found to produce a characteristic response in the orbicularis oris channel only: long latency, low amplitude, and higher in threshold than the facial nerve response[70] (Fig. 178-4). Initial confusion between the nervus intermedius and a facial nerve strand at the time of stimulation is possible, because the entire course of the facial nerve may not be visually apparent to the surgeon as it passes anterior to the tumor—most common surgical approaches are from the posterior. Furthermore, tumor growth causes the facial nerve to be stretched and widened, so it often cannot be identified as a solitary trunk but rather is seen as a wide ribbon. The surgeon must recognize that stimulation of the nervus intermedius can cause EMG activity in the facial nerve monitoring channels (at least the orbicularis oris) but that the main trunk of the facial nerve may lie in an entirely different location within the cerebellopontine angle (Fig. 178-5). To protect this critical structure, it is imperative for the surgeon to locate the facial nerve itself by stimulation.

Spontaneous and Mechanically Evoked Activity

EMG responses to intracranial stimulation are the most specific indicators of cranial nerve localization and functional status. However, spontaneous EMG activity and EMG responses related to intraoperative events also are useful in preserving neural function. Some patients, particularly those with significant preoperative facial deficits,

Intraoperative electrophysiological identification of the nervus intermedius.* Otol Neurotol. *2005;26:274.)*

demonstrate baseline tonic facial EMG activity; this often decreases as the nerve is decompressed with opening of the dura and draining of CSF. Virtually all patients exhibit some mechanically evoked facial EMG activity during tumor dissection, retraction, irrigation, or other intraoperative maneuvers. An increase in EMG activity associated with a particular surgical maneuver often is the earliest indicator of the location of the facial nerve. When such activity is elicited, the stimulator should then be used to search the area in question to positively identify the nerve if possible. Frequently, operative manipulations elicit EMG activity, even if the nerve is not in the immediate area, because of transmission of traction or pressure from the tumor to the nerve. In such cases, a negative response to electrical stimulation indicates that dissection can proceed. In other cases, stimulation after mechanically elicited activity results in identification of the nerve, which can then be precisely localized as described previously.

Finally, ongoing EMG activity often is an indirect indicator of depth of anesthesia, which is of particular concern when no muscle relaxants can be used. A simultaneous increase in spontaneous EMG activity on all channels is unlikely to result from localized dissection. When such a generalized increase occurs, the anesthesiologist should be notified immediately, because overt patient movement often occurs within a few seconds.

Patterns of Mechanically Evoked Electromyographic Activity

Prass and Lüders[6] distinguished two types of EMG activity associated with intraoperative events: *burst* and *train* activity. These investigators suggested that the phasic "burst" pattern, characterized by short, relatively synchronous bursts of motor unit potentials, corresponded to a single discharge of multiple facial nerve axons, and was associated with direct mechanical nerve trauma, free irrigation, application of pledgets soaked with lactated Ringer's solution over the facial nerve, or electrocautery. When burst activity occurs, it usually indicates that the facial nerve is being stimulated enough to result in depolarization and production of EMG response but not necessarily to the point of injury.[71] It generally is accepted that the occurrence of burst activity of small amplitude (less than 500 μV in amplitude) is not of major concern, and accordingly, the surgeon need not be warned each time such activity occurs.[72,73] On the other hand, the occurrence of large-amplitude burst activity (greater than 500 μV in amplitude) during the critical stages of dissection or final stages of drilling usually indicates a degree of facial nerve injury, the extent of which differs with the force and number of impacts.

As described by Prass and Lüders,[6] the second pattern, tonic or "train" activity, consisted of episodes of prolonged asynchronous grouped motor unit discharges that lasted up to several minutes. These episodes were most commonly associated with facial nerve traction, usually in the lateral to medial direction. The investigators further divided such train activity into higher-frequency trains (50 to 100 Hz), dubbed "bomber potentials" because of their sonic characteristics, and lower-frequency discharges (1 to 50 Hz), which were more irregular and had a sound resembling popping popcorn. The onset and decline of "popcorn" activity were more gradual than the more abrupt onset and decline of "bomber" activity.

Subsequently, Romstock and coworkers[72] classified train activity into three distinct patterns: A, B, and C trains. *A trains* are characterized by a sinusoidal symmetrical sequence of high-frequency and low-amplitude signals that have a sudden onset; *B trains* are regular or irregular sequences of repeated spikes or bursts with maximum intervals of 500 msec; and *C trains* are characterized by continuous irregular EMG responses that have many overlapping components. Although B and C trains did not correlate with postoperative function, the authors suggested a relation between the occurrence of A trains and poor postoperative facial nerve function.

Nakao and colleagues[74] classified train activity that occurred during the last stage of tumor resection into an *irritable* pattern with frequent EMG responses to the slightest stimuli, a *silent* pattern with few or no EMG responses, a *stray* pattern with persistent train responses up to 20 minutes despite temporary discontinuance of surgical manipulation, and an *ordinary* pattern related to mechanical stimulation of the nerve but not easily elicited. These workers found an association between the occurrence of silent or stray EMG patterns and poor postoperative outcome. The occurrence of train activity does not always imply an impending nerve injury but indicates the proximity of the facial nerve to the region of dissection and thus should be considered a reassuring sign denoting an intact and responsive nerve.[71] However, train activity of large amplitude (greater than 500 μV in amplitude) has been linked to postoperative nerve injury of variable degree,[75,76] and such events require prompt warning to the surgeon. The absence of large-amplitude train activity, on the other hand, does not always mean safe dissection, especially with large tumors producing significant facial nerve compression. The nerve axons become stretched, partially damaged, and less responsive than healthy ones, generating little EMG activity despite significant manipulation.[77] Therefore, spontaneous EMG activity may not be a reliable warning sign in large tumors, and the frequent use of electrical stimulation is important to map the tumor surface and measure any change of threshold from baseline to assess the condition of the nerve. Figure 178-6 shows representative samples of different types of EMG activity often encountered in vestibular schwannoma removal.

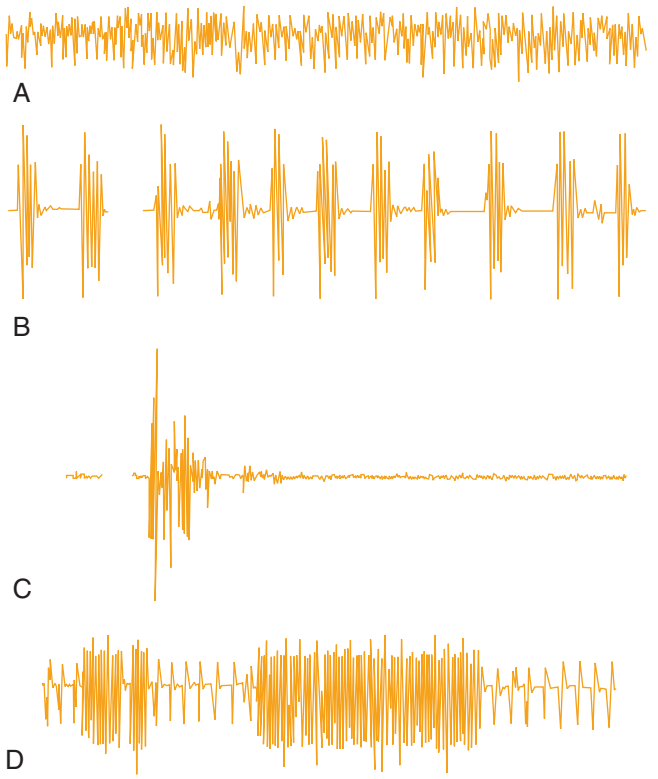

Figure 178-6. Illustrative examples of three types of electromyographic activity often seen during vestibular schwannoma surgery. **A,** Dense tonic (sustained) activity, often associated with nerve stretch and demonstrating a sinusoidal pattern. **B,** Lower tonic activity, called popcorn activity. **C,** Phasic (transient) burst activity typically associated with direct contact with the nerve. Such events are not of major significance unless they involve large-amplitude trains and occur during critical stages of dissection. **D,** Burst activity superimposed on ongoing small-amplitude train; it is important not to overlook such events overlapping on background activity, because they may pass unnoticed despite their significance. *(From Yingling CD, Ashram YA. Intraoperative monitoring of cranial nerves in skull base surgery. In: Jackler R, Brackmann DE, eds.* Neurotology. *2nd ed. Philadelphia: Elsevier; 2005:958.)*

Limitations of Electromyographic Monitoring

Despite the wide use of intraoperative EMG monitoring, it still has its limitations. A major problem with EMG monitoring is its relatively low specificity. EMG channels can easily pick up artifacts, and the distinction between them and true EMG activity may sometimes be

difficult. An example is artifacts produced by bimetallic potentials as a result of contact between surgical instruments made of different metals; because these may be associated with intraoperative events similar to those producing true EMG responses, they can be difficult to recognize. Some useful criteria include the fact that artifacts typically are higher in frequency content than EMG activity and thus sound more "crackly" than true EMG activity, which has more of a "popping" sound; and the tendency for artifacts to appear simultaneously on several channels, which is unlikely for EMG activity (Fig. 178-7). Experienced monitoring personnel are in an optimal position to make such decisions, rather than surgeons, who are focused on the operative field. Another limitation of EMG monitoring is that it is virtually useless during electrocautery, when the facial nerve is potentially at high risk. Attempts to reduce the artifact from bipolar cautery have met with limited success, because such devices generate high-amplitude, broadband noise that is difficult to filter out. Techniques based on detection of motion, which are not subject to electrical interference, such as video monitoring, may provide an important adjunct to EMG monitoring despite their relatively lower sensitivity. In our experience, the practical way to deal with this problem is to use electrical stimulation before bipolar electrocoagulation to confirm that the area to be cauterized is free from facial nerve fibers. The absence of a response to higher levels of electrical stimulation (up to 1 V) in an area about to be cauterized is an indication that electrocautery can proceed safely.

Another problem with EMG monitoring is that facial nerve integrity with stimulation cannot be assessed unless the nerve is accessible in the surgical field. However, with large tumors, the facial nerve is at risk of being traumatized before it is visually apparent to the surgeon and may not be responsive to mechanical manipulation. In this situation, the facial nerve location can be anticipated by use of a flexible-tipped probe to stimulate within dissection planes or even behind the tumor, out of the surgeon's view, without concern for damaging unseen vascular or neural structures. However, the development of continuous facial nerve monitoring methods that do not rely on visual identification of the nerve remains one of the major challenges for future research.

Microvascular Decompression

Microvascular decompression procedures for treatment of trigeminal neuralgia and hemifacial spasm involve potential damage to cranial nerves in the posterior fossa; therefore, EMG and ABR monitoring frequently are used with such procedures,[78] with the same techniques described elsewhere in this chapter.

In the specific case of microvascular decompression for hemifacial spasm, however, Møller and Jannetta[40] described a different technique. This method is based on the finding of abnormal muscle response in patients with hemifacial spasm, in whom muscles innervated by one branch of the facial nerve respond when another branch is stimulated. This response is due to abnormal spread of activity from one branch of the facial nerve to another on the affected side. Because it is not suppressed by anesthesia, it can be recorded intraoperatively so long as the patient is not paralyzed.

For a typical procedure, recording electrodes are inserted into the mentalis muscle (innervated by the marginal mandibular branch of the seventh nerve) and the orbicularis oculi (temporal branch). Subdermal needle electrodes also are inserted adjacent to the marginal mandibular and temporal branches of the seventh nerve for stimulation. Of note, the stimulation voltage required will be higher (4 to 20 V) than for direct stimulation of the nerve intracranially. Intracranial stimulation as described previously can, of course, also be used to ensure the integrity of the facial nerve in decompression procedures for hemifacial spasm. Figure 178-8 shows typical results with such a procedure.

If the abnormal response is not seen at the outset, it generally can be triggered by a brief train of stimuli at a high frequency (50 Hz). The amplitude of the abnormal response typically is lower than that of the normal response and may drop even further after the dura is opened, presumably because of a shift in the relation of the vessel to the nerve. Nevertheless, an abnormal response at some amplitude generally can be seen until the nerve is decompressed. Møller and Jannetta[40] recommend that the decompression be carried out until no abnormal response can be elicited. They state that the abnormal response disappears immediately when the offending vessel is removed from the nerve, a finding also reported by Halnes and Torres,[30] although in our experience, it may take a few minutes for the abnormal response to disappear completely. Debate continues over the association between the persistence or disappearance of the abnormal muscle response and ultimate clinical outcome. Kong and associates[79] found that long-term outcomes were

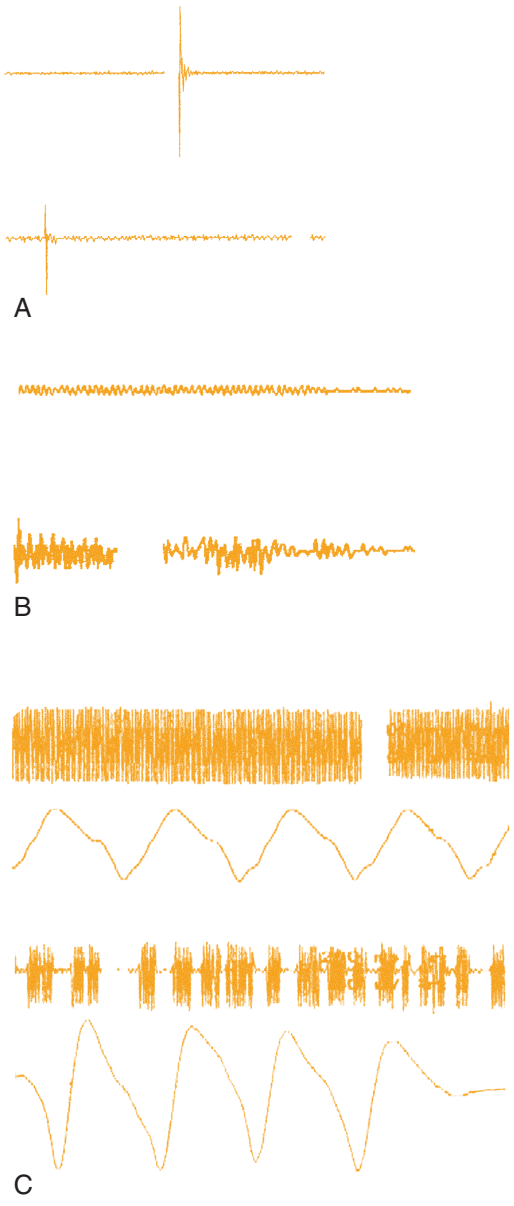

Figure 178-7. Electromyography (EMG) activity versus artifacts. **A,** *Upper trace*: Artifact produced by contact of different metallic instruments in surgical field. Note sharp edges on waveforms with exponential decay (may be confused with spike activity). *Lower trace*: Single electromyographic spike with a low-amplitude EMG background and no exponential decay. **B,** *Upper trace*: Regular sinusoidal artifact produced during drilling of the internal auditory canal (IAC). *Lower trace*: Irregular EMG activity while drilling IAC. **C,** *Upper two traces*: Regular artifact with two time scales, 200 msec/cm and 5 msec/cm. *Lower two traces*: EMG activity on the same two time scales. At 200 msec/cm, it may be difficult to differentiate between true EMG and artifact. However, with the faster 5 msec/cm time base, trace 2 shows that the artifact waveform is regular and synchronized, whereas trace 4 reveals the irregularities that characterize true EMG activity. *(From Yingling CD, Ashram YA. Intraoperative monitoring of cranial nerves in skull base surgery. In: Jackler R, Brackmann DE, eds.* Neurotology. *2nd ed. Philadelphia: Elsevier; 2005:958.)*

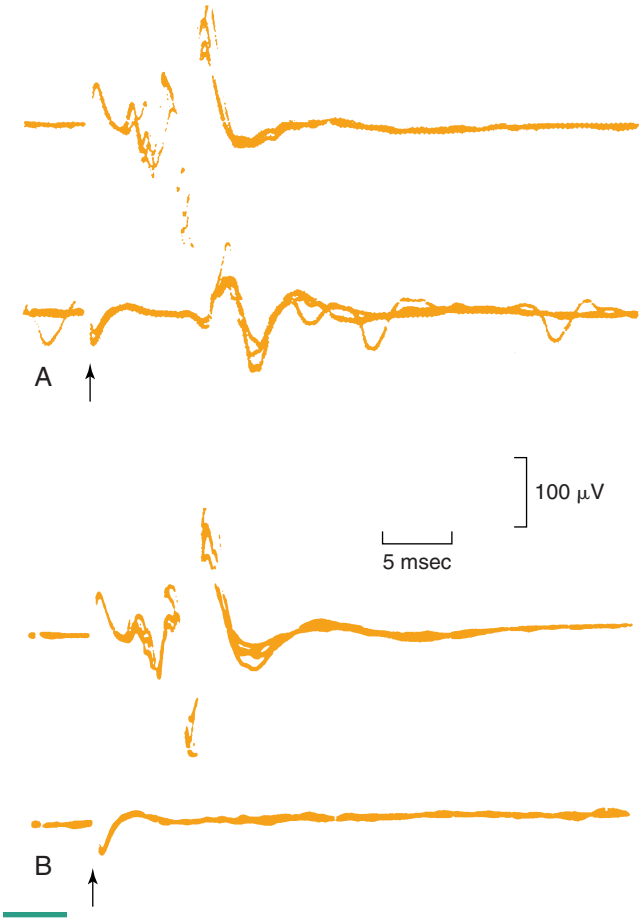

Figure 178-8. Responses during intraoperative monitoring of microvascular decompression for hemifacial spasm. Stimulating electrodes in temporal branch of facial nerve; recording channels orbicularis oculi *(top)* and mentalis *(bottom)*. **A,** *Before decompression*: The normal response in the orbicularis oculi to stimulation of the temporal branch is seen in the upper channel. The lower channel shows the abnormal response at prolonged latency in mentalis to stimulation (at time indicated by *arrow*) of temporal branch. **B,** *After decompression*: Abnormal response in mentalis no longer seen, normal response in orbicularis oculi unchanged. *(From Yingling CD. Intraoperative monitoring of cranial nerves in skull base surgery. In: Jackler RK, Brackmann DE, eds.* Neurotology. *St Louis: Mosby; 1994:967.)*

significantly better in patients whose abnormal response disappeared completely after decompression than in those with a persistent abnormal response; however, other investigators failed to prove this association.[80] More work is still necessary to elucidate the prognostic significance of the abnormal muscle response.

Parotid Surgery

Facial nerve monitoring during parotidectomy is similar to facial nerve monitoring in cerebellopontine angle surgery, except that the seventh nerve generally is the only nerve at risk. Thus, rather than using multiple EMG channels to monitor several nerves, all available channels can be used to monitor different branches of the facial nerve, which divides within the parotid gland (pes anserinus). Our typical four-channel montage includes closely spaced bipolar electrode pairs in the frontalis muscle (temporal branch of the seventh nerve), lower orbicularis oculi (zygomatic), upper orbicularis oris (buccal), and mentalis (marginal mandibular). The pattern of responses obtained with electrical stimulation can be used to determine which branch is being stimulated. EMG activity in a single channel indicates activation of a single branch of the nerve distal to the pes, activity in two or three channels generally indicates a location within the pes, and a response on all channels indicates activation of the main trunk of the nerve between the pes and the stylomastoid foramen. This is true both for mechanically elicited activity and for responses to electrical stimulation. The methods for recording both mechanically elicited activity and responses to electrical stimulation are similar to those used intracranially; of note, however, because the intracranial portion of the facial nerve lacks the thick epineurium found distally, thresholds for direct stimulation of the nerve within the parotid gland will typically be somewhat higher than those in the posterior fossa.

Other Otologic Surgery

Facial nerve monitoring also may be useful in many otologic procedures. For example, congenital aural atresia may be associated with an anomalous course of the facial nerve or may require rerouting of the nerve to expose the oval window. Surgery for chronic otitis media and cholesteatoma also may benefit from facial nerve monitoring, particularly when preoperative findings include preexisting facial dysfunction or computer tomographic (CT) evidence of fallopian canal erosion. Revision tympanomastoidectomies carry a higher risk of facial nerve injury because landmarks may be obscured by scar tissue. However, monitoring is not necessarily indicated in every routine case. There is no simple rule for determining when monitoring is indicated; a number of factors must be taken into consideration, including preexisting deficits, size and location of lesions, previous surgery, and the surgeon's experience. Besides serving as a guide to drilling, dissection, and verifying the integrity of the nerve, monitoring also is useful in detecting facial nerve dehiscence.[81,82] Noss and associates[81] suggested that the electrical stimulation threshold of the facial nerve is more reliable than surgical observation alone in identifying risk for injury secondary to dehiscence. These workers found that a facial nerve stimulation threshold less than 1 V identifies a nerve that is electrophysiologically dehiscent and thus should be considered at increased risk for injury.

Other Motor Nerve Monitoring

Third, Fourth, and Sixth Nerve Monitoring: Extraocular Muscles

Monitoring of the oculomotor (third), trochlear (fourth), and abducens (sixth) nerves, which innervate the various extraocular muscles, frequently is necessary in surgery for more anterior skull base lesions. These may include, for example, cavernous sinus tumors, prepontine tumors, and petrous apex lesions with significant anterior or medial extension. Although the basic principles are the same as for facial nerve monitoring, the relative inaccessibility of the target muscles causes special difficulties.

Paired hookwire electrodes are now preferred for monitoring of extraocular muscles, because they are flexible and thus less likely to traumatize the eye. The hookwire electrodes are inserted through the eyelids into proximity with the tendons of the target muscles, where they pick up volume-conducted activity from the muscles themselves (Fig. 178-9).

The oculomotor nerve (third nerve) is the easiest from which to obtain specific responses, because it innervates all of the extraocular muscles except for the lateral rectus and superior oblique. Placement of an electrode at the infraorbital margin, roughly one third of the distance out from the inner canthus, will result in pickup of activity from the inferior oblique or inferior rectus muscle, both of which are innervated by the third nerve (see Fig. 178-9). Similarly, activity in the lateral rectus muscle, innervated by the abducens (sixth) nerve, can be detected by an electrode inserted from the lateral canthus. The trochlear nerve (fourth nerve) is the most difficult to monitor, because the superior oblique muscle does not connect to the eyeball in the same straightforward fashion as for the other extraocular muscles. We have described these procedures in greater detail elsewhere.[2]

The latency of responses in the extraocular muscles to stimulation of the third, fourth, or sixth nerve typically is 2 to 3 msec, much shorter than that of responses to seventh nerve stimulation. This short latency helps prevent confusion of true third, fourth, or sixth nerve responses with seventh nerve activity, which is a common contaminant of recordings from these muscles (Fig. 178-10).

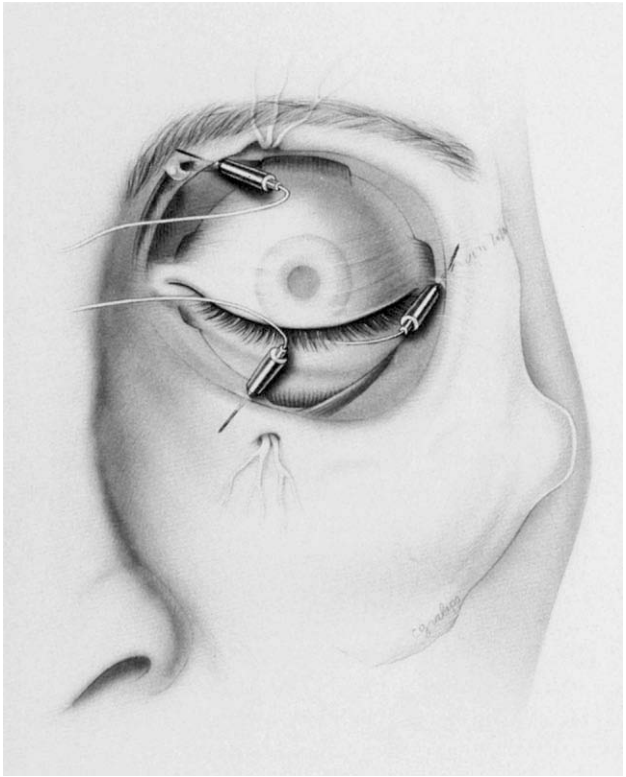

Figure 178-9. Placement of electrodes in extraocular muscles for monitoring cranial nerves III, IV, and VI. Electrodes are inserted through closed eyelids (drawn as if transparent), against inner surface of bony orbit, to record from inferior rectus/inferior oblique (third nerve), superior oblique (fourth nerve), and lateral rectus (sixth nerve). The illustration shows monopolar needle electrodes; flexible bipolar hookwire electrodes are now preferred for recording from extraocular muscles (see text for details). *(From Yingling CD. Intraoperative monitoring of cranial nerves in skull base surgery. In: Jackler RK, Brackmann DE, eds.* Neurotology. *St Louis: Mosby; 1994:967.)*

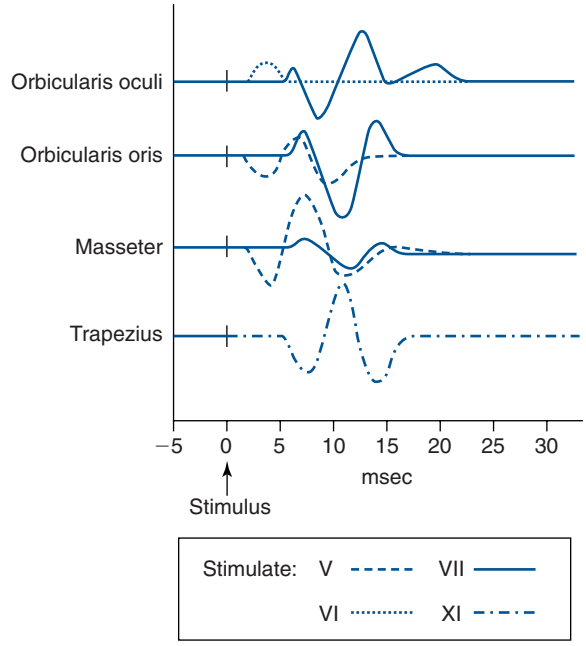

Figure 178-10. Schematic representation of responses obtained in four-channel montage (see Fig. 178-1) with intracranial stimulation of different motor nerves. Despite crosstalk in fifth and seventh nerve channels, these nerves can be clearly distinguished by the shorter latency of the responses to fifth nerve stimulation. Stimulation of the sixth nerve produces a short latency response localized to the orbicularis oculi channel because of volume conduction from the lateral rectus to the electrode at the outer canthus; stimulation of the eleventh nerve produces response restricted to the trapezius (see text for details). *(From Jackler RK, Pitts LH. Acoustic neuroma.* Neurosurg Clin N Am. *1990;1:199.)*

Complications (other than transient bruising) from monitoring of extraocular muscles are fortunately rare. It should be kept in mind, however, that the placement of electrodes near the globe is not without risk. In one of our patients, placement of an electrode near the superior oblique muscle resulted in bleeding and increased intraocular pressure, complicated by obstructed venous drainage due to compression of the posterior orbit by a neoplasm. Fortunately, this was detected before draping; the surgery was aborted and a lateral canthotomy was performed to relieve the excessive intraocular pressure. The tumor was removed a few days later, without further attempt to monitor fourth nerve function. Furthermore, diagnostic ocular EMG has been associated with rare occurrences of ecchymoses of the conjunctiva, subcapsular hemorrhage, and exposure keratitis, all of which clear without sequelae. Of greater concern is inadvertent perforation of the globe, which is more likely to occur in the presence of undetected glaucoma.[83]

Trigeminal Motor Branch Monitoring

Most efforts at intraoperative monitoring of the fifth nerve have concentrated on the motor portion (V3m), which is a branch of the third division of the nerve. There have been very few attempts to monitor the sensory branches, largely because of the technical problems encountered in overcoming stimulus artifact in trigeminal SEP recording, which is due both to the short latency of trigeminal SEPs and the proximity of the stimulation and recording sites.[84,85] However, Soustiel and coworkers[86] obtained good results with use of alternating-polarity stimuli to cancel the stimulus artifact.

The principles of monitoring V3m are the same as for seventh nerve monitoring. In practice, however, crosstalk between channels complicates the situation. Stimulation of V3m can produce large-amplitude CMAP responses that will be recorded by electrodes in masseter or temporalis and transmitted to facial muscles. Similarly, activity in facial muscles may be seen in the masseter or temporalis channels, creating the possibility of crosstalk in both directions. This overlap may pose a problem in interpreting the origin of mechanically elicited EMG activity. To minimize crosstalk, the V3m recording electrodes should be located where they will be minimally affected by facial muscle activity. We currently use hookwire electrodes placed in the temporalis muscle underneath the zygomatic arch, unless this is not possible because of the surgical approach (i.e., subtemporal or middle fossa); in such cases, the electrodes must be placed in the masseter.

Crosstalk presents less of a problem with the use of electrical stimulation because it is possible to distinguish between V3m and the seventh nerve by the latency of responses. Stimulation of the seventh nerve produces CMAP with an onset latency that typically ranges between 6 and 8 msec, depending on the exact site of stimulation, although it may be as short as 5 msec with stimulation in the far lateral internal auditory canal or delayed to as long as 20 msec if the nerve has been severely compromised by the tumor. On the other hand, stimulation of V3m produces responses of significantly shorter latency, ranging from approximately 3.5 to 5 msec. (Taken together, these findings suggest a useful mnemonic: "fifth nerve less than 5, seventh nerve approximately 7.") The differential pattern of responses seen in a typical acoustic neuroma case is shown in Figure 178-10.

Monitoring of Lower Cranial Nerves: Ninth, Tenth, Eleventh, and Twelfth Nerves

Larger acoustic neuromas with a significant inferior extension may involve the lower cranial nerves, and intraoperative monitoring of these nerves will be beneficial. More commonly, cranial nerves IX and XII are involved by tumors of the posterolateral cranial base, such as glomus

jugulare tumors, meningiomas, or schwannomas of the ninth, tenth, or eleventh nerve. The morbidity associated with removal of tumors in this region is due primarily to neural damage, which may result in deterioration of voice, swallowing difficulties, or weakness and pain in the shoulder. These nerves can be monitored with EMG techniques analogous to those already described, with appropriate placement of recording electrodes.[87-89]

The glossopharyngeal (ninth nerve) nerve primarily mediates sensation to the upper pharynx and taste to the posterior third of the tongue. The only muscle innervated by this nerve is the stylopharyngeus, which is not easily accessible for insertion of EMG recording electrodes. However, electrodes in the posterior part of the soft palate ipsilateral to the tumor will pick up volume-conducted activity from the stylopharyngeus (Fig. 178-11; see also Fig. 178-13). The electrodes are inserted intraorally after intubation and are best sutured in place to prevent accidental dislodgement.

In contrast with other lower cranial nerves, mechanical stimulation of the ninth nerve during dissection typically produces little EMG activity, so it is the nerve for which function most commonly is lost. Fortunately, the deficits produced by isolated ninth nerve damage are relatively minor. Electrical stimulation of this nerve produces EMG responses at a latency of approximately 5 to 7 msec, which generally are of low amplitude, because recording electrodes are not placed directly in the stylopharyngeus. Similar responses often are seen with stimulation of the tenth nerve; however, it is easy to distinguish between the ninth and tenth nerves with multichannel recordings, because stimulation of the tenth nerve, but not the ninth nerve, also produces responses in the vocalis muscle (see later).

The vagus (tenth) nerve is one of the most complex cranial nerves, with myriad functions affecting the cardiac, respiratory, and gastrointestinal systems, as well as providing motor innervation to pharyngeal and laryngeal musculature. The vagus nerve commonly is monitored using an endotracheal tube with integral EMG electrodes (Medtronic-Xomed, Jacksonville, Florida), so that bipolar recordings can be obtained from both left and right vocalis muscles without additional electrodes (Fig. 178-12A).

Laryngeal surface electrodes (RLN Systems, Jefferson City, Missouri), which are inserted intraorally, posterior to the larynx, after intubation with a standard endotracheal tube also have been used (see Fig. 178-12B). They have a flat contact surface that records from the posterior cricoarytenoid muscle. The large contact surface may provide more stable recordings and greater reliability than are achievable with other methods.[90] Another laryngeal surface electrode is the bipolar electrode, which wraps around and adheres to a standard endotracheal tube and is positioned between the vocal cords as the tube is inserted (Neurovision Medical, Ventura, California). Finally, Leonetti and coworkers[91] have described a method for transcricothyroid membrane placement of bipolar hookwire electrodes in the vocalis muscle.

The latency of EMG responses to electrical stimulation of the tenth nerve varies with the site of stimulation. Intracranial stimulation in the posterior fossa or jugular foramen produces response latencies ranging from roughly 4 to 6 msec. Stimulation of the recurrent laryngeal nerve in the neck, as during thyroid surgery, produces a much faster response (2 to 3 msec latency). Another important consideration with stimulation of the vagus nerve is cardiac effects; bradycardia and even asystole have been documented with traction on the tenth nerve in both the posterior fossa and jugular foramen regions. (In such circumstances, however, the total heart rate in the OR generally remains constant, because that of the anesthesiologist rises in compensation!) Fortunately, this effect generally is not seen with threshold-level electrical stimulation; however, during surgery in this region, the anesthesiologist should be prepared to administer anticholinergic agents on short notice if necessary.

Monitoring of the eleventh nerve with electrodes in the trapezius muscle (Fig. 178-13) has already been briefly considered earlier, because activity of this muscle is the most readily observable marker for identifying the nerves of the jugular foramen in removal of large acoustic neuromas or other cerebellopontine angle tumors. During monitoring for tumors of the jugular foramen region itself, it also may be useful to place electrodes in the sternocleidomastoid muscle if extra channels are

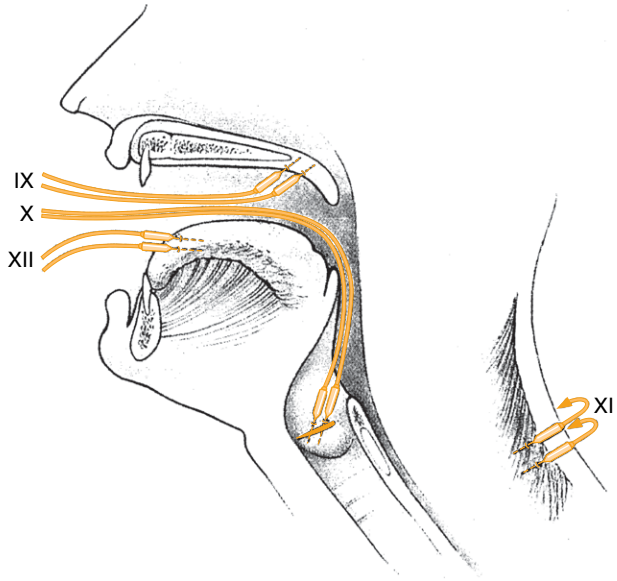

Figure 178-13. Sagittal view of placement of needle electrodes into the muscles used for lower cranial nerve monitoring. Needle electrode pairs are placed into the soft palate (ninth nerve), false vocal cord (tenth nerve), trapezius (eleventh nerve), and tongue (twelfth nerve). The electrodes placed in the false cord are unnecessary if one of the electrodes shown in Figure 178-12 is used instead. *(From Lanser M, Jackler R, Yingling C. Regional monitoring of the lower (ninth through twelfth) cranial nerves. In: Kartush J, Bouchard K, eds.* Neuromonitoring in Otology and Head and Neck Surgery. *New York: Raven Press; 1992.)*

available, especially if preoperative findings include preexisting eleventh nerve deficits and wasting of the trapezius. Because excessive movement from activation of trapezius muscles can be dangerous during surgery, stimulation of the eleventh nerve should be carried out at as low an intensity as feasible.

Finally, the twelfth cranial nerve provides motor innervation to the muscles of the tongue. Damage to this nerve produces the well-known sign of ipsilateral deviation seen on protrusion of the tongue, because of the predominance of the genioglossus muscle on the intact side, but in isolation does not usually produce major functional problems. However, damage to this nerve can lead to problems with chewing and swallowing, particularly in combination with deficits involving the eleventh and tenth nerves. This should be taken into account when facial reanimation with twelfth to seventh nerve anastomoses is under consideration in patients with lower cranial nerve deficits. The twelfth nerve can be monitored readily by insertion of electrodes into the lateral aspect of the anterior third of the ipsilateral tongue, with the electrodes sutured into place to prevent accidental dislodgement (see Figs. 178-11 and 178-13).

Cochlear Nerve (Eighth Nerve) Monitoring

The cochlear nerve is one of the most fragile of the cranial nerves and usually is much more intimately involved with acoustic tumors than the facial nerve. Thus, preservation of hearing generally is more difficult and less likely to be achieved than preservation of facial nerve function. However, recent advances in surgical and monitoring techniques have made preservation of hearing an attainable goal in removal of many smaller acoustic neuromas. Furthermore, the cochlear nerve is at risk in many other posterior fossa procedures, including resection of meningiomas and other nonacoustic tumors, vestibular neurectomies, and microvascular decompression of the fifth or seventh nerve. The most commonly used method for cochlear nerve monitoring has been intraoperative recording of the ABR.[2,11,38,55,93-110] ABR recording from the contralateral ear may be useful in cases with brainstem compression from large tumors, even if there is no hearing on the operated side.[92] More recently, direct eighth nerve action potentials,[11,38,45,49,77,111-114] electrocochleography (ECoG),[11,38,45,112,115-117] and recordings from the surface of the cochlear nucleus[118] also have been used. Finally, the use of evoked otoacoustic emissions, a more recently developed diagnostic technique, has been proposed as a potential method for monitoring cochlear nerve function.[119,120]

Auditory Brainstem Response Recording in the Operating Room

Since the ABR was first described in 1971,[121] ABR testing has become one of the most common neurophysiologic diagnostic modalities because of its ease of administration, relatively low cost, and ability to localize lesions in the peripheral auditory pathway.[122] The methods used in the OR are similar to those used clinically, with slight modifications.

Stimulus and Recording Parameters, Electrodes, and Placement

In clinical settings, stimuli for eliciting the ABR typically are delivered at rates of approximately 10 to 15 per second. For OR use, higher rates of 20 to 30 per second may be desirable to reduce averaging time. Stimulus intensity is maintained at a high level, usually at 95-dB peak sound pressure level (SPL) or higher, to obtain the best possible signal-to-noise ratio (SNR) (this is at least 60 dB above subjective click threshold levels). Although this is a high level for continuous stimulation, it does not seem to pose a problem; we are not aware of any reports of compromised hearing traceable to ABR recording over extended periods. Nevertheless, it is prudent to set the stimulus intensity at the lowest level that produces consistent waveforms.

It is necessary to use miniature earphones that do not compromise the surgical field. Møller[123] has successfully used small in-the-ear transducers designed for use with portable audio cassette players. Higher-quality transducers such as Etymotic Tubephones (Etymotic Research, Elk Grove Village, Illinois), which duplicate the frequency response of standard audiometric earphones, offer a more consistent, although expensive, alternative. For OR use, the main concern is obtaining clear definition of wave I, which often is the only useful ABR component in patients with acoustic neuroma. Any earphones that meet this criterion can be used with good success.

To minimize stimulus artifact, plastic tubing is used to conduct sound into the ear from a transducer placed a few inches away. The tube is terminated with a foam plug covered with a conductive gold foil (Tiptrode, Nicolet, Madison, Wisconsin), which also serves as one of the recording electrodes. In addition to providing acoustic isolation, this electrode provides improved definition of wave I over that obtainable with an earlobe or mastoid placement because of its closer proximity to the distal eighth nerve, the generator of wave I. The other electrode is placed at the vertex (Cz) or any point along the midsagittal plane between midforehead (Fpz) and vertex.

Because most of the power in the ABR is concentrated between 400 and 1400 Hz,[124] relatively narrow filter settings (i.e., 300 to 1500 Hz) produce more stable waveforms than wider settings (10 to 3000 Hz) typically used in the clinic, thereby facilitating rapid data collection. It also is desirable to collect a control ABR from the contralateral ear at the same time as that from the operated ear. This can be done by delivering stimuli alternately to each ear and separately averaging the left and right ear trials. Immediate comparison of the ABR from the operated side with that obtained from the contralateral ear provides a useful control for detection of nonspecific effects from factors such as anesthesia or temperature change. Of note, both ears must not be stimulated *simultaneously*, because the response from the contralateral ear could mask the loss of a response on the operative side.

Reducing Electrical and Acoustic Interference

It is imperative to take whatever steps are possible to minimize both electrical and acoustic artifacts. Electrical artifacts, which are of concern in both EMG and ABR monitoring, have already been covered. In addition, acoustic interference becomes a significant problem when either ABR or direct eighth nerve CNAPs are recorded. Drilling of the temporal bone to open the internal auditory canal can pose serious

obstacles to auditory nerve monitoring because of acoustic masking, which can degrade or even obliterate the ABR or CNAP.

Unfortunately, the cochlear nerve, as well as the inner ear itself, is at great risk during this period in typical retrosigmoid approaches. It may therefore be necessary to deliberately halt drilling periodically to obtain valid readings. Alternately, the neurophysiologist can manually start and stop the averaging process to collect data during intervals in the drilling—for example, when changing drill burrs.

Because time is a major concern, efforts have been made to develop monitoring techniques that greatly reduce data collection times. The two major approaches that have been advocated are (1) emphasizing near-field recording techniques obtained from an electrode placed directly on the cochlear nerve and (2) the use of digital in addition to analog filtering.[123-125]

Interpretation of Responses in Surgical Context

ABRs are relatively unaffected by the level of anesthesia or the type of anesthetic agents used, provided normal brain temperature is maintained. Above 32° C, ABR absolute and interpeak latencies increase as a function of decreasing temperature at a rate of approximately 0.17 to 0.2 msec/° C.[126,127] Even though core temperature is maintained at near-normal values, brainstem temperature may still decrease, especially in tissue bordering the exposed cerebellopontine angle, and especially if it is irrigated with saline that is cooler than body temperature. If core temperature is not maintained, recording ABRs from the contralateral ear can help determine whether any changes are systemic or localized.

Another factor that typically affects the ABR is the craniotomy itself. New pathways for current flow caused by the craniotomy, changes in the local environment of the cochlear nerve with removal of CSF, and exposure of the nerve to air or insertion of metallic retractors into the opening all create differences in the relationship between the sites of ABR generation in the eighth nerve and brainstem and the recording electrodes. These changes are of no clinical significance but can lead to shifts in ABR amplitude, latency, and waveform that may be as large as those associated with intraoperative events that significantly affect auditory pathways. Fortunately, most of these changes occur in the early stages of the procedure before the cochlear nerve is in serious jeopardy; it is, however, important to obtain a new intraoperative baseline after opening and placement of retractors, rather than relying on the pre-incision baseline.

In most acoustic neuroma surgeries, ABR recordings from the operated side progressively deteriorate over the course of surgery, Cerebellar retraction, trauma from dissection, acoustic trauma, decreased local temperature, and disruption of cochlear perfusion may all affect ABR peak I, III, and V amplitude and latency values.[93,106] Retraction of the cerebellum, particularly in the medial to lateral direction,[102] is thought to be one of the principal maneuvers responsible for significant ABR deterioration.[93,94] Every effort should be made to reverse such effects by adjustment of the cerebellar retractor, by temporarily halting dissection, or by attempting dissection from a different angle or direction.[100] Occasionally, wave I amplitude will be acutely enhanced, possibly because of mechanical trauma to auditory efferent (inhibitory) fibers, which travel with the vestibular nerve. This enhancement often is followed by a rapid decrease in amplitude, suggesting disruption of the blood supply to the cochlea. Figure 178-14 shows typical ABR results from three patients undergoing surgical removal of acoustic neuroma.

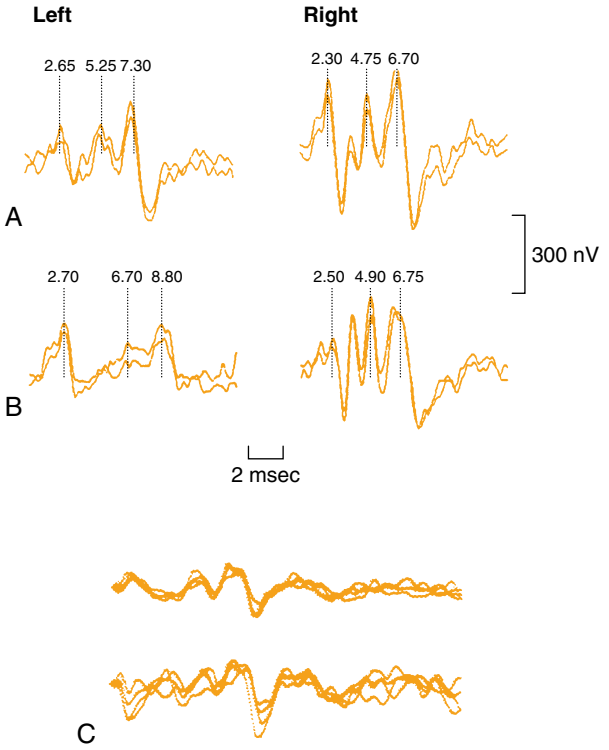

Figure 178-14. Representative examples of intraoperatively recorded auditory brainstem responses (ABRs) from three patients undergoing surgery for removal of acoustic neuroma. **A,** A 0.8-cm left-sided tumor in a 38-year-old woman with mild high-frequency hearing loss and speech discrimination scores of 92% for the left ear and 100% for the right ear. Pre-incision baseline shows well-defined ABRs on both sides. Note differences in interpeak latencies between left and right ears. **B,** A 1.8-cm tumor in a 52-year-old woman with moderate to moderate-severe sloping hearing loss and speech discrimination scores of 56% for the left ear and 90% for the right ear. Note that wave V is desynchronized and reduced in amplitude and that wave III is absent on the left side. Stimuli were alternating-polarity 100-msec clicks, presented at 80 dB above normal hearing level (nHL), 33.3/sec; 0.9-msec acoustic delay; averaged responses (N = 4000) were recorded from ipsilateral ear canal to vertex. Duplicate averages are overlaid. **C,** Intracanalicular right-sided tumor in a 48-year-old woman with nearly normal hearing, operated on by means of the middle fossa approach. *Top traces* are pre-incision baseline; *bottom traces* show preservation of auditory brainstem response after total removal of tumor, although a slight increase in latencies of waves IIII and V can be seen. Alternating-polarity 100-msec clicks, 80 dB above nHL, 21/sec; 0.9-msec acoustic delay; averaged responses (N = 1024) recorded from ipsilateral ear canal to midforehead. Four consecutive averages are overlaid. *(**A** and **B,** From Yingling CD, Gardi JG. Intraoperative monitoring of facial and cochlear nerves during acoustic neuroma surgery.* Otolaryngol Clin North Am. *1992;25:413; **C,** from Yingling CD. Intraoperative monitoring of cranial nerves in skull base surgery. In: Jackler RK, Brackmann DE, eds.* Neurotology. *St. Louis: Mosby; 1994:967.)*

Correlation of Intraoperative Auditory Brainstem Response with Postoperative Auditory Function

If ABR wave V is found to be intact after the tumor has been completely removed, preservation of useful hearing usually is achieved.[128] However, even with such favorable intraoperative findings, hearing may still be lost. Sometimes, hearing is present in the immediate postoperative period but disappears within 2 or 3 days. The mechanism of this delayed loss is unclear, but it may involve vasospasm of the cochlear artery.[129] If only wave I of the ABR is intact, preservation of useful hearing is much less likely. In several cases, we have recorded an intact wave I for more than an hour after the cochlear nerve was transected at the brainstem, an event that is unlikely to be compatible with hearing preservation! Furthermore, transient changes in wave I and the cochlear microphonic potential, even if the response returns over the course of surgery, may reflect pathogenic changes to the nerve with poor long-term prognosis.[38,112]

Most studies with intraoperative ABR recording agree that if waves I and V are preserved, the chances of hearing preservation are excellent,[109,130,131] although exceptions have been noted.[95,109] Conversely, if waves I and V are lost, there is little or no chance of hearing preservation,[42,109,128,131] although rare exceptions have been reported.[94,132] Therefore, the surgical decision to transect the cochlear nerve, even to facilitate tumor removal, should not be based solely on ABR findings.

Matthies and Samii[133] reported that loss of wave V, although the most definite sign of postoperative hearing loss, is the least helpful in hearing preservation, because its occurrence is a late indication of compromise of hearing. Relying on earlier warning criteria would seem to be more practical, such as a wave V latency increase by 0.5 msec[134] and observation of wave III for change. Wave III is the earliest and most sensitive sign of cochlear nerve affection; change or loss of wave III is an early sign that usually is followed by wave V loss. Wave III changes therefore warrant special attention to permit prompt warning to the surgeon.

Direct Eighth Nerve Action Potentials

Placement of Electrodes

To provide more rapid feedback on the functional status of the cochlear nerve, the rate of data acquisition can be enormously speeded up by recording near-field auditory CNAPs with an electrode placed directly on the cochlear nerve near the brainstem root entry zone.[11,45,111,135,136] With this configuration, clear averages can be obtained with 64 to 128 trials or less, compared with the 1000 or more usually required to record a reproducible ABR. The averaging time is thereby reduced from nearly 1 minute to approximately 5 seconds, permitting virtually on-line feedback to the surgeon, provided that the averaging computer can be programmed to automatically collect sequential averages and display the results so that changes can be readily identified. We have described this technique in detail elsewhere.[2]

Stimulus and Recording Parameters

The same stimuli used to elicit the ABR (brief clicks of fixed or alternating polarity) also are suitable for CNAP recording. Because the direct signal from the nerve is of higher amplitude than that of the ABR, however, the amplifier gain should be 5 to 10 times lower than for ABR recording; filter settings can remain the same. Usually 64 to 128 trials per average will produce an adequate waveform; at a stimulus rate of 20 per second, a new average can thus be obtained in approximately 5 seconds. An automated protocol for collecting sequential averages becomes important in this context to reduce the time to begin a new average after the previous one finishes.

Detection and Interpretation of Changes

It is important to determine the inherent amplitude and latency variability of the CNAP before operative manipulations that may potentially affect the cochlear nerve are undertaken, because this variability forms the background against which meaningful changes must be assessed. With an accurate and stable placement of the recording electrode on the nerve, the response can be quite repeatable from one average to the next. However, if the electrode position changes slightly, the variance may increase substantially. Unfortunately, some of the manipulations that may jeopardize the cochlear nerve (e.g., movement of a retractor) also are among the most likely to move the electrode. Figure 178-15 shows an example of a typical reversible change in CNAP amplitude.

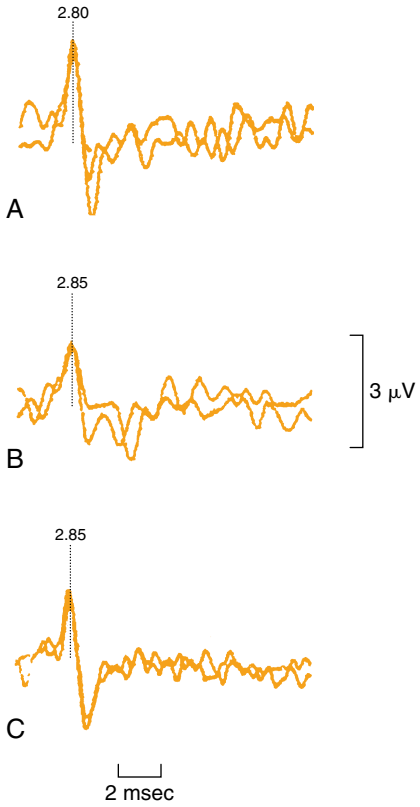

Figure 178-15. Representative changes in cochlear nerve compound action potentials during removal of a 0.6-cm intracanalicular acoustic neuroma. **A,** Just before mobilization of tissue adherent to cochlear nerve. **B,** Mobilization of tumor caused a sharp reduction (approximately 50%) in compound nerve action potential amplitude. **C,** Partial recovery of response after release of traction on nerve. Stimuli as described for Figure 178-14; 100 trials/average, duplicate averages are overlaid. (***A*** *to* ***C,*** *From Yingling CD, Gardi JG. Relation of Monitoring to Outcome

Facial and Other Motor Cranial Nerve Preservation

Several studies have evaluated postoperative facial nerve function in series of cases with and without facial nerve monitoring.[31,32,36,37,43,51,137-139] As a result of these studies, it can now be generally accepted that although monitoring results in a small increase in the proportion of subjects with good outcomes (grade I or II), the main effect of monitoring has been to greatly decrease the incidence of poor outcomes (grade V or VI). This finding undoubtedly reflects the relative ease of locating and preserving the facial nerve in smaller tumors, coupled with a greater impact of monitoring with resection of larger tumors, when the nerve is more likely to be stretched and distorted and thus more difficult to identify by anatomic criteria alone.

The National Institutes of Health (NIH) consensus conference on vestibular schwannoma[140] concluded: "The benefits of routine intraoperative monitoring of the facial nerve have been clearly established. This technique should be included in surgical therapy for vestibular schwannoma." Facial nerve monitoring for vestibular schwannoma surgery is therefore now clearly established as the standard of care. Although less formal data are available concerning monitoring of other cranial motor nerves, the techniques and applications are virtually identical and should achieve similar benefits. The same NIH consensus panel concluded: "Routine monitoring of other cranial nerves should be considered." Accordingly, it is unequivocally recommended that EMG monitoring with as many simultaneously recorded channels as necessary be used during any skull base surgery in which cranial motor nerves are at risk.

Cochlear Nerve Preservation

No such unequivocal consensus has emerged concerning the usefulness of cochlear nerve monitoring. In studies in which tumor size was restricted to less than 2.0 cm, useful to adequate hearing preservation was maintained in approximately 30% to 45% of patients, as determined by preoperative and postoperative pure tone audiometry and speech discrimination testing.[42,109,131,141-144] At present, conservation of hearing is more a function of diagnostic (gadolinium-enhanced magnetic resonance imaging [MRI] detection of smaller tumors) and surgical (increased use of middle fossa approach) factors than of intraoperative monitoring. It is hoped that improved methods for rapid detection of intraoperative changes in cochlear and cochlear nerve function will help eighth nerve monitoring to contribute more substantially to improving clinical outcome.

Attempts to compare CNAP and ABR monitoring techniques during vestibular schwannoma surgery have revealed that although both

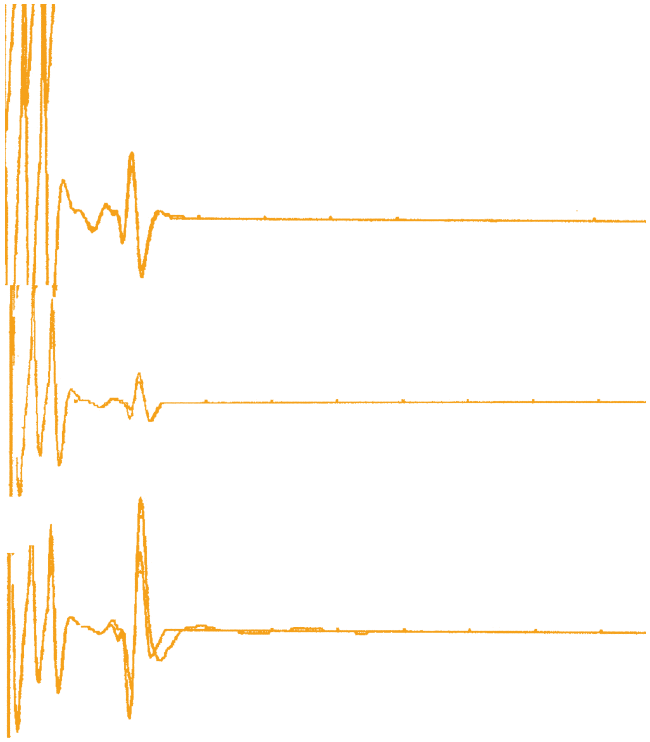

Figure 178-16. *Top*, Blink reflex recorded intraoperatively. *Middle*, Ipsilateral (R1) response recorded from orbicularis oculi after three-pulse train stimulus to supraorbital nerve. *Bottom*, Habituation of reflex response after repeated train stimulation. Restoration of reflex amplitude (dishabituation) after train stimulation of contralateral supraorbital nerve. *(From Yingling CD, Ashram YA. Intraoperative monitoring of cranial nerves in skull base surgery. In: Jackler R, Brackmann DE, eds.* Neurotology. *2nd ed. Philadelphia: Elsevier; 2005:958.)*

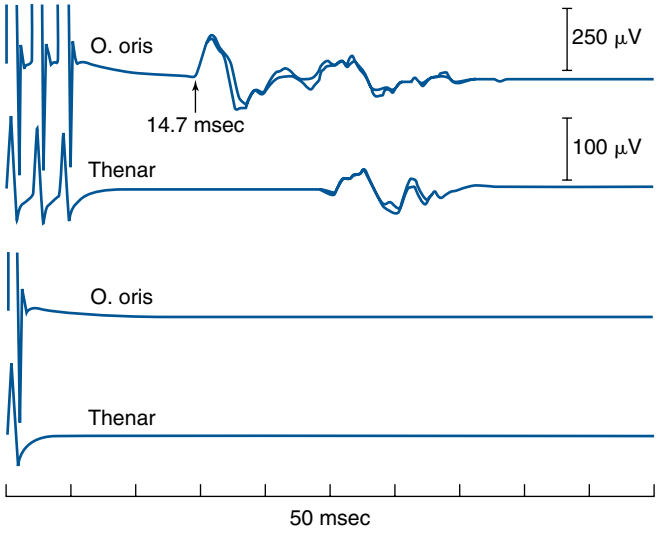

Figure 178-17. Intraoperative recordings of transcranial motor evoked potentials (tcMEPs). An example of facial MEP recorded from the left orbicularis oris (O. oris) muscle. The facial MEP response *(top trace)* is 300 mV in amplitude, generated by transcranial electrical stimulation of 3 pulses, 2-msec interstimulus interval, and 150 V. During stimulation, the anode was at M4 and the cathode at Mz. A simultaneous thenar muscle response also is shown *(second trace)*. Note the absence of same-intensity single-pulse responses *(third and fourth traces)* and the facial MEP onset latency of 14.7 msec, which indicate a central origin. Whether the apparent dispersion of the facial MEP relative to the expected duration of standard facial compound muscle action potentials (CMAPs) reflects preoperative facial nerve damage or normal temporal dispersion of facial motor neuron depolarization with pulse trains cannot be clearly determined without comparable normative data. *(From Dong CCJ, Macdonald DB, Akagami R, et al. Intraoperative facial motor evoked potential monitoring with transcranial electrical stimulation during skull base surgery.* Clin Neurophysiol. *2005;116:588.)*

ABR and CNAP are useful for predicting postoperative hearing, CNAP is more frequently obtainable, and CNAP monitoring is associated with a higher chance of hearing preservation.[145] Furthermore, CNAP monitoring is possible in patients with unrecordable ABR waveforms and may minimize cochlear nerve trauma.[146]

Colletti and associates[134] compared the value of ABR, ECoG, and directly recorded CNAPs in detecting damage to auditory structures during acoustic neuroma surgery. These investigators found that CNAPs had the highest predictive score for postoperative hearing. In particular, when a permanent loss of CNAPs occurred, sensitivity and specificity were 100%. These workers noted that ECoG activity was recorded in patients with lost CNAPs. This discrepancy was attributed to disconnection of the ear from the central auditory pathways associated with cochlear nerve damage,, with persistence of peripheral auditory function without propagation of the neural input. ABR monitoring was highly sensitive in detecting auditory damage, but its prognostic usefulness was marred by its poor specificity.

Future Directions and Conclusions

It is clear that facial nerve monitoring has had a marked impact on preservation of function in acoustic neuroma surgery. Although published data for other cranial motor nerves are more limited, the benefits are likely to be similar, because the principles are identical. The impact of monitoring on hearing preservation is less clear-cut, although the results thus far are improving and promising.

Equally clear is that much room for improvement remains. It is hopeful that the next decade will see improved techniques in a variety of areas, including better methods for automatic identification and rejection of artifacts; procedures for quantification of ongoing EMG activity; development of more sensitive non–EMG-based methods; and, perhaps most important, development of a technique for continuous assessment facial nerve integrity without direct electrical stimulation, analogous to continuous ABR recordings for assessing cochlear nerve function. This would be especially important with larger tumors, in which the nerve may be inaccessible for stimulation until extensive dissection has been done.

A possibility is to use the well-studied blink reflex,[83] which is elicited by stimulation of the supraorbital nerve (trigeminal afferents) and consists of an early ipsilateral EMG response (R1) and a later bilateral response (R2), both mediated by the facial nerve; it is the R1 response that can be recorded intraoperatively. Despite the usefulness of the blink reflex in clinical testing, it has not yet been reliably elicited in surgery because of the suppression of reflex activity by general anesthetics. It may become possible to overcome this problem by greater reliance on intravenous anesthetics, such as propofol, together with repetitive train stimulation (Fig. 178-16).

Another potentially valuable development is adapting the transcranial motor evoked potential (tcMEP) technique, now commonly used in spinal surgery, to facial nerve monitoring.[147-149] This technique entails placing a pair of stimulating needle electrodes on the scalp over the face motor area with the anode placed contralateral to the side of surgery.[150] The cortex is stimulated by multipulse constant-voltage stimulation, and EMG responses are recorded from appropriate facial muscles. The technique has some limitations, including the potential for excessive patient movement, which may not be appropriate for delicate intracranial surgery, generation of large stimulus artifact, and the possibility of extracranial current spread with peripheral facial nerve excitation; however, these limitations can be reduced by use of suitable electrode configuration and stimulation parameters.[148] Figure 178-17 shows intraoperative MEP recording from the orbicularis oris channel after multipulse transcranial electrical stimulation.

Finally, much is still to be learned about the relationship between intraoperative recordings and long-term clinical outcome. More con-

trolled studies, with carefully characterized patient populations and standardized monitoring techniques with quantification of response parameters, are needed to address many of the issues discussed previously. The only certainty is that improvements in monitoring techniques and routine inclusion of professional monitoring personnel in the surgical team, coupled with advances in early diagnosis and microsurgical techniques, will continue to improve the prognosis for preservation of cranial nerve function in patients undergoing skull base surgery.

CHAPTER ONE HUNDRED AND SEVENTY-NINE

Stereotactic Radiation Treatment of Benign Tumors of the Cranial Base

D. Bradley Welling

Mark D. Packer

Key Points

- Stereotactic radiation therapy demonstrates good short-term control for many benign cranial base tumors.
- Short-term quality of life outcomes favor stereotactic radiation therapy over conventional surgical management.
- Radiation-induced cranial nerve injury has been reduced as lower doses of radiation have come into use.
- Long-term control and radiation-induced malignancy risk will be known in the next decade with further study.

Stereotactic radiation therapy is an option for the treatment of most benign cranial base tumors including vestibular schwannomas. The literature to date, however, consists of retrospective studies, with their inherent biases. The same also is true of the alternative treatments, including surgical and observational protocols. Long-term prospective outcome studies with blinded independent observations are needed as a strong supplement on which to base clinical treatment.

Since the late 1990s, stereotactic radiation therapy has become an increasingly popular treatment for benign tumors of the cranial base, including vestibular schwannomas. After its introduction for clinical use in 1967 by Lars Leksell, the initial acceptance of this modality waned as early complications included brainstem radiation damage, hydrocephalus, and cranial neuropathies.[1] However, as delivery has become more precise through improved stereotactic guidance, and as the tolerance levels of cranial nerves for radiation have become better elucidated, the technique has gained popularity and now offers an alternative to surgical intervention or observation for many cranial base tumors. Additionally, the combined use of radiation and surgical treatment may be considered for tumors for which incomplete excision may be planned to reduce the danger to adjacent cranial nerves. The goal of stereotactic irradiation for the treatment of benign tumors generally is considered to be growth arrest.

This chapter summarizes the principal advantages, disadvantages, and areas needing further research related to this technique. When possible, standardized definitions of tumor control and hearing preservation are specified, but this is not possible for all studies reviewed.

Principles of Stereotactic Radiation Therapy

In general, *stereotactic radiation therapy* denotes the application of any kind of ionizing radiation in a precise dosing mechanism to a target while limiting radiation exposure and damage to the adjacent surrounding tissues. Several delivery techniques for stereotactic irradiation have been developed.

With gamma knife radiotherapy techniques, well-collimated beams of radiation from 201 cobalt-60 sources are directed through ports in a semispherical helmet, allowing the beams to converge and deliver a much higher dose to the target than to the surrounding structures. The precise delivery of the beam is increased by direct fixation of a head frame attached with surgical pins to the cranium (Fig. 179-1). Although the procedure commonly is referred to as stereotactic "radiosurgery," this is a misnomer, because the therapy is accomplished by the delivery of external radiation without a surgical incision. Today most teams are composed of neurosurgeons or neuro-otologic surgeons, a radiation oncologist, and a radiation biologist. The advantage of gamma knife techniques at present is the capability for highly controlled delivery of radiation by way of multiple isopoints to the tumor target. Additionally, newer units have more fully automated coordinate adjustments, allowing more rapid dosing. A disadvantage is that tumors located much below the level of the cranial base are not readily accessible for stereotactic radiation delivery by the gamma knife. Rigid fixation of the skull to a metal frame that locks into the radiation chamber allows precise, submillimeter stereotactic radiation delivery, but the gamma knife does not lend itself to multiple fractionated treatments.[2]

An alternative to the gamma knife was developed through the application of linear accelerators (LINACs). Instead of multiple sources aimed at a central designated target, the LINACs rotate the treatment beam of the unit around the target in a variable number of rotational arcs.[3] Although the tumor margin doses are similar to those achieved with the gamma knife, LINAC delivery typically uses fewer isocenters, and the dose to the tumor may be less precisely applied. Thermoplastic molded mask systems to limit positional variation in the radiation delivery allow for the potential of fractionated schedules without the placement of pins into the skull but may not restrict movement of the target as surely as rigid fixation. Controversy exists regarding the potential benefit of fractionated stereotactic radiation protocols. Some inves-

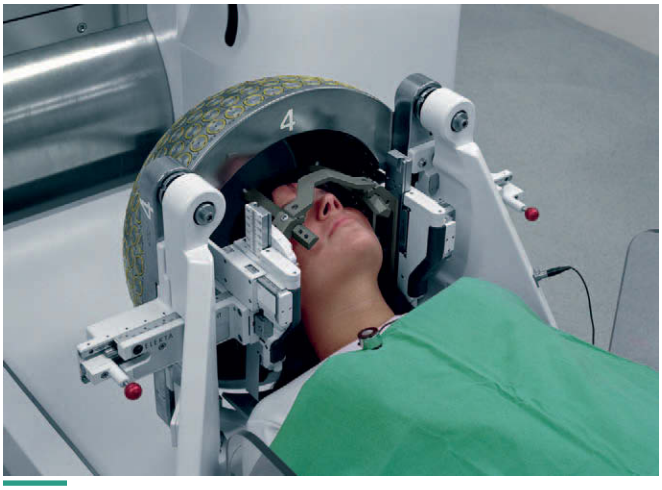

Figure 179-1. The gamma knife helmet. *(Courtesy of Elekta, Inc.)*

tigators maintain that a fractionated regimen, given over days or weeks, takes advantage of radiobiologic principles to reduce late toxicity while maintaining tumor control. However, in the case of vestibular schwannomas, both the tumor and the surrounding cranial nerves are late-reacting tissues; therefore, fractionating theoretically reduces the post-irradiation complications to the surrounding cranial nerves but also reduces the likelihood of desired tumor damage, DNA disruption, and apoptotic cell death.

Radiobiology

The therapeutic role of ionizing x-rays and gamma rays lies in their ability to alter and compromise DNA and other important biologic molecules of the cells targeted. Specifically, ionizing radiation excites electrons, which cause free radical damage of the involved cell structures. DNA damage prevents entering into the cell cycle and can lead to programmed cell death (apoptosis). Radiation damage to the phospholipids of the cell membrane also may lead to cell death. Ionizing radiation comes in two general varieties—electromagnetic, which consists of photons or packets of energy, and particulate radiation. X-rays and gamma rays are forms of electromagnetic radiation resulting when a photon indirectly transfers its energy to a target tissue. In an x-ray, a collision between an electron and the target tissue occurs, whereas gamma rays are produced when the contents of the nucleus of an atom return to their initial energy state from an excited level, a process known as gamma decay. As the electromagnetic waves pass through the tissues, they are absorbed, producing electron recoil and tissue damage as they lose their strength.

Protons are heavy charged particles that cause damage directly. They are positively charged and of a much higher mass than electrons. When a proton beam strikes its target, it delivers almost all of its energy at its delivery range, which results in a rapid dropoff of energy level, thereby limiting tissue damage past the target of interest. This characteristic is exploited to deliver a high dose of radiation directly to the target tissues with sparing of tissues deep to the delivery area. Dose inhomogeneity may increase the risks of complications for large target volumes treated with stereotactic radiation when the target area is less than a perfect match for the radiation delivery field. Complications were fewer with conformal multiple-isocenter gamma knife treatment plans than with less elaborate two-isocenter LINAC stereotactic radiation plans, which were associated with a higher risk of complications, with possible high-dose overlap regions extending into normal tissues.[4] The newer, more precise delivery systems are less likely to expose tissues out of the target regions to high doses of radiation.

Imaging

Typically, a lesion is diagnosed and confirmed by magnetic resonance imaging (MRI). On the day of the planned radiation treatment, a second MRI study is performed to precisely plan the radiation delivery after the patient's head has been fixed in the head frame. Post-irradiation MRI scans are obtained at 6 months and then yearly thereafter to observe the effect of the stereotactic radiation. Because of the long-term potential for delayed growth of the tumors and also because of the potential for malignant change, at present we recommend that yearly follow-up MRI scans be obtained.

Dose Selection

Dose selection in stereotactic radiotherapy has been evolving over the past decade as experience has been gained. Early animal studies by Kondziolka and associates[4a] demonstrated that xenograft vestibular schwannomas in the renal capsule of athymic mice showed significant reductions in tumor volume following stereotactic radiation with 40 Gy at 2 weeks and after 1 month in a 20-Gy group. Tumor vascularity was reduced in the 20- and 40-Gy groups respectively, but not in the 10-Gy group at 3-month follow-up evaluation. In humans today, however, in order to decrease facial nerve neuropathies, 17 Gy or less is delivered to the 50% isodose line (Fig. 179-2). Also, the auditory portion of the eighth cranial nerve appears to have a tolerance for approximately 11 Gy, with an 50% hearing preservation rate.[4b] Simply put, the lower the dose, the lower the complication rate—but the lower the likelihood of tumor control over the long-term follow-up period of observation.

Benign Tumors of the Cranial Base: Vestibular Schwannoma

Vestibular schwannomas have increasingly been treated with stereotactic radiation. Some centers favor this therapy over conventional surgical techniques or observation. In reporting the outcomes with gamma knife, LINAC, and fractionated stereotactic irradiation, "tumor control" has been defined in two ways. Some investigators define tumor control as no growth, whereas others report the percentage of tumors that required no further treatment. The latter definition may overestimate the true control rate, because cases in which tumors may have been growing but not requiring surgical intervention would be counted as those with successful outcomes. The most useful information that can be gleaned from the literature at this time is a compilation of reported outcomes. The lack of well-controlled studies has been duly noted. The longer the follow-up, the more valuable the study. Outcomes data extracted from the recent literature, including reports on tumor control, facial nerve function, hearing preservation, and trigeminal neuralgia, are summarized in Tables 179-1 to 179-3.

Fractionation versus Nonfractionation

Considerable debate is ongoing regarding whether or not fractionated stereotactic radiation is more favorable than single-dose stereotactic radiation for cranial nerve functional preservation in vestibular schwannoma treatment. Although fractionated radiation may give less immediate damage to the surrounding cranial nerves, damage to the slowly growing schwannoma cells also is less likely, thereby increasing the likelihood of growth. Flickinger[4c] argues that the available data in the literature are simply inadequate to allow definitive conclusions regarding which of the two delivery plans is better for cranial nerve preservation and tumor control; carefully planned, prospective controlled longitudinal studies are needed to address this concern. Indeed, the data shown in Tables 179-1 to 179-3 seem to confirm his opinion.

Traditionally, in our own practice, stereotactic radiation has been reserved for a select patient subset for the treatment of vestibular schwannoma. Elderly patients with small to medium-sized tumors with proven growth or those not fit for a surgical resection have been recommended to receive stereotactic radiation treatment. Chen, reporting data for three 5-year periods between 1990 and 2005, noted that vestibular schwannomas were being diagnosed at statistically higher ages, at smaller sizes, and in a greater proportion of patients older than 65 years of age.[5] During these periods, the frequency of observation as a treatment choice for vestibular schwannoma rose from 12% to 37%, microsurgery was performed in 59% of patients, and frequency of use of stereotactic radiation therapy rose to 4% of cases. As life expectancy

is increasing, it seems likely that vestibular schwannomas under expectant management will be more likely to show growth when observed over longer periods of time, as demonstrated by Charabi and associates.[6] Smouha and colleagues, in a retrospective meta-analysis of patients managed without intervention, demonstrated that 43% of 1244 vestibular schwannomas showed growth over a mean follow-up period of 3.2 years.[7] Hearing loss occurred in 51% of 347 patients. Only 20% of 1001 patients from 15 studies eventually failed observation, showing growth sufficient to warrant active treatment. Smouha's data are similar to our own prospective findings, which demonstrated that 66% of tumors grew more than 15% when measured volumetrically after a mean follow-up period of 3.8 years.[8]

Outcome Assessment

Advocates of the use of stereotactic irradiation as a primary treatment for vestibular schwannomas without first documenting growth must bear in mind that over the short term, many tumors do not demonstrate growth. This calls into question whether or not post-irradiation stability of a nongrowing tumor should be considered to represent treatment success. In fairness, many patients in whom tumors are removed surgically are not followed to determine growth before treatment either. However, a fundamental difference remains between outcome assessments of the different treatment modalities. The key anatomic measure of outcome in surgery—absence of tumor or a residual of a small portion of the original tumor—typically

differs from the growth of persistent tumor after stereotactic irradiation.

Information on outcomes pertaining to the therapeutic use of stereotactic radiation treatment is expanding. Moreover, although debate continues regarding the optimal treatment of vestibular schwannomas, a growing consensus is that focal radiation therapy, delivered in single- or fractionated-dose regimens, has an important role in the treatment of selected skull base tumors.

Because stereotactic radiation treatment of vestibular schwannomas is still evolving, results are not easily comparable on a study-to-study basis, nor are they easily grouped to add power to institutional reporting by meta-analysis. Dosing parameters have changed over time and differ among patients, among doctors, and among institutions within studies.[9-11] This variability in retrospective studies is problematic, making optimal dosing parameters difficult to discern. Dose planning is enhanced with improved imaging shot selection, and blocking strategies that safeguard neural structures. Automation in delivery systems and better understanding of the biologic effect of radiation also should result in improved outcomes.[10,11]

Because the goal of stereotactic irradiation differs from that of microsurgery and with observation, outcomes are difficult to compare. In most cases, microsurgery results in complete tumor removal. Imaging

assessment gives an immediate quantifiable result. Imaging assessment of stereotactic radiation outcomes is subject to the inherent variability of the tumor response to treatment, the quality and resolution of the imaging, the examiner's judgment, the accuracy of post-imaging software, and interobserver comparison of imaging at different time points. The definition of success is not standardized at present but appears to be moving toward a crterion of progression-free survival. Since the objective of stereotactic radiation is tumor control rather than eradication of disease, criteria for success should be objectively compared to the natural progression of these slow-growing benign tumors.

After irradiation, tumors show signs of treatment effect by loss of central enhancement within the first 6 to 12 months.[12,13] Approximately one fourth (23%) will show *expansion*, or transient tumor swelling (on average 2 to 4 mm but as much as 10 mm) generally 6 to 24 months after treatment, but swelling can be seen up to 5 years after treatment. This temporary expansion may take 6 months to 5 years to resolve.[2] Fifty percent of these tumors will undergo a loss of central contrast enhancement that may correlate histopathologically with tumor necrosis.[14] Eventually, residual tumors show return of enhancement and possibly further shrinkage. Few show peritumoral edema. More recent studies recognize these signs of radiation effect, and continued observation often validates eventual stability or regression.[2] This understanding alone has prevented surgery for what was thought to be tumor progression in earlier studies and is manifested in improved control rates in newer data. Tumors that were excised, possibly for mistaken post-irradiation progression, have shown histopathologic evidence of radiation-induced vascular changes, including intimal thickening, perivascular inflammation, and focal hemorrhage.[14] Profuse interstitial fibrin deposits also were seen. Schwannomas surgically removed after stereotactic radiation failure also have shown typical and viable schwannoma cells with increased vascularity, as well as other foci showing delayed radiation changes such as nucleolar and cytoplasmic enlargement, proliferation of endothelial cells, and necrosis.[15-17]

In 2006, Weil and colleagues published a thorough review of the English language literature regarding single-fraction stereotactic radiation.[10] Similarly, Backous and Pham and Likhterov and associates reviewed the current literature and summarized the stereotactic irradiation data, including outcomes of fractionated stereotactic radiation protocols, through 2005.[2,3] Tables 179-2 and 179-3 present outcomes data from these reviews, along with those from the most recent studies on stereotactic irradiation.[10,12,14,15,18-39] Studies with fewer than 15 patients or less than 12 months of follow-up were excluded.

Tumor Control

Current data show that after irradiation, 1% to 2% of vestibular schwannomas resolve completely; however, tumor control is achieved in 74% to 100% over varied durations of follow-up. The definition of tumor control has not been consistent. Control in some series is considered no radiographic enlargement over some set parameter (e.g., 2 mm in tumor diameter or 10% change in tumor volume). Failure in others is considered progression requiring microsurgical resection. Some centers do not consider repeat stereotactic irradiation or neurosurgical relief of radiation-induced or tumor-related hydrocephalus by ventriculoperitoneal shunting to represent treatment failure, whereas other centers do. Outcomes in patients in earlier series may have been counted as failures before recognition of the phenomenon of transient tumor expansion, thereby falsely lowering control rates in those studies. A more recent trend in reporting tumor control is to provide actuarial data. Few studies have data to report beyond a median follow-up period of 48 months. To make up for this shortcoming, probable data are generated from the few leading patients in each study to provide Kaplan-Meier survival curves with confidence intervals predicting progression-free statistics. Considering the foregoing caveats, for the studies reviewed, the weighted summary of the 5-year-progression-free tumor control was 95% for single-dose stereotactic irradiation and 94% for fractionated regimens.

Hearing Outcomes

Hearing outcomes have steadily improved since the early 1980s as a result of decreasing marginal doses, improved conformality and shielding of important structures, or better patient selection, or a combination of these factors. Dose tolerances of the cochlea, cochlear nerve, and cochlear nucleus are still under investigation.[2,22,33] In a prospective follow-up study of 34 patients, Thomas and colleagues found the cochlear dose to be the only variable that was statistically predictive of hearing preservation.[33] These investigators showed that if the percentage volume of the cochlea exposed to 90% of the total treatment dose was less than 73.3%, the median hearing loss was 10 dB, compared with 25 dB for the cochleas exposed more than 73.3%. Paek and coworkers found that treatment doses to the cochlear nucleus below 10 Gy were the only statistically significant prognostic indicator for hearing preservation in their study of primary gamma knife therapy in a select group of 25 patients with pretreatment Gardner-Robertson hearing of grade I or II.[22] Chopra and colleagues have shown that hearing outcomes improve when the marginal dose to the tumor is reduced to 13 Gy or less. Increased age, tumor swelling, radiation exposure to greater lengths of the cochlear nerve, and increased dose to the cochlear nucleus also have been associated with poorer hearing outcomes.[40] Massager and colleagues analyzed the radiation doses delivered to the cochlea during gamma knife stereotactic irradiation and concluded that the cochlea received significantly higher radiation doses in patients with worsening of hearing after treatment. The cochlear dose was significantly associated with the intracanalicular dose of radiation delivered.[41,42]

Table 179-4

Gardner-Robertson Scale*

Hearing Grade		Pure Tone Average (dB)	Speech Discrimination (%)
Grade I	(good to excellent)	0-30	70-100
Grade II	(serviceable)	31-50	50-71
Grade III	(nonserviceable)	51-90	5-49
Grade IV	(poor)	91-max	1-4

*If pure tone average and speech do not correlate, the lower grade is assigned.

Hearing status and hearing outcomes are not universally evaluated and have not been examined in a standardized fashion if included, causing difficulty in comparing data.[10,31] Because fewer patients have serviceable hearing than the already low number of patients in some series, the power of reporting hearing outcomes in these studies is compromised. The timing of audiometric follow-up testing is not always clear and does not necessarily match the duration of tumor control surveillance. Few studies offer serial data on the hearing data they collect. Thomas and colleagues reported the only prospective series of outcomes encountered.[33] Not all studies rely on objective audiometric data for reporting, and some include the use of telephone or survey information with the hearing outcomes. When audiometric data are used, the definition of serviceable hearing has varied, using either hearing levels or speech discrimination, or a combination. The Gardner-Robertson classification of hearing is most commonly used today as a scale to gauge useful hearing (Table 179-4). Class I or II hearing, or speech reception thresholds better than 50 dB and speech discrimination better than 50%, is considered to be serviceable hearing for a majority of studies (see Table 179-4). That being said, preservation of any sound perception is important and useful for lip reading and voice modulation when the contralateral hearing is compromised, as in cases of neurofibromatosis type 2 (NF2).

After stereotactic irradiation, hearing loss becomes evident over the ensuing 6 to 24 months. Hearing levels decline by 15 to 20 dB on average after treatment. Hearing continues to decline with the duration of follow-up.[2,20] A profile of progressive loss is similar to that in natural history trends derived from tumor observation data but presumably is

related to radiation effect. Tumor size may impede attempts at hearing preservation. Prasad and associates showed that useful hearing was retained in 75% of patients with tumors smaller than 1 cm^3, whereas 57% of those with tumors larger than 1 cm^3 demonstrated a hearing level of Gardner-Robertson class I or II.[43]

Hempel and coworkers documented an average drop of 18 dB with treatment.[20] These workers reported standardized follow-up data for 123 patients for a mean of 8.2 years after stereotactic gamma knife irradiation of median 1.6-cm^3 vestibular schwannomas treated with a mean marginal dose of 13 Gy. Pre- and post-treatment audiometric data were available for analysis in 63 patients. Post-treatment audiograms were obtained 1 to 24 months after treatment; in 46 of the patients (73%), audiometry was not performed until more than 5 months after treatment. Hearing declined an average of 18 dB, moving the group from a 42% pretreatment slight to moderate hearing difficulty level, on average, to 60% post-treatment moderate to high-grade hearing loss. No audiometric hearing loss occurred in 17 of 63 patients (29%), and subjectively, 53 patients (47.3%) reported that their hearing had not changed with treatment.

Thomas and colleagues, using fractionated stereotactic irradiation, conducted a prospective follow-up study in a select group of 34 patients with small tumors and good hearing and reported standardized hearing results at a median of 36.5 months.[33] Patients received doses of 50 Gy in 25 fractions to the 90% isodose line, treating median tumor volumes of 1.06 cm^3. As assessed using the Gardner-Robertson grading scale (see Table 179-4), 28 patients had grade I hearing levels before treatment, 5 had grade II hearing, and 1 had grade III hearing but was included in this select group because he felt subjectively that his hearing was serviceable. Speech reception thresholds were 20 dB on average before treatment and 40 dB after. Twenty patients (59%) retained serviceable hearing and 12 (35%) retained their pre–irradiation course Gardner-Robertson grade. Actuarial hearing preservation rates at 2, 3, and 5 years were 63%, 63%, and 56%, respectively.

Overall, reported hearing preservation rates range from 33% to 100% with gamma knife irradiation, from 47% to 96% with LINAC-based irradiation, and from 46% to 100% with fractionated protocols. The weighted average of pooled gamma knife data for more than 100 patients over more than 36 months showed a hearing preservation rate of 68%. No studies with single-dose LINAC-based protocols with more than 100 patients reported hearing outcomes; however, fractionated protocols showed a weighted hearing preservation rate of 69%.

Facial Nerve Outcomes

Stereotactic irradiation continues to offer excellent results in regard to function of the facial nerve. Improved outcomes were achieved by reducing the marginal tumor dose to less than 16 Gy, which decreased the rate of facial neuropathies to 15%. At 13 Gy or less, persistently improved facial nerve outcomes are achieved. Today, facial nerve injury is rare and usually transient. Improved outcomes are further enhanced by better conformality of treatment planning and limiting the irradiation field to the minimum length of nerve necessary for adequate tumor treatment. Tumor volume is debatable as a predictive factor for cranial neuropathy.[31,44] Reported rates of facial nerve injury in the low-dose era of treatment (12 to 14 Gy) range from 0% to 10.3% after gamma knife irradiation with up to 5.2% permanent injury, 0% to 11.8% with up to 8% permanent with LINAC-based radiotherapy, and 0% to 6% with up to 6% permanent for fractionated protocols. Facial synkinesis and spasm are sometimes discussed separately; according to the available evidence, they occur at similar rates.

Trigeminal Nerve Outcomes

Trigeminal nerve toxicity is seen in a low number of patients treated by stereotactic irradiation. Reported symptoms range in severity from trigeminal neuralgia to mild hypesthesia. The incidence ranges from 0% to 16% after gamma knife irradiation but more consistently falls between 2% and 5%. Single-dose LINAC protocols produce injury in 0.7% to 18% but more commonly in 7.5% to 10.8%. Fractionated protocols show trigeminal nerve injury in up to 14%, and routinely in up to 5% (see Tables 179-1 to 179-3).

Neurofibromatosis 2–Related Vestibular Schwannoma

In patients with the burden of multiple intracranial and spinal tumors, an effective method of treatment less invasive than surgical removal would be of great value. Concern arises, however, over irradiating benign tumors in young patients who have an inherited predisposition to tumor formation from loss of the NF2 tumor suppressor gene. In a retrospective study by Vachhani and Friedmann[45] of stereotactic radiation treatment of 14 NF2-related schwannomas, with a mean follow-up period of 38 months, no growth was noted in the radiation-treated tumors in 92% at 2 years and in 92% at 5 years. In the untreated tumors, 78% showed no growth at 2 years and 21% at 5 years.[45] Mathieu and colleagues reported the University of Pittsburgh experience, which included stereotactic radiation treatment of 74 schwannomas in 62 patients with NF2. These workers found tumor volume to be a significant predictor of local control. Actuarial control rates were 85%, 81%, and 81% at 5, 10, and 15 years, respectively. The actuarial serviceable hearing preservation rate for the 35% of patients presenting with serviceable hearing was 73% at 1 year, 59% at 2 years, and 48% at 5 years after gamma knife radiation treatment.[18]

Cystic Schwannomas

Debate is ongoing regarding the effectiveness of stereotactic radiation control of cystic vestibular schwannoma. Pendl and colleagues initially advised caution in recommending stereotactic irradiation to patients with cystic vestibular schwannoma.[46] These recommendations were based on a series of treatment failures that manifested as progressive neurologic symptoms after treatment with a mean dose of 13.8 Gy to the tumor margins. Surgical intervention was required in five of the six patients. Shirato and colleagues also claim that patients with cystic vestibular schwannomas are at significant risk for experiencing subacute expansion of the cyst after fractionated-dose stereotactic irradiation and reported that 45% showed growth in the 3-year actuarial follow-up period.[47]

In an effort to characterize the phenomenon of tumor expansion, Hasegawa and colleagues reported that of 254 vestibular schwannomas treated with high-dose irradiation between 1991 and 1998, 42 tumors (17%) continued to grow.[12] Of the 42 expanding tumors, 14 were characterized by central necrosis, 16 were solid tumors, and 12 demonstrated cystic formation or expansion. Of the 14 patients whose tumors demonstrated central necrosis, 3 required further salvage treatment. Of the 16 patients with solid tumors, 7 required additional treatment (including treatment for the malignant transformation of one tumor). All of the 12 patients in whom cysts developed or expanded eventually required craniotomy. The investigators concluded that patients shown to have cyst enlargement with neurologic deterioration after irradiation or those with new cyst formation will require surgery.

Delsanti and Régis showed only a 6.4% treatment failure rate for stereotactic irradiation of these tumors.[48] It is possible that these discrepancies are due to the low proportions of vestibular schwannoma that are cystic, or to the selection bias inherent in retrospective analysis. It is likely that truly cystic vestibular schwannomas do not respond as well as solid vestibular schwannoma to treatment by stereotactic irradiation. Further prospective studies of this variety of vestibular schwannoma are necessary before firm recommendations can be made.

Hydrocephalus

Hydrocephalus occurs in a low percentage of patients after stereotactic irradiation. Theoretically, this problem could be due to post-irradiation tumor or tissue swelling, or to new cyst formation with consequent obstructive hydrocephalus, radiation-induced fibrosis, or hemorrhage resulting in cerebrospinal fluid malabsorption and communicating hydrocephalus. Treatment by ventriculoperitoneal shunting resolves this problem in most situations, but salvage microsurgery for failed tumor control or to remove new cyst formation sometimes is necessary. Hydrocephalus occurs in 0.8% to 8% of cases with gamma knife treatment, 0% to 7.5% of LINAC single-dose protocols, and 0% to 12% of fractionated protocols, although more commonly 0% to 4%. See Tables 179-1 to 179-3.

Treatment of Stereotactic Radiation Failures

Fortunately, in most patients treated by stereotactic irradiation for vestibular schwannoma, tumor control is achieved, and follow-up with careful observation constitutes adequate management. Surveillance protocols vary, but follow-up imaging should be carried out indefinitely, or until longer-term follow-up studies in adequate numbers of patients treated at current dosing levels show this to be unnecessary. Stereotactic irradiation failure is defined as progression of tumor volume or diameter beyond the expected post-treatment expansion, progressive neurologic symptoms from active growth, or threatened brainstem compression. Although most failures manifest within 3 years of treatment, reports of failures beyond 5 years also are seen.[11,32,35,42]

Tumor volume has been shown to be a predictor of treatment failure. Hasegawa and colleagues showed actuarial 10-year progression-free control rates of 57% for tumors larger than 15 cm^3 and 95% for those smaller than 15 cm^3.[11] These workers also reported two occurrences of failures more than 5 years after stereotactic irradiation. One case involved new cyst formation, presumably secondary to intratumoral hemorrhage at 69 months, and the other involved malignant transformation of a vestibular schwannoma at 51 months. Chan and colleagues saw a similar statistical difference in progression-free survival. The 5-year actuarial rates of freedom from any neurosurgical intervention was 97% for patients with tumor volume less than 8 cm^3 and 47% for patients with tumor volume of at least 8 cm^3.[31]

The outcomes with microsurgical treatment of radiosurgical failures are unclear. Friedman and associates compared data for resection of 38 tumors after radiosurgical failure with those for resection of 38 matched primary tumors.[15] The mean follow-up period was 3.3 years. These workers noted moderate to severe adherence to the facial nerve in 89% of radiation failures, compared with 63% of primary resections. House-Brackmann grade I or II facial nerve outcomes were obtained in 37% of irradiated cases, compared with 70% of primary treatment cases. Limb and colleagues found similar difficulty for resection of radiosurgical failures compared with matched controls.[49] They also described increased operative time and uncertainty about the completeness of tumor removal. Shuto and colleagues reported data for 12 patients operated on after failed stereotactic irradiation.[50] Four also had had a previous microsurgical dissection. These investigators described difficult identification and dissection of the facial nerve and resorted to subtotal resections in order to preserve its integrity. They also found difficulty dissecting the tumor from the brainstem owing to adhesions. Hearing was sacrificed in all cases. Bleeding was scant, possibly as a result of the irradiation. Shuto's group recommend subtotal excision in revision cases and showed that growth of the residual tumor was rare.

The ultimate failure of stereotactic irradiation would be the transformation of a benign process into a malignant disease. The risk at present appears to be on the order of 0.01% to 0.3% for non–NF2-associated vestibular schwannomas.[35,51] Malignant change of a schwannoma has been reported up to 18 years after radiation treatment. Such extensive follow-up has been achieved in only a few patients.[30,52] Malignant transformation usually is a fatal event and may take more than 30 years to develop, as indicated by data on the treatment of other benign disease processes and from occupational exposure to radiation sources. The peak occurrence takes place approximately 15 years after low-dose radiation exposure, but the relative risk remains elevated well past 40 years.

The current literature does not have adequate numbers of procedures to be predictive of long-term risk. Actuarial data, although often quoted, are of no value in predicting malignant changes. Evans and colleagues as well as Ron and colleagues note an 18.8-fold increased relative risk of schwannoma induction and a 9.5-fold increased relative rate of meningioma induction after radiation doses of 2.5 Gy for the treatment of tinea capitis, adenotonsillar disease, and capillary hemangiomas.[53,54] The radiobiologic effect was dose-dependent, similar to the tissue effect and tumor growth response observed in post–World War II Japan.[55] Preston and colleagues showed that vestibular schwannomas were the most abundant intracranial tumors encountered, with a high propensity for Schwann cell mutation in response to radiation damage.[55] Overall, the risk of radiation-induced tumors appears to be approximately 0.1% to 3% after 30 years.[51,53] In light of the 33% to 40% lifetime risk of malignancy in the general population, Evans and colleagues feel that the benefits of single-dose radiation treatment for vestibular schwannoma is justified for patients with documented tumor growth who refuse surgery, or for the elderly or infirm. However, patients with NF2 in particular are the disproportionate recipients of radiation-induced malignant tumors. In a series of 829 subjects with vestibular schwannomas, 62 (7%) had NF2; yet in a review of the documented cases of malignant changes induced by stereotactic irradiation of vestibular schwannomas, 50% occurred in NF2 patients. Evans and colleagues strongly caution against the use of radiation treatment for benign tumors in childhood and in tumor-prone conditions such as neurofibromatosis.[53] We concur.

Quality of Life

In treatment of a benign disease with a natural history of general slow progression, the patient's satisfaction with the treatment outcomes is highly relevant. Quality of life measurements are useful tools for obtaining such information. Pollock and colleagues have reported the only prospective quality of life assessment to date.[56] They matched 36 microsurgical (suboccipital 69%, middle cranial fossa 6%, or translabyrinthine 25%) patients with 46 patients that underwent stereotactic irradiation. The surgical therapy group was composed of statistically older patients and showed a trend to larger tumor size when compared with the radiation therapy group. Outcomes were measured by a health status questionnaire, dizziness handicap inventory (DHI), and a tinnitus and headache survey. The questionnaires were evaluated at 3 months, 1 year, and the last follow-up. The mean follow-up period was 48 months. Responses showed statistically significant decline in the health status questionnaire parameters for the microsurgical group that resolved with follow-up. The parameters of bodily pain and mental health remained significantly different from the stereotactic irradiation group, although scores for both groups were elevated from baseline. The stereotactic irradiation group had lower DHI scores than those for the microsurgery group at last follow-up evaluation.

Myrseth and coworkers retrospectively looked at 168 patients, using the SF-36 questionnaire and the Glascow Benefit Inventory (GBI) as a measure of subjective quality of life.[57] Patients in the microsurgical therapy group (retrosigmoid 38%, translabyrinthine 62%) were significantly younger (mean age of 48.2 years, vs. 53.9 years). A larger group was lost to follow-up because of death in the stereotactic therapy group (16 vs. 8). Data were obtained by subject response for 83.3% of the patients over a 1-year follow-up period. The investigators concluded that the SF-36 did not bring out the differences between the two cohorts as well as the GBI, which showed that at 1 year, the score for the "general" category was significantly lower in the microsurgery group, although the two cohorts did not differ significantly on the "physical" and "social" scales.

Sandooram and associates also used the GBI as a quality of life measure.[58] This retrospective study, based on an 80% response from 165 subjects, included 102 patients managed with microsurgery and 10 with stereotactic irradiation. No significant age or tumor size difference was found between patients choosing microsurgery (49% retrosigmoid, 51% translabyrinthine) or stereotactic irradiation. The patients in the microsurgery group were followed for a median period of 4.8 years, whereas those in the stereotactic irradiation group were followed for a median 1.8 years. Patients in both groups showed decline in their GBI scores, although the decrease in the stereotactic irradiation group did not reach significance. A minimum follow-up period of 3 years should be sought for quality of life studies.[9] Longer follow-up is recommended for the following clinical reasons: (1) the natural progression of vestibular schwannoma shows nonlinear growth; (2) the progression of vestibular schwannoma growth in observed patients in our series was 66% at 3.8 years; and (3) the long-term failure rate for stereotactic radiation therapy is yet unknown. These considerations reinforce the need to standardize surveillance protocols and reporting definitions and measures so that future recommendations can be based on actual evidence.

No truly prospective randomized study with sufficient power or duration of follow-up that would give sufficient power has been conducted to compare the results of stereotactic irradiation. Meta-analysis

Table 179-5

Stereotactic Irradiation Protocols and Outcomes for Treatment of Glomus Jugulare Tumors

Study with Radiation Source	No. of Tumors	Local Control Rate	Hearing Preservation	Cranial Neuropathy		Dose*
				Facial Nerve	Cranial Nerves IX, X, XI	
Sharma et al, 2008[61] Gamma knife	15 primary, 9 secondary; 10 patients with follow-up	100% at 24 mo in 10 patients	NR	NR	15/24 (62%)	16.4 Gy
Lim et al, 2004[62] Cyberknife plus LINAC	16	100% at 41 mo	1 transient loss	NR	1/16 (6%)	14-27 Gy
Eustacchio et al, 1999[63] Gamma knife	10 primary, 9 recurrent	95% at 46 mo	NA	NA	NA	13.5 Gy in a 91-year-old patient who died 9 months later
Liscak et al, 1999[64] Gamma knife	30 primary, 24 recurrent	100% at 24 mo	11/14	NA	5%	16.5 Gy
Pollock, 2004[60] Gamma knife	19 primary, 23 recurrent	98% at 44 mo	81% at 4 yr	11% 43%	3%	14.9 Gy

*Mean marginal dose of 16.4 Gy.
LINAC, linear accelerator (stereotactic irradiation); NR, not reported; NA, not available.

of retrospective data can be helpful, but a meta-analysis by Weil and colleagues in 2006 concluded that current studies are subject to a number of confounding factors, are not sufficiently statistically powered, and present limited long-term actuarial outcome data.[10] These investigators did not provide sufficient confidence to support the claim that low-dose stereotactic radiation is as effective as higher doses. Hearing results also are shown to decline over time. This also is true in patients with untreated tumors under observation. Weil's group noted that the small size of patient cohorts and the small proportion of patients at 5 years provide for large confidence intervals with considerable uncertainty. Furthermore, a recent study with longer follow-up suggests worse actuarial tumor control in patients treated with a marginal dose less than 12 Gy, compared with doses of 12 Gy or higher.[14]

Despite these difficulties in comparing reports, the short-term efficacy of stereotactic irradiation for treatment of vestibular schwannoma is impressive. Stereotactic irradiation is a valuable option for treatment of sporadic vestibular schwannomas in elderly patients. It may be useful in limiting the morbidity of microsurgery or stereotactic irradiation alone when used as an adjunct to subtotal resection of tumors with large volumes. Caution is still warranted in considering its application for tumors with undocumented growth, or in younger or tumor-prone patients.

Jugular Foramen Schwannomas

Martin and associates reported results of stereotactic irradiation in 34 patients with 35 jugular foramen schwannomas treated with gamma knife protocols between 1990 and 2005.[59] Twenty-two patients had undergone previous surgical resection, and 13 patients, in whom the diagnosis was based on imaging studies, underwent primary stereotactic irradiation. One or more cranial nerve deficits were present before stereotactic irradiation in all 34 patients. The marginal dose ranged from 12 to 18 Gy, and the dose to the maximum range was 21 to 36 Gy. Follow-up periods ranged from 1.5 to 14 years, with a mean or median of 7 years. These workers reported that 33 of 35 lesions decreased in volume or were stable at 5 years. When the lower motor cranial nerves (glossopharyngeal, vagus, spinal accessory, and hypoglossal) were considered as a group, a total of 105 ipsilateral nerves were affected at the time of stereotactic irradiation; 35 were intact, with no associated symptoms. Improvement of the affected cranial nerves was noted in 22 (20%), whereas 81 (77%) remained stable and only 2 were worse. All 35 unaffected cranial nerves remained unaffected.

Paraganglioma

Paraganglioma treatment reports in the literature have fewer numbers and shorter follow-up than those for vestibular schwannomas, but reported control rates are similarly encouraging (see Table 179-5).[60-64] A summary of five representative studies in the recent literature follows. In a report by Pollock, 42 patients underwent gamma knife surgery as the primary management (19 patients) or for recurrent glomus jugulare tumors (23 patients).[60] Facial weakness and deafness were more common in patients with recurrent tumors than in those in whom primary gamma knife stereotactic irradiation was performed (48% compared with 11%). The mean tumor volume was 13.2 cm^3; the mean tumor margin dose was 14.9 Gy. The mean follow-up period for the 39 patients in whom evaluation was possible was 44 months (range, 6 to 149 months). After gamma knife surgery, 12 tumors (31%) decreased in size, 26 (67%) were unchanged, and one (2%) grew. The patient whose tumor grew underwent another course of stereotactic irradiation. Progression-free survival after gamma knife surgery was 100% at 3 and 7 years and 75% at 10 years. Six patients (15%) experienced new deficits (hearing loss alone in three, facial numbness and hearing loss in one, vocal cord paralysis and hearing loss in one, and temporary imbalance or vertigo in one). In 26 patients in whom hearing could be tested before stereotactic radiation therapy, hearing preservation was achieved in 86% and 81% at 1 and 4 years after treatment, respectively. No patient suffered a new lower cranial nerve deficit after one stereotactic radiotherapy session.

Other studies evaluating stereotactic irradiation for paragangliomas similar to Pollock's are summarized in Table 179-5. The difficulty in preserving the lower cranial nerves with the excision of glomus jugulare tumors makes stereotactic irradiation an attractive alternative if the long-term results are as good as the reported short-term results, and if the cranial nerve preservation rates with these irradiation protocols are better than the surgical salvage rates.

Conclusions

Stereotactic radiation therapy is a useful addition to the armamentarium for the treatment of benign cranial base tumors. Good short-term and mid-term outcomes with quick recovery times have been shown in largely retrospective studies. The literature to date, on both the surgical and radiation treatments for these lesions, is marked by the biases inherent in the retrospective study design, and the evidence presented is at best level 4—not strong enough on which to base dogmatic opinions regarding critical clinical decisions. Therefore, the patient's personal preference often is the deciding factor, after a thorough discussion of the advantages and disadvantages of all the possible treatment options. Long-term prospective outcome studies with blinded independent observations are necessary to obtain high-quality of data to advance clinical care in this area.

CHAPTER ONE HUNDRED AND EIGHTY

General Considerations in Pediatric Otolaryngology

J. Scott McMurray

Key Points

- Children are physiologically different from adults. Familiarity with these differences is required for safe management of their medical and surgical problems.
- Providing optimal pediatric care requires attention to the child as patient and the adult guardians.
- Involving the child in play may alleviate anxiety regarding procedures in the physical examination.
- With practice, physical examination can be conducted in expedient fashion and will be relatively painless for the child, yet complete for the surgeon.
- Management of the pediatric otolaryngology patient often requires a multidisciplinary team approach.

For many practitioners, there is no greater reward than helping children afflicted with illness. Pediatric otolaryngology has developed as a subspecialty within otolaryngology as a bridge between the surgical discipline and pediatric medicine. Nearly every otolaryngologist will treat children during his or her professional career. An estimated 25% to 50% of a general otolaryngologist's practice may be related to pediatric problems. Pediatric otolaryngology has therefore become an important part of all training programs in this field.

As the saying goes, children are not simply little adults. Often unique approaches are required for their evaluation, diagnosis, and management. Although the child is of prime concern, the parents—as the child's guardians, who must make decisions regarding the ultimate treatment options—also must be kept informed and must be approached with compassion. This is obvious to nearly all persons who have had to make medical decisions for a loved one but may not be as obvious to those who have not. The love for and emotional bond with a child may make even the most calm and rational person unable to comprehend events and medical explanations. It is up to the surgeon to monitor and modify his or her approach and explanations to both the child and the parent. This is not always an easy task but one that is highly rewarding.

Smaller and more premature neonates are surviving and sicker children are recovering from significant illnesses as neonatal and pediatric intensive care units, as well as the skills of the physicians who care for them, continue to advance. This development has led to a demand for practitioners well versed in the management of disorders encountered in this population—namely, intubation trauma, bronchoesophageal processes, infectious disease, tumors, and congenital malformations. A multidisciplinary approach often is required. Agreement among the pediatric specialists and with the general pediatrician is important, raising a third layer of communication that is required for successful treatment of the child and family.

Physiologic differences among infants, children, and adults have occupied major research efforts and constitute the subject of complete textbooks. This chapter outlines basic differences relevant to the practice of otolaryngology, along with some related considerations. In the following discussion, the material presented for each of the major body systems is intended as a general introduction, to be used as a starting point for further investigation.

Respiratory System

Control of Ventilation

Emergence from an underwater world, in which the child relied on placental exchange of gases and nutrition, induces tremendous changes in the neonate's physiology and anatomy. Some of these changes occur rapidly at birth; others proceed more slowly. These significant changes can complicate interpretation of the neonate's problems. In particular, the assessment of the control of ventilation in the neonate may be difficult. Interventions used to obtain measurements, such as placement of a facemask or insertion of a laryngotracheal tube, may induce significant changes in ventilation. Measurements of ventilation to assess respiratory drive also depend on the assumption that the respiratory muscles are capable of converting this drive into work—which is not always the case in infants and neonates.

Muscle fibers have been found to fall into two categories. *Type I* fibers are slow twitch, highly oxidative, and fatigue resistant. *Type II* fibers are fast twitch and are easily fatigable. Newborns have a paucity of type I muscle fibers but develop them shortly after birth. The muscle fibers in the diaphragm of a preterm infant are composed of less than 10% of type I fibers. The muscle fibers of a full-term infant may be 30% type I fibers. The percentage of type I fibers increases to 55%, the expected adult level, during the first year of life. Preterm infants are more prone to respiratory fatigue; this predilection disappears as they reach maturity.

Other subtle differences in sleep patterns also affect control of ventilation. Preterm infants spend as much as 50% to 60% of their sleep state in the rapid eye movement (REM) state. During REM sleep,

the intercostal muscles are inhibited, as are most of the other skeletal muscles. This places a greater burden on the diaphragmatic activity. Much of this activity may be wasted, because the chest wall can move paradoxically in the very young. This purposeless movement readily leads to hypoventilation, increased respiratory drive, and diaphragmatic fatigue.

Biochemical and reflex controls of ventilation are similar but incompletely developed in full-term neonates when compared with adults. Neonates have a higher basal metabolic rate than that in adults. This is reflected in higher ventilatory rates relative to body mass at any given partial pressure of carbon dioxide. Increases in ventilation are proportionately similar, however, in infants and adults with an increased partial pressure of carbon dioxide. This concordance in response is not seen in preterm infants. Their response to increases in partial pressure of carbon dioxide is blunted when compared with that in full-term infants and adults. Differences also are seen in the response to partial pressure of oxygen between premature infants and full-term infants and adults. The administration of 100% oxygen decreases ventilation in the very young, suggesting the existence of chemoreceptor activity not generally seen in adults.

Gestational age, postnatal age, body temperature, and sleep state modify the ventilatory response of newborns to hypoxia. Preterm and full-term infants less than a week old who are awake and euthermic usually demonstrate biphasic breathing patterns. They often experience tachypnea followed by hypoventilation. Hypothermic infants demonstrate a blunted response to hypoxia with respiratory depression, but they do not have the initial hyperpnea. The central effects of hypoxia on the respiratory center may cause depression of ventilation. Active peripheral chemoreceptors are unable to maintain a significant influence over this response. REM sleep also may decrease the response to hypoxia in these infants. Sleep states other than REM are associated with an increase in the ventilatory response to hypoxia. Arousal from sleep during hypoxia is not seen in newborns but develops during the first few weeks of life. In these slightly older infants, further maturation of the chemoreceptors increases their ventilatory drive to hypoxia. Of interest, a decreased response to hypercarbia associated with hypoxia also occurs in newborns but not in older infants and adults.

Reflexes arising from the lung and chest wall probably are more important in maintaining ventilation in newborns and in determining the respiratory tidal volume. Periodic breathing is common in preterm and full-term infants. These periods of alternating rapid ventilation followed by apnea may be common and can be considered normal. Periodic breathing is thought to result from dyscoordination of the feedback loops controlling ventilation. During the apneic part of periodic breathing, partial pressure of carbon dioxide may increase, but changes in heart rate do not. Generally, no serious physiologic consequences are seen. This response often ceases by the age of 6 years. Some preterm infants, however, may demonstrate serious and potentially life-threatening episodes of apnea. These episodes may last longer than 20 seconds and are accompanied by bradycardia. Apneic episodes may represent a failed response to hypoxia. Because these episodes are more commonly seen during REM sleep, ventilatory fatigue, as well as impaired chemoreceptor response to hypoxia, may be the cause. Usually, stimulation is all that is required to terminate the apneic event. Aminophylline treatment generally decreases the apneic episodes through central stimulation. Continuous positive airway pressure (CPAP) also may be helpful to decrease apneic episodes by modifying the lung and chest wall reflexes.

Laryngospasm

The primary function of the larynx is to protect the lungs from aspiration. Hence, the laryngeal adductor response is a very strong reflex. The robustness of the reflex has been shown to change with age and maturity in animal models. It is strong enough to be lethal in some instances. When laryngeal adduction is coupled with tachycardia, hypertension, and apnea, it is termed the *laryngeal chemoreflex* (LCR). The LCR can be induced by laryngeal exposure to acid, base, and pressure, but it is most sensitive to water and is ablated by saline. This may have implications for sudden infant death syndrome (SIDS). Evolving responses with age to hypoxia, hypercarbia, and the laryngeal stimulation that causes the LCR may explain the age pattern seen with SIDS. Deaths attributed to SIDS have dramatically decreased as a result of a change in the recommended sleep position of children—from prone to supine. Elimination of hypercarbia from rebreathing may be the mechanism behind the decrease in SIDS deaths. Hypercarbia is a known potentiator of the LCR. An increased awareness of and more aggressive stance toward the treatment of infant reflux also may have decreased a potential stimulus for the LCR. Decreased bolus size, increased feeding frequency, frequent burping, and positioning to discourage regurgitation have been helpful to decrease the incidence of reflux in infants and perhaps the incidence of apneic spells and infant breathing issues.

Lung Volumes

In proportion to body size, the total lung capacity, functional residual capacity, and tidal volume are roughly equivalent in adults and in infants. In the full-term infant the total lung volume is approximately 160 mL, with functional residual capacity at one half of this volume. Tidal volume is approximately 16 mL and dead space is approximately 5 mL. In comparison with adults, however, any increase in dead space is much more significant in infants, related to their small lung volumes. In contrast with static lung volumes, however, alveolar ventilation is proportionately much greater in newborns (100 to 150 mL/kg of body weight) than in adults (60 mL/kg of body weight). This higher alveolar ventilation in infants results in a higher alveolar–functional residual capacity ratio, 5:1, compared with 1.5:1 in adults. Consequently, the functional residual capacity is much less of a buffer in infants, so that changes in the concentration of inspired gases are much more rapidly reflected in alveolar and arterial levels. This explains why induction of anesthesia using inhalational techniques is easier in infants than in adults. Along with the higher metabolic rate for body weight seen in infants, this differnce also explains why the ventilatory reserve in infants is not as great as in adults. The time from apnea to oxygen desaturation is much shorter in infants than in adults. Accordingly, surgical maneuvers that require short apneic periods may pose more of a challenge in infants than in adults.

The total surface area of the air-tissue interface of the alveoli in infants is small (2.8 m^2). When this relatively small gas exchange area is combined with the higher relative metabolic rate, infants have a reduced reserve capacity for gas exchange. This difference is of increased importance when congenital defects interfere with lung growth and development or if the lung parenchyma becomes damaged. The remaining healthy lung may not be adequate to sustain life.

Respiratory Rate

The most efficient respiratory rate for newborns has been calculated to be around 37 breaths per minute. This rate is close to that observed for average newborns. Full-term infants are similar to adults in requiring approximately 1% of their metabolic energy to maintain ventilation. The cost of breathing is then 0.5 mL/0.5 L of ventilation. In preterm infants, this nearly doubles to 0.9 mL/0.5 L of ventilation. The cost of respiration also dramatically increases if the lung parenchyma is diseased or damaged by processes other than prematurity. In either case, the result is higher caloric and nutritional demands. Respiratory rate can directly affect the infant's ability to complete the suck-swallow-breathe cycle as well. If gas exchange is poor, ventilation rates may increase. This increase in respiratory rate may not allow adequate time for the suck-swallow portion of feeding. Caloric intake decreases precipitously as the infant chooses breathing over feeding. This vicious circle can eventuate in failure to thrive.

Ventilation-Perfusion Relationships

Ventilation and perfusion are imperfectly matched in the neonatal lungs. Some persistent anatomic shunts in the newborn circulatory system, as well as a relatively high closing volume in the lungs, cause this mismatch. The normal arterial oxygen tension in a newborn breathing room air is 50 mm Hg. This increases dramatically during the first 24 hours of life with changes in fetal circulation and maturation of lung parenchyma. It continues to change slowly during the ensuing months and years (Table 180-1).

Table 180-1

Arterial Oxygen Tension (Pao_2) in Healthy Infants and Children

Age	Pao_2 in Room Air (mm Hg)
0-1 week	70
1-10 months	85
4-8 years	90
12-16 years	96

Table 180-2

Normal Heart Rate for Children by Age

	Heart Rate (beats/minute)	
Age	Average	Range
Newborn	120	100-170
1-11 months	120	80-160
2 years	120	80-160
4 years	100	80-120
6 years	100	75-115
10 years	90	70-110

Cardiovascular System

Newborn Heart and Cardiac Output

The heart of a healthy neonate is much different from that of an adult. The thickness of the right ventricle exceeds that of the left, as seen by the normal right axis deviation on the neonatal electrocardiogram. Shortly after birth and with closure of the fetal circulation, the left ventricle enlarges disproportionately. By the age of 6 months, the adult right-left ventricular size ratio is established.

The newborn myocardium is significantly different from the adult myocardium as well. The newborn myocardium contains fewer contractile fibers and more connective tissue. Consequently, neonatal ventricles are less compliant at rest and generate less tension during contraction. The usual Starling curves of contractility for adult cardiovascular physiology do not hold true for the neonatal heart. Cardiac output is rate-dependent in the neonatal heart. Bradycardia invariably equates with reduced cardiac output. Because of the differences in compliance and contractility in the neonatal heart, the increased contractility necessary to maintain cardiac output during bradycardia is not possible. The low compliance of the relaxed ventricle limits the size of the stroke volume; therefore, increases in preload are not as important in neonatal physiology as is heart rate. This distinction is extremely important to recognize during surgical and anesthetic procedures, which may induce bradycardia. Autonomic innervation also is incomplete in the neonatal heart, with a relative lack of sympathetic elements. This relative underdevelopment may further compromise the ability of the less contractile neonatal myocardium to respond to stress.

Heart rate is crucially important in the very young. The normal range for the newborn is 100 to 170 beats per minute. The rhythm is regular. As the child grows, the heart rate decreases (Table 180-2). Sinus arrhythmia is common in children, but all other irregular rhythms should be considered abnormal. The average newborn systolic blood pressure is 60 mm Hg; the diastolic pressure is 35 mm Hg.

Blood Volume

Intravascular blood volumes vary tremendously during the immediate postnatal period, related to the amount of blood transferred from the placenta to the child. "Stripping" the cord after birth or delays in clamping the umbilical cord may increase the blood volume by more than 20%, resulting in transient fluid overload and respiratory distress. Conversely, fetal hypoxia during labor causes vasoconstriction and a shift of blood to the placenta. Thus, fetal hypoxia may lead to hypovolemia after birth.

Because the total blood volume of an infant is small, significant blood loss can accompany relatively minor surgical blood loss. It has been observed during exchange transfusions that withdrawal of blood parallels a decline in systolic blood pressure and cardiac output. This decline is reversible to normal parameters with replacement of the same blood volume that was removed. Changes in arterial blood pressure with normal heart rates are thus proportional to the degree of hypovolemia. A newborn's ability to adapt the intravascular volume to the available blood volume is limited because of less efficient control of capacitance vessels and to immature or ineffective baroreceptors.

In the infant, systolic arterial blood pressure is closely related to circulating blood volume. Blood pressure is then an excellent guide to the adequacy of blood or fluid replacement during anesthesia, a fact that has been confirmed by extensive clinical experience.

Response to Hypoxia

Because of the relatively high metabolic rate typical of neonates and the relatively low reserve for gas exchange as described earlier in this chapter, hypoxemia can develop rapidly in neonates, in whom the first sign is bradycardia. During surgery, any unexplained episode of bradycardia should be initially treated with oxygen and increased ventilation. During hypoxemia, pulmonary vasoconstriction and hypertension occur more dramatically in the neonate than in the adult. Such changes can shift the infant back into fetal circulation, compounding the problem. Changes in cardiac output and systemic vascular resistance also differ from those in older children and adults. During hypoxemia in adults, the principal response is systemic vasodilation that, together with an increase in cardiac output, helps to maintain oxygen transport to the tissues. Fetuses and some neonates respond to hypoxemia with systemic vasoconstriction. In the fetus, hypoxemia shifts blood to the placenta to improve gas exchange and oxygenation. After birth, however, hypoxemia may lead to decreased cardiac output, thereby further limiting oxygen delivery and increasing cardiac work. In infants, early and pronounced bradycardia may result from myocardial hypoxia and acidosis.

Neonates exposed to hypoxemia suffer pulmonary and systemic vasoconstriction, decreased cardiac output, and bradycardia. Rapid recognition and intervention are necessary to prevent cardiopulmonary collapse, cardiac arrest, and death.

Blood Volume and Oxygen Transport

Neonatal blood volume is approximately 80 mL/kg at term and 20% higher in preterm infants. The hematocrit is 60% and the hemoglobin content is 18 g/100 mL. The values vary by infant, depending on when the umbilical cord is clamped. Little change in these values occurs during the first week of life, after which the hemoglobin level declines. The hemoglobin level change occurs more rapidly in preterm infants.

Approximately 70% to 90% of the hemoglobin in a full-term infant is the fetal type. Fetal hemoglobin has a higher affinity for oxygen than that of adult hemoglobin. It combines with oxygen more readily but also releases oxygen less efficiently at the tissue level than does adult hemoglobin. The increase in hemoglobin content in neonates is required to overcome this higher affinity of fetal hemoglobin for oxygen. A concentration less than 12 g/100 mL constitutes anemia. Correction of anemia by blood transfusion is indicated if the infant requires oxygen or is experiencing apnea.

Table 180-3

Ideal Electrolyte Composition for Infants

	Na^+ (mEq/L)	K^+ (mEq/L)
Intracellular	10	150
Extracellular	140	4.5

Table 180-4

Expected Fluid Losses in Children

System	Fluid Loss (mL/100 cal/day)
Sensible Losses	
Kidneys	55
Insensible Losses	
Lung	15
Skin	30
Total	100

Table 180-5

Children's Maintenance Fluid Intake Calculated by Weight

Weight (kg)	Estimated Fluid Intake (mL/hour)
0-10	4 mL/kg/hour
11-20	40 mL/hour (2 mL/kg/hour)
>20	60 mL/hour (1 mL/kg/hour)

During the first weeks of life, the hematocrit drops as a result of early suppression of erythropoiesis. The fetal type of hemoglobin is replaced with the adult type of hemoglobin with more optimal oxygen-carrying capacity. This physiologic anemia reaches its nadir at 2 to 3 months with a hemoglobin content of 9 to 11 g/100 mL. Provided that nutrition is adequate, the hemoglobin level will then gradually rise over several weeks to 12 to 13 g/100 mL, which is maintained throughout childhood.

Fluids and Fluid Management

As in adults, preoperative, intraoperative, and postoperative fluid management is extremely important in children. Some of the physiologic differences outlined earlier in this chapter make fluid administration even more critical. Because of their small intravascular volume (70 to 80 mL/kg), infants who experience small changes in fluid balance can easily become either dehydrated or overloaded with fluid. Extreme vigilance, early recognition, and tight control are required in managing fluid balance in children. Compartmentalization of total body water changes with age, but intracellular and extracellular electrolyte composition remains stable (Table 180-3). Calculating the maintenance fluid requirements for a child can be based on relatively simple formulas that vary according to metabolic and physical activity. The calculation of water loss per calorie is described in Table 180-4. The correspondence of necessary fluid intake proportional to weight is described in Table 180-5.

Complex fluid and electrolyte deficits are beyond the scope of this discussion. In most such cases, consultation with pediatric medical specialists is advised.

Pain Management

The management of pain in infants and children has undergone tremendous advances in recent years. It had been commonly believed that infants and newborns did not perceive pain because of their immature nervous system and that they do not have memory of pain if it occurs. Direct physiologic consequences have been observed in infants as a response to pain. Changes in heart rate, blood pressure, and respiration rate have been documented in infants experiencing painful stimuli. These changes can be physiologically as well as emotionally deleterious to the child.

The perception of pain depends on both sensory and emotional experiences that may be altered by various psychological factors. These factors may be specific for each individual patient, based on his or her expectations and past experiences. Efforts to reduce stress, anxiety, and fear will help decrease the apprehension and perception of pain during procedures in the office or in the operating room. In patients of the appropriate age, relaxation techniques such as guided imagery, deep breathing, and hypnosis may diminish the emotional component of pain. An adequate and age-appropriate explanation of expectations also will reduce anxiety, increase cooperation, and decrease perceived pain. The caregiver or parent also should be coached regarding expectations, because children often look to the psychological state of their parent for cues. An anxious parent often increases the anxiety of the child. Conversely, a calm and collected parent can help calm the child during uncomfortable procedures.

Non-narcotic analgesics are helpful for pain management. Acetaminophen in doses ranging from 10 to 15 mg/kg every 4 hours is useful. Other nonsteroidal anti-inflammatory medications also are excellent for pain management. They often inhibit platelet function, however, and should be used only at the discretion of the surgeon.

Narcotic analgesics are indicated for moderate to severe pain in all age groups. Optimal use requires consideration of the needs of the individual patient. Neonates require special observation during the administration of narcotics. As noted previously, ventilatory responses to hypoxia and hypercarbia are diminished in this age group. Narcotics may further decrease these responses to potentially life-threatening levels. The metabolism and half-life of narcotics are different in neonates from those in older children and adults. The permeability of the blood-brain barrier also may be increased in neonates. The use of intravenous, intramuscular, and oral narcotics is safe in the appropriately monitored setting and with the proper dose. Unlike adults, who usually self-administer and therefore self-regulate narcotic analgesics, pediatric patients often rely on caregivers to administer pain medication, which can lead to underdosing, as well as overdosing.

Sedation

More often today, professional certification and credentialing for pediatric sedation are required at institutions caring for children. The development of sedation teams, often staffed by pediatric intensivists, has increased safety and monitoring for these patients. Otolaryngologists can participate in the team effort by assessing the airway of the patient referred for sedation. Occasionally, a general anesthetic procedure with a secured airway is required for the proper level of safety for a sedated patient. Although the otolaryngologist can accomplish assessments of airway safety, the professionals on the sedation team have the final word on whether they are willing to sedate a child. The requirements for certification, the makeup of the sedation team, and the success of the interaction as measured by family satisfaction and patient outcome are dependent on the institution involved. It is important to adhere to the guidelines of the institution and to work together as a team.

Referral Sources

Unlike adults, most pediatric patients have a primary caregiver—the pediatrician or family practice physician. School-aged children require

vaccinations and usually will have a physician who provides this level of care. In turn, most pediatric patients seeking help for problems related to the ears, nose, and throat will be referred to the specialist by their primary care physician. Pediatric medicine is a specialty that legitimately considers its practitioners to be advocates for their patients. The child's primary care physician is responsible for his or her overall health and well-being. This physician can serve as a tremendous ally to help identify and refer problems early on, as well as to help translate the complex problems related to surgical management when adequate communication lines have not been established. Although every patient encounter requires an element of trust building and rapport development, a long-term relationship usually has already developed between the child's doctor and the family.

Pediatric medicine and its interface with surgery have a slightly different culture from its counterpart in the typical adult world. Often a multidisciplinary approach is used in the perioperative period. Although this approach can enhance the care of the patient, clear delineation of duties and responsibilities and open lines of communication are essential.

Although all parties involved must understand that the surgeon is ultimately responsible for the care of any patient undergoing surgery, a decision to proceed should always be accepted by the parents, as well as the referral source. Occasionally, expectations for surgery are initiated before the evaluation by the otolaryngologist. In such cases, how a decision is made must be explained clearly and logically. The surgeon makes the final recommendations for or against surgical management of a problem. All parties must clearly understand the steps leading to a logical decision.

Finally, pediatric otolaryngologists often direct their educational efforts directly to the families of the patients they treat. Education of their colleagues, specifically the primary care physicians caring for these patients, also is very important. Keeping these practitioners up to date through small education forums will maximize their ability to help with perioperative management, as well as increasing the visibility of the otolarygologist's contributions.

Patients

Although the entire family is involved in the care of a child, the child is the patient. Children experience the same fears of pain and discomfort as in adults but may lack the maturity and skills to overcome these fears. Delayed gratification is not often a concept familiar to a child. Whereas adults often bring themselves to the doctor and therefore have made the first hurdle toward obtaining medical care, children are brought by their parents and often have no idea why they are there. Establishing rapport with the child is important for myriad reasons. Not only will this put the child at ease, but it will often put the parents at ease when they see that the physician has a genuine interest in the well-being of their child. Children take cues from their parents. If the parent is apprehensive, the child will often be as well. It is important to explain not only to the parent what is to be expected during the history and physical examination but also to the child—on a level he or she may understand. Procedures that may be uncomfortable are best left to the end of the examination and are performed quickly but thoroughly.

Quickness and experience allow for a brief, but relatively complete, physical examination without undue stress on the child or the parent. Restraining an older child who may have been traumatized by a previous forceful examination is wrong and could be dangerous. In these cases, sedation or a general anesthetic is appropriate to complete the required examination.

Parents

Parents can find themselves in an uncomfortable position. They must make decisions for their sick child, decisions that may include treatment that may carry some discomfort and risk. It is important for the surgeon to be open and honest regarding the options and risks involved. Alternative treatment plans often are possible, and all of the options, with their set of risks and benefits, as well as expected outcomes, should be explained to the family. Finally, a single best option may exist, and the reasons that a surgeon considers one option better than others should be explained. Parents often have questions that may be biased by previous experiences or the advice of other family members or friends, or by exposure to the media. Time must be allotted to answer these questions.

Often, families have been referred by the primary care physician, who usually has answered many of the relevant questions. Having been referred to a specialist, the parents often identify the otolaryngologist as a person with expertise and added ability. It is important not to be placed in the situation of persuading parents to proceed with surgery. If they continue to have difficulties deciding after all of their questions have been answered, it may be suggested that they contact their primary care physician for another view. Finally, it may be more comfortable for families to make decisions regarding surgery at home with the understanding that they can call if more questions arise and will schedule an appointment if they wish to proceed.

Congenital Anomalies

Children with developmental or hereditary abnormalities often require a health care professional team approach for optimal treatment. As an example, for children with craniofacial anomalies, a craniofacial team consisting of at least an otolaryngologist, a craniofacial surgeon, dentist, geneticist, audiologist, speech-language pathologist, and social worker will bring the greatest benefit. It is important that a unified voice come from the specialists at hand. Conflicting information will only confuse the often devastated parents. Guilt regarding inheritable defects may be overwhelming to the parents. Counseling should be available from specialists in genetics when needed.

The goal of caring for children with congenital anomalies or developmental delays is to maximize their individual potential. It is important to know what difficulties a child may have from a particular disorder and then to offer advice or techniques proven to help such families cope with or manage the disability. This will be different for each child, family, and situation.

At one time, genetic counseling was routinely advised for families of all children with congenital abnormalities. The feeling today is that genetic counseling should be offered only to parents who desire it. Other than speaking in general terms of the inheritable nature of sensorineural deafness, cleft palate, or other problems, the clinician should not force the parents to face information they do not wish to acknowledge. The denial phase is related to their eventual acceptance of their child's problem. Once they have adapted to the child's abnormality, the parents are much more receptive to genetic counseling.

History

In treating children, several sources are available for historical data. A referral letter from the primary care physician often will accompany the child. This aspect of the history is important but does not replace the history taken from the parents or the child. Historical data from the primary physician give the added advantage of allowing the specialist physician to verify that the information provided by others and the data gathered during the examination are in agreement. The parents often give the history. They usually are very astute regarding their child's behaviors or symptoms and should therefore be listened to carefully. The child can be questioned as well, although he or she may not understand or be able to identify a problem. Often, chronic symptoms are not seen as problems to the child because such symptoms have been lifelong. The child, not ever having experienced life any other way, does not recognize his or her symptoms as abnormal. The difficult part for the pediatric otolaryngologist is to synthesize sometimes conflicting data into a coherent story.

Occasionally, admission to the hospital for observation is required. This allows for further collection of historical data. Symptoms described by the caregiver can be documented and perhaps better understood. Further testing also may document whether the child's safety is compromised because of symptoms or the severity of potential problems.

It also is very important to obtain a general family history, as well as a history of any diseases or illnesses affecting the child's siblings. Information regarding the pregnancy and delivery of the child also is important. Insight into any family stresses or school problems that may influence the child's psychosocial development also is helpful.

Physical Examination

Physical examination of a child can be done in a nonthreatening and calm manner. Rapport and trust are the key elements. Engaging the child as an active participant often leads to more cooperation. One technique is to let the child hold or examine the instruments before they are used. This often reduces the child's anxiety. Because many well child examinations are accompanied by vaccinations, children unfortunately often equate any visit to the doctor with a shot. The resulting apprehension and perhaps an attempt at maintaining independence or control of the self may underlie seemingly irrational behavior during an examination.

Most of the head and neck examination should be painless. Otoscopy generally is managed without difficulty. Pneumatic otoscopy can be performed but should be explained before proceeding so as not to surprise the child. Explanations build a child's trust in the examining physician. The use of a head mirror or headlamp light during the examination is the surgeon's choice. Things that cover the examiner's face often frighten children, which may decrease cooperation. Nasal endoscopy can be performed with the otoscope and a larger speculum, thereby eliminating the need to introduce a new instrument to the child. Oral examination often can be accomplished without a tongue depressor, although occasionally use of a depressor may be required to view the posterior pharynx. Palpation of the neck can be accomplished without any significant discomfort to the child, and masses or tenderness can be documented.

During the examination, further observations of the child's facial features can be made. It is important to ensure that the ears look normal, without pits or fistulas. The eyes also should be symmetrical in shape and alignment, without apparent hypertelorism or heterochromia. The nasal airway should be assessed for chronic mouth breathing and to help identify any abnormality of the palate. Listening to the child breathe, for the sounds of stridor or stertor, can help identify the level or site of potential airway obstruction. Auscultation of the neck and chest also generally is performed. The otolaryngologist will concentrate the physical examination on the particular area of interest, which is the head and neck. A general physical examination should be performed in a brief but complete manner, however.

Special Considerations

Microscopic Examination of the Ear

Otomicroscopy is an invaluable tool for assessing the ears. Children can have anxiety about this portion of the examination, however. Often, allowing the child to look through the microscope at the examiner's thumb will show that the microscope is simply a tool to obtain a magnified view of the ear. The parent can assist in reminding the child to hold still for the examination while cerumen or debris is removed from the ear canal. With the parent reclined on the examination chair or table, the child may lie on the parent like a table. The parent can then hug the child, to hold the arms and body still, while an assistant helps steady the head. Use of a papoose is possible in smaller children but often is not successful in older children. Sedation usually is not necessary but may be used in certain cases, in accordance with the sedation policies of the institution. Occasionally a general anesthetic is required to permit a complete and thorough examination.

Although usually not painful, suctioning is loud and can be frightening. The suction device is a very useful tool to quickly clean away debris and drainage. Some clinicians prefer to use cotton-tipped applicators instead. It is important to have a number of techniques in reserve and to use the one that will quickly and effectively accomplish the required task without undue stress and discomfort to the child.

Flexible Endoscopy

Nasopharyngoscopy is an invaluable tool for the otolaryngologist. With advances in technology, smaller-caliber endoscopes are being developed with improving optics. Although the mirror examination is useful, the fiberoptic endoscope allows for a dynamic examination of the nose, vellum, pharynx, hypopharynx, and larynx. When combined with videotaping, slow-motion replay is possible—an important option if only brief glimpses are obtained in a child who is not able to cooperate fully with the examination.

As in adults, topical anesthesia and nasal decongestion, with lidocaine gel or Pontocaine (tetracaine) spray and oxymetazoline, is very useful. Use of cocaine in young children is not advisable because of variable absorption rates. In infants, cocaine can produce unwanted irritability and nervousness. The parents should be counseled that after the topical anesthetic, the child should not eat or drink for approximately 30 minutes. Sedation generally is not necessary for this examination.

Complications from nasopharyngoscopy are rare. An emergency cart for airway management and the skills to use it are important to have on hand. Nasal bleeding, if it occurs, often is self-limiting or requires little intervention.

Needle Biopsy

Fine-needle aspiration (FNA) can be performed in children to obtain a biopsy specimen for histopathologic examination. Ideally, a cytopathologist should be available for interpretation of results. Many of the typical masses of the head and neck are very different from those encountered in adults and may be more difficult to characterize. This does not make FNA less useful, however. Children usually are very frightened of needles or sharp objects. EMLA cream (Astra Pharmaceuticals, Westborough, Massachusetts) or other anesthetic creams that are topically applied can render the introduction of the needle painless.

The site is prepared in a sterile manner. The 22- or 23-gauge needle, attached to a 10-mL syringe, is then placed into the mass while suction is applied. The sample obtained within the needle core is then applied to a glass slide and is placed in a fixative. It is optimal if the cytopathologist can attend or perform the procedure to provide immediate feedback regarding the adequacy of the specimen. If the specimen is inadequate and the child appears able to tolerate another attempt, FNA may be repeated using the same anesthetic. An adhesive bandage is applied when the procedure is done. FNA should be no more traumatic than obtaining a blood sample and should be explained in those terms to the parent.

Audiology

Every child can be tested for hearing loss. Pediatric otolaryngologists can help to accomplish this goal by educating the families and especially the primary care physicians of their patients. It has been shown that in children with hearing loss, early detection and treatment lead to dramatic increase in language ability later in life. Audiologists interested in pediatric screening generally are able to test children as young as 6 months of age with visual response audiometry. Visual response audiometry in experienced hands can be very reliable. Other techniques for younger children or children who are unable to conform to the demands of the task include otoacoustic emissions and auditory brainstem response (ABR) testing.

Early detection of hearing loss is extremely important to the speech and language development of the child. Currently, newborn hearing screening programs with automated ABR testing are being set up nationwide. If a screening test identifies the infant as requiring further investigation, it is essential for the otolaryngologist to provide any necessary referrals and follow-up evaluations. If no action is taken once a child has been diagnosed with hearing impairment, the test is useless and does not benefit the child or the family.

Preparation for Hospitalization and Surgery

Once the decision to proceed with hospitalization or surgery has been made, the child and parents should be readied emotionally to achieve a successful outcome. The details and expectations should be reviewed with the family by persons familiar with the process. Some institutions and most children's hospitals have programs to introduce the family to the hospital, operating room, and operating room procedures. A sense of familiarity and an understanding of what to expect will be helpful to all involved. Children can then role-play before hospital admission or surgery. With a clear understanding of what is expected, parents also are less apprehensive and help calm the child.

It is important to clarify arrival times and nothing-by-mouth requirements to the family. Special films and booklets are valuable tools for education. The parents must be encouraged to be truthful, to the best of their ability, about preparation for the upcoming surgery. It also is important that the surgeon communicate directly with both parents and child so that all questions are answered completely.

Hospital

A dedicated children's hospital is the preferred venue for pediatric otolaryngologic surgery, providing a team of physicians, nurses, and other professionals who can best handle a hospital stay or surgical procedurefor the pediatric patient. Children's hospitals constitute an important medical resource, and every surgeon involved in the care of children should support them. Unfortunately, not every community has one. In such instances, it is important to identify the best facilities in the community in which the physical plant, physicians, nurses, and support staff are capable of and enjoy caring for children. Ensuring an optimal environment for pediatric treatment will encourage the best outcomes and lead to the greatest satisfaction among patients and their families.

The concept of a team of professionals who deal strictly with pediatrics is not new; moreover, a team approach is becoming increasingly accepted as the standard of care. When complications arise, as they inevitably do in the course of even the best medical care, having the support facilities and the personnel available to handle any need promptly is vital for the best outcome possible.

Selecting Anesthesia

Pediatric anesthesia is a subspecialty in itself. Reaching a degree of proficiency to deliver an anesthetic to children of all ages requires considerable training and experience. The younger the patient, the more complex the problems encountered. As in all aspects of medicine, this subspecialty includes practitioners with special interests and expertise in particular fields. Those with expertise in safely delivering anesthesia to children should be sought when their assistance is required. Reliance on these specialists benefits both the patient and the surgeon.

With practice and special expertise, the interested clinician can devise techniques to safely and effectively perform nearly any technique. Local anesthesia as a primary anesthetic technique for pediatric surgery is possible but requires a cooperative child and an adept surgeon. Generally, local anesthetics are used for immediate postoperative pain management after surgery performed with the patient under general anesthesia. Young children generally do not understand the need for painful injections and have short attention spans, making it difficult for them to sit still for the procedure. The use of sedation for extended periods is not recommended unless support personnel are available to monitor the child during the sedation process. Many institutions have strict guidelines and require a certification process for the use of conscious sedation in children. Most invasive or painful procedures require a general anesthetic.

Postoperative Management

Probably the most important part of postoperative management is preoperative teaching. If the parent and the child are adequately prepared about the effects of surgery, they are more capable of handling the postoperative period in terms of decreased stress and optimal adherence to the postoperative regimen. Detailed teaching about the expected clinical course and unexpected possibilities is important. Providing written instructions, along with contact telephone numbers if the parents should have questions, also is very helpful. Knowing what to expect is the single most important factor in uneventful recovery from a surgical procedure without multiple phone calls and excessive concern from both patient and physician.

If a child must be hospitalized, it has been shown that the presence of a parent makes the stay less fearsome and stressful for the child. Whenever possible, parents should be encouraged to stay with the child while in the hospital. Arrangements should be made for this to be possible if it is not the norm at the hospital where the child will stay.

More often, short-stay and outpatient procedures are being performed. It is helpful for the child to return to the home setting as soon as possible. Safety is the main concern, however, and monitoring in the hospital should be done as long as necessary.

An awareness that modifications in surgical technique may be required in the management of pediatric problems is important. Dressing changes, suture removal, and postoperative manipulations should be kept to the required minimum so as not to provoke fear and discomfort in children who must undergo minor procedures. Sometimes sedation or a general anesthetic for packing or suture removal, not often required for adults, may be necessary in children. It is reasonable to plan ahead at the time of surgery to use absorbable suture material and dressings that need infrequent changing.

A Rewarding Experience

The care of children is an extremely rewarding experience. Children may become ill quickly but often recover just as quickly if put on the right pathway. Watching children grow and develop makes for lasting memories and personal satisfaction. For many clinicians, helping children with chronic illness to overcome disabilities and difficulties and watching them reach their full potential as they grow to adulthood have no match for reward.

CHAPTER ONE HUNDRED AND EIGHTY-ONE

Anatomy and Developmental Embryology of the Neck

Daniel O. Graney

Kathleen C. Y. Sie

Key Points

- Anatomy of the neck is predictable. A detailed understanding of neck anatomy is critical for the otolaryngologist–head and neck surgeon.
- Congenital anomalies of the neck are related to the embryology of the neck.

Most descriptions of the neck divide the anatomy, for discussion purposes, into triangles. The use of triangles is simply an organizational approach to manage the volume of anatomic detail in the neck by parceling it into reasonable study units. When an incision is made over the carotid triangle, surgeons can thereby predict the structures they will encounter in precise order. Similarly, the embryologic correlates of the triangles are important in understanding the development and differential diagnosis of masses in the various triangles of the neck.

This chapter begins with descriptions of the posterior triangle and the subdivisions of the anterior triangle. Also presented is a description of the root of the neck that relates the anatomy of the two major triangles to the radical neck procedure. The chapter concludes with a discussion of the embryology of the branchial arches and the pharyngeal pouches and their contribution to various masses in the neck.

Strictly speaking, the term *triangle* connotes a planar form (i.e., a flat structure). The "triangles" in the neck, however, are three-dimensional spaces that should be visualized as shallow triangular boxes. These boxes have not only three sides but also a roof (top) and a floor (bottom). Most of the triangles are three-dimensional spaces bounded by bone and muscles, with distinct fascial layers forming the roof and floor of the space. In general terms, the triangular space contains blood vessels, nerves, lymphatic vessels, and lymph nodes. Using this somewhat contrived schema, the organization of the neck can be greatly simplified.

Posterior Triangle of Neck

The posterior triangle is bordered by the sternocleidomastoid muscle, the anterior border of the trapezius muscle, and the middle third of the clavicle (Fig. 181-1). Specific layers of deep fascia form the floor (medial wall) and roof (lateral wall) of the triangular box. An understanding of the fascial relationships in the neck is important not only because of the boundary relationships but also because fasciae form planes that provide routes of surgical access or pathways for hemorrhage and infection. For this reason, a brief discussion of the fascial planes is necessary before proceeding with the anatomy of the posterior triangle.

Fascia of Neck

One of the earliest lessons in anatomy is that there are two types of fascia in the body: the superficial and the deep. In the region of the abdominal wall, superficial fascia consists of two layers—a fatty layer (Camper's fascia) and a deeper, membranous layer (Scarpa's fascia). The deep fascial layer of the abdominal wall is not subdivided but simply envelops the abdominal muscles. In the neck the superficial fascia is very thin and is not divided into layers, whereas the deep fascia is divided into three layers.[1] The names of these layers vary with different authors, resulting in a somewhat chaotic terminology. Regardless of the terminology used, the divisions are arbitrary at best. A simple approach can provide a workable solution for either the anatomist or the surgeon.

Superficial Layer of Cervical Fascia

As just noted, the superficial layer of cervical fascia is a single layer of fascia underlying the skin. It usually is thin, except in the obese person, in which case it is thickened by adipose tissue. Its primary surgical significance is that it provides a fascial pad that protects underlying structures when a skin incision is made. In exceptionally lean people, however, the paucity of this layer may not protect underlying structures, such as the accessory nerve, so the surgeon should be wary when operating on such patients.

Deep Fascia

The deep fascia is divided into three layers, demonstrated best when the neck is viewed in cross section (Fig. 181-2). These are the external, middle, and internal layers of the deep cervical fascia. The external layer of deep fascia underlies the platysma muscle and completely invests or encircles all of the superficial neck structures. For these reasons, the external layer is also known as the superficial layer, or investing layer, of deep fascia. In the region of the sternocleidomastoid and trapezius muscles, it splits and envelopes the individual muscles. A middle layer of the deep cervical fascia encloses the visceral structures of the neck (the trachea and esophagus). Hence the synonym for the middle layer is the *visceral fascia*.

The third, or internal, layer of the deep cervical fascia surrounds the deep muscles of the neck and cervical vertebrae (Fig. 181-3). This

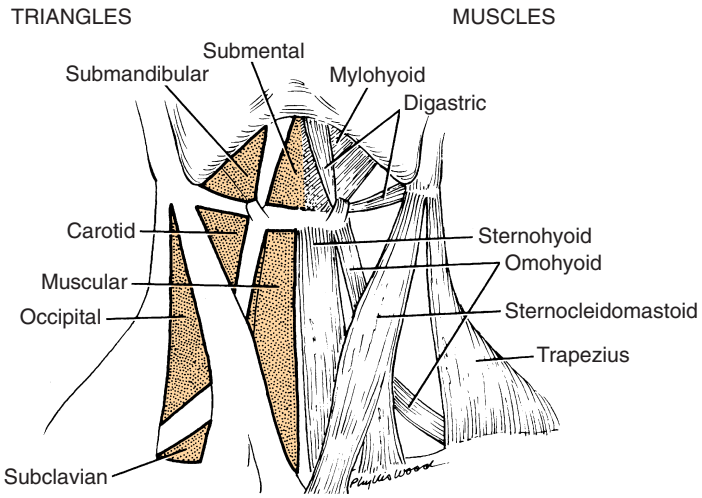

Figure 181-1. The triangles of the neck and their boundaries.

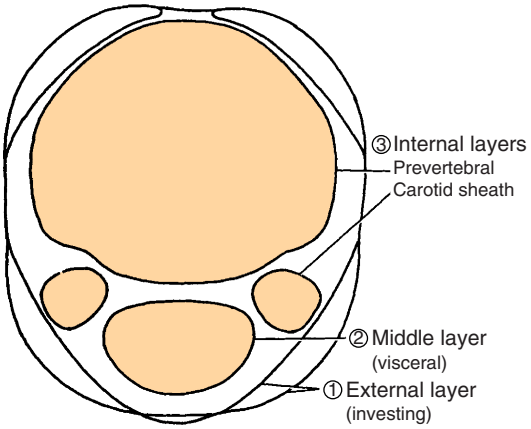

Figure 181-2. Divisions of the deep cervical fascia seen in transverse section at the level of cranial nerve VII.

layer also is known by its descriptive term *prevertebral fascia* (although "paravertebral fascia" would have been more appropriate). The muscles enclosed by the prevertebral fascia include the deep muscles of the neck (the cervical part of the erector spinae); the levator scapulae; the scalenus anterior, middle, and posterior muscles; and the longus colli and longus capitis muscles, which lie on the anterior aspect of the cervical vertebrae. The last-named pair of muscles serve as flexors of the vertebrae; the longus capitis also assists in flexion of the skull. The scalenus group underlies the prevertebral fascia in the region of transverse processes of the cervical vertebrae. The anterior tubercles of the transverse processes provide origin for the scalenus anterior muscle, whereas the posterior tubercles provide the origin for the scalenus medius and posterior muscles. Continuing posteriorly, in order, are the levator scapulae and deep cervical muscles already noted.

The internal layer of deep fascia is described by some authors as enveloping the carotid and jugular vessels. Hence, the carotid sheaths are included as part of the definition of the internal layer of deep fascia. An effective means of visualizing the spatial relationships of these layers of fascia is to examine a cross section of the neck. This view not only is informative in defining the three layers of deep fascia but also serves to relate them to the posterior triangle of the neck (see Fig. 181-2). Placing a finger over the middle of the posterior triangle (i.e., between the trapezius and sternocleidomastoid muscles) will clarify that the roof (lateral wall) of the triangle is formed by the superficial layer of deep fascia. Palpation deeper into the triangle will bring the tip of the finger into contact with the prevertebral fascia that forms the floor of the posterior triangle and invests the prevertebral muscles. If the superficial layer of the deep fascia is incised, a finger inserted into the space, exploring anteriorly between the sternocleidomastoid and prevertebral muscles, will encounter the carotid sheath. This is a surgical approach to the retropharyngeal area or to the carotid vessels for vascular surgery.

Contents of Posterior Triangle

The major contents of the posterior triangle are the cutaneous branches of the cervical plexus, the accessory nerve (cranial nerve XI), two arterial branches of the thyrocervical trunk, and an abundant number of lymph nodes associated with the veins of the region.

Cutaneous Branches of Cervical Plexus

The sensory branches of the cervical plexus contained within the posterior triangle are four cutaneous nerves, which supply the skin of the head and neck from the area of the posterior scalp to the supraclavicular region. These cutaneous nerves are the (1) lesser occipital, (2) great auricular, (3) anterior, and (4) supraclavicular (Fig. 181-4). The first three of these nerves contain cervical segments C2 and C3 and the supraclavicular nerves C3 and C4. The topographic relations of these nerves and their distribution to the skin are illustrated in Figure 181-5. The important landmark for the cervical nerves is the accessory nerve at the point where it enters the posterior triangle from under cover of the sternocleidomastoid muscle. If this point is viewed as the center of a clock face, the cervical nerves mimic the hands pointing in different directions (see Fig. 181-4, inset). For instance, on the right side, the lesser occipital nerve is approximately at the 11 o'clock position, the great auricular is at the 12 o'clock position, and the anterior cutaneous nerve of the neck can be found at the 3 o'clock position. The supraclavicular nerves consist of three or four bundles of filaments scattered between the 5 and 7 o'clock positions on the clock's face. Continuing this analogy, the accessory nerve can be seen to traverse the posterior triangle along the line of the 8 o'clock position until it enters the deep surface of the trapezius muscle. Viewed in this manner, the accessory nerve serves as a focus for organizing the pathways of the cutaneous nerves, as well as for emphasizing cranial nerve XI as a motor nerve in the posterior triangle.

Accessory Nerve

The accessory nerve supplies both the sternocleidomastoid and trapezius muscles; however, in the posterior triangle, the only fibers remaining in the nerve are those destined for the trapezius. The accessory nerve should be preserved whenever possible because paralysis of the trapezius muscle produces devastating effects on shoulder joint function. The range of shoulder abduction is diminished by at least 50 degrees when scapular rotation is impaired because of a trapezius palsy.

The accessory nerve is the only motor nerve in the posterior triangle as just defined. However, if the prevertebral fascia is incised, it is possible to encounter the motor nerves of the deep cervical muscles,

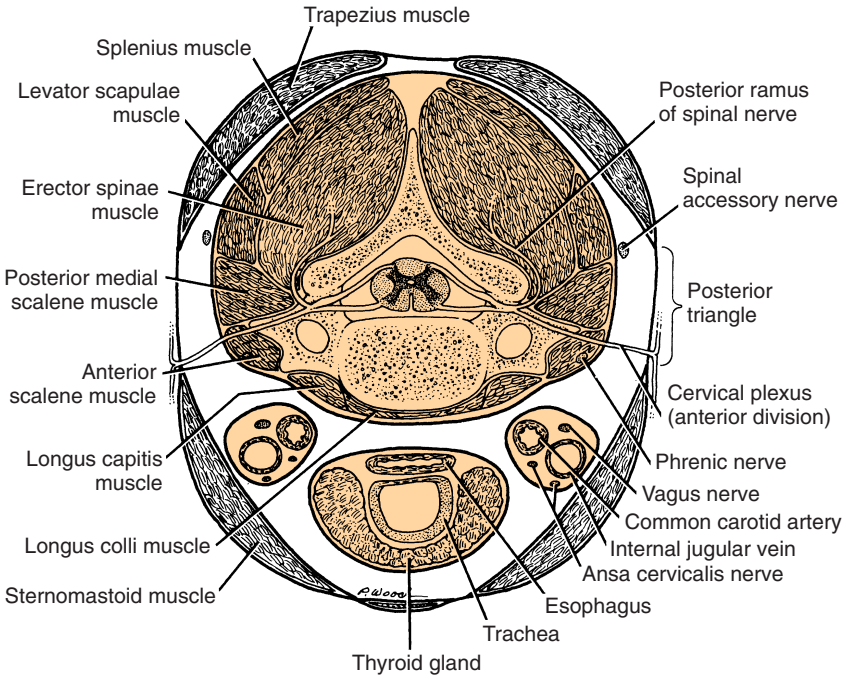

Figure 181-3. Structures contained by the deep cervical fascia seen in transverse section at the level of the cranial nerve.

the phrenic nerve, or the brachial plexus. With regard to its innervation of the sternocleidomastoid and trapezius muscles, cranial nerve XI is in fact a spinal nerve. Cell bodies of motor neurons innervating these muscles lie near the ventral horn in the upper cervical spinal cord, in the region of segments C2 through C4. The axonal fibers exit the anterior lateral portion of the cord as a series of fine filaments before becoming bundled as a nerve fiber within the subarachnoid space of the vertebral canal. The nerve ascends in the subarachnoid space, enters the posterior fossa through the foramen magnum, and joins with the cranial root of the accessory nerve before exiting the skull through the jugular foramen on the deep surface of the internal jugular vein. As the nerve descends the neck adjacent to the carotid sheath, motor or sensory filaments may join the nerve directly from segments C2 through C4.[2] After crossing the deep surface of the sternocleidomastoid muscle, the nerve enters the posterior triangle, as already described.

Arterial Branches

The major arteries of the posterior triangle are the suprascapular and transverse cervical arteries, located in the supraclavicular fossa near the base of the triangle. The arteries are derived from the thyrocervical trunk of the subclavian artery at the medial border of the scalenus anterior muscle. These arteries cross the muscle and the fossa transversely to course deep to the sternocleidomastoid muscle. Ascending and descending branches of the transverse cervical artery are usually described. The descending branch is of interest because it divides into a superficial branch that parallels the accessory nerve and a deep branch that parallels the nerve to the rhomboid muscle. The suprascapular artery, after crossing the fossa, is directed toward the suprascapular notch, where it supplies the posterior scapular muscle.

In addition to transverse cervical and suprascapular veins that parallel the course of the arteries, the posterior triangle contains the external jugular vein. It enters the triangle after crossing the superficial aspect of the sternocleidomastoid muscle in company with the great auricular nerve. The vein courses inferior to the base of the supraclavicular fossa, where it may anastomose with small vessels before entering the subclavian vein near the junction with the internal jugular vein.

Anterior Triangle of Neck

The anterior triangle of the neck is complementary to the posterior triangle and is bounded by the sternocleidomastoid muscle, the body of the mandible, and the midline of the neck. This space can be further subdivided into smaller triangular units, such as the submandibular triangle, and carotid and muscular triangles, which are included in this discussion (see Fig. 181-1).

Carotid Triangle

The carotid triangle is bordered by the posterior belly of the digastric muscle, the superior belly of the omohyoid muscle, and the midportion of the sternocleidomastoid muscle. The roof (lateral wall) of the carotid triangle is bounded by the superficial layer of deep fascia, whereas the floor (medial wall) is formed by the prevertebral fascia of the vertebral column and the visceral fascia covering the pharynx and larynx.

The contents of the carotid triangle are the carotid sheath structures. These include the common carotid with its internal and external branches, the last four cranial nerves (cranial nerves IX, X, XI, and XII), and the ansa cervicalis. In the carotid triangle, only a small branch of cranial nerve IX is left to supply the carotid sinus, because its main portion exits the sheath to enter the posterior third of the tongue. Cranial nerve XI, which also is in the upper portion of the carotid sheath, enters the sternocleidomastoid muscle at the apex of the carotid triangle, where the posterior belly of the digastric crosses the sternocleidomastoid muscle. The vagus nerve travels the entire length of the carotid sheath between the internal jugular vein and the carotid artery. Whereas the cranial nerves just mentioned lie in the posterior aspect of the carotid sheath, cranial nerve XII lies on the lateral and anterior aspect of the carotid sheath. At the level of the hyoid bone, cranial nerve XII courses anteroinferiorly to pass deep to the posterior belly of the digastric onto the surface of the hyoglossus muscle before entering the substance of the tongue.

The major focal point of the triangle is the bifurcation of the common carotid artery (Fig. 181-6). The internal carotid artery ascends the neck without branching. The external carotid artery provides several branches, many of which are important landmarks. The external carotid artery has anterior, posterior, and terminal branches.

Three anterior branches are common. In ascending order, they are the superior thyroid, lingual, and facial arteries. In some persons, the lingual and facial arteries form a common linguofacial trunk. Another important variation is the origin of the superior thyroid from the common carotid rather than the external carotid. The latter variation is important, because the external carotid occasionally is ligated (for

chronic epistaxis) at its origin from the common carotid. If the superior thyroid artery is used as a landmark in patients with this particular anatomic variation, it is possible to ligate the common carotid inadvertently instead of the external carotid.

The posterior branches of the external carotid are the occipital and the posterior auricular. The occipital is noteworthy for its small sternocleidomastoid branch, which supplies the sternocleidomastoid muscle. The origin of this small artery hooks cranial nerve XII as it courses anteroinferiorly and prevents it from ascending further in the neck. Thus, the sternocleidomastoid artery can be used to trace the position of cranial nerve XII. Similarly, the sternocleidomastoid artery enters its muscle near the point of cranial nerve XI, thereby also providing a means of locating the accessory nerve.

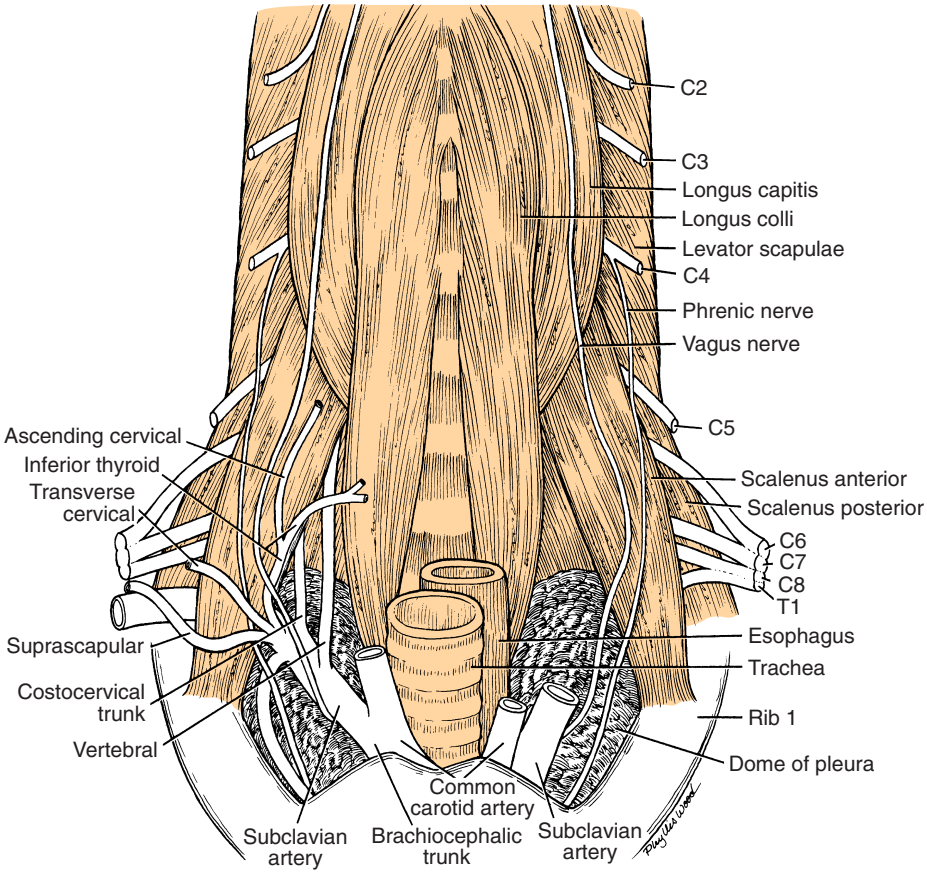

Figure 181-8. Root of the neck and subclavian artery. T1, first thoracic root; Rib 1, first rib.

Ansa Cervicalis

The ansa cervicalis is part of the cervical plexus. Its essential role is to supply the infrahyoid muscles: the sternohyoid, sternothyroid, and omohyoid muscles (Fig. 181-7). C1 fibers, which descend the neck, enter the hypoglossal nerve and travel as far as the occipital artery. At this point the hypoglossal nerve curves anteroinferiorly, but C1 fibers descend the neck to form the branch of cranial nerve XII, termed the superior root of the ansa. Fibers from C2 and C3 form an inferior root, which descends the carotid sheath on the surface of the internal jugular vein before turning anteroinferiorly to join the superior root. The ansa cervicalis is thus formed by the union of the two roots of the ansa. Three muscles are supplied directly by the ansa: the sternohyoid, sternothyroid, and omohyoid. At the origin of the superior root of the ansa, some C1 fibers do not follow the superior root but rather continue in the hypoglossal nerve transversely across the neck, before leaving cranial nerve XII to supply either the thyrohyoid muscle or the geniohyoid muscle (see Fig. 181-7). In summary, all four of the infrahyoid muscles are supplied by the ansa. In addition, one suprahyoid muscle, the geniohyoid muscle, also is supplied by the C1 fibers that have continued en route with the hypoglossal nerve. Except for proprioceptive fibers carried within the ansa, it is a motor nerve.

Thus far, two major groups of nerves of the cervical plexus have been discussed: the ansa cervicalis (principally motor) and the sensory (or cutaneous) branches of the posterior triangle. The cervical plexus comprises two other groups of fibers. One group of fibers is composed of motor filaments from cervical roots 3 and 4, supplying the levator scapulae muscle and located deep to the prevertebral fascia. The other group of fibers constitutes the phrenic nerve, derived from cervical segments C3, C4, and occasionally C5. This nerve not only is motor to the diaphragm but also supplies sensory fibers to the region of the central tendon of the diaphragm.

Root of Neck

The boundaries of the root of the neck are somewhat ill defined. The base of it is the plane of the thoracic inlet and can be traced from the manubrium laterally along the first ribs and then posterosuperiorly to the transverse process of C6 (Fig. 181-8). It contains the neck viscera and vessels. For the purposes of this discussion, it is divided unilaterally by the midline into a pyramidal space—bounded laterally by the scalenus anterior muscle, inferiorly by the first rib, and medially by the tracheoesophageal tract and midline.

The contents of the root of the neck include the great vessels emerging from the mediastinum, principally subclavian and common carotid arteries, brachiocephalic vein, vagus nerve, sympathetic trunk, and thoracic duct. As the great vessels traverse the thoracic inlet from the mediastinum, their course is divided by the scalenus anterior muscle. The subclavian vein crosses anterior to the muscle, whereas the subclavian artery courses between the cleavage plane of the scalenus anterior and scalenus medius muscles. In this region the subclavian vessels usually divide into three parts: the first part proximal to the scalenus, the second part posterior to the scalenus anterior muscle, and the third part between the lateral border of the scalenus and the lateral edge of the first rib.

A majority of the vascular branches arise from the first portion of the subclavian artery. The first branch of the subclavian artery normally is the vertebral artery, which ascends the root of the neck between the scalenus anterior and longus colli muscles to enter the foramen processus transversus of C6. The next is the thyrocervical trunk, which normally has four described branches. The first is a small ascending cervical, which supplies the prevertebral muscle region. The second branch of the thyrocervical trunk is the inferior thyroid artery coursing to the inferior pole of the thyroid gland. The inferior thyroid artery commonly supplies both the superior and inferior parathyroid glands. The third and fourth branches are the transverse cervical artery and the

suprascapular artery, already described in relation to the posterior triangle of the neck. Two branches arise from the inferior surface of the subclavian artery: the costocervical trunk and the internal thoracic artery, which descends over the suprapleural fascia into the mediastinum and anterior chest wall. Multiple variations of these vessels have been described, as detailed by Daseler and Anson.[3]

The thoracic duct ascends into the root of the neck on the left side, anterior to the thyrocervical trunk. The thoracic duct empties chyle into the venous system at the junction of the left internal jugular and subclavian veins.

Other important relationships of this region are those involving the major nerves. On the right side, the vagus nerve lies in the posterior aspect of the carotid sheath and gives off its recurrent laryngeal branch at the level of the first rib. The recurrent branch circles the lateral aspect of the subclavian artery to cross medially and enter the tracheoesophageal groove. On the left side, the recurrent nerve arises from the vagus at the aortic arch and hooks posteriorly around the ligamentum arteriosum. It enters the tracheoesophageal groove, ascending the mediastinum and neck until it enters the larynx at the level of the cricothyroid membrane.

In the most posterior part of the root of the neck, against the longus colli muscle, the sympathetic trunk ascends from the mediastinum, following the prevertebral space to the level of C2, where the superior cervical sympathetic ganglion is located. The inferior cervical ganglion lies close to the level of C7, and sometimes a middle sympathetic ganglion is described at approximately the level of C4. Injury to the cervical sympathetic chain may result in Horner's syndrome, consisting of ptosis, miosis, and anhydrosis.

This region is of particular importance during radical neck surgery, because the deep dissection usually is begun by detaching the sternocleidomastoid muscle from its attachments to the manubrium and clavicle. This exposes the carotid sheath and its contents and opens up the posterior and anterior triangles. As the dissection proceeds, the internal jugular vein is mobilized, exposing the carotid and its branches, which have been left in place. Because the en bloc mass of the internal jugular vein and sternocleidomastoid muscle is mobilized superiorly, it is important to leave the prevertebral fascia intact. With this precaution, the fascia willprovide a protective veil over the brachial plexus, phrenic nerve, sympathetic trunk, and motor nerves to the deep cervical muscles. When the prevertebral fascia is exposed, two muscles—the scalenus anterior and the longus capitis—serve as important landmarks for the spinal nerves. As the nerves emerge from the intervertebral foramina, they lie in a groove on the transverse process of the cervical vertebrae. If the vertebrae and prevertebral muscles are envisioned as being enclosed in a cylinder of prevertebral fascia, the logical conclusion is that the spinal nerves must penetrate this fascia to reach superficial structures in the neck (see Fig. 181-3). With these guidelines it is possible to identify cervical nerves C1 through C4 at the lateral border of the longus capitis, and the roots of C5 through T1 can be identified at the lateral edge of the scalenus anterior (see Fig. 181-8).

At this point in the radical neck dissection, the cutaneous nerves of the posterior triangle are encountered at their origin from the spinal nerves, and the surgeon has returned to the anatomic relationships of the posterior triangle, as discussed at the beginning of this chapter.

Lymphatic Drainage of Head and Neck

Earlier in this chapter the deep cervical fascia was described as having external, middle, and internal layers. This same rule can be applied to the lymphatic drainage of the head and neck. This plan is similar to one described by Last.[4] The external layer can be thought of as an outer circle of superficial or regional lymph nodes, the middle layer as a visceral layer of nodes draining the viscera of the neck such as the larynx and pharynx, and the internal circle of nodes composed of the paired carotid sheaths containing the internal jugular vein and deep cervical lymph nodes. The deep cervical lymph nodes are tributaries for both the superficial and visceral circles of lymph nodes.

Superficial Lymph Nodes

The superficial nodes may be thought of as a circle of nodes beginning on the face and extending posteriorly to the occipital area of the scalp. The efferent lymphatics of these nodes drain inferiorly along the major veins of the face and scalp. On the anterior face, buccal nodes in the cheek and facial nodes along the path of the facial vein drain inferiorly across the mandible, into the submandibular triangle, and to submandibular nodes. Inferior to the mandible, the superficial circle is composed of submandibular and anterior cervical lymph nodes. Sublingual nodes adjacent to the tongue receive afferent lymphatics from the anterior part of the face, particularly the lower lip and tip of tongue, and then drain superficially on the neck to deep cervical nodes approximately at the level of the omohyoid. The lymphatics from these nodes then enter the plexus of lymphatics in the carotid sheath, follow the internal jugular vein, and connect with other deep cervical nodes.

In the more posterior portion of the face (in the region of the parotid), afferent lymphatics begin in the scalp along the path of the superficial temporal vessels and drain inferiorly to parotid nodes in the superficial aspect of the parotid gland. Efferent lymphatics from parotid nodes course inferiorly along the common facial vein and thence to deep cervical nodes. Posterior to the ear, retroauricular nodes and occipital nodes follow their major channels to the deep cervical nodes of the internal jugular vein.

The general rule is that in the more anterior regions of the face, lymphatic drainage to the lower portion of the neck is more rapid, because it occurs along a sparser chain of nodes before proceeding to the deep cervical nodes. By contrast, in the deeper and more posterior portions of the face, the chain of lymphatic nodes and channels usually is more complicated, so that drainage requires more time before reaching the jugular lymph chain.

Deep Cervical Lymph Nodes

The deep cervical lymph nodes are a series of nodes that parallel the course of the internal jugular vein from the base of the skull to its terminus at the brachiocephalic junction. Most of the nodes are closely associated with the vein within the carotid sheath and lie deep to the sternocleidomastoid muscle. Two particular areas are notable. One is the region in which the posterior belly of the digastric crosses the internal jugular. This region usually is the site of one or more palpable lymph nodes termed the jugulodigastric nodes. Similarly, another large node or series of small nodes exists at the junction of the superior belly of the omohyoid and sternocleidomastoid muscles, which are termed the jugulo-omohyoid nodes. Efferent lymphatics from the deep nodes drain into the internal jugular trunks, which ultimately enter the venous system at the jugulosubclavian angle.

Lymphatic Drainage of Pharynx and Larynx

The upper portion of the pharynx, the nasopharynx, drains directly to the upper deep cervical lymph nodes along the jugular chain. The oropharynx and, particularly, the tonsil drain through the parapharyngeal spaces to the region of the midportion of the jugular and particularly the jugulodigastric nodes. In some descriptions, the jugulodigastric nodes are referred to collectively as the tonsillar node. The region of the hypopharynx and larynx drains principally along the vascular pedicles of the hypopharynx and larynx. The upper portion of the larynx from the false cord drains along the superior laryngeal vessels to deep cervical nodes on the internal jugular vein near the bifurcation of the common carotid artery. The lower half of the larynx (from the true cords proceeding inferiorly) drains along the interior laryngeal vessels to nodes about the pretracheal region and eventually to deep nodes near the base of the internal jugular vein.

Classification of Cervical Lymphatics

Nomenclature of the cervical lymphatics historically has been inconsistent. As the focus of oncologic surgery has shifted from radical extirpation to functional preservation, it has become more important to standardize the classification system for the cervical nodes. The American Academy of Otolaryngology–Head and Neck Surgery, along with the American Society of Head and Neck Surgery, has developed a standardized classification system for the cervical lymphatic system and for neck dissections.

The groups of lymph nodes are designated as levels I to VI. *Level I* includes nodes in the submental and submandibular triangles. *Level*

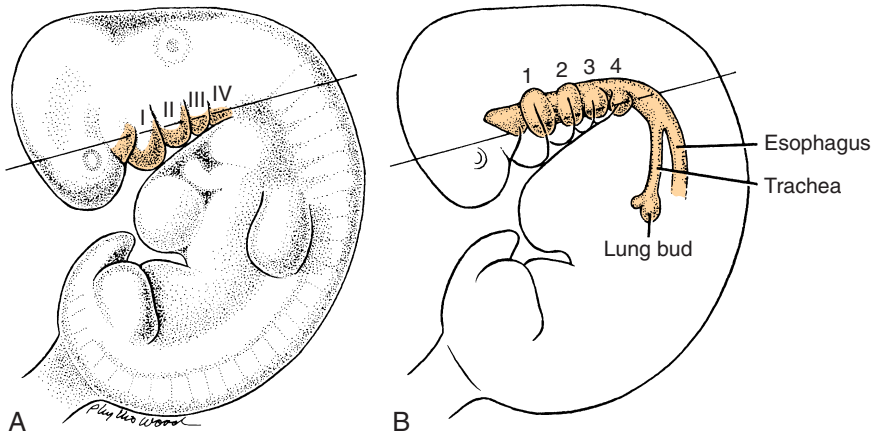

Figure 181-9. **A,** Branchial arches. **B,** Pharyngeal pouches.

II includes the upper jugular nodes located around the superior one third of the jugular vein and spinal accessory nerve extending from the carotid bifurcation or hyoid, inferiorly, to the skull base, superiorly. The anterior and posterior boundaries of this nodal group are the lateral border of the sternohyoid and the posterior border of the sternocleidomastoid muscle, respectively. *Level III* includes the middle jugular nodes around the middle third of the jugular vein, extending from the carotid bifurcation, superiorly, to the omohyoid (or cricothyroid notch, inferiorly). The anterior and posterior boundaries are the same as for level II. *Level IV* includes the lower jugular group surrounding the jugular vein from the omohyoid to the clavicle. The anterior and posterior borders are the same as in levels II and III. *Level V* is the posterior triangle group, consisting of the nodes surrounding the lower half of the spinal accessory nerve and the transverse cervical artery, including the supraclavicular nodes. The anterior boundary of level V is the posterior border of the sternocleidomastoid muscle and the posterior boundary is the anterior border of the trapezius muscle. *Level VI* includes the anterior compartment group surrounding the visceral structures of the neck from the hyoid, superiorly, to the sternal notch, inferiorly. The lateral boundary on either side of level VI is the medial aspect of the carotid sheath. This space crosses the midline and includes the perithyroidal, paratracheal, and precricoid nodes, as well as the nodes along the recurrent laryngeal nerve.[5] The terminology for neck dissection is discussed in Chapter 116.

Embryology of Head and Neck

The development of many structures in the head and neck is intimately related to either the branchial arches or the pharyngeal pouches (Fig. 181-9). These are transient embryonic structures that undergo substantial remodeling so that their original embryonic form is essentially unrecognizable by the time the infant is born. The derivatives of these structures nevertheless are important to adult morphology: Aberrations in branchial arch development may produce significant malformations.

Embryology of Branchial Arches

At 5 weeks of gestation, the area of the future face and neck of the embryo consists of five or six pairs of fingerlike masses of tissue named the *branchial arches*. Prominent in lateral profile (see Fig. 181-9), these masses are aligned in transverse orientation to the plane of the neck and are separated by clefts, termed the *branchial clefts*. The surface of the arches and clefts is lined by ectoderm, with mesodermally defined tissues contained within the branchial arches. The tissues underlying the region of the clefts are thin because of the close approximation of outpouchings from the foregut region called *pharyngeal pouches* (see Fig. 181-9). The derivatives of the arches and pouches are different because of the embryonic germ layers contained within the branchial arch (the mesoderm), whereas the pharyngeal pouches are composed of endoderm. Because of the differences in the embryonic germ layers, the following generalization can be made: In the adult, the derivatives of the branchial arch will be structures composed of muscle, bone, or similar mesodermal derivatives; the derivatives of the endodermal pharyngeal pouch will be glandular or associated with the digestive tract.

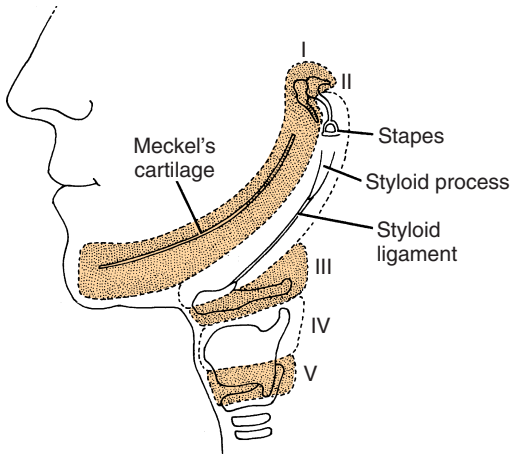

Figure 181-10. Skeletal derivatives of the branchial arches.

Derivatives of Branchial Arches

In the early phase of branchial arch development, the mesodermal mass of the arch forms a bar of cartilage, which remodels into bone, cartilage, or other connective tissue elements in the adult. Similarly, the adult musculature of the face and neck also develops from the mesoderm of the arches. The development of these structures is considered separately.

Skeletal Derivatives

The first branchial arch is the proximal part of the first arch cartilage (Meckel's cartilage), which is remodeled and contributes to the formation of the ramus of the mandible (Fig. 181-10). The distal part of the cartilage withers, and the body of the mandible is formed from intramembranous bone. Other structures formed by the proximal part of the cartilage are the sphenomandibular ligament, anterior malleolar ligament, malleus (except for the manubrium, which is from the second arch), and incus (except for its long process, which is from the second arch).

The second branchial arch is the cartilage of the second branchial arch (Reichert's cartilage), which forms bony structures proximally and distally. Its central portion withers, leaving a fibrous band—the stylohyoid ligament. Proximally, it forms the styloid process, the manubrium of the malleus, the long process of the incus, and the stapes suprastructure. The stapes footplate is mostly derived from the otic capsule.[6,7] Distally (anteroinferiorly), the second arch cartilage forms a portion of the body of the hyoid and the lesser cornu of the hyoid bone.

In the adult, it is possible to trace the path of the embryonic second arch cartilage from the styloid process, to the stylohyoid ligament, ending at the lesser cornu of the hyoid bone (see Fig. 181-10).

The third branchial arch composes the remaining portions of the hyoid bone (i.e., the body and greater cornu).

The fourth through sixth branchial arches comprise the cartilaginous elements. These arches contribute to the formation of the thyroid, cricoid, arytenoid, corniculate, and cuneiform laryngeal cartilages.

Muscular Derivatives

In the first branchial arch, the muscles formed by mesodermal elements include the muscles of mastication: the temporalis, masseter, and medial and lateral pterygoid muscles. In addition, the tensor tympani, tensor veli palatini, anterior belly of the digastric, and mylohyoid muscles also are derived from first arch mesoderm.

In the second branchial arch, the muscles formed from mesoderm include all of the muscles of facial expression from the region of the scalp, inferiorly, to the platysma muscle in the neck. In addition to those muscles, grouped as the muscles of facial expression, the posterior belly of the digastric, the stylohyoid, and the stapedius muscles also are derived from second arch mesoderm.

In the third branchial arch, only one muscle is formed from mesoderm—the stylopharyngeus muscle, a small muscle that aids in elevating the pharynx during swallowing.

In the fourth through sixth branchial arches, the muscles include the muscles that form the pharynx and larynx. Pharyngeal muscles include the superior, middle, and inferior constrictor muscles. In addition, the mesodermal elements from these branchial arches also form the striated muscle composing the upper half of the esophagus. The inferior part of the esophagus usually is composed of smooth muscle derived from the splanchnic mesoderm of the primitive foregut.

The laryngeal muscles are also formed from mesodermal elements in the fourth, fifth, and sixth arches. These include the extrinsic muscle of the larynx and the cricothyroid, as well as all of the intrinsic muscles associated with movement of the arytenoid cartilage and true and false vocal folds.

Innervation

Because of the proximity of the developing branchial arches to the brainstem, each branchial arch receives motor or sensory innervation from an adjacent cranial nerve. A comparable parallel to this pattern occurs in the trunk, where a muscle is derived from the myotome region of a somite and receives its innervation from the adjacent segmental spinal nerve. In both cases, regardless of where the primordial muscle cell migrates, it retains its primary embryonic innervation. After each arch receives its cranial nerve innervation, then the adult pattern is established, regardless of its future migration onto the back of the head or base of the neck.

The nerve of the first branchial arch is the trigeminal nerve, which supplies motor innervation to all of the muscles derived from the first arch. In addition, sensory innervation is provided not only over the region of the mandible by the third division of the trigeminal but also over the maxillary process of the first arch and the frontal nasal process by the second and first divisions of the trigeminal nerve.

The nerve of the second branchial arch is the facial nerve, which supplies motor innervation to all of the muscles derived from this mesoderm. Other than a small sensory branch of cranial nerve VII, which may supply part of the external auditory meatus, sensory distribution of cranial nerve VII to ectoderm is absent.

Cranial nerve IX supplies the single muscle derived from the third arch—the stylopharyngeus muscle. As described later on, however, it also supplies sensory innervation to parts of the pharynx associated with this region.

The vagus nerve and the cranial part of the accessory nerve supply the muscles derived from branchial arches 3 through 6. Originating in the nucleus ambiguus of the medulla, the axonal processes of these nerves descend in the vagus nerve after exiting the skull through the jugular foramen. Specifically, the pharyngeal constrictors are supplied by the pharyngeal branch of the vagus and the transitional portion of the pharynx and esophagus by its recurrent laryngeal branch. The superior laryngeal nerve supplies sensation to the larynx by its internal branch and motor innervation to the cricothyroid muscle by the external branch. The recurrent laryngeal nerve supplies the intrinsic muscles of the larynx.

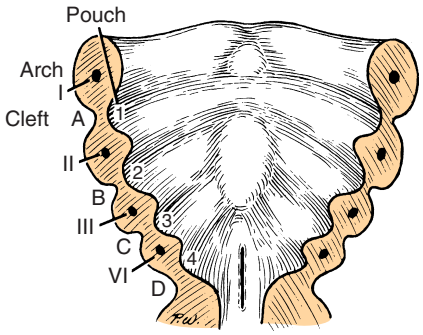

Figure 181-11. Relationships of the pharyngeal arches, clefts, and pouches in the floor of the mouth: stage I.

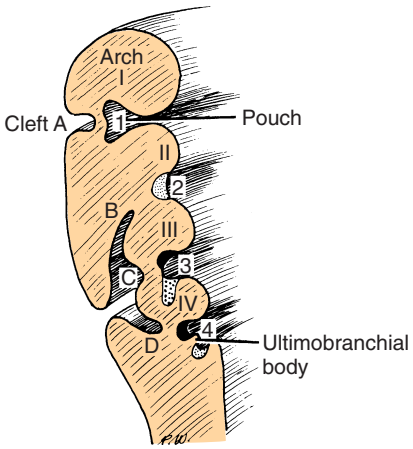

Figure 181-12. Derivatives of the pharyngeal pouches and formation of the cervical sinus: stage II.

Embryology of the Pharyngeal Pouches

The pharyngeal pouches are lateral outpouchings of the foregut or region of the primitive pharynx (see Fig. 181-9). At the extreme lateral wall of each pharyngeal pouch, the endodermal lining contacts the ectodermal epithelium of a branchial cleft (Fig. 181-11). Thus, the branchial clefts are named in relation to the pharyngeal pouch with which they are apposed. The endodermal epithelium lining of either the branchial arch or the pharyngeal pouch contributes to the formation of specific elements of the pharynx in the adult.[8]

First Pharyngeal Pouch

The first pharyngeal pouch becomes elongated and incorporated into the temporal bone and forms the epithelial lining of the middle ear (Fig. 181-12). The most lateral portion of the pouch, along with the first closing plate of the first branchial cleft, forms the tympanic membrane (see Fig. 181-12). From this relationship, it is clear that the external auditory canal is nothing more than a remodeling of the first branchial cleft (Fig. 181-13).

Second Pharyngeal Pouch

The endodermal layer of the second pharyngeal pouch forms the epithelial lining of the palatine tonsil, whereas underlying mesenchymal elements contribute to the formation of the tonsil itself (see Figs. 181-12 and 181-13).

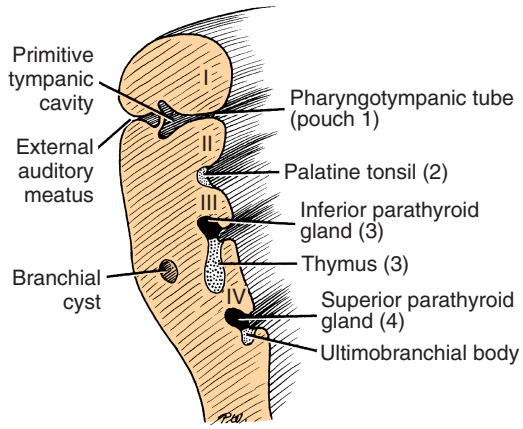

Figure 181-13. Maturation of the pharyngeal pouches: stage III.

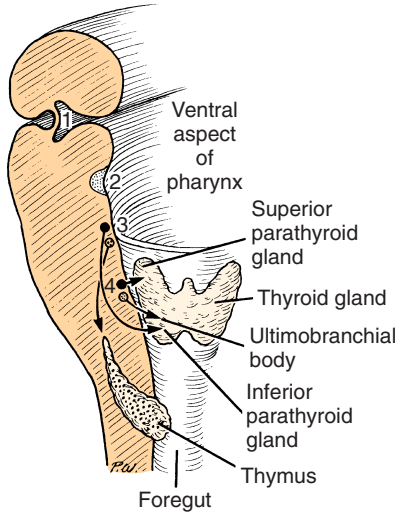

Figure 181-14. Migration of the pharyngeal derivatives into the neck: stage IV.

Third Pharyngeal Pouch

The region of the third pharyngeal pouch is subdivided into superior and inferior portions. The superior portion forms cells that eventually differentiate into the inferior parathyroid (see Fig. 181-12). The inferior portion of the third pouch becomes thymic tissue, which eventually migrates in the neck and mediastinum to form the thymus (Fig. 181-14).

Fourth through Sixth Pharyngeal Pouches

The endoderm of the fourth pouch forms the superior parathyroid gland. The adjacent area is variably named as the fifth or sixth pouch or the ultimobranchial body (see Fig. 181-13). Subsequently, the ultimobranchial body is infiltrated by cells migrating from the neural crest region. These cells eventually are incorporated into the thyroid gland and become the parafollicular cells (C cells) responsible for the secretion of calcitonin.[9,10]

Craniofacial Syndromes Related to Branchial Arch Structures

Hemifacial microsomia is thought to be related to a vascular injury in the region of the stapedial artery, resulting in microtia and mandibular hypoplasia.[11] Patients with this defect often have associated aural atresia. Mandibulofacial dysostosis, or Treacher Collins syndrome, is related to abnormalities of the first and second branchial arches. This syndrome is characterized by lid colobomata, down-slanting palpebral fissures, hypoplastic zygoma and mandible, and malformations of the external ear.[12] Other syndromes related to dysmorphogenesis of the first and second branchial arches include oculoauricular vertebral dysplasia (i.e., Goldenhar's syndrome) and branchio-oto-renal syndrome.

Branchial Cleft Remnants

The first branchial cleft becomes part of the external auditory canal, but the remaining branchial clefts are remodeled and normally do not form derivatives identifiable in the adult. However, the complicated morphodynamics of the branchial arch region seem to predispose this area to abnormalities, ranging from minor cysts to major orofacial malformations. The clinical terminology of the various branchial abnormalities is confusing. Part of the confusion results from the clinical spectrum of these anomalies—they may manifest as cysts, sinuses, or fistulae. A *cyst* has no communication with the body surface; a *sinus* communicates with a single body surface, either the skin or pharynx; and a *fistula* communicates with two body surfaces. A cystic dilation of the tract may be associated with either a sinus or a fistula. The terms *branchial cleft* and *branchial pouch* often are used interchangeably, although they refer to distinct structures. Occasionally, *groove* is used instead of *pouch* or *cleft*.

Abnormalities of First Branchial Cleft

Aberrant development of the first branchial cleft may lead to the formation of a cervical cyst or sinus in the region of the ear. Work[13] and Aronsohn and colleagues[14] emphasized the difference in the embryogenesis of preauricular cysts versus cysts of the first branchial cleft. Preauricular cysts or pits occur anterior to the external auditory canal, usually superior to the region of the tragus. In essence, they are inclusion cysts related to fusion of the ectodermal hillocks from the first and second branchial arches during formation of the auricle.[15]

By contrast, true first branchial cleft abnormalities are duplications of the membranous part of the external auditory canal, and they manifest clinically as cysts, sinuses, or fistulas. Work[13] has classified these into two types: type I, of ectodermal origin, involving only the membranous part of the canal; and type II, involving both ectoderm and mesoderm, in which duplication of cartilage also is a feature. As cystic masses or sinus tracts they may involve the parotid gland and cranial nerve VII (this particularly true of type II) or lie inferior to the ear, in the superior neck.

Abnormalities of Second through Fourth Branchial Clefts and Pouches

During closure of the cervical sinus lying between the second branchial arch and the epipericardial ridge, ectoderm may become trapped, resulting in an inclusion cyst at a later time (see Figs. 181-12 and 181-13). These are the more familiar branchial cleft cysts or sinuses, which lie on the lateral neck anterior to the sternocleidomastoid muscle. As such, they may overlie the carotid or muscular triangles of the neck. The fistulous forms of these abnormalities are surgically challenging because they may extend from the superficial area of the neck near the clavicle, superiorly, to the bed of the palatine tonsil. The course of the tract through the deep part of the neck usually lies between the internal and external carotid arteries. The pathway of this tract is easily explained on an embryologic basis. The medial wall of the cervical sinus is the region of closing plates 2 to 4 (see Fig. 181-12). A fistulous pathway breaking through into the pharynx will penetrate one of these closing plates and thereby enter either into the tonsillar bed (the second), the thyrohyoid membrane (third), or pyriform sinus or cricothyroid membrane (fourth).

Third branchial cleft sinuses, which communicate with the pharynx, travel deep to the carotid artery system in their superior extent. Thymopharyngeal cysts represent third branchial cleft remnants. As congenital cystic lesions of the neck, these are easily confused with lymphatic malformations. Remnants of the fourth branchial pouch, or pyriform sinus fistulas, may manifest as recurrent suppurative thyroiditis and usually are located on the left side.[16,17] These lesions may be associated with parathyroid, thymic, or thyroid tissue.

Isolated branchial arch remnants may manifest as subcutaneous cartilaginous tags along the anterior border of the sternocleidomastoid muscle.

Midline Lesions of the Neck

Thyroglossal duct cysts and dermoids are the most common midline lesions of the neck in children. These often are difficult to recognize clinically. The thyroglossal duct cyst derives from persistence of the embryonic thyroglossal duct, anywhere between the foramen cecum and the thyroid gland. Because of the attachments to the base of tongue, thyroglossal duct remnants will move superiorly in the neck when the patient protrudes the tongue. The thyroglossal duct remnant may contain ectopic thyroid tissue. Occasionally the cyst contains all of the functioning thyroid tissue. Because of the potential for permanent hypothyroidism after surgical excision, many investigators advocate routine preoperative assessment of the thyroid.[18,19] Ultrasound examination of the neck provides information regarding consistency of the cystic lesion and also can be used to assess for the presence of thyroid tissue in its normal position lower in the neck. Ultrasound examination is easily tolerated by children but does not give functional information. Radionuclide thyroid scans provide functional information regarding thyroid tissue (e.g., the possibility of malignancy within these lesions). Surgical excision is the treatment of choice. Thyroglossal duct remnants often involve the central part of the hyoid, necessitating removal of the midportion of the hyoid to minimize the risk of recurrence.[20]

Another midline developmental abnormality of the neck is the midline cleft. The clinical presentation varies, ranging from an area of subcutaneous absence of midline tissue, manifesting as a bluish area in the midline of the neck, to a midline vertical band. The vertical band becomes more restrictive with growth of the child and may interfere with mandibular excursion. Treatment involves excision of the band and Z-plasty.

Summary

The otolaryngologist–head and neck surgeon must be familiar with the developmental anatomy of the neck. A working knowledge of neck anatomy and embryology is critical in diagnosing and treating patients effectively.

CHAPTER ONE HUNDRED AND EIGHTY-TWO

Anesthesia in Pediatric Otolaryngology

Veronica C. Swanson

Heike Gries

Jeffrey Koh

Key Points

- When anesthetic risk is correlated with age, children younger than 1 month of age are at the highest risk for adverse events during the procedure. The greatest improvements in patient safety have been in reducing the frequency of respiratory events. Elective procedures should be deferred until after the age of 6 months, when appropriate.
- The anesthetic plan is tailored to the patient's age—for physiologic differences as well as differences in psychological development.
- Preoperative preparation that includes patient education leads to greater satisfaction with the overall hospital experience for both child and parent.
- Routes of premedication and induction of anesthesia include oral, intranasal, intramuscular, intravenous, and inhalational.
- Decisions regarding deep versus awake extubation require careful consideration of clinical factors: Awake extubation is always the appropriate choice in patients who have difficult airway anatomy or full stomach physiology.
- Postoperative nausea and vomiting are best treated with multimodal therapy; a second dose of antiemetic agent in the same class of drug already given is rarely effective.
- Effective pain assessment and management are mandated by The Joint Commission for institutions to receive accreditation.
- Multimodal therapy for pain relief, with or without opioids, is now accepted as a more balanced approach to pain management in surgical patients. Such therapy aims to decrease the dose of any single agent, thereby improving antinociception and reducing side effects.
- Anesthetizing patients in locations outside the operating room minimizes interference with surgical needs and contributes to efficient delivery of care.
- Medical conditions with particular impact on aesthetic implications include upper respiratory infections, asthma, cystic fibrosis, diabetes mellitus, and congenital heart disease.
- The 2007 American Heart Association guidelines for the prevention of infective endocarditis in patients with congenital heart disease seek to minimize unnecessary exposure to antibiotics using evidence-based practices.
- Management of patients for bronchoscopy, adenotonsillectomy, and laryngeal surgery requires careful planning preoperatively and clear communication between surgeon and anesthesiologist throughout the procedure.

Because of the inherent complexity of the structure-function relationship in otolaryngology, pediatric otolaryngologists and anesthesiologists must work together closely in the operating room to provide optimal care to the patient. This chapter focuses on anesthesia topics that are relevant for the pediatric otolaryngologist, beginning with the safety of anesthesia for children, followed by preoperative assessment of pediatric patients. Perioperative management, including choice of drug and technique to match the situational demands, is described next. Finally, the anesthetic implications of specific diseases and the anesthetic considerations in commonly performed pediatric otolaryngology procedures are reviewed.

Anesthesia for Children

Anesthesia carries increased risk in children as compared with adults, as reported more than 50 years ago.[1] Work from the 1960s correlated this increased risk with age less than 1 year.[2] Nowadays children younger than 1 month of age are recognized as being at the highest risk,[3] which suggests that the risk of adverse events with anesthesia induction in infants is inversely proportional to age. In view of the physiologic changes that occur during the first year of life, this is not surprising. Respiratory control is immature in infants; carbon dioxide (CO_2) response curve is lower than it is in older children and adults, and hypoxia may induce apnea rather than hyperventilation.

Box 182-1

Intraoperative Monitoring Standards

Continuous presence of qualified anesthesia personnel in the operating room

Continuous evaluation of the following:

- Oxygenation
- Inspired oxygen concentration with an oxygen analyzer
- Blood oxygenation with a pulse oximeter
- Ventilation

Qualitative assessment, including chest excursion, observation of the reservoir bag, and auscultation of breath sounds

Quantitative assessment with end-tidal CO_2 analysis

A low-pressure disconnect alarm when mechanical ventilation is used

Circulation

Continuous electrocardiogram

Arterial blood pressure at least every 5 minutes

At least one of the following:

- Palpation of pulse
- Auscultation of heart sounds
- Intra-arterial blood pressure monitoring
- Ultrasound peripheral pulse monitoring
- Pulse plethysmography

Body temperature

Cardiovascular responses also are immature: The myocardium is poorly compliant, so cardiac output is rate dependent. Similarly, responses to anesthetic agents differ in accordance with patient age. Preterm and full-term newborns require lower concentrations of inhaled anesthetics than those needed in older children or adults. Inhalational agents may cause more depression of cardiac output in infants and may have a more profound effect on baroreflexes. Pharmacokinetic parameters of volume of distribution, hepatic clearance, and renal clearance differ profoundly from those in older children, affecting the dose of nearly every drug.

These differences in physiology and pharmacology are reflected in the types of anesthetic mishaps that tend to occur in newborns and infants. Inadequate ventilation and anesthetic overdose have been the most frequent sources of anesthetic morbidity and mortality in the 1980s.[4] Changes in anesthetic practice, such as improvement in monitoring (e.g., pulse oximeters and CO_2 monitors) and use of different drugs (e.g., sevoflurane instead of halothane) have decreased respiratory events and shifted the number of anesthesia-related cardiac arrests in infants toward cardiovascular causes of cardiac arrest.[5,6]

Adherence to the American Society of Anesthesiologists (ASA) monitoring standards[7] is basic to all anesthesia care performed by an anesthetist and has reduced the incidence of intraoperative complications.[8] The components of these standards are presented in Box 182-1. Most anesthesiologists consider pulse oximetry to be an indispensable part of the intraoperative monitoring armamentarium, although it has been difficult to document improvement in outcome as a result of this technique, even in a very large series.[9,10] The use of pulse oximetry alone or in combination with capnography has reduced the relative frequency of adverse respiratory events as compared with adverse cardiovascular events, perhaps because pulse oximetry and capnography are more effective for preventing respiratory events than cardiovascular events.[11]

Elective procedures should be deferred until the infant is at least 6 months to 1 year old, when anesthetic risk is likely to be lower. This is particularly true in infants who were born prematurely, because they have an increased risk of postoperative apnea until approximately 55 weeks of postconceptual age (see following). The use of trained subspecialty pediatric anesthesiologists for the care of infants and children has been suggested to be associated with improved outcomes,[12] although this contentious claim is difficult to prove.[13] More recent concern has been raised about the potential for neuronal damage in the developing brain caused by anesthetic agents. The available data are still preliminary, and no definitive human studies proving this concept have been performed. The United States Food and Drug Administration (FDA) recently launched the first phase of SAFEKIDS (Safety of Key Inhaled and Intravenous Drugs in Pediatrics), an initiative to provide seed funding for several clinical projects.[13a] Pediatric practitioners should be aware that more information probably will be presented in the coming years and may influence decisions about what age is safe to perform elective procedures.[14]

Current estimates of anesthetic mortality vary widely, depending on the definition of anesthetic death. However, mortality in healthy pediatric outpatients as the result of an anesthetic-related cause is very rare, with rates perhaps as low as 0.36 in 10,000 cases.[6,15] Accordingly, parents of otherwise healthy children can be reassured that outcomes in modern-day pediatric anesthesia are excellent.

Preoperative Assessment

Today's emphasis on cost containment has forced many changes in the practice of pediatric anesthesia. More and more patients with complex medical problems are having procedures as outpatients, which forces the preoperative contact between the anesthesiologist and the patients and family into a very few minutes. In addition, efficiency pressures have forced institutions to search for ways to maximize patient flow in surgery areas and to minimize unexpected delays or cancellations. Preoperative anesthesia clinics have developed in response to these changes.

A visit to the preanesthesia clinic before the day of surgery affords the opportunity for taking an anesthetic history; performing a physical examination; obtaining necessary laboratory tests; and informing the family about the anticipated procedures, including times for restriction of oral intake to nothing by mouth (i.e., NPO [*nil per os*]) status), premedication, anesthetic induction and maintenance, and postoperative pain management techniques. It also allows confirmation that all necessary paperwork, such as consent and surgical history and physical, is present in the medical record. An attending anesthesiologist is available for consultation for more complicated cases or to address specific clinical questions. Anesthetic risk can be discussed with patients and their families, with ample time allowed for them to ask questions. In addition, the clinic nurse can take this opportunity to educate the patient and family about the impending surgical visit and to identify fears and concerns of the parents and child.

A preoperative medical assessment includes a review of body systems and the patient's response to previous anesthetics, current medications, allergies, recent illnesses (including upper respiratory infections), and family history of problems with anesthesia. The physical examination concentrates on airway anatomy, including the mouth, jaw, teeth, and neck, and includes chest and heart auscultation to confirm the absence of significant cardiorespiratory disease. Laboratory tests are obtained as indicated by the child's condition and type of surgery planned, rather than as a routine component of the assessment.[16] Identification of clinical problems at a preanesthesia visit also allows appropriate evaluation or referral before surgery, thereby avoiding delay or cancellation on the day of surgery.

Preparation for Anesthesia

Behavioral Preparation

The days and hours leading up to surgery can be an anxious time for both children and parents. Fears about hospitalization are common among children, including fear of separation, pain, loss of control, and even death. Many of these fears are dependent on the child's age[17] (Table 182-1). Awareness of these developmental stages allows the anesthesiologist to better anticipate the needs of most children. In addition, understanding the impact of parental anxiety on a child's anxiety can help in the selection of interventions that will be helpful to both the child and the parents.

Details of the anesthetic and surgical experience should be presented in age-specific language for children of appropriate age.[18] Children who are given specific information before surgery have been shown to be less anxious than children who are given only general information.[19] Movies or videotapes can help children and parents cope with

Table 182-1

Age-Specific Concerns of Children

Age	Specific Concerns
Infant (6-18 months)	Separation anxiety
Toddler (1-2 years)	Fear of strangers, loss of mastery of the environment
Preschool (2-5 years)	Separation anxiety; difficulty distinguishing reality from fantasy; fear of pain, mutilation
School age (6-12 years)	Fear of the unknown, pain, mutilation, loss of control, autonomy
Adolescent (13-18 years)	Precarious sense of self; fear of pain, mutilation, loss of control, autonomy

From Orr RJ, Lynn AM. *Curr Rev Clin Anesth*. 1991;12:29.

the mysteries of hospital routines.[20] Comprehensive preoperative preparation programs have been shown to be helpful for reducing preoperative anxiety and enhancing coping behavior in children.[21] This may be especially important for children who will require repeated procedures, allowing them to learn coping strategies and to develop a better understanding of the environment in which they will receive their care. Parents also should be involved in these programs, because decreasing their anxiety is likely to provide the added benefit of decreasing the child's anxiety further.[22] These efforts are important even if pharmacologic agents will be used to decrease anxiety, because the combination of psychological and pharmacologic interventions can produce synergistic effects.[23]

Premedication

The choice of premedication is based on the age and specific needs of the patient. The usual goals of premedication are to reduce anxiety and to ease separation from parents. Because most children fear needles, the oral administration of sedatives has become the standard of care at many institutions. Children who are younger than 8 months of age generally do not need premedication and separate easily from their parents. Children between 8 months and 8 years of age often experience enough preoperative anxiety that preoperative medication may be helpful. Midazolam (0.5 to 1.0 mg/kg up to a maximum of 20 mg), mixed in flavored syrup and administered orally 10 to 20 minutes beforehand, usually smoothes the separation from the parents and induction of anesthesia, and has become the most popular agent for preoperative sedation for children.[24] Midazolam usually is well tolerated, although a rare decrease in oxygen saturation or blood pressure may be observed. In addition, intravenous flumazenil (10 µg/kg, administered over 1 minute, repeated as needed for a total of 5 doses; maximum 0.2 mg/dose, and 1 mg total dose) can be administered to reverse adverse effects such as oversedation, paradoxical effect, or emergence delirium.

Older children may be willing to have an intravenous line started preoperatively, especially if a topical anesthetic cream such as EMLA (eutectic mixture of local anesthetics) or ELA-Max (Ferndale Laboratories, Ferndale, Michigan) is used. EMLA cream is a mixture of lidocaine and prilocaine that penetrates intact skin and, when applied for 60 minutes or more, significantly decreases the pain associated with an intravenous insertion.[25,26] EMLA should be used with caution in children younger than 3 months of age or in children who are receiving other medications that may induce methemoglobin because of the risk of methemoglobinemia.[27] Plasma concentrations of lidocaine and prilocaine achieved with topical application are well below the toxic level,[27] but they may be higher in children with traumatized or inflamed skin. Another effect of EMLA that may be problematic is vasoconstrictive blanching, which makes the identification of potential intravenous insertion sites difficult for some practitioners. ELA-Max is an alternative to EMLA, and it contains only lidocaine in a liposomal matrix that allows for effective absorption across intact skin.[28] ELA-Max has been shown to provide equal topical anesthesia to EMLA, and it has a quicker onset of 30 minutes.[8,29] ELA-Max also produces less blanching than that seen with EMLA. If an intravenous line is placed, midazolam or another sedative can be titrated intravenously until the desired effect is achieved. Although the topical anesthetic creams are the most frequently used, alternative methods for providing topical anesthesia may be standard in some institutions.

Younger children may not accept oral premedication well, making this method of administration as anxiety-provoking as separating the child from his or her parents without any premedication. Alternative methods do exist. Intranasal administration of midazolam (0.2 to 0.3 mg/kg) using either an atomizer or simply a needle-less tuberculin syringe is easy in a patient small enough to be held or restrained.[30] This agent begins acting immediately after dosing and reaches peak concentrations by 14 minutes, having the advantage of increased bioavailability with minimal first-pass metabolism in the liver.[31] Intramuscular administration of premedication becomes necessary in larger children with behavioral issues that limit patient cooperation—autism, for instance. Because intramuscular injection is technically easier than intravenous line placement, this technique can be achieved quickly, and the child then be allowed some time with the parent, to minimize the trauma from the encounter. Intramuscular ketamine at a dose of 2 to 5 mg/kg or a combination of intramuscular ketamine and midazolam causes sedation and dissociation from the environment, making the patient more approachable for procedures, anesthesia induction, and so on. Larger doses of ketamine administered intramuscularly (up to 10 mg/kg) can induce general anesthesia (see following discussion). Anticholinergic agents may be desirable when copious airway secretions (commonly seen with ketamine) are a concern, or when vagal tone from airway manipulation produces decreases in heart rate and cardiac output. Halothane, an inhalation agent used only in a few countries outside of the United States, is more likely to cause bradycardia and a significant reduction in cardiac output in children younger than 6 months of age, than in in older children. The routine use of anticholinergic agents with halothane in these younger patients can prevent these changes.[32] Atropine (0.02 mg/kg) or glycopyrrolate (0.01 mg/kg) given intravenously at the time of induction can obviate the pain of an intramuscular injection.

Nothing-by-Mouth Orders

To minimize the risk of the aspiration of gastric contents during the induction of anesthesia, an adequate period of fasting must be maintained. Traditionally, both food and fluids have been withheld after the midnight before surgery. However, a prolonged period of fasting is uncomfortable for children, is unpleasant for the family, and risks hypovolemia. It has recently been recognized that the administration of clear liquids to children up to 2 to 3 hours before induction does not increase gastric residual volume or acidity as compared with a more prolonged fast.[33,34] In addition, morbidity and mortality rates for aspiration of gastric contents in children are exceedingly low.[35] Thus, fasting guidelines have been liberalized in recent years, and they are shown in Table 182-2. There is some debate about whether breast milk should be considered a solid or clear liquid, with many institutions allowing breastfeeding within the same guidelines as clear liquids. Nevertheless, in giving these instructions to parents, it is important to emphasize the safety issues involved to maximize compliance and avoid unnecessary delays in the start of the procedure.

Anesthetic Induction

Anesthesia can be induced by mask inhalation of a potent anesthetic agent in oxygen with or without nitrous oxide (inhalation induction), by injection of a sedative-hypnotic agent through an intravenous catheter (intravenous induction), or by intramuscular injection. As much as possible, the choice of technique is given to children; younger children tend to fear needles and prefer an inhalation induction, whereas

Table 182-2

Recommended Preoperative Fasting Guidelines for Children

Ingested Material	Minimum Fasting Period (hours)
Clear liquids	2
Breast milk	4
Infant formula	6
Light meal*	6

*A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time.
Adapted from Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: a report by the American Society of Anesthesiologists Task Force on Preoperative Fasting. *Anesthesiology*. 1999;90:896-905.

older children and teenagers usually accept an intravenous induction. Inhalation induction will take longer in teen aged and older patients than in younger patients because of age-related physiologic differences. This prolonged time to effect must be taken into consideration if an inhalation induction is selected in this age group but does not preclude such an induction. Certain clinical factors (e.g., obesity, severe gastroesophageal reflux, full stomach) also may influence the choice of induction technique toward intravenous.

Parental Presence

With increasing frequency, parents are expressing a desire to be present at the time of their child's anesthetic induction.[36] Although parents' motives vary, most hope that the child's anxiety will be lessened by the emotional comfort of their presence. Some hospitals have induction areas outside of the sterile envelope of the operating room. If not, parents can be dressed in cover gowns and escorted into and out of the operating room for the induction.

Studies examining the impact of parental presence have had variable results, with some showing no significant impact,[37] some showing a decrease in patient anxiety,[38,39] and others showing an increase in patient anxiety.[40] Parents with a high anxiety level seem to have a negative impact on their child, whereas calm parents seem to have a positive impact on their anxious child during induction.[41] One survey reported that a majority of anesthesiologists are in favor of the practice of having parents present during induction,[42] and many hospitals tend to support this request as a mechanism to improve patient and parent satisfaction. Thus, it is likely that the trend will continue. Parents should be thoroughly educated about what to expect and how they can best help their child. They must agree to leave the induction area immediately when instructed to do so, and one member of the care team must be identified to help them during the induction. Highly anxious parents should be encouraged not to participate.

Inhalation Induction

For many years, halothane was the agent of choice for inhalation induction because of its lack of pungency relative to other agents. A more recently developed alternative, sevoflurane, is even less pungent than halothane and has fewer cardiovascular side effects, making it the current pediatric inhalational induction agent of choice. A small amount of favorably scented liquid (e.g., bubble gum flavor, for instance) applied to the inside of the mask disguises the odor of the anesthetic agent and improves the patient's acceptance of the technique.

Many anesthesiologists will begin the induction with the patient breathing 50% to 70% nitrous oxide (which is odorless) before introducing sevoflurane, thus making the addition of the sevoflurane less distressing. Noise in the room should be kept to a minimum during anesthesia induction, and the anesthesiologist often tells the child an entertaining story to direct the child's thoughts away from the reality of the situation. As the concentration of the anesthetic agent is increased, most children lose consciousness in less than 1 minute. The parents, if present, can be ushered out at this point, and an intravenous catheter can then be placed.

Intravenous Induction

Intravenous induction requires the presence of an intravenous catheter and thus is reserved for older children or teenagers, children with a preexisting intravenous catheter, children who need a rapid-sequence induction because of a full stomach, or children who object to an inhalation induction. Owing to slower uptake of inhaled anesthetic agents, inhalational induction takes much longer in older, heavier children, with consequently higher risk for laryngospasm and bronchospasm. An intavenous induction is therefore also the preferable method in this patient group.

The most common agent for intravenous induction is propofol, an alkylphenol that is formulated as a 1% solution in a white soybean oil, egg lecithin, and glycerol emulsion. Propofol is highly lipophilic and rapidly redistributes throughout body compartments, with a distribution half-life of approximately 2 minutes and an elimination half-life of approximately 30 minutes. The dose for the induction of anesthesia varies with age[43]: Infants 1 to 6 months of age require approximately 3 mg/kg, whereas older children require approximately 2.5 mg/kg. The major advantages of propofol are a rapid, clear-headed recovery with minimal associated nausea and vomiting. This has made it the intravenous induction agent of choice for outpatient procedures. The major disadvantage is pain on injection, particularly into small veins.[44] Lidocaine (0.5 to 1.0 mg/kg) administered intravenously before or during propofol injection may decrease the incidence of pain. Propofol may cause hypotension, apnea, and desaturation. Propofol also can be used for anesthesia maintenance as an intravenous infusion of 100 to 200 µg/kg per minute. This technique can be very useful for patients who have a history of severe postoperative nausea or who are undergoing procedures in which postoperative nausea is especially common (e.g., tympanoplasty). Many pediatric anesthesiologists use a propofol infusion to provide anesthesia during bronchoscopy, because it provides a reliable, stable method of administering anesthesia with spontaneous ventilation while sharing the airway and decreases the exposure of the surgeon to unscavenged anesthetic gases.

An alternative intravenous agent for induction is thiopental, an ultrashort-acting barbiturate that produces sleep in healthy, unpremedicated children; a dose of 4 to 6 mg/kg induces sedation within 1 minute of administration.[45] This drug can produce hypotension through both vasodilating effects and direct myocardial depression and must be used with caution in hypovolemic patients or patients with poor myocardial contractility. It also can produce prolonged sedation as a consequence of accumulation in fat stores if higher doses or repeated doses are given.

Rapid-Sequence Induction

Patients with a full stomach are at increased risk for the aspiration of stomach contents during the induction of anesthesia. Patients who require full stomach precautions include those who have not fasted for an adequate period, those with gastrointestinal obstruction, trauma patients whose gastric motility is depressed, or those who are at a mechanical predisposition for aspiration (e.g., patients with ascites). It is mandatory that these patients have an intravenous induction. Patients are preoxygenated with 100% oxygen by mask and then given an induction dose of a hypnotic and a rapid-acting muscle relaxant—either succinylcholine (2 mg/kg) or rocuronium (1.2 mg/kg). Application of manual pressure over the cricoid (known as the Sellick maneuver) can be performed in an attempt to seal the esophagus and to prevent passive regurgitation.[46] Pressure is not released until the endotracheal tube is in place, proper position is confirmed, and the cuff, if necessary, is inflated. At the end of the procedure, these patients should be allowed to emerge completely before extubation, to ensure adequate airway protection.

Intramuscular Induction

Ketamine is a derivative of phencyclidine with potent analgesic and amnestic properties. Anesthetic induction can be achieved with the recommended dose of 1 to 3 mg/kg intravenously or 5 to 10 mg/kg intramuscularly. As noted previously, ketamine is very useful as an intramuscular induction agent in children who are combative or unable to cooperate with a standard inhalation or intravenous induction, often because of intellectual disabilities and behavioral disorders. Ketamine is an excellent choice for anesthetic induction in hypovolemic patients because of its sympathomimetic properties; it rarely causes hypotension in these patients. Ketamine may be the intravenous induction agent of choice in patients with reactive airways[47] because it increases circulating catecholamines and causes the relaxation of tracheal, bronchial, and alveolar smooth muscle.

Ketamine tends to produce copious secretions and should be accompanied by the administration of atropine or glycopyrrolate. Nystagmus and diplopia are common side effects and will resolve as the drug is cleared from the patient's circulation. Intraoperative and postoperative dreams and hallucinations have been reported,[48] more often in older than in younger children, and less often when other sedative-hypnotic agents are used in conjunction with ketamine. If this agent is given preoperatively with the parents still present, they should be informed to expect these side effects.

Anesthesia Maintenance

Inhalational Agents

Nitrous Oxide

Nitrous oxide is a widely used inhalational induction agent in children. Its popularity is a result of its low solubility, which results in rapid uptake and distribution. Nitrous oxide also is odorless and does not cause cardiovascular depression. Although nitrous oxide allows the delivery of lower concentrations of other anesthetic agents, nitrous oxide itself is not a very potent anesthetic agent. Consequently, it must be delivered in high concentration to have an analgesic and hypnotic effect, thereby limiting the concentration of oxygen that can be delivered; it is not useful for patients who require high concentrations of oxygen and should be avoided in patients with pulmonary hypertension as it may aggravate it. Because of the lack of potency and the controversial increased incidence of postoperative nausea and vomiting (PONV), it has been used less and less for anesthesia maintenance. A 34-fold difference has been noted in the blood-gas coefficients of nitrogen (0.013) and nitrous oxide (0.46); thus, nitrous oxide will enter air-filled cavities faster than nitrogen can leave. In a fixed cavity such as the middle ear, the result is an increase in pressure. During tympanoplasty, the middle ear pressure generated by nitrous oxide can lift off the tympanic membrane graft. Therefore, nitrous oxide usually is avoided entirely during those procedures.[49] Nitrous oxide use also may present a hazard for patients with previous reconstructive middle ear surgery.[50]

Sevoflurane

Sevoflurane has completely taken the place of halothane in pediatric institutions in the United States. It is a valuable addition to the anesthesiologist's armamentarium for several reasons. First, it is less pungent than halothane, and it is even better tolerated during inhalation induction. Second, it has a blood-gas partition coefficient similar to that of nitrous oxide, so induction and emergence times are shorter than with halothane. Third, it has fewer cardiovascular effects than halothane.

Sevoflurane has several disadvantages: Its offset is so rapid that without adjunctive administration of narcotics, the perception of and response to pain may be accentuated.[51] There are reports in the literature of a significant incidence of emergence excitement associated with cases in which sevoflurane was used.[52] For these reasons, sevoflurane has assumed a role as an induction agent and a maintenance agent for very short procedures, but it often is replaced by isoflurane or desflurane after induction, depending on case type and anesthesiologist preference. Like all halogenated inhalational agents, it is a potential trigger agent for malignant hyperthermia and should be avoided in susceptible patients.

Isoflurane

Isoflurane has been used for many years as a standard maintenance inhalational agent for children and adults. In practice, it offers no clear advantage for the pediatric otolaryngology patient. It is more pungent and not nearly as well accepted by children during inhalation induction as sevoflurane. Isoflurane does increase rather than decrease heart rate. It also causes decreases in blood pressure, but unlike with halothane, the mechanism is peripheral vasodilation rather than direct myocardial depression.[53]

Desflurane

Desflurane is the newest inhalational agent to be introduced into clinical practice. Its principal advantage is its quicker time to recovery as compared with sevoflurane.[51] It appears to be well tolerated as a maintenance anesthetic, because it provides stable hemodynamics and respiratory parameters during its use. Similar to sevoflurane, desflurane has been associated with increased agitation and emergence delirium.[44] However, this effect does not seem to occur frequently enough to avoid its use in children.

Desflurane does have an irritant effect on the airway, making it contraindicated for inhalational induction or for use during airway procedures such as bronchoscopy. However, many centers have adopted a practice of inducing anesthesia with sevoflurane and then switching to desflurane to take advantage of its quick recovery time while avoiding its airway effects during induction. It also has been suggested that this agent may be particularly useful in neonates and formerly premature babies, in whom residual anesthesia effects may increase the risk of apnea postoperatively.[54]

Intravenous Agents

Opioids

Fentanyl

Fentanyl is the most commonly used supplement to anesthesia in children. Although the usual intravenous dose is 1 to 2 µg/kg, doses in excess of 100 µg/kg have been given to cardiac surgery patients with minimal cardiovascular depression.[55] An initial peripheral vasodilation occurs, but tachyphylaxis to this side effect occurs with additional dosing. Preterm and full-term newborns have variable and prolonged clearance, probably related to reduced hepatic blood flow.[56] In addition, they are extremely sensitive to the effects of fentanyl on chest wall rigidity. In neonatal patients who are not intubated, fentanyl should be given only in small increments.

The effect of low-dose fentanyl is terminated largely by redistribution, thereby resulting in a rapid reduction in clinical effect. Because fentanyl is highly lipophilic, however, higher or repeated doses result in drug accumulation. Clearance then becomes dependent on metabolism,[57] and the clinical effect, including respiratory depression, may last for hours. Chest wall rigidity has been reported after rapid fentanyl administration, although the etiology of this problem is unclear. Bradycardia may occur as a result of increased vagal tone, especially when given with other agents that may have a similar effect.

Morphine Sulfate

Overall, morphine is the most frequently used opioid in children. It can be used in the operating room to supplement inhalational agents and to provide postoperative analgesia. The usual intravenous dose is 0.05 to 0.1 mg/kg as part of a balanced anesthetic technique, although higher doses may be used for a narcotic-based technique. The dose may need to be reduced in critically ill children or young infants. The half-life after intravenous administration is approximately 3 hours in older children but is significantly longer in infants as a result of diminished clearance.[58] The major side effect is respiratory depression, which results in diminished minute ventilation, with a greater effect on respiratory rate than tidal volume. Many believe that newborns are at higher risk than older children for respiratory depression, although it is unclear whether this reflects a difference in pharmacokinetics or pharmacodynamics. Infusions of morphine at rates of 10 to 30 µg/kg per hour have been described in small infants without significant respiratory depres-

sion.[59] Appropriate monitoring for apnea should occur in premature infants and those neonates with a history of apnea and bradycardia. Histamine release is also common with the administration of morphine, and it most commonly results in a localized or generalized rash. Bronchospasm and hypotension have been reported, but they are much less common.

Hydromorphone

Hydromorphone has become a commonly used alternative to morphine. It is approximately five to seven times more potent than morphine, with the usual intravenous dose ranging from 0.015 to 0.02 mg/kg. Its half-life is similar to that of morphine, and it has a similar duration of action. Hydromorphone may be useful in patients with renal failure, because its metabolic by-products are less active than morphine's are. In addition, hydromorphone may be a good alternative for those patients who suffer side effects (e.g., itching, nausea, hallucinations) with morphine. As with other opioids, respiratory depression is the most concerning side effect, but it is rare with appropriate dosing.

Meperidine

The use of meperidine has dramatically decreased due to its unique side effect profile and the availability of equianalgesic alternatives. The principal metabolite of meperidine is normeperidine, a compound that can cause neurologic excitation manifested as tremors, irritability, or seizures. This side effect is especially pronounced with prolonged use or in patients with hepatic or renal dysfunction. Meperidine's superiority over other opioid agonists in the treatment of postoperative shivering probably is related to its kappa receptor activity and the one reason that it has not become entirely obsolete.

Alfentanil

As a short-acting analog of fentanyl, alfentanil commonly is used for short outpatient procedures. It is approximately one-fourth as potent as fentanyl and has one-third the duration of action. It has a very fast onset of action (1 minute) and a short elimination half-time (1.5 hours). It is less lipophilic than fentanyl, and the dose range is 10 to 20 μg/kg, given intravenously. Renal failure does not alter the clearance of alfentanil. Besides the opioid-related side effects, thorax rigidity and bradycardia may be seen.

Remifentanil

Remifentanil has the same analgesic potency as that of fentanyl. The key feature of remifentanil is the ester side chain hydrolysis by blood and tissue esterases, resulting in rapid metabolism (elimination half-time is 10 to 20 minutes). This results in zero order kinetics, meaning that its offset of action is 10 to 20 minutes after discontinuation of the infusion, regardless of the duration of the infusion. Said differently, it does not accumulate. It does have a rapid onset, and because of its short duration of action, it usually needs to be administered as an continuous intravenous infusion at the rate of 0.05 to 1 μg/kg/min for neonates and up to 2 μg/kg/min for older children. Pharmacokinetic parameters of remifentanil are unchanged by hepatic or renal disease. Disadvantages are the high cost and the lack of postoperative analgesia, which can be overcome with application of longer-acting opioids at the end of surgery.

Muscle Relaxants

Succinylcholine

Succinylcholine is the only depolarizing muscle relaxant. With the advent of intermediate-acting nondepolarizing relaxants, the use of succinylcholine for routine surgical procedures is declining, primarily as a result of side effects that relate to its depolarizing mode of action (see later). However, it remains the most rapid-acting of all muscle relaxants, and it is still indicated for use in rapid-sequence inductions and in the treatment of laryngospasm. Intravenous administration of 1.5 to 2.0 mg/kg achieves 95% twitch depression in 40 seconds,[60] resulting in excellent intubating conditions. Succinylcholine also can be given intramuscularly (4 to 5 mg/kg) if the intravenous route is unavailable, although the clinical effect is delayed in onset, depending on perfusion to the area of deposition.

The side effects of succinylcholine are numerous. Some degree of increase in masseter muscle tone is common and, in some cases, is extreme enough to mimic true trismus.[61] This is an important distinction to make, because as many as 50% of patients with trismus after succinylcholine are biopsy positive for susceptibility to malignant hyperthermia.[62] Succinylcholine can also cause bradycardia as a result of an increase in vagal tone; this effect is especially prominent in younger children and infants. The decline in heart rate usually is transient and, if not, is responsive to intravenous atropine; occasionally, asystole is seen. Hyperkalemia can be seen as a result of depolarization of the myoneural junction; increases of serum potassium of 0.5 mEq/L occur even in normal children.[63] Life-threatening hyperkalemia after succinylcholine administration can occur in children with burns, tetanus, paraplegia, encephalitis, crush injuries, and neuromuscular disease.[63] Myoglobinemia occurs in approximately 40% of children anesthetized with halothane who are given succinylcholine; this effect can be partially attenuated with a previous dose of a nondepolarizing agent to prevent fasciculations. A series of cardiac arrests were reported in boys who were given succinylcholine, with subsequent development of massive muscle breakdown and potassium release. The presumed etiology was previously undiagnosed muscular dystrophies.[64] In 1994, in response to these reports, the manufacturer placed a warning on the package insert cautioning the practitioner about the routine use of succinylcholine. As a result, many pediatric anesthesiologists have abandoned the routine use of succinylcholine except for rapid-sequence inductions and to treat laryngospasm. Succinylcholine may soon be replaced in that role by rocuronium, which has an onset of action of less than a minute, making it suitable for a rapid sequence induction. The disadvantage of rocuronium has been the long time to reversal after an intubating dose has been given. This makes it suboptimal and perhaps contraindicated for patients with a difficult airway. Sugammadex**,** a selective relaxant-binding agent, is in phase 3 trials. If approved, it would make rocuronium rapidly reversible and thereby make the risks of succinylcholine unnecessary. Sugammadex is not yet available for use in the United States.

Of note, 90% of an intravenous dose of succinylcholine is rapidly hydrolyzed in the plasma by pseudocholinesterase. Patients with deficient or reduced levels of pseudocholinesterase exhibit a prolonged effect from succinylcholine.

Nondepolarizing Muscle Relaxants

A variety of nondepolarizing muscle relaxants are available. These agents vary in dose, speed of onset, and duration of action. As shown in Table 182-3, the pharmacologic properties of these drugs may be different in infants from those in older children. The choice generally is based on the duration of the surgical procedure. As noted, rocuronium has been shown to produce good intubating conditions, but with a slightly longer onset of action (less than 1 minute) than with succinylcholine (less than 30 seconds).

Total intravenous anesthesia (TIVA) is a continuous titration of intravenous drugs for maintenance of anesthesia. Drugs used often are a propofol-remifentanyl or propofol-alfentanil combination. This technique provides malignant hyperthermia–safe anesthesia in the malignant hyperthermia–suscepctible patient; it often is used in patients with severe postoperative nausea and vomiting and is also the technique of choice in some airway cases (see later on).

Emergence from Anesthesia

The decision of whether to extubate a patient while he or she is awake or under surgical planes of anesthesia (deep extubation) depends on a number of factors. Deep extubations are smoother and facilitate rapid turnover. Considerations in making this decision include the patient's age, airway anatomy, underlying disease, the presence of blood or secretions in the airway at the time of extubation, the presence of a full stomach preoperatively, the ability of the postanesthesia care unit staff to manage an obstructed airway, and the immediate availability of an individual skilled in reintubation should it be required. Deep extubation is preferred in patients with asthma or in those for whom coughing would be contraindicated. Factors that favor awake extubation include a full stomach at the start of the procedure, age younger than

Table 182-3

Intubation Doses, Onset Times, and Recovery Times for Commonly Used Muscle Relaxants

	Intubating Dose (mg/kg)			
	Adults	Children	Onset Times* (min)	Recovery Times in Infants (min)
Mivacurium	0.3	0.2-0.3	1.5-2	15-20
Atracurium	0.5	0.5	2	40-60
Cisatracurium	0.1	0.1-0.2	2.5	53
Vecuronium	0.07-0.1	0.1	2.4	35
Rocuronium	0.5-1.0	0.6-1.2	1.3	42
Pancuronium	0.1	0.1	2.5	50

*Time to maximal blockade.

6 months, difficult airway anatomy for either masking or intubating, copious blood or secretions in the airway, and a predisposition to apnea. Systematic comparisons of awake versus deep extubation have revealed that patients extubated while awake have lower oxygen saturations (probably because of coughing during emergence), but there is no difference in overall morbidity or mortality.[65,66] Either technique can be performed safely; the anesthesiologist should have both approaches in his or her armamentarium and, using clinical judgment, choose the one that best fits the situation.

Postoperative Management

Nausea and Vomiting

Nausea and vomiting can result in an unpleasant recovery from surgery and anesthesia as well as a delayed discharge from the postanesthesia recovery unit and an increase in overall cost. In the pediatric population, the incidence is variable and depends on the type of surgery, the type of anesthetic used, gender, age, history of motion sickness, and adequacy of hydration.[67] Although the overall incidence is lower in children younger than 2 years of age, children older than 3 years have an average vomiting incidence of more than 40%. Procedures such as tonsillectomy and middle ear surgery may be associated with an incidence of vomiting as high as 70%. The use of narcotics, halogenated inhalational agents, and perhaps nitrous oxide increases the risk of nausea and vomiting. By contrast, propofol reduces the incidence of vomiting as compared with that with halothane in children undergoing adenotonsillectomy.[17]

Therefore, antiemetics often are given prophylactically for children at risk for PONV and a multimodal approach has been shown to be the most effective one.[68] The use of intravenous ondansetron (50 to 100 µg/kg up to 4 mg), intravenous dexamethasone (150 to 500 µg/kg up to 8 mg), and intravenous droperidol (50 to 75 µg/kg up to 1.25 mg) is evidence-based for prophylaxis for patients at risk for PONV and for treatment of patients with PONV.

Serotonin (5-hydroxytryptamine$_3$)-receptor antagonists, such as ondansetron, have shown efficacy and safety in prophylaxis and therapy of PONV, having a greater antivomiting than antinausea effect.[69] When prophylaxis with serotonin receptor antagonist fails, a rescue therapy with serotonin receptor antagonists is not recommended within the first 6 hours of surgery because it confers no additional benefit.[70]

Another drug that has been shown to help control PONV during the 24 hours after surgery is dexamethasone. Children who receive a single intraoperative dose of dexamethasone were two times less likely to vomit during the first 24 hours than children who received placebo. Routine use in four children would be expected to result in posttonsillectomy emesis experienced by one fewer patient. Additionally, children receiving dexamethasone were more likely to advance to a soft to solid diet on posttonsillectomy day 1 than were those children receiving placebo.[71]

Droperidol is an antidopaminergic antiemetic. While effective in the treatment of PONV, its sedating and extrapyramidal side effects should be considered when choosing it.[72] In 2001, the U.S. FDA issued a black box warning against the use of this drug due to concerns of serious cardiac arrhythmias secondary to QT prolongation. Since that time, the restriction has been lifted. However, it has never returned to the prevalent use that was seen prior to the ban. An overwhelming majority of anesthesiologists surveyed (92%) did not consider the ban warranted, as torsades de pointes was seen mostly when the drug was administered in very high doses or when there were confounding factors. Still, prudence would limit its use to cases in which patients do not have underlying cardiac disease, other classes of antiemetics have been exhausted, and the maximum total pediatric dose is less than 100 µg/kg or 2.5 mg total.[73]

Finally, an inexpensive but effective method of reducing the incidence of nausea and vomiting is to withhold oral fluids during the postoperative period until the child asks for them, because forced oral fluids increase the incidence of vomiting and delay discharge.[67,74,75] This can be safely done by generously hydrating the patient with intravenous fluids intraoperatively. Nontraditional treatment methods such as acupressure are being studied and thus far confirm their effectiveness in the prevention of PONV; they are useful adjuncts, especially in view of the total absence of side effects.[76]

Postintubation Croup

In children up to approximately 8 years of age, the subglottis is the narrowest portion of the airway, and it may be the source of postoperative airway obstruction secondary to mucosal swelling. A reduction in the reported incidence of postintubation croup from 1%[77] to 0.1%[78] may be obtained with use of proper-sized, non–tissue-reactive tubes that allow an air leak around the tube at 25 cm H_2O or less.

Racemic epinephrine (0.5 mL of 2.25% in 2.5 to 3.0 mL of normal saline for children weighing 15 kg or more) nebulized in oxygen is the management of choice for postintubation croup; the effect is thought to result from the vasoconstriction of the subglottic mucosa. (The dose varies, ranging from 0.2 mL for infants weighing less than 5 kg, 0.3 mL for 5- to 10-kg infants, and 0.4 mL for 10- to 15-kg infants.) Because symptoms can recur within 2 to 4 hours, the child should be observed for 4 hours after treatment before being sent home. If frequent and repeated treatments are necessary, hospital admission should be considered. Dexamethasone (0.3 to 0.5 mg/kg) also may be tried,[79] although its effect is slow in onset if it occurs at all.

Pain Management

The theory that children, particularly neonates, perceive pain less acutely and therefore do not need pain medication is no longer accepted.[80] As a result, since the early 1990s there has been a significant change in how pediatric pain is approached. Perhaps the most powerful sign of this change was that the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]) added pain management to its accreditation review in 2000. Areas that now must be addressed by accredited institutions include pain assessment, pain treatment, and education about pain management.[81]

Pain assessment can be challenging in children. Assessing the degree of pain in preverbal children is problematic, although several observational scales have been developed to assist with this population.[82] Children 4 to 8 years of age have been shown to be capable of giving a self-report with simplified tools, and older children can use the same scales as those for adults.[83] Patients in the intensive care unit setting (immediately postoperatively) and cognitively impaired children remain populations to be studied in the area of pain assessment.

Intravenous opioids—whether given by bolus, infusion, or patient-controlled analgesia—are the mainstay of therapy for severe pain.[84] Children 8 years of age and older (and some mature 6- to 7-year-old children) do well with patient-controlled analgesia, tend to use less total drug, and have a better feeling of control than with traditional methods of administration. Younger children requiring intravenous opioids may benefit from administration accomplished using parent- or nurse-controlled analgesia. Appropriate parent education is a necessary prerequisite to parent-controlled analgesia.

Milder degrees of pain can be handled with nonopioid analgesics. Acetaminophen (10 to 15 mg/kg every 4 to 6 hours to a maximum of 4 g every 24 hours), alone or with oxycodone (0.1 to 0.15 mg/kg), is useful for children who can take oral medications. Rectal acetaminophen can also be given, although doses of 20 to 40 mg/kg are necessary to achieve serum levels equivalent to those obtained with 10 to 15 mg/kg given orally.[85] Ketorolac (0.5 mg/kg IM or IV every 6 hours for up to 48 hours) is a nonsteroidal anti-inflammatory agent that has potent analgesic properties; these may be equivalent to those of morphine[86] but without the respiratory depression or nausea associated with opioids. However, ketorolac requires 30 to 45 minutes for onset, has a 12% incidence of nausea, and may be associated with a higher incidence of bleeding because of effects on platelet function.[87] Nonopioid analgesics also are a good adjunct to opioid and other pain medications: multimodal therapy has been shown to be most effective in the treatment of pain, especially in difficult-to-treat cases.

Codeine, often used as a first-line oral opioid, seems to be a weak analgesic. Essentially a prodrug of morphine, it needs to be converted to its active form in the liver. Approximately 10% of the population lack the enzyme CYP2D6 and will not achieve pain relief from codeine. Accordingly, a more rational approach is to use a stronger oral analgesic as a first-line agent, especially after significantly painful procedures. As with all opioids, nausea and vomiting are potential side effects and may be more prevalent with use of codeine.

Sedation and Anesthesia Outside of the Operating Room

Over the past 10 years, an increasing number of procedures have been performed outside of the operating room. Reasons for this development include physician time constraints, reimbursement changes, new technology for procedures that cannot be done in the operating room, and the development of new anesthetic agents. This practice has been recognized to be accompanied by a risk of adverse events potentially greater than that for operating room procedures, as a result of monitoring variation, poor presedation evaluation, inadequate training, and lack of adequate recovery procedures.[88] More recently, a greater degree of scrutiny has been given to the practice of sedation for children outside of the operating room. In an effort to improve safety, the Joint Commission has been instrumental in forcing institutions to develop policies to improve the care of children and adults who are receiving sedation, as part of overall accreditation efforts. In addition, specialty organizations have developed policy statements about this topic.[89-91] In many institutions, this has meant that pediatric anesthesiologists are more directly involved with this activity than in the past.

A large number of procedures that are performed in hospitals may require use of sedation or analgesia, especially in children. Painful procedures (e.g., lumbar puncture, bone marrow biopsy, chest tube placement) are obvious examples. Other procedures, such as magnetic resonance imaging or gastrointestinal endoscopy, also may require sedation or anesthesia because of the distressing nature of one or more aspects of the examination or the need for immobility. In the context of otolaryngology, the most common candidates for out-of-the-operating-room or clinic procedures may be patients requiring the removal of pressure equalization tubes, nasal ciliary biopsy, fine-needle aspiration, or the removal of sutures. One report suggests that these procedures can be performed in the clinic safely and with less cost using intravenous sedation as compared with general anesthesia in the operating room.[92]

In general, a pediatric sedation service oversees sedation or anesthesia for a majority of out-of-the-operating-room procedures performed at our institution. All children scheduled for procedures receive a phone call before their appointment to identify any significant medical problems and to provide NPO instructions. On the day of the procedure, the patient arrives approximately 30 minutes before the planned time of the procedure for application of topical anesthesia cream. A sedation nurse then starts an intravenous line, after which the pediatric anesthesiologist provides intravenous sedation or anesthesia. After the procedure is completed, the sedation nurse oversees the patient's recovery until he or she is ready for discharge. For less invasive procedures in cooperative patients, the sedation nurse may provide conscious sedation with oral, intravenous, or intranasal medications rather than use the method described previously.

Another option is for the otolaryngologist to provide the sedation, often with oral or intravenous midazolam, possibly combined with fentanyl. Even with this type of conscious sedation, practitioners should be aware of their institution's policy about sedation. A preprocedure evaluation should be documented, monitoring should be performed during the procedure and documented, and appropriate recovery procedures should be followed. Documentation of NPO status also may be relevant, depending on the depth of sedation planned.

Medical Conditions with Anesthetic Implications

A number of medical conditions may modify preoperative preparation and intraanesthetic or postanesthetic management.

Upper Respiratory Infection

The decision of whether to anesthetize a child with an upper respiratory infection (URI) is recurrent in pediatric anesthesia. In making this decision, it is helpful to know the risks involved. Deterioration in pulmonary function is typical during a URI, including a decrease in flow rates such as forced expiratory volume in 1 second (FEV_1),[93] a decrease in mucociliary clearance,[94] and an increase in airway reactivity.[95] Resolution of these abnormalities can take up to 6 weeks after the resolution of symptoms.

These changes in pulmonary function have other clinical correlates. McGill and colleagues[96] reported on 11 cases (no denominator) of intraoperative atelectasis identified by chest radiography in children anesthetized within 4 weeks after a URI. Children with a URI may be at increased risk for postoperative desaturation,[97] croup, laryngospasm, airway obstruction, and reactive airway disease. Another prospective study evaluated adverse respiratory events in 1078 children with URIs undergoing elective surgical procedures. This study identified a significantly higher incidence of respiratory events among children with URIs, although none of these events was associated with long-term sequelae. Risk factors associated with adverse events included a history of prematurity, a history of reactive airway disease, parental smoking, and surgery involving the airway.[98,99] Conversely, a prospective study of a series of nonintubated children undergoing myringotomy failed to

show a difference in perioperative complications between asymptomatic children and children with URI symptoms.[100]

Other factors also must be considered. Do the symptoms result from allergy rather than infection? How severe is the URI? A child with fever, cough, malaise, and myalgias may be at higher risk than a child with mild rhinorrhea. How elective is the surgery? How much inconvenience would result for the family from cancellation or postponement? Is an escalation in care likely from proceeding with the surgery at that time? How often is the child symptom-free? In view of the frequency of URIs in some children and the time required for the resolution of pulmonary function abnormalities, it may be difficult to find a disease-free interval.

Frequently, the decision seems to involve more art than science. In equivocal cases, a leukocyte count and a chest radiograph may be helpful.[98] Measurement of hemoglobin saturation in a patient breathing room air may identify some at-risk children, but it is not very sensitive. Unfortunately, no combination of historical features, physical findings, or laboratory tests can identify the child at risk. A discussion of the potential risks and benefits with the parents will allow them to participate in the decision-making process. Good communication between the anesthesiologist and the otolaryngologist is essential for establishing some consistency in approach.

Premature Infants

In the early 1980s, a high incidence of apnea was reported after the administration of general anesthesia during the first few months of life to children who had been born prematurely (at 37 weeks of gestational age or before).[101,102] The risk probably extends to approximately 55 weeks of postconceptual age, with the curve approaching but never reaching a zero percent risk, and is inversely related to both postconceptual and postgestational age and hematocrit.[45]

Although the etiology of apnea is unknown, most episodes are central in origin; however, nearly one third are associated with airway obstruction.[103] Halogenated inhalation anesthetics blunt the ventilatory response to CO_2 and hypoxia, even in subanesthetic concentrations,[29] thereby accentuating preexisting abnormalities of respiratory control that may result in an apneic event. Although apnea has been reported after general, spinal,[104] and caudal[105] anesthesia, one prospective series has suggested that the incidence is lower after regional techniques without adjunctive sedation than after either general or regional anesthesia with intravenous sedation.[106] Administration of caffeine intraoperatively also may lessen the incidence of postoperative apnea.[107]

Elective procedures should be postponed until premature infants reach 55 weeks' postconceptual age, at which time the incidence of apnea is less than 1%.[45] Children at risk for postoperative apnea should have cardiorespiratory and pulse oximetry monitoring for a period of time after surgery. There is some institutional variability in the exact duration of monitoring; however, most will monitor for a period of 4 to 24 hours, depending on the infant's actual postconceptual age, history of apnea, and overall health status.

Asthma

A history of asthma in a child is important to the anesthesiologist, because good preoperative preparation and careful intraoperative anesthetic management can usually prevent serious episodes of bronchospasm. History of severity (e.g., current medication, recent wheezing history, past need for emergency department visits or hospitalization) correlates well with intraoperative risk. For children with a history of frequent asthma attacks, consultation with the child's primary care provider can help ensure that treatment is maximized before surgery. A thorough physical examination that includes chest auscultation is necessary to rule out active bronchospasm. Elective surgery should not be performed in the presence of active wheezing. In a child with active wheezing, pulmonary function testing (especially FEV_1) may be useful for documenting the extent of obstructive disease and the potential for reversal with bronchodilators. Improvement in expiratory flow rates after a trial of bronchodilators suggests that adjustments in bronchodilator therapy before elective surgery may be beneficial.[108] A variety of bronchodilator compounds are available for preoperative and intraoperative use, including β_2-agonists, corticosteroids, and anticholinergics.[108] Nebulized β_2-agonists such as albuterol are the most commonly used agents during the perioperative period because of ease of administration, good efficacy, and low incidence of side effects. Preoperative administration of albuterol may be helpful for decreasing the incidence of intraoperative bronchospasm.

The most common cause of bronchospasm in susceptible patients is instrumentation of the airway under light planes of anesthesia.[109] Both general and regional anesthetic agents can be used to obtund airway reflexes. Lidocaine (1 to 2 mg/kg) can be sprayed into the trachea or given intravenously to prevent reflex-induced bronchospasm.[110] All inhaled halogenated anesthetics prevent or ameliorate bronchospasm by increasing bronchial caliber and pulmonary compliance, decreasing pulmonary resistance, and improving gas exchange during active bronchospasm.[111,112] Ketamine also acts as a bronchodilator and may be useful as an induction agent in patients with active wheezing. Extubation of the trachea while the patient is under surgical planes of anesthesia, followed by a slow, smooth emergence, minimizes the risk of bronchospasm. However, careful attention must be paid to airway patency until the child is awake.

Cystic Fibrosis

Early diagnosis and antibiotic treatment, management of chronic pulmonary disease and malabsorption have improved the health and survival of children with cystic fibrosis (CF); currently, nearly 50% of affected patients are older than 18 years of age.[112a] Pansinusitis develops in more than 90% of children with CF, and nasal polyps in 20%; the latter may require surgery. The child with CF presents a significant challenge to the pediatric anesthesiologist; malnutrition, dehydration, and pulmonary insufficiency are all potential concerns. One series reported that 13% of patients with CF had some anesthetic complication.[113]

Preoperative evaluation of patients with CF is important for minimizing postanesthetic morbidity. The severity of pulmonary disease can be quantitated with historical features (e.g., degree of exercise intolerance, amount of sputum production) and a thorough physical examination (e.g., respiratory rate, work of breathing, quality of breath sounds, skin color). Patients with evidence of significant disease should have oximetry and perhaps arterial blood gas analysis. Electrocardiogram and echocardiogram also should be considered to screen for right ventricular dysfunction (cor pulmonale). If the patient is cooperative, pulmonary function tests may help to quantitate the degree of pulmonary compromise and serve as a baseline to assess the impact of preoperative therapy. Consultation with the pulmonologist caring for the patient also may provide important information about baseline condition and medical therapy.

In patients with significant pulmonary disease, a preoperative "tune-up" may help prevent perioperative complications. A regular program of chest physiotherapy includes chest percussion and postural drainage. Sputum samples are sent for culture and sensitivity, and antibiotic therapy may be indicated. The patient should be well hydrated to avoid inspissation of secretions. Patients not taking oral vitamin K supplements are given enteral vitamin K. If premedication is required, a benzodiazepine can be given with minimal risk of respiratory depression. An anticholinergic can be given if desired; the concern about excessive drying of secretions has not been a significant clinical problem. General anesthesia can be maintained with inhalational agents, because they are potent enough to allow for the administration of high-concentration oxygen, and they provide bronchodilation. The shorter-acting inhalational agents (e.g., sevoflurane) may be of particular benefit because of their shorter recovery time. An endotracheal tube usually is placed to deal with the most commonly reported complications, which include copious secretions, airway irritability, and compromised oxygenation.[103] Ventilation usually is assisted or controlled, to prevent intraoperative loss of lung volume and subsequent atelectasis. All delivered gases are humidified, and intravenous hydration is maintained to facilitate the clearance of secretions. Tracheal suctioning is performed as necessary, with emphasis on maximal pulmonary toilet before extubation. At the end of the procedure, the trachea is extubated after the patient is awake and breathing spontaneously.

Diabetes Mellitus

The key to the successful anesthetic management of a child with diabetes mellitus is careful administration of dextrose and insulin and frequent monitoring of blood glucose. Knowledge of the patient's daily insulin type and amount and the resulting blood glucose is important to the development of an anesthetic plan. A normal diet and insulin regimen should be maintained up to the day of surgery. Diabetic children should be scheduled for the first surgical procedure of the day when possible, because this timing usually simplifies their glucose management.

One of several approaches to the management of glucose and insulin can be taken[114]:

1. On the morning of surgery, half of the usual morning insulin dose is given as regular insulin (onset in 30 minutes; peak effect in 2 to 4 hours; duration of action of 6 to 8 hours) after an intravenous infusion of 5% dextrose in 0.45% normal saline is established at 1500 mL/m^2 per day. Serum glucose levels are monitored frequently before and after surgery and are maintained between 100 and 200 mg/dL, with a sliding scale of regular insulin given until the patient is eating and can resume the usual insulin regimen.

2. On the morning of surgery, a continuous infusion of insulin and glucose is initiated (1 or 2 units of insulin per 100 mL of 5% dextrose). Adjustments can be made in the ratio to maintain blood glucose in the desired range.

3. For procedures that are brief and will allow oral intake in the recovery room (e.g., myringotomy), no insulin and no glucose are given. These cases should be scheduled as the first of the day. When oral intake is reinitiated, 40% to 60% of the usual daily insulin dose is given subcutaneously, and blood glucose is monitored carefully.

The appropriate use of short-acting anesthetic agents and nonsedating antiemetics will allow this group of patients to return to oral intake as soon as possible. Preoperative endocrinology consultation may be helpful for patients with poorly controlled blood glucose.

Congenital Heart Disease

Patients with congenital heart disease are seen by many other surgical specialists for management of congenital abnormalities associated with a specific syndrome, as well as for treatment of other diseases found in children without heart disease. Some will have had their defect already repaired (e.g., neonatal coarctation of the aorta). Some will have received surgical palliation and thus have achieved a state that is physiologically better tolerated but does not represent series circulation (e.g., hypoplastic left-sided heart syndrome in a patient who has had a stage 1 Norwood procedure). Some will not yet have had the defect repaired because it is of secondary priority to more urgent problem (e.g., a patient with an atrial septal defect who has a foreign body in the airway). In each of these situations, an in-depth understanding of the patient's anatomy and physiology will dictate anesthetic goals.

The first issue is whether the patient requires antibiotics for subacute bacterial endocarditis (SBE) prophylaxis. In 2007, the American Heart Association, in collaboration with a number of interested medical organizations, published revised evidence-based guidelines for the prevention of infective endocarditis. Of the underlying principles from which the previous (1997) guidelines had been formed, whether antimicrobial prophylaxis was effective in humans was called into question by the committee. The new guidelines pointed toward use of infective endocarditis prophylaxis in significantly fewer patients[115] (Tables 182-4 and 182-5). If given orally, the antibiotics should be administered 1 hour before the procedure. If given intravenously or intramuscularly, they should be administered within 30 minutes before the start of the procedure (Table 182-6). For recommendations outside the scope of otorhinolaryngology, appropriate practice guidelines should be consulted.

Premedication is the next consideration in this group of patients. In general, cardiac patients tolerate premedications well. We routinely give 0.7 to 1.0 mg/kg of oral midazolam 10 to 30 minutes before taking the patient to the operating room. In patients for whom this premedication has been insufficient in the past, we may add 5 to 10 mg/kg of oral ketamine, with the recognition that this will prolong recovery time. If an intravenous line has already been established, the usual doses of intravenous premedication agent is given. The relative exceptions are the patient with pulmonary hypertension and the patient in whom an increase in pulmonary vascular resistance (PVR) will cause right-to-left shunting—specifically cyanotic patients. Elevation in CO_2 as a result of hypoventilation from premedication causes this shift. With this patient population, an anesthesiologist should be in close proximity should the premedication not be well tolerated and control of the airway and ventilation becomes necessary. Monitoring is always indicated in these patients for administration of premedication.

For patients with a pacemaker, the child's electrophysiology cardiologist should be consulted about intraoperative recommendations, because all pacemakers are different. In most cases, the recommendation will be to have a magnet available that, when placed over the pacemaker, puts it into an asynchronous mode. In this case, it will fire

Table 182-4

Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis for which Prophylaxis Is Recommended

Prosthetic cardiac valve
Previous infective endocarditis
Congenital heart disease (CHD)* • Unrepaired cyanotic CHD, including cases in which palliative shunts or conduits have been placed • Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months afte the procedure† • Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization)
Cardiac transplant recipients in whom cardiac valvulopathy develops

*Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
†Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.[114]

Table 182-5

Ear, Nose, and Throat Procedures and Subacute Bacterial Endocarditis Prophylaxis

Prophylaxis	Procedures
Recommended	Tonsillectomy, adenoidectomy Surgical procedures that involve respiratory mucosa Rigid bronchoscopy
Not recommended	Endotracheal intubation Flexible bronchoscopy Tympanostomy tube insertion

Table 182-6

Prophylactic Regimens for Oral and Respiratory Tract Procedures[115]

Regimen/ Patient Factors	Drug	Dosage
Standard		
Oral dosing	Amoxicillin	50 mg/kg PO up to 2.0 g
No oral dosing	Ampicillin *or*	50 mg/kg IM or IV up to 2.0 g
	Cefazolin *or*	50 mg/kg IM or IV up to 1.0 g
	Ceftriaxone	50 mg/kg IM or IV up to 1.0 g
Penicillin-allergic		
Oral dosing	Cephalexin *or*	50 mg/kg PO up to 2.0 g
	Clindamycin *or*	20 mg/kg PO up to 600 mg
	Azithromycin *or*	15 mg/kg PO up to 500 mg
	Clarithromycin	15 mg/kg PO up to 500 mg
No oral dosing	Cefazolin *or*	50 mg/kg IM or IV up to 1.0 g
	Ceftriaxone *or*	50 mg/kg IM or IV up to 1.0 g
	Clindamycin	20 mg/kg IV up to 600 mg

Table 182-7

Factors Influencing Pulmonary Vascular Resistance and Systemic Vascular Resistance

Vascular Resistance	Increases	Decreases
Pulmonary	PEEP, high airway pressure	Low airway pressure
	Low Fio_2	High Fio_2
	Acidosis, high $Paco_2$	Alkalosis, low $Paco_2$
	High hematocrit	Low hematocrit
	Sympathetic stimulation	Anesthesia
	Hypoxia	Drugs (e.g., NO, sildenafil)
	Atelectasis	
Systemic	Vasoconstrictors	Vasodilators
	Direct manipulation	Potent inhalation agents

Fio_2, inspired oxygen concentration; NO, nitric oxide; $Paco_2$, arterial carbon dioxide concentration; PEEP, positive end-expiratory pressure.

without sensing (VOO mode). This is rarely necessary, because most (but not all) implanted pacemakers will do this automatically when faced with prolonged periods of electromagnetic interference. Finally, the grounding pad for the electrocautery should be placed as far away from the pulse generator as possible so that the path from electrocautery to grounding pad does not cross the mediastinum.

In managing the anesthetic procedure, it is important to prevent the administration of air bubbles in the intravenous fluids. Many of these patients have shunts that may allow air to pass from venous to systemic circulations, thereby increasing the risk for stroke, myocardial ischemia, renal ischemia, and so on.

For classification of the anatomy and circulation, the clearest view of the anatomy is obtained by visualizing a red blood cell traveling through the circulation, including all points at which a shunt may exist. Adopting this scheme makes it easier to sort out the anesthetic goals. Regardless of how the anatomy is arranged, it features a pulmonary circulation and a systemic circulation. With an understanding of their relationship to each other, the clinician can manipulate the resistances of the respective circulations and, in so doing, influence the degree and direction of shunting within the boundaries of what the anatomy will allow (Table 182-7). Poor ventricular function will dictate choice of an anesthetic that relies more on narcotics and less on inhalation agents.

In patients with cyanotic heart disease, polycythemia develops as a compensatory state to improve oxygen delivery in the long term. Hematocrit should therefore be measured early as a baseline and should be kept near 40 to support oxygen delivery. However, blood flow becomes sluggish when the hematocrit rises above 60. In these patients, phlebotomy may be considered to prevent ischemia resulting from stasis. The patient's cardiologist should be consulted if phlebotomy is considered as a therapeutic option.

Patients with congenital heart disease have very special needs. Except for the most severely ill of them, they tolerate noncardiac surgery quite well. However, their care needs to be optimized by an anesthesiologist who is familiar with the care of this patient population; understanding their physiology and anatomy is critical.

Anesthetic Considerations for Specific Procedures

Rigid Bronchoscopy

Anesthesia for rigid bronchoscopy presents a significant challenge for the pediatric anesthesiologist, for several reasons. First, bronchoscopy most often is indicated for the diagnosis and management of children younger than 1 year of age, predominantly because of congenital defects[116] (Table 182-8); this is relevant because anesthetic risk appears to be highest in this age group.[2,3] Second, patients who require bronchoscopy often present with difficult airway anatomy or with compromised oxygenation and ventilation; these factors may predispose them to intraoperative problems. Finally, the need to share the airway with the endoscopist demands effective two-way communication and coordination to ensure a smooth anesthetic and to prevent complications. Thus, the importance of communication between anesthesiologist and endoscopist during preoperative planning and intraoperative management cannot be overstated. Preparation should include assessment of

the bronchoscope to facilitate a connection between the bronchoscope and the anesthesia circuit.

Anesthetic technique may be modified in accordance with the child's age and the suspected diagnosis, the underlying impairment of oxygenation and ventilation, the estimated duration of the procedure, and the training and experience of both the endoscopist and the anesthesiologist. The choice of anesthetic agents and techniques often is driven by the diagnosis. In evaluating a patient with stridor or other evidence of a compromised lumen, spontaneous breathing allows for the dynamic assessment of the pathophysiology that is critical for appropriate diagnosis. Anesthesia can be induced with either intravenous (sodium thiopental, ketamine, or propofol) or inhalation (sevoflurane) agents with oxygen. Inhaled rather than fixed agents are preferred when high-grade obstruction of the upper airway is suspected, because their effect is more readily reversed, and they more reliably preserve spontaneous ventilation during induction. In either case, after induction of anesthesia, total intravenous anesthesia (as with an infusion of propofol and alfentanil, for instance) avoids the disadvantageous situation of nonscavenging of inhaled anesthetics, with exposure of inhaled anesthetics to the health care team. Nitrous oxide must be used with caution in patients with compromised oxygenation, and it is contraindicated in patients with air trapping because of the risk of lung overinflation. Heliox, a low-density gas mixture that contains 70% helium and 30% oxygen, seems to be effective for improving the respiratory condition of infants with acute bronchiolitis or croup by increasing laminar gas flow through the narrowed bronchioles, thereby improving gas delivery and reducing accompanying tachycardia and tachypnea.[117]

After the patient is adequately anesthetized, the airway can be sprayed with 4% lidocaine, which provides local anesthesia to the larynx and trachea and reduces the total requirement of anesthetic agents. Lidocaine doses up to 7 mg/kg have been proved to be safe if they are administered over 15 minutes.[118] Intravenous lidocaine (1 to 2 mg/kg) is helpful,[119] but it is not as effective as the properly administered topical agent.

Use of a pediatric bronchoscope and rod lens telescope permits good visualization of the airway while oxygen with or without an inhaled anesthetic is delivered by way of the side-arm attachment. Use of the 2.5-, 3.0-, and 3.5-mm internal-diameter bronchoscopes, however, is associated with increased resistance to breathing. In combination with anesthetic agents that depress respiration, this increased resistance may result in compromised ventilation and oxygenation during spontaneous breathing.[120] The telescope should be removed periodically to allow the child to breathe without the resistive load. Constant communication between the anesthesiologist and the endoscopist is essential.

When spontaneous ventilation is not necessary, the adjunctive administration of short-acting muscle relaxants can allow the use of lighter planes of anesthesia. Propofol can be used adjunctively with airway topical anesthesia and a muscle relaxant or narcotic. Propofol has the advantage that it can be given continuously during the procedure, thereby resulting in a more constant level of anesthesia than can be achieved with inhalational agents, the delivery of which may be interrupted repeatedly. The choice of muscle relaxant can be made on the basis of the anticipated duration of the procedure. In practice, most bronchoscopic procedures are performed without any muscle relaxant; paralysis is the exception rather than the rule. Infusion of a short-acting narcotic (e.g., alfentanil, remifentanil) may be an alternative to a muscle relaxant, thereby allowing for adequate depth of anesthesia without muscle relaxation. Another advantage of total intravenous anesthetic is that the health care professionals in the room are not exposed to the inhalational gases that cannot be scavenged effectively using the side arm of a bronchoscope.

During the removal of a foreign body, close communication between the anesthesiologist and the endoscopist is essential. A joint decision should be made about maintaining spontaneous ventilation versus using positive-pressure ventilation. Adequate relaxation of the upper airway and glottis reduces the risk that the foreign body will be lost when it is pulled out of the airway with the grasping forceps and the bronchoscope.

In 1967, Sanders described a system in which oxygen at 50 to 60 psi was directed down the bronchoscope in intermittent bursts.[121] With this system, duration of bursts is determined by balancing chest rise with estimated airway pressures. Exhalation is then passive and depends on the recoil of the chest wall musculature. Although the device usually is successful for both oxygenating and ventilating patients, a number of potential problems exist. Because room air is entrained by the Venturi effect, hypoxemia may be seen in some patients. Peak inflation pressures and flow rates are influenced by the driving pressure, the diameter and shape of the bronchoscope, the diameter and length of the injector, and the angle from the axial line of the bronchoscope. Because of the smaller diameter of pediatric bronchoscopes, flow rates tend to be lower and inflation pressures to be higher than with use of adult bronchoscopes. Tidal volumes may be low in patients with poor lung compliance. Because of the higher inflation pressures, pneumothorax or pneumomediastinum may occur.[122] Finally, blood, infectious, or particulate matter in the airway may be forced distally by high-pressure bursts.

Hypoxemia and CO_2 retention are the most frequent complications of bronchoscopy. Early detection and prompt intervention usually result in resolution without incident. Pulse oximetry monitoring is mandatory. Monitoring of ventilation with capnography is impossible during bronchoscopy because of dilution of expired gas with high fresh gas flows, making observation of chest wall movement essential. A precordial stethoscope also is useful to auscultate breath sounds. Pneumothorax, although rare, must be kept in mind if acute deterioration of ventilation and oxygenation occurs, particularly if accompanied by a decrease in lung compliance and blood pressure. A portable chest radiograph should be obtained if the index of suspicion is high. Ventricular premature beats can occur in the presence of hypercarbia and light levels of anesthesia. Normal sinus rhythm usually returns promptly with a reduction in the CO_2 tension, an increase in the anesthetic depth, the administration of intravenous lidocaine (1 mg/kg), or a change to another anesthetic agent.

Bronchospasm can also occur during bronchoscopy, particularly in patients with a history of reactive airway disease or active inflammation of the airway. Frequently, bronchospasm results from instrumentation of an inadequately anesthetized airway, particularly if the bronchoscope is in contact with the carina. Removal of the instrument and deepening the anesthetic topically or systemically usually will resolve the problem. If these measures do not, administration of a β-sympathomimetic agent such as aerosolized albuterol (0.05 to 0.15 mg/kg in 5% solution) is indicated.

When the examination is complete, the bronchoscope is removed, and bag-and-mask ventilation with 100% oxygen is instituted. An endotracheal tube may be inserted if the patient is apneic; if bleeding, presence of secretions, or difficult anatomy makes the airway tenuous; or if the patient has a full stomach. Otherwise, the patient may be awakened without an endotracheal tube so long as close observation by qualified personnel can be provided until airway reflexes have returned.

Adenotonsillectomy

Adenotonsillectomy has become a less common procedure during the past decades, because the indications for this surgery have changed. With more effective antimicrobial therapy, the percentage of patients with recurrent infection as the indication for surgery has declined, and the percentage of patients with obstructive symptoms has increased; today, 75% of tonsillectomies are performed to remove obstructions.[123] With this change has come a greater appreciation that adenotonsillar hypertrophy may lead to obstructive sleep apnea (OSA) (Box 182-2) and, in the extreme, to cor pulmonale (see Chapter 183, Obstructive Sleep Apnea Syndrome). Because of the need to prevent cor pulmonale in patients with OSA, the adenotonsillectomy population has become younger; 60% of children operated on for obstruction are younger than 8 years of age.[124] Of children younger than 3 years who require tonsillectomy, 81% have an obstruction.[124] A careful history of coagulation disturbance in either the patient or a family member should be elicited preoperatively, with appropriate laboratory workup performed only for positive histories.

Box 182-2

ICSD-2 Criteria for Pediatric Obstructive Sleep Apnea

1. Parent or caregiver report of snoring, labored breathing, or other obstructive symptoms during sleep
2. Parent or caregiver report of at least one associated symptom:
   Paradoxical chest wall motion during inspiration
   Movement arousals
   Excessive perspiration
   Unusual sleeping positions (e.g., neck hyperextension)
   Daytime symptoms: hyperactivity, aggressive behavior, or sleepiness
   Impaired growth
   Headache on waking
   Secondary enuresis
3. Polysomnograph (PSG) documents at least one scoreable respiratory event lasting at least two respiratory cycles in duration per hour of sleep (criteria subject to revision as additional data become available)
4. PSG demonstrates either—
   At least one of the following findings:
   i. Frequent arousals associated with increased respiratory effort
   ii. Oxygen desaturation with apneic events
   iii. Hypercapnia in sleep
   iv. Excessively negative esophageal pressure fluctuations
   Periods of abnormal gas exchange during sleep (hypoxemia, hypercapnia, or both) with snoring, paradoxical chest wall motion, and at least one of the following:
   i. Frequent arousals during sleep
   ii. Excessively negative esophageal pressures swings
5. The disorder is not better explained by other sleep disorders, medical or neurologic conditions, or by medication or substance use

From American Academy of Sleep Medicine. *The International Classification of Sleep Disorders*. 2nd ed. Westchester, Ill: American Academy of Sleep Medicine; 2005.

Sedative premedication should be used with caution in children with OSA, because these patients are sensitive to both the sedative and the ventilatory depressant effects of sedative-hypnotic drugs. An inhalation induction is most commonly used, with careful monitoring and attention to airway patency, which often can be improved with jaw thrust, insertion of an oral airway, or the addition of continuous positive airway pressure during spontaneous breathing.

Intubation can be accomplished either with the patient under deep inhalational anesthesia or after the administration of a short- or intermediate-acting nondepolarizing muscle relaxant. An oral Ring-Adair-Elwyn (RAE) tube generally is used because of the low profile it provides under the self-retaining mouth gag. Careful monitoring of breath sounds is necessary, because the tube can become obstructed or dislodged during placement, insertion of and removal of the mouth gag.

Recently, the flexible laryngeal mask airway (LMA) has begun to be used as an alternative to intubation for adenotonsillectomy.[125] The flexible LMA has tubing that is much more flexible than that of the original LMA, thereby allowing use of the mouth gag without fear of dislodging the LMA from its proper position. Reports thus far suggest that the LMA is safe and reliable for managing the airway during this procedure,[113,126] and its use has become more common. Factors that may contraindicate the use of the LMA include full stomach, inability to ventilate adequately through the LMA, and surgeon preference. One study has directly compared LMA with the endotracheal tube for tonsillectomy, with results suggesting that the use of the LMA resulted in inferior surgical access.[127]

Anesthesia usually is provided with a volatile agent, most often sevoflurane, combined with nitrous oxide and oxygen. Delivered oxygen concentration should be measured at less than 50% before the initiation of electrocautery to prevent airway fires. Muscle relaxants may be used, but they generally are not necessary. Titration of supplemental narcotics helps provide a smooth anesthetic and emergence, but this must be done cautiously in patients with OSA. Because these patients have down-regulation of their mu receptors, their increased sensitivity dictates the use of short-acting narcotics, and in lower-than-usual doses. Once the child awakens, postoperative pain should be appropriately treated, but the total dose of narcotic usually is lower than in patients without OSA for reasons of this down-regulation. The decision regarding timing of extubation is left to clinical judgment, as previously discussed. Patients with OSA usually are extubated while awake, whereas patients without OSA can be extubated deep. If a deep extubation is chosen, thorough pharyngeal suctioning, placement of an oral airway, and lateral head-down positioning allows blood and secretions to drain cephalad.

Occasionally, reoperation is required for persistent hemorrhage; this occurs most commonly during the first 24 hours after the operation or at 7 to 10 days after the operation. Careful assessment of volume status and hematocrit are mandatory, and so is intravenous rehydration before anesthesia induction. Patients requiring reoperation have full stomachs and are candidates for rapid-sequence induction. Awake intubation should be considered if airway anatomy is distorted.

Most adenotonsillectomies can be performed on an outpatient basis, so long as the patient is monitored closely for at least 6 hours postoperatively.[128] Historically, most anesthesiologists have recommended overnight hospitalization after adenotonsillectomy in patients with OSA. However, a study that found improvements in polysomnograms in patients with mild OSA the night after adenotonsillectomy suggests that hospitalization is necessary only for high-risk patients.[129] At particular risk are children with OSA who are younger than 3 years of age, because the incidence of airway complications and delayed oral intake is higher in this age group. Other conditions that increase risk include cerebral palsy, seizure disorders, congenital heart disease, definitive syndromes, and prematurity.

Laryngeal Surgery

Like bronchoscopy, laryngeal surgery is challenging for the anesthesiologist, because the airway is shared with the surgeon and because the surgery often is performed on infants with congenital laryngomalacia, laryngeal clefts or webs, vocal cord disorders, or laryngeal tumors. Other common indications are acquired subglottic stenosis and recurrent laryngeal papillomatosis.

Several techniques allow the surgeon and the anesthesiologist to occupy the airway simultaneously. One such technique is the spontaneous ventilation technique, which is useful when the surgeon needs to assess airway dynamics.[130-132] If inhalation technique is used, the delivered concentration of agent must be high enough to prevent coughing or laryngospasm but not so high as to cause significant cardiovascular depression or apnea. Because this balance is difficult to achieve, especially with short-acting inhalation agents, adjunctive agents (e.g., propofol, narcotics) may be used to reduce the need for high concentrations of inhalational agent. Thorough topical anesthesia with 4% lidocaine (delivered either by atomizer or by syringe with a metal or plastic introducer needle) provides additional anesthesia and also may reduce systemic anesthetic requirements. As noted previously, a continuous infusion of propofol may be used instead of an inhalational agent to reduce operating room pollution and to provide a stable anesthetic level.

The spontaneous ventilation technique has been very useful for children with recurrent papillomatosis. The anesthetic technique for these children is basically the same as that described for bronchoscopy. Many of these children become psychologically sensitized by frequent needs for laser surgery, making good behavioral support important.

Premedication usually can be used in this population, unless the airway is particularly marginal. Child life or similar services have behavioral support programs that can also be especially helpful for these children. Often just the sight or smell of the anesthesia mask or inhalational agent can be quite anxiety-provoking for these children. An acceptable alternative to mask induction may be EMLA cream application followed by an intravenous start (sometimes with a butterfly needle) and then a propofol induction.

The apnea technique may be preferred if spontaneous ventilation is not necessary and if the anesthesiologist is uncomfortable with the unprotected airway. Anesthesia is provided with a combination of a muscle relaxant, high-concentration oxygen, and halothane or propofol. Topical anesthesia of the airway is accomplished before intubation. After the suspension laryngoscope is set up, the tube is removed, and the surgeon proceeds while the patient is apneic. The tube is replaced when the pulse oximeter indicates decreasing saturation, with a threshold established by the team. Repeated reintubation and ventilation are performed until the procedure is completed. The potential for CO_2 retention is high, particularly if only short periods of ventilation are used between periods of extubation and apnea.

Supraglottic jet ventilation incorporates the use of an intravenous anesthetic such as propofol with a muscle relaxant. After topical anesthesia is provided to the airway, the suspension laryngoscope is introduced, and a jet-ventilating device is attached. The characteristics and potential risks of this technique are the same as those for rigid bronchoscopy.

Finally, it is possible to place a small endotracheal tube around which the surgeon works, although this frequently proves to be awkward. With the availability of small-cuffed endotracheal tubes, older children can be more effectively ventilated with these smaller-diameter tubes.

CHAPTER ONE HUNDRED AND EIGHTY-THREE

Obstructive Sleep Apnea Syndrome

Laura M. Sterni

David E. Tunkel

Key Points

- Obstructive sleep apnea syndrome (OSAS) is a common medical condition that can lead to significant morbidity in children.
- Sequelae of OSAS in children include poor growth, learning and behavior problems, and cardiovascular complications, with potential long-term consequences.
- The definitive diagnosis of OSAS in children is made using overnight polysomnography. Adult criteria for the scoring and interpretation of polysomnographic data cannot be applied to children.
- First-line therapy for OSAS in most children is adenotonsillectomy, with improvement expected in many. Children with severe OSAS or with significant risk factors for OSAS beyond adenotonsillectomy may require further evaluation and therapy.
- Children with OSAS at risk for postoperative respiratory compromise may be identified preoperatively. Risk factors include age younger than 3 years, severe OSAS documented by polysomnography, and abnormalities of upper airway tone or structure, as may be seen in children with neuromuscular disease, craniofacial anomalies, or obesity.
- Continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BPAP) are the most commonly used nonsurgical modalities for management of OSAS and can be applied safely and successfully in children.

The stupid-lazy child who frequently suffers from headaches at school, breathes through his mouth instead of his nose, snores and is restless at night, and wakes up with a dry mouth in the morning, is well worthy of the solicitous attention of the school medical officer.

—W. Hill, 1889[1]

More than 100 years ago, clinicians began to recognize the manifestations of sleep-related breathing obstruction in children. Today, the obstructive sleep apnea syndrome (OSAS) is recognized as a common and important pediatric health problem. Sleep-related upper airway obstruction can lead to a variety of nighttime and daytime symptoms in children. If diagnosis and treatment are delayed, the consequences of OSAS can be severe.

Classification of Sleep-Related Upper Airway Obstruction

Snoring is the common feature of three clinical syndromes of sleep-related upper airway obstruction in children. The diagnoses of primary snoring, upper airway resistance syndrome (UARS), and OSAS separate patients according to the severity of their sleep-related upper airway obstruction and resulting clinical complications.

Primary Snoring

Approximately 10% of children snore during sleep on most or all nights, and the majority of these children have primary snoring.[2-5] *Primary snoring* has been defined as snoring during sleep without associated apnea, gas exchange abnormalities, or excessive arousals.[6] The factors that predispose children to primary snoring are similar to those described for OSAS and are discussed in detail later in this chapter. Major risk factors for snoring in otherwise healthy children are obesity, decreased nasal patency (rhinitis, septal deviation, nasal obstruction), and adenotonsillar hypertrophy.[7,8] Snoring in 6- to 13-year-old children also has been strongly associated with parental cigarette smoking.[4,7]

Primary snoring does not appear to progress to OSAS in young children and may resolve over time. Investigators have performed polysomnography in children 1 to 3 years after their diagnosis of primary snoring and found no significant difference in the apnea index or nighttime gas exchange.[9,10] Ali and coworkers found that 50% of children who were described by their parents as habitual snorers at 4 years of age had stopped snoring without treatment at a 2-year follow-up evaluation.[2]

In the past, primary snoring was considered a benign condition; however, more recent studies have challenged this assumption. O'Brien and colleagues found that primary snoring was associated with an increased probability of neurobehavioral deficits in children.[11] Daytime symptoms such as sleepiness, inattention, aggressiveness, and hyperactivity are reported commonly in habitual snorers and children with OSAS.[3,12-15] Disrupted microsleep architecture has now been demonstrated in children with primary snoring, providing a possible link between neurocognitive dysfunction and habitual snoring in children.[16,17]

Upper Airway Resistance Syndrome

Children with UARS snore and have partial upper airway obstruction that leads to repetitive episodes of increased respiratory effort ending in arousals and sleep fragmentation. Daytime symptoms similar to those seen with OSAS may exist.[18-20] Children with UARS have no evidence

Table 183-1

Childhood versus Adult Obstructive Sleep Apnea Syndrome

Feature	Adults	Children
Presentation		
Excessive daytime sleepiness	Main presenting complaint	Infrequent complaint
Associated obesity	Majority of patients	Minority of patients
Underweight/failure to thrive	Not seen	Frequent finding
Daytime mouth-breathing	Not seen	Frequent finding
Gender	Male/female = 2:1	Male/female = 1:1
Enlarged tonsils and adenoids	Rarely seen	Frequent finding
Sleep Pattern		
Obstructive	Obstructive apnea	Obstructive apnea or obstructive hypoventilation
Arousal with obstruction	Common	May be less frequent
Disrupted	Common	Not often seen
Management		
Surgical	Minority of patients with inconsistent results	Definitive in many
Medical (positive pressure)	Most common management	Only in selected patients

Adapted from Carroll JL, Loughlin GM. Diagnostic criteria for obstructive sleep apnea syndrome in children. *Pediatr Pulmonol*. 1992;14:71.

of apnea, hypopnea, or gas exchange abnormalities on polysomnography. The diagnosis of UARS currently is made with the use of esophageal pressure monitoring to identify increased respiratory effort with related arousals. When polysomnography is performed without esophageal pressure monitoring, snoring with marked paradoxical breathing movements or repetitive arousals may be suggestive of UARS. Treatment options for UARS are identical to those for OSAS and are discussed later in the chapter. The incidence of UARS in children is unknown, but some centers believe it may be more common than OSAS.[19]

Obstructive Sleep Apnea Syndrome

Approximately 1% to 3% of all children will have OSAS, and as many as 40% of snoring children referred to a sleep clinic or otolaryngologist may have OSAS.[21-25] Childhood OSAS has been defined as episodes of upper airway obstruction during sleep that usually are associated with a reduction in oxyhemoglobin saturation or hypercarbia, or both. Sleep-related upper airway obstruction in children may manifest as obstructive apnea or obstructive hypoventilation.[26] Obstructive hypoventilation results from continuous partial airway obstruction, which leads to paradoxical respiratory efforts, hypercarbia, and often hypoxemia. This pattern may be more common in children, who are less prone than are adults to collapse of the upper airway.[27] Diagnosis of obstructive hypoventilation in children requires end-tidal CO_2 monitoring during polysomnography. Despite the absence of complete airway obstruction during sleep, children with obstructive hypoventilation are at risk for all of the reported complications of OSAS.

Obstructive hypoventilation generally is not seen in adults with OSAS. A number of other important differences between adults and children with OSAS are detailed in Table 183-1.

Symptoms and Signs of Childhood Obstructive Sleep Apnea Syndrome

Children with OSAS almost always present with a history of snoring and difficulty breathing during sleep.[23,28,29] Parents often report nighttime sweating, restlessness, and unusual sleeping positions in their affected children. Chest retraction, use of accessory muscles, and paradoxical rib cage motion during inspiration are seen during episodes of upper airway obstruction. Paradoxical breathing (inward movement of the thorax during inspiration) can be normal during sleep in infants and toddlers. During rapid eye movement (REM) sleep, the tonic and phasic activity of the intercostal muscles disappears, and the infant chest wall becomes more compliant. The negative intrathoracic pressures generated during inspiration result in the paradoxical inward movement of the thorax. Paradoxical breathing decreases with age and is rare in healthy children older than 3 years of age.[30] Paradoxical respirations in older children are almost always the result of upper airway obstruction.

Enuresis has been associated with OSAS in children but is not a consistent finding.[29,31,32] Enuresis associated with OSAS may be related to disrupted, restless sleep patterns that affect arousal. Several studies have reported resolution of nocturnal enuresis after adenotonsillectomy in children with symptoms of nocturnal upper airway obstruction or polysomnography that is diagnostic for OSAS.[33-35]

Daytime symptoms associated with OSAS include mouth breathing, nasal obstruction, and hyponasal speech. Morning headaches have been associated with nighttime breathing obstruction, but controlled studies comparing children with OSAS with children with normal polysomnography results have found no significant difference in the frequency of this symptom.[29,31,36] Adults with OSAS often present with excessive daytime sleepiness, but this complaint is less frequent among children with OSAS.[23,31,32,37] OSAS can lead to significant cardiopulmonary complications, poor growth, and problems with learning and behavior. These important sequelae are discussed next.

Complications of Childhood Obstructive Sleep Apnea Syndrome

Growth Impairment

Failure to thrive was commonly described in early reports of children with OSAS.[28,29,36] Although overt failure to thrive is now seen less frequently, as a result of earlier diagnosis and management of OSAS, children with OSAS often grow poorly. Improved growth has been reported in childhood OSAS after treatment with adenotonsillectomy.[38-40] Marcus and colleagues reported decreased growth in children with even mild OSAS that appeared to be related to the increased work of breathing during sleep. After adenotonsillectomy, the patients had improved growth and decreased energy expenditure during sleep.[38] Nocturnal growth hormone secretion also appears to be decreased in children with sleep-related upper airway obstruction.[41] OSAS should be considered in the differential diagnosis for failure to thrive or impaired growth that is unexplained by other conditions.

Behavior and Learning Problems

Sleep-related breathing obstruction in children can lead to significant neurocognitive and behavioral complications. A comprehensive review

of available data shows that pediatric OSAS is associated with shortfalls in academic performance, deficits in behavior and emotional regulation leading to problems such as hyperactivity and aggressiveness, difficulty with sustained and selective attention, and decreased alertness.[42] It also has been suggested that childhood OSAS may lead to problems with memory, intelligence, and executive functioning, but findings are inconclusive to date. Although the exact cause-and-effect relationships are unknown, both sleep fragmentation and intermittent hypoxia are emerging as likely components in the pathophysiology of neurobehavioral morbidity associated with sleep-disordered breathing.[43-45] Gozal and associates found that a group of children with OSAS and neurocognitive abnormalities had significantly increased levels of morning C-reactive protein when compared with children with OSAS and no cognitive dysfunction and with control subjects (i.e., children without OSAS).[46] This finding suggests that the greater the inflammatory response elicited by OSAS, the greater the risk of neurocognitive dysfunction, possibly secondary to neuronal injury.

In an encouraging trend, several studies have documented posttreatment improvement in children with OSAS who exhibited preoperative disturbances in behavior and cognition.[39,47-50] In one study of 12 children with moderate to severe OSAS, a significant reduction in inattention, aggression, and hyperactivity was seen after treatment, as assessed by the Conners Parent Rating Scale. The study authors also noted an improvement in vigilance on a continuous performance task.[47] Owens and colleagues found modest improvement after treatment in a small group of children with mild to moderate OSAS who had behavioral problems and mild deficits in executive functioning, attention, and motor skills.[50] Gozal reported evidence of learning difficulties in children with OSAS by documenting an increased incidence of snoring and nocturnal gas exchange abnormalities in a group of 297 first-grade children who were in the lowest 10th percentile of their class.[48] Of perhaps greatest interest, the children with sleep-associated gas exchange abnormalities who received treatment showed an improvement in academic performance in the second grade, whereas no academic improvements were seen in the affected children whose parents did not seek therapy.

Mitchell and Kelly assessed behavioral abnormalities in children with OSAS using the Behavioral Assessment System for Children before adenotonsillectomy, and again within 6 months after surgery and 9 to 18 months after surgery.[51] These investigators found improvements in behavioral measures after adenotonsillectomy that seemed to persist during long-term follow-up, although to a lesser degree than seen shortly after surgery. Similarly, Chervin and coworkers found that children undergoing adenotonsillectomy for any clinical indication (most often, suspected sleep-disordered breathing in this study) had increased difficulty with hyperactivity, inattention, and daytime sleepiness and were more likely to be diagnosed with attention deficit–hyperactivity disorder than control children undergoing other surgical procedures.[49] At 1 year after adenotonsillectomy, improvements were seen in all measures.

Clearly, sleep-disordered breathing, even in the mild to moderate range, carries a risk for significant and at least partially reversible neurobehavioral morbidity. It is not clear, however, if the cognitive and behavioral complications of OSAS are completely reversible. Gozal and Pope reported that children with lower academic performance in middle school were more likely to have snored loudly and frequently and to have required an adenotonsillectomy for snoring during early childhood.[52] These investigators suggested that the neurocognitive effects of sleep-related upper airway obstruction in young children may be only partially reversible and lead to a "learning debt" that adversely influences subsequent school performance. The diagnosis of OSAS should be considered in children with learning and behavior disorders. Although the ultimate prognosis remains uncertain, early recognition and therapy may help reduce possible life-long neurobehavioral limitations.

Cardiopulmonary Complications

Severe untreated OSAS can lead to pulmonary hypertension and cor pulmonale (Fig. 183-1).[28,29] Pulmonary hypertension results from the recurrent, severe, nocturnal hypoxemia, hypercarbia, and acidosis that occur during obstructive hypoventilation and apnea. Cor pulmonale generally is reversible with treatment for OSAS, but perioperative precautions are required in these high-risk patients. Amin and colleagues found that OSAS in children led to structural changes and hypertrophy of both right and left ventricles.[53] Most notably, the left ventricular hypertrophy seen in their OSAS patients was related to the degree of severity of the OSAS. These workers noted that left ventricular hypertrophy is a known risk factor for future cardiovascular disease. A follow-up study in children demonstrated a "dose-dependent" decrease in left ventricular diastolic function with increasingly severe OSAS.[54] Systemic hypertension, a frequent complication of adult OSAS, also has been reported in children with OSAS.[29,55-57] Pediatric OSAS has been shown to be associated with an increased systemic inflammatory response thought to increase the risk for atherosclerotic disease, as demonstrated by elevated levels of C-reactive protein and changes in levels of proinflammatory and anti-inflammatory cytokines.[58-60] Improvement in these inflammation indicators was noted after adenotonsillectomy, supporting the importance of early diagnosis and treatment of OSAS to avoid long-term cardiovascular morbidity.[58,59]

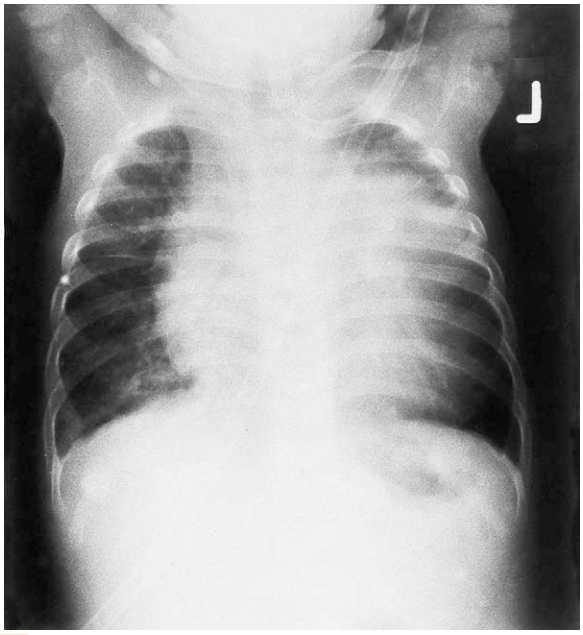

Figure 183-1. Chest radiograph of a child with cor pulmonale secondary to obstructive sleep apnea syndrome.

Pathophysiology of Obstructive Sleep Apnea

The upper airway is a collapsible muscular tube that includes the nasopharynx, oropharynx, and hypopharynx. Patency of the upper airway is determined by the tonic activity of the pharyngeal dilating muscles, as well as phasic contraction of these muscles in response to negative upper airway pressure (inspiration). Skeletal and soft tissue structures such as the tonsils and adenoids affect upper airway diameter and resistance and are important in determining airway patency. During sleep, reduced upper airway inspiratory muscle tone and diminished reflex dilation lead to airway narrowing. These effects are most pronounced in REM sleep, leading to increased obstructive events in predisposed patients.

In otherwise healthy children, adenotonsillar hypertrophy is a significant risk factor for OSAS.[36] However, no strict correlation has been found between size of the lymphoid tissues and the presence or severity of sleep-related breathing obstruction.[61-63] One child with significantly enlarged tonsils and adenoids may be asymptomatic (i.e., have no difficulty with sleep-related upper airway obstruction), whereas another with only moderate adenotonsillar hypertrophy will have severe OSAS. Furthermore, OSAS develops in only a small percentage of children with adenotonsillar hypertrophy. It is likely that a combination of structural factors and neuromotor abnormalities must be present for OSAS to occur.

Marcus and associates demonstrated that the pediatric upper airway behaves as a Starling resistor.[64] In the Starling resistor model, maximum inspiratory flow through the collapsible upper airway is determined by upstream (nasal) pressure and the pressure surrounding the collapsible segment. When airway collapse occurs, flow is independent of the downstream (tracheal) pressure. Airway collapse occurs when the pressure surrounding the airway becomes greater than the pressure within the collapsible segment. The pressure outside the airway is dictated by structural factors, as well as activity of the airway dilator muscles. These investigators found that children with OSAS had greater airway collapsibility than those with primary snoring. Although airway collapsibility was reduced after adenotonsillectomy in children with OSAS, it remained greater than in the patients with primary snoring.

Structural factors other than adenotonsillar hypertrophy may play a role in OSAS in otherwise healthy children. Arens and colleagues used magnetic resonance imaging to study the airway of children with OSAS and found a smaller upper airway volume than in control subjects.[65] In a second study, Arens' group found that the upper airway of children with OSAS was restricted along the upper two thirds, with greatest narrowing in the region of overlap of the tonsils and adenoids.[66]

Isono and associates studied children with OSAS who were given neuromuscular blockade under general anesthesia. These researchers found that the closing pressure of children with OSAS was positive and greater than that of normal children.[67] Collapsibility of the retropalatal and retroglossal segments was significantly increased in their OSAS subjects. They also determined that the cross-sectional area of the narrowest segment of the airway was significantly smaller in children with OSAS.

It appears that children with OSAS have subtle abnormalities in upper airway structure or neuromuscular control, in addition to adenotonsillar hypertrophy.

High-Risk Groups

Adenotonsillar hypertrophy is the leading cause of childhood OSAS. A number of other medical conditions also are strongly associated with OSAS in children, as listed in Table 183-2. Close follow-up is indicated in children in these high-risk groups to look for the development of signs and symptoms that may suggest sleep-related airway obstruction. Such signs and symptoms warrant polysomnographic testing to assess for the presence and severity of OSAS.

Obesity

Obese children are at risk for sleep-related breathing obstruction.[68,69] Deposition of adipose tissue within the muscles and soft tissues surrounding the upper airway in combination with external compression from the neck and jowls leads to upper airway narrowing in these patients.[70] Upward displacement of the diaphragm by the obese abdomen when the affected child is supine and decreased chest wall compliance lead to lower lung volumes during sleep, decreased oxygen stores, and increased risk of desaturation with obstructive events. Obese children are at increased risk for persistent OSAS after adenotonsillectomy. Mitchell and Kelly studied 30 obese children with OSAS and found a decrease in respiratory disturbance index (RDI) (see later under "Polysomnography") from a mean of 30 preoperatively to a mean of about 12 after adenotonsillectomy.[71] Although all children had an improved quality of life as defined by a validated questionnaire, OSAS was decreased in severity but not cured in these obese children.

Craniofacial Abnormalities

Children with craniofacial anomalies often have a multifactorial etiology for OSAS. Evaluation is directed toward examination of craniofacial issues such as skull base shape, maxillary size and shape, tongue size and support, and mandibular size and shape. Concomitant central nervous system abnormalities can affect pharyngeal tone, and any coexisting laryngotracheal anomalies should be evaluated. OSAS in such children may persist after adenotonsillectomy, and additional surgical and nonsurgical therapies may be necessary. Infants with craniofacial anomalies can be difficult to treat and may require tracheotomy.

Children with skeletal dysplasias such as achondroplasia may have mixed apnea syndromes. Compression of the brainstem at the craniocervical junction may cause abnormalities of ventilatory drive and central apnea. Cervicomedullary compression also can affect upper airway control, leading to airway obstruction during sleep. Adenotonsillar enlargement and the craniofacial features seen in these patients may also contribute to the development of OSAS.[72] Sisk and associates diagnosed OSAS in 38% of children with achondroplasia.[73] Adenotonsillectomy usually is effective, but additional therapy with continuous positive airway pressure (CPAP) or tracheotomy may be needed in such complicated cases.[74] Craniocervical decompression has been used in some patients with achondroplasia, but the effects on OSAS remain controversial.[75]

Table 183-2

Medical Conditions Associated with Obstructive Sleep Apnea Syndrome*

Achondroplasia and similar skeletal dysplasias
Apert's syndrome
Beckwith-Weidemann syndrome
Cerebral palsy
Choanal stenosis or atresia
Cleft palate after repair
Crouzon syndrome
Cystic hygroma
Down syndrome
Goldenhar syndrome/hemifacial microsomia
Hallermann-Streiff syndrome
Hypothyroidism
Klippel-Feil syndrome
Mucopolysaccharidosis
Obesity
Osteopetrosis
Papillomatosis (oropharyngeal)
Pierre Robin sequence
Pfeiffer's syndrome
Pharyngeal flap surgery
Prader-Willi syndrome
Sickle cell disease
Treacher Collins syndrome

*Other conditions not listed also may be associated with this syndrome.

Neuromuscular Disease

Cerebral palsy in children is associated with decreased pharyngeal tone, resulting in OSAS. Adenotonsillectomy is a useful initial procedure for OSAS associated with pharyngeal hypotonia.[76] These children are at high risk for respiratory complications or persistent OSAS after adenotonsillectomy.[77-79] When pharyngeal hypotonia is marked, tracheotomy may be necessary to relieve OSAS. Aggressive craniofacial and pharyngeal surgical approaches have been used to avoid tracheotomy in neurologically impaired patients with OSAS.[80] Primary muscular diseases such as Duchenne muscular dystrophy also have been associated with the development of OSAS secondary to loss of upper airway muscle tone.[72]

Patients with Down syndrome have a high incidence of OSAS. A study of OSAS in these patients found that adenotonsillectomy alone was not adequate therapy for more than 60% of the patients.[81] It was concluded that the generalized hypotonia and anatomic abnormalities such as obesity, macroglossia, and midfacial and mandibular hypoplasia all contribute to nocturnal airway obstruction in these patients. Lefaivre and coworkers described a multilevel surgical approach to the manage-

ment of OSAS in children with Down syndrome, using a combination of facial and mandibular bony advancement and pharyngeal soft tissue surgery to achieve improvement in sleep-related upper airway obstruction.[82] Merrell and Shott described the use of lateral pharyngoplasty (plication of the tonsillar pillars), along with adenotonsillectomy, in children with Down syndrome but found polysomnographic abnormalities in 75% of these children after adenotonsillectomy with or without this modification.[83]

Mucopolysaccharidoses

Mucopolysaccharidoses, such as the Hunter and Hurler syndromes, are associated with severe progressive OSAS in affected children. The head and neck manifestations in these syndromes include short neck, depressed nasal dorsum, macroglossia, adenotonsillar enlargement, and craniofacial abnormalities.[84] Bredenkamp and colleagues reported upper airway obstruction in 17 of 45 patients (38%) with mucopolysaccharidoses, 7 (16%) of whom required tracheotomy.[85] Leighton and associates found OSAS in more than 90% of patients with mucopolysaccharidoses, with the most severe OSAS found in the Hurler and Hurler-Scheie types.[86] Laryngeal tissues can be infiltrated and tracheal size decreased from mucopolysaccharide deposition, leading to airway obstruction at multiple levels.[87] Adenotonsillectomy and tracheotomy may be part of the surgical treatment of OSAS in such complicated cases.[88] Although its clinical applications are far from clear, enzyme replacement therapy may stabilize mild OSAS in children with Hurler syndrome and may improve upper airway size.[89]

Acute-Onset or Rapidly Progressive Obstructive Sleep Apnea Syndrome

Abrupt onset or rapid progression of OSAS in children suggests rapid enlargement of lymphoid tissue in the pharynx or other lesions rapidly growing near the airway. Viral syndromes can be associated with marked lymphoid hyperplasia and severe OSAS in children, the common example being infectious mononucleosis secondary to Epstein-Barr virus infection. Acute OSAS associated with Epstein-Barr virus infection is treated with a nasopharyngeal airway and steroids until the lymphoid hyperplasia resolves.[90]

Malignant and benign tumors of the head and neck may cause sleep-related upper airway obstruction, as discussed later on. A full head and neck examination should be directed at a search for intrinsic and extrinsic masses causing airway compromise. Biopsy, when clinically indicated, should be performed to direct additional therapy.

Diagnosis

Early diagnosis and treatment of OSAS in children will result in decreased morbidity. A study by Richards and Ferdman found that the mean period between onset of symptoms and treatment of OSAS in a group of 45 children was 3.3 years.[91] Delays in treatment were related to physician, parent, and third-party factors. Early diagnosis also may be cost-effective: Children with OSAS have been shown to have a 226% increase in health care utilization when compared with control subjects during the 1 year before they receive evaluation and treatment.[92] A clinical practice guideline on the diagnosis and management of OSAS in children released by the American Academy of Pediatrics has recommended that all children be screened for snoring as part of routine health care maintenance.[93] If snoring is reported, a more detailed evaluation is recommended.

History

Numerous studies have demonstrated that OSAS cannot be distinguished from primary snoring in children, based on clinical history and physical examination alone.[23,25,36,94-96] In one report, 89% of parents of children with OSAS observed the child struggling to breathe during sleep, as did 58% of parents of children with primary snoring.[23] A majority of parents of children with both disorders were frightened by their child's nighttime breathing, often staying up nights to watch the child breathe. Goldstein and associates evaluated 30 snoring children referred to a pediatric otolaryngology clinic using a focused history and physical examination in addition to a review of audiotaped breathing of the children during sleep.[25] In only one half of the 18 children believed to have definite OSAS clinically was polysomnography diagnostic for OSAS. In a systematic literature review, Brietzke and coworkers found that 11 of 12 articles in the literature concluded that clinical assessment is inaccurate in the diagnosis of childhood OSAS.[97] Although the clinical history may not be diagnostic, a thorough evaluation of daytime and nighttime symptoms is helpful in planning subsequent studies and interpreting the findings.

Physical Examination

The diagnosis of childhood OSAS is suggested by the patient's history and confirmed by polysomnography. The physical examination should note height and weight, because growth may be impaired by OSAS. Cardiopulmonary abnormalities associated with OSAS should be identified. A full otolaryngologic examination of the head and neck should establish the likely site or sites of dynamic or static airway obstruction.

Tonsil and adenoid size should be assessed in children with symptoms of nocturnal airway obstruction. Signs of adenoidal hypertrophy include decreased nasal airflow with an adequate nasal airway on rhinoscopy, a hyponasal speech pattern, and an open mouth breathing posture. Nasal examination should be focused to exclude obstructive septal deformity, intranasal masses, and mucosal or turbinate swelling within the nose. The oral examination should center on tonsil size and symmetry, pharyngeal dimensions, palate shape and size, and tongue size and motion.

Routine oral and nasal examination can be supplemented with fiberoptic nasal endoscopy to assess nasal patency, adenoid size, and effect of tonsil size and anatomy on awake respiration.[98] Croft and associates used fiberoptic endoscopy to evaluate the site of obstruction in children with polysomnogram-proven OSAS.[62] These workers identified distinct adenoidal, adenotonsillar, tongue base, and laryngeal sites of obstruction based on fiberoptic endoscopy and planned successful surgical therapy based on these findings.

The physical examination of children with craniofacial anomalies is directed at craniofacial structure, jaw size and position, and tongue size and position. Assessment of pharyngeal and laryngeal tone is necessary in children with neuromotor diseases such as cerebral palsy or muscular dystrophy. When sleep-disordered breathing is accompanied by daytime airway symptoms such as stridor or hoarseness, laryngotracheal examination with flexible or rigid endoscopy should be performed.

Polysomnography

Overnight polysomnography in a sleep laboratory is the "gold standard" method for diagnosing childhood OSAS. An accurate diagnosis of OSAS will ensure that appropriate treatment is provided when needed and will avoid unnecessary surgery in patients with primary snoring. The quantitative data obtained from polysomnography also can help predict which children are at risk for perioperative complications. Severe OSAS on polysomnography has been shown in several studies to be an important risk factor for postoperative respiratory compromise after adenotonsillectomy.[78,79]

Pediatric sleep laboratories should involve clinicians with expertise in pediatric respiratory disorders or sleep medicine to ensure that the studies are performed and the findings interpreted appropriately for this age group. Overnight polysomnography is recommended. Although a nap study that is positive for obstructive sleep apnea correlates well with the presence of obstructive apnea on an overnight study, a negative nap study result does not exclude the diagnosis of OSAS.[99] Nap studies are limited by the short recording time and the possible absence of REM sleep periods. The use of sedatives and sleep deprivation are not recommended because both may increase upper airway obstruction artifactually.[100,101]

In children, end-tidal CO_2 should be monitored to detect obstructive hypoventilation. The consensus statement adopted by the American Thoracic Society, Standards and Indications for Cardiopulmonary Sleep Studies in Children, also recommends measurement of (1) respiratory effort, as assessed by movement of the chest wall and abdomen; (2) airflow at the nose or mouth; (3) measurement of arterial oxygen saturation (Sao_2) by pulse oximetry; (4) electrocardiographic recording to monitor cardiac rate and rhythm; (5) electromyography performed

Table 183-3

Polysomnography for Obstructive Sleep Apnea Syndrome in Children

Sleep State
Electroencephalogram
Electro-oculogram (right and left)
Electromyogram (submental)

Respiratory Variables

Oronasal airflow (thermistor)
End-tidal CO_2
Arterial oxygen saturation with pulse oximetry

Nonrespiratory Variables
Electrocardiogram
Electromyogram (tibial) to document movements and arousals

Recommended but Not Required
Audiovideo recording

in the anterior tibial region to monitor arousals; and (6) appropriate electroencephalography, electro-oculography, and electromyography measurements for sleep staging[102] (Table 183-3).

Sleep-related upper airway obstruction is diagnosed in children who have more than one obstructive apneic episode per hour or show evidence of significant obstructive hypoventilation. In adults, obstructive apnea is considered abnormal only if the episode lasts more than 10 seconds. Significant obstructive apneic episodes in children often are shorter than 10 seconds. Because of the higher oxygen consumption in children and the fall in functional residual capacity during sleep, Sao_2 may fall after only a few seconds of upper airway obstruction in the infant or toddler. Obstructive apneas or hypopneas lasting two or more consecutive breaths generally are considered abnormal in children. *Obstructive apnea* is defined as near-complete cessation of airflow despite ongoing respiratory effort. *Obstructive hypopnea* is diagnosed when partial upper airway obstruction results in a greater than 50% reduction in airflow associated with either an arousal or a desaturation of 3% or greater from baseline. Generally, obstructive apneas and hypopneas are combined to provide the apnea-hypopnea index (AHI), which reflects the number of discrete obstructive events per hour. Many laboratories may refer to this index as the respiratory disturbance index (RDI), whereas other laboratories will use the RDI to report the number of all scored respiratory events, including central apneas, per hour. Normal children have more frequent central apneas when compared with adults. Only an obstructive event index should be used to make the diagnosis of OSAS.[103]

Obstructive hypoventilation is diagnosed when peak end-tidal CO_2 is greater than 50 mm Hg for 25% or more of total sleep time in the presence of paradoxical respirations or snoring and in the absence of lung disease.[104] *Hypoxemia* is defined as an Spo_2 less than 92% and is correlated with the child's baseline readings and respiratory events. Sleep architecture is examined as well, because an adequate study should contain at least one REM period. Sleep efficiency and frequency of arousal from sleep in association with respiratory events also are analyzed.

Data correlating polysomnographic parameters with clinical outcomes in children are lacking, and no standard guidelines exist for classifying the severity of OSAS. OSAS and obstructive hypoventilation are diagnosed when polysomnographic parameters associated with upper airway obstruction fall outside the values that are currently accepted as normal.[105-107] In our laboratory, we classify children as having either mild, moderate, or severe OSAS based on the clinical

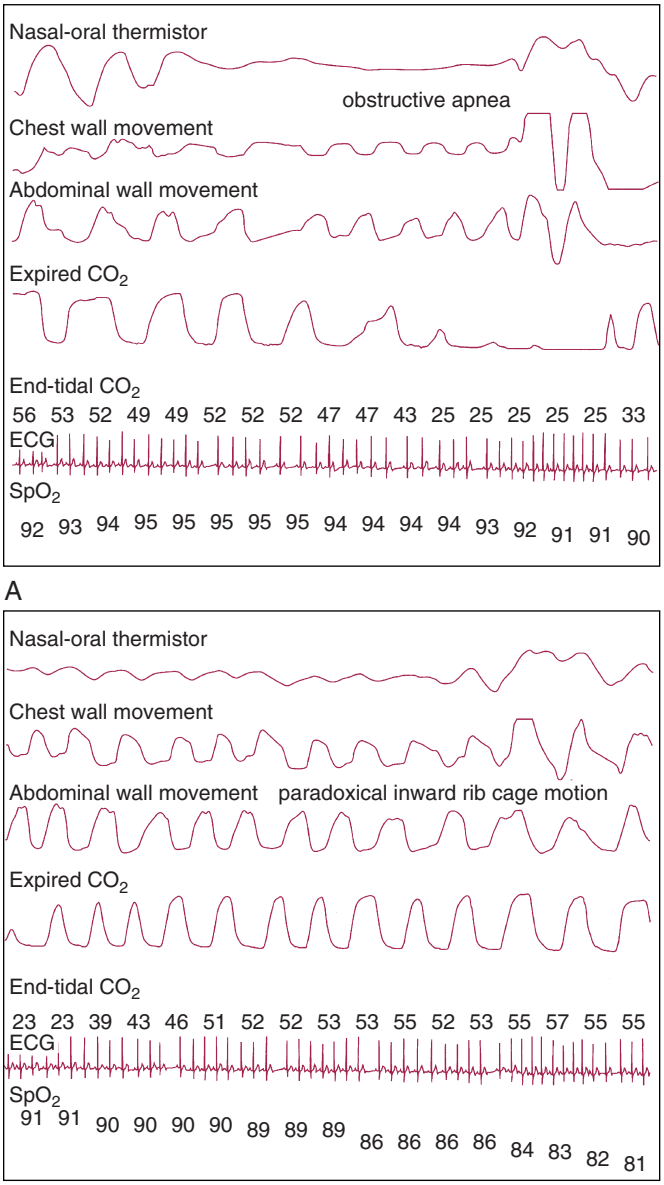

Figure 183-2. Typical polysomnographic recordings. **A,** Obstructive apnea. **B,** Obstructive hypoventilation. Evidence of paradoxical inward rib cage motion is seen in both tracings. In **A,** nasal-oral thermistor and expired CO_2 tracings flatten during the obstructive apneic episode, while respiratory efforts continue. Note the fall in arterial oxygen saturation (specifically, peripheral oxygen saturation [Spo_2]) measured by pulse oximetry that occurs shortly after the approximately 10-second event. In **B,** continuous partial airway obstruction results in elevated end-tidal CO_2 readings and a fall in Spo_2.

picture, number of obstructive events per hour, peak end-tidal CO_2 pressure ($PetCO_2$) or duration of elevated end-tidal CO_2 measurements, and frequency and severity of oxygen desaturation. We classify OSAS as severe if the patient has an obstructive event index of 10 or greater per hour because of the increased risk of respiratory compromise after adenotonsillectomy.[78] Representative polysomnographic tracings from pediatric patients are shown in Figure 183-2.

Other Studies

Because full polysomnography in children may be difficult to obtain, expensive, or inconvenient, screening methods to diagnose OSAS have been investigated. Having medical personnel directly observe a child

experiencing apnea, retractions, and paradoxical respirations during sleep may allow the diagnosis of OSAS.[102] Making a diagnosis by observation, however, does not allow characterization of the severity of the OSAS, which may be important in determining management. Videotapes, audiotapes, and continuous pulse oximetry have been helpful in predicting OSAS when results are positive but unfortunately do not rule out OSAS when results are negative.[108-110] Therefore, children with negative results on screening studies should undergo a more comprehensive evaluation. Likewise, positive results on daytime nap studies have been shown to predict OSAS, whereas negative study results do not exclude the possibility of finding OSAS on an overnight study.[99,111] Questionnaires with emphasis on the symptoms and potential health outcomes of sleep-disordered breathing in children have not been shown to have sufficient sensitivity and specificity to diagnose OSAS in individual patients.[23,31,112,113] Reports from one center suggest that evaluation for sleep-disordered breathing may be accomplished with unattended home polysomnography.[114,115] The home test performed included measurement of oxygen saturation, ventilation, and video recordings. These tests are not widely available, and additional validation of unattended home sleep studies is needed.

Other diagnostic tests may be useful when evaluating a child for OSAS. A chest radiograph, electrocardiogram, and echocardiogram should be considered for any child with symptoms or signs of cardiovascular complications, such as congestive heart failure or hypertension. Children with multiple or lengthy episodes of hypoxemia or extremely severe hypoxemia on polysomnography may require formal cardiopulmonary evaluation as well. Children with these cardiovascular complications of OSAS should have repeat polysomnography after therapy to confirm resolution of OSAS.

Although airway radiographs, cephalometric studies, and computed tomography scans may assist in designing the treatment plan for high-risk children with OSAS caused by unusual anatomic abnormalities, these studies are of limited use in the diagnosis of OSAS in otherwise healthy children. Li and coworkers determined a ratio of tonsil size and pharyngeal depth on lateral radiographs that correlated with severity of OSAS, even though clinical measurements of tonsil size did not.[116] Jain and Sahni were able to predict OSAS based on a ratio of adenoid size to nasopharyngeal depth on lateral radiographs, although clinical tonsil size measurements were not helpful.[117] Sleep fluoroscopy has been described by Gibson and associates for evaluating children at risk for upper airway obstruction at multiple levels.[118] Although dynamic assessments of airway anatomy and function using endoscopy or imaging such as cine-magnetic resonance imaging during sleep have been used in adults with OSAS and in some children with OSAS within a complex clinical picture, these techniques require additional investigation before they can be recommended for widespread use in children.[119,120]

Indications for Polysomnography

Polysomnography remains the gold standard modality for diagnosing sleep apnea in children, because clinical assessment alone is sensitive but not specific for OSAS. The controversies regarding the use of polysomnography in otherwise healthy children with suspected OSAS are reviewed by Messner, who recognizes both the need for this test to diagnose childhood OSAS and the impracticalities of mandatory use before adenotonsillectomy.[121] Children who undergo adenotonsillectomy for recurrent pharyngeal infection may have obstructive symptoms as well. These children do not require polysomnography on a routine basis. Polysomnography is recommended to invetigate concerns that the patient also may have severe OSAS requiring intensive postoperative monitoring. The use of preoperative polysomnography is most controversial in healthy children with obstructive adenotonsillar hypertrophy and no other surgical indication. Historically, adenotonsillectomy has been used to manage obstructive symptoms in healthy children without preoperative polysomnography. In fact, in a recent survey of otolaryngologists and pediatric otolaryngologists by Kay and associates, history alone remains the most common method of establishing OSAS as a surgical indication for adenotonsillectomy in children.[122] Weatherly and colleagues estimated that less than 5% of children with sleep-disordered breathing undergo laboratory-based polysomnography before adenotonsillectomy.[123] An important point is that this practice will lead to potentially unnecessary tonsillectomy in some children with obstructive symptoms but without OSAS.

The use of polysomnography to both diagnose OSAS and assess perioperative risk is recommended in children with suspected sleep-related upper-airway obstruction prior to adenotonsillectomy by both the American Academy of Pediatrics and the American Thoracic Society. The use of preoperative polysomnography is especially important in high-risk patients, including those with craniofacial anomalies, neuromotor disease, or associated medical conditions that may complicate surgical management of OSAS. Baseline preoperative polysomnography is useful to assess postoperative improvement in such high-risk patients. Polysomnography also is useful in the evaluation of children for whom information from the history or physical examination may be inconsistent. Follow-up polysomnography is recommended for children who exhibit persistent snoring or other symptoms of sleep-related upper airway obstruction 4 to 6 weeks after surgery. A follow-up sleep study also should be considered for patients with significant complications from OSAS (e.g., cor pulmonale, failure to thrive), patients with severe OSAS on an initial sleep study, or patients who are very young (younger than 1 year of age) to ensure resolution of nighttime breathing abnormalities.[102]

Surgical Management

Tonsillectomy or Adenoidectomy

Tonsillectomy, adenoidectomy, or adenotonsillectomy is the most common surgical treatment for childhood OSAS. Adenoid and tonsillar hyperplasia appears to be a key element in the compromise of airway patency during sleep in otherwise healthy children with OSAS.[124,125] Brodsky and coworkers demonstrated that children undergoing adenotonsillectomy for obstruction had decreased lateral oropharyngeal dimensions compared with children undergoing adenotonsillectomy for chronic infection.[126] These investigators suggest that decreased oropharyngeal size, in addition to adenotonsillar hyperplasia, may contribute to OSAS in children. Removal of enlarged lymphoid tissue in Waldeyer's ring is curative for most of these children.[39,127-129] Adenotonsillectomy can be recommended for initial treatment of medically complicated children with complex OSAS as well, because this surgical procedure may be curative in appropriately selected children.[130]

Perioperative management of children undergoing adenotonsillectomy for OSAS should be individualized, with the recognition that these children have more frequent postoperative complications and the potential for serious respiratory compromise.[78,79] Children younger than 3 years of age, children with severe OSAS documented by polysomnography, and children with craniofacial anomalies or neuromotor impairment are at greatest risk for perioperative respiratory compromise.[77,78,131-133] Preoperative risk assessment centers on the severity of sleep disturbance as documented by polysomnography. A recent report noted the predictive value of polysomnography in identifying children at risk for respiratory compromise after adenotonsillectomy. The study investigators suggested that preoperative nocturnal oximetry may have similar value.[134] Patients with severe OSAS may be treated with CPAP before adenotonsillectomy if surgery is to be delayed or if significant cardiovascular complications are present. Children with OSAS should undergo routine assessment of hemostatic factors and anesthetic risk for adenotonsillectomy.[135,136]

Preoperative sedation should be used judiciously in children with documented or suspected severe OSAS. Cultrara and coworkers reported on a series of 65 children who were sedated with oral midazolam before adenotonsillectomy for OSAS, diagnosed either clinically or by polysomnography.[137] No adverse respiratory events were seen in any of these patients. In a similar prospective study of 70 children with OSAS, Francis and associates noted brief self-limited respiratory events in only two children after sedation with oral midazolam before adenotonsillectomy.[138] These results should be interpreted with some caution, owing to small numbers in these studies and heterogeneity of the sample population, including variability in the severity of OSAS.

Adenotonsillectomy is performed using standard techniques, with attention to minimizing edema in children at risk for postoperative obstruction. A majority of children who undergo adenotonsillectomy

for mild OSAS experience immediate improvement as shown by sleep studies performed on the first postoperative night.[139] However, children with severe OSAS or complicating anatomic or neuromotor disorders often have a prolonged recovery or incomplete relief of OSAS.[77-79]

Radiofrequency tonsil reduction is a new technique that has been introduced as a potential treatment, in combination with surgical adenoidectomy, for OSAS in children. A pilot study of this technique demonstrated less pain when compared with conventional tonsillectomy and improvement in several clinical and polysomnographic parameters of OSAS.[140] Intracapsular subtotal tonsillectomy using several different surgical methods also has been introduced as a method of reducing perioperative morbidity in children being treated for OSAS.[141-143] Powered intracapsular tonsillectomy and adenoidectomy can reliably achieve at least short-term cure of moderate OSAS as documented by polysomnography in otherwise healthy children.[143a] The long-term efficacy of these techniques, as compared with conventional adenotonsillectomy, needs to be demonstrated in future studies.

Inpatient postoperative management, along with cardiorespiratory monitoring and pulse oximetry, is necessary for high-risk children who have moderate to severe OSAS.[78,133,144] Recovery should occur in an area in which signs of respiratory depression and airway swelling can be recognized and prompt intervention can be instituted.[136] Narcotics should be used judiciously, and postoperative oxygen supplementation should be used with careful monitoring for signs of depression of ventilatory drive. Several studies have demonstrated increased sensitivity to narcotics with regard to analgesic effects and respiratory depression in children with OSAS.[145,146] Steroids often are administered perioperatively, and nasopharyngeal airways are used in high-risk patients to support the airway after surgery. CPAP or bilevel positive airway pressure (BPAP) can be used for children with obstructive symptoms after adenotonsillectomy, including those necessitating airway support in the immediate postoperative period.[147-149]

Expected Results of Adenotonsillectomy for Obstructive Sleep Disorders in Children

Several authors have documented the clinical effectiveness of adenotonsillectomy for nocturnal upper airway obstruction in children.[128,150] Helfaer and colleagues performed polysomnography on otherwise healthy children with mild OSAS on the first night after adenotonsillectomy.[139] The number of apnea events decreased and oxygen saturation during sleep improved immediately after surgery in these children.

In some children, OSAS may persist after surgical treatment. Suen and coworkers reported that children with severe OSAS (RDI greater than 19.1) on preoperative polysomnography were likely to have residual OSAS after surgery.[95] Mitchell and Kelly found persistent OSAS in the majority of children with severe OSAS, as defined by a preoperative RDI 30 or greater, although most were improved by polysomnographic and quality of life measures.[151] In a large cohort of children diagnosed with OSAS by polysomnography, adenotonsillectomy resulted in significant relief of sleep and respiratory abnormalities found preoperatively but resulted in complete cure (defined as as obstructive apnea index of 1 or less) in only 25%.[152] In this study, 29% of the patients had an obstructive event index of 5 or higher after surgery. Children with high preoperative AHI and obese children were the least likely to be cured by surgery. Rapid relief of obstructive symptoms can be expected after adenotonsillectomy in children with mild OSAS, but OSAS may persist in severe cases or in children with significant risk factors for OSAS including obesity.

Brietzke and Gallagher performed a meta-analysis of available literature to try to determine the cure rate for adenotonsillectomy perfomed for childhood OSAS.[153] They identified 14 studies, all case series, and found a post-surgery reduction in AHI by approximately 14 events per hour. The summary success rate was 83%. Gozal and Kheirandish-Gozal reported a cure rate of 77% in a recent review but noted residual OSAS in up to 45% of children after adenotonsillectomy in their own prospective study.[154]

Of interest, more snoring and increased inspiratory effort during sleep were noted in teenagers studied 12 years after adenotonsillectomy.[155] This finding emphasizes the need for long-term study of both the natural history of and treatment outcomes for OSAS in children.

Quality of life improves for children after adenotonsillectomy for sleep apnea. De Serres and colleagues reported the results of a multicenter study of quality of life changes after adenotonsillectomy in children who had adenotonsillectomy for treatment of obstructive sleep disorders.[156] Large changes in quality of life were documented in almost 75% of children, with the most improved domains being sleep disturbance, caregiver concerns, and physical suffering. The OSA-18 is a well-validated quality of life instrument that has been useful in assessing the outcomes of patients treated for sleep-disordered breathing in several studies.[157] Using the OSA-18, Goldstein and associates found similar improvements in quality of life, again with the most significant improvements seen in the domains of sleep disturbance, caregiver concerns and physical discomfort, with concomitant improvements in behavior after adenotonsillectomy.[158] Mitchell and coworkers have documented more long-term quality of life improvements in children at 9 to 24 months after adenotonsillectomy.[159]

Other Pharyngeal Surgery

Resection of palatal and pharyngeal tissue in children as management of OSAS is almost always performed in combination with or subsequent to adenotonsillectomy. Uvulopalatopharyngoplasty (UPPP) is not widely used for the management of children with OSAS. It is used primarily for children at high risk for persistent obstruction because of neuromuscular dysfunction after adenotonsillectomy.[160] Seid and associates reported on the use of UPPP in combination with adenotonsillectomy in 10 children with obstructive apnea and mental retardation with neuromotor disease of diverse causes.[131] Only two patients required additional surgery to relieve OSAS, and one 15-month-old patient with cerebral palsy required subsequent tracheotomy. Tracheotomy was avoided in nine patients, but postoperative sleep studies were not performed.

Kosko and Derkay noted similar favorable results with UPPP combined with adenotonsillectomy in neurologically impaired children with OSAS, with 12 of 15 children showing improvement on pulse oximetry or formal polysomnography.[161] Donaldson and Redmond and also Strome have successfully used UPPP as part of the surgical management of OSAS in children with Down syndrome.[162,163] Kerschner and coworkers treated a diverse group of neurologically impaired children with OSAS with UPPP and adenotonsillectomy.[164] These workers noted long-term improvement in two thirds of their 15 patients but emphasized the need for close follow-up, because one third of their patients had recurrent or persistent upper airway obstruction severe enough to recommend tracheotomy. Potential postoperative velar dysfunction and voice alteration should be considered in the decision-making process for management of such high-risk children with OSAS. Fiberoptic endoscopy of velopharyngeal anatomy may be useful before UPPP is considered, especially in children with poor pharyngeal tone secondary to neuromotor disease.

Tongue reduction surgery has been proposed for the management of macroglossia in conjunction with OSAS, such as is seen in Beckwith-Wiedemann and Down syndromes.[165] Anterior tongue reduction probably improves cosmesis more than airway function, because the central and posterior tongue size may be more critical to airway patency. Rimell and colleagues noted that children with Beckwith-Wiedemann syndrome often required tracheotomy when airway obstruction occurred during the neonatal period.[166] These investigators also found that adenotonsillectomy probably was more beneficial than tongue reduction for managing OSAS in these children with macroglossia. Central tongue reduction has been reported to relieve symptoms of OSAS in children with Down syndrome and other craniofacial disorders.[167,168]

Obstructive sleep apnea has been described in children who have undergone pharyngeal flap surgery for correction of velopharyngeal incompetence.[169,170] Sleep-associated airway obstruction usually is most pronounced in the immediate postoperative period, and obstructive symptoms subside as the flap atrophies during the next several months. In a subset of these children, chronic OSAS may develop that may require flap revision or takedown. Predisposing anatomic factors may include tonsillar or adenoidal hypertrophy, micrognathia, or abnormalities of pharyngeal tone. OSAS after pharyngeal flap surgery appears to be more common in children born with the Pierre Robin

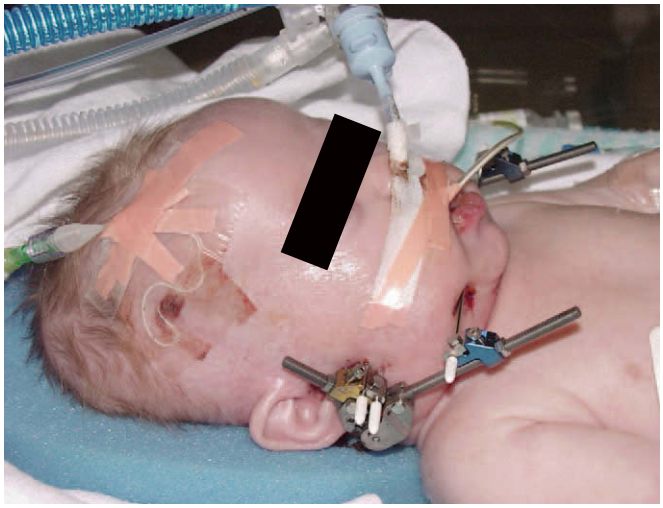

Figure 183-3. Neonate with mandibular distraction device to correct retrognathia.

sequence.[171,172] The need for close follow-up of children after pharyngeal flap surgery is emphasized by Liao and associates, who reported that 90% of children had abnormalities on polysomnograms done 6 months after flap surgery. This group used the strictest criteria for diagnosing OSAS in children: anRDI of 1 or greater.[173] Modifications of the pharyngeal flap technique, including the use of a shorter, more superiorly based flap in a procedure performed several months after planned first-stage adenoidectomy, can reduce the risk of OSAS in syndromic children.[174] Fortunately, when flap division is required for treatment of children with OSAS that persists, the speech and voice benefits of the flap surgery usually are preserved.[175]

Craniofacial Surgery

A variety of surgical procedures have been proposed to manage OSAS in children with complex craniofacial disorders or neuromotor disease. Burstein and associates successfully used mandibular advancement, tongue reduction, tongue-hyoid suspension, and other nasal and pharyngeal procedures to manage children with OSAS with abnormal craniofacial anatomy with or without neuromuscular disease.[167] Tracheotomy was avoided in 90% of this heterogeneous group of children with complex OSAS, including children with hemifacial microsomia, Down syndrome, and cerebral palsy.[176]

Children with severe OSAS and micrognathia may benefit from mandibular advancement or tongue suspension. Tracheotomy often is required in neonates and infants with these conditions to secure the airway until craniofacial growth and neuromotor maturation relieve the sleep-disordered breathing. Tomaski and coworkers have noted that children with isolated Pierre Robin sequence usually can be managed conservatively with nasopharyngeal tube placement and positioning, whereas syndromic children with associated anomalies often require tracheotomy for relief of airway obstruction.[177]

The principles of distraction osteogenesis have been used to treat children with OSAS from isolated mandibular hypoplasia.[178] Mandibular distraction has been used in children with more complex craniofacial conditions such as Treacher Collins syndrome or hemifacial microsomia, both to avoid tracheotomy and to achieve early decannulation.[179,180] A recent study documented dramatic improvement in polysomnographic measures in 10 syndromic children with upper airway obstruction after treatment with mandibular distraction.[181] Lin and associates documented the long-term benefits of mandibular distraction by performing polysomnography 4 years after surgery for neonatal upper airway obstruction[182] (Fig. 183-3). Four children had no evidence of residual or recurrent OSAS, whereas one child had severe OSAS requiring treatment. Midface distraction has been used to achieve decannulation in two patients with achondroplasia and OSAS.[183] Long-term follow-up of these children with complex OSAS-causing conditions is essential after such surgery, especially because relapse of upper airway obstruction after initial improvement has been observed in some children after mandibular distraction.[184]

Tracheotomy

Tracheotomy is indicated for the management of severe OSAS in children with complicated anatomic or neuromotor issues. A review of the literature on pediatric tracheotomy indicated that tracheotomy is now performed more often for dynamic airway issues such as severe OSAS than for fixed airway lesions.[185] Tracheotomy bypasses the areas of airway obstruction during sleep.

Tracheotomy should be considered for patients with severe OSAS associated with neuromotor disease. Tracheotomy can be avoided in some cases by UPPP, pharyngeal surgery, craniofacial surgery, or CPAP.[78,161,167] Although tracheotomy is almost always successful in relieving upper airway obstruction, the decision to perform tracheotomy must be made in the context of underlying medical conditions in the child with OSAS and the recognition of the detrimental effects of tracheotomy on the quality of life.[186]

Other Surgical Management

OSAS may be caused or worsened by nasal abnormalities or nasopharyngeal masses. Choanal atresia or stenosis can cause OSAS in neonates, and transnasal and transpalatal approaches for surgical repair are described earlier in this chapter. Nasal septal deviation as an isolated finding rarely causes childhood OSAS. Septoplasty and turbinate reduction have been used to relieve nasal obstruction and improve nocturnal breathing in adults.

Intranasal masses can cause snoring or OSAS in young infants, and removal usually is curative. Obstructive intranasal masses in children include foreign bodies, inflammatory polyps, mucoceles, and congenital masses such as nasolacrimal duct cysts.

Benign and malignant tumors of the head and neck can manifest with symptoms of OSAS. Supraglottic or parapharyngeal lymphangiomas (cystic hygroma) can cause symptoms of obstructive sleep apnea. Excision of such masses can relieve airway symptoms.[187] Nasopharyngeal carcinoma, juvenile nasopharyngeal angiofibroma, lymphoma, and rhabdomyosarcoma can manifest with obstructive symptoms when nasal or pharyngeal patency is affected. Appropriate oncologic treatment using combinations of surgery, chemotherapy, and radiotherapy can relieve airway symptoms, but airway support may be necessary until tumor regression occurs.

Nonsurgical Management

Children who fail to respond to or are not candidates for surgical intervention often can be managed successfully with nasal CPAP or BPAP.[148,149,188,189] Both modalities are safe, efficacious, and well tolerated by children. The level of positive pressure required to eliminate obstructive apneas and normalize ventilation and nighttime oxygen saturation must be determined in the sleep laboratory. Studies have demonstrated the need for serial evaluation and adjustment of CPAP in growing children, because their pressure requirements will change with time.[148,190]

Complications of CPAP or BPAP usually are minor. Local discomfort or irritation may result from poor mask fit. Regular follow-up to assess mask fit is important. Nasal symptoms such as congestion or rhinorrhea also are common. Nasal steroids or humidification of the delivered air can help relieve nasal obstruction. Hypoventilation and increased central apneas can be seen in children using CPAP or BPAP ventilators.[149] In these children, bilevel ventilation with a back-up rate can be employed. Potentially serious complications of CPAP and BPAP ventilation, including pneumothorax and clinically significant reductions in cardiac output, have not been reported in children treated for OSAS. One case report described the development of midface hypoplasia in a 15-year-old boy treated with nasal CPAP for 10 years for OSAS.[191] With long-term use of a nasal mask in children, regular evaluation of maxillomandibular growth and development is warranted.

Poor compliance is the greatest limitation to the use of CPAP and BPAP in the management of OSAS.[148,192] Pediatric centers have

estimated compliance at 50% to 100%, with adolescents being the least compliant.[148] Rains improved compliance with CPAP therapy in four developmentally delayed children with OSAS by using intensive behavioral interventions including parent training, modeling, and desensitization.[193] In many cases, compliance problems are attributable primarily to the parent or caregiver rather than to the child.[148,192] With careful attention to training of caregivers and children, prompt and aggressive treatment of minor side effects, and close follow-up, the vast majority of families can be trained to successfully use CPAP or BPAP ventilation.

Nocturnal oxygen supplementation has been studied as a temporary treatment for hypoxemia associated with OSAS until definitive therapy can be provided.[194,195] Supplemental oxygen therapy in patients with OSAS may suppress hypoxic ventilatory drive, decrease upper airway tone, and worsen OSAS.[196] Aljadeff and coworkers administered supplemental oxygen to 16 children with OSAS secondary to adenotonsillar hypertrophy and found a decrease in apneic events, lessened paradoxical breathing, increased REM sleep, decreased arousals during sleep without hypoventilation, and increased central apneas.[194] Marcus and colleagues, however, noted significant hypercarbia in 2 of 23 children with OSAS when breathing supplemental oxygen.[195] In most cases, supplemental oxygen therapy will improve oxygenation during sleep without exacerbating sleep-disordered breathing. However, nocturnal oxygen therapy for children with OSAS should be initiated only under monitored conditions. Despite normalization of oxygen saturations, patients with OSAS treated with supplemental oxygen continue to have upper airway obstruction with resulting increased work of breathing, arousals and hypercapnia. Therefore, definitive therapy must still be pursued to prevent the long-term complications of OSAS.

Corticosteroids have been used with some success to treat obstructive symptoms in acute conditions that increase adenoid and tonsil size, such as infectious mononucleosis. A 5-day course of oral prednisone was not effective in treating children with OSAS from chronic adenotonsillar hypertrophy.[197] A few studies have demonstrated a beneficial response to topical intranasal steroids in pediatric patients with OSA. In one small trial, nasal fluticasone given for 6 weeks led to modest improvement in polysomnographic parameters in the treatment group.[198] Many patients, however, continued to have an abnormal apnea index after treatment and a significant number eventually had surgery. In a second study, a 4-week course of nasal budesonide led to an improvement in the mean AHI (from 5.2 to 3.2) and a mean symptom score. The improvement in the symptom score was sustained for several months after discontinuation of therapy.[199] Leukotriene receptor antagonists also have been examined in the treatment of children with OSAS. A small group of children with mild OSAS treated for 16 weeks with daily montelukast were found to have significant reductions in adenoid size and improved breathing during sleep documented by polysomnography.[200] Leukotriene receptor antagonists in combination with intranasal steroids were studied in 36 children with mild residual OSAS after adenotonsillectomy. After 12 weeks of therapy, children in the treatment group had improved AHI, higher nadir oxygen saturation, and decreased respiratory arousals compared with control subjects.[201] Both topical intranasal steroids and leukotriene receptor anatagonists may have promising roles in the management of OSAS, particularly mild OSAS, in children. However, further studies to evaluate effectiveness and appropriate dosing and duration of therapy are needed.

The use of orthodontic devices in the treatment of OSAS in children also appears encouraging in early studies. Rapid maxillary expansion (RME) is an orthodontic treatment that widens the palate and nasal orifices. The use of RME in children with OSAS described as having maxillary contraction has led to resolution of OSAS in this select group.[202,203] Use of orthodontic devices designed to advance the mandible also has led to improvements in sleep-related upper airway obstruction.[204,205] Again, further studies are needed to define the indications and candidates for and the effectiveness of orthodontic treatment in children with OSAS.

As in adults, weight loss is an important component of the management of OSAS in obese children.[206-209] Because weight loss will also lead to other significant health benefits, nutritional counseling with aggressive follow-up is necessary for these patients.

Summary

Obstructive sleep apnea in children is an important and common medical condition that can lead to significant morbidity. The diagnosis of obstructive sleep apnea in children requires clinical suspicion supplemented with the use of specific diagnostic tests. Polysomnography remains the key to diagnosis and helps assess the need for treatment, the risk for perioperative respiratory compromise, and the likelihood of persistent OSAS after treatment. Adenotonsillectomy is the mainstay of treatment, although children with complex medical conditions affecting upper airway anatomy and tone may require additional treatment.

CHAPTER ONE HUNDRED AND EIGHTY-FOUR

Characteristics of Normal and Abnormal Postnatal Craniofacial Growth and Development

Frederick K. Kozak

Juan Camilo Ospina

Key Points

- All theories of facial growth control mechanisms are speculative, and none is fully satisfactory.
- In Moss's functional matrix hypothesis, regulation of growth of cartilage and bone is exerted by the functional matrix surrounding them.
- The craniofacial complex can be divided into three regions: neurocranium, nasomaxillary complex, and mandible.
- Asymmetry is recognized as an intrinsic facial characteristic.
- Ionizing radiation negatively affects developing bone and soft tissue, causing several side effects and facial alterations, both functional and cosmetic.
- The correlation between animal and human experiments regarding the effects of nasoseptal and sinus surgery on craniofacial growth remains unclear.
- Effects of functional endoscopic sinus surgery (FESS) on facial growth are yet to be consistently proven.
- The use of resorbable hardware systems is highly recommended in pediatric craniofacial surgery.
- Debate is ongoing regarding the correction of nasal septal deformity or deviation in neonates and older children. A conservative approach may be warranted until more definitive data are available.
- Controversy exists in the literature regarding the role that nasal or nasopharyngeal obstruction plays with regard to dentofacial growth and development.
- Robin sequence can appear as an isolated entity or as part of several craniofacial syndromes.
- Craniofacial surgery in patients with mandibulofacial dysostosis (Treacher Collins syndrome) using osteotomies and advancement techniques appears to assist in the orientation of subsequent growth in a more normal direction and to enlarge the airway at the same time.

Volumes of literature have been written on facial growth and development, and entire academic careers have been spent researching various concepts and theories. Searching through the published literature can be overwhelming. This chapter provides a place to begin the study of facial growth and development and reviews major changes in growth from birth to late adolescence. *Growth* refers to an increase in size, whereas *development* indicates an increase in complexity of structure and function.

An understanding of the abnormal first requires comprehension of the normal. Accordingly, this chapter is divided into two parts: A brief review of the main theories of postnatal craniofacial growth and the characteristics of normal postnatal facial growth and development is presented first. Subsequently, abnormal facial growth and development are examined through several clinical examples of relevance in pediatric otolaryngology. Embryology of the head and neck is covered in Chapter 181.

Theories of Craniofacial Growth

Postnatal facial growth appears to be a complex, multifactorial phenomenon. It is clear from the resemblance of children to their parents in both facial structure and soft tissue development that genetic factors play a significant role in basic facial pattern. However, "environmental" factors most certainly influence facial growth as well. These factors can range from intercellular influences to biomechanical forces (i.e., physical forces acting on bone). This essentially is Wolff's law (1870), which states that "changes in the function of a bone are attended by alterations in its structure."[1] Bone is a tissue that responds to the stresses placed on it. Bone remodels.

The genetic and environmental control mechanisms of postnatal facial growth and development are poorly understood. The three main theories of postnatal facial growth control are the genetic preprogrammed theory, the cartilage-mediated growth theory, and the functional matrix hypothesis. Following is a brief review of these theories, none of which is fully satisfactory.

Genetic Preprogrammed Theory (Growth Sites)

Early theorists believed that the sizes and shapes of bones were genetically determined within their cells and that sutural patterns were therefore predetermined. Because bone size and shape are defined by sutures in the head, these pioneers theorized that the position of sutures limits and controls the expansion of bones. Baume[2] described "growth centres" as places of endochondral ossification with tissue-separating force, resulting in an increase in skeletal mass, and "growth sites" as regions of periosteal or sutural bone formation and modeling resorption that are adaptive to environmental influences.[3] The cells of the sutures grew into the void left as the bone segments pulled apart from the tissue-separating force. In other words, growth sites are where growth literally takes place, and growth centers are areas in which genetically predetermined growth takes place. This theory was tested by experiments involving suture removal and transplantation, and the conclusion was that sutures are not primarily responsible for growth.[4] This theory is no longer accepted as correct.

Cartilage-Mediated Growth (Scott)

In 1953, Scott theorized that the cartilage of the nasal septum "is an extension of the cartilage of the cranial base."[5] In its growth, the cartilage of the nasal septum separates the facial bones from one another and from the cranial portion of the skull and allows growth to take place at the sutures by the ordinary mechanism of surface deposition. He held that the nasal septum and also the mandibular condyles and synchondroses (otherwise known as cephalic cartilages) are growth centers. As the nasal septum grows, it puts tension on the sutures of the nasomaxillary complex, thereby displacing it forward and downward, with resultant growth occurring at pressure-related growth sites. Tension occurring in the maxillary sutures causes new bone growth when the sutures are pulled apart. Therefore, suture growth is passive and secondary.

Latham[6] theorized that a septomaxillary ligament (connection between the septum and maxilla) in the fetus causes the maxilla to be pulled forward by the septum as the maxilla grows. It is unknown whether this ligament plays a role in postnatal growth, and experimentation related to the role of the nasal cartilage in this concept is unknown. Animal experimentation involving removal of septal cartilage shortly after birth[7] or secondary to trauma seems to result in midface hypoplasia, but such experiments cannot clearly prove that the cartilage removal causes the growth deficiency. Cartilage seems to play some role that has not yet been precisely determined.

The Functional Matrix Hypothesis (Moss)

The most fundamental dictum of the functional matrix hypothesis was stated by Moss,[8,9] as follows:

> The origin of all skeletal units, all of their subsequent changes in size, shape and location and their subsequent maintenance and being, are always, and without exception, secondary, compensatory and mechanical obligatory responses to the morphogenetically and temporally prior and primary alterations of the operational (functional) demands of their specifically related functional matrices. Put more succinctly, "Bones do not grow, they are grown."[10]

The basic premise of this theory is that bone and cartilage do not regulate their own growth. This theory proposes that craniofacial bony growth occurs as a reaction to—or in response to—the functional matrix surrounding it. A functional matrix consists of the cells that comprise muscle, soft tissue, teeth, glands, and nerves, as well as the functioning volumes of various cavities associated with the head and neck region (e.g., nasal, orbital, oral, pharyngeal, and neurocranial). A feedback system exists between the functional matrix and the bone and cartilage involved. Growth of cranial size occurs in response to growth of the brain, growth of the bony orbits occurs in response to the size of the orbit, and growth of the facial bones occurs in response to growth of the surrounding soft tissues. The resultant enlargement of the associated cavities of the head and neck occurs because of the functional demands of the airway, breathing, and eating "spaces." The craniofacial bones are in a dependent relationship with the surrounding soft tissues. Critics state that Moss's theory explains *what* happens during growth but does not explain *how* it happens. Moss's theory is quite useful in clinical practice because it allows separate assessment of each functional unit in the craniofacial skeleton (i.e., brain = cranium, eye = orbit, jaws (mandible) = mastication, nasomaxillary complex and associated airways = respiration, and the ear = temporal bone). The functional matrix operates within the genetic constraints of the cells and tissues involved.

Facial growth involves intimate morphogenic and biomechanical relationships among all of its component tissue parts, each influenced by and in turn influencing the other. A fundamental principle is that no part is developmentally independent or self-contained.[11]

At this time, all theories of growth control mechanisms are speculative, with strengths and faults in each. Further research is required before any definite conclusion can be made.

Bone Growth Concepts

Osteogenesis

A review of bone formation is required for a discussion of craniofacial growth. The initial step in osteogenesis is the laying down of primary or woven bone. *Primary bone* is immature bone defined by random orientation of collagen fibers and is temporary, except in a few locations such as the tooth sockets and sutures of the cranial bones. Primary bone generally either becomes secondary (lamellar) bone or is removed to leave bone marrow cavities. *Secondary bone* differs from primary bone in that its collagen has an orderly pattern and it has an increased number of osteoblasts. Osteogenesis occurs through intramembranous ossification in mesenchyme and endochondral ossification in preexisting cartilage.

Intramembranous Bone Formation

During intramembranous bone formation, mesenchymal cells differentiate into osteoblasts and accumulate in the area where bone is laid down. The osteoblasts begin to produce osteoid, which consists of collagenous fibers and a homogeneous matrix that is primary bone. Secondary bone replaces the primary bone through ossification of the osteoid.

Endochondral Bone Formation

In endochondral bone formation, simultaneous removal of cartilage and subsequent formation of bone occur. Endochondral bone formation is more complex than intramembranous bone formation. Various zones exist in active endochondral bone formation, including the zones of reserve cartilage, proliferating cartilage, hypertrophic cartilage, calcified matrix, and resorption. The hypertrophic cartilage cells enlarge, and the surrounding matrix becomes calcified. A separate collar of bone forms around the circumference of the center of this cartilage bar. This is periosteal or, more precisely, perichondral bone. A vascular bud migrates into the cartilage and a primary marrow cavity forms. Meanwhile, activity at the various zones continues. Erosion of the cartilage takes place at the two ends of the expanding primitive marrow cavity, and bone forms on the spicules of the cartilage at the erosion front. The epiphyseal plate of long bones allows simpler visualization of this process (Fig. 184-1).

This descriptive review of bone formation can be supplemented by a molecular view of bone formation.[12]

Remodeling and Displacement

Enlow and Hans[11] described the two basic types of growth movement: remodeling and displacement. This concept pertains to both bone and

the surrounding soft tissues in the craniofacial complex. *Remodeling* involves changes in the size and shape of bone, the joining of separate bones and how they fit together, the adaptation intrinsically and extrinsically of these newly joined bones, and finally the relocation of these bones—each influenced by their overall enlargement. *Displacement* is the process whereby a space is created between bones as they enlarge. Resorption and deposition are ongoing in bones throughout the craniofacial complex during growth as part of the remodeling and displacement processes.

According to Rodan, "bone formation and bone resorption are finely regulated processes, controlled by local and systemic factors, carried out by a family of different interacting cells which communicate via cytokines, cell contacts, and elaboration of matrix which feeds back on cellular behavior."[13]

Figure 184-1. Endochondral bone formation at an epiphyseal plate.

Facial Changes during Normal Growth and Development

General

The faces of infants and children clearly differ from those of adults. Matching an infant's photograph with that of the corresponding adult photograph is challenging because of the changes that occur with growth and development of the craniofacial region. A baby's face is pudgy and round, relatively wide, and vertically short; the nose is small; the eyes appear relatively far apart; and there is a prominent forehead.

Infants have a large head relative to their body size. Their facial complex, which includes the nasomaxillary complex and mandible, is much smaller than the calvaria and basicranium (Figs. 184-2 through 184-4). With growth and development of the facial complex come changes in the size ratio of the cranium to the face. In infants the cranium-to-face ratio is approximately 3:1; whereas in adults it is approximately 2:1 (see Fig. 184-4).

With growth, increasing demands are made on the respiratory and masticatory systems. As part of the growth of the facial complex, the nose, mandible, and maxilla increase in size—resulting in the larger, coarser features of the adult face in comparison with the child's (see Fig. 184-3). The facial complex increases in size relative to the cranium. Similarly, body size increases relative to head size, to result in normal adult body and head proportions (Fig. 184-5).

Craniofacial Regions of Growth

The craniofacial complex can be divided into three regions: (1) the neurocranium, which is further divided into the calvaria and basicranium; (2) the nasomaxillary complex; and (3) the mandible. Figures 184-2 and 184-3 show the changes that occur in the craniofacial complex from birth to adulthood. The embryonic human skull has 110 ossification centers, many of which fuse, to result in 45 bones in the neonatal skull and ultimately 22 bones in the young adult skull.[1] Table 184-1 summarizes the changes in size of various anatomic sites that take place during growth and development from infancy to adulthood.[1,14-25]

Neurocranium (Calvaria = Roof and Basicranium = Floor)

Calvaria

The calvaria comprises the frontal, parietal, and parts of the temporal, occipital, and sphenoid bones. These bones are formed by intramembranous ossification, with the exception of noncalvarial parts of the occipital, temporal, and sphenoid bones, which are formed through endochondral ossification. These bones initially are separated by fontanelles, which develop into sutures early and then finally fuse in adult life (Fig. 184-6).

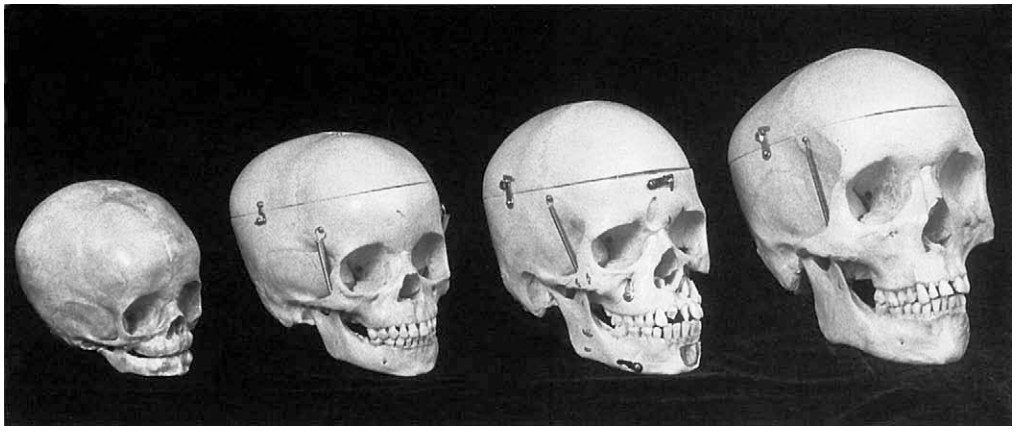

Figure 184-2. The skulls of an infant (approximately 8 months of age), a 5- to 6-year-old, a 10- to 12-year-old, and an adult. Note the bony craniofacial changes with increasing age.

Figure 184-3. Photographs of two siblings from birth to adulthood, demonstrating changes in the craniofacial complex with growth and development. The girl is shown at birth, 10 months, 2.5 years, 6 years, 10 years, 14 years, and 18 years of age, with the last photo in adulthood at 25 years of age. Her brother male is shown at birth, 7 months, 2 years, 5 years, 9 years, 15 years, 19 years, and 25 years of age.

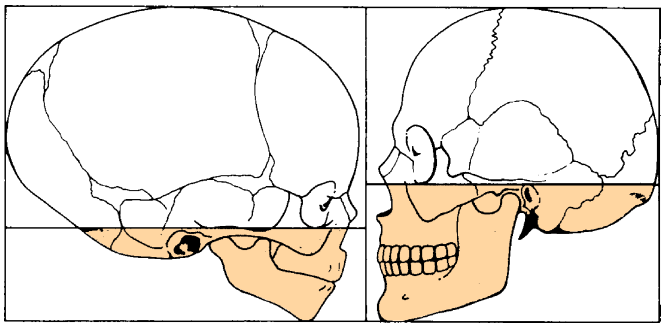

Figure 184-4. The size ratio of the cranium to the face changes considerably during growth and development. In the newborn, the cranium/face ratio is approximately 3:1, whereas in adults, this ratio is approximately 2:1. *(From Proffit WR.* Contemporary Orthodontics*. 2nd ed. St Louis: Mosby; 1993.)*

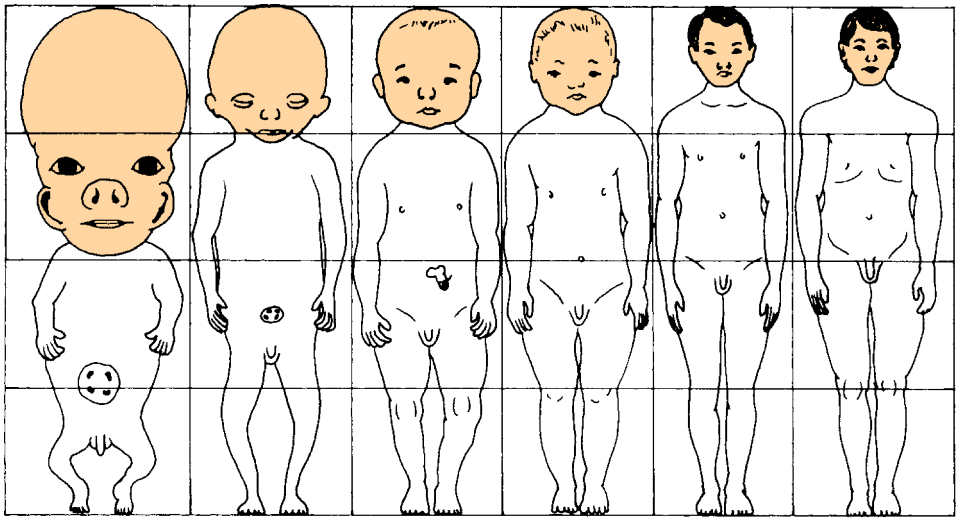

Figure 184-5. Schematic drawing showing the changes in body proportions during normal growth and development. *(From Proffit WR.* Contemporary Orthodontics*. 2nd ed. St Louis: Mosby; 1993.)*

Table 184-1

Normal Craniofacial Growth and Development

Growth Aspect	Age/Development
Neurocranium growth	Birth/25% of ultimate growth 6 months/50% of ultimate growth 2 years/75% of ultimate growth 10 years/95% of ultimate growth
Facial skeletal growth	10 years/65% of ultimate growth
Neurocranium/face size ratio	Birth/8:1 2 years/6:1 5 years/4:1 Adult/2.1:1 to 2.5:1
Brain size	Birth to adulthood/3.5∞ increase
Fontanelle closure	3 months after birth/anterolateral Second year of life/posterolateral 2 months after birth/posterior Second year of life/anterior
Orbits	2 years/50% of ultimate growth 7 years/100% of ultimate growth
Inner ear	6 months of fetal life/full adult size
Brain weight	Full-term infant/25% of eventual weight 6 months/50% of eventual weight 2 years/80% of eventual weight 10 years/almost eventual weight
Postnatal brain growth	1 year/60% of ultimate growth 2 years/80% of ultimate growth 8 years/95% of ultimate growth Minimal growth continues to at least age 25 years
Facial height (males)	Birth/40% to 61% of ultimate growth
Upper facial height	1 year/63 to 86% of ultimate growth 3 years/72 to 90% of ultimate growth 5 years/82 to 100% of ultimate growth (mean, 89%)
Total facial height	Birth 38% to 45% of ultimate growth 1 year/50 to 66% of ultimate growth 3 years/66 to 78% of ultimate growth 5 years/68 to 82% of ultimate growth (mean, 77%)
Facial dimension	3 months/equivalent to 40% of adult size 2 years/equivalent of 70% of adult size 5 years/equivalent of 80% of adult size
Nasal height and nasal bridge length	Fully mature in boys at age 15, girls at age 12
Nasal tip protrusion	Boys age 15, females age 13
Upper and lower nasal dorsum	Males age 14, females age 12
Anterior and posterior nasal depth	Males age 14, females age 12
Foramen magnum	1 year/80% of transverse adult size 1 year/74% of sagittal adult size
Skull base (basion = nasion)	Birth/56% of adult length 2 years/70% of adult length 10 years/90% of adult length Prechordal part contributes 75% of the postnatal length and parachordal (basioccipital) contributes to 25%
Dentition eruption	8 months-2.5 years/primary teeth 6 years-20 years/permanent teeth
Maxillary antrum height	Birth/20% 7 years/50% 10 years/55%
Bizygomatic width	Birth/60% 3 years/80% 5 years/82% 10 years/85%
Cranial width	Birth/65% 3 years/85% 5 years/92% 10 years/95%
Cranial length	Birth/60% 3 years/85% 5 years/90% 10 years/95%

Data from references 1, 14-25.

As the child's brain grows, the calvarial bones are displaced. This displacement theoretically results in the deposition of new bone on the sutural edges. Growth of bone is seen on both the internal and external tables of the calvaria. This also results in an expanded medullary space. Significant thickening occurs from infancy to adulthood. The ascendancy (dominance) of the neurocranium over the facial complex during the early stages of life is clearly related to the inordinately early development of the brain.[21] The major portion of calvarial growth is completed by the age of 4 years (Fig. 184-7).

Basicranium

Growth of the cranial base creates space for the enlarging brain and oronasal structures with their associated airway. The basicranium grows more slowly than the neurocranium. At birth and at 10 years of age, the cranial base exhibits 63% and 95%, respectively, of its ultimate size.[21] The basicranium comprises parts of the occipital, temporal, sphenoid, and ethmoid bones. The occipital, temporal, and sphenoid portions form through endochondral ossification. The ethmoid and inferior nasal concha form solely by intramembranous bone formation.

In the midline, synchondroses are present (Fig. 184-8). These synchondroses remain after the chondrocranium (cartilage precursor of the basicranium) has ossified. During childhood, the spheno-occipital synchondrosis is the principal growth cartilage of the basicranium, and its growth persists into early adolescence.[3,11] Other synchondroses of the basicranium are the sphenoethmoidal, intersphenoidal, sphenofrontal, and frontoethmoidal synchondroses, all of which play a minimal

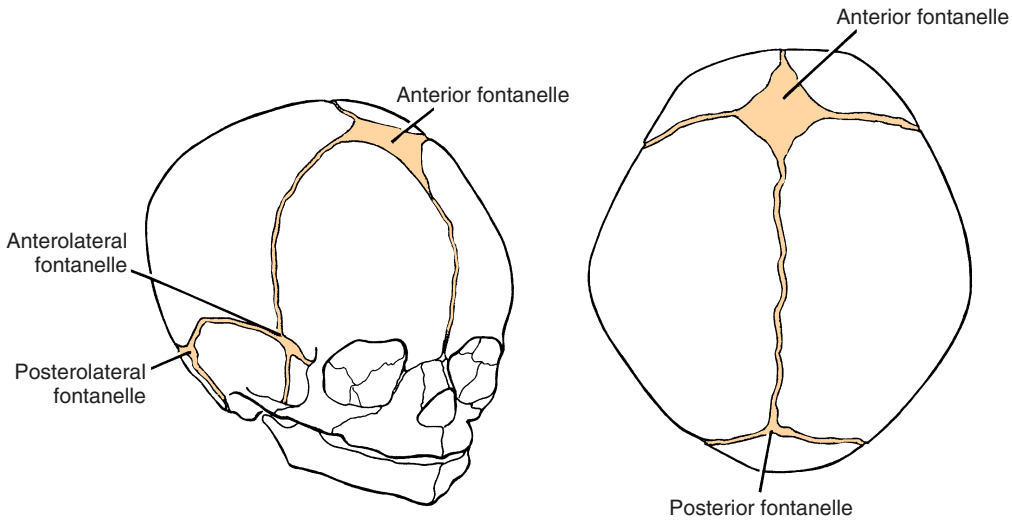

Figure 184-6. Newborn skull fontanelles.

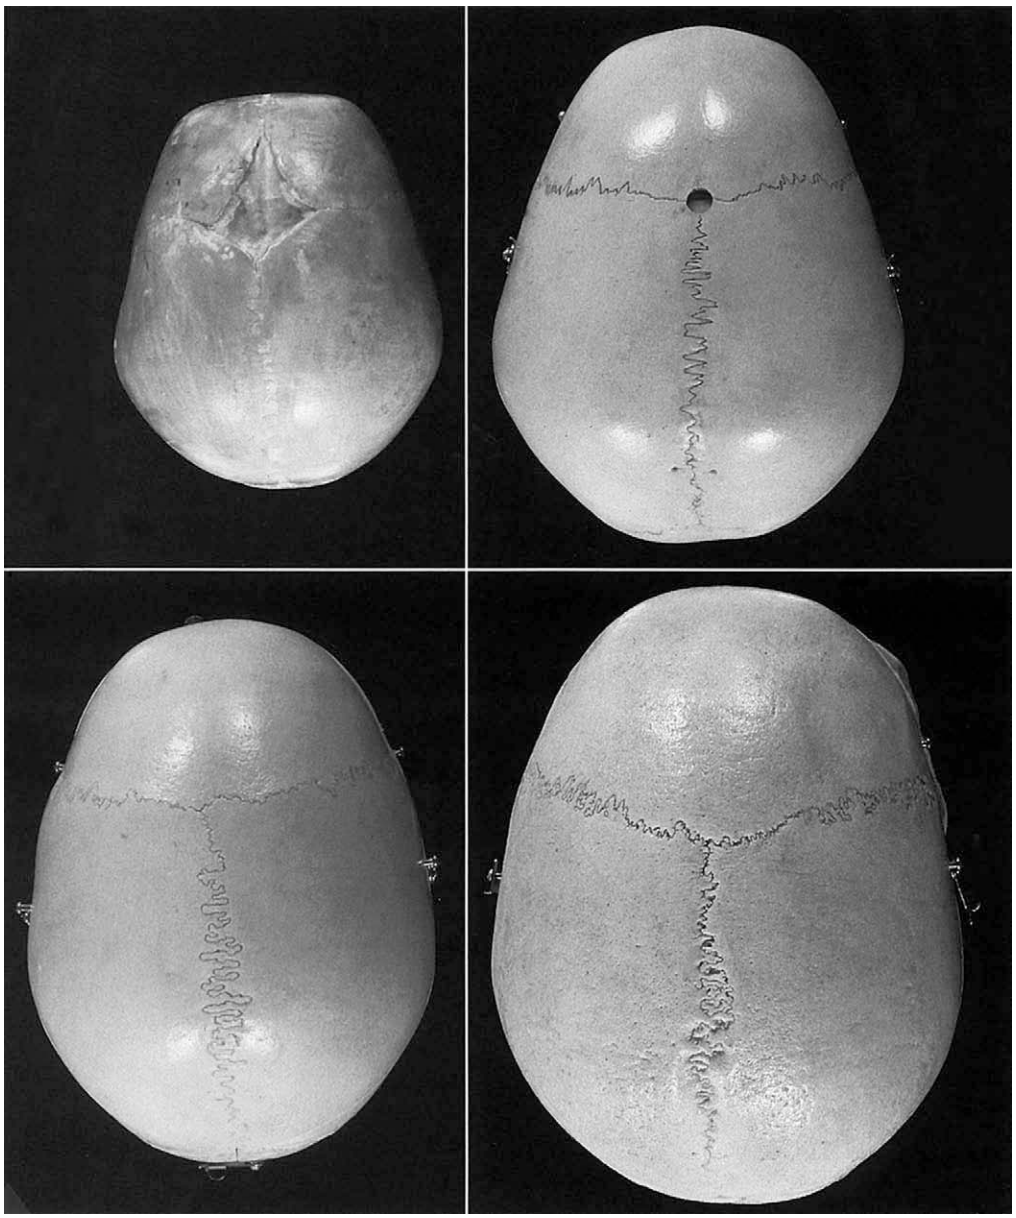

Figure 184-7. Top view of skulls showing the shape change that occurs from infancy to adulthood. Shown are infant (approximately 8 months of age), 5- to 6-year-old, 10- to 12-year-old, and adult skulls.

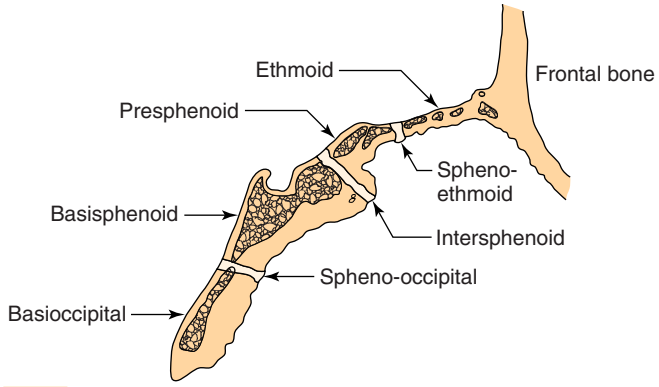

Figure 184-8. Diagrammatic representation of the synchondroses of the cranial base, showing the location of these important growth sites. *(From Proffit WR. Contemporary Orthodontics. 2nd ed. St Louis: Mosby; 1993.)*

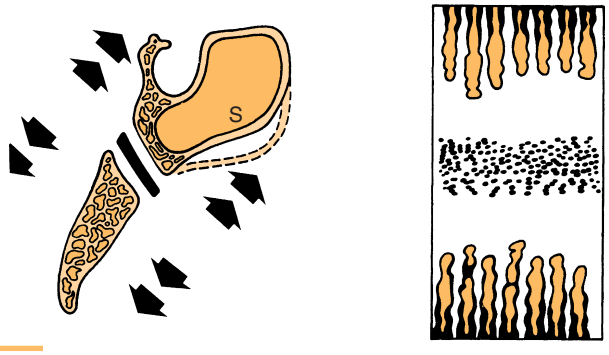

Figure 184-9. Diagrammatic representation of growth at the intersphenoid synchondrosis. A bank of immature proliferating cartilage cells is located at the center of the synchondrosis, whereas a band of maturing cartilage cells extends in both directions away from the center. Endochondral ossification occurs at both margins. Growth at the synchondrosis lengthens this area of the cranial base. S, sphenoid sinus. *(From Proffit WR. Contemporary Orthodontics. 2nd ed. St Louis: Mosby; 1993.)*

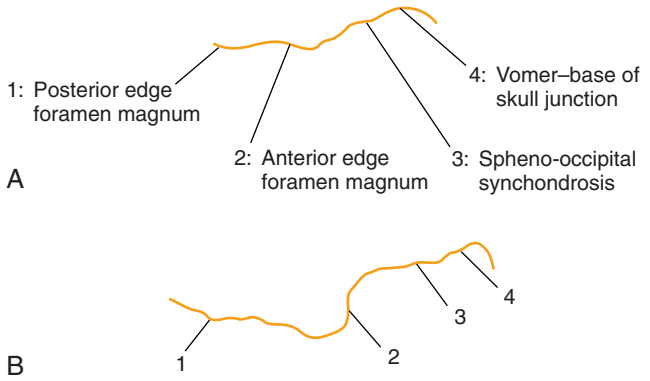

Figure 184-10. Flexion of the cranial base. With growth, a more convex superior or flexed appearance develops from infancy to adulthood. **A,** Infant. **B,** Adult.

role in postnatal growth. The synchondroses have zones similar to those in the epiphyseal cartilage of long bones. However, growth occurs in two directions, resulting in elongation of the basicranium until its ultimate ossification is completed (Fig. 184-9).

The development of ossification center sutures and synchondroses in the chondrocranium throughout childhood hase been chronicled by means of computed tomography (CT). These data can provide standards for skull base maturity. In addition, postnatal normal CT variants and magnetic resonance imaging (MRI) assessment of the cranial base have been characterized.[26,27]

In newborns and infants, the cranial base is quite flat. With growth into childhood, a more convex superior or flexed appearance emerges, with further enlargement during adolescence and adulthood. The spheno-occipital synchondrosis becomes more flexed as the maxillary portion of the nasomaxillary complex moves toward the foramen magnum and moves under the anterior cranial fossa (Fig. 184-10). Components of the cranial base can be seen more clearly in older pediatric skulls than in infant skulls. The foramen magnum approaches adult size and the primary dentition has erupted by 3 years of age. By 8 years of age, the occipital bone has fused around the foramen magnum, and the secondary dentition is erupting. The major difference between the adolescent and adult skull is fusion of the spheno-occipital synchondrosis. Fusion of this synchondrosis begins at approximately 15 years of age for boys and at 12 or 13 years of age for girls on the cerebral surface. Ossification on the external aspect is complete by age 20[1] (Fig. 184-11). The chondrocranium-basicranium is a junction between both the neurocranial and facial complex bones. Its alteration affects not only neurocranial and skull growth but also facial morphology.[3]

Nasomaxillary Complex

The nasomaxillary complex develops through intramembranous ossification. It includes the nasal, lacrimal, maxillary, zygomatic, pterygoid, and vomer bones.

The nasomaxillary complex is displaced forward and downward from the cranial floor (basicranium) as a result of growth of the associated soft tissues. New bone growth occurs at sutural contact surfaces on both sides of the suture, with a resultant increase in the size of both bones involved (Fig. 184-12). Bone is added at the frontal maxillary, zygomaticotemporal, zygomaticosphenoidal, zygomaticomaxillary, ethmoidomaxillary, frontoethmoidal, nasomaxillary, nasofrontal, frontolacrimal, palatine, and vomerine sutures. Interaction between the basicranium and the nasomaxillary complex constantly occurs. Rotatory displacement is caused by the downward and forward growth of the middle cranial fossa, resulting in greater or lesser amounts of displacement and remodeling growth in the posterior and anterior parts of the maxilla, depending on the biomechanical forces involved.[11]

The anterior surface of the maxilla is an area of significant resorption (Fig. 184-13). Even though bone is being resorbed here, the maxilla is still growing forward. This is a good example of remodeling and displacement (Fig. 184-14). Growth and development of the nasomaxillary complex are shown in Figure 184-15. Vertical nasomaxillary growth occurs at the frontomaxillary, frontozygomatic, frontonasal, ethmoidomaxillary, and frontoethmoidal sutures as a result of orbital and nasal growth.

The orbits, which are linked to cranial growth, are quite large at birth because of their relationship with the globe. Orbital remodeling is quite complex—50% of postnatal orbital growth is achieved by the age of 2 years, and it is almost complete by age 7 years.[21] The superior aspect of the orbit in toddlers is similar to that in adults, although the inferior aspect differs. The floor of the nose is almost at the level of the inferior orbital rim in infants; then the distance progressively increases so that the floor is significantly lower in adults. The eyes in the adult face are not much farther apart than those in a child's. According to Enlow and Hans,[11] however, "because of the larger nose, higher nasal bridge, increase in the vertical facial dimension and the widening of the cheekbones, the eyes of the adult appear much closer together." The main contribution to the widening face is from the lateral expansion of the zygomaticomaxillary sutures and the intermaxillary suture growth. Eruption of the primary and secondary teeth results in an increase in the size of the maxilla. As the maxilla moves downward and forward and secondary teeth erupt, the maxillary sinuses increase in size as well.

Sinuses

At birth, the maxillary sinus is large enough to be seen radiologically. Relatively rapid growth occurs between ages of 1 and 4 years; by age

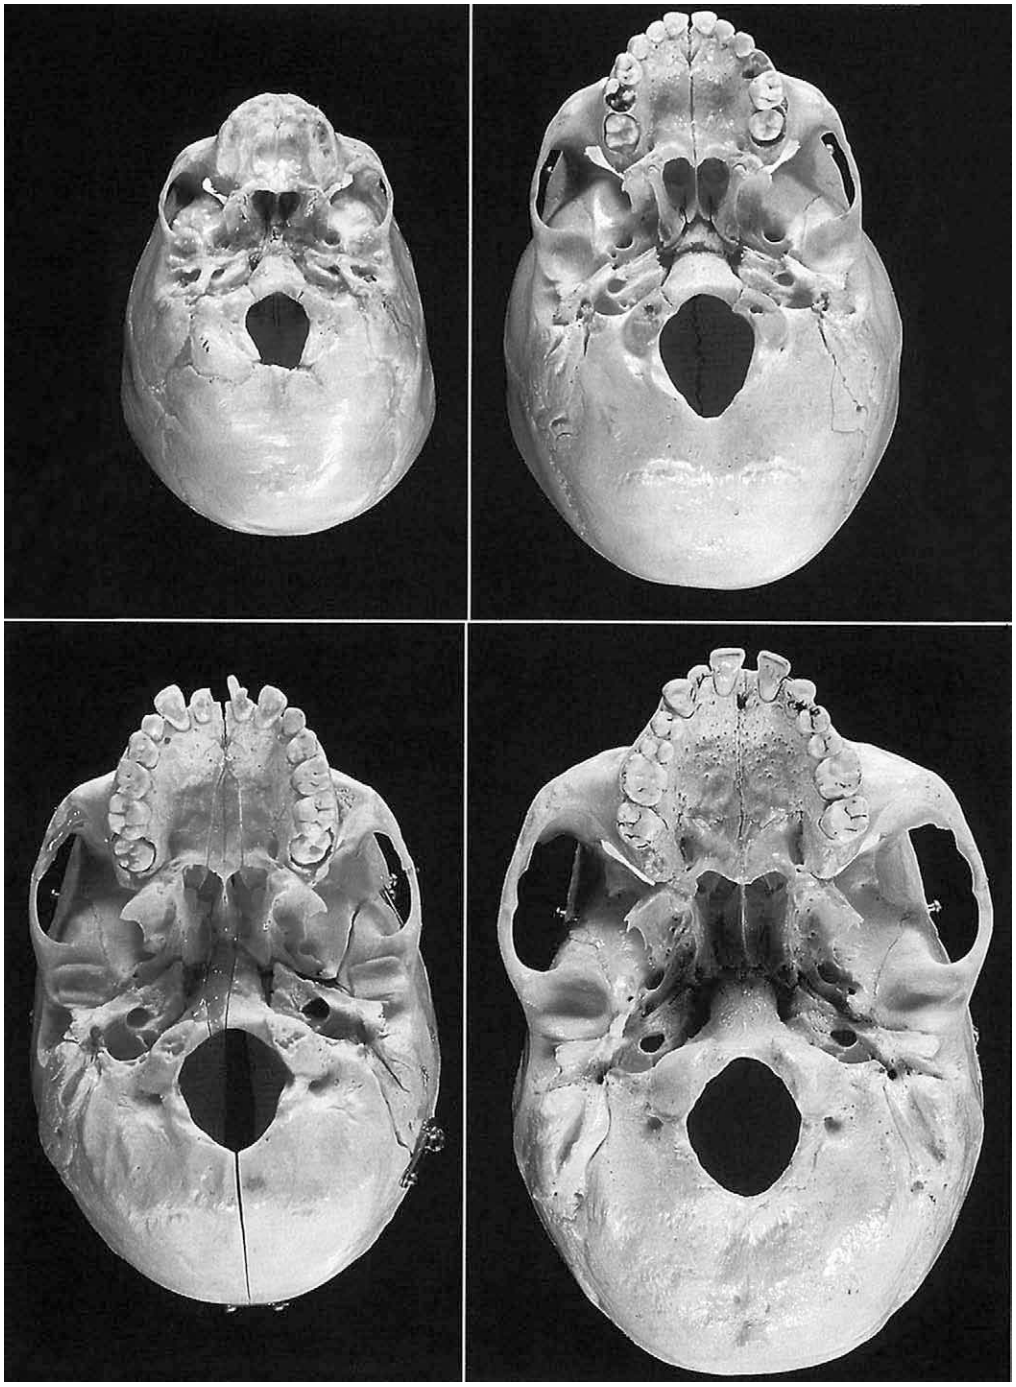

Figure 184-11. Basal extracranial views of the skulls of an infant (at 8 months of age), a 5- to 6-year-old, a 10- to 12-year-old, and an adult. Components of the cranial base are more clearly seen in the older skulls. Note the open spheno-occipital synchondrosis in the 5- to 6-year-old skull and that the most posterior molar on the right side of the photograph is not the patient's—it was inserted.

5, the sinus has started to expand laterally beyond the infraorbital foramen, although its floor does not extend below the nasal cavity. As the permanent dentition erupts, there is growth inferiorly of the floor of the sinus. By the age of 16 years, the maxillary sinus reaches full size (Fig. 184-16). The ethmoid sinuses are present at birth and have attained adult size by the early teens. The frontal sinus distinguishes itself from the ethmoids around age 5 and demonstrates a variable growth rate until reaching adult size in late puberty. The sphenoid sinus is the last to develop and is present radiologically at approximately age 6. Growth of the sphenoid sinus continues well past puberty into the early adult years.[28]

Shah and coworkers reviewed 91 CT scans in 66 patients (16 obtained serially over time) between the ages of 0 and 12 and demonstrated periods of significant growth in the paranasal sinuses in children. The ethmoid sinuses were the first to fully develop, followed by the maxillary, sphenoid and frontal sinuses.[29]

Mandible

The mandible forms in relation to the first branchial cartilage, otherwise known as Meckel's cartilage. Meckel's cartilage is interesting in that it is not replaced by bone. Instead, membranous bone forms lateral to Meckel's cartilage, and Meckel's cartilage then disappears[30] (Fig.

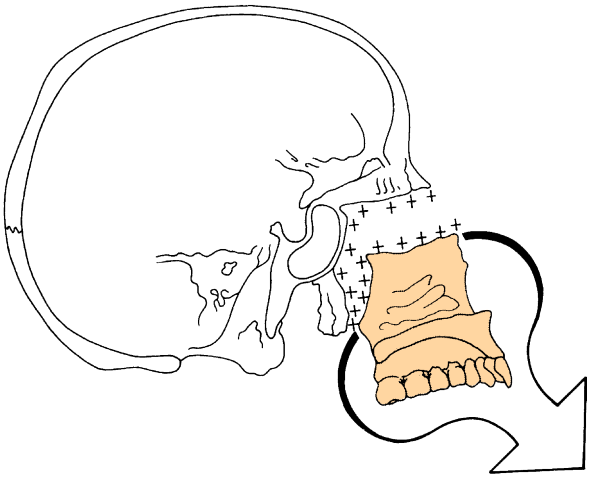

Figure 184-12. As growth of the surrounding soft tissues translates the maxilla downward and forward, opening space at its superior and posterior sutural attachments, new bone is added on both sides of the sutures. *(From Proffit WR.* Contemporary Orthodontics. *2nd ed. St Louis: Mosby; 1993.)*

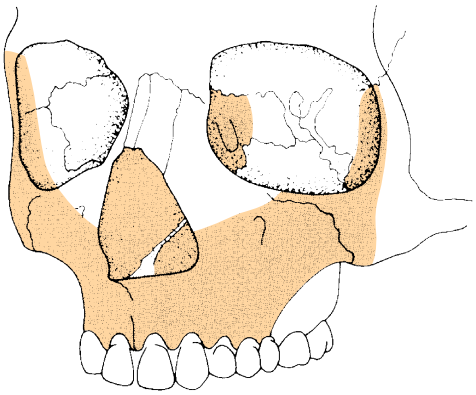

Figure 184-13. As the maxilla is carried downward and forward, its anterior surface tends to resorb. Resorption surfaces are shown in *gold*. Only a small area around the anterior nasal spine is not affected. *(From Proffit WR.* Contemporary Orthodontics. *2nd ed. St Louis: Mosby; 1993.)*

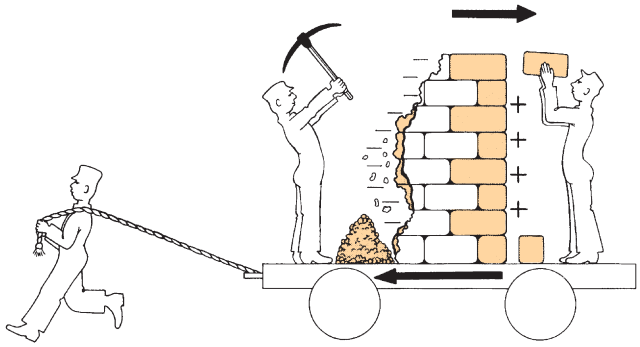

Figure 184-14. Surface remodeling of a bone—in the direction opposite that in which the bone is being translated by growth of adjacent structures—creates a situation analogous to that depicted in this cartoon. The wall is being rebuilt to move it backward at the same time the platform on which it is mounted is being moved forward. *(From Proffit WR.* Contemporary Orthodontics. *2nd ed. St Louis: Mosby; 1993.)*

184-17). At birth, the mandible comprises two bones with the symphysis menti between them. This suture closes by the age of 1 year, after which the major portion of mandibular growth occurs posteriorly.

Resorption occurring anteriorly and deposition occurring posteriorly result in the overall growth of the mandible (Fig. 184-18). Although the condyles are a major site of growth, they are not a master growth center, as was previously thought.

Variation of endochondral bone growth occurs at the articular contact portion of the condyle. The main contribution of condylar cartilage is to provide regional adaptive growth by maintaining the condylar area in a proper anatomic relationship with the temporal bone as the whole mandible is simultaneously being carried downward and forward.[11] The mandible grows by enlarging and widening in response to the increase in size of the muscles of mastication and an enlarging oropharynx, which accommodates the concomitant growth of the nasomaxillary complex. The ramus grows posteriorly and at the same time increases the inter-ramal dimension along with the laterally expanding cranial floor. The coronoid processes grow superiorly and buccally, with the anterior edges of the rami being continually resorbed in the process. The condyles grow posteriorly, superiorly, and laterally (Fig. 184-19). Even though it is a single bone, Sperber[1] described the mandible functionally as six skeletal subunits. These subunits are the alveolar, coronoid, and angular bones, the condylar process, and the chin, all of which are attached to the "body" of the mandible. Moss's concept of functional matrices then influences the growth of each subunit (teeth: alveolar unit; action of the temporalis muscle: coronoid process; masseter and medial pterygoids: angle and ramus; lateral pterygoid–condylar process, perioral muscles, tongue, and expanding oropharyngeal cavity: entire mandible).

The infant mandibular arch is U-shaped; whereas the adult arch is more V-shaped (Fig. 184-20). The gonial angle (the angle between the ramus and the body) is more obtuse in infants than in adults (Fig. 184-21). Mandibular growth takes place in two specific growth spurts, the first between the ages of 5 and 10 years and the second between ages 10 and 15 years.[31] Growth in mandibular width is completed during early adolescence. Growth in mandibular length is complete 2 to 3 years after menstruation in females and approximately 4 years after attainment of sexual maturity in males. Growth in mandibular height is complete in the late teens in females and early twenties in males (see Fig. 184-21).

Internal and external rotational changes of the mandible occur during growth and, of course, in conjunction with rotational changes in the maxilla (Fig. 184-22). Bjork and Skieller[32] described this in detail using metallic implants. Miller and Kerr[31] supported their findings but used a digitizer program for longitudinal follow-up with cephalograms in a number of patients. Overall mandibular growth is not uniform and steady, because corpus length and ramus height grow in an irregular pattern.[25,34] Jaw rotation influences the degree of tooth eruption.

Craniofacial cephalometric and anthropometric studies are abundant in the literature, and normative data are available. A review of these topics is beyond the scope of this chapter; however, these measurements may be used to assist in the interpretation of optimal growth and development in the clinical situation.[35-42]

Abnormal Facial Growth and Development

Asymmetry of the human face is well recognized as a normal finding and in fact is an intrinsic facial characteristic. According to Ferrario and colleagues, "the skeletal structures show a greater degree of asymmetry than their soft tissue drape."[43] Age is certainly one factor that influences asymmetry. Melnik[44] found that the left side of the face was larger at the age of 6 years, whereas the right side of the face was larger at age 16. Disagreement exists in the literature regarding the degree, side, and localization of normal facial asymmetry, although some researchers believe that this is because of methodologic differences.[43] Normal facial asymmetry involves many subtle differences that are not readily apparent to the viewer. Conversely, abnormal facial asymmetry typically is quite obvious.

Our culture is obsessed with physical attractiveness, which to a large extent is based on facial symmetry and what is perceived to be "normal." Langlois[45] found that the preference for attractive persons is

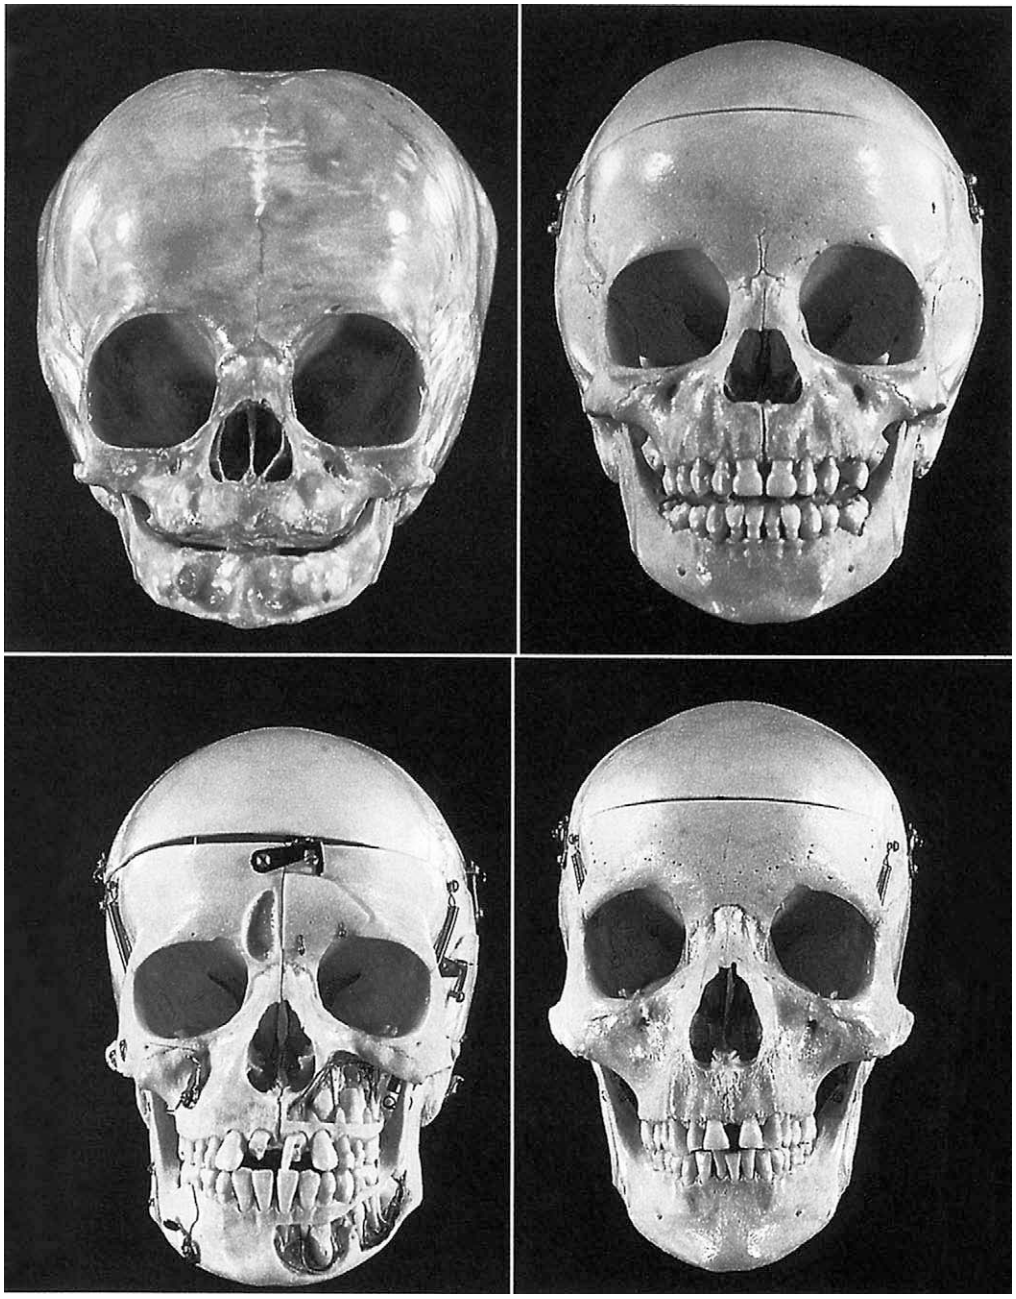

Figure 184-15. Anterior view of the skulls of an infant (8 months of age), a 5- to 6-year-old, a 10- to 12-year-old, and an adult. Note the overall change of skull shape and the facial complex/cranium ratio, the relationship of the orbits to the floor of the nose, nasomaxillary and mandibular growth, and dental changes.

evident early in life and involves all age groups and races. As a result, people whose appearance is divergent from the "norm," with or without intellectual impairment, are viewed differently in our society.

Abnormal facial growth and development may be of iatrogenic, traumatic, mechanical, or genetic etiology: Radiotherapy, functional endoscopic sinus surgery (FESS), internal fixation, nasoseptal trauma and surgery, and nasal obstruction related to dentofacial growth, as well as genetic conditions, all have been recognized as causes. Some etiologic categories relevant to pediatric otolaryngology are reviewed next.

Radiotherapy

Ionizing radiation is widely recognized as detrimental to the growth of developing tissue. In a majority of cases, this consequence is a result of the application of full doses to radiosensitive tumors.[46] Rhabdomyosarcoma and undifferentiated sarcomas constitute the most common type of malignant tumor of soft tissue of childhood. Of these sarcomas, 35% are found in the head and neck region. Retinoblastoma is the most frequent malignant ocular tumor in childhood and is a frequent indication for radiotherapy in the pediatric population.[47,48] Multimodal therapy (radiotherapy and chemotherapy) has been effective in the treatment of these tumors with a 3-year relapse-free survival rate of between 70% and 100%.[49-52] The value of radiotherapy has not been questioned given its success rate,[53] but as more children have been cured of cancer and the survival rates have increased, concerns about the long-term side effects of these therapeutic regimens (alone or in combination) have arisen.[50,51]

The effects of radiation therapy on facial growth, as well as radiation's collateral effects, are detailed in Table 184-2. Virtually 100% of children who have received radiotherapy suffer from alterations in the development of facial soft tissues, and in more than 60% of these

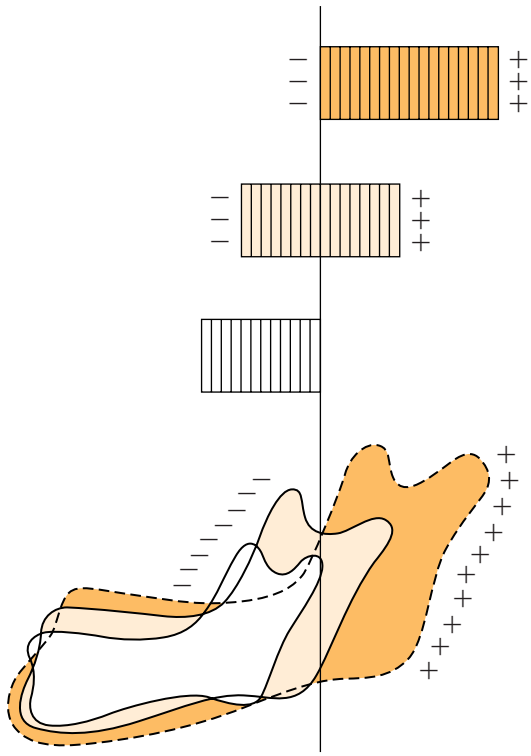

Figure 184-18. As the mandible lengthens, the ramus is extensively remodeled—so much so that the bone at the tip of the condylar process at an early age can be found at the anterior surface of the ramus some years later. Given the extent of surface remodeling changes that occur, it is an obvious area to emphasize endochondral bone formation at the condyle as the major mechanism for growth of the mandible. *(From Proffit WR. Contemporary Orthodontics. 2nd ed. St Louis: Mosby; 1993.)*

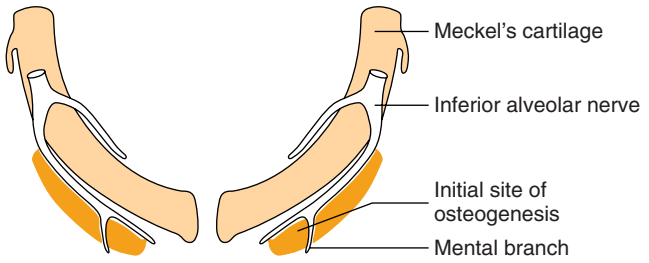

Figure 184-17. Diagrammatic representation of the relation of the site of initial bone formation in the mandible to Meckel's cartilage and the inferior alveolar nerve. Bone formation begins just lateral to Meckel's cartilage and spreads posteriorly along it without any direct replacement of the cartilage by the newly forming bone of the mandible. *(From Proffit WR. Contemporary Orthodontics. 2nd ed. St Louis: Mosby; 1993.)*

children, the facial bones are affected.[47,54] The younger the patient at the time of irradiation, the greater the effects on craniofacial development.[51,55,56] These side effects are more frequent and more severe within the first 10 years after irradiation.[54]

It has been difficult to determine the safest dose of irradiation that keeps side effects on growing tissue to a minimum but at the same time is effective in eradicating the cancer.[46,53,54] Techniques for radiotherapy administration have changed during the past 20 years. The principal aim is to achieve a balance between cure and late toxicity of the treatment.[54] Changes to minimize undesirable effects include radiotherapy with megavoltage, hyperfractionation, three-dimensional therapy, intensity-modulation, and conformal radiation with multiple fields.[47,55] In all children undergoing radiotherapy of the head and neck, it is mandatory that multidisciplinary follow-up be part of the ongoing management.

Functional Endoscopic Sinus Surgery

FESS has become the standard of care in the surgical management of chronic sinusitis and other sinus disorders in the pediatric population. Its effectiveness has been accepted when clear indications for surgery are established.[57,58] However, concerns have arisen regarding potential negative effects on the growth and development of paranasal sinuses and the nasomaxillary complex in the pediatric patient.[59]

A knowledge of sinus anatomy during different stages of development, as well as of pathologic circumstances such as chronic sinusitis, is imperative in decisions regarding FESS in the pediatric population.[28,60-62]

The absolute and relative indications for FESS in the pediatric population varied during the 1990s and into the millennium. These changes were related to the evolving definitions of sinus disorders and short- and long-term outcome measures.[60,63-68] This topic is covered in Chapter 195.

Although the relationship between nasal breathing and sinus development remains unclear, it is generally accepted that the development of the paranasal sinuses is linked to the growth of the nasomaxillary complex. A reasonable assumption, therefore, is that any intervention at this level, either an endoscopic technique or a Caldwell-Luc procedure, on a growing patient will have negative effects on the normal process of remodeling, expansion, and pneumatization.

Results of animal studies have varied depending on the species and the intervention. Kraut and Kronman examined 36-day-old New Zealand White rabbits and unilaterally filled their maxillary sinuses with polyhydroxyethylmethacrylate without adverse effect on

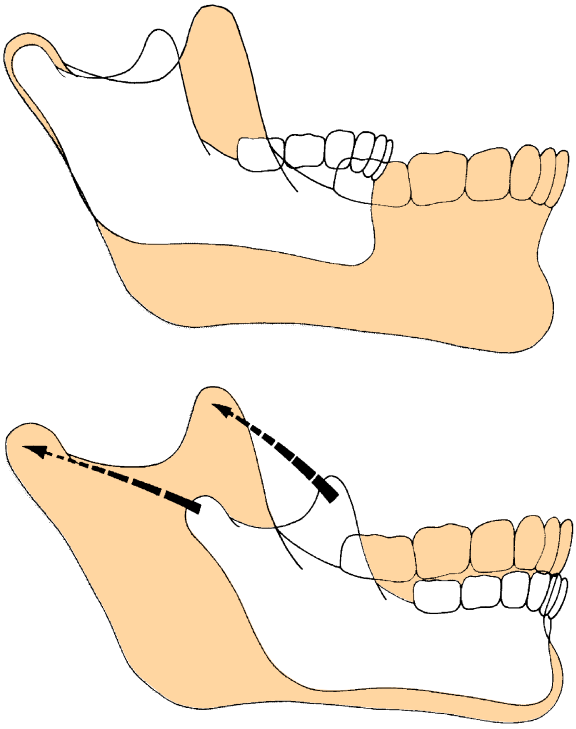

Figure 184-19. Mandibular growth as viewed from the perspective of vital staining dyes. Note the minimal changes in the body and chin area, whereas exceptional growth and remodeling occur in the ramus, moving it posteriorly. The correct concept of mandibular growth is that the mandible is translated downward and forward and grows upward and backward in response to this translation, maintaining its contact with the skull. *(From Proffit WR.* Contemporary Orthodontics. *2nd ed. St Louis: Mosby; 1993.)*

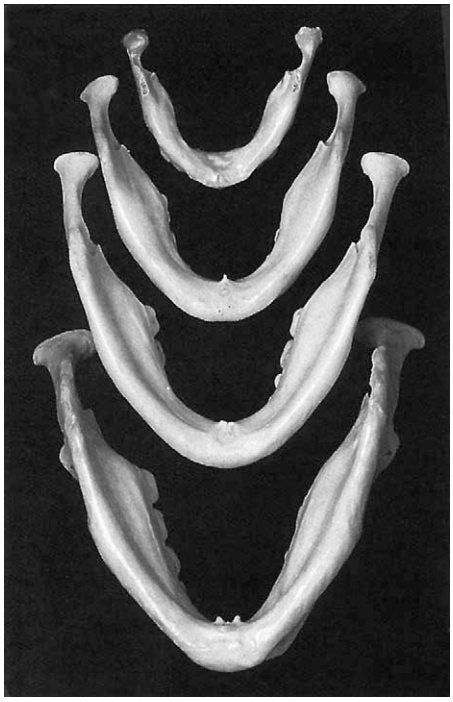

Figure 184-20. With mandibular growth, the U shape of the infant mandible *(top)* changes to more of a V shape, as seen in the adult *(bottom)*.

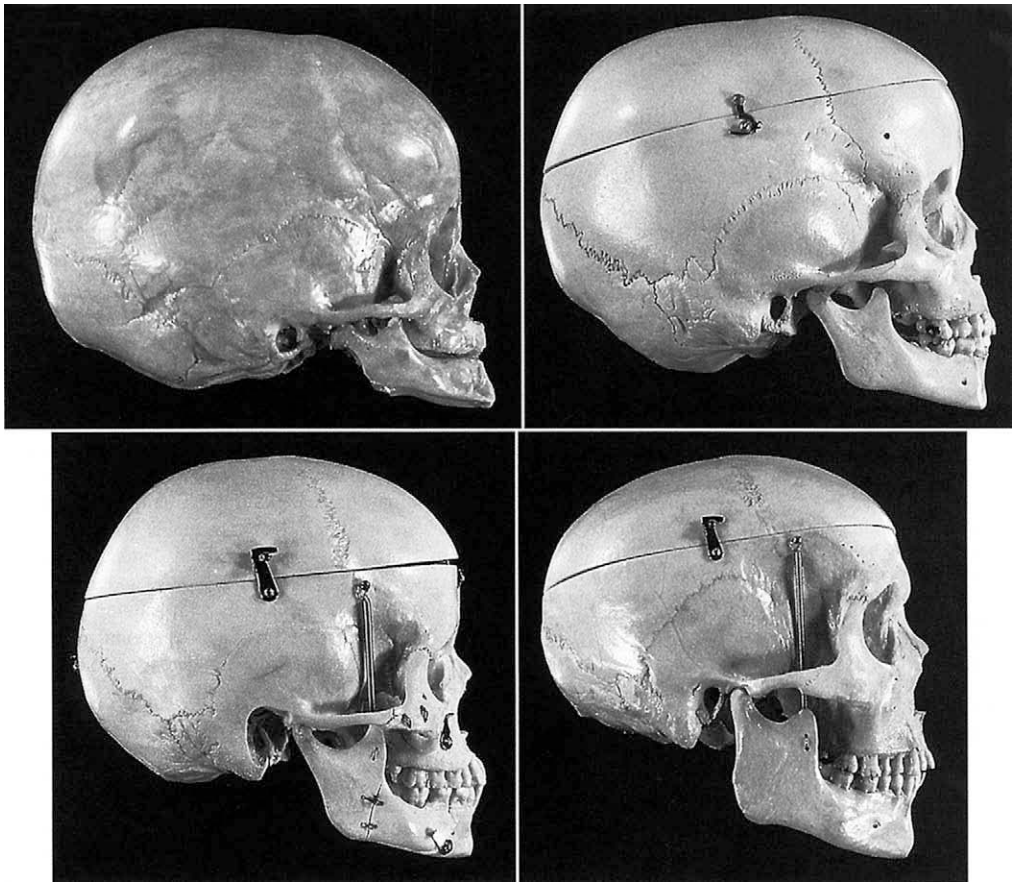

Figure 184-21. Lateral view of the skulls of an infant (at 8 months of age), a 5- to 6-year-old, a 10- to 12-year-old, and an adult. Note that the gonial angle of the mandible is more obtuse in the infant. The overall change in size of the mandible through time is dramatic.

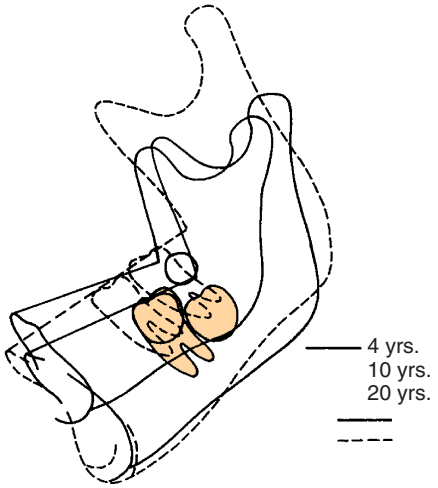

Figure 184-22. Superimposition on implants for a patient with a normal growth pattern showing surface changes in the mandible from ages 4 to 20 years. For this patient, there was a –19 degree internal rotation but only a –3 degree change in the mandibular plane angle. Note dramatic remodeling in the area of the gonial angle, with a net resorption during this period. This surface remodeling or external rotation compensates for, and conceals the extent of, the internal rotation. *(From Bjork A, Skiller V. Normal and abnormal growth of the mandible: a synthesis of longitudinal cephalometric implant studies over a period of 25 years.* Eur J Orthod. *1983;5:1.)*

craniofacial growth.[69] Mair and coworkers studied eight newly weaned piglets subjected to unilateral FESS. The researchers examined the piglets 6 months after surgery, noting significant reduction of the facial growth and maxillary-ethmoidal sinus development on the operated side.[70] Carpenter and associates found significant restrictive effects on piglet facial skeletal development after FESS.[71] Verwoerd-Verhoef and Verwoerd demonstrated that controlled resection of the bony sinonasal wall and partial resection of anterior ethmoid did not affect later development of nasal bones and maxilla on 20 young New Zealand White rabbits.[72]

Several studies in children have been undertaken. Mair and coworkers analyzed the uncinate processes and ethmoids of 84 children (mean age of 6 years; age range, 1 to 18 years) who previously had undergone FESS. In children younger than 9 years of age, woven and lamellar bone were present, in contrast with the presence of exclusively lamellar-mature bone in the children older than 9 years of age. These results suggest that the safest age at which a pediatric patient should be operated on is 9 or older.[70] Kosko and colleagues in 1996 presented five cases of children (mean age of 30 months) who had undergone bilateral FESS for refractory chronic sinusitis. At mean postoperative month 42, four children showed unilateral maxillary hypoplasia and one child showed bilateral hypoplasia without apparent changes in facial symmetry.[59] Sinus hypoplasia can be from primary causes related to individual development or secondary causes associated with a response to facial trauma, chronic sinusitis, or FESS, which has affected the activation of bone formation factors or the removal of growth centers.[59,61,73] In 2000, Senior and associates did not find long-term significant differences in sinus volumes in eight patients (age range, 2 to 14 years) who had required FESS after unilateral orbital complications of acute sinusitis, but the age range was so wide they could not determine any age-related association.[74] In a 2002 retrospective study, Bothwell and coworkers reported no evidence of facial growth disruption 10 years after FESS in 67 children between 2 and 4 years of age.[63]

Lusk and colleagues reported results of a 10-year retrospective follow-up study in children (aged 2 to 5 years) treated with FESS for chronic rhinosinusitis. Parental satisfaction regarding nasal symptoms was significantly higher in the surgically managed group than in the medically treated group. The study focused on six symptoms: day cough, night cough, irritability or crankiness, headaches, nasal airway obstruction, and purulent rhinorrhea. In comparisons of individual symptoms, no statistically significant difference was found between the two groups. However, when the mean was controlled for baseline symptom severity and CT severity, additional analysis noted a statistically significant decrease in nasal airway obstruction and in rhinorrhea in the surgical treatment group.[75]

In a small series of 14 patients with cystic fibrosis ranging in age from 9 to 28 years, Van Peteghem and Clement found no impact on the outcome of facial growth in comparison with their control group of 5 patients with cystic fibrosis who did not require surgery.[76]

In view of the small sample sizes in several studies and the lack of prospective studies, concerns still remain regarding FESS in the pediatric population. Unless the patient has an acute complication of sinus origin, FESS for chronic sinusitis should ideally be delayed until maximal medical therapy has been undertaken in order to avoid potential negative effects on facial growth.[58,77] It is recommended that one be prudent regarding the timing and extent of FESS in children and that clear indications for surgery be followed. If FESS is performed, conservative treatment preserving as much as possible of the normal mucosa, periosteum, and bone is recommended.[59,64,70,71] Further prospective studies in both animal and humans are required to clarify the role of FESS in the facial growth of children.

Internal Fixation and Facial Growth

Midface skeletal maturity is complete by approximately age 12 years. An important point is that any trauma or reconstructive surgery before this age may adversely effect facial growth.[78] However, according to Singh and Bartlett's review of data for surgically treated children for craniofacial fractures, a majority of cases had a favorable outcome with regard to facial growth and development on long-term follow-up, except for isolated condylar fractures and patients with complex centrofacial trauma.[79] There were significant limitations to this retrospective descriptive paper.

Some basic principles should be followed in planning the management of these patients. Complete clinical and image-guided assessment, early repair of fracture and soft tissue injury, minimal but sufficient surgical exposure, and correct technical application of fixation devices are required to achieve good bone stability without disrupting long-term facial growth.[78,80-83]

The direct effect of plates and screws on facial skeletal development has been studied. Lin and associates found significant growth retardation in a craniofacial segment in kittens that underwent osteotomies in conjunction with different fixation systems.[84] However, Mooney and coworkers did not find significant effects in rabbits.[85] These workers suggested, along with Carinci and colleagues, to avoid crossing sutures with plates and screws, because of the risk of synostosis.[86] Yaremchuk and coinvestigators found that osteotomy and fixation in the infant rhesus monkey affected craniofacial growth.[87] Growth deformity in selected craniometric parameters was greater when the complexity of fixation (longer plates and more screws) were used.[87,88] Courtemanche and associates found that the use of rigid internal fixation in the growing skull of piglets resulted in a contour deformity of the calvaria, and that the microplate and screw became completely incorporated into the bone. These workers suggested that this type of fixation not be used in the infant craniofacial skeleton.[89] Salyer and colleagues concluded that absorbable materials did not disrupt bone growth in canine puppies, but in this study, osteotomies were not performed.[90] In 1996, Canady and coworkers designed an animal model using conventional vitallium hardware after osteotomies without the restriction from routine rigid fixation. This system permitted more normal growth of the rabbit head compared with the rigid fixation system.[91,92] Laurenzo and associates concluded in 1995 that experimental osteotomies cause severe bony restriction in rabbits, regardless of the use of rigid plate fixation, supporting the theory that trauma itself affects growth and development.[93] However, the validity of studies using animal models has been criticized because of the lack of full applicability in humans.[87]

Imola and colleagues published a 2001 retrospective study of patients treated with resorbable plate fixation systems, concluding that this method is safe, with results comparable to those with use of metal

Table 184-2

Side Effects of Radiotherapy

Category	Manifestations
Skin	Dryness, abnormal pigmentation, telangiectasis, malignant degeneration, atrophy, alopecia, sebaceous cysts
Mucosa	Xerostomia, atrophy, fibrosis
Soft tissues	Atrophy, hypoplasia, sensitivity to infections
Facial bones	Growth retardation, hypoplasia, dysplasia, appositional growth restriction, weak resistance to infections, loss of cortical bone density, atrophy of alveolar process, micrognathia, facial asymmetry, condylar hypoplasia, "bird face," abnormal occlusion
Teeth	Failure to erupt, disturbed eruption, damage to tooth buds, anodontia, hypodontia, pseudoanodontia, mineralization, caries, root foreshortening, enamel dysplasia, atypical root morphology
Orbit	Bone and soft tissue hypoplasia, persistent infections.
Eyes	Cataracts, xerophthalmia, retinopathy, corneal lesions, loss of vision, keratoconjunctivitis, dryness of globe, enophthalmos, stenosis of lacrimal duct
Head and neck muscles	Atrophy, trismus, fibrosis
Risk of second malignancy	Osteogenic sarcoma, soft tissue sarcomas usually within radiation fields, thyroid, breast, acute myeloid leukemia, histiocytoma
Brain	Cerebral function damage
Middle ear	Serous otitis media, chronic otorrhea
Paranasal sinuses	Bone hypoplasia, chronic sinusitis
Audiology	Sensorineural or conductive hearing loss
Speech	Velopharyngeal incompetency
Hormonal	Growth retardation, growth hormone deficiency
Psychologic	Psychologic disorders
Cosmetic	Bone or soft tissue hypoplasia, facial asymmetry, severe neck fibrosis, nuchal asymmetry
Various	Nutritional and vitamin deficiency

plates, but without the negative effect on the growth and development of the facial skeleton, because of its resorptive capacity once the fracture is healed.[94]

As more data over time are acquired regarding internal fixation and facial growth in the pediatric population, clarity regarding long-term outcome is sure to be achieved.

Nasoseptal Trauma and Surgery

It has long been suggested that nasal trauma or surgery has a detrimental effect on the nasofacial development of growing children. The literature notes that in adults with a deviated nasoseptal complex, up to 65% had sustained trauma in childhood.[95] It is important to recognize that nasoseptal deformities are a result of a complex interaction of factors, including trauma, surgery, inheritance, and individual growth patterns. Surgical correction of nasoseptal deformities during childhood remains very controversial because of potential adverse functional or aesthetic long-term sequelae.[96-98]

Animal Studies

Historically, various animal models of nasal septal trauma have been analyzed in attempts to find a valid correlation with humans. Sarnat and Wexler reported that in 1858 Flick removed septal cartilage from several different types of newly weaned animals and found significantly shortened hard palates on autopsy specimens suggesting that palatal growth depended on the growth of the nasal septum. They also reported that the degree of snout deformity was proportional to the amount of septum and perichondrium resected from rabbits.[99] Wexler confirmed these findings in a follow-up study.[100] Moss and colleagues wrote that the septum played a passive role in the development of the midface, acting only as a support structure in guinea pigs.[101] Hartshorn had similar findings after septectomies in puppies.[102] Stenstrom and Thilander studied guinea pigs, noting that in this species the septum is not the primary structure determining facial growth.[103]

Beginning in the 1970s, experimental models changed because the animal procedures to date frequently had been carried out in a destruc-

tive fashion and not as they would have been carried out in humans. Bernstein did not find growth retardation in dogs after conservative septoplasties in which the mucoperichondrium was preserved and the removed cartilage was reinserted but not sewn in.[104] Nordgaard and Kvinnsland noted severe deformities in rats after septoplasty, regardless of whether there was preservation of the mucoperichondrium.[105] Verwoerd and associates reported that the basal portion of cartilage, the perpendicular lamina, and the junction between cartilage and the premaxilla and cartilage with the sphenoid were the key areas in nasal development in rabbits.[106] Cupero and colleagues found that septal surgery preserving mucoperichondrium did not affect facial development in ferrets.[107] However, concerns persisted in the literature because of the lack of clear correlation between animals and humans.

Human Studies

In human studies it is difficult to differentiate the proportion of long-term sequelae on nasofacial growth and development attributable to trauma alone or in combination with surgery. A number of authors have theorized on the growth centers of the septum[106,108-111] (Fig. 184-23). Clinical cases such as that seen in Figure 184-24 invite researchers to question the role the septum plays in nasal growth. In the case depicted, a septal abscess developed at the age of 1 year. Serial photographs of the patient follow nasal growth at ages 1, 7, and 12 years. Nasal size appears to be smaller than expected; however, until the patient goes through a facial growth phase as an adolescent, it is difficult to comment on what the final proportion of his nose to the rest of his face will be. Clinically, he also has nasal obstruction secondary to a significantly deviated septum.

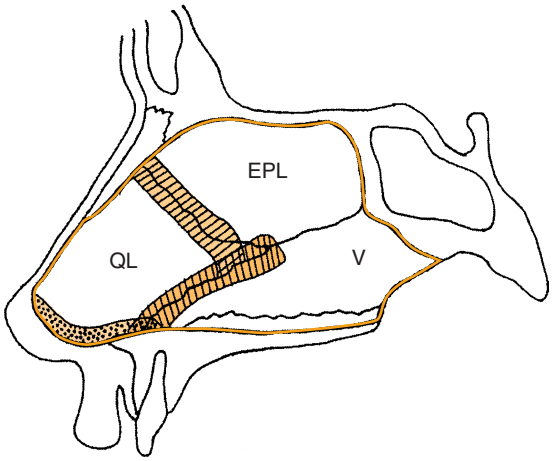

Figure 184-23. Proposed growth centers of the septum. EPL, ethmoid perpendicular lamina; QL, quadrangular lamina; V, vomer.

Alpini and colleagues examined 423 newborns, finding pyramid deformities with septal dislocation and columella deviation, assumed to be related to labor trauma with vaginal delivery. No infant delivered by cesarean section had a pyramid deformity. Septal deviation and subluxation were postulated to be related to developmental defects, and findings were essentially the same in the vaginally delivered and cesarean section–delivered infants.[112]

Traditionally, it has been accepted that nasoseptal surgery in children should be delayed until nasal maturity has been reached, at approximately the age of 15 years in boys and 12 years in girls. Parameters for the male and female such as facial maturity (15 and 12 years, respectively), near complete projection of the nasal tip (16 and 14 years, respectively), and the completion of growth spurts at ages 1 to 6 years and 12 to 16 years have been used to justify delay of surgical correction.[14,98,113] Akguner and coworkers, after analyzing anthropometric studies of 140 boys and 140 girls (age range, 11 to 17 years), concluded that the safest age for a septorhinoplasty in children was 15 years for boys and 13 for girls.[14] El-Hakim and associates compared 11 anthropometric variables in children who had undergone open rhinoplasty and found no long-term sequelae, although Béjar and colleagues previously had found a trend in growth retardation in the dorsum length (length from nasion to pronasale), which was not statistically significant.[96,114]

As noted by Pirsig, several clinical trials and studies with children were published during the early to mid-twentieth century: Krieg (1900), Freer (1902), Killian (1908), Metzembaum (1929), Cottle (1939, 1964). Those studies suggested that septoplasty be undertaken at the age of 16 years.[115] Farrior and Connolly postulated that a preadolescent could undergo conservative septoplasty in cases of severe deformity or impairment of nasal function.[116] In Pirsig's series of 261 children 4 to 14 years of age who underwent septoplasty, 80% achieved positive functional and aesthetic long-term outcomes, whereas 15% did not.[115] Pirsig, as well as other investigators, classified failures as the following anomalies found after trauma or surgery or both: mucosal atrophy, soft tissue scars, resorption or regeneration of cartilage (frequently ectopic) resulting in septal redeviation, bony resorption, fibrosis, hypoplasia (after septal hematoma or abscess), or hyperplastic changes (resulting in humps or crests).[95,115] Ortiz-Monasterio and

Figure 184-24. **A,** Septal abscess in a 1-year-old boy. **B1** and **B2,** Nasal profile in the same patient at ages 1 and 7 years, respectively. **C,** Nasal profile in the same patient at age 12.

Olmedo demonstrated no long-term negative outcomes in 44 children (8 to 12 years of age) after formal rhinoplasty including medial and lateral osteotomies. In this series, 65% of patients underwent septoplasty with limited dissection of mucoperichondrium and minimum cartilage excision and, when indicated, cartilage was crosshatched and replaced. Patients were followed up with preoperative and postoperative photographic and anthropometric studies.[117]

Surgical Timing and Approach

Timing of nasal surgery depends on when the injury or traumatic event has taken place and the amount of time to presentation to the surgeon. Some investigators have addressed the possibility of intervention in neonates with septal deviations secondary to delivery related injuries. Emami and Sooknundun and their coworkers advocate closed reposition or reduction of anterior septal nasal deformities and subluxations within the first few days of life in order to avoid future deformities.[118,119] However, many deviated noses of the newborn, both externally and internally do resolve on their own over several days to weeks. Kawalski and Spiewak concluded that anterior septal deviations caused by birth injuries are likely to resolve spontaneously within the first 3 days of life, suggesting that any intervention should be considered only for older children.[120]

Hippocrates (fifth century BC) described in detail the technique of nasal fracture reduction.[121] Pirsig suggested that the best time to correct nasal fractures in the pediatric population was between 6 and 10 days after injury.[95] He also felt that open reduction 2 to 3 weeks after injury was possible in cases of "massive pathologic signs." Many surgeons advocate waiting a period of 7 to 10 days after injury for the optimal time frame for fractures requiring closed reduction. Timing for surgery in patients presenting long after the traumatic event is more varied in the literature. Farrior and Connolly believed that it was wise to delay the procedure until achieving complete facial maturity, except in cases of severe functional impairment, in which it was important to do a limited resection, with proper reposition of cartilage. Alar or dorsum procedures were recommended to be delayed as long as possible.[116] It should be noted that much of the literature is anecdotal or lacks a scientific basis for the recommendations and opinions expressed.[122]

Different surgical approaches have been proposed. Loh and Chang described the basic septoplasty technique in children, with no noteworthy differences from adults, except for the conservative excision of cartilage and bone.[123] For severe deformities, Jugo proposed open rhinoseptoplasty, excising, and replacing the septum, without violating the K point (i.e., the junction between nasal bones and upper lateral cartilages on the nasal dorsum), neither cutting the septospinal ligament nor dissecting inferior tunnels. In less severe cases, a conventional Cottle's septoplasty is advised.[124] Koltai and colleagues agreed with this.[125] Crysdale's group proposed two approaches in children 6 years of age and older. When the deviation is located caudally and posterior to an imaginary line from the anterior nasal spine to the anterior aspect of the nasal bones, a hemitransfixion incision and limited excision of cartilage, maxillary crest, and vomer is indicated. If the deviation is anterior to this line, they suggested an open approach removing the whole quadrilateral cartilage and replacing it using its posterior edge, creating a "new" septal midline.[96,98,114,126,127]

In conclusion, rhinoseptoplasty in children remains a controversial topic.[127-130] It would appear impossible not to interfere to some degree with the growth pattern in operating on a developing nose. Farrior and Connolly in 1970 counseled prudence in this regard:

> There has not been adequate documentation by anatomic sections, embryologic study, and clinical verification of just what components of the nasal structure should not be disturbed or removed and what portions of these various structures should be either removed or preserved. The actual rates of growth of each component and what precisely located surgical trauma would do to future development have not been well studied. In any event, conservatism and repositioning without removal of tissue, or with minimal tissue disturbance, seems to be the wise approach.[116]

Although further study has taken place since Farrior and Connolly's delineation of the problem, questions remain regarding timing of and approach to this not uncommon reconstruction. Therefore, these procedures should be performed conservatively and, when possible, delayed until facial maturity is attained. However, should severe deformities be present, corrective procedures are indicated. A second surgical repair may be required once facial growth is completed or nearly completed, depending on the age of the child at the time of the initial procedure. Before proceeding to surgery, the child's functional, aesthetic, and psychologic parameters must be considered, and it is paramount that these considerations be discussed fully with the patient and the family.

Nasal Obstruction and Dentofacial Growth

Genetic factors clearly play a role in dentofacial growth in humans. Controversy exists in the literature regarding the role that nasopharyngeal obstruction plays with regard to dentofacial growth and development. Two schools of thought prevail: (1) that nasal obstruction plays a role and (2) that it does not.[131,132]

Nasal obstruction results in increases in both nasal flow resistance and nasal power (rate of energy required to move air through the nose), such that the child may be forced to switch to mouth breathing. When mouth breathing, the child has an open-mouth posture (OMP)—the mandible and tongue are displaced downward and backward and the head is tilted backward. It has been hypothesized that OMP affects the direction of jaw growth and the interaction of the teeth both horizontally and vertically. Stress from the suprahyoid muscles and the platysma is thought to influence growth on the lower aspect of the mandible. Sperber[1] makes reference to Moss's functional matrix hypothesis, noting that the nasal cavity also may influence growth of the face. Enlarged adenoids in young children are one of the most common causes of nasal obstruction, potentially resulting in the typical "adenoid facies" (narrow, increased facial height, protruding teeth, OMP, short upper lip and larger lower lip, small nose, high-vaulted palatal arch, and the appearance of a vacant or dull facial expression (Fig. 184-25). However, the cause-and-effect relationship of nasal obstruction and this facial morphology has not been substantiated. Heredity also may be involved to some degree.[1]

It should be noted that the term *mouth breathing* is in fact a misnomer, because most persons identified as using this mode of breathing are in fact oronasal breathers. Complete mouth breathing is unusual, and Ung and colleagues reported only 2 of the 49 children they studied to be 100% mouth breathers.[133] In fact, the accurate determination of respiratory mode (oral, nasal, or oronasal breathing) remains elusive, leading to significant difficulties in researching the effect of nasal obstruction on facial growth. The nasal valve area also may play a significant role in nasal obstruction. Ung's group found that the breathing modes of growing children varied on different days of testing. Hairfield and associates concluded that "the variation in respiratory mode we observed may make it impossible to identify clear cause-and-effect relationships regarding upper airway function on facial development."[134] The lack of normative data on nasorespiratory breathing and problematic measurement of respiratory mode must be kept in mind in reviewing the literature regarding implications of nasal obstruction on facial growth and development.

Open Mouth Posture

OMP in children may result from nasal obstruction secondary to enlarged adenoids, from significant allergic disease, from habit developed during previous nasal airway blockage, or from lack of encouragement from adult caregivers to maintain closed-mouth posture. However, oral respiration and OMP are quite common in children and may be unrelated to nasal airway obstruction. Indeed, it may be a normal part of development for some children. Warren and coworkers found that, before the age of 8 years, the proportion of nasal breathers and that of oral breathers were roughly equal. After 8 years of age, a majority of

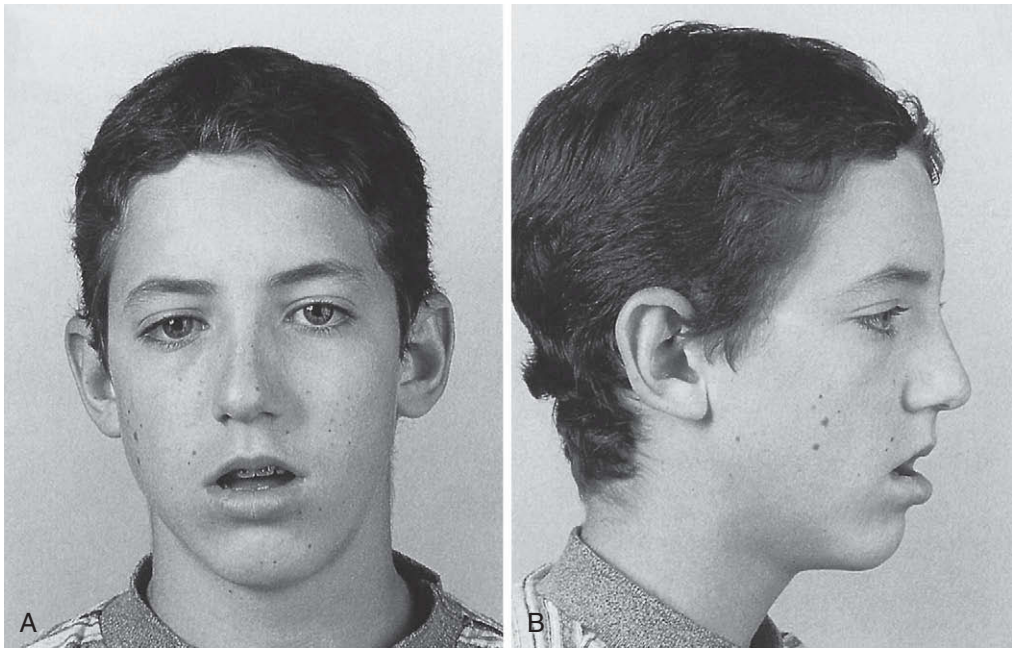

Figure 184-25. **A** and **B,** Typical "adenoid facies" in a 14-year-old boy. Note the long face, open mouth posture, short upper lip, larger lower lip, small nose, and dull facial expression.

children were nasal or predominantly nasal breathers.[135] Black children appear to abandon OMP more quickly over time at a faster rate than that noted in white children.[136] In evaluating children for chronic mouth breathing, OMP does not necessarily imply significant nasal obstruction, because some children will have OMP but are nasal breathers. In their study of children with severe nasopharyngeal obstruction, Woodside and colleagues found that 80% converted to nasal breathing after adenoidectomy.[137] The remaining 20% of their study population did not convert to nasal breathing following adenoidectomy. Soft tissue components of the oral cavity also may contribute to OMP (e.g., the tongue, by means of tongue thrusting).

Review of the Literature

Several studies have considered the specific effect of nasal airway obstruction on dentofacial growth. Complete nasal obstruction appears to alter dentofacial growth.[138] Paul and Nanda[139] and Gross and coworkers[136] found that children with OMP had less growth of the maxillary arches compared with children with closed-mouth posture. Brodie postulated that in some patients, the force of the buccinator muscle and its attachment may result in poor maxillary arch expansion.[140] A narrow maxillary arch frequently is associated with skeletal open bite and anterior crossbite.[22,141] Oulis and associates[142] found that the presence of posterior crossbite was high in children with severe upper-airway obstruction. Linder-Aronson summarized the conclusions of several studies[143-146]:

1. Monozygotic twins are more alike in mandibular growth direction than dizygotic twins, indicating some genetic influence.

2. Children with enlarged adenoids resulting in nasopharyngeal obstruction and subsequent mouth breathing have a longer total and longer lower anterior facial height. They also have an inclination toward a retrognathic mandible in comparison with unaffected children. Children with enlarged adenoids experience subsequent alteration of the dentofacial structures, resulting in an increase in the incidence of open bite, posterior crossbite, and narrower upper maxillary arches.

3. Children with enlarged adenoids and malocclusion, at 5-year follow-up after adenoidectomy, were found to have an increase in maxillary arch width and a decrease in lower facial height and mandibular plane angle. Affected girls demonstrated more horizontal mandibular growth.

4. Some children may undergo partial reversal of dental and skeletal anomalies after relief of nasal obstruction. Specifically, after adenoidectomy some children have shown evidence of a "partial recovery" from abnormal facial growth direction of the mandible and a decrease in lower facial height.

5. Changes in specific tooth positioning (incisors) after adenoidectomy have been noted.

In their study of 38 children observed over 5 years after adenoidectomy, Woodside and others[137] concluded that mandibular growth was greater in both males and females at the chin than in control subjects and that midface growth was greater in males, although no change in maxillary growth direction was observed for either gender.

Extended head posture is characteristic with mouth breathing and reverses when normal nasal breathing is resumed.[141] Studies in primates with obligatory oral breathing have shown that partial recovery of lower facial height and mandibular steepness occurred when normal respiration was resumed.[147,148] Extrapolation of primate studies on nasal obstruction and growth to humans is not clear. Houston[149] postulated that "growth in anterior face height is determined primarily by growth in the length of the cervical column and the associated stretch of the cranio-cervical fascia and musculature." Muscular influence in this area is supported by the primate studies noted previously.

In many of these studies the differences in measurements were statistically significant but not greatly so. In comparing "long face" and "normal face" adolescents, Fields and colleagues[150] showed data suggesting that decreased nasal respiration may add to a long face phenotype but is not the only cause. Although a large proportion of oral breathers are represented in the long face population, a significant number of long face persons do not have nasal obstruction.[22] Ung and coworkers[133] found a weak association of maxillary and mandibular incisors and class II malocclusion with retroclination. These workers questioned the clinical significance, even though the correlation was statistically significant. In addition, the association between dentofacial variables and respiratory pattern was weak in establishing generalizations about causal relationships when assessed subjectively and objectively. Mahony and associates, in their study of 80 children (45 with

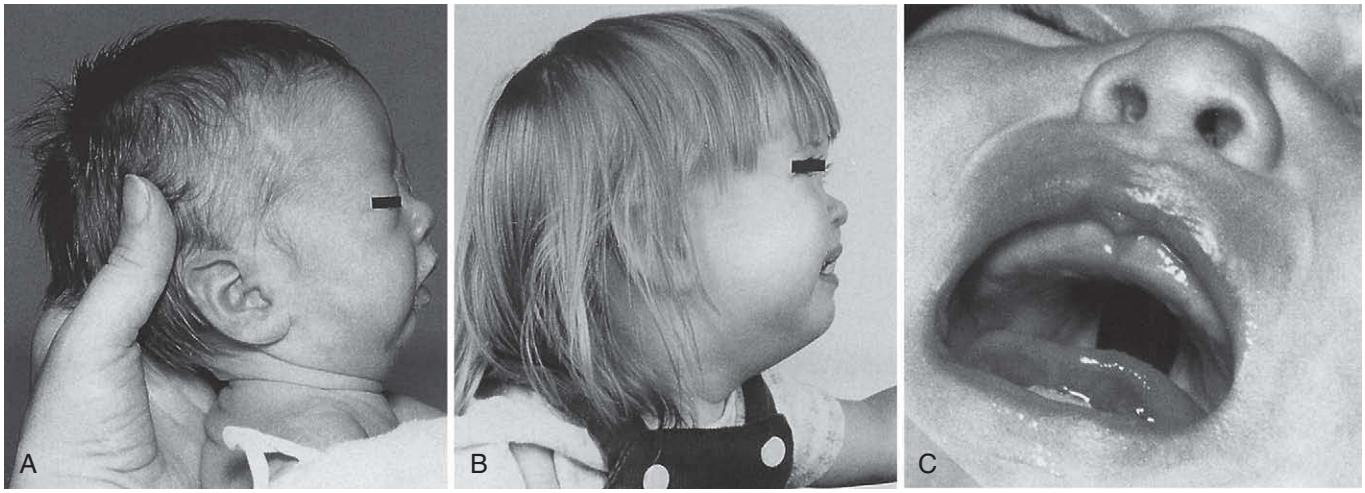

Figure 184-26. **A,** A newborn with Robin sequence. **B,** The same child at 2 years of age. Note the partial mandibular catch-up growth. **C,** U-shaped cleft palate in a patient with Robin sequence.

nasal obstruction who received an adenoidectomy and 35 age- and sex-matched controls), concluded that the changes in the dentoalveolar heights of the maxillary molars and the ratio of the upper and lower anterior face heights seem to be associated with the change in mode of breathing from mouth to nose breathing after adenoidectomy.[151] Hartgerink and Vig[152] could find no significant correlation between the respiratory and morphologic features studied, although they described associations among lip posture, lower anterior facial height, and nasal resistance.

Perhaps there is a period in facial growth and development during which a decrease in nasal breathing and an increase in oral breathing critically influence dentofacial growth. If so, then the timing of intervention would be important to alleviate or lessen the adverse aspects of the ultimate facial result.[133]

Rapid maxillary expansion (RME) with and without surgery has been shown to decrease nasal resistance and increase repiratory area. The study investigators advocate that the pubertal or prepubertal age period is the most suitable age for this intervention in patients with both maxillary constriction and a posterior cross-bite.[153] RME improved obstructive sleep apnea by changing the anatomic structure (widening of the nasal fossa and release of the septum) in 42 patients reported by Pirelli and colleagues; however, this study did not include a control group.[154]

Taking into account the research conducted in this area, the role that breathing patterns and modes play in dentofacial growth is still open to debate. Although the evidence is not entirely clear and the exact mechanisms remain unknown, it appears that craniofacial changes occur in persons with significant nasal obstruction secondary to adenoidal hypertrophy. This has led some researchers in the field to say that adults should watch for OMP in children and encourage them to "maintain appropriate lip seal posture" because of the high incidence of OMP in the orthodontic population. In the event that closed mouth posture cannot be maintained, the clinician should search for a treatable cause of OMP, such as an adenoidectomy.

Variations in response to the relief of nasal obstruction occur in patients, and it may be difficult to decide who would benefit from an adenoidectomy. Although the literature contains a growing body of data that nasal obstruction influences facial characteristics and that reversal may occur under certain conditions, this is still open to debate.

Hartgerink and Vig[152] concluded that "neither orthodontists nor otolaryngologists can predict or accurately diagnose nasal airway impairment from the patient's facial proportions or lip separation at rest." The prudent otolaryngologist should review in detail the findings in a specific case before embarking on a surgical procedure to possibly alter or reverse dentofacial growth.

Craniofacial Abnormalities

Robin Sequence (Pierre Robin Syndrome)

The combination of micrognathia, cleft palate, and glossoptosis is known as the Robin sequence (Fig. 184-26). Previously known as Pierre Robin syndrome, this entity is now recognized to demonstrate etiologic heterogeneity; thus, it does not meet the criteria for a syndrome, with a single identifiable etiology. Cohen[155] proposed that "etiologic heterogeneity suggests pathogenetic heterogeneity in Robin sequence."

There are various definitions of the Robin sequence, including the presence or absence of a cleft palate, glossoptosis, and airway difficulty. This variability has caused confusion in the literature. The Robin sequence can be classified as either isolated (nonsyndromic) or in association with a syndrome (syndromic). Shprintzen[156] found that approximately 20% of patients had isolated Robin sequence, with the remaining 80% of cases associated with various syndromes. The primary clinical implications of this condition are airway obstruction and feeding difficulty. Anatomically, the larynx is under the base of the tongue in patients with micrognathia and glossoptosis, making direct laryngoscopy or intubation difficult and occasionally impossible.[157] Cleft palate and respiratory difficulty can hamper feeding and contribute to failure to thrive.

Whether the Robin sequence is isolated or associated with a syndrome has very significant implications with respect to mandibular growth. A common error made by physicians is to convey to the family of a newborn with Robin sequence that the child's mandible will reach relatively normal size within a couple of years.[158] If the Robin sequence is associated with a known syndrome (primary error or nondeformational cause), such as Treacher Collins or Stickler syndrome, mandibular hypoplasia will persist throughout the patient's life unless surgical intervention is undertaken. In these cases, postnatal catch-up growth does not occur.

If the Robin sequence is isolated, however, with the etiologic pathogenesis related to deformation, then catch-up growth does occur. Pruzansky[159] believed that postnatal growth potential should be included in the analysis of differences between malformed mandibles and that "some mandibles are capable of considerable postnatal recuperations."

It was formerly thought that once affected patients were full-grown, their mandibles would be of essentially normal size. Pruzansky[159] noted that the mandible in such patients differed from the normal mandible in that "the gonial angle was more obtuse, the condyle extended distally from the ramus, and ramus-to-body proportions were deviant because of the greater reduction in body length." He also noted that these features persisted from infancy into adulthood. The mandible appears to grow faster than normal in such patients during the first

few months of life, resulting in alleviation of breathing problems and feeding difficulty in many. Not all patients are so fortunate, however, and numerous measures have been advocated to address these issues: positioning, subperiosteal tongue release, and tracheostomy, among others.[156,157,160-163]

Even in the isolated Robin sequence, full or complete catch-up growth does not occur (see Fig. 184-26A and B). Figueroa and associates[164] performed a retrospective longitudinal cephalometric study analyzing size, growth, and the relation of the mandible, tongue, and airway in isolated nonsyndromic Robin sequence infants. These investigators found that the increased mandibular growth rate in these infants was significant but did not reach values seen in healthy infants. Craniofacial variables were significantly different between healthy patients and those with the Robin sequence. This study supported the concept of "partial mandibular catch-up growth." The investigators also discussed an unpublished study from their institution in which adolescent patients with Robin sequence were compared with healthy children. Results indicated that craniofacial dimensions, including the maxilla, mandible, and airway, were smaller in Robin sequence patients. Laitinen and Ranta[165] and Laitinen[166] found the dental arches at birth of patients with Robin sequence (isolated or possibly syndromic) and those of patients with isolated cleft lip and palate to be equal. By the age of 6 years, the dental arches in patients with Robin sequence were smaller than isolated cleft palate arches, which in turn were smaller than those in children without clefts.

The U-shaped cleft palate in Robin sequence and its mode of development are different from those of the usual V shape seen in primary defects (see Fig. 184-26C). Hanson and Smith[167] hypothesized that with micrognathia, the posteriorly displaced tongue is interposed between the palatal shelves. The palatal shelves do not close, resulting in less posterior growth of the soft palate and subsequently the U-shaped cleft palate. That is, the small mandible causes the tongue to be placed abnormally in the posterior portion of the oral cavity, in between the palatal shelves, and the subsequent lack of closure and growth of the palatal shelves and the lack of growth of the soft palate result in the U-shaped defect.

Robin sequence is relatively common, occurring in approximately 1 in 8500 births. Prevalence is confusing, however, because of the isolated versus syndromic differentiation. The most important issue in these patients is first to ensure an adequate airway and feeding; and then to determine whether there is an associated syndrome in order to communicate to the family the degree of intervention that is likely to be needed.

Down Syndrome (Trisomy 21)

Down syndrome (trisomy 21) is the most common malformation syndrome (Fig. 184-27). It occurs in approximately 1 in 650 live births, and the prevalence is greater with increasing maternal age. Affected persons, who have an extra copy of the genetic material on chromosome 21, have a highly characteristic appearance.[168,169] More than 100 different physical signs can be present with Down syndrome. The main features, in addition to intellectual deficit, are the craniofacial physical characteristics listed in Box 184-1. These characteristics make persons with Down syndrome appear significantly different from the rest of the population. Pueschel and Pueschel[170] extensively reviewed the biomedical concerns of Down syndrome patients, including growth and devel-

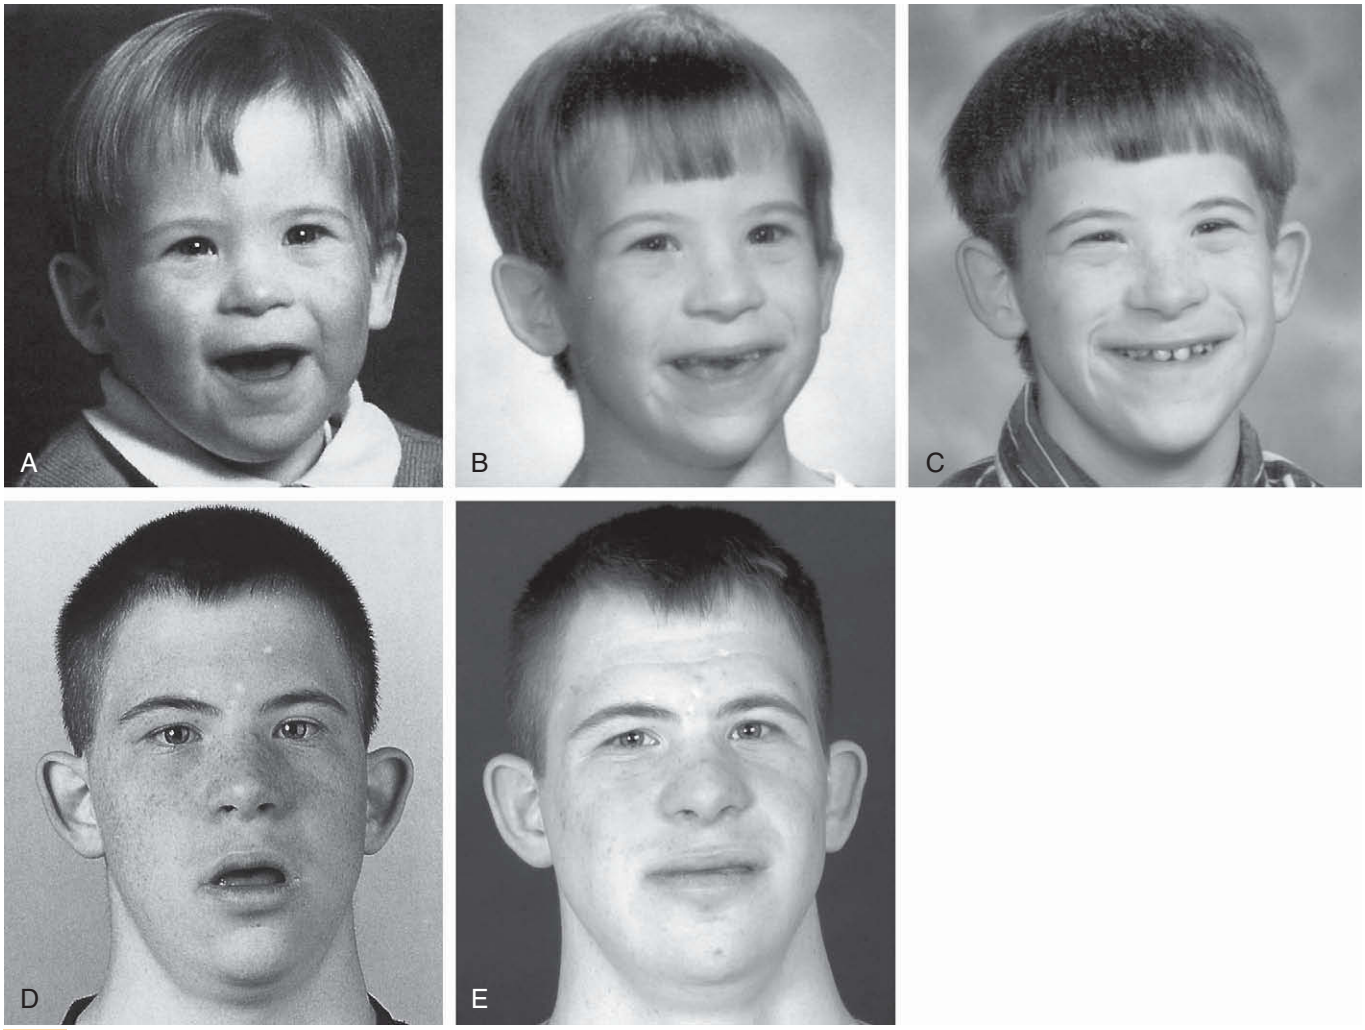

Figure 184-27. **A,** A 2-year-old boy with Down syndrome (trisomy 21). **B,** At age 5. **C,** At age 11. **D,** At age 14. **E,** The patient at age 20.

Box 184-1

Craniofacial Features of Down Syndrome

Brachycephaly
Flat occiput
Upward-slanting palpebral fissures
Epicanthic folds
Short, small nose
Abnormal small ears
Short neck
Midface hypoplasia
Large fissured lips
Large fissured tongue
Dental abnormalities

opment. The specific dysmorphic facial features of Down syndrome, outlined in Box 184-1, can be further classified into five main regions: skull, midface, mandibular and oral, ears, and eyes. The growth changes in each of these regions are reviewed next.

Skull

A majority of patients with Down syndrome have brachycephaly. Head breadth (the largest lateral diameter of the head) and head length (measured from the nasion to the largest length across the occiput) were found to be essentially normal in the first 6 months of life when compared with healthy children.[171,172] At 6 months and 1 year, however, the mean values were less by 1 SD for head breadth and 2 to 3 SDs for head length. The greater difference in head length versus head breadth suggests that cranial growth is more reduced at the cranial base than in the area of the calvaria. In 1979, Hamill and associates[173] determined that head circumference is smaller in persons with trisomy 21; however, this reduction from the norm is thought to be a reflection of overall body size. When head circumference is plotted against body/length ratios, these values are found to be within normal range. Head circumference is related to intracranial or brain growth; whereas cranial base growth probably is under the same control as for total body growth. The occiput also is found to be flat, which is especially noticeable in the profile view. Allanson and colleagues[174] obtained 21 craniofacial anthropometric measurements from patients with trisomy 21 between the ages of 6 months and 61 years of age. Their data were compared with normal known standards and were in agreement with previous studies involving craniofacial findings in Down syndrome. These investigators specifically mention brachycephaly, round face, and small ears but add that underdevelopment of the maxilla in comparison with the mandible also occurs. More recently, computerized anthropometry has been used in patients with trisomy 21 and compared with normal reference data. Several differences have been noted, particularly related to midfacial hypoplasia, decreased nasal protrusion, and a lower facial third region (mandible).[175] Allanson's group found that as age increases, maxillary growth is reduced in comparison with mandibular growth, resulting in a change from the usual round face seen in infants to the more oval shape seen in older patients (see Fig. 184-27).

Sperber[1] indicated that the reduced cranial base results in an increased angulation because of the loss of the flattening effect of the growth of the spheno-occipital synchondrosis. In a skull of normal or reduced capacity, an increase in the basal angle is highly suggestive of Down syndrome.[176] This results in a "dish" deformity of the midface, accentuated by the large neurocranium. The anterior fontanelle is late to close, and the so-called third fontanelle, an open sagittal suture in the region of the parietal bone, is present.[177] A metopic suture is quite common in Down syndrome patients.

Midface

Benda[178,179] noted a deficiency in postnatal development of the nasal bones, the ethmoid, and the maxilla that results in continuance of the fetal proportions of the face in persons with Down syndrome. He also noted that hypoplastic or even absent paranasal sinuses also contribute to midface hypoplasia. Shapiro and associates[180] found that Down syndrome patients have narrower and shorter palates. The deficiency in palatal length, in comparison with that in healthy persons, was so great in the patients from their study (age range, 7 to 18 years) that they could distinguish between a Down syndrome patient and a healthy person on the basis of this dimension alone. Palatal vaults previously were thought to be abnormal (higher-arching) in patients with trisomy 21, but Shapiro's group confirmed that they are within the normal range.[180] Smaller nasal bones appear to contribute to the saddle nose–small nose of these patients.[1] Interorbital distance is reduced, and the mandible is more obtuse.[181] The angle between the base of the skull and the hard palate is less acute than normal in patients with trisomy 21, and the nasopharynx generally is small because of soft tissue encroachment. Although limited by a small sample size, another study compared rapid maxillary expansion in 13 children and no intervention in 13. Acoustic rhinometry measured nasal patency; those children undergoing expansion showed a significant increase in the total nasal volume. The investigators also noted that the widening of the maxillary bones also gives more space for the tongue in the oral cavity and that there is positive dental improvement. However, these two areas were not reviewed objectively in this article.[182]

Sperber[1] theorized that the neural crest tissues involved in facial bone formation, (including the nose) either "may be deficient in number, may not complete migration to their destination, or fail in their inductive capacity or cytodifferentiation." The generalized retardation in midface growth, along with the underdevelopment of the sinuses in patients with trisomy 21, results in the overall poor development and flat facial profile of the midface.

Ears

Persons with Down syndrome have long been recognized to have small ears. The ears are frequently small and boxlike and can be low-set with abnormal overlapping or folding of the helix. Aase and colleagues[183] noted that "of all the anthropomorphic measurements studied, the longitudinal dimensions of the pinna fell furthest below the expected norm at all age levels studied." This finding usually was greater than 2 SDs below the norm in newborns to 1-year-olds and 1 SD in patients older than 1 year of age. External ear canal narrowing is extremely common, and middle ear abnormalities exist.[184,185] The mastoid abnormalities in Down syndrome are mainly hypoplasia and sclerosis.[186] These abnormalities may have an inflammatory etiology from increased problems of middle ear pathology secondary to eustachian tube dysfunction. Generalized hypotonia in Down syndrome may affect the tensor veli palatini muscle, resulting in eustachian tube dysfunction.

Mandible and Oral Manifestations

The oral manifestations of Down syndrome are outlined in Box 184-1. Thickened and fissured lips as the patient advances in age, a large, fissured tongue (possibly related to a relatively small oral cavity), and various dental abnormalities are very common in these patients.[170,187-191] After the age of 16 to 18 years, progressive mandibular prognathism may occur and is believed to be related to the large tongue in a small oral cavity.[192]

Eyes

Using radiographic methods, Gerald and Silverman[181] described narrowing of the interorbital distance in patients with Down syndrome and concluded that this orbital hypotelorism is the skeletal substrate for the characteristic face in these patients. Cohen and associates[193] agreed that ocular hypotelorism is true when measured; however, they also noted that the hypertelorism may appear to be more pronounced in these patients because of the characteristic epicanthic folds and low nasal bridge. Other factors that contribute to the illusion of extreme hypertelorism include exotropia, narrow palpebral fissures, dystopia canthorum, and widely spaced eyebrows. In Down syndrome, epicanthic folds appear to result from underdevelopment of the nasion.[178] An alternative theory is that the epicanthic folds result from an abnormal distribution of the orbicularis oculi muscle, with some fibers passing

circularly in front of the tendon rather than inserting wholly into the ligament.[23]

Abnormal and Poor Growth in Down Syndrome

No specific gene or genes on chromosome 21 have been identified to contribute to the current understanding of how the many phenotypic findings arise in Down syndrome. However, it is postulated that a dosage effect occurs because of the extra chromosome. No growth-regulating genes have been mapped on chromosome 21, but Pueschel and Pueschel[170] postulate that "gene coding for growth-regulating proteins may play a part in the growth retardation observed in individuals with Down syndrome." According to this theory, the extra chromosome 21 is responsible for the abnormal embryogenesis of the fetus with Down syndrome, and somehow the balance in the growth process is altered. Further studies in the molecular biology of growth and development will ultimately delineate this unknown.

Achondroplasia

Achondroplasia is the most common of the chondrodysplasias. A full description of this disorder of bone formation can be found in the works of Jones[169] and Gorlin and colleagues[168] and in the Online Mendelian Inheritance in Man (OMIM) database.[194]

Achondroplasia is an autosomal dominant disorder, with a majority of cases representing a new mutation. Bone formed from cartilage is abnormal because of a mutation in the fibroblast growth factor receptor-3 gene, *FGFR3*, which is located at 4p16.3.[195,196] Two different point mutations have been found in *FGFR3* in patients with achondroplasia, and both lead to the substitution of an arginine residue for a glycine at position 380 of the mature protein, which is in the transmembrane domain of *FGFR3*.[194] In addition to expression of the receptor in cartilage, *FGFR-3* transcripts are present in fetal and adult brains, which have the highest levels of any tissue. This finding may indicate that the effects of the gene involve calvarial content as well as skeletal cartilage, leading to true megalencephaly.[194,197] The exact process leading to the phenotypic appearance is unclear.

Persons affected by this disorder have short stature secondary to rhizomelic shortening of the limbs, as well as abnormalities of a number of other bones, including the lumbar spine, carpals, metacarpals, phalanges, and pelvis (Fig. 184-28A and C). The characteristic facial appearance of achondroplasia results from early spheno-occipital closure, a short cranial base, a small foramen magnum, and resultant megalocephaly with frontal bossing, sunken bridge of the nose, and midface hypoplasia (see Fig. 184-28B and D). In addition, the eustachian tube is shortened. Head growth normally is rapid in the first 6 months of life in patients with achondroplasia.[198]

It is postulated that the genetic defect in achondroplasia leads to reduced growth of the occipital bones, resulting in the small foramen magnum.[19] Premature fusion of the associated synchondroses could also explain the abnormal foramen magnum configuration. Measurement of the foramen magnum may identify affected persons at risk for possible neurologic complications in achondroplasia. Basilar kyphosis is present, with the angle between the ethmoidal plane and clivus reduced to 85 to 90 degrees (normal angle, 110 to 120 degrees).[199] The clivus is vertical, and the sphenoid sinus frequently extends into it.[200] The sella may be small and abnormally J-shaped.[201] The petrous portion of the temporal bone is very distorted, and the internal and external acoustic meatus and labyrinths are abnormally oriented. Of interest, balance is not affected in these patients. Mastoid development is minimal.[200] The chondrocranium is short and narrow, as noted earlier. Dorst[16] observed that the midface is recessed in profile because the facial bones "hang down" from the chondrocranium. Articulation is normal.[199] The mandible is not affected by the genetic mutation but appears disproportionately large. Class 3 dental occlusion is common. Surgical correction using standard craniofacial procedures and nasal bone grafting improves the cosmetic appearance if this is desired.[201,202]

Mandibulofacial Dysostosis (Treacher Collins Syndrome, Franceschetti-Klein Syndrome)

Mandibulofacial dysostosis (MFD), also known as Treacher Collins syndrome, is a rare malformation syndrome associated with a very characteristic appearance,[203] as shown in Figure 184-29. The craniofacial abnormalities in mandibulofacial dysostosis are outlined in Box 184-2,[168,169] and the syndrome is covered in detail elsewhere.[168,169,204]

Box 184-2

Craniofacial Findings in Mandibulofacial Dysostosis (Treacher Collins Syndrome)

Eyes
- Downward-slanting palpebral fissures
- Lower lid coloboma
- Partial to total absence of lower eyelashes

Ears
- Auricular malformations with or without tags and preauricular blind fistulas
- Stenosis or atresia of the external ear canals
- Middle ear and ossicular abnormalities

Face
- Malar hypoplasia (hypoplastic zygomatic bones) and nonfusion of the zygomatic arches
- Flat frontal nasal angle
- Hypoplastic supraorbital rims and ridges
- Narrow nares and hypoplastic alar cartilages
- Tongues of hair onto cheeks

Mandible and Oral Cavity
- Mandibular hypoplasia and severe hypoplasia of the mandibular condyle
- Microstomia
- High-arched, narrow, or cleft palate
- Dental abnormalities

Data from Gorlin RJ, Cohen MM Jr, Levin LS, eds. *Syndromes of the Head and Neck*. 3rd ed. New York: Oxford University Press; 1990; and Jones KL, ed. *Smith's Recognizable Patterns of Human Malformation*. 5th ed. Philadelphia: WB Saunders; 1997.

Mandibulofacial dysostosis is a rare autosomal dominant condition with complete penetrance and variable expression. Sixty percent of cases are the result of spontaneous new mutations. The gene was first localized to 5q32-33.1 by linkage analysis and was subsequently identified by positional cloning.[205] The identification of mutations in the *TCOF1* gene (also referred to as the *TREACLE* gene) in five different families confirmed the causative nature of this gene in MFD. Its function is unknown. At present, linkage analysis or mutational analysis can be undertaken to identify affected family members who may exhibit only mild phenotypic features of this syndrome.

Marsh and colleagues[21,206] provide an exhaustive, outstanding review of the cranial dysmorphology in mandibulofacial dysostosis, deriving their data both from the literature and from three-dimensional reformation imaging from CT scans. From a clinical standpoint, pharyngeal hypoplasia in affected persons is significant because it makes these patients prone to airway difficulty both early in life and later in life. Pharyngeal hypoplasia existed in all 11 patients with mandibulofacial dysostosis reviewed by Shprintzen and coworkers.[207] In fact, patients with a mild or incomplete phenotype were equally at risk. Shprintzen's group recommended nasopharyngoscopy and anterior posterior roentgenography to aid in the diagnosis. With growth, there is an increase in basilar kyphosis exacerbating the problem. MFD patients reported in the literature have responded to craniofacial surgery to alleviate their apnea.[208,209]

Patients with MFD have an abnormal acute cranial base that is 2 to 3 SDs below normal.[156] Peterson-Falzone and Figueroa[210] reviewed the longitudinal measurements of cranial base angulation in 24 patients with mandibulofacial dysostosis. These investigators showed an increase

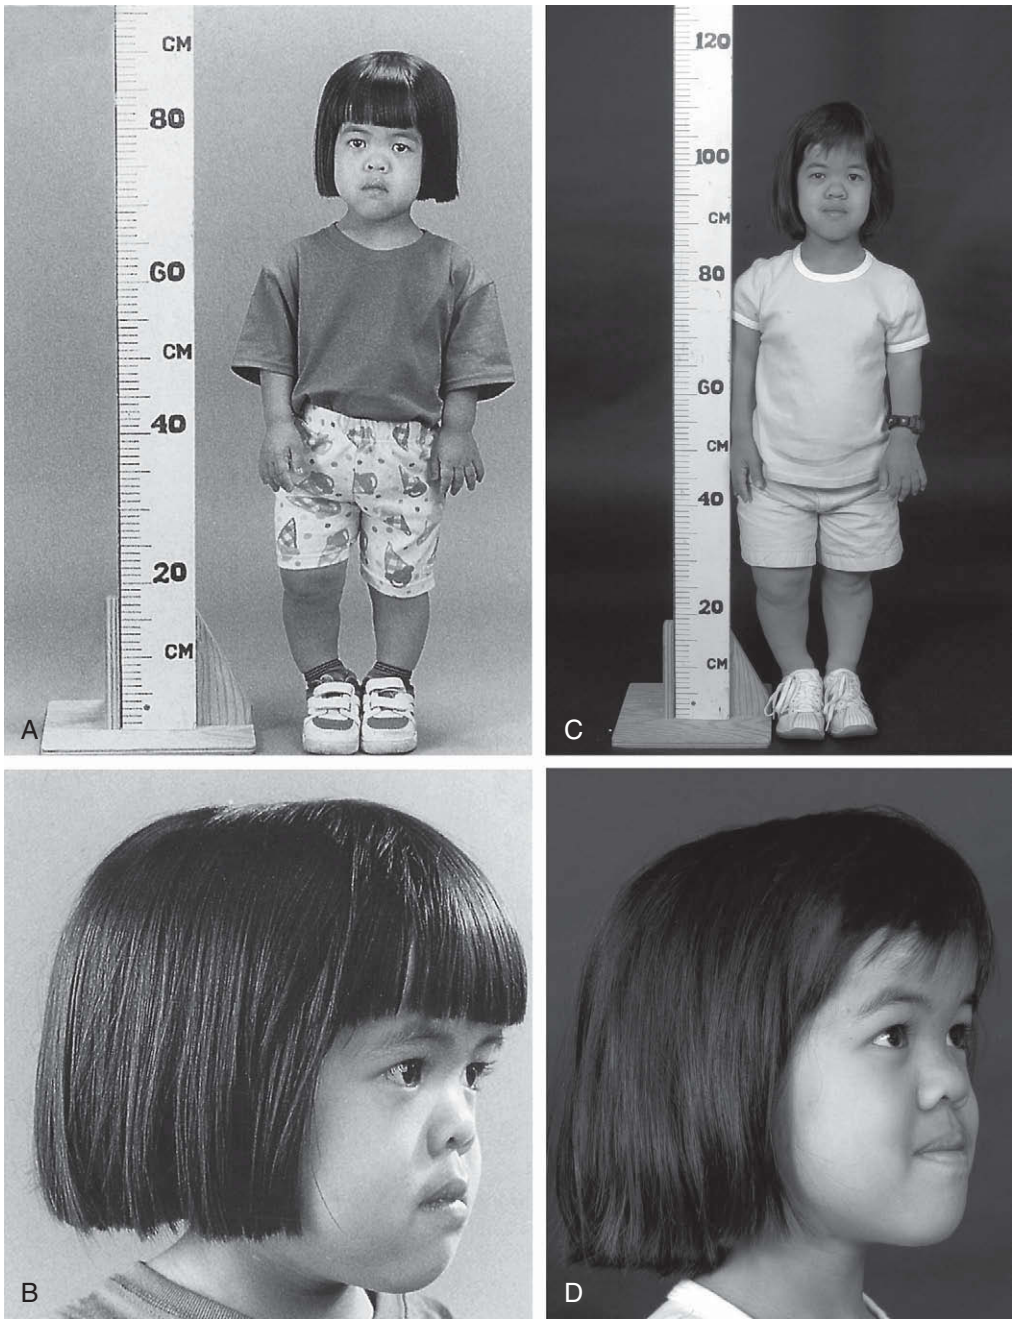

Figure 184-28. **A,** A 6-year-old girl with achondroplasia. **B,** The child manifests the characteristic facial appearance of achondroplasia: frontal bossing, sunken bridge of the nose, and midfacial hypoplasia. The normal mandible appears larger than usual. **C** and **D,** At age 12 years.

in the flexure of the cranial base angle over time, with more than 50% of cases falling into the kyphotic range, confirming previous reports of this finding in the literature. The investigators attribute the increasing flexion to intracranial resorption and extracranial bony apposition as described by Hans[11] and Enlow.[17] They speculate that the increased flexion may be greater in mandibulofacial dysostosis because the clivus resorbs to a greater degree during cranial base development. This may be because of a disproportion between normal brain mass in persons with mandibulofacial dysostosis and the reduction in facial height and the association with the anterior cranial base.

Deficient growth of the spheno-occipital and intersphenoidal synchondroses also plays a role in the formation of the abnormal cranial base. Kreiborg and Dahl[211] studied craniofacial growth in two children with MFD. Progressive basilar kyphosis occurred in both children, and the researchers hypothesized that bending took place at the sphenofrontal suture. They believed that this, along with abnormal growth of the mandible, led to impairment of the airway, that the calvaria appeared to rotate backward and downward in relation to the anterior cranial base, and that the sphenofrontal suture acted as a joint. Kreiborg and Dahl also concluded that the abnormal growth of the mandible occurred at the condyle, which is in agreement with Enlow and Hans' work.[11,17] This study also is consistent with previous findings of hypoplasia of the greater wings of the sphenoid and pterygoid plates.

The mandible in mandibulofacial dysostosis is hypoplastic. The gonial angle (ramus to body angle) is obtuse. The condyles are hypoplastic or completely absent. Antegonial notching (the concavity on the inferior border of the mandible anterior to the ramus-body junction) has been described as characteristic of mandibulofacial dysostosis, distinguishing it from other syndromes that involve the mandible. These features have been presented from studies of lateral cephalograms, longitudinal roentgen cephalometric analyses using metallic implants, and a review of dry skulls.[212-214] Grayson and coworkers[215] disputed this

Figure 184-29. **A,** Characteristic facial appearance of a 10-month-old child with mandibulofacial dysostosis (Treacher Collins syndrome). **B,** Oblique view of same patient. Note the absent external ear canal, which is bilateral, and the headband, which holds bone conduction hearing aids. **C** and **D,** At age 6.

conclusion, although their methods did not employ classic cephalographic landmarks. They believed that complex craniofacial deformities require assessment from more than just conventional methods of measurement.[216]

Moss's functional matrix theory involves the concept that the mandible exhibits plasticity as it relates to the functional matrix with which it is involved, namely the anatomic features related to respiration and feeding. To know what the relationship is between the abnormal mandible—seen in mandibulofacial dysostosis and its functional matrix (respiration and feeding) in the context of Moss's functional matrix hypothesis in experimental form—would be helpful to better understand how the abnormal mandible functions in affected patients.[4,7-10]

Arvystas and Shprintzen[35] used 12 patients, ranging in age from 3 to 22 years (mean age, 10 years 4 months), as a sample population of mandibulofacial dysostosis. A number of cephalometric analyses were undertaken. These workers concluded that the characteristic appearance of the face in Treacher Collins syndrome (i.e., mandibulofacial dysostosis) is a product of the distinctive relationship among the abnormal basicranium, the dysmorphic mandible, and anomalous maxillary-malar complex. The anterior displacement of the temporomandibular joint, the short ramus, short mandibular body, synthesis distortion, and displaced maxilla all result in the characteristic appearance in this syndrome.[35]

Craniofacial surgery for patients with Treacher Collins syndrome is mandatory when problems with the airway become life threatening or are so severe as to compromise the individual. Previously, onlay techniques and soft tissue augmentation were used. However, craniofacial surgery using osteotomies and advancement techniques appears to assist in the orientation of subsequent growth in a more normal direction and to enlarge the airway at the same time. This results in both cosmetic and functional improvement.

As patients with MFD grow, their abnormally formed bones also grow, maintaining their original anatomy. "As they are malformed, so shall they grow."[217] Some researchers believe that the facial appearance of MFD individuals may improve during childhood growth.

Other Conditions and Syndromes

Numerous other syndromes and conditions may result in abnormalities of craniofacial growth and development. Cleft lip and palate and the craniosynostoses are two complex conditions resulting in abnormal

craniofacial growth and development. These conditions cannot be given justice in a brief review, and the reader is directed to the significant body of literature covering these topics.

Conclusions

Craniofacial growth and development are extremely complex. Despite the voluminous amount of literature on this topic, little is known about the control mechanisms involved, even though the current understanding has increased because of the genetic revolution. The latter part of this chapter has described craniofacial growth in several genetic conditions from a primarily anatomic perspective, because at present this is all that is known.

Genetic predetermination is involved to a certain extent in facial growth and development, and many studying the field of craniofacial growth support the concept of Moss's functional matrix hypothesis and its interaction within the genetic constraints of the cells and tissues involved. As some critics have stated, however, Moss's theory explains *what* happens during growth but does not explain *how* it happens. The same can be said in describing abnormal facial growth and development. The cellular interaction within and between craniofacial regions remains unknown. It also seems likely that genes related to craniofacial growth and development are related to neurodevelopment. In the mid-1990s, an understanding of molecular genetics and craniofacial malformations began to emerge.[218,219] Although much progress has occurred in the study of genes for growth factors and signaling factors, much more is still to be learned.[220]

CHAPTER ONE HUNDRED AND EIGHTY-FIVE

Craniofacial Surgery for Congenital and Acquired Deformities

Jonathan Z. Baskin

Sherard A. Tatum, III

Key Points

- Craniofacial anomalies are relatively common deformities, many of which can treated by the otolaryngologist–head and neck surgeon with pediatric and/or facial plastic training.
- Craniofacial defects are often part of a larger syndrome affecting many functional systems.
- Appropriate care is best rendered by a clinically diverse team.
- The underlying pathology is etiologically diverse and heterogeneous.
- Craniofacial skeletal anomalies can be treated surgically with techniques that are reliable and reproducible.
- The application of craniofacial surgical principles, developed to treat congenital problems, also serves well for tumor extirpation and trauma repair.
- Several materials are currently available to reconstruct the craniofacial skeleton, but there is wide effort to develop more biomimetic bone substitutes.

Craniofacial surgery is a broad and continually growing field that addresses a wide array of congenital and acquired deformities. Much of the growth in this field has occurred in the last few decades, thus it is a relatively young discipline that is still actively evolving. This medical and surgical subspecialty includes a set of approaches and techniques developed in the last 50 years that allow for safe, reliable manipulation of the craniofacial skeleton. Although the field is focused primarily on congenital problems, the techniques can be broadly applied to trauma and tumor surgery of the craniofacial structures. *Craniofacial anomaly* refers to any malformation that involves the face, cranium, and cranial base. In the pediatric population the field is more commonly concerned with congenital anomalies, whereas in adults the more commonly encountered applications relate to trauma and neoplasm.

Congenital craniofacial deformities commonly occur as isolated defects and less often as part of a syndrome. The Committee on Nomenclature and Classification of Craniofacial Anomalies of the American Cleft Palate Association has organized craniofacial malformations into the following five categories: (1) facial clefts/encephaloceles and dysostoses; (2) atrophy/hypoplasia; (3) neoplasia/hyperplasia; (4) craniosynostosis; and (5) unclassified. Clinical entities such as orbital hypertelorism often exist with a syndrome that clearly fits into one of the aforementioned classifications.[1] Hypoplasia of the midface and micrognathia would be incorporated into the second category. In children, hematologic disorders and overly aggressive cerebrospinal fluid (CSF) shunting can result in secondary craniofacial disorders, which can be put into the third or fifth category. Acquired deformities of the craniofacial complex also include those inflicted by means of a traumatic event. Neoplasm (third category) and its treatment are classified as acquired deformities.

As is plainly evident, the field of craniofacial surgery is large with many and varied subfields. The objective of this chapter is to provide an overview of craniofacial surgery. The pathophysiology of major craniofacial anomalies is discussed in order to provide a framework for an understanding of the important clinical issues. The focus of the discussion is on cranial vault and craniofacial bony defects. Those disorders of first and second branchial arch derivatives that give rise to known craniofacial anomalies are briefly described. Trauma and neoplasm are important contributors to craniofacial disease and are examined briefly in this chapter but discussed in greater detail elsewhere in the text. Facial and palatal clefting is a very important subject in craniofacial surgery and is briefly discussed from a basic perspective. A clinical discussion of these defects, however, is the focus of another chapter.

Epidemiology

Craniofacial anomalies have been reported to constitute approximately one third of all congenital defects. The incidence of assorted individual deformities and syndromes varies. However, the overall incidence is considered to be 0.2 to 0.5 per 1000 births.[2] Interestingly, some craniofacial deformities occur at a uniform rate across racial and ethnic populations, whereas others occur at a frequency that varies as a function of race and ethnicity.

Several craniofacial malformations appear to have a genetic etiology. Several familial types have been well documented, and transmission can occur via autosomal dominant or recessive modes. With occasional exceptions males and females tend to have similar incidences for most anomalies. Craniofacial anomalies have been reported to occur as part of a genetic condition in about 20% of cases.[2] However, with the discovery of new syndromes and the recognition that "isolated defects" often have a genetic etiology, the 20% figure is probably an underestimate. Furthermore, as discussed here, the pathogenesis of craniofacial anomalies is complex, and generally it is most accurate to describe their etiology as multifactorial.

Mechanisms of Postnatal Facial Growth

It was once thought that craniofacial growth (like all other growth) was regulated, to a large extent, by the central nervous system. It is now understood to be much more complex. On a cellular level, the signal-sensitive membranes of the many types of cells respond to several different cues. On a developmental level, the functional needs of a particular structure and its relationship to adjoining structures strongly influence patterns of growth. Craniofacial bony growth is secondary to neural tissue growth and expansion. The brain as an organ mass develops early in embryogenesis. The developing brain highly influences the morphology of the basicranium, which in turn functions as a template for subsequent facial growth. The face can be viewed as a series of stratified vertical levels or fields that are strongly affected by growth of the brain and basicranium.[3]

Physiologically, there are two primary forces at play during the growth of individual craniofacial bones and structures, displacement and remodeling (Fig. 185-1). Growth does not indicate uniform enlargement of a structure; rather, it refers to a combination of displacement and remodeling. Displacement occurs when the bone is pushed away from its articulation with other bones (by the combined effects of growth of the surrounding soft tissue and growth center/sutural activity). Remodeling occurs by resorption and deposition of new bone that result in a net vector of growth. It is in this way that the correct tissue mass is achieved and that enlargement occurs proportionally and in the appropriate direction.

In the craniofacial complex the basicranium (along with the related soft tissues) influences the naso-orbito-maxillary complex and the ramus of the mandible, which conform through continual remodeling. Growth of the naso-orbito-maxillary complex displaces the maxillary dento-alveolus. This displacement together with growth of the mandibular ramus then affects growth of the corpus (body) of the mandible. The importance of soft tissues in growth is demonstrated in such clinical manifestations as the "adenoid face." The entire system is plastic and in flux throughout the growing period (even after periods of growth, albeit to a far lesser extent). It is for this reason that rigid nonbiologic implants such as those of titanium have the potential to interfere with normal growth if used during active development; they lack the plasticity that is so vital to dynamic growth.[4-6]

Throughout the period of craniofacial growth an overriding homeostasis exists among the different fields of growth. Small aberrations in one field can be counterbalanced by compensatory growth in another, resulting in constant equilibrium. This is very important for the physician to bear in mind when planning surgical or orthodontic intervention. Treatment failure or relapse is likely if that equilibrium is significantly disrupted.[7] Generally, interventions are more likely to succeed if the cause of the abnormality is addressed during periods of rapid growth. In contrast, the effect of the abnormality is more successfully treated during periods of slow growth.[3]

Craniofacial synostosis, or premature closure of a suture, is a good example of the morphologic consequence of defective skeletal growth. It also illustrates the importance of homeostasis in craniofacial development. The causes of craniosynostosis are likely multifactorial and the source of some controversy.[8,9] It has been shown to be associated with abnormalities in sutural biology, various biomechanical forces,[10] and defects in the primary growth centers of the involved bones. Sutural growth is also affected by surrounding tissue interactions. The contacting dura, for instance, influences the continued patency of sutures and helps regulate its closure.[11-14]

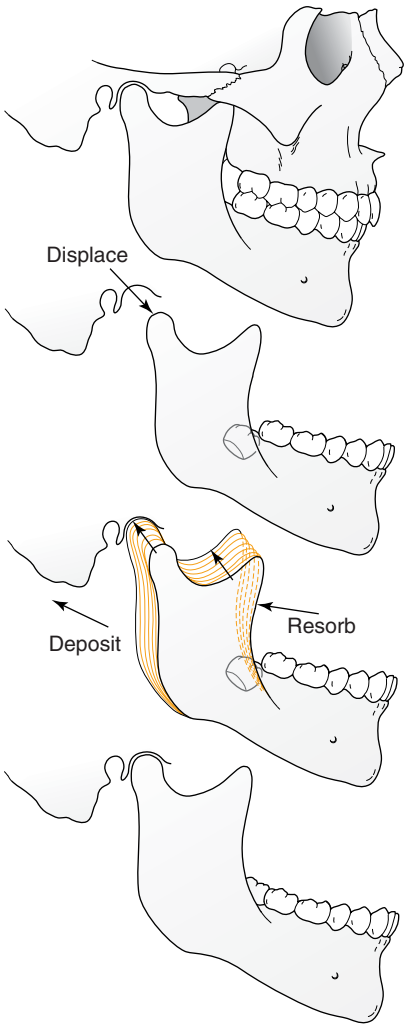

Figure 185-1. Schematic representation of displacement and remodeling in the mandible. Remodeling occurs through a combination of resorption and deposition. *(From The facial growth process. In Enlow: DH (ed). Facial Growth. 3rd ed. Philadelphia: WB Saunders; 1990.)*

Regardless of the underlying etiology, the morphologic cause of the defect is premature closure of the suture, and this disruption in normal growth upsets the homeostasis inherent to the process. Consequently, compensatory growth occurs elsewhere as a means of achieving a new homeostasis. If the synostotic suture is treated early in life (while craniofacial growth is still quite active) the normal homeostasis can be restored by releasing the synostotic suture and thereby addressing the cause of the problem. If it is treated later in life, when active growth is largely complete, the morphologic results of the defect (including the anatomy associated with the compensation) have to be addressed because the sutural growth is no longer relevant.

Fusion of the facial processes during embryogenesis is another fundamental aspect of facial growth that is critical to normal development. Orofacial clefting results from a defect in this process. For opposing facial processes to fuse in the midline, the contacting epithelia must be eliminated so that the underlying mesenchymal tissue can become continuous. In the palate this elimination has been shown to occur through apoptosis, epithelial to mesenchymal cell transdifferentiation, or cell migration.[14-17] Underdevelopment of the mesenchyme of the involved subunits might preclude proper fusing, as can excessive apoptosis. Inadequate migration or proliferation of neural crest ectomesenchyme might have the same result. Facial clefting can also result from constricting anatomic defects. In the case of stunted mandibular growth, a Pierre Robin sequence can ensue whereby the palatal shelves are prevented from fusing in the midline.

Pathophysiology

As previously mentioned, the etiology of congenital craniofacial disorders is most often multifactorial and incompletely understood. A diverse and heterogeneous group of factors can contribute to abnormal craniofacial development. Various genetic defects have been implicated in the development of craniofacial anomalies. This field of study has yielded an enormous amount of information in the last few decades. In addition, numerous metabolic diseases are known to interfere with bone growth and suture function. Environmental factors have also been shown to exert important influences on embryologic craniofacial development.

Molecular Genetics

Several genetic defects have been identified that are directly associated with various craniofacial defects (Table 185-1). The products of these genes tend to fall into one of the following categories:

- Growth factor receptors: fibroblast growth factor receptors (FGFRs) 1, 2, and 3; tumor growth factor-β receptors (TGFβRs) 1 and 2; PTC and FGDY gene products
- Ephrins: membrane-anchored ligands for Eph receptor tyrosine kinases
- Transcription factors: MSX2, ALX4, GLI3, MITF, PAX3, RUNX2, TWIST
- Connective tissue structural proteins: type II and XI collagen, fibrillin-1 (FBN1)

These genetic defects have been linked to syndromes as well as isolated defects. For instance, defective FGFRs have been identified as the etiologic basis of some types of craniosynostosis as well as various syndromes (see Table 185-1).[18-45]

FGFRs are transmembrane receptors for fibroblast growth factors (FGFs). FGFs are involved in regulating cell proliferation, differentiation, and migration through a number of pathways. The receptor is made up of an extracellular domain (receptor-ligand binding), a transmembrane domain, and an intracellular tyrosine kinase enzymatic domain (Fig. 185-2A). There are several variations of the FGFR protein—all with important cell growth functions. Signaling via FGFR1, for instance, has been shown to facilitate neural crest migration, and a defective receptor has been linked to midline facial clefting in mice.[45] Defects in FGFR1 have been found to cause Kallmann's syndrome 2, which can include cleft lip and palate (see Fig. 185-2B).[46] Defects in FGFR1 and FGFR2 have been linked to syndromes such as Pfeiffer's syndrome (in which both receptors are defective) and to conditions of which craniosynostosis is a feature.[38,47] Defects in FGFR2 alone have been found in Apert's syndrome,[20,48] Jackson-Weiss syndrome,[28] Crouzon's syndrome,[29] and Beare-Stevenson cutis gyrata syndrome.[49] A defective FGFR3 protein is responsible for Crouzonodermoskeletal syndrome (Crouzon's syndrome with acanthosis nigricans),[30] for Muenke-type craniosynostosis,[32] and also for the disease process seen in achondroplasia.[50] In this disease the epiphyseal growth plates in long bones prematurely fuse. There are gross and histological similarities of long bone growth plates to the synchondroses of the calvaria. This work has led to the understanding that FGFR3 is involved in regulation of skeletal growth. In FGFR3 knockout mice (mice in which the gene that encodes this protein has been eliminated), there is severe retardation of skeletal maturation.[48,51-53]

The link between known syndromes or anomalies and genetic defects, however, can be complex and difficult to characterize. Defects in each of the three domains (in different FGFRs) have been discovered in association with craniofacial abnormalities, yet defects in the same domain of one FGFR type can cause two separate syndromes. For instance, identical mutations have been discovered in patients with Crouzon's, Pfeiffer's, and Jackson-Weiss syndromes, suggesting the involvement of other factors in the ultimate phenotypic expression.[38] Conversely, as is evident in Figure 185-2B, mutations in several distinct domains on one particular FGFR can result in the same phenotype.

As previously mentioned, defects in transcription factors and connective tissue proteins are also implicated in the pathogenesis of craniosynostosis. MSX2 is a homeobox gene that encodes a DNA binding transcription factor. It has been associated with nonsyndromic craniosynostosis (Boston type),[24,54] and ALX4, another homeobox gene, has been linked to parietal foramina.[34] Most cases of Saethre-Chotzen syndrome are caused by haplo-insufficiency of the TWIST gene, which appears to encode a transcription factor.[41] The GLI-3 gene and the transcription factor that it encodes are defective in Grieg's cephalopolysyndactyly (a rare syndrome that can include craniosynostosis).[31,55]

Genetic defects encoding several different extracellular matrix constituents can lead to anomalies of the craniofacial complex. Defective collagen, such as that seen in osteogenesis imperfecta, is clearly associated with bony abnormalities, although this disease only occasionally affects the craniofacial skeleton. Defective fibrillin (encoded by FBN1) results in Shprintzen-Goldberg syndrome with craniosynostosis and maxillary/mandibular hypoplasia.[43] The defective genes responsible for Stickler's syndrome are *COL2A1* and *COL11A2*, which encode types II and XI collagen, respectively.[56,57]

Metabolic Disorders

Several metabolic derangements are known to interfere with craniofacial development. The best known is the group of disorders known as the *mucopolysaccharidoses*. This group of disorders is characterized by a deficiency of lysosomal enzymes that results in a buildup of mucopolysaccharides. Although there are several clinical entities, patients with some of the more severe variations of the disease have large and dolichocephalic (long and narrow) skulls with premature closure of the sagittal suture and poorly developed mastoids and paranasal sinuses. Mucolipidosis, hyperthyroidism, and rickets are also known causes of craniosynostosis.[58,59]

Intrauterine Causes

In utero environmental contributors to craniofacial maldevelopment fit into the following four general categories: teratogenic, infectious, nutritional, and mechanical. Fetal alcohol syndrome can involve a wide range of defects, including holoprosencephaly. Tobacco use during critical periods of embryogenesis has also been shown to adversely affect craniofacial development. Medications such as hydantoin, phenytoin, valproic acid, and isotretinoin (a vitamin A derivative used in the treatment of acne) can exert deleterious effects on embryogenesis, as can toluene, the environmental contaminant dioxin, and ionizing radiation.[14,60,61]

Viral infections during pregnancy have been shown to cause cleft lip/palate via mutations in PVRL1 and IRF6.[62,63] Nutritional intake is also clearly linked to craniofacial development. Sonic hedgehog signaling, which is important in mediating parts of craniofacial development, is modulated by cholesterol. Therefore diets and medications that profoundly influence cholesterol levels can cause craniofacial malformations.[64,65] The link between a diet deficient in folic acid and neural tube defects has been well documented and has led to the widespread supplemental addition of folic acid to many processed foods throughout the developed world.

Finally, intrauterine constraint can cause deformation of the craniofacial skeleton. Factors that have been associated with intrauterine constraint include breech presentation, persistent fetal lie, early pelvic engagement of the head, oligohydramnios, prima gravidity, multiple gestations, uterine malformations, amniotic bands, and defects in fetal neuromuscular development.[66,67]

Acquired Craniofacial Deformities

Several postnatal conditions predispose an infant to disrupted craniofacial growth. Hematologic diseases such as thalassemias, sickle cell anemia, congenital hemolytic icterus, and polycythemia vera are known to cause craniosynostosis. Hyperplasia of the bone marrow leads to bony overgrowth in the skull. This in turn can cause the calvarial sutures to fuse prematurely.[68] Iatrogenic craniofacial anomalies can occur in patients who require ventricular shunts. If the shunt volumes in such patients are excessive, there is a lack of tension across the

Table 185-1

Craniofacial Anomalies with Phenotype and Known Gene Mutation

Condition	Craniofacial Phenotype	Gene*	OMIM Code†	Chapter Reference(s)
Aortic aneurysm, arterial tortuosity, hypertelorism, cleft palate/bifid uvula, craniosynostosis	Craniosynostosis, cleft palate, hypertelorism	TGFβR1 TGFβR2	190181 190182	19
Apert's syndrome	Craniosynostosis (brachycephaly); wide midline defect closes by coalescence of bony islands; midface malformations; dental crowding; cleft or narrow palate with swellings	FGFR2	101200	20-22
Beare-Stevenson cutis gyrata syndrome	Craniosynostosis (kleeblattschädel)	FGFR2	123790	23
Boston-type craniosynostosis	Craniosynostosis (kleeblattschädel), forehead retrusion, frontal bossing	MSX2	123101	24
Cleidocranial dysplasia	Delayed suture closure, frontal parietal bossing, wormian bone(s), hyperdontia, tooth eruption defects	RUNX2	119600	25
Craniofrontonasal syndrome	Craniosynostosis (brachycephaly), central defect between frontal bones, hypertelorism, divergent orbits	EFNB1	304110	26
Craniolacuna and pansynostosis	Multiple rounded calvarial bone defects, widespread craniosynostosis, hydrocephalus	FGFR2		27
Crouzon's syndrome	Craniosynostosis (brachycephaly), pronounced digital impressions of skull, midface hypoplasia, shallow orbits	FGFR2	123500	28, 29
Crouzonodermoskeletal syndrome	Craniosynostosis	FGFR3	134934	30
Grieg's cephalopolysyndactyly	Craniosynostosis in small percentage of cases, frontal bossing, sagittal ridging, hypertelorism	GLI3	175700	31
Muenke-type craniosynostosis (nonsyndromic)	Craniosynostosis (brachycephaly)	FGFR3	602849	32, 33
Parietal foramina	Symmetric parietal bone defects, cleft lip/palate	MSX2 ALX4	168500 605420	34-36
Parietal foramina with cleidocranial dysplasia	Symmetric parietal bone defects	MSX2	168550	37
Pfeiffer's syndrome	Craniosynostosis (brachycephaly)	FGFR1 FGFR2	101600	38-40

Novel fibroblast growth factor receptor 1 mutations in patients with congenital hypogonadotrophic hypogonadism with and without anosmia. *J Clin Endocrinol Metab.* 2006;91:4006-4012.)

sutures, which produces an environment that mechanistically resembles the one seen in microcephaly. In these conditions there is an increased risk of secondary craniosynostosis.[58] Etiologically, trauma and neoplasm can cause acquired craniofacial deformity, although they do so rarely.

Clinical Manifestations

Congenital Craniofacial Abnormalities

Craniofacial anomalies range from mild functionally asymptomatic defects (certain single-suture craniosynostoses) to severe anomalies that are not compatible with life (forms of holoprosencephaly). Typically, the pediatrician consults the craniofacial surgeon about a neonate who has an abnormally shaped head or unusual appearance. A fundamentally important point is to suspect the deformity to be part of a wider syndrome and to initiate a comprehensive examination in search of other abnormalities. However, the majority of cases of craniosynostosis are isolated with no associated anomalies.[69] Descriptions of some of the more common craniofacial abnormalities follow.

Craniosynostosis

Craniosynostosis refers to premature closure of the involved bony suture. The consequence is that growth is inhibited in the direction perpendicular to the suture line (Fig. 185-3). Ensuing developmental growth occurs in a compensatory pattern that permits, to the extent possible, continued expansion of the intracranial content in unrestricted directions. It must be stressed that the compensatory growth that occurs is the normal biologic response to sutural constraint. The functional and aesthetic imbalance that occurs is, in part, a byproduct of normal physiology. The various types of craniosynostosis are as follows.

Scaphocephaly

Scaphocephaly is the most common of cranial synostotic conditions. The sagittal suture, or part of it, prematurely fuses (Fig. 185-4). This anomaly prevents calvarial growth in the transverse dimension. The compensatory growth occurs in the anteroposterior (AP) direction, leaving the patient with decreased biparietal and bitemporal dimensions. The resulting head shape is long and narrow. There are several variations ("saddle deformity," "football deformity"), depending on the extent of premature sagittal fusion and also on whether the metopic suture is involved.

Trigonocephaly

Trigonocephaly refers to a triangular forehead (as viewed from above) and is associated with metopic suture synostosis. There is a decrease in bifrontal diameter. It is a mild form of craniosynostosis with rare func-

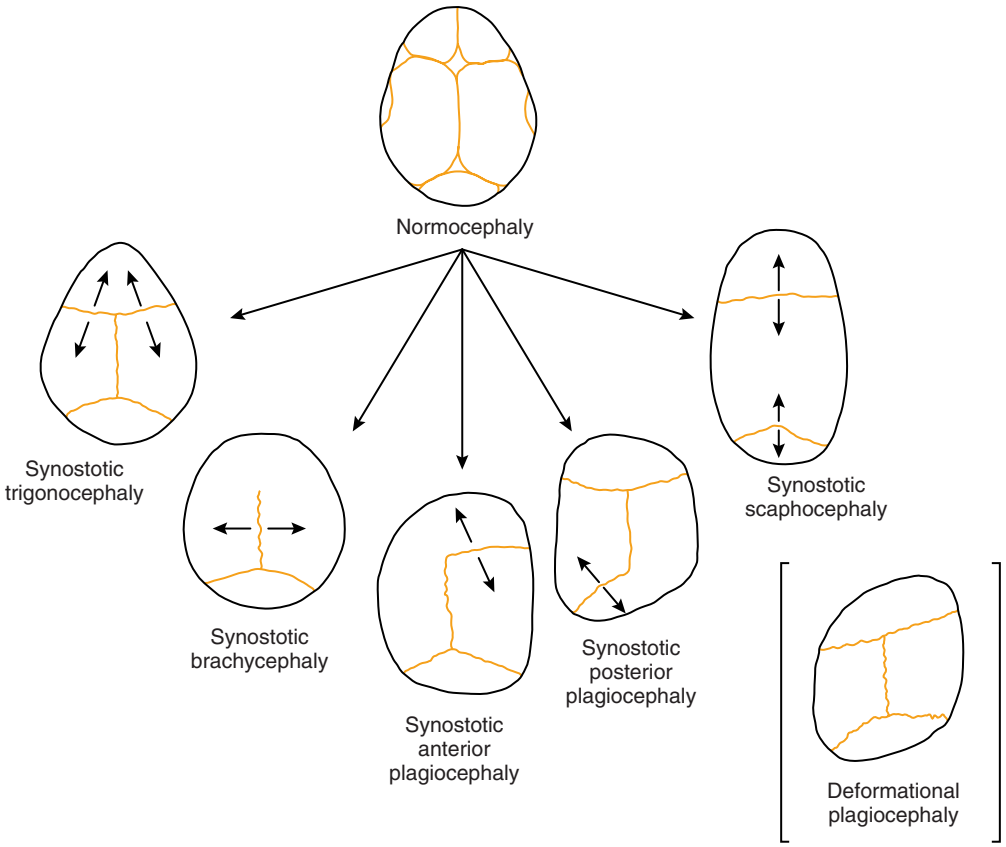

Figure 185-3. In craniosynostosis, growth is prevented from occurring across the fused suture. *Arrows* demonstrate compensatory growth that occurs across open sutures with continued intracranial expansion. (From Cohen MM Jr, Maclean RE. *Craniosynostosis: Diagnosis, Evaluation and Management*. 2nd ed. New York: Oxford Press; 2000:122.)

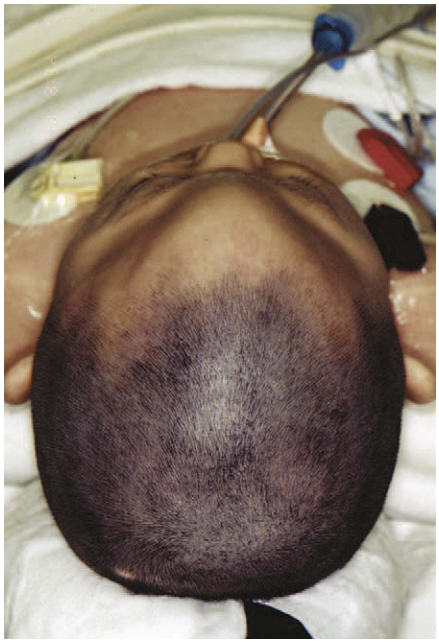

Figure 185-5. Metopic suture synostosis resulting in trigonocephaly.

tional consequences (Fig. 185-5). The suture area is thickened, resulting in an anterior midsagittal ridge. This appearance has been described as resembling the keel of a ship. There can be associated hypotelorism. In mild cases there may be only suture ridging without significant forehead deformity.

Plagiocephaly

In *plagiocephaly,* the head is asymmetric, flattened in one or more regions. It can be either synostotic or deformational and can be anterior or posterior. *Synostotic plagiocephaly* refers to either unilateral coronal (Fig. 185-6) or lambdoid synostosis. In coronal synostosis the forehead

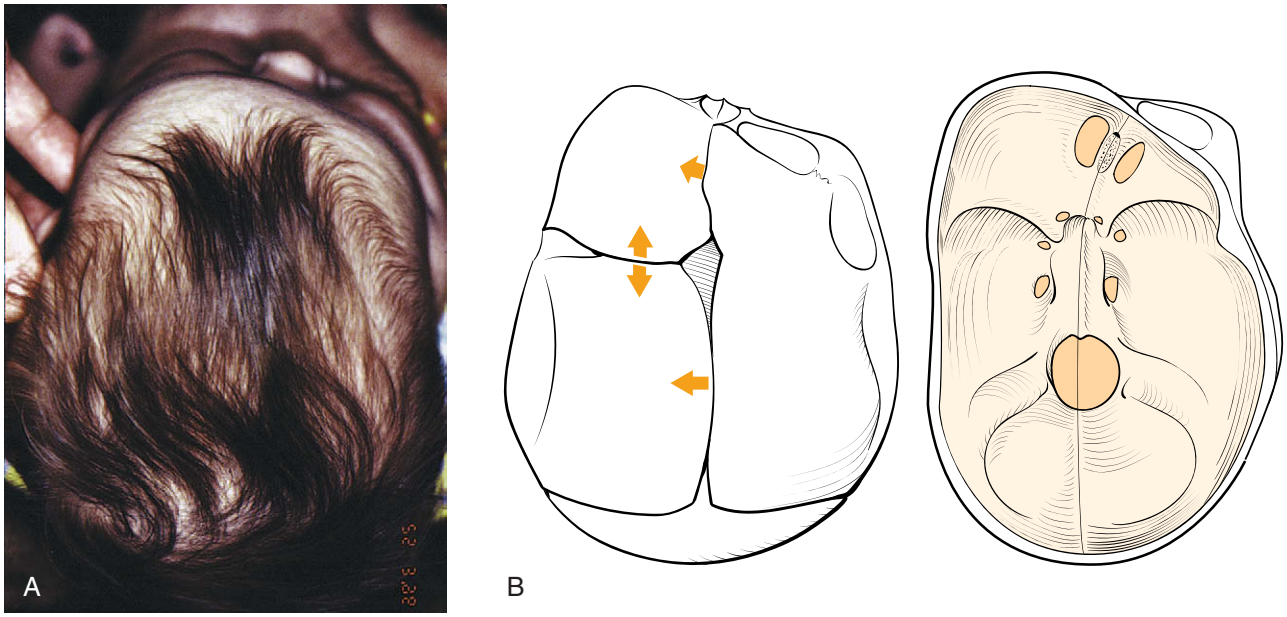

Figure 185-6. **A,** Unilateral coronal synostosis resulting in plagiocephaly. Note that the cranial vault irregularities are not confined to those ipsilateral to the defect. Compensatory growth has resulted in frontal bossing on the contralateral side. **B,** A schematic representation of plagiocephaly.

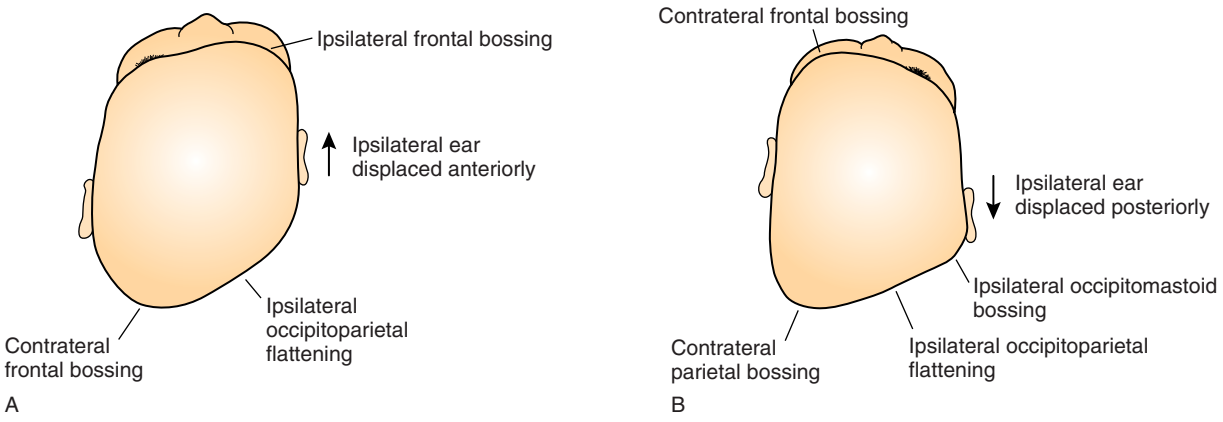

Figure 185-7. Deformational and synostotic plagiocephaly give rise to different characteristic head shapes. **A,** Posterior deformational plagiocephaly results in a parallelogram shape to the head with an anteriorly displaced ipsilateral ear. **B,** Unilateral lambdoid synostosis gives rise to contralateral posterior and occasional anterior bossing. The ipsilateral ear is displaced posteriorly. *(From Cohen MM Jr, Maclean RE.* Craniosynostosis: Diagnosis, Evaluation and Management. *2nd ed. New York: Oxford Press; 2000:128.)*

of the affected side is flat whereas the supraorbital rim is elevated and displaced posteriorly. The rim lies at or posterior to the plane of the cornea although it should normally be about 1 cm anterior to the cornea. The nasal root can be deviated to the side of the defect. The contralateral forehead is bossed, and the supraorbital rim can be pushed down. The ipsilateral auricle is anteriorly displaced but the occiput is minimally affected.

In unilateral lambdoid synostosis, there is an occipital flatness on the affected side. The ipsilateral auricle is posteriorly displaced, but the forehead is not typically affected. True lambdoid synostosis is a rare entity. Lambdoidal synostosis is frequently confused with posterior deformational plagiocephaly.

Deformational plagiocephaly is far more common and can be influenced by the previously noted intrauterine constraint factors, hypotonia, and prematurity. It is further compounded by sleeping in the supine positioning, with a predilection of the infant to sleep on one side owing to a prominent occiput and poor head control. This phenomenon has increased since the American Academy of Pediatrics, in an effort to reduce sudden infant death syndrome (SIDS), issued its recommendations to place sleeping infants in the supine position.[58,69] Additionally, persistent fetal lie, vertebral anomalies, muscular disorders, ocular abnormalities as well as assorted other conditions, can cause torticollis, further aggravating sleep position problems. The sutures in deformational plagiocephaly remain open so there is no ridging. The differences in head shape between synostotic and deformational plagiocephaly are illustrated in Figure 185-7.

Brachycephaly

Brachycephaly is the term used for bilateral coronal synostosis (Fig. 185-8). It is often accompanied by turricephaly (tall head) or acrocephaly (pointed head). As a result of this sutural synostosis, the skull is unable to expand in the AP dimension. In order to accommodate the expanding intracranial content, the skull grows in the lateral and superior dimensions. The neonate's cranium, therefore, has a smaller AP distance and greater lateral dimensions. The forehead comes right off the nose with a low hairline, and the glabellar depression is absent.

Figure 185-8. Bilateral coronal suture synostosis resulting in brachycephaly.

Figure 185-9. Coronal and sagittal suture synostosis in this child with Apert's syndrome resulted in acrocephaly.

Acrocephaly

Acrocephaly (also known as oxycephaly and turricephaly) consists of a skull that is high and conical (Fig. 185-9). This abnormality can develop as a result of progressive postnatal involvement of both the sagittal and coronal sutures. Compensatory growth occurs through the anterior fontanel.

Kleeblattschädel

Kleeblattschädel is also known as cloverleaf skull (Fig. 185-10). It results from synostosis of all the sutures previously discussed except for the metopic suture. The bone overlying the sutures is very thick but the intervening bone is thin. The expanding intracranial content tends to cause a ballooning of the thin bone between the sutures. This compensatory growth, in addition to expansion through the remaining open sutures, gives the characteristic lobular appearance of a cloverleaf. The skull growth falls drastically short of the needs of intracranial expansion, giving rise to neurologic impairment, increased intracranial pressure (ICP), and, often, secondary hydrocephalus. These patients exhibit exorbitism and therefore are at risk for globe exposure, and their optic nerves can also be at risk for damage. This anomaly requires prompt surgical attention to release the binding skull.

Figure 185-10. Premature fusion of all the cranial sutures except for the metopic and squamosal sutures results in kleeblattschädel or cloverleaf skull. (From Cohen MM Jr, Maclean RE. *Craniosynostosis: Diagnosis, Evaluation and Management.* 2nd ed. New York: Oxford Press; 2000.)

Facial Clefts

Facial clefts make up a large category of facial anomalies. A facial cleft is classified on the basis its position relative to the midsagittal plane. Although rare, facial clefts can present uniquely challenging problems to the surgeon. A further discussion of facial clefts is beyond the scope of this chapter.

Encephalocele

An *encephalocele* is a protrusion of intracranial content through a defect in the craniofacial skeleton (Fig. 185-11). It is classified according to its position in the skull. If the protruding content contains meninges, it is referred to as a *meningocele*. If it contains meninges and brain, it is called a *meningoencephalocele*, and if the protrusion additionally contains ventricle, it is known as a *meningoencephalocystocele*.[70]

Syndromes

The syndromes that cause craniofacial anomalies are quite varied in their clinical presentation. Because craniofacial anomalies frequently manifest as part of these syndromes, a familiarity with some of the well-described syndromes is important. This knowledge leads to more focused examination. Once a full survey is done, the proper consultations can be sought. Brief descriptions of several syndromes follow.

Crouzon's Syndrome

Crouzon's syndrome is an autosomal dominant condition that exhibits complete penetrance and variable expressivity. It often results in brachycephaly, but multiple sutures can also be affected. The calvarial suture defects can occur prenatally or throughout the first 5 years of life. There is associated midface (maxillary) hypoplasia, which leads to a class III malocclusion (the mandible is typically near normal). Exorbitism occurs as a result of decreased bony orbital volume (in contrast to exophthalmos, which results from greater intraorbital content). Intelligence is usually normal if patients are appropriately managed.

Apert's Syndrome

Apert's syndrome resembles Crouzon's syndrome in several ways. Most cases of Apert's syndrome arise sporadically through new mutations, although some familial cases with autosomal dominant transmission have been reported.[71] The disorder is characterized by brachycephaly

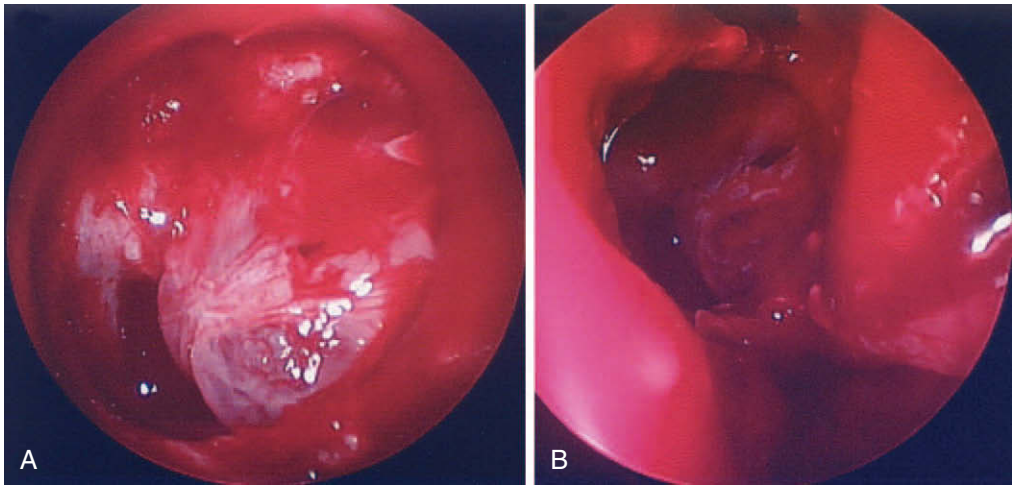

Figure 185-11. An endoscopic view of a meningoencephalocele protruding through the lateral wall of the sphenoid sinus. This was associated with a cerebrospinal fluid leak and a history of bacterial meningitis. **A,** An endoscopic view of the sphenoid ostium, which has been widened to allow sufficient access to the skull base defect. **B,** After mild (intrathecal) decompression but prior to endoscopic repair, the dural defect is clearly seen.

(with resultant turricephaly) and midfacial hypoplasia (with associated orbital and dental issues). Unlike patients affected with Crouzon's syndrome, patients with Apert's syndrome have symmetric syndactyly of the hands and feet as well as other axial skeletal abnormalities. The palate frequently has a high arch and may be cleft. The defects in Apert's syndrome are present at birth, and intelligence is often decreased.

Pfeiffer's Syndrome

Pfeiffer's syndrome is an autosomal dominant disorder that features craniosynostosis. The coronal sutures are frequently involved, giving rise to brachycephaly, but the sagittal and lambdoid sutures can also be involved. Affected patients can have midface hypoplasia (with associated orbital and dental issues) as well as enlarged thumbs and big toes.

Jackson-Weiss Syndrome

Jackson-Weiss syndrome is an autosomal dominant disorder with high penetrance and variable expressivity that resembles Pfeiffer's syndrome. Brachycephaly is common, the big toes are abnormally wide, but the thumbs are typically normal. Midfacial hypoplasia is more common than in Pfeiffer's syndrome. Jackson-Weiss syndrome was originally identified in an Amish population but can affect other individuals as well.

Saethre-Chotzen Syndrome

Saethre-Chotzen syndrome is an autosomal dominant disorder with full penetrance. Affected patients have craniosynostosis (often brachycephaly) with a low hairline, ptosis, brachydactyly, and a high arched palate with occasional palatal clefting. Midface hypoplasia is not common.

Carpenter's Syndrome

Carpenter's syndrome is a rare syndrome that is autosomal recessive. Patients affected by this syndrome usually suffer from craniosynostosis that can involve the sagittal, lambdoid, and coronal sutures. Midfacial hypoplasia can be a component but is usually mild. Other features are preaxial polysyndactyly of the feet and other syndactyly. Children with Carpenter's syndrome generally have developmental delays.

Stickler's Syndrome

Stickler's syndrome, also known as arthro-ophthalmopathy, is an autosomal dominant syndrome and is one of the more common syndromes, affecting about 1 in 10,000 people. It is caused by mutations in genes that encode type II collagen, type XI collagen, or both. This connective tissue disorder has ocular, orofacial, skeletal, cardiac, and auditory manifestations. The phenotypic orofacial expression is characterized by occasional midface underdevelopment, mandibular hypoplasia, and cleft palate. Stickler's syndrome is the most common syndrome to be associated with Pierre Robin sequence. It has been estimated that between 30% and 40% of patients diagnosed as having the Pierre Robin sequence (micrognathia, cleft palate, and glossoptosis) in fact have Stickler's syndrome. Given its variable expressivity, this syndrome, in its mild forms, often goes unrecognized.

Velocardiofacial Syndrome

Velocardiofacial syndrome is autosomal dominant with variable expressivity and penetrance and may be the most common syndrome after Down syndrome. There are numerous associated anomalies aside from the well-documented craniofacial, cardiac, and vascular malformations. The craniofacial anomaly broadly consists of a more open angle of flexion in the basicranium. This has an impact on the appearance of the midface and lower face (mandible). Clefting of the secondary palate can be overt or can take the form of an occult cleft that is apparent only on nasopharyngoscopy.[72] Velocardiofacial syndrome can easily be overlooked because affected patients are often not obviously abnormal in appearance.

Mandibulofacial Dysostosis

Mandibulofacial dysostosis, also known as Treacher Collins syndrome, is an autosomal dominant disorder with variable penetrance and expressivity. It involves numerous bilateral developmental abnormalities in structures that derive from the first and second branchial arches. Clinical features include zygomatic hypoplasia, micrognathia, dysplastic ears, antimongoloid slants to the eyes, colobomas of the lower eyelids, and deficient eyelashes in the medial two thirds of the lower eyelids. Mandibulofacial dysostosis is associated with Pierre Robin sequence and palatal clefting in 35% of cases. Severe obstructive apnea secondary to the micrognathia and glossoptosis often requires medical intervention.

Facio-Oculo-Auriculo-Vertebral Spectrum

Facio-oculo-auriculo-vertebral spectrum (FOAVS) refers to a group of anomalies that originate from unilateral defects in the first and second branchial arches. Most cases are sporadic, although familial cases have been reported. There is evidence that this syndrome results from a unilateral hemorrhagic event involving the stapedial artery during early craniofacial development.[73] FOAVS (also known as hemifacial microsomia), which includes Goldenhar's syndrome, can be quite diverse in terms of severity and scope. It is a rare disorder (1/5600 live births) that is present at birth. It involves the unilateral soft and skeletal tissues of the face and external and middle ear. It can manifest as temporal, zygomatic (malar), maxillary, and mandibular hypoplasia, hypoplastic

facial musculature, and cleft lip and palate. It involves a wide variety of external and middle ear deformities related to structures that derive from the first and second branchial arch. Atresia of the external auditory canals and preauricular skin tags can all exist in FOAVS. The eye can be involved, with the occurrence of colobomas, epibulbar choristomas, blepharophimosis, and strabismus. Vertebral anomalies include fusion of vertebrae, spina bifida, and other more specific abnormalities. A variety of other, non-craniofacial abnormalities are associated with FOAVS.

Trauma

The basic concepts of craniomaxillofacial trauma and treatment are similar in the pediatric and adult populations. The differences mostly concern patterns of fracture in young children and how repair of fractures affect subsequent craniofacial growth. The pattern of facial fractures in children is influenced by several factors. The facial bones are not fully mineralized and are therefore more pliable and elastic, resulting in more "greenstick" fractures. Tooth buds replace much of the bone of the dental arches, creating a different stress-strain curve in the mandible and maxilla. Depending on the patient's age the sutures may not be fused, and there is a higher proportion of cancellous bone with thinner cortices. The face is also much smaller relative to the cranial cavity with minimal aeration of the sinuses, and the buttress system is not fully developed. In adolescence the face has matured sufficiently so that patterns of facial fractures more closely resemble those seen in the adult.

The incidence of facial fractures in the pediatric population has been estimated to range from 1% to 14.7%, and head injuries are frequently associated with them. The group least likely to suffer from facial trauma is children younger than 5 years. The preponderance of injuries in children has been reported to occur in boys, though some studies have found no gender predilection. According to some reports motor vehicle accidents are responsible for these injuries in up to 80% of cases. However, in the last 20 years, with the wider use of seatbelts and federally approved child-safe car seats, the incidence has significantly declined. Injuries that do result in pediatric maxillofacial trauma are usually quite severe and therefore are frequently accompanied by other systemic injuries.[74,75]

In general, fractures involving the forehead, frontal sinus, naso-orbital-ethmoid complex, and optic canals, as well as Le Fort fractures are managed through the craniofacial techniques similar to those developed for congenital anomalies. Facial trauma that is best managed via craniofacial techniques is usually severe but fortunately also rare. Complex midface fractures including Le Fort fractures are uncommon. (Although the Le Fort system is used to describe complex midface fractures in children, later classification systems tend to be functional and are based on the force of the impact and the resultant extent of bony disruption.) Fronto-orbital fractures and other fractures of the upper face occur with an even lower frequency.

Neoplasm

Craniofacial or skull base tumors are fortunately rare occurrences in the pediatric population. Head and neck tumors account for about 5% of all childhood cancers, and those involving the skull base are a small proportion of that figure. Of the solid nonhematologic lesions, brain tumors are the most common, followed by neuroblastoma and rhabdomyosarcoma, non-rhabdomyosarcoma sarcomas, salivary gland tumors, and teratomas. Benign tumors in the craniofacial region are also rare; they include fibrous dysplasia (Fig. 185-12), angiofibromas, granulomas, pituitary adenomas, and other unusual lesions.

Patient Evaluation

Craniofacial Team

Given the complexity of the problems found in the patient with a craniofacial disorder, the principle that care must be delivered by a clinically diverse and highly trained team has become the standard of care. Careful timing and coordination of procedures maximize benefits while minimizing trauma to the patient and family. In addition to the craniofacial surgeon, a typical team might consist of a pediatrician, neurosurgeon, ophthalmologist, dentist, orthodontist, oral surgeon, prosthodontist, geneticist, nurse, speech pathologist, audiologist, anthropologist, psychologist, and nutritionist. The emphasis is on taking a comprehensive approach to the health care of the individual. This approach is based on the recognition that these abnormalities, as well as their treatment, can affect many different functional systems. Open and unimpeded communication among the different members of the team is essential for full realization of the benefit of this approach.

History and Physical Examination

At the initial evaluation, a personal, family medical, and genetic history must be obtained. It is prudent to suspect that any defect of the craniofacial complex is part of a larger syndrome, so a full body survey is performed. All anomalies are noted, with an attempt to group them into a known syndrome. The head shape should be observed from front, rear, sides and vertex. The forms and positions of the eyes and ears are examined. The head is evaluated by palpation of the sutures and fontanelles to detect not only patency but also ICP. There should be no sutural ridging, and the fontanelles should not be bulging. The head circumference, the AP, bifrontal, bitemporal, and biparietal diameters, and the vertical height of the skull from the supraorbital border are all measured. In normal children the posterior and anterior fontanelles close at approximately 3 and 18 months, respectively, and the cephalic index (the ratio of the greatest width of the head to its greatest

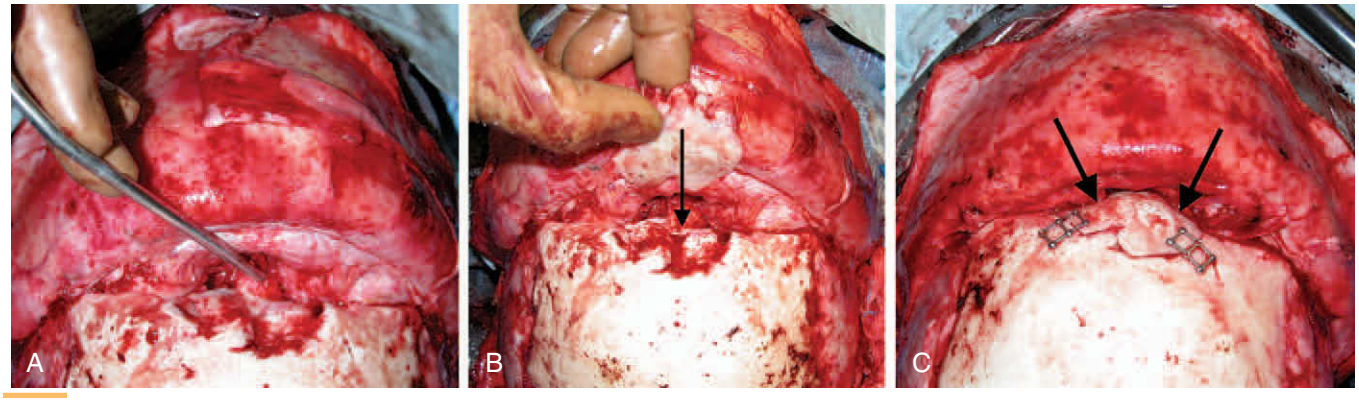

Figure 185-12. Operative images of a patient with fibrous dysplasia involving the anterior skull base who initially presented in her teenage years. Earlier endoscopic attempts at removal had failed and left the patient with strabismus, a mucocele of the frontal sinus, and exposed dura. **A,** A subcranial approach was utilized to remove the fibrous dysplasia. The suction tip is pointing to the lesion. **B,** The lesion has been removed, and the *arrow* is pointing to the area of dural exposure. The bone flap is shown. **C,** The bone flap has been replaced. *Arrows* are pointing to the pericranial flap that has been placed under the bone flap and used to seal the dural defect and obliterate the frontal sinus.

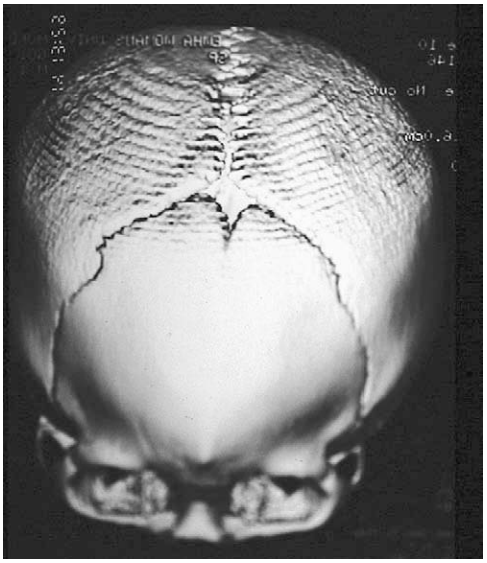

Figure 185-14. Three-dimensional computed tomography reconstruction demonstrating trigonocephaly.

length multiplied by 100) is 75 to 80. Although occlusion cannot be evaluated in the neonate, the relative dimensions of the mandible and midface are noted. The symmetry and range of motion of the neck must be examined as well.

Imaging

Plain radiographs can be useful in certain circumstances. The absence of normal sutural lucency may indicate synostosis. In plagiocephaly and brachycephaly, premature fusion of the frontoethmoid and frontosphenoid sutures causes elevation of the lesser wing of the sphenoid, producing the harlequin mask appearance (either unilateral or bilateral) on a plain AP film of the skull (Fig. 185-13). The hammered-copper or thumb-printing appearance of the inner table of the skull on cranial radiographs is associated with increased ICP and craniosynostosis; although its presence is easily detected, its clinical significance has been questioned.[76] Lateral and AP cephalometric radiographs continue to be useful, especially for evaluation of the progress of craniofacial growth.

However, for most defects computed tomography is the ideal modality for evaluation. Given its ubiquity and declining costs it has largely replaced plain radiography. Additionally, the software for three-dimensional reconstruction is widely accessible and provides detail of the bony anatomy that is unsurpassed (Fig. 185-14). Various cephalometric and volumetric analyses can be easily achieved. If necessary, a stereolithographic model based on three-dimensional studies can be built that provides an accurate template of the patient's craniofacial skeleton. Sophisticated software is also available to help in planning reconstruction (Fig. 185-15). Planning software is particularly helpful when one is preparing to reconstruct unilateral or some asymmetric defects. Although valuable information about the central nervous system can be obtained with computed tomography, magnetic resonance imaging is usually the modality of choice for evaluating the brain.

Indications for and Timing of Intervention

When one is considering treatment for craniofacial diseases and anomalies, it is helpful to stratify a patient into one of the following three categories based on the nature of the problem: life-threatening issues, functional impairments, and aesthetic issues. Issues classified as life-threatening include upper airway obstruction. An example is a neonate with severe Pierre Robin sequence. Another example is severe syndromic craniosynostosis affecting multiple sutures with dangerous ICP elevations. The second category, functional impairment, includes a broad spectrum of problems that range from visual impairment to neurocognitive problems as the child reaches school age. The third category is that of a mild deformity that results in what society might consider an abnormal aesthetic appearance.

The treatment algorithm for life-threatening problems is usually straightforward. The neonate with upper airway obstruction is treated either by distraction of the mandible (discussed in greater detail later) or a tracheotomy. The patient with kleeblattschädel requires urgent release of the binding skull by total cranial vault remodeling, and the child with dangerously high ICP is often treated with a ventriculoperitoneal shunt. The algorithm becomes more complex, however, for neonates with functional impairment.

The complexity arises because the consequences of not intervening or of the intervention itself are not always fully understood. Significant fronto-orbital retrusion is at the more severe end of the spectrum, as it may portend serious functional, neurologic, or ophthalmic problems. The presence of more than one synostosis is often associated with neurocognitive compromise. Anomalies of the maxilla and mandible not only affect appearance but also can impact the airway, dentition, and speech and therefore frequently require therapeutic intervention. Hypertelorism and other orbital dystopias can manifest as significant visual issues, in which case surgical reconstruction is necessary. Nonsyndromic single-suture craniosynostosis (SSC) is particularly difficult to classify because the association between the anomalies and functional sequelae is controversial. The incidence of increased ICP and neurocognitive deficiencies in nonsyndromic single-suture craniosynostosis is still debated, and further investigation of this issue is warranted.[77-79]

When the neonate has the mildest of craniosynostoses, such as some types of single-suture craniosynostosis or partial synostosis, positional plagiocephaly, mild FOAVS, and other mild craniofacial anomalies, the problem can be classified as aesthetic in nature. In such cases the craniofacial team and the involved family members must weigh the severity of aesthetic deformity against the risks of surgical intervention. The temptation to develop a strict algorithm based on the defect alone has to be resisted, as demonstrated by metopic suture synostosis. This deformity manifests with a wide range of severity in fronto-orbital malposition and hypotelorism, and the metopic suture closes earlier than previously thought.[80] The implication that prior standards used to guide the surgeon in deciding when to intervene surgically are not quite as relevant. In the case of positional plagiocephaly, the treatment does tend to be more clear-cut. Changing sleep position, treating causes

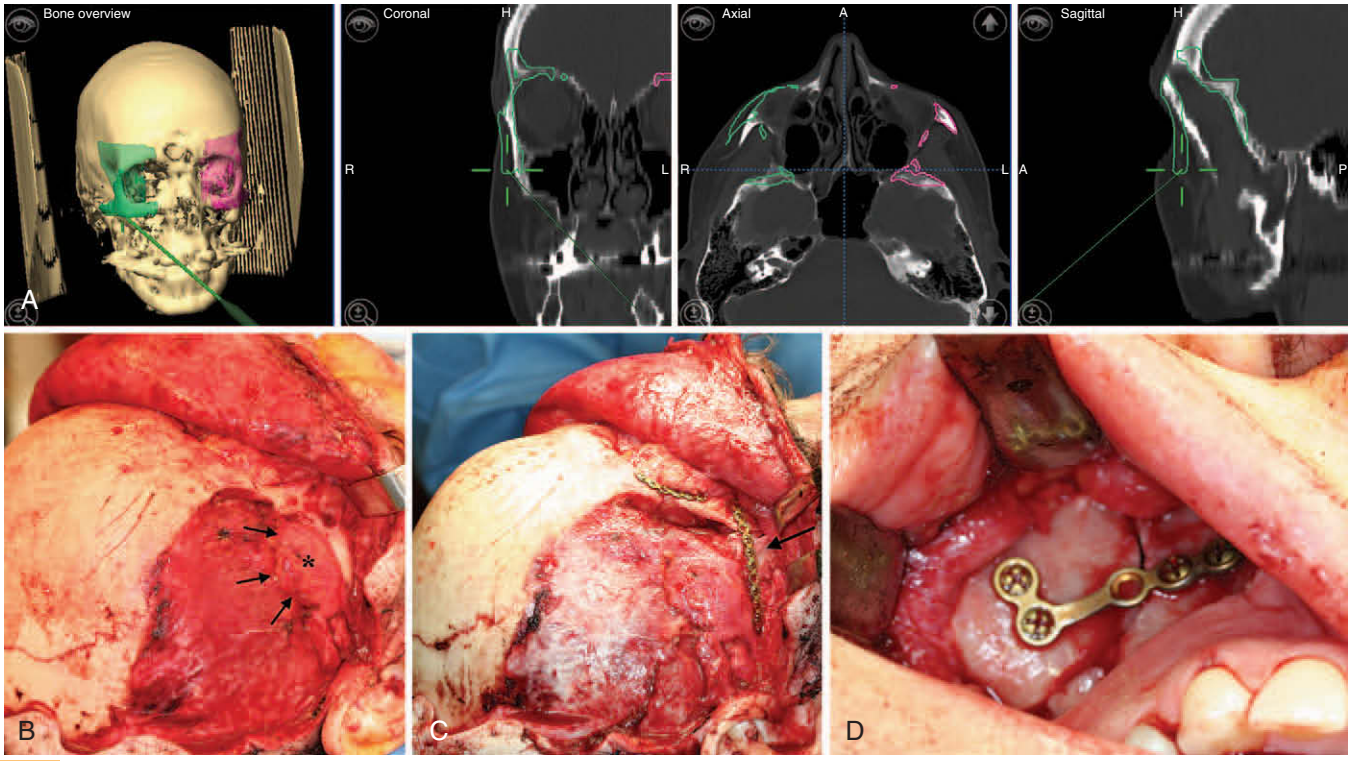

Figure 185-15. Images of a patient who had suffered from traumatically displaced fractures of the orbit and zygomatico-maxillary complex (ZMC) about a half year prior to presentation. Because of the delay in treatment, the skeletal segments healed in a malunion, resulting in a facial deformity as well as orbital dystopia. **A,** With the use of planning cranio-maxillo-facial software, the facial skeleton is displayed in the coronal, axial, and sagittal planes. The *green line* in the upper left image of the skull refers roughly to the planes in which the other three slides are shown. **B,** A bicoronal flap has been elevated to expose the orbit and ZMC. *Arrows* indicate where the superficial layer of the deep temporalis fascia has been incised at the temporal line of fusion and elevated to expose the temporal fat pad (indicated by *asterisk*). This is necessary to gain wide exposure to the zygomatic arch, which had been fractured in multiple places. **C,** Appropriate osteotomies have been made, and the displaced segment mobilized. Using the reconstructed image generated by the planning software the image guidance system helps in the proper placement of the osteotomized segment, which is fixed in place with titanium plates (this patient is old enough to allow for nonresorbable fixation). *Arrow* indicates calvarial bone grafting that was used to buttress the new construct (harvest not shown). **D,** A sublabial incision is necessary to make the inferior cut and apply the fixation.

of torticollis, and cranial molding orthotics can all be used quite effectively when appropriately applied.

The age at which surgical correction is appropriate depends on the particular anomaly, the extent of functional compromise, and the overall health of the patient. Pediatric anesthesia has greatly improved in the last several years, making surgery in infants significantly safer. This issue is particularly important in craniofacial surgery because many of the procedures are easier to conduct in young patients. Patients younger than 1 year have remarkable bony regenerative capacity. The bone is also thinner and more pliable, making it easier to cut and contour. Of course, with younger patients, there are risks that must be considered, such as intolerance to even mild blood loss.

Neonates suffering from airway obstruction are treated immediately if extubation fails. In the case of kleeblattschädel, multiple synostectomies must be performed within the first few weeks of life to prevent severe functional deficits and even death. Early intervention is also indicated for increased ICP and corneal exposure. Simple synostectomies (in treating scaphocephaly, for example) are often performed in patients 2 to 6 months old. The authors generally perform frontoorbital advancement and cranial vault remodeling procedures in infants 6 to 9 months old. Monobloc surgery of the forehead, orbits, and midface is often done at 3 to 4 years, although with distraction osteogenesis, the tendency is toward earlier intervention. Whole orbit movements are typically done while patients are 2 to 4 years old. Surgery effecting change in the occlusal relationships is often delayed until the teenage years. Depending on the severity and scope of the deformities, multiple procedures may be required to maximize the correction.

Surgical Techniques

Congenital Craniofacial Abnormalities

Because much of the surgery for craniofacial anomalies is performed on very young patients, special attention needs to be given to tightly monitoring and regulating the patient's vital functions. Infants have such a small blood volume blood that transfusion is often required in lengthy craniofacial procedures. Young patients also have decreased thermoregulatory capacity, so the room temperature is kept relatively high, especially during induction of anesthesia. Venous and arterial lines are inserted, as is a bladder catheter, preferably with a core temperature sensor. In a combined extracranial-intracranial procedure, antibiotics and steroids are routinely given. Shaving of the scalp for the incision is optional and based on the surgeon's preference. The scalp is scrubbed with a soap solution and povidone-iodine solution, and the face is generally also prepared with antiseptic scrub. The oral and nasal cavities should be irrigated if there is a likelihood that they will be part of the surgical field.

The eyes are protected by gentle application of ophthalmic ointment followed by covering with a clear plastic dressing. If access to the eyes is necessary, no taping is applied. Corneal shields are avoided when a bicoronal flap is elevated because the flap, when turned on itself, can often exert a fair amount of pressure on the shields, which could lead to eye damage. If necessary, a tarsorrhaphy suture can be used to protect the eyes.

Given that the head position is frequently altered during these procedures, it is very important to properly secure the endotracheal

tube to the patient and, if necessary, bring part of the tube into the field. If access to the maxilla is necessary, then the tube must be secured to the mandible. Although prone and sphinx positions are preferred by some surgeons, we prefer to perform most craniofacial procedures with the patient supine and the head flexed. In orthognathic procedures it is generally necessary to intubate the patient nasally. The tube must be draped in such a way so as to make it easily accessible to the anesthesia team if inspection of the ventilatory circuit is necessary. During draping of the patient, it is best to leave as much of the face (including the ears) in the field as possible. This exposure is helpful to maintain orientation. Prior to incision, a vasoconstricting agent can be injected into the skin, but doses must be carefully titrated in the young pediatric population. An epinephrine solution of 1 : 200,000 or 1 : 400,000 is recommended.

Although the coronal incision is the most widely used approach for gaining access to the craniofacial skeleton, other, smaller incisions are used for different applications. For cases of mild to moderate sagittal synostosis, an endoscopic approach can be used or a midsagittal (wavy) incision can be employed to gain access to the synostotic portion of the suture. However, whenever access to the supraorbital bar is necessary, the bicoronal incision is necessary.

Coronal Incision

The coronal incision can extend pre- or postauricularly. When extended into the postauricular area, the incision is hidden, and adequate exposure of the cranium and the upper and part of the middle thirds of the face can still be obtained. The incision is designed as a wavy line that extends across the vertex of the head (Fig. 185-16).[13,81] The overall incision can be rotated more anteriorly to allow more anterior/inferior retraction of the flap. Some surgeons sharply zigzag the incision so as to make multiple V-Y closures possible if the advancement is so significant as to preclude normal closure of the coronal flap. The flap can then be elevated in a subperiosteal or subgaleal plane over the calvarium. The dissection is continued to the deep temporalis fascia elevating the temporal-parietal fascia. Dissection in this plane enables the frontal branch of the facial nerve to be elevated in the flap. If access to the zygomatic arch is required, the superficial layer of the deep temporalis fascia is elevated starting at the temporal line of fusion (see Fig. 185-15). This maneuver has the added advantage of adding an extra layer of tissue in between the dissection and the facial nerve branch. In some types of cranial vault remodeling, it is necessary to elevate the temporalis muscle as well, but this step is performed independent of the scalp elevation.

Sagittal Synostosis

Sagittal synostosis requires that the skull be allowed to expand in the transverse dimension and reduced in the AP dimension. There is a spectrum of procedures for scaphocephalic correction. Mild cases treated before 3 months of age may be managed with strip craniectomy alone (Fig. 185-17). A strip craniectomy is performed by removing sagittal or parasagittal sections of bone. Severe cases and patients treated after 9 to 12 months may require total cranial vault remodeling. In these cases coronal and lambdoid osteotomies can be made, and the parietal bones out-fractured. In severe cases the frontal bone can be significantly bossed and often has to be reshaped or transposed to improve the contour of the forehead. This requires a coronal incision (Fig. 185-18).

Fronto-Orbital Advancement

Centrally, the dissection exposes the supraorbital bar in the subperiosteal plain (if the dissection was done in a subgaleal layer, the periosteum is incised 2 cm above the supraorbital rims). The supraorbital rims and frontonasal region are fully exposed, with preservation of the supraorbital neurovascular bundles, which can be quite small in the neonate. In the very young patient this structure rarely exits via a foramen; rather, it lies in a groove in the medial half of the supraorbital rim, generally over the pupil. If there is a foramen, the inferior rim must be osteotomized in order to dissect and mobilize the neurovascular bundle. Progressing medially, the lacrimal crests can be exposed, if necessary, after separation of the medial canthal ligaments from their bony attachments and elevation of the lacrimal sac. In the midline the

dissection is carried just past the nasofrontal suture. Laterally, exposure is extended from the zygomatic arch medially to the body of the zygoma. Fronto-orbital procedures generally require inferior exposure only to the level of the frontozygomatic suture. The lateral orbital rim is then exposed, and this dissection is connected to that of the supraorbital bar. The orbital roof is carefully dissected in the subperiosteal layer. The lateral orbital walls are exposed by elevation of the anterior aspect of the temporalis muscle from the temporal fossa.

Once the dissection is complete, intended osteotomy sites for both the supraorbital bar and the bifrontal craniotomy are marked. A side-cutting power craniotome is typically used once strategic bur holes have been drilled. The bifrontal craniotomy (Fig. 185-19) is done initially, with care taken to leave a transverse bar of bone above the supraorbital rims that is between 10 and 15 mm in width. The dura is freed from the anterior aspect of the anterior cranial fossa but left adherent over the cribriform plate. The supraorbital bar or bandeau is then marked for osteotomy. The superior osteotomy for the supraorbital bar was created by the bifrontal craniotomy. If a strip of bone was left over, the sagittal sinus it is cut from the bandeau. Laterally, the superior bandeau osteotomy is extended into the squamous portion of the temporal bone. Inferiorly, the central transverse osteotomy is made at or just above the

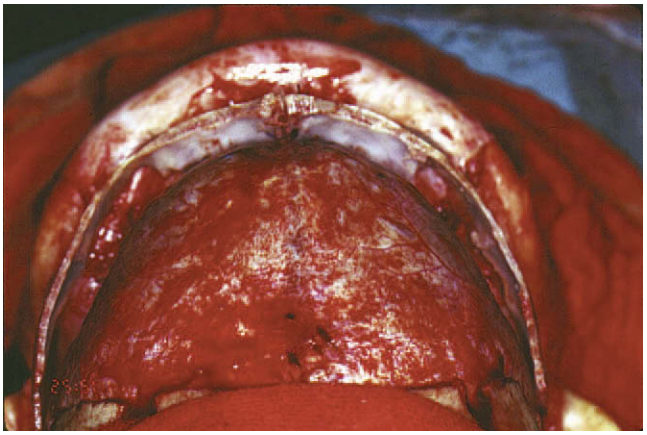

Figure 185-19. A bifrontal craniotomy has been performed. Note the elevation of the dura from the anterior cranial fossa in preparation for removal of the bandeau.

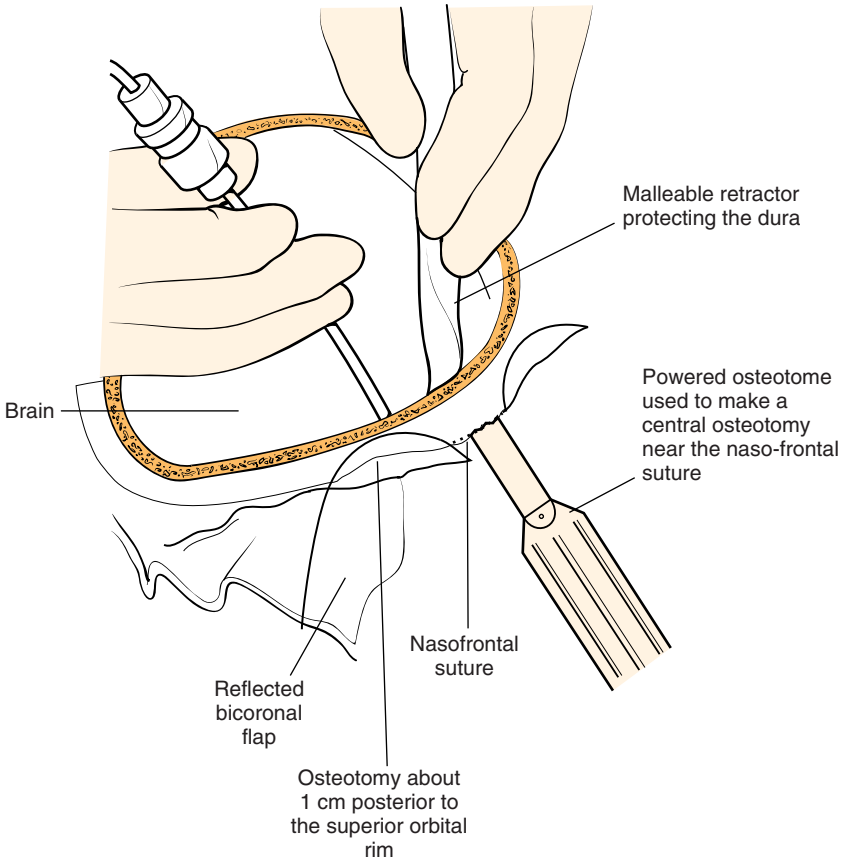

Figure 185-20. The central cut of the bandeau is illustrated. This cut is made above the nasofrontal suture. It is extended into the anterior cranial fossa anterior to the crista galli while protecting the brain with a malleable retractor. This way olfaction is preserved, and the barrier between the intracranial and nasal cavities is left intact. *(Adapted from Salyer K.* Techniques in Aesthetic Craniofacial Surgery. *New York; Gower Medical; 1989:35.)*

frontonasal suture (Fig. 185-20). This cut extends directly to the anterior cranial fossa at a point anterior to the crista galli. This location preserves olfaction as well as the barrier between the brain and the nasal cavity. The osteotomy is then carried into the medial orbit just above the lacrimal fossa. The osteotomy turns superiorly 5 to 10 mm inside the orbital rim, traverses the orbital roof around 10 mm posterior to the superior orbital rim, and extends down the lateral orbital wall to the level of the zygomaticofrontal suture. The lateral orbital rim is cut at the suture, and that cut extends posteriorly into the greater wing of the sphenoid and the squamous portion of the temporal bone parallel to and 10 to 15 mm inferior to the previous cut into this region. This site corresponds intracranially with the junction of the anterior and middle cranial fossae near the pterion. Enough length of the temporal portion of the bandeau will allow a tongue-and-groove action at this lateral point in order to increase the bony contact once the advancement has been completed. This maneuver facilitates bony stability. Removal of the bandeau is frequently hindered by incomplete osteotomy at the trifurcation (of the anterior extent) of the middle cranial fossa, the lateral orbital wall, and the greater wing of the sphenoid. The anterior tip of the temporal lobe must be protected while this cut is completed.

Once the bony segments are removed, they are reshaped on a separate table. The supraorbital bar can be reshaped to the extent required by the deformity (Fig. 185-21). Bone is removed as needed in thickened areas to facilitate bone bending. In unilateral synostosis (plagiocephaly) the central angle of the forehead is mildly affected, and only small alterations are necessary to increase the central angle to 150 to 170 degrees. Although only one side is affected in plagiocephaly, minor changes are required on the unaffected side because of compensatory frontal bossing. More drastic measures might be required for trigonocephaly, in which the central angle of the forehead can be as acute as

Figure 185-21. The bandeau following removal.

90 degrees. It is sometimes necessary to split the bandeau in the midline and add a bone graft in order to widen the central angle (Fig. 185-22). The components are then fixed to one another with absorbable plates, sutures, or both. Just above the lateral orbital rims, the angle between the supraorbital rim and the temporal fossa is adjusted to between 100 and 110 degrees. The orbital bar is then replaced in an advanced position.

The extent of advancement obviously depends on the nature of the anomaly. In trigonocephaly and plagiocephaly, the orbital advancement is predominantly lateral, with the medial portion advancing little if any. In brachycephaly the entire bandeau is usually advanced, but the movement is still greater laterally than medially (Fig. 185-23). Maintaining contact between the supraorbital bar and the root of the

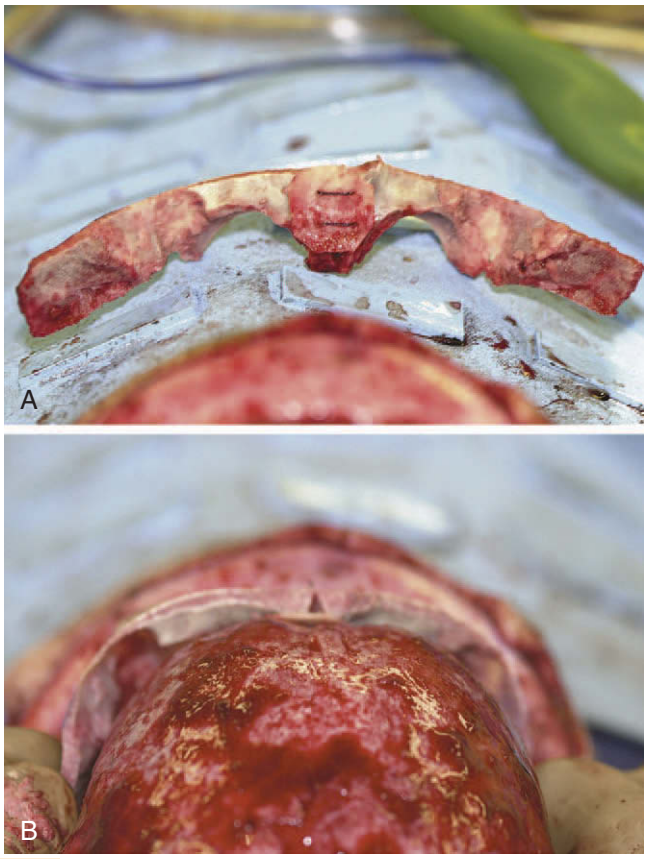

Figure 185-22. **A,** The bandeau can be split and a graft used to stabilize the new supraorbital construct. **B,** The bandeau is in place.

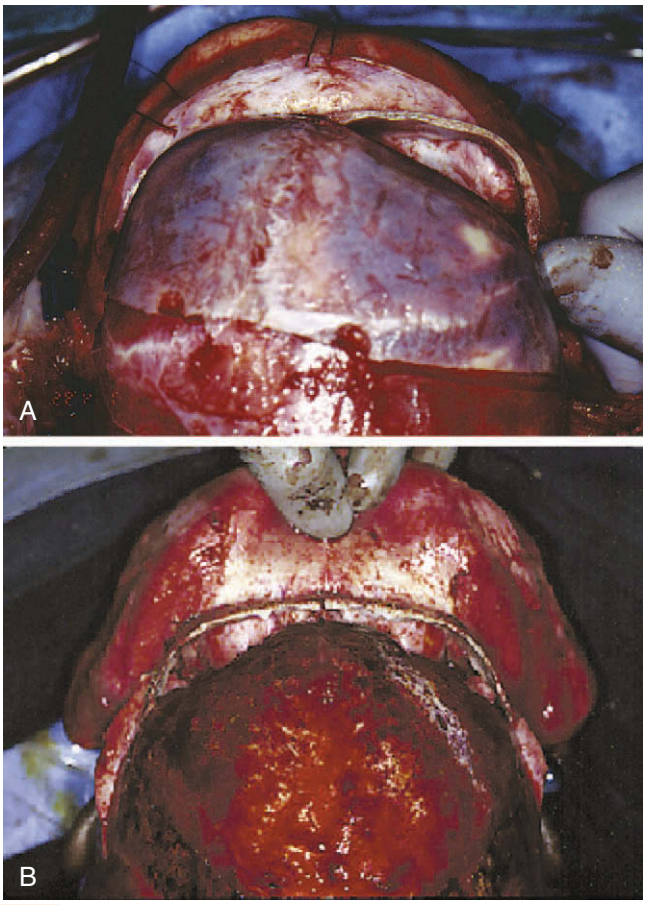

Figure 185-23. **A,** In this plagiocephalic repair, the lateral advancement of the bandeau is dramatic, whereas centrally little advancement was necessary. **B,** In this brachycephalic repair, there is more central advancement relative to the plagiocephaly repair but still far less than the lateral advancements.

nose is also important from the perspective of frontal sinus development, which later enhances central forehead projection.[82] It is important to establish symmetry with the advancement. Both rims should be about 1 cm anterior to the cornea. In severe cases the bandeau can be advanced as much as 2 cm, but bone grafting may be necessary. The supraorbital bar is fixed to the skull with absorbable plates, sutures, or both at the nasion and laterally (Fig. 185-24).

Lambdoid synostosis is repaired in much the same way as coronal synostosis. However, instead of removing and reshaping a supraorbital bar, the surgeon removes an occipital bar and advances it posteriorly and the occipitoparietal complex is reshaped to create posterior symmetry. Other types of cranial vault remodeling, including severe scaphocephaly, are also done via the coronal incision.

Resorbable plate technology represents a breakthrough in this treatment.[83] It offers dependable rigid fixation without the use of metallic plates.[84] Resorbable plates are less likely to interfere with craniofacial growth and development the way that titanium plates can, and they also rarely require removal.[85] The problem of intracranial plate migration with growth is avoided as well—typically the plates lose a large proportion of their strength within the first 6 months and are resorbed in less than 18 months. The calvarial bone flaps are then reshaped to provide normal contour to the head. Sometimes it is necessary to further osteotomize the flaps. The various components can be replaced in different positions to give the best contour. The bones are then fixed to the surrounding skull with absorbable plates or sutures. Maintaining large pieces of bone that are bent to the desired conformation, rather than creating small segments of bone with many osteotomies, provides for a more stable construct with less fixation than would be required if the bones were cut into smaller pieces.

Because of the advancement, there will be defects in the bone at various places. In patients younger than 1 year, bony defects are generally not of major concern because of bone regeneration. However, in older children and adults, large defects must be addressed. The orbital roofs represent a clear example. If there is a persistent communication between the orbit and the brain, pulsatile ophthalmopathy can develop. Therefore, these defects must be repaired with bone grafts (Fig. 185-25). Calvarial defects in the child or adult can be repaired with bone grafts or other bone replacement materials.

When the skeletal reconstruction is complete, attention is directed to a multilayer and precise closure. If the temporalis muscle has been elevated, it must be advanced to the lateral orbital rim and sutured. If this step is not performed, temporal hollowing occurs, creating an unaesthetic appearance. The muscle can be sutured to holes drilled in the lateral orbital rim or to one of the fixation plates. The galea aponeurosis is reapproximated with absorbable suture. The skin can then be closed with permanent or absorbable suture. We prefer to avoid suture removal in young children, so we perform a subcuticular closure with absorbable suture. In older children, skin staples can be used. If a sharp zigzag incision was used and the skin cannot be easily approximated (particularly in repair of severe brachycephaly), cutaneous closure can be performed, with use of the V-Y technique at each peak of the zigzag. We avoid using drains, especially in young patients. A gentle pressure and occlusive dressing is placed over the head.

Monobloc Advancement

Older children (>2-4 years) who present with fronto-orbital retrusion in conjunction with midface retrusion are potential candidates for a one-stage procedure. The (frontofacial) monobloc advancement originally described by Ortiz-Monasterio and colleagues[86] combines a fronto-orbital advancement with a Le Fort III level facial advancement (Fig. 185-26). The procedure is performed through the coronal inci-

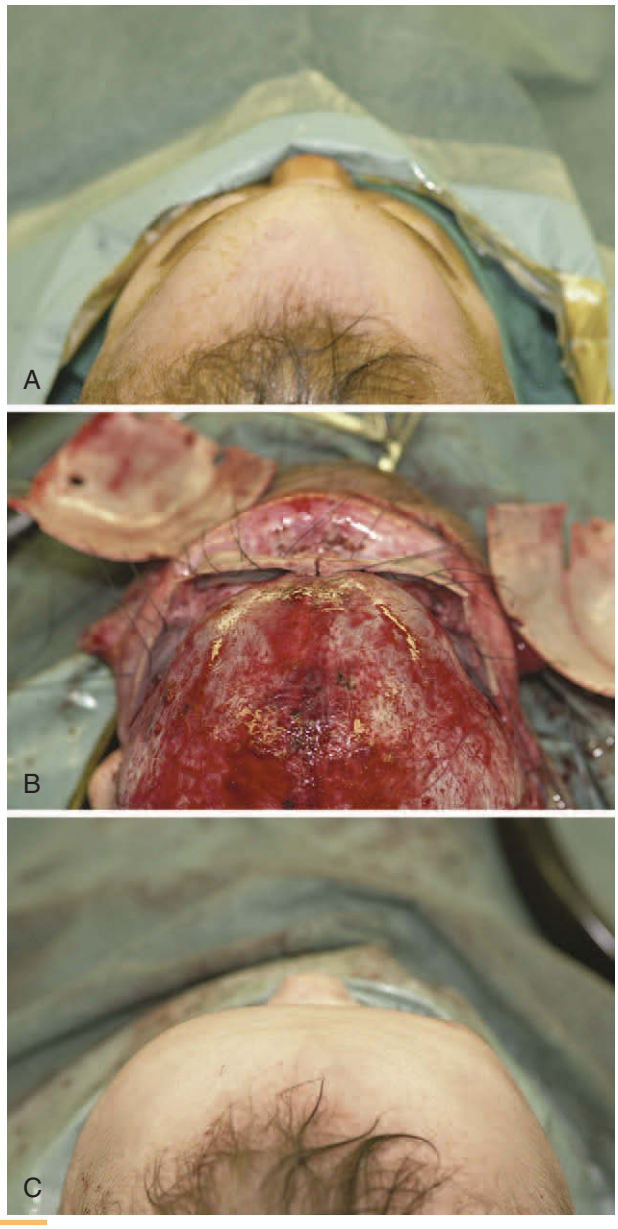

Figure 185-24. Trigonocephalic repair. **A,** Preoperative view. **B.** Intraoperative view. **C,** Postoperative view.

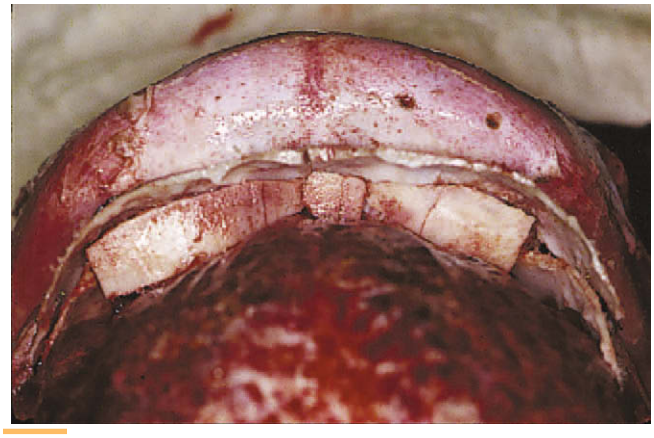

Figure 185-25. Bone grafts are placed between the orbit and the anterior cranial fossa in an effort to reconstitute the orbital roof.

sion. The craniotomy is similar to the one performed in a fronto-orbital advancement. The zygomatic arches are cut. The frontal bar is included with the Le Fort III segment. Circumferential orbital bony cuts are made with use of both extracranial and intracranial approaches. The lateral and inferior orbital walls are osteotomized starting in the inferior orbital fissure. The medial wall is cut just posterior to the posterior lacrimal crest. The orbital roof osteotomy is made intracranially. The nasal septum is cut via the frontoethmoid osteotomy. Finally, through the infratemporal fossa or the mouth, the maxilla is separated from the pterygomaxillary junction. The monobloc segment is then advanced and rigidly fixed with use of absorbable or titanium plates.

In some craniofacial deformities, such as those commonly seen in patients with Apert's syndrome, hypertelorism is present in association with maxillary deformities. Facial bipartition is a technique used to simultaneously correct hypertelorism and maxillary arch abnormalities (Fig. 185-27). Bone grafts are used to help maintain the advancement. Pericranial flaps and tissue glues are also used to create a seal between the anterior cranial fossa and the nasal cavities.

Although combining the two corrections into one procedure, has an obvious advantage, it is also associated with a higher rate of infection, presumably because of an incomplete seal of the central nervous system from the nasal cavities. It is for this reason that patients must be carefully selected for such a procedure. In situations in which the monobloc advancement is clearly the procedure of choice, distraction (in place of craniofacial advancement during the operation) may offer a safer way to achieve the desired results (see Fig. 185-26). The approach and the osteotomies are no different from the en bloc advancement just described.

Orbital Hypertelorism and Dystopia

In the correction of orbital hypertelorism, the approach is similar to that used in a fronto-orbital advancement, except that circumferential periorbital elevation is required. A bifrontal craniotomy is performed; however, a 1- to 1.5-cm strip of bone is left intact just above the orbital rims and below the bifrontal craniotomy. The anterior cranial fossa is exposed but the cribriform plate and crista galli are left intact to preserve olfaction. The periorbita is freed up to the infraorbital fissure. Four (box) osteotomies are made to encircle the entire bony orbit. The cuts outside the supraorbital, lateral, and medial rims can be made via the bicoronal exposure; however, the inferior cuts are facilitated by either a transconjunctival or subciliary incision. The bony orbits are mobilized by making a second set of circumferential osteotomies inside the orbit (using the inferior orbital fissure as a landmark) to separate the anterior part of the orbit from the posterior part. Upon mobilization of the orbits, a central bony block is osteotomized from the naso-ethmoid complex. The anterior ethmoid fovea and air cells are often removed in this maneuver. The cribriform plate, along with the olfactory fibers and mucosa, are left intact. The bony orbits are then translocated to more medial positions. Vertical or rotational dystopia can be addressed at this point by addition or removal of bone in the appropriate areas to achieve proper orbital position. The bony segments are then fixed in their new positions with either resorbable or metallic plates. Closure proceeds as previously discussed. Because of instability of the mobilized orbit in the very young child, this type of correction is typically deferred until after age 2 years.

Distraction Osteogenesis

Distraction osteogenesis has been employed in the long bones for just under a century now. It was first applied to the craniofacial skeleton more than 80 years ago[87] but has come into widespread clinical use only in the last 25 years.[88] *Distraction osteogenesis* refers to creation of a controlled fracture in a bony structure followed by separation of the bony segments in a controlled and gradual manner. This process induces the formation of new bone in between the distracted segments. The advantages of using distraction osteogenesis in the craniofacial skeleton are numerous. It allows for skeletal lengthening and advancement in three dimensions. The process is a gradual one that allows the skin–soft tissue envelope to adapt to and accommodate skeletal movement.[89] It is also safer than many of the traditional skeletal techniques. Distraction osteogenesis is less involved and requires less operative time

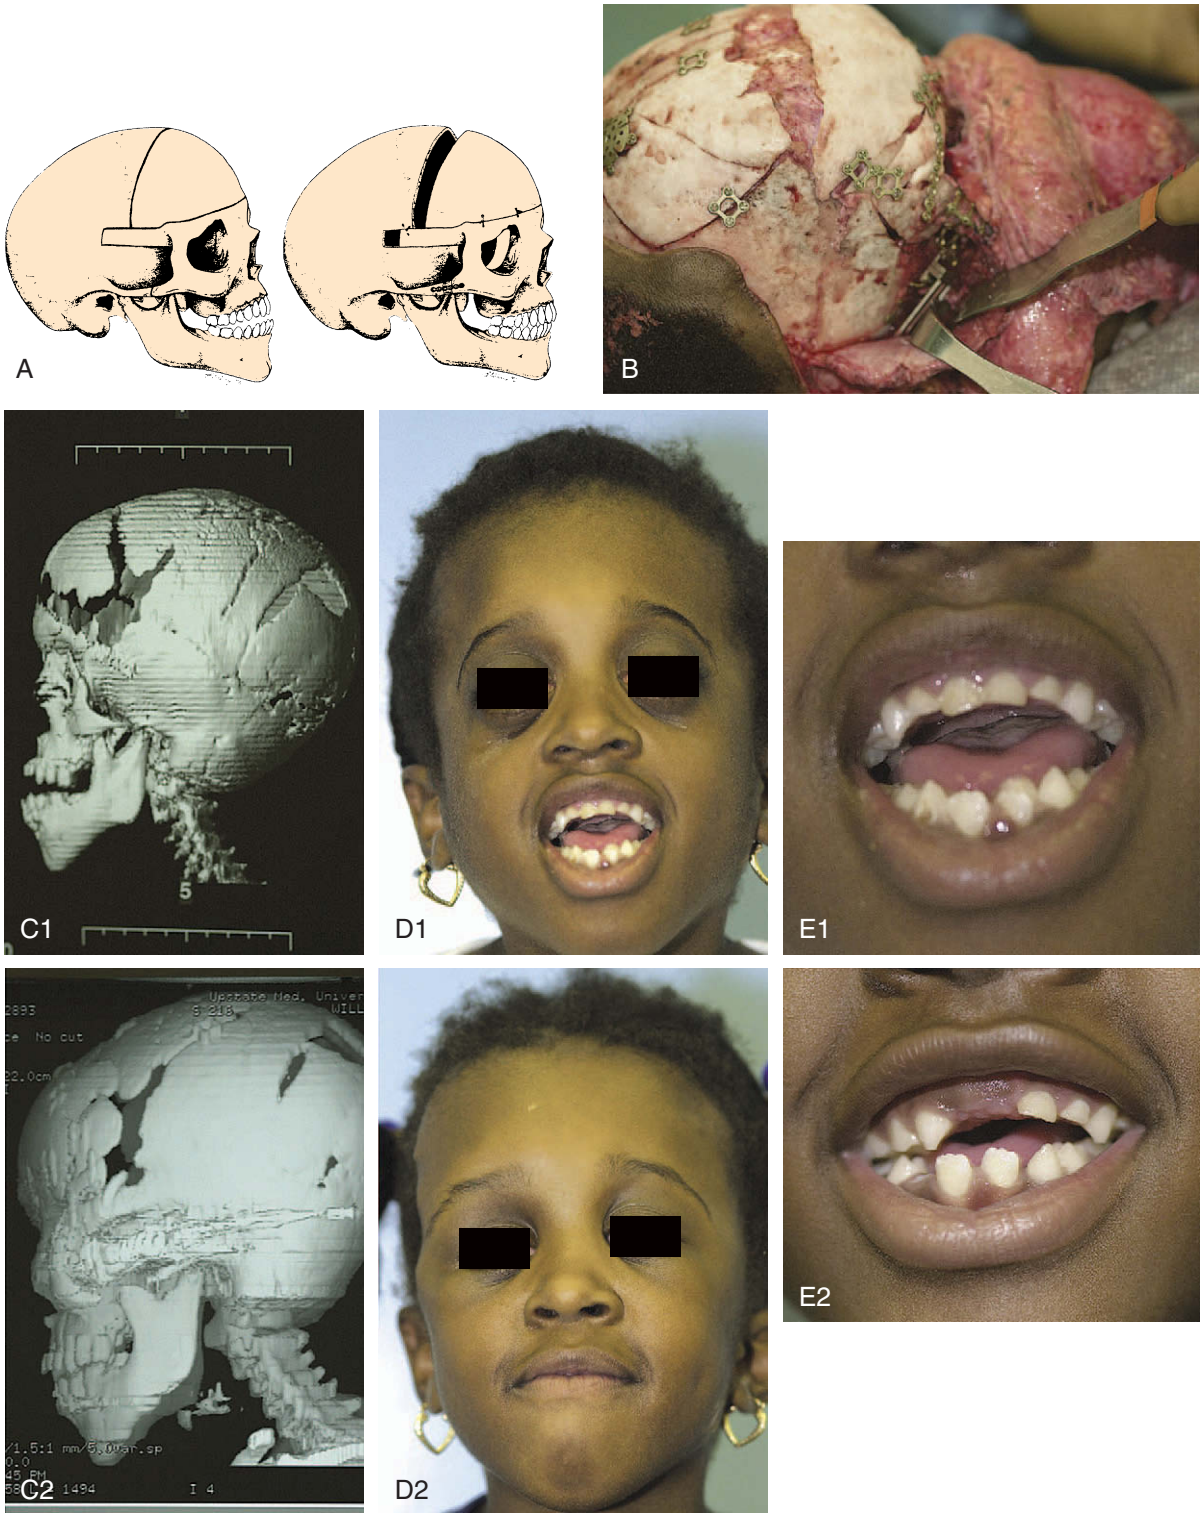

Figure 185-26. **A,** The monobloc advancement: Le Fort III osteotomies are performed in concert with a bifrontal craniotomy and mobilization of the bandeau. Fronto-orbital as well as midfacial advancements are then performed. **B,** Monobloc advancement with an internal distractor used to gradually advance the facial segment. (Note the right internal distractor device at the end of the retractors.) **C,** Preoperative (C1) and postoperative/postdistraction (C2) three-dimensional computed tomography scans. **D,** Preoperative (D1) and postoperative/post-distraction (D2) frontal photographs. **E,** Preoperative (E1) and postoperative/post-distraction (E2) dental/occlusal photographs.

(generating less blood loss) than the techniques it has replaced. As a result it is an attractive treatment alternative for children and infants with some craniofacial anomalies.

Distraction osteogenesis can be carried out with internal or external devices (Fig. 185-28). Internal devices have the advantage of not requiring big and bulky hardware protruding from the face and can, at times, be applied intraorally. The extent of control over the vectors of distraction is limited with internal devices. The external devices allow for three-dimensional distraction and better control of the vectors of distraction (see Fig. 185-28). The disadvantage lies in their bulkiness.

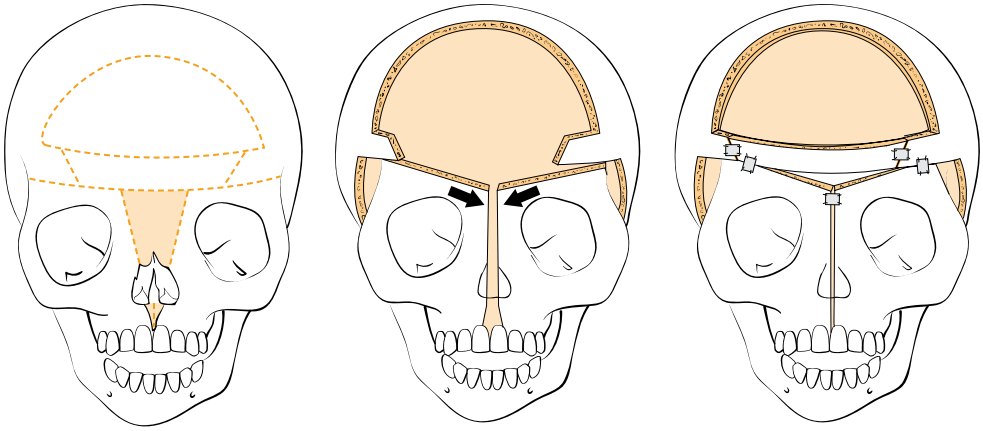

Figure 185-27. Facial bipartition can be used to move the orbits into more medial positions and narrow maxillary width as well. An inverted triangular wedge of bone is removed from the midline extending from the supraorbital ridge to the maxillary arch. The skeletal segments are then rotated, bringing the orbits into closer alignment and also reducing an open bite deformity. This procedure is also employed in the repair of some midfacial clefts. *(From Salyer K.* Aesthetic Craniofacial Surgery. *Philadelphia; Lippincott; 1989:67.)*

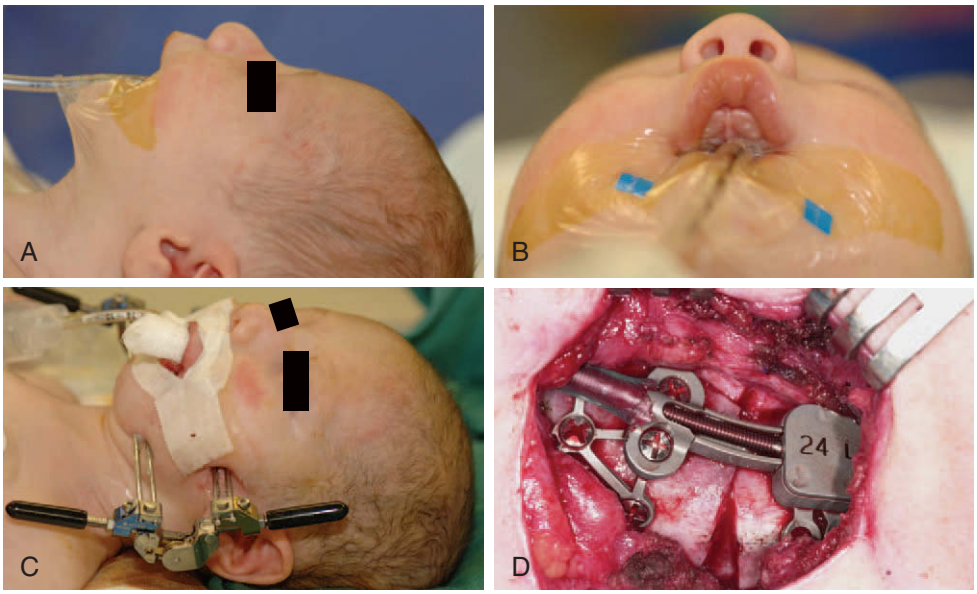

Figure 185-28. Distraction osteogenesis of the mandible. Profile view **(A)** and base view **(B)** of a neonate with Pierre Robin sequence. This patient could not achieve adequate ventilation without mechanical respiratory support. **C,** External distractors were placed after bilateral intra-oral osteotomies were created. The patient's mandible was ultimately distracted more than 1 cm, eliminating the need for any respiratory assistance. **D,** Internal distraction in a different patient. The distractors were applied after osteotomies were created through extra-oral incisions.

Pin migration scars can be significant as well. However, this is a rapidly evolving technique, and new devices are constantly being introduced. As the internal devices become more sophisticated, their roles will continue to expand.

The most common application of distraction osteogenesis in the craniofacial skeleton is the mandible. It is used for maxillary advancement and in the upper face and cranial vault as well. The process consists of several phases. At the time of surgery, the skin or mucosa and soft tissue are incised to expose the part of the facial skeleton that is to be distracted. The periosteum is incised directly over the intended site of osteotomy, which is marked out. The appropriate holes are drilled for fixation of the distraction device before the controlled osteotomy is made. In the mandible, the cortical cuts are made carefully to protect dental and neurovascular structures. Full mobility about the osteotomy sites must be confirmed to ensure total disunion of the bony segments; any bony continuity would hinder or prevent distraction. The distraction hardware is then put into place. Placement involves anchoring the device on both sides of the osteotomy with screws for an internal device or percutaneous pins for an external device. Some devices are borne by teeth or a dental implant. Distraction osteogenesis has a place in alveolar bone reconstruction and dental restoration as well.

A latency period is observed following osteotomy and placement of the device before actual distraction is begun. During this time the healing process commences with callus formation. The duration of the latency period depends on the age of the patient. In very young patients it can be as short as 24 hours, and in adults it can be as long as 1 week. It is more detrimental to wait too long than to begin too early, for premature fusion would render the distraction difficult or impossible. The beginning of distraction initiates what is termed the *distraction phase*. During this period, new immature bone is laid down between the osteotomized bony edges. The rate of distraction and the frequency with which it is done depend on the nature of the defect and the age of the patient. These variables are the subject of some debate, although the rate of distraction typically varies between 1 and 3 mm/day in one to three installments.

In the period subsequent to the distraction phase, the bone remodels and matures in what is known as the *consolidation phase*. The distraction hardware is left in place for a variable time. The rule of thumb we use is to allow consolidation to occur for a period that is at least twice the duration of distraction period. During the consolidation phase, the regenerate mineralizes and the soft tissue continues to change its shape and orientation so as to achieve balance with the new position of the bone. After several months the new bone is similar in volume to the native bone but with somewhat reduced mineral content and strength.

Trauma

The goal of treatment is the restoration of function and three-dimensional architecture. For severe and displaced fractures, internal fixation is often necessary.[90] The window of time in which fractures can be repaired is shorter in children as a result of the rapidity of their healing time. Many surgeons advocate using resorbable plates and screws for internal bony fixation, although others prefer using small titanium plates, arguing that complications from permanent (mini)plates are minimal.[75,85,91-93]

Neoplasm

Approaches to the skull base for tumor extirpation also require an intimate understanding of craniofacial anatomy because normal anatomy is often effaced. Several craniofacial approaches have been described in the pediatric population that can be used to gain access to tumors of the anterior and middle cranial fossae.[94] Historically, tumors of the anterior skull base were approached with a frontal craniotomy combined with a facial incision such as a lateral rhinotomy with or without a Weber-Ferguson facial incision. However, tumors of the anterior cranial fossa can be adequately exposed with a subcranial (subfrontal) approach without facial incisions (see Fig. 185-12). As previously mentioned, this latter exposure involves removal of the frontonasal complex. The extent of frontal and orbital rim bone removal is determined by the size, location, and nature of the lesion. In an extended subcranial approach, large sections of the bony orbit can be removed.[95]

The middle cranial fossa can be approached through a variety of techniques. The endoscopic transnasal-transsphenoidal approach can be effective in resection of midline tumors associated with the sella turcica, sphenoid cavity, and posterior nasal cavity. Figure 185-11 demonstrates repair of a sphenoid sinus encephalocele via this endoscopic approach. Even malignant or locally destructive lesions are occasionally accessible via this approach. Le Fort I, transpalatal, and midfacial degloving techniques can be used to gain limited access to lesions of the skull base.[96] More aggressive lesions that are off the midline (such as petroclival lesions) can be approached via the infratemporal fossa (or a modified version) or other transbasal approaches.[97] The cranio-orbito-zygomatic and transcondylar approaches provide excellent exposure of the infratemporal fossa. A frontotemporal craniotomy extends the exposure to the middle cranial fossa and the petrous internal carotid artery as well as other petroclival structures. When a lesion involves the middle cranial fossa, the infratemporal fossa, and the nasopharynx, a wider exposure is frequently necessary. The facial translocation procedure provides very wide exposure to lesions in this area and is well suited for malignancies, for which a margin of healthy tissue must be removed as well. It involves extended facial incisions as well as transection of facial nerve branches that are later reanastomosed. A maxillary-zygomatic bony segment is removed in order to gain access to the necessary extracranial lesion. A subtemporal craniotomy then provides intracranial exposure. In reconstruction of the bony framework, the same principles must be followed as for any other craniofacial procedure.

Biomaterials in Skeletal or Cartilaginous Defect Repair

When selecting materials for reconstituting craniofacial skeletal defects, the surgeon must recognize that no one material fills all needs. Several materials are available, reflecting the reality that there is no truly superior product in the field. The craniofacial surgeon starts the process of selecting a material by identifying a specific clinical need and a tissue substitute that will fill as much of that need as possible. Three types of factors are primarily responsible for outcomes of the use of bone substitute material, host factors, surgical technique, and the features of the material.

Host factors are of fundamental importance whenever a graft or implant is to be used. They include any systemic conditions, such as autoimmune illness, as well as the local environment. The local environment is profoundly influenced by anything that alters its vascularity, such as radiation therapy. The functional demands of the tissue being replaced are carefully considered. A calvarial defect, for instance, has different requirements from those of a mandibular defect, which has much greater load-bearing requirements. The extent of soft tissue coverage and mobility to which the implant is exposed are also key factors. Implants that work in the malar eminence might not work in the ear or nose.

Surgical technique can also play an important role in how well an implant is tolerated. Intra-oral approaches carry an increased risk of infection if closure is not executed with meticulous attention. For all approaches, appropriate handling of the soft tissues and the periosteum (when available) can be critical to success. Material preparation, such as pretreatment with an antimicrobial agent, can also be important in improving the likelihood of success.

The third factor is the material itself. On a general level a material that is nontoxic, noncarcinogenic, and nonimmunogenic to biologic systems is said to be *biocompatible*. Inflammation, which in previous discussions of the subject was considered a negative quality, can actually be advantageous as long as it is resolvable. The concept of biocompatibility, however, is more complex than even this definition implies. As previously discussed, a material that is biocompatible in one area may not be so in another. The use of expanded polytetrafluorethylene (ePTFE) is an excellent example. ePTFE has been successfully used for many years in vascular surgery,[98] but the use of Proplast, a closely related material, in reconstruction of the temporo-mandibular joint produced disastrous complications.[99] In some applications and locations, a material that causes a local but temporary reaction is desirable, whereas in others, a totally inert material is required. On the basis of this analysis, it is more precise to include application and local factors in the definition of biocompatibility.

Furthermore, it is most useful to think of biocompatibility as a broad spectrum with autogenous grafts on one end and alloplastic (synthetic) materials on the other. Allografts (homografts) and xenografts fall in the middle of that spectrum. Autogenous materials represent the "gold standard," but this category is not homogeneous. Cancellous bone grafts are quite different from cortical grafts. Cortical grafts can be further subclassified as endochondral or intramembraneous bone, with functional differences between the two.[100-102] Although there is a vast and successful experience with autogenous grafting,[103] this method still has its limitations. Donor site morbidity should not be taken lightly. In a prospective study evaluating iliac crest donor site pain, Sasso and colleagues[104] reported that a significant proportion of patients still had donor site pain 2 years after surgery. In addition, incomplete resorption and remodeling of cortical bone occurs in autogenous grafts, and unpredictable remodeling can be an issue as well.[105,106]

Allografts can be used in place of autogenous grafts. Demineralized bone matrix and irradiated cadaveric bone are examples of allografts currently used by some surgeons. Xenografts are also used; they include various collagen preparations that are employed as bone substitutes. The final category is synthetic biomaterials or alloplasts. This category consists of metals, ceramics, polymers, and biomimetic materials. This final subcategory refers to materials that mimic bone structurally or biologically and includes tissue-engineered constructs.

The metal most commonly used for craniofacial reconstruction is titanium. This metal not only has some osteoconductive properties but also has a modulus of elasticity that approaches that of bone. This feature results in less stress shielding than observed with stainless steel or Vitallium, both of which are rarely used today. Gold is inert, and its high density has made it useful in some applications, such as facial reanimation.

Polymers include a diverse set of materials some of which are nonresorbable and some resorbable. They have a successful track record for use in facial augmentation.[107] Methacrylates are nonresorbable and

have been widely used for calvarial reconstruction since World War II. High-density porous polyethylene is a straight-chain aliphatic hydrocarbon that is inert and also nonresorbable. It has been used successfully in some craniofacial applications. The primary problem with these materials is associated with their risk for infection or extrusion during the life of the recipient. Implants fabricated from polylactic acid and polyglycolic acid are resorbable and have sufficient strength for some load-sharing applications. This material has been promising as a means of bony fixation without the use of a permanent material.

Ceramics include calcium phosphates such as hydroxyapatite and bioglass. Hydroxyapatite, which has the advantage of being closely related to the carbonated apatite found in bone, has been shown to be reasonably effective in animal models and has proven clinical efficacy in some applications.[108,109] However, in the sintered and cement forms, it is not entirely accessible to the remodeling activities of osteoclasts. Its osteoconductivity and osteoinductivity are often less than ideal.[106,110,111] Bioglasses are very osteoconductive, but some of their properties, such as stiffness and elasticity, render them inappropriate for many craniofacial applications.

The final subcategory is synthetic biomimetic materials. They are designed to replicate bone on a structural and biologic level. They are often composites and can include bioactive factors such as bone morphogenic proteins or cells in a tissue-engineered material. This field is very promising in offering the hope of an off-the-shelf material that can simulate bone and stimulate the bone remodeling cycle—so that it is resorbed via osteoclastic remodeling coupled with osteoblastic bone deposition. Biomimetic biomaterials are theoretically replaced with normal lamellar bone. Given the pace of research in this field, a true bone substitute material of this nature is certainly on the horizon.

Conclusion

The field of craniofacial surgery is a rapidly developing and complex field. Appropriate care can best be rendered by a multimember team with diverse and in-depth training. The craniofacial defects encountered are often part of a larger syndrome affecting many functional systems. The underlying pathology is etiologically diverse and heterogeneous. The application of craniofacial principles developed to treat congenital problems also serves well for tumor extirpation and trauma repair. Several materials are currently available to reconstruct the craniofacial skeleton, but there is also a wide effort to develop more biomimetic materials.

CHAPTER ONE HUNDRED AND EIGHTY-SIX

Cleft Lip and Palate

Oren Friedman

Tom D. Wang

Henry A. Milczuk

Key Points

- Cleft lip and palate deformities constitute the most common congenital defect of the head.
- The etiology of clefting is multifactorial. Its prevalence varies among ethnic groups and within families. Syndromes are common, especially among patients with cleft palate.
- Surgical decisions should be based on careful analysis of the defects. The goals are restoring function (e.g., lip closure, nasal airway, normal speech, eustachian tube function, useful dental occlusion) and maximizing lip, nose, and midface symmetry.
- Numerous surgical (and medical) approaches have been developed, and different teams use various management strategies for patients with clefting.
- Patients with cleft lip or cleft palate are best managed using a multidisciplinary approach. A coordinated medical and surgical care plan provides optimal long-term outcomes. The patient's medical and surgical needs change over time.

Cleft lip and cleft palate are among the more common congenital deformities. Patients with these deformities often may have associated problems including otologic disease, speech and language problems (delayed onset, articulation disorders, velopharyngeal incompetence or insufficiency), dental deformities (e.g., malocclusion; missing, malformed, or supernumerary teeth), facial growth deficiencies, and psychosocial issues. Some children have associated genetic syndromes or chromosomal abnormalities.

This chapter discusses some of these problems and their treatment strategies for the child with cleft lip or palate, or both, with emphasis on the need for a well-coordinated multidisciplinary approach to management.

Classification of Cleft Lip and Palate

A variety of classification systems have been proposed, but few have found wide acceptance. The embryologic development of the lip and palate serves as the foundation for a number of cleft classification systems. Some useful terms and concepts for cleft classifications are described in this section.

The incisive foramen divides the palate into the primary palate and the secondary palate. The secondary palate develops after completion of development of the primary palate, and extends from the incisive foramen anteriorly to the uvula posteriorly. The primary palate, which has the incisive foramen as its posterior border, consists of the premaxilla, lip, nasal tip, and columella.[1]

Cleft lip is classified as unilateral or bilateral, and its extent may be classified as complete or incomplete. A complete cleft involves the entire vertical thickness of the upper lip, and is often associated with an alveolar cleft, because the embryologic origins of the lip and primary palate are the same (Fig. 186-1). An incomplete cleft lip involves only a portion of the vertical height of the lip, with a variable segment of continuity across the cleft region. The variable continuous segment may present as a simple muscular diastasis with intact overlying skin or as a wide cleft with only a thin band of skin crossing the region of the cleft (Fig. 186-2). *Simonart's band* is the bridge or bar of lip tissue, of variable size, that bridges the cleft gap. Simonart's band usually consists of skin only, although some histologic studies have shown some muscle fibers to lie within the band.[2] Unilateral clefts of the lip should include a designation of whether the right or the left side is involved.

Palatal clefts also are described as being unilateral or bilateral, and their extent may be classified as complete or incomplete. In addition, cleft palates are classified according to their location relative to the incisive foramen. Clefts of the primary palate occur anterior to the incisive foramen, and clefts of the secondary palate involve the segment posterior to the incisive foramen. A unilateral cleft of the secondary palate is defined by a cleft in which the palatal process of the maxilla on one side is fused with the nasal septum (Fig. 186-3). A bilateral complete cleft of the secondary palate has no point of fusion between the maxilla and the nasal septum (Fig. 186-4). A complete cleft of the entire palate involves both the primary and secondary palate, including one or both sides of the premaxilla/alveolar arch, and frequently involves a cleft lip. An isolated cleft palate usually involves the secondary palate only, and has varying degrees of severity. The least severe incomplete cleft is the submucous cleft palate (SMCP) in which the underlying palatal musculature is deficient and inappropriately attached. Associated features include a bifid uvula, a zona pellucida (bluish midline region representing the muscle deficiency), and a notch in the posterior hard palate[3] (Fig. 186-5). All three elements are not required for the diagnosis of SMCP, however.

Embryology

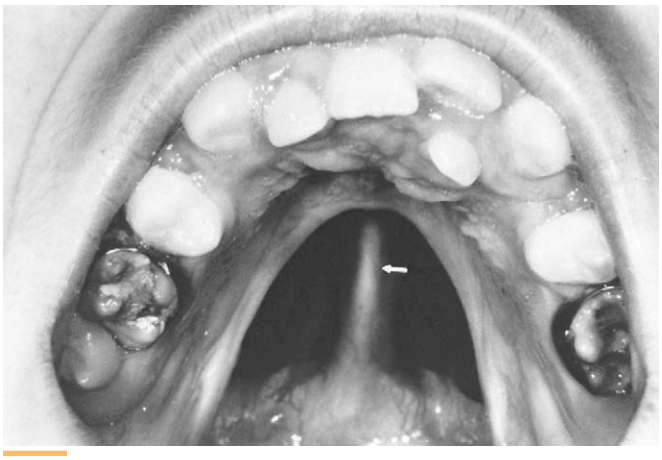

Figure 186-4. A patient with bilateral complete cleft palate. *Arrow* marks the nasal septum, which is not connected to either palatal shelf.

is essential. At the end of the fourth embryonic week, the neural crest–derived facial prominences appear from the first pair of pharyngeal arches. The maxillary prominences are found laterally (Fig. 186-6). The frontonasal prominences, formed by the proliferation of mesenchyme ventral to the forebrain, form the upper border of the stomodeum. On either side of the frontonasal prominences are local thickenings of surface ectoderm which form the nasal placodes.[1]

During the fifth week of embryonic development, the nasal placodes invaginate to form the nasal pits. This invagination process creates a ridge of tissue around the pit, called the lateral nasal prominences laterally, and the medial nasal prominences medially (Fig. 186-7).

Over the next 2 weeks, the paired maxillary prominences grow medially and approximate the paired medial nasal prominences (Fig. 186-8). Over time, fusion of the paired medial nasal prominences and paired maxillary prominences occurs, thereby forming the upper lip. The medial nasal prominences fuse to form the philtrum, medial upper lip, nasal tip, and columella. The maxillary prominences form the lateral aspects of the upper lip. The lateral nasal prominences are not involved in the formation of the upper lip, but form the nose (Fig. 186-9).[1,3]

The nose is formed from five facial prominences: The frontonasal prominence forms the bridge, the fused medial nasal prominences form the tip and columella, and the lateral nasal prominences form the nasal alae (Table 186-1).

Palatogenesis begins at the end of the fifth week, with complete fusion occurring by 12 weeks of development. As the maxillary prominences grow and push the medial nasal prominences medially, the medial nasal prominences fuse not only at the surface but also at deeper levels (Fig. 186-10). Thus, the intermaxillary segment, or primary palate, which includes the central maxillary alveolar arch that houses the four incisor teeth and the hard palate anterior to the incisive

foramen, is formed by the deeper levels of fusion of the two medial nasal prominences. Once the primary palate is completely developed, the secondary palate begins to develop.[1,3]

The secondary palate makes up the major portion of the palate. It is formed from the palatine shelves, which are two shelflike outgrowths of the maxillary prominences. In the sixth week of embryonic development, the palatine shelves are directed obliquely downward on either side of the tongue (Fig. 186-11). By the seventh week, the palatine shelves migrate inferomedially to lie horizontally above the tongue. It is in this horizontal position that the palatine shelves fuse in the midline to form the secondary palate (Fig. 186-12). The palatine shelves fuse with the previously formed primary palate anteriorly, and the nasal septum fuses with the newly formed secondary and primary palate. Palatal fusion occurs from anterior to posterior, beginning at the incisive foramen at 8 weeks of gestation and reaching completion by week 12 with uvular fusion (Fig. 186-13). The degree of clefting noted clinically is a consequence of the point in fetal development when the fusion process is interrupted.

Diagnosis

Prenatal Diagnosis

The advent of ultrasonography for use in prenatal care and improvements in imaging now permits antepartum diagnosis of cleft lip and palate[4,5] (Fig. 186-14). Routine prenatal ultrasonography is now the standard practice in most communities. More reliable prenatal diagnosis can be made of cleft lip than of cleft palate.[6] Diagnostic accuracy is improved if two-dimensional ultrasonography is combined with three-

Table 186-1

Structures Contributing to the Formation of the Face

Prominence	Structures Formed
Frontonasal*	Forehead; bridge of the nose, medial and lateral nasal prominences
Maxillary	Cheeks, lateral portion of the upper lip
Medial nasal	Philtrum of the upper lip, crest and tip of the nose
Lateral nasal	Alae of the nose
Mandibular	Lower lip

dimensional ultrasonography.[7] The diagnosis can be made as early as 18 weeks, although the accuracy improves with the age of the fetus.[8] It is estimated that 12% of these fetuses will have other anomalies.[5] The parents frequently will want additional information and often are referred to cleft teams for counseling. Most families find antenatal counseling helpful in planning for care of the child with an orofacial cleft.[9]

Molecular Genetics of Orofacial Clefts

Clefts of the lip and/or palate are influenced by both genetic and environmental factors. Monozygotic twins demonstrate a concordance rate of 40% to 60% for clefting. Failure to reach 100% concordance in monozygotic twins suggests that genetics alone does not determine orofacial clefts. Embryology and genetics suggest that clefts of the primary palate, those that involve the lip with or without the remaining palate (CLP), arise from a different mechanism from that operative with clefts involving the secondary palate only (CP).[10] Currently, approximately 70% of CLP patients are thought to be nonsyndromic, whereas 50% of CP patients are nonsyndromic.[11] Syndromic clefts may be the result of a single gene transmission as occurs in autosomal dominant, autosomal recessive, or X-linked heredity. Facial clefting is a possible association in more than 200 syndromes.[12] The most common syndrome associated with cleft lip is van der Woude syndrome. Lower lip pits and CLP are the characteristics features of this syndrome, although CLP and isolated CP can be seen in the same

family and lip pits are not found in 10%. Genetic studies indicate that the gene responsible for this autosomal dominant disorder is on chromosome 1.[13] A number of signaling molecules, transcription factors, and growth factors have been identified that are particularly important to the development of the lip and palate.[14] Mutations to the gene, delay in expression of the gene product, or exposure to an environmental factor affecting the gene or its product may result in a cleft.

Several teratogens have been implicated in cleft development. These include alcohol,[15] tobacco smoke,[16] phenytoin,[17] and retinoic acid.[18] Meta-analysis did not find maternal age to be a factor.[19] Multivitamin supplements lower risk for CLP and possibly isolated CP.[20] Whether preconceptual folic acid supplementation alone can reduce clefting is controversial.[21,22] Potential mechanisms of genetic, environmental, and biochemical interactions have been suggested and reviewed.[20,23] Human teratogen studies should be interpreted with caution due to the potential for confounding variables and recall bias.

Genetic linkage studies have suggested a number of potential loci for clefts,[24,25] though only loci on chromosome 6p have consistently demonstrated linkage to CLP.[26,27] Linkage studies are limited by small numbers of families available for study. Transgenic mouse models and mouse strains with spontaneous clefts have identified candidate genes that may also affect human clefting. Mice deficient in the *Msx1* gene, implicated in signaling between tissue layers during embryogenesis, all developed clefts of the secondary palate.[28] Another putative mediator of orofacial clefting is transforming growth factor beta-3 (TGF-β_3). Knockout of the TGF-β_3 gene in mice results in clefts, but the addition of TGF-β_3 to embryonic murine tissue culture stimulates palatal shelf adhesion.[29] Studies of South American children with CLP suggest and

interaction between *Msx1* and TGF-β_3 loci increasing cleft susceptibility.[30] Transforming growth factor alpha also is considered to be a factor modulating CLP in humans.[31]

Epidemiology

Cleft lip and palate deformities are thought to be the most common congenital anomalies of the head and neck. Cleft lip with or without cleft palate must be distinguished from isolated cleft palate deformities because of different embryologic, etiologic, and epidemiologic factors.[32] Cleft lip occurs in 1 in 1000 live births in the United States, whereas cleft palate deformity occurs in 1 in 2000 live births. Cleft lip deformities occur with the highest incidence among Native Americans (3.6 in 1000 births), Asians (2.1 in 1000), and whites (1 in 1000) and with the lowest incidence among blacks (0.41 in 1,000).[12] By contrast, the incidence of cleft palate does not differ among ethnic groups, being reported as 0.5 in 1000 live births. Cleft lip occurs more commonly in boys than in girls, whereas cleft palate occurs more commonly in girls than in boys. Fusion of the palatine shelves 1 week later in girls than in boys is thought to be responsible for the higher frequency of cleft palate in girls.[1]

Recurrent risk rates for cleft lip with or without cleft palate and for isolated cleft palate have been determined and may be useful in counseling parents about the risk of cleft in future pregnancies.[32] Two unaffected parents with one child affected with a cleft have a 4.4% chance of having another child with a cleft lip and palate and a 2.5% chance of having a child with isolated cleft palate. One parent affected with a cleft has a 3.2% chance of having a child with cleft lip and palate and a 6.8% chance of having a child with isolated cleft palate. Presence of a cleft in one parent and in one sibling is associated with a 15.8% chance that the next child will have a cleft lip or palate, and a 14.9% chance that the next child will have a cleft palate.[32]

Multidisciplinary Cleft Team

Comprehensive care of the child with cleft palate is best done within a team of health care professionals trained in the care of various disorders that accompany and develop as a result of the cleft lip or palate.[33-35] This approach recognizes that no single discipline possesses all of the expertise needed for proper management of the many problems of these patients. The cleft team also will focus on the needs of the patient and family. Standards have been recommended by the American Cleft Palate–Craniofacial Association.[36] Specialties that often make up a cleft care team are listed in Box 186-1. Members should meet face to face to discuss patient care at least six times a year. Continuing education for the care of patients with cleft deformities should be an integral part of membership in a cleft team.

Team care begins when an infant is identified as having a cleft. The nursing staff or the pediatrician, within the context of a cleft care team approach, monitor feeding, growth, and development of the child. Parents are provided counseling, genetic information as needed, and verbal and written instructions regarding care plans. Most teams develop protocols for the management of children with cleft lip and palate deformities. These algorithms for care are based on the experience of the team members and assign care for anticipated needs of the child. A sample management protocol is outlined in Table 186-2. The otolaryngologist carries the roles of airway management, otologic care, and evaluation of velopharyngeal insufficiency and, in some teams, serves as the facial reconstructive surgeon.

Box 186-1

Specialty Members of a Cleft Care Team

Reconstructive surgeon
Otolaryngologist
Plastic surgeon
Oral maxillofacial surgeon
Speech-language pathologist
Orthodontist
Pediatric or prosthodontic dentist
Developmental or general pediatrician
Genetics counselor
Audiologist
Nurse
Social worker
Psychologist

Nursing Care

Special problems that are encountered in nursing care of the patient with a cleft deformity include initial feeding, postoperative airway and feeding management, and family care issues centered on frequent medical and surgical needs. Nurses often provide an additional and, for some parents, more secure source of information regarding treatment

Table 186-2

Example Protocol for Multidisciplinary Approach to Care of Patients with Cleft Lip and Palate

Age Range	Intervention
Prenatal	Refer to Cleft Palate Team Medical diagnosis Genetic counseling Address psychosocial issues
Neonatal (0-1 month)	Same as above Provide feeding instructions Monitor growth Hearing screening
1-4 months	Monitor feeding and growth Repair cleft lip Monitor ears and hearing
5-15 months	Monitor feeding, growth, and development Repair cleft palate Monitor ears and hearing; consider ear tubes Instructions in oral hygiene
16-24 months	Assess speech and language development Monitor ears and hearing; ear tubes if indicated Monitor development
2-5 years	Monitor speech and language development; manage velopharyngeal insufficiency Monitor ears and hearing; ear tubes if indicated Assess development and psychosocial needs Consider lip/nose revision before child reaches school age
6-11 years	Monitor speech and language; manage velopharyngeal insufficiency Orthodontic evaluation and treatment Alveolar bone graft Monitor school and psychosocial needs
12-21 years	Monitor school and psychosocial needs Orthodontics and restorative dentistry Genetic counseling Rhinoplasty (if needed) Orthognathic surgery (if needed)

Figure 186-16. Mead-Johnson feeder.

plans. Parents may feel more comfortable revealing their concerns or frustrations related to their child to nursing staff. The participation of dedicated and skilled nurses is valuable within the cleft care team.

Infants with a cleft palate are limited in their ability to suck. The common cavity between the nose and the mouth permits air to leak as the infant tries to suck. Cleft lip alone usually does not cause feeding problems. Accordingly, a number of strategies have been devised and different feeders have been created for feeding the infant with a cleft palate. Generally, breast feeding is ineffective. Alternately, expressed (pumped) breast milk can be delivered using one of the specialized feeders. The three most commonly used cleft palate feeders are the Mead-Johnson, Haberman, and Pigeon bottles (Figs. 186-15 to 186-17). Each allows for parent-controlled delivery of the meal (expressed breast milk or formula). Parents and caregivers need to be taught how to properly use the feeder and observed for the first feed to insure proper use of the feeder.[37,38] Trial and error may be needed to discover the best technique and feeder for the infant. Children with cleft palate generally swallow much more air during feeds. Frequent burping often is necessary; this should be explained to parents. Attention should be paid to the child's growth. Following weight and length gains using standardized growth charts is very useful to ensure that the infant stays on the appropriate growth curves.

Nurses can help families find the best position and technique for feeding after surgery. Oral and facial wounds affect placement of a feeding nipple. Often, the same cleft feeder can be used as before surgery, although the feeding technique may need to be modified owing to pain and swelling. Wound care also can be taught by nursing staff. Fresh lip wounds should be kept clean (with soap and water) and moist with ointments. Often, padded elbow restraints that prevent flexion of the elbow but permit other arm and hand motion are placed after surgery. Children are discouraged from placing fingers or other things into the mouth that may potentially disrupt the suture line. Restraints also may be used after palatoplasty. The restraints are left on until the intraoral wounds have epithelialized. Close monitoring by nursing staff will facilitate return to normal activities after surgery.

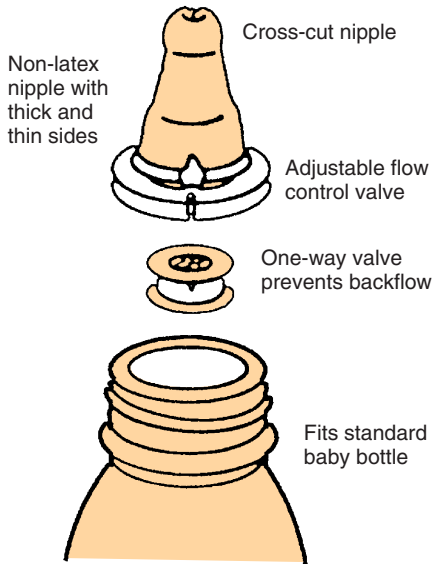

Figure 186-17. Pigeon feeder.

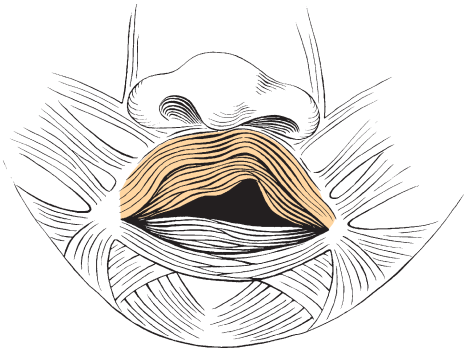

Figure 186-18. Muscle abnormality in an incomplete cleft lip that involves less than two thirds of the lip. Lower muscle fibers insert into tissue at the cleft margins; upper muscle fibers in the medial and lateral segment connect over the top of the incomplete cleft, forming a partial oral sphincter.

Anatomy

Anatomy of the Cleft Lip Deformity

The normal upper lip is divided into red and white components. The red lip is a mucous membrane, whereas the white lip is a cutaneous structure. The mucocutaneous junction at the vermilion border between the red and white lips is an important anatomic boundary that must be reconstructed meticulously in cleft lip repair for a natural-looking result. Failure to do so will draw attention to the irregularity at the vermilion border and create a poor cosmetic result.[3,39,]

In unaffected persons, the orbicularis oris muscle forms a complete sphincter around the oral cavity, providing the substrate for proper form and function of the lips and mouth. All patients with cleft lip deformities have muscular deficiencies and irregularities of varying degrees, leading to the abnormal appearance and function of the lip and mouth (Figs. 186-18 and 186-19). For proper correction of cleft lip deformities, it is essential not only to create symmetry of the lip superficially, at the skin level, but also to re-create the complete orbicularis muscular sling, for long-lasting cosmetic and functional results, and to re-establish complete mucosal coverage to ensure optimal healing and prevent distorting wound contracture. The muscle fibers in cleft lip deformities run in an inferior-to-superior direction along the margins of the cleft. They insert into the columella medially and along the nasal ala laterally. These fibers must be detached from their

Figure 186-19. Abnormal direction and insertion of muscle fibers of medial and lateral segments of the cleft into the cleft margin, the area of the ala nasi (laterally), and the base of the columella (medially). *Dark line* indicates arterial supply.

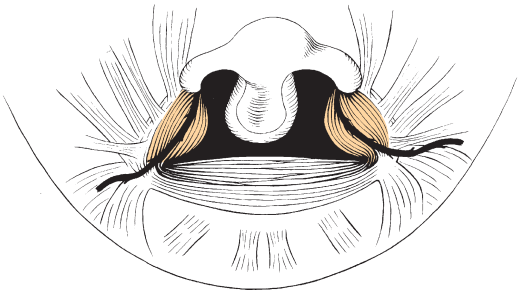

Figure 186-20. Abnormal muscle anatomy of a complete bilateral cleft. Both lateral muscle segments insert into the alae nasi, with the prolabium completely devoid of muscle tissue. Arterial supply is indicated by a *dark line*.

insertions and reoriented in a horizontal direction to bridge the cleft and create a complete muscular sling around the entire circumference of the oral cavity.[3,39]

Bilateral clefts also have abnormally oriented muscle fibers that run along the edges of the lateral aspect of the cleft (Fig. 186-20). Typically, the prolabial segment does not contain any useful muscle but is filled with connective tissue. In addition to the muscle and cutaneous irregularities, patients with bilateral cleft deformities have premaxillary and alveolar protrusion relative to the nasal septum. The premaxillary bony deformity may push the lip so far anteriorly and superiorly toward the nasal tip that the columella is severely diminished in strength and height and may even be obliterated completely (Fig. 186-21). There is often inadequate length to the medial crura; consequently, there is inadequate columellar skin. One of the major challenges in bilateral cleft repair is columellar reconstruction.[3,39]

The anatomic characteristics of the unilateral cleft lip nasal deformity include irregularities of the tip, columella, nostril, alar base, septum, and skeleton[40] (Fig. 186-22). The nasal tip is deflected toward the noncleft side, with a relatively short medial crus and long lateral crus on the cleft side. In addition, the lateral crus of the lower lateral cartilage is caudally displaced on the cleft side. The columella is shorter than normal on the cleft side, and the columella lies on the non-cleft side due to the unopposed action of the intact orbicularis oris muscle. The nostril on the cleft side is horizontally oriented rather than the normal vertical orientation.[17] Similarly, the nasal septum is deflected to the noncleft side. The alar base on the side of the cleft is displaced laterally, inferiorly, and posteriorly. Finally, there is a deficiency of maxillary bone on the cleft side, with the nasal floor often being absent.

The bilateral cleft lip nasal deformity differs from the unilateral deformity in several aspects other than laterality. The degree of nasal deformity relates to the severity of the cleft lip deformity—whether the cleft lip is complete or incomplete. It also is affected by the degree of

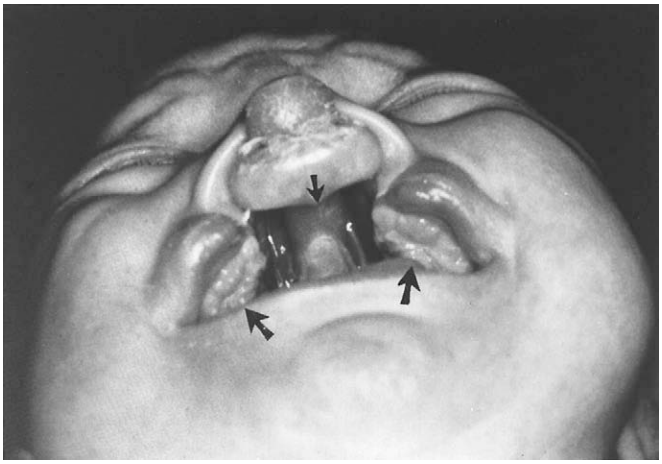

Figure 186-21. A patient with complete bilateral cleft lip and palate: *Top arrow*, protruding premaxilla; *bottom arrows*, collapse of alveolar arches.

Figure 186-22. Classic nasal deformity associated with the unilateral cleft lip.

premaxillary protrusion. Bilateral cleft lip nasal deformities are symmetrical, making the repair of the nose somewhat simpler with regard to gaining tip symmetry. The challenging aspect of the bilateral cleft lip nasal deformity is the lack of adequate columellar tissue. This lack of tissue includes deficiencies in the length of the lower lateral cartilages, as well as deficiency of skin overlying these shortened cartilages. The tip usually is broad and flat, and the alae are laterally displaced, with resultant horizontally oriented nostrils.[40]

Cleft Palate Deformity

Various degrees of deformity involving all tissue layers are seen in cleft palate. With soft palate cleft, deficiencies of the muscle and mucosal layers also are characteristic.

Five muscle pairs contribute to the soft palate. Normally, the levator veli palatini muscle has a transverse orientation, occupying the midportion of the soft palate, thereby creating a muscular sling for the velum.[41] This muscular sling is the principal structural component in closure of the nasopharynx during speech and swallowing. Other muscles that contribute to the velopharyngeal sphincter include the palatopharyngeus, superior constrictor, and musculus uvulae. The musculus uvulae runs beneath the nasopharyngeal musculus and extends from the tensor aponeurosis to the base of the uvula.[42] During speech, its contraction increases the midline bulk of the posterior edge of the soft palate. Deficiency of the musculus uvulae like that seen in

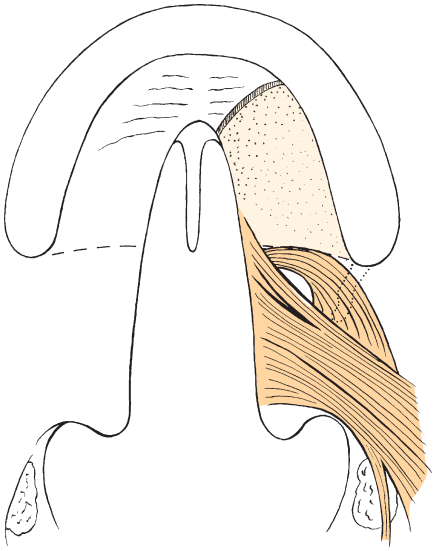

Figure 186-23. Abnormal muscle insertion into the posterior margin of the hard palate in a patient with clefting. Muscles are directed along the margins of the cleft, rather than across the soft palate as occurs normally.

submucous cleft palate may lead to velopharyngeal insufficiency and speech disorders (see Chapter 187, Velopharyngeal Dysfunction). The tensor veli palatini (TVP) muscle runs from its origins at the skull base and eustachian tube, wraps around the hamulus, and inserts into the posterior edge of the hard palate and forms an aponeurosis in the anterior midline of the soft palate.[43] Its functions are dilation of the eustachian tube and support for the soft palate during contraction.

In patients with cleft palate, the muscles of the soft palate may be hypoplastic,[44] in addition to exhibiting misdirection and abnormal insertions into the posterior hard palate (Fig. 186-23). Mucosa that envelops these muscles is deficient, except in the case of a submucous cleft palate. If the cleft involves the hard palate, then a midline bony deficiency of variable degree will extend toward the incisive foramen. The vomer usually is unattached in isolated cleft palate but may or may not be attached if there is a cleft lip. Abnormal muscle insertions combined with tissue absence or hypoplasia lead to palatal dysfunction. Palatoplasty aims to restore function by reorienting the muscles and reconstructing the continuity of the tissues.

Cleft Lip Repair and Cleft Rhinoplasty

The timing of cleft lip repair varies among surgeons. Some have suggested that lip repair be performed within 48 hours of the child's birth to prevent a separate hospitalization and to allow the parents to leave the hospital with a healthy-appearing newborn. Others prefer to delay surgery to allow for more tissue availability for the repair, more time for parent-child bonding, and more time for the parents to gain a better understanding and acceptance of the infant's congenital deformity. Commonly, the "rule of 10s" is applied, which suggests that surgery proceed when the infant is at least 10 weeks old, weighs 10 pounds, and has a hemoglobin level of 10 g/dL. We typically perform cleft repair during the child's second to third month of life, to gain the advantages just described.

Definitive Unilateral Lip Repair

Probably the most common technique for cleft lip repair is the Millard technique. Other techniques have been described, but this chapter focuses on only the Millard technique. The Millard rotation advancement closure for unilateral cleft lip repair entails the downward and lateral rotation of the medial segment of the cleft lip combined with the medial advancement of the lateral cleft segment into the defect. All cleft lips have a discrepancy between the vertical height of the lip from the Cupid's bow peak to the columellar base on the cleft and noncleft sides of the lip (philtral ridge height). The design and length of the rotation flap and the degree of back-cut required will depend on the difference in vertical height between the two sides. Advancement of tissue from the lateral segment of the cleft medially not only closes the tissue defect to bridge the gap but also serves to maintain the rotation flap in position and thus to maintain the amount of vertical height gained by the rotation flap and back-cut.[3,44]

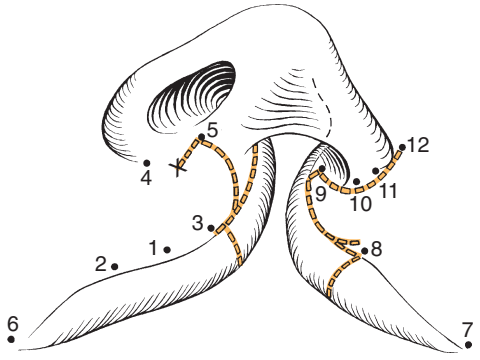

Figure 186-24. Rotation advancement technique: landmarks and incisions. See text for details.

The procedure begins with the skin markings, as shown in Figure 186-24. Skin markings are made with a 30-gauge needle and methylene blue dye. Extreme care should be paid to the measurements and placement of the skin markings, because these serve as the foundation for the surgical repair and provide stable anatomic landmarks in a changing surgical field.[31] The first marking, labeled 1 on the figure, is a point made at the mucocutaneous junction at the exact low point of Cupid's bow, which marks the central point of the upper lip. A second point (2) is placed at the height of Cupid's bow on the noncleft side of the upper lip. The distance between points 1 and 2 is measured—it normally is between 2 and 4 mm—and is used to establish the location of point 3, which represents the height of Cupid's bow on the cleft side of the upper lip. Thus, the distance from point 1 to point 2 is equal to the distance from point 1 to point 3. Point 4 marks the alar base on the noncleft side, and point 5 marks the columellar base on the noncleft side. Point 5 represents the superiormost extent of the vertical portion of the rotation flap, as discussed further later on. Point x, the back-cut point, is made at a variable distance from point 5 and is determined by estimating the amount of tissue needed to create symmetrical philtral ridges and to make up for the discrepancy in vertical height of the lip at the philtral ridge. Point x should never cross the philtral ridge on the noncleft side but should lie medial to it, so that the back-cut of the rotation flap runs parallel and medial to the normal philtral ridge on the noncleft side. This helps to maintain a scar-free philtral ridge on the noncleft side and improves the ultimate cosmetic result of cleft lip repair.

Point 6 marks the noncleft oral commissure, and point 7 marks the oral commissure on the cleft side. Point 8 marks the peak of Cupid's bow on the cleft side. It is placed at a distance from the commissure on the cleft side (distance from points 7 to 8) equal to that for the point placed at the peak of Cupid's bow on the noncleft side relative to the commissure on the noncleft side (distance from points 2 to 6). Point 9 is the medialmost point of the advancement flap and is placed at a distance from point 8 that is equivalent to the distance between point 3 and point 5 + x. Thus, the philtral ridge is formed by the union of the cleft edge on the side of the advancement flap (line 8-9) and the cut edges of the rotation flap on the non-cleft side (line 3-x). Point 10 is the cleft side alar base, point 11 is along the alar-facial crease, and point 12 is placed at the estimated lateralmost aspect of the advancement flap.

Surgical Technique—Rotation Flap

The normal philtral ridge height is 10 mm, and the rotation flap is designed to create a 10-mm-long segment for use in establishing philtral ridge symmetry. The rotation incision starts at point 3 and extends toward point 5, following a gentle curve and providing 4 to 5 mm of

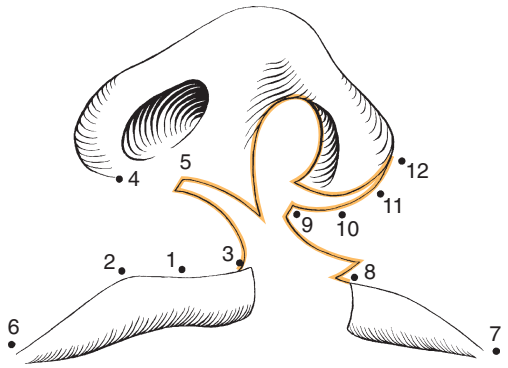

Figure 186-25. Rotation advancement technique: flaps incised and elevated. See text for details.

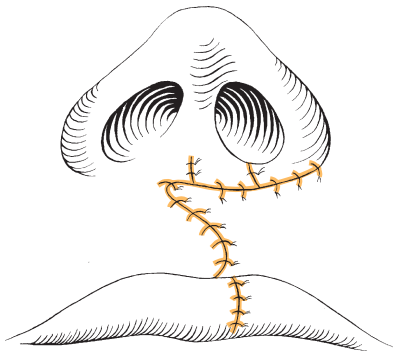

Figure 186-26. Rotation advancement technique: final suturing.

length toward the goal of 10 mm (Fig. 186-25). At the columellar base, the rotation flap incision follows a gentle curve and hugs the base of the columella, passing through point 5. This curve along the base of the columella adds an additional 3 mm of length toward the 10-mm goal. The final discrepancy in vertical height is compensated for with a back-cut to point x, using a stab incision with the No. 11 blade. The extension to the back-cut adds 2 to 3 mm of additional height that will be used to create philtral ridge symmetry. The back-cut is made at a 90-degree angle to the curved incision at the columellar base, to run parallel to rather than crossing the uninvolved philtral ridge. The rotation incisions are carried through the entire thickness of the orbicularis muscle and oral mucosa, to allow a complete release of the medial aspect of the cleft. Undermining along the edges of the rotation flap incision is continued for 1 to 2 mm on the cutaneous and mucosal surfaces, to permit eversion of the wound edges during skin closure.[32]

After completion of the rotation flap cuts, a "c" flap remains, which is a segment of skin that ran between the cut edge of the rotation flap and the edge of the cleft. The "c" flap may be used to add tissue length to the columella, which typically has a tissue deficiency.

Surgical Technique—Advancement Flap

The advancement flap starts with an incision from point 8 to point 9, creating the lateral edge of the new philtral ridge, which will be sutured to the edge of the previously created rotation flap (see Fig. 186-25). Thus, the length of line 8-9 is equal to the length of line 3-x. Release of the advancement flap is then achieved by continuing the incision horizontally along the alar base. Similarly, release of the gingivobuccal sulcus mucosa is performed with sharp dissection, to permit greater mobility. All incisions are carried down to the face of the maxilla, and blunt dissection along the face of the maxilla with scissors is performed, allowing the lateral lip segment freedom of mobility with minimal tension on the closure. Undermining the cutaneous and mucosal surfaces will allow eversion on wound closure.[3,32,45]

Closure—Rotation Advancement Flap

Once the rotation and advancement flaps are developed, approximation of the flaps is achieved with the help of skin hooks, followed by suturing of the flaps to one another to complete the lip reconstruction (Fig. 186-26). Four-0 Vicryl suture is used for all deep muscle stitches and oral mucosal stitches, and 6-0 fast-absorbing gut is used for the skin closure. The first key stitch attaches the muscle at the tip of the advancement flap to the muscle at the rotation flap back-cut point x. The next throw attaches the muscle layers of the advancement and rotation flaps at the level of the vermilion border. It is essential to align this stitch precisely in order to give a natural-appearing vermilion. Additional 4-0 Vicryl stitches are then used to reinforce the muscle layer of closure along the length of the philtral ridge. The mucosa is closed with 4-0 Vicryl suture placed in simple interrupted fashion. Skin closure is achieved with simple interrupted stitches of 6-0 fast-absorbing gut suture. The skin at the vermilion is closed with great precision to provide optimal cosmesis.[3,45]

Primary Rhinoplasty

The cleft lip deformity is always associated with nasal abnormalities. The extent of the nasal abnormality is related to the severity of the cleft lip. Nasal deformities associated with incomplete cleft lips are less severe than those associated with complete lip clefts. The goals of primary rhinoplasty include closure of the nasal floor, repositioning the lower lateral cartilages, and repositioning the alar base. These goals may be achieved through the same incisions that are used for the cleft lip repair, so that no additional incisions are required if the nasal deformity is addressed at the time of cleft lip repair.[40,46] Once the lip incisions are made, the muscle and soft tissue attachments of the ala are separated from the maxilla. Subsequently, through the same incisions, the lower lateral cartilages are freed from the overlying nasal skin along the entire nasal tip. Suturing of the lateral crura to the septum or to the ipsilateral dome helps to reposition the crura and alar base medially, increases tip projection, and creates greater symmetry between the two sides. Although secondary rhinoplasty frequently is still needed, the patient achieves greater social acceptance in the formative years when primary rhinoplasty is performed.

Bilateral Cleft Lip Deformities

The primary difference between the unilateral and bilateral cleft deformities lies in the position and characteristics of the premaxilla and prolabium. The lateral segments of the bilateral cleft lip deformity are similar to the lateral segments of the unilateral deformity. The difference lies in the medial segment of the cleft, the premaxilla. In bilateral deformities, the premaxilla is either partially or completely detached from both maxillae. The premaxilla and prolabium protrude anteriorly and superiorly and generally are unrelated to the maxilla itself. The columella is most often shorter than normal. Moreover, it may not be evident on surface inspection, though medial crura of the lower lateral cartilages are present. The prolabial soft tissue, though relatively scarce, should be used to form the full vertical length of the lip. The prolabial vermilion is used for the intraoral lining. The central vermilion is built up with vermilion-muscle flaps created from the lateral lip segments, and the vermilion ridge comes from the lateral lip segments. It may be helpful to use preoperative orthodontics to rotate the premaxillary segment posteriorly and rotate the lateral maxillary segments medially in order to increase the soft tissue available for closure and reduce the tension on the repair.[47] The repair we prefer for bilateral clefts is the single stage approach described by Millard, in which the orbicularis is advanced across the cleft, and straight vertical closure lines along the skin lie in the newly created philtral ridges[48] (Fig. 186-27A to F).

Cleft Palate Repair

All palatoplasty techniques share the same goals. These include separation of the nasal cavity from the oral cavity, creation of a competent velopharyngeal valve for both swallowing and speech, preservation of midface growth, and development of functional occlusion.

Controversy surrounds timing of cleft palate repair. Improved speech outcomes are seen when the soft palate is repaired early. Dorf and Curtin[49] demonstrated a 10% occurrence of articulation errors when palatoplasty was completed by 1 year and an 86% incidence of

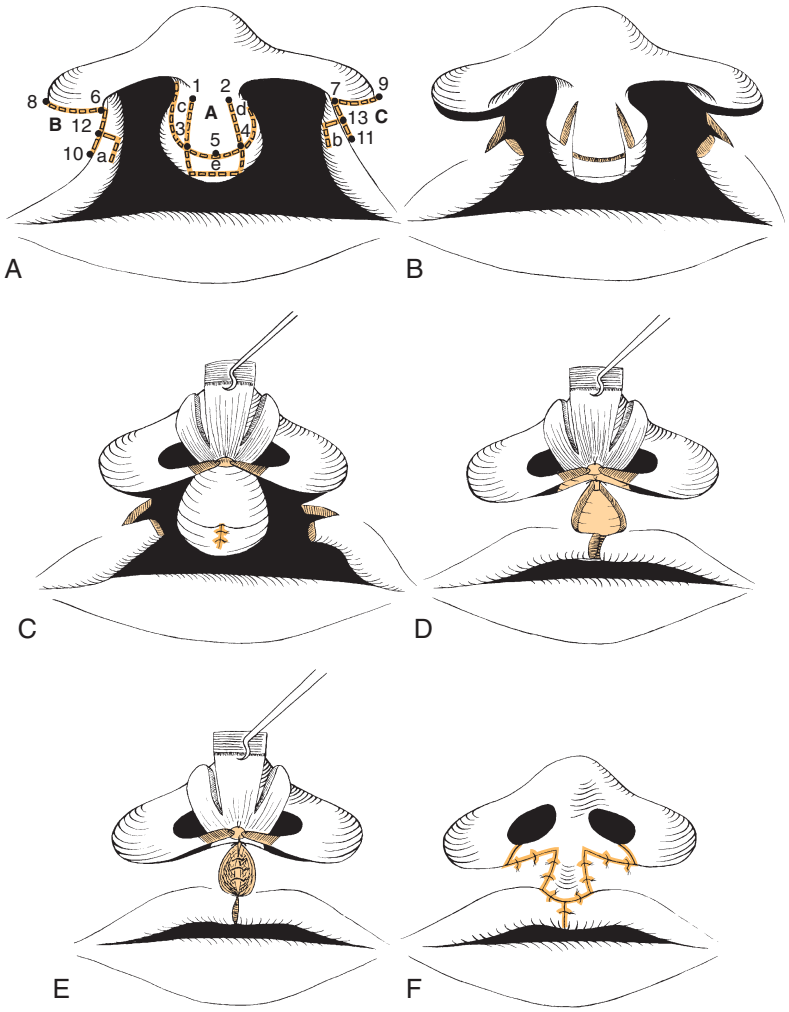

Figure 186-27. **A**, Bilateral cleft lip repair: landmarks and incisions. Prolabium provides philtral flap, A; forked flaps, c and d; and tubercle-reinforcing flap, e. Lateral lip provides flaps B and C and midline vermilion flaps a (within B) and b (within C). **B**, Bilateral cleft lip repair: flaps incised and elevated. **C**, Tips of the ala nasi de-epithelialized and sutured medially at the base of the prolabium. Excess prolabial mucosa provided the medial lining of the labial sulcus. **D**, Tips of the flaps sutured medially beneath the prolabium. **E**, Bilateral cleft lip repair: orbiuclaris oris muscle and mucosal approximation. **F**, Placement of forked flaps in the nasal sill and final suturing. Flap e (see **A**) may be used to reinforce the tubercle from behind.

articulation errors when repair was completed after 1 year. Similar results were found comparing early and late palatoplasty in isolated cleft palate. Haapanen and Rantala[50] compared three groups of children whose palatoplasty was done at mean ages of 12.9 months, 18.5 months, and 22.1 months. Significantly fewer children in the groups undergoing repair before 18 months had hypernasal speech or articulation errors or required secondary surgery to correct speech. Most surgeons and speech pathologists believe that soft palate repair should be done before the age of 12 months in order to minimize speech disorders.

Palate surgery during childhood may adversely affect facial growth. Case studies of adults with unrepaired clefts demonstrate normal midface development.[51,52] Animal studies suggest that disruption of the hard palate mucoperiosteum inhibits maxillary growth.[53] To preserve growth potential, some centers prefer a staged approach: early repair of the soft palate, obturation of the hard palate, then later surgical closure of the hard palate.[54,55] However, others have not found significant difference in maxillary development between patients who have single-stage palatoplasty versus two-stage repair.[56,57] Other factors that need to be considered are the type and severity of clefting. It appears that inherent growth deficiencies are associated with different cleft types.[58] More severe tissue deficiencies at birth in unilateral cleft lip and palate patients predict more growth retardation after cleft repair.[59] Given that this controversy over timing and staging of cleft palate repair has continued for several decades, prospective, multicenter clinical trials will be required to resolve many of the issues.

Palatoplasty Techniques

Preparation for palatoplasty requires analysis of abnormal anatomy. Knowledge of different techniques in palate repair will allow for an individualized surgical approach. The basic surgical techniques include primary veloplasty (Schweckendiek palatoplasty), bipedicled flap palatoplasty (von Langenbeck), V-Y pushback palatoplasty, unipedicled two-flap palatoplasty, and the double-opposing Z-plasty (Furlow) palatoplasty. Although credit is given to the original description of a palatoplasty technique by creating an eponym, it is important for the cleft surgeon to document the details of the technique used. Over time, many modifications have been advanced for each procedure. Important considerations for each technique are closure with minimal tension, layered closure, and reconstruction of the levator sling. The two most common techniques for palate closure are outlined next.

Two-Flap Palatoplasty

The two-flap palatoplasty is a commonly used technique for cleft palate repair and involves incisions that extend to the alveolar portion of the cleft or to the incisive foramen (Fig. 186-28). The nasal cavity can be

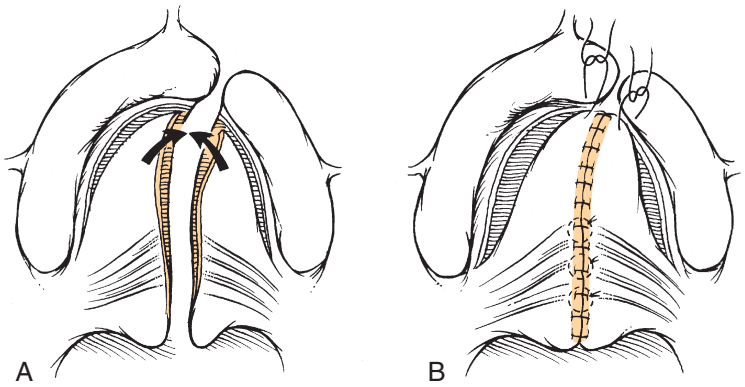

Figure 186-28. Two-flap palatoplasty. **A**, Incisions used to create unipedicled palate flaps. *Arrows* demonstrate rotation of bilateral flaps. **B**, The levator sling is reconstructed and closure is complete. In many cases, the hard palate mucoperiosteum can be reapproximated to the medial edge of the gingival incisions. This can minimize exposure of palate bone, which is believed to inhibit maxillary growth.

reconstructed by elevating vomer flaps, thereby creating four flaps used for reconstruction (not shown in Fig. 186-28). Vomer flaps are rotated laterally to unite with the mucosa at the medial edge of the nasal floor. The mucoperiosteal flaps are then rotated medially to close the cleft. The alveolar cleft is not closed using this method, nor is the palate lengthened unless a double-opposing Z-plasty (described next) is used to reconstruct the soft palate. This latter technique often is used for repair of complete primary and secondary cleft palate.

Furlow Palatoplasty (Double-Opposing Z-plasty)

The double-opposing Z-plasty palatoplasty was first described by Furlow in 1986.[60] This technique lengthens the soft palate and reconstructs the muscle sling. The two flaps containing muscle are rotated posteriorly and the two mucosa-only flaps are transposed anteriorly. It is more difficult to perform, especially in wide clefts. It can be combined with a unipedicled closure of the hard palate.[61] It also is commonly used to correct velopharyngeal insufficiency in patients with submucous cleft palate.[62] Speech outcomes are improved compared with those achieved with other palatoplasty techniques.[63,64]

Surgical Technique

Basic Principles

The patient should not have any active medical problems (other than otitis media). A family history of bleeding warrants an evaluation for a coagulopathy. Plans for airway management, especially for patients with Robin sequence, should be discussed with the anesthesiologist. A reinforced oral endotracheal tube should be used, to minimize kinking and ventilation problems while the mouth gag is in place. Most surgeons prefer the Dingman mouth gag for exposure of the oral cavity and pharynx. This mouth gag can exert significant pressure on the tongue.[65] If the mouth gag is then suspended from a Mayo stand, the exerted pressure may exceed arterial perfusion pressure to the tongue. Postoperative tongue edema risks airway obstruction and prolonged intubation. To minimize this risk, periodic release of the mouth gag during palatoplasty is recommended. Perioperative steroids (dexamethasone sodium phosphate 0.25 mg/kg) lower postoperative airway distress[66] and can reduce length of hospitalization[67] after primary palatoplasty. Perioperative antibiotics also may reduce the risk of infection. Injection of a topical anesthetic containing epinephrine into the planned incision and dissection sites and, if possible, into the greater palatine foramen helps reduce intraoperative blood loss.

Two-Flap Palatoplasty

Once general anesthesia has been achieved and the patient is in a supine position, the margins of the cleft at the junction of the nasal and oral epithelium are identified. The margins are incised sharply with a scalpel, separating the mucosa. Lateral releasing incisions are made medial to the alveolus and down to bone, and care is taken to avoid injury to the tooth buds and the neurovascular pedicle at the greater palatine foramen. This lateral incision is carried posteriorly just into the retromolar area and through mucosa only at this point (Fig. 186-29).

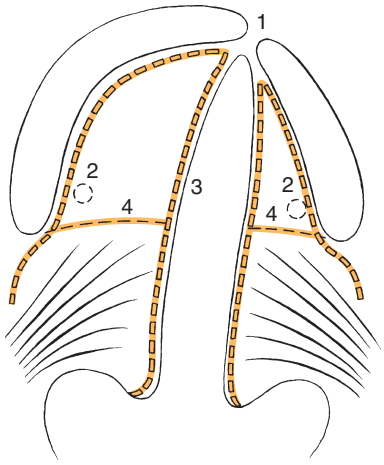

Figure 186-29. Two-flap palatoplasty. Landmarks are as follows: 1, alveolar cleft; 2, neurovascular bundle at the greater palatine foramen; 3, vomer; 4, posterior edge of hard palate. Incisions are indicated by the *dotted lines*.

Dissection begins with the separation of the soft palate muscle from the nasal mucosa. At least 3 mm of mucosa is elevated sharply. To perform an intervelar veloplasty, the muscle should be freed from most of its nasal mucosa attachments laterally. This dissection is technically difficult, because the muscles adhere tightly to the nasal mucosa. In similar fashion, the oral mucosa is elevated from the soft palate muscles.

Next, the mucoperiosteum of the hard palate is elevated using a periosteal elevator. Anteriorly, this dissection is easy, but caution is taken posteriorly near the greater palatine foramen. Once the neurovascular bundle is identified, the surrounding fibrous attachments are carefully dissected from the bone. This maneuver will provide additional medial displacement of the flaps and minimize tension during repair. On the cleft side, the medial edge of the mucoperiosteal flap is released from the nasal mucosa. On the noncleft side, the mucoperiosteum is elevated from the vomer. Continuity is maintained between the vomerine mucoperiosteum and the nasal mucosa of the soft palate on this side. The soft palate muscles are then released from their abnormal attachments at the posterior edge of the hard palate (Fig. 186-30).

Rotating the flaps medially with forceps tests mobility of the flaps. If additional mobility is needed, then several other maneuvers can be used. A back-cut at the posterior edge of the vomer will allow easier closure of the nasal cavity. Extension of the relaxing incision posteriorly

combined with blunt dissection between the pterygoid process and the superior constrictor muscle (space of Ernst) will further mobilize the anterior soft palate region. Wide clefts may require medial fracture of the hamulus, thereby releasing tension on the TVP, although concern about the potential adverse effect on eustachian tube function has been raised.[42]

Repair of the palate is done in three layers. Absorbable suture is used throughout. The nasal surface is closed with 4-0 or 5-0 suture. Tension usually is greatest at the junction of the hard and soft palate. In patients with wide clefts, primary closure of the nasal surface at this junction may not be possible. Clark and associates[68] report using acellular dermal grafts (LifeCell, Branchburg, New Jersey) placed between the nasal and oral surfaces to provide a biologic surface for healing by secondary intention. Several buried sutures placed using a horizontal mattress technique are used to repair the soft palate muscles and to reconstruct the levator sling (Fig. 186-31). The oral surface is closed first along the cleft edge. Mattress sutures help evert the edge of the mucoperiosteum. Simple sutures are used to close the oral mucosa. Laterally, closure is completed by reapproximating the mucoperiosteum to the medial alveolus; only sutures that do not increase tension along the cleft edge should be used (Fig. 186-32). If there is exposed bone or tissue (for example, the stippled area in Fig. 186-32), usually in the region of the hamulus and posterior hard palate, then microfibrillar collagen (Avitene; Bard, Salt Lake City, Utah) is packed into the open wounds to optimize hemostasis.

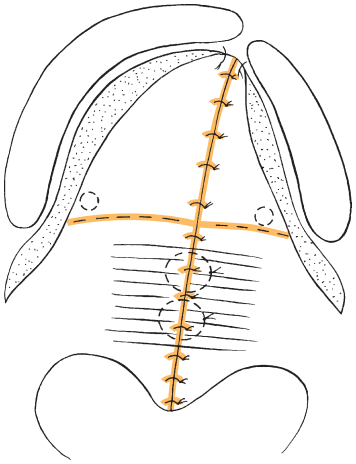

Figure 186-32. Two-flap palatoplasty: oral layer closed.

Double-Opposing Z-plasty Palatoplasty (Furlow Palatoplasty)

The double-opposing Z-plasty palatoplasty (Furlow palatoplasty) applies specifically to the repair of the soft palate and reconstruction of a levator sling. If the patient has a cleft involving the hard palate, closure of the hard palate is the same as for a two-flap palatoplasty. It is recommended that the soft palate dissection be completed before the incisions and elevation of flaps that are performed on the hard palate. By keeping the hard palate tissues intact, tension is provided to enable easier dissection of the soft palate needed for the Furlow palatoplasty. Elevation of the muscles from the nasal mucosa is technically challenging and is easier if the instruments are handled using a "forehand" grip and movements. For a right-handed surgeon, this means dissecting the muscles from the left aspect of the soft palate. Handedness then determines the types of flaps created elsewhere in the soft palate. A left-handed surgeon would perform the double-opposing Z-plasty in a mirror image of what is described next.

Incisions are first made sharply along the left cleft margin separating the oral and nasal mucosa. (If a double-opposing Z-plasty palatoplasty is being performed for repair of a submucous cleft palate, the midline incision should go only through the oral mucosa and leave the nasal mucosa intact until later.) A second incision is made from the apex of the cleft or 3 mm posterior to the junction of the hard and soft palate to just posterior to the hamulus. This incision parallels the posterior margin of the hard palate. It is important to leave at least 2 mm of mucosa posterior to the bony margin. Care must be taken not to tear or cut through the nasal surface. Dissection proceeds to the lateral pharyngeal wall from just superior to the tonsillar fossa to beneath the hamulus. The levator veli palatini muscle is released from the posterior edge of the hard palate using electrocautery (Fig. 186-33).

An anteriorly based oral mucosa flap is then created on the right soft palate. Incisions are made along the cleft margin and from the base of the uvula to just posterior to the hamulus. The mucosa and submucosa, a fatty layer that contains several unnamed feeder vessels, are elevated sharply from the muscle layer. This dissection plane is indistinct. By maintaining tension between the mucosa and muscle, thin muscle fibers are identified at the inferior edge of the muscle bundle. The oral mucosa flap is elevated to the posterior edge of the hard palate and over the hamulus (Fig. 186-34).

The right soft palate muscle is released from the posterior edge of the hard palate. Care must be taken to maintain at least 3 mm of nasal mucosa posterior to the edge of the hard palate. If this incision is too close to the bony edge, then suture closure becomes quite difficult once the left mucosa flap is transposed. The fourth flap is created from the left nasal mucosa. Scissors are used to incise from the base of the uvula to beneath the hamulus (Fig. 186-35). If a hard palate cleft repair is needed, the mucoperiosteal flaps are raised after creating the four flaps from the soft palate.

These four flaps are transposed so that the mucosa-only flaps are rotated anteriorly and the muscle-containing flaps are rotated posteri-

orly. Suturing is done with 4-0 or 5-0 absorbable suture. Use of a small needle with a high degree of curvature (P-2 needle; Ethicon, Somerville, New Jersey) often is necessary for closure along the posterior edge of the hard palate incisions. The nasal layer is closed before the oral layer (Fig. 186-36). It is helpful to first suture the apex of the flap into the recipient corner, thereby stretching the flap. Any length discrepancy between incisions can be accounted for during closure. The uvula should be reconstructed. Contracture of the oral mucosa-muscle flap may restrict its advancement during the oral closure. Occasionally, a short V-Y advancement can be done at the right anterior corner to facilitate watertight closure of the oral surface.

Complications

During palatoplasty, hemostasis should be secured with pressure and electrocautery. Typically, less than 50 mL of blood is lost if epinephrine is used during initial injections and careful hemostasis is maintained. Postoperative bleeding is rare unless open wounds exist. After removal of the mouth gag and before extubation, the floor of mouth and tongue should be inspected for signs of edema. Prolonged tongue ischemia may result in edema with the potential for airway obstruction. Periodic

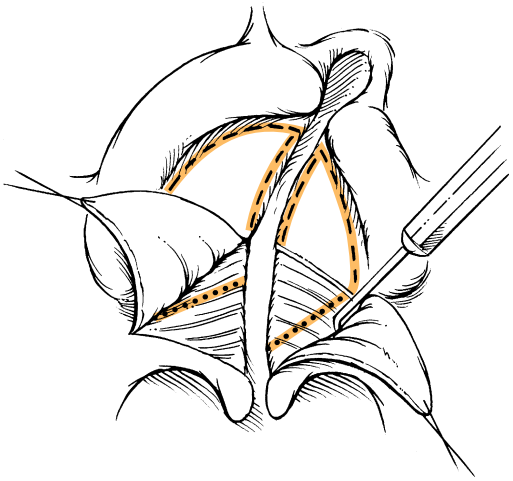

Figure 186-34. Oral mucosa flaps fully elevated. Soft palate muscles are seen on the right, and only the submucosa of the nasopharynx is exposed on the left. The *dotted lines* indicate where the incisions are planned for the next two flaps on the soft palate. *Dashed lines* on the hard palate indicate where incisions are to be made.

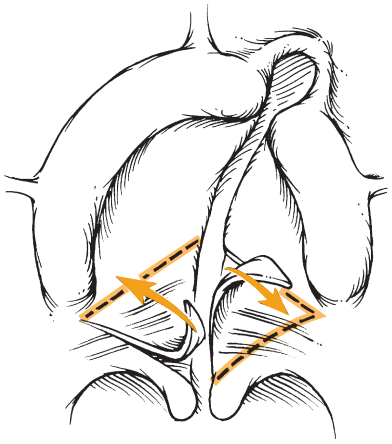

Figure 186-33. Double-opposing Z-plasty (Furlow) palatoplasty for a unilateral left complete cleft palate. Initial incisions and elevation of the first two flaps are indicated by the *arrows*. The left flap consists of oral mucosa and soft palate muscles. The right flap consists of oral mucosa and submucosa (perspective shown is that of a right-handed surgeon).

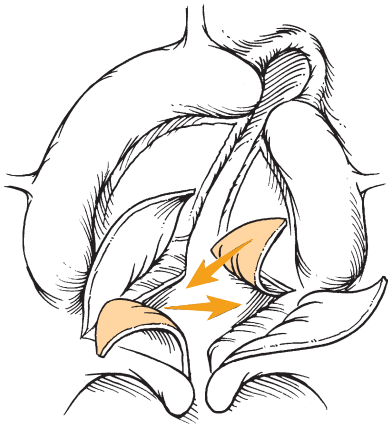

Figure 186-35. The nasopharyngeal mucosa flap from the left is transposed anteriorly. The flap containing soft palate muscle and nasopharyngeal mucosa from the right is transposed posteriorly.

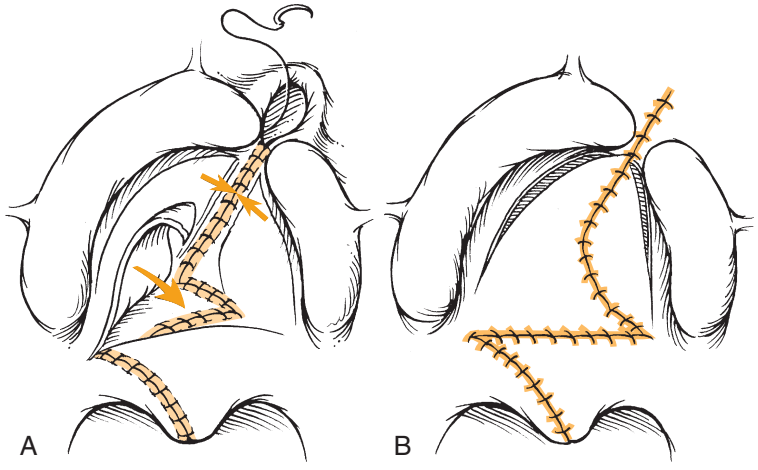

Figure 186-36. **A,** Closure of the oral surface of the soft palate. The muscle-mucosa flap from the right has been transposed and the oral mucosa is rotated anteriorly *(single large arrow)*. Nasal closure for double-opposing Z-plasty (Furlow) palatoplasty in a unilateral left complete cleft palate is also shown *(opposing smaller arrows)*. Nasal mucosa has been released along the cleft edge. Mucoperiosteal flaps were elevated bilaterally and pedicled from the greater palatine foramen *(not shown)*. **B,** Closure of the oral mucosa of both the hard and soft palate has been completed. If the incisions medial to the alveolus can be closed without substantially increasing tension, this is now performed.

release of the mouth gag during surgery should help prevent tongue ischemia.[65] Before extubation, a heavy silk suture typically is placed around the tongue tip. This "tongue stitch" may be used in lieu of an oral airway to aid postoperative airway management. This suture often is removed once the child is fully aware in the postanesthesia care unit but may be left until a safe airway is secure.

Historically, high rates of oronasal fistula formation have been reported after palatoplasty. When only fistulas that occur in the areas after primary repair (i.e., not intentional) are considered, the frequency of oronasal fistula is 8.7% to 23%.[69-71] Severity of clefting and type of cleft were the main risk factors identified. Recurrence rates after fistula repair range from 25% to 33%. Sites of fistulization typically are the anterior hard palate and the junction of the hard and soft palate.

The most common complication after palatoplasty is velopharyngeal insufficiency. Surgical technique may be a factor, with lower rates reported for double-opposing Z-plasty than for more traditional methods.[72] This topic is fully discussed in Chapter 187, Velopharyngeal Dysfunction.

Special Considerations in Patients with Cleft Palate

Robin Sequence

First described in 1923 in his native France and subsequently reported in the English literature in 1934, the Robin sequence is named for Dr. Pierre Robin, who highlighted the importance of the combination of micrognathia, glossoptosis, and cleft palate.[73,74] In the absence of other congenital abnormalities, the triad is considered a sequence because the micrognathia is the primary cause of the glossoptosis and cleft palate. However, the Robin sequence often is found associated with other abnormalities.[75,76] In such cases, the term "syndromic Robin sequence" has been used. Associated abnormalities are found in 52% to 83% of patients with Robin sequence. Stickler syndrome is the most common syndrome in children with Robin sequence, seen in 14% to 34% of cases. Sensorineural hearing loss and myopia are common findings in infants with Stickler syndrome. It is recommended that all children who present with features suggestive of Robin sequence have early hearing and vision screening. In nonsyndromic Robin sequence, it is unclear whether compensatory or "catch-up" growth occurs in the first years of life. The work of some investigators suggests that mandibular growth may be stimulated by tongue activity and oral motor development.[77,78] However, other work has shown that growth of the mandible in patients with Robin sequence is not significantly different from that in control subjects.[79-81]

Glossoptosis is an important factor that contributes to the upper airway obstruction commonly seen in Robin sequence. Retrodisplacement of the tongue into the oropharynx and inadequate support from the genioglossus muscle are the consequences of specific anatomic deficiencies of the mandible in these patients: a small body and short ramus. Negative pressure within the pharynx during inspiration and swallowing, combined with the anatomic and physiologic limitations imposed by micrognathia, frequently result in an unstable airway and dysphagia.[82-84] Severity of obstruction can be assessed by clinical evaluation, pulse oximetry, or polysomnography.[85]

Several strategies have been advocated for treating the airway obstruction in patients with Robin sequence.[82,83] These include prone positioning, which allows the tongue to fall away from the posterior pharyngeal wall.[82] If this strategy is ineffective in maintaining airway patency, a nasopharyngeal airway can help.[86] Maintenance of the nasopharyngeal airway can be challenging, as the tube requires suctioning and changing periodically. Oral feeding in this setting is made difficult owing to the frequent reflux of the meal through the tube. Gavage feeding may be needed in such cases.[87] Other centers will perform a glossopexy or lip-tongue adhesion in infants in whom positioning fails to maintain airway patency.[88-90] High success rates are reported when patients are selected on the basis of nasopharyngoscopy findings of an anterior-to-posterior collapse by the tongue, causing occlusion of the airway.[88] Complications of glossopexy include dehisence, which has been reported as high as 56%.[91]

Tracheostomy has traditionally been used for those patients with Robin sequence who also have severe airway obstruction or synchronous airway lesions, or in those infants in whom airway management by other methods has been unsuccessful.[82,83,92,93] Tracheostomy establishes an airway distal to the pharyngeal obstruction, and it has minimal impact on oropharyngeal swallowing mechanics. Another advantage of the tracheostomy is that it can be used during subsequent surgical procedures such as palatoplasty. A secure airway during palatoplasty is important, because airway problems occurring immediately after palatoplasty were most commonly seen in children with Robin sequence.[94] Nearly all patients with isolated Robin sequence who have tracheostomy performed to relieve airway obstruction can be decannulated after palatoplasty.[93] However, tracheostomy is not without difficulties in management and risks of serious complications.

Mandibular distraction osteogenesis is another method used to address the inadequate airway in infants with Robin sequence. First described in children in 1992,[95] the procedure is now advocated as primary treatment to relieve upper airway obstruction in these patients.[96,97] Bilateral mandibular osteotomies are performed and a distraction device is placed on either side of the osteotomy. Over the next several weeks, the distraction and subsequent consolidation across the osteotomy sites act to regenerate bone of the mandible, thereby lengthening the body or the ascending ramus. This in turn advances the tongue away from the posterior pharynx. In one series, all patients were successfully extubated or decannulated using this technique.[97] Selection criteria for mandibular distraction versus other airway management strategies have not been established.

Velocardiofacial or Microdeletion Chromosome 22 Syndrome

Velocardiofacial syndrome (VCFS) encompasses numerous phenotypic manifestations. It is the most common syndrome associated with isolated patients with isolated cleft palate.[98] It has become increasingly recognized in cleft palate patients and patients who present with velopharyngeal insufficiency (see Chapter 187, Velopharyngeal Dysfunction).[99,100] In one large series, 9% of patients had cleft palate and 32% had velopharyngeal insufficiency.[101] The palatal evaluation may reveal overt, submucous, or occult submucous clefting. Its phenotypic expression overlaps with DiGeorge syndrome and conotruncal anomaly face syndrome.[102] Because of the phenotypic overlap among these three syndromes, each a result of a deletion in the long arm of chromosome 22, the name "22q11 deletion syndrome" has been suggested.[103] More than 100 anatomic and functional abnormalities have been described in patients with VCFS.[101,104] The incidence of this deletion is estimated at 1 in 3000 to 1 in 4000 children.[105] Fluorescence in situ hybridization probes are available to identify patients with this deletion. The prevalence of patients with the phenotypic diagnosis of VCFS who test positive for the deletion is 68% to 81%.[102,106] Although its transmission is as an autosomal dominant trait, most cases represent a de novo deletion.[101,107]

The head and neck manifestations of VCFS are numerous. Facial dysmorphism can be subtle and several different findings are described. These include an elongated midface ("adenoid facies"), a shortened midface with malar hypoplasia, broad nasal base, low-set ears, thickened helical rims, mandibular micrognathia, and microcephaly.[108-110] Dysphagia is common and may present during infancy.[111] The dysphagia may be independent of cleft palate or cardiac involvement and may persist beyond infancy. Pharyngeal hypotonia and poor oral phase of swallowing are both felt to contribute to the dysphagia. Middle ear disease is common, with reports of 22% to 88% of patients affected.[108,109] Conductive hearing loss and chronic suppurative otitis media may result. These patients may require repeated tympanostomy tube placement. Adenoidectomy should be carefully considered in patients with VCFS, because a high incidence of postoperative velopharyngeal insufficiency has been described.[99] In addition to the high frequency of clefting seen in these patients, other factors may contribute to the eustachian tube dysfunction. An abnormally flattened basisphenoid has been described in patients with VCFS,[112] and palatal muscle dysplasia also is seen (Fig. 186-37). Medialized carotid arteries are found in some patients with VCFS, increasing risk for injury during pharyngeal

Figure 186-37. Magnetic resonance image of the soft palate in a patient with velocardiofacial syndrome. Note the increased signal intensity of this T1-weighted image, suggesting increased fat composition within the soft palate as compared with the surrounding facial and pharyngeal muscles.

surgery.[113] Imaging of the pharynx using magnetic resonance angiography is suggested,[114] although spontaneous resolution has been described.[115] Searching for pulsations along the posterior pharyngeal wall during nasendoscopy is recommended for this population. Velopharyngeal insufficiency is common in VCFS; the evaluation and management of this problem are covered elsewhere (see Chapter 187, Velopharyngeal Dysfunction). Vocal cord nodules may be found. Patients with velopharyngeal insufficiency may compensate by using glottal stops. Anterior laryngeal web also may be seen in these patients.[101]

Submucous Cleft Palate

A bifid uvula, a notch in the posterior hard palate due to the absence of the posterior vomerine spine, and a translucent zone in the midline of the soft palate constitute the classic findings with submucous cleft palate (SMCP) (see Fig. 186-5). Large population-based studies suggest a prevalence for SMCP of 1 in 1250.[116] An occult SMCP, not evident on oral examination, occurs when only the muscularis uvulae is dehiscent.[117] The diagnosis of occult SMCP is made during nasendoscopy for evaluation of velopharyngeal insufficiency[118] (see Chapter 187, Velopharyngeal Dysfunction).

The cause for the palatal dysfunction seen in patients with SMCP may involve several factors. Abnormal insertion of the levator palatini into the posterior margin of the hard palate and diathesis of the muscularis uvulae may result in the inability of the posterior margin of the soft palate to fully contact the pharyngeal wall. Histologic analysis of surgical specimens from patients with SMCP revealed increased fibrosis, especially within muscle fascicles; fascicular disorganization; and hypoplastic myocytes.[44] However, there does not appear to be differences in craniofacial morphology between symptomatic and asymptomatic children with SMCP.[119] Longitudinal studies indicate that more than 50% of patients with SMCP will develop speech disorders requiring surgery.[120,121] These studies were conducted in tertiary referral cleft clinics, thus the actual frequency of symptomatic patients with SMCP may be lower. SMCP appears more frequently in association with other craniofacial abnormalities. Occult SMCP is the most common palatal abnormality associated with VCFS, seen in 67% to 69% of affected patients. Overt SMCP may be found in another 24% of patients with this syndrome.[108,109] The soft palate should be diligently inspected and palpated prior to adenoidectomy because of the high prevalence of SMCP in cleft lip–only patients. The relationship between SMCP and otitis media is unclear. Higher rates of recurrent otitis media or need for tympanostomy tube placement in the first year of life were found in children with bifid uvula, but the difference was not significant. This difference was not seen at 3 years.[122] Similarly, no difference in effusions was found between surgical patients with and without bifid uvula.[123] Whether bifid uvula–only is an adequate marker for other deficiencies in SMCP is unknown. The discovery of SMCP in infancy or early childhood requires follow-up evaluation through adolescence. Because many children remain asymptomatic, surgical correction of the palatal deformity is indicated only when clinical problems are refractory to medical therapy.

Ear Disease

It has been recognized for some time that children with cleft palate have a very high frequency of middle ear disease compared with the noncleft population. Paradise and colleagues[124] first reported that all children with cleft palate examined by pneumatic otoscopy and otomicroscopy showed effusions. Muntz[125] reported that 96% of children with cleft palate required tympanostomy tube placement. Nearly 50% of these children required repeat tympanostomy tube placement. Complications in this group included chronic tympanic membrane perforation in 13%, chronic suppurative otitis media in 6%, and cholesteatoma in 1%. Dominguez and Harker[126] revealed the importance of routine follow-up care by an otolaryngologist to minimize complications of ear disease. The rates of cholesteatoma formation were reduced from 9% to 3% when a coordinated team approach to care of the CLP patient was instituted.

Otitis media with effusion develops within the first months of life in a child with cleft palate. In a prospective study, Dhillon[127] found middle ear effusions by aspiration in 97% of ears at 4 months of age. This study also demonstrated that eustachian tube function did not return within 2 years after palatoplasty in 80% of patients. Other prospective studies support poor eustachian tube function and otitis media as problems that persist during the first few years after palatoplasty.[128,129] It should be noted that in each of these studies, a "traditional" palatoplasty was performed. The potential effect that the type of palatoplasty has on otologic outcomes is unknown.

Frequency of otitis media decreases with increasing age of the child with cleft palate. Smith and colleagues[130] used audiology and tympanometry to determine that the average recovery time for eustachian tube function was 6 years after palatoplasty. Among children followed for at least 6 years, 70% of ears had normal eustachian tube function. More than 90% of the ears that recovered eustachian tube function were able to maintain normalcy. Tympanoplasty results were similar for patients with cleft palate (including SMCP) and children without cleft deformity with regard to postoperative air-bone gap, graft survival, and need for postoperative ventilation tube.[131]

Abnormalities of the cartilage and muscles surrounding the eustachian tube are responsible for the high prevalence of otitis media associated with cleft palate. Paratubal cartilage abnormalities have been described that may contribute to dysfunction in patients with cleft palate. Hypoplasia of the lateral cartilage relative to the medial cartilage was found in infants with cleft palate.[132,133] The curvature of the eustachian tube lumen, as determined by the shape of the surrounding cartilage, also was found to be abnormal when compared with noncleft specimens. Cephalometric data suggest that the width and angulation of the skull base with respect to the eustachian tube are different in patients with cleft palate.[134] Abnormal insertions of the TVP and levator veli palatini muscles into the cartilages and skull base also may adversely affect their role in eustachian tube function. Matsune and

colleagues[135] studied temporal bone specimens from patients with cleft palate and compared them with those from non-cleft control subjects. No insertion of the TVP muscle to the lateral paratubal cartilage was found in 40% of CP specimens. All normal specimens demonstrated an insertion of the TVP to the lateral cartilage. Moreover, the length of TVP muscle inserted into the cartilage was reduced in CP specimens. Huang and coworkers[43] dissected fresh cadavers of normal adults. Their detailed analysis of the anatomy of the TVP and levator veli palatini muscles suggests that the TVP opens the eustachian tube directly by traction on the lateral cartilage. The levator veli palatini may open the eustachian tube by displacement of the medial cartilage. Some studies have identified the muscle fibers inserting into the lateral cartilage as a distinct muscle, the dilatator tubae.[136,137] It remains unclear to what degree the altered anatomy of the paratubal muscles directly affects eustachian tube dysfunction, because the levator veli palatini muscle is more severely affected by cleft palate.

Insertion of ventilation tubes is the standard treatment for otitis media in patients with cleft palate. Controversy surrounds the timing of ear tube placement. Otitis media with effusion is known to decrease hearing thresholds. Decreased hearing at a very young age may affect future speech and language development, especially in this high-risk group of patients. However, high rates of otorrhea from ears with ventilation tubes placed before palatoplasty have been reported; excessive compliance of the eustachian tube before palatoplasty has been suggested as the etiologic basis.[138] Chronic otorrhea resolved only after palatoplasty in four children who had early ear tube placement.[139] No long-term studies have been conducted to determine whether early placement of ventilation tubes, and correction of hearing loss, affect speech outcomes in patients born with cleft palate. Newborn hearing screening can provide an early indication of auditory function and help with treatment decisions such as when ear tubes should be placed.

CHAPTER ONE HUNDRED AND EIGHTY-SEVEN

Velopharyngeal Dysfunction

Harlan Muntz

Marshall E. Smith

Cara Sauder

Key Points

- Velopharyngeal inadequacy refers to any type of dysfunction and may be categorized as insufficiency, incompetence, and mislearning.
- "Phoneme-specific" velopharyngeal dysfunction (VPD) is diagnosed when one or more phonemes are abnormally produced with increased resonance while the rest of the speech is normal. The increased resonance most often is noted with /s/, /sh/, and /z/, and rarely, /f/ phonemes.
- Recommendations for management of VPD are best made jointly by a team that includes the surgeon, speech-language pathologist, and dentist or prosthodontist if needed.
- Compensatory articulation errors that are a result of VPD alone do not frequently occur with oral motor weakness. Therefore, oral motor exercises are not appropriate unless there is evidence of oral motor weakness in addition to VPD.
- The Furlow palatoplasty reorients the levator while also thickening and lengthening the palate.
- All surgical corrections of VPD may lead to airway obstruction.
- It is helpful for the otolaryngologist, speech-language pathologist, and other team members to take a "transdisciplinary" approach to the management of VPD.

In the English language, only three phonemes normally are produced with nasal air escape—/n/, /m/, and /ng/. All of the other sounds are produced with oral air flow. In speech production, the velopharynx is considered an articulator, as are the jaw, tongue, lips, pharynx, and larynx. These articulators work together to produce the various sounds of speech. Normal velopharyngeal function varies according to the sounds of speech produced. Factors that affect velopharyngeal valving include vowel height, consonant type, proximity of nasal sounds to oral sounds, utterance length, speaking rate, and tongue height. For vowels, velar position is higher for vowels with a high pharyngeal constriction such as /i/ and /u/ than for low-pharyngeal-constriction vowels such as /a/. The velar port generally is closed for vowels, except when the vowel is in proximity to a nasal consonant. The velopharyngeal port therefore changes its relatively open and closed states depending on the balance of oral versus nasal consonants occurring in the speech stimuli. Velar movement may vary widely in velocity and displacement with the tasks of the particular speech, particularly speaking rate.

If the velopharynx is not functioning correctly or if a defect in the palate allows the oral sound to resonate through the nose, speech may be perceived as abnormal. Incompetence of the velopharyngeal mechanism leads to increased hypernasality, nasal turbulence, or nasal emission. If an obstruction to nasal airflow is present, the resonance is hyponasal. Speech intelligibility is determined primarily by articulation; however, abnormal speech resonance distorts speech production, impairs overall speech quality, and can adversely affect intelligibility.

Functional Anatomy

The velopharyngeal port closes as the velum moves in a posterior-to-superior direction. The lateral pharyngeal walls may move medially. Occasionally, anterior movement of the posterior wall will be seen. The muscles of the velopharynx contribute to this closure (Table 187-1).

The elevation and posterior motion of the velum are attributed to the levator veli palatini (LVP). This is the main muscle mass of the velum.[1] Variation in the angle of insertion to the base of skull may change the elevation.[2] The palatoglossus and palatopharyngeus muscles pull the palate down, opposing the LVP. The palatopharyngeus muscle pull tends to stretch the velum laterally, thereby increasing the velar area and altering the shape of the contact.[2] This muscle can make subtle changes to velar height, especially when the velum is in the elevated position.[3] The musculus uvulae adds bulk to the dorsal side of the velum.

Lateral wall motion varies from person to person and depends on speech context. The greatest movement usually is below the levator eminence at the level of the full length of the velum and hard palate.[4] This movement is attributed to selective movement of the uppermost fibers of the superior constrictor. Because of the relationship between the lateral fibers of the superior constrictor and the palatopharyngeus, it has been suggested that this muscle is involved in the lateral wall motion as well.[5]

Passavant's ridge is a posterior wall feature seen in some persons during speech or swallow. It has been associated with lateral wall motion and is thought to be caused by a similar movement of the uppermost fibers of the superior constrictor and palatopharyngeus.[6] It may be involved in velopharyngeal closure in as many as one third of patients in whom Passavant's ridge is observed.[7,8] Its movement also can be seen below the level of the velopharyngeal port and therefore does not assist in the closure.

Table 187-1

Muscles of the Velopharynx

Muscle	Origination	Attachment	Function	Innervation
Tensor veli palatini	Vertical portion arises from the scaphoid fossa at the base of the internal pterygoid plate, from the spine of the sphenoid, and from the outer side of the cartilaginous portion of the eustachian tube	Terminates in a tendon that winds around the hamular process	Tenses the soft palate; opens the auditory tube during swallowing	Mandibular branch of the trigeminal nerve
Levator veli palatini	Arises from the undersurface of the apex of the petrous portion of the temporal bone and from the inner surface of the cartilaginous portion of the eustachian tube; found to occupy the intermediate 40% of the length of the soft palate*	Fibers spread out in the soft palate, where they blend with those of the opposite side	Acts as a sling when contracted to pull the velum in a posterosuperior direction[4]; major elevator of the velum[13]; positions the velum†	Pharyngeal plexus derived from the glossopharyngeal and vagus nerves and the facial nerve‡; course of the facial nerve is through the greater petrosal nerve§
Musculus uvulae	Palatal aponeurosis in a circumscribed area posterior to the hard palate‖	Inserts into the uvula	Adds bulk to the dorsal surface of the soft palate	Pharyngeal plexus; pharyngeal plexus derived from the glossopharyngeal and vagus nerves and the facial nerve‡
Palatoglossus	Has a fan-shaped attachment from the anterior surface of the soft palate¶	Courses through loose connective tissue within the anterior faucial pillar and has a tapering termination in the side of the tongue¶	Elevates the tongue upward and backward to constrict the pillars and probably lowers the velum**; positions the velum†	Pharyngeal plexus composed of branches from the glossopharyngeus and vagus cranial nerves and from the sympathetic trunk
Palatopharyngeal	Arises from the soft palate	Inserts with the stylopharyngeus into the posterior border of the thyroid cartilage	Adducts the posterior pillars, constricts the pharyngeal isthmus, narrows the velopharyngeal orifice, raises the larynx, and lowers the pharynx††; positions the velum†	Pharyngeal plexus
Superior constrictor	Arises from the lower third of the posterior margin of the internal pterygoid plate and its hamular process	Inserts into the median raphe	Medial movement of the lateral aspects of the pharyngeal walls[4]; high levels of activity are related to laughter[13]; may function to draw the velum posteriorly[13]; pulls the posterior wall and posterolateral angle	Pharyngeal plexus derived from the glossopharyngeal and vagus nerves and the facial nerve‡

Approach to Diagnosis and Management of Velopharyngeal Dysfunction

Evaluation of velopharyngeal dysfunction (VPD) requires an understanding of the causes of the condition to make an appropriate diagnosis. Assessment includes an accurate study of the degree and nature of velopharyngeal function and its impact on speech production. This information is then used to formulate management recommendations, which generally include speech therapy, surgical intervention, or prosthetic obturation. These management options are reviewed later in the chapter.

Causes of Velopharyngeal Dysfunction

Velopharyngeal dysfunction refers to abnormal function of the velopharyngeal sphincter mechanism. However, it does not identify the cause. Perceptually, this dysfunction is considered a dysphonia because it affects the sound quality of the voice. The cause of the dysphonia needs to be identified. Campbell and associates[9] reported on 427 children referred to a pediatric voice and resonance clinic for voice problems. Of those children, 16% were actually found to have velopharyngeal, rather than laryngeal dysfunction. Different terminology has been used to describe the causes of VPD, and relevant terms and concepts are used inconsistently throughout the medical literature. In this chapter, we use the definitions summarized by D'Antonio and Crockett.[10] *Velopharyngeal inadequacy* refers to any type of VPD and can be divided into three etiologic categories: insufficiency, incompetence, and mislearning. Velopharyngeal *insufficiency* encompasses structural defects that result in insufficient tissue to accomplish closure—a well-known example being cleft palate. *Incompetence* describes impairment of motor control secondary to neurologic dysfunction, such as paresis or paralysis. Causes of incompetence include the sequelae of skull base surgery and tumors around the jugular foramen and vagus nerve, or central nervous system (CNS) impairment from brainstem stroke. *Mislearning* is the result of etiologic factors that are independent of structural defects or neuromotor pathology.

Congenital anatomic conditions affecting velopharyngeal function most commonly are attributable to clefting of the palate. VPD in the absence of an overt cleft palate also occurs. Affected children may have other anatomic abnormalities or functional disorders causing velopharyngeal insufficiency. These include congenital short palate, palatopharyngeal disproportion, a less overt palate deficiency called occult submucous cleft palate (absence of the musculus uvulae), and longitudinally oriented levators. Hypertrophic tonsils occasionally can cause insufficiency by impeding palate closure. Neurogenic causes of velopharyngeal incompetence include muscular dystrophies, myasthenia gravis, traumatic brain injury, Down syndrome, and velocardiofacial syndrome (22q11 deletion). An adenoidectomy can create or unmask VPD in any of these settings. In velopharyngeal insufficiency, a large adenoid can compensate for a short palate. In velopharyngeal incompetence, adenoidectomy can compensate for a poorly mobile palate. With removal of the adenoidal tissue, the mechanism of compensation is eliminated. Velopharyngeal inadequacy has been reported to occur after 1 in 1500 adenoidectomies.[11,12]

Assessment

Perceptual Speech Analysis

Most otolaryngologists will encounter children with VPD in their practice. In taking the history of a child referred for a voice or speech problem, the clinician should listen carefully to input from the parent or caregiver, who typically spends the most time hearing the child speak. Then, attention needs to be paid to the speech of the child, who often is shy and does not speak voluntarily. Playing games or asking direct questions can stimulate the child to begin spontaneous speech. This perceptual evaluation will provide the clinician with a sense of the language level, articulation, and the nasal resonance as the child is speaking. The possibility of a diagnosis of VPD should be considered even in children referred for other concerns.

If VPD is suspected, a few easy tests will further elucidate the problem. Many of these tests are quickly and easily performed in the office setting with a reasonably cooperative patient. These include nasal occlusion and mirror fogging tests during the child's production of various phonemes or phrases selected to provoke the symptoms.

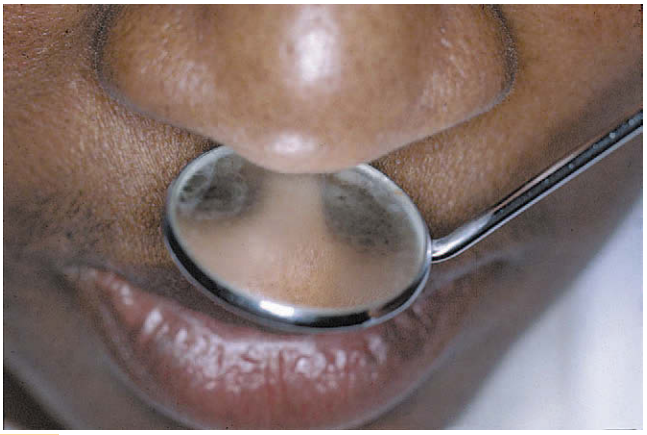

Figure 187-1. Mirror technique; note the fogging with nasal air escape.

Table 187-2

Examples of Tasks to Evaluate

Nasal Consonants	
Ma ma	Money
Na na	Monkey
Momma made lemon jam	Nancy is a nurse

Hyponasal resonance is most noted in the sounds /m/, /n/, and /ng/. These nasalized consonants will be altered with decreased nasal airflow. The /m/ will be changed to sound like /b/, the /n/ changed to sound like /d/, and the /ng/ to a hard /g/. Humming the /m/ sound will not change with nose plugging if the nose is already occluded. In addition, the examiner will not feel nasal vibrations. Normally, a mirror held under the nose should fog with voicing of the nasal consonants (Fig. 187-1). If the voice quality is the same with or without occlusion of the nose, then nasal or nasopharyngeal obstruction is present. Hyponasal resonance can be described as that quality of speech associated with the congestion of a common cold. Large adenoids or congested nasal turbinates also may be seen. Repetition of words or sentences that are loaded with nasal consonants will aid in documentation of this abnormality (Table 187-2). The velopharynx continues to be active during production of words and phrases with nasal consonant sounds but will be between a relaxed and a closed state.

Hypernasality or increased nasal resonance will be noted with production of non-nasal phonemes (Table 187-3). Because most sounds (vowels and consonants) in the English language are non-nasal, there are many phonemes to work with. The early phonologic repertoire usually includes the bilabial plosives /p, b/ and lingua-alveolar phonemes /t, d/. Using phonemes—words and sentences loaded with these sounds—allows the listener to assess speech resonance (normal or hypernasal). Plugging the nose while the child repeats the /p, b, t, d/ sounds or during sustained production of /s/ or /sh/ will result in noticeable change in resonance if there is hypernasality on these sounds. The use of a mirror beneath the nose during speech tasks also will assist in the detection of the nasal air escape (see Fig. 187-1). Fogging of the mirror typically is observed only for production of nasals and nasalized vowels. Increasing the complexity of the tasks (i.e., sounds to words to phrases to sentences) may document deterioration of the velopharyngeal competence. The degree of openness is determined by the phonetic environment. Some children will do less well if nasal and non-nasal phonemes are mixed. Repetition of tasks during a period of minutes

Table 187-3

Examples of Tasks to Evaluate

Non-Nasal Consonants		
Pa pa pa	Daddy did it	Sustain "s"
Baby	Too tight	Sustain "sh"
Puppy	Go get an egg	Count from "sixty to seventy"
Puffy	Forty-four fat fish	Baby bib
Daddy	Sissy saw it	Get it out

may unmask velopharyngeal fatigue, as seen in myasthenia gravis. Velar height or elevation is most pronounced during the "high" vowels of /i/ and /u/[13] and the fricative /s/.[14] Even if velopharyngeal function is improving, production of these sounds may remain difficult.

The clinician also may encounter "phoneme-specific" VPD, or mislearning. In this entity, one or more phonemes are produced abnormally with increased resonance, while the rest of the speech is normal.[15] It most often is noted with production of /s/, /sh/, /z/, and rarely, /f/ phonemes. A nasal fricative substitution is characteristic. Because these are predominant sounds in the English language, the patient often is believed to be globally hypernasal. Because other non-nasal sounds demonstrate no air escape, however, the velopharynx should be recognized to be otherwise functional. Appropriate articulation therapy usually will correct this abnormality.

The diagnosis of hypernasality may be confounded by concomitant dysphonia or hyponasality. Hoarseness will distort the sound enough that mild VPD may be overlooked. More than 40% of children with VPD also have dysphonia.[16] The use of the mirror test helps separate VPD from laryngeal pathology.

Children with VPD also may have nasal or pharyngeal airway obstruction that affects the nasal consonants. In such cases, both hyponasality and nasal air escape on production of non-nasal phonemes can occur. The abnormality is described as "mixed."

The presence of velopharyngeal insufficiency has a significant impact on the child's and the family's quality of life. Emotional and communication aspects are primarily affected. Parents seem to be an appropriate proxy in determining the impact of the altered speech on the child's quality of life.[17]

When VPD has been suspected on clinical examination, further testing is indicated. There are a number of techniques used for evaluation. Indirect measures to assess for VPD include nasometry and pressure-flow measurements. Imaging studies of the VP mechanism include lateral cephalometrics, speech videofluoroscopy, and speech endoscopy. Further specific resonance-related articulation assessment also is an important component in assessment of these patients.

Nasometry

Nasometry is an objective standardized assessment that measures the ratio of sound intensity between the nose and the mouth. This typically is done with voicing of standard phrases and passages. Standardized values exist for specific tasks. Calculation of the number of standard deviations from normative values for each phonemic set yields a measure of the severity of the resonance pattern. Nasometry can be used in the initial evaluation to document the degree of dysfunction. Perhaps more important, it is used in assessing progress during speech therapy or in following other interventions.[18] A discrepancy may exist between nasal scores and the perceived degree of hypernasality.[19] Figure 187-2 shows the Kay Elemetrics headgear used for this test.

Pressure Flow

Pressure and airflow measurement is another method of assessing velopharyngeal function during speech.[20-22] The nose is covered with a small mask to permit accurate measurement of nasal airflow. A probe is placed into the mouth to measure oral pressure. In the child with normal velopharyngeal function, no airflow will be detected during production of non-nasal phonemes. Oral pressure will be present if nasal air escape is detected during non-nasal sounds. An advantage to the pressure-flow technique is the ability to determine the timing of the air escape.[14] The pressure-flow technique also is used to calculate the cross-sectional nasopharyngeal airway area from the pressure-flow measures.

Figure 187-2. Nasometer apparatus in position.

Imaging Studies

An imaging study of the velopharyngeal mechanism is indicated when speech therapy is not progressing, if speech evaluation reveals significant hypernasality, if a diagnostic dilemma is present, or when surgery is under consideration. Lateral cephalometric x-ray studies were done in the past but are limited by a sagittal plane view and do not provide information on dynamic movement of the velopharyngeal mechanism. Current methods of imaging velopharyngeal function include speech videofluoroscopy and speech nasal endoscopy. Endoscopy has largely supplanted videofluoroscopy in most clinics today. Children older than 3 years of age most often will cooperate with the evaluation. The speech nasal examination may not be useful, however, in the child with significant developmental delays. If the child cannot produce appropriately articulated phonemes, the study will not give adequate speech information. The accuracy of articulation has a direct effect on the closure.[23] Velopharyngeal closure on swallow does not yield information regarding speech.[6] To be of value, the assessment requires appropriate articulation of phonemes.

Speech Videofluoroscopy

Videofluoroscopic evaluation has been a standard tool in assessment of the speech mechanism.[24] Generally, a speech-language pathologist attends this examination with a radiologist in the hospital imaging department, as is done for modified barium swallow studies. A small amount of barium is introduced through the nose to coat the velopharynx and improve visualization. While under fluoroscopy, the child repeats or reads a set of phoneme-specific speech tasks. Because the velopharyngeal sphincter functions in several planes of movement, accurate analysis will require at least two and preferably three views. The lateral view demonstrates the length, thickness, anterior-posterior, and superior motion of the palate, as well as the anterior movements of the posterior pharyngeal wall (Passavant's ridge). The anterior-posterior view assesses the lateral wall motion. An en face view (e.g., Towne's or submental vertex view) will look down the velopharynx and demonstrate lateral wall, velar, and posterior wall motion.

Videofluoroscopy has some limitations. Because of the radiation exposure, the speech sample may need to be shortened. Cooperation of the patient is still needed. Interpretation of the radiographs requires experience with analysis of the images. The examining team must include both a radiologist and a speech therapist with experience in this

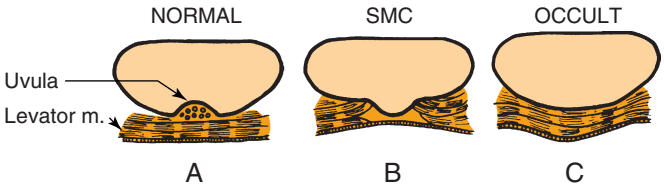

Figure 187-3. Muscle orientation of normal (**A**), submucous cleft (**B**), and occult submucous cleft (**C**). SMC, submucous cleft.

area of practice. With videofluoroscopy, closure patterns can be well defined and the level of Passavant's ridge and its participation in closure can best be assessed. Nevertheless, this assessment may still miss small fistulas and intermittent closure patterns. In addition, it is difficult to evaluate postsurgical changes. Many teams are moving toward the use of endoscopy as the standard first-line assessment tool.[25,26]

Speech Endoscopy

Speech endoscopy is now considered the most useful tool for evaluation.[27] Many otolaryngologists and some speech-language pathologists are experienced in the use of this minimally invasive diagnostic test. Ideally, the test is conducted with both the physician and speech-language pathologist in the room at the same time. If this is not possible, the examination can be video recorded for review. After topical anesthesia of the nose has been accomplished, a flexible nasopharyngoscope is introduced into the velopharynx.

The best image is obtained with the scope positioned higher in the nasopharynx to reduce parallax and fish-eye distortions. Passing the flexible scope in the middle meatus region (rather than along the floor) of the nose facilitates this optimal positioning. As with speech videofluoroscopy, a series of words, phrases, and sentences are spoken while the endoscopic images are recorded. It is important to use a microphone and record the voice, not just the video images. Endoscopy allows assessment of the static anatomy such as the nasal septum, eustachian tube orifice, adenoid pad, and structure of the musculus uvulae. Absence of the musculus uvulae is seen with occult submucous clefting (Fig. 187-3).

During speech tasks, the examiner observes velar and lateral wall motion and looks for Passavant's ridge. Incomplete closure can be documented by viewing the unclosed port or bubbling of mucus in the velopharynx. Contribution of the adenoid pad to closure, adenoid or posterior wall irregularities, and interference by the tonsils can be seen. There is no restriction on the duration of the speech sample, as constrained by the speech videofluroscopy. A clear and specific assessment can be made of both structure and function.

Four primary velopharyngeal closure patterns have been observed, as depicted in Figure 187-4.[28] These can be seen in both endoscopy and speech videofluoroscopy. These patterns are best understood in terms of the residual gap orientation on incomplete closure of the velopharynx.

The *coronal* closure pattern has a coronally oriented gap (seen in 55% of the population). The palate (velum) moves posteriorly without much contribution from the lateral walls or posterior wall. The *sagittal* closure pattern (seen in 10% to 15% of the population) leaves a gap oriented in a sagittal plane, because the major contribution to closure is from the lateral walls. The *circular* closure pattern has significant motion of the velum and the lateral walls, leaving a circular central gap (seen in 10% to 20% of the population). If the closure is *circular with Passavant's ridge*, then there is motion of the velum and lateral walls with additional presence of Passavant's ridge (seen in 15% to 20% of the population). Passavant's ridge may be present without contributing to closure.

The closure pattern may assist in prescribing surgical or prosthetic intervention. Knowing where the "gap" is should allow the clinician to decide how best to obturate that gap, as discussed next.[29-31]

Treatment

Management of VPD generally involves speech therapy or prosthetic or surgical treatment of the velopharyngeal defect, or combinations of

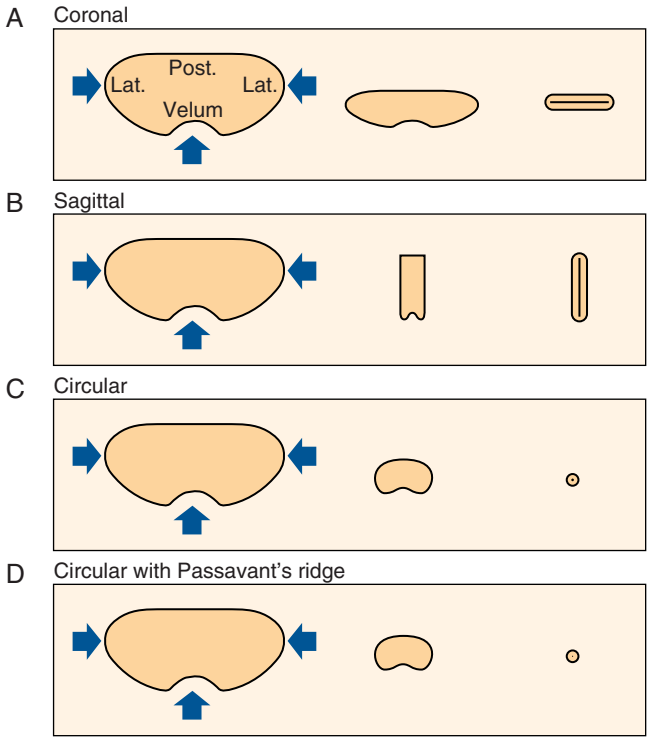

Figure 187-4. The closure patterns in the velopharynx. The pattern is based on the shape of the gap as it closes: **A,** coronal; **B,** sagittal; **C,** circular; **D,** circular with Passavant's ridge.

these approaches. Recommendations for each child generally are made jointly by a team that includes the surgeon, speech-language pathologist, and dentist or prosthodontist if needed.

Speech Therapy

Candidacy for and timing of speech therapy for children with VPD need to be examined closely by an experienced speech-language pathologist and the otolaryngologist. Speech therapy will not repair a deficiency in structure of the mechanism. Therefore, candidacy for therapy generally is limited to the following clinical circumstances: mild VPD in a child in whom appropriate stimulation yields improvement, inconsistent VPD, VPD occurring only when the child is fatigued, VPD with inappropriate articulation, VPD associated with oral-motor dysfunction, and failure of compensatory misarticulation to resolve spontaneously after surgical correction has been done. For patients who are candidates for speech therapy, the time of initiation of these services and the types of therapy recommended will depend on age, etiology, severity of VPD, cognition, hearing, phonetic inventory, expressive vocabulary, and the child and family's ability to participate in a therapeutic program.

Development of maladaptive articulations is common in children with VPD.[32,33] Excellent results from surgery can eliminate VPD, but impaired articulation may remain and greatly affect intelligibility. These abnormal articulation patterns include backing patterns, pharyngeal fricatives, glottal stops, and impaired sibilants. Speech intelligibility often is affected more by the presence of these articulation errors than by the resonance itself. If the maladaptive articulation is habituated, it may be difficult to reverse. Children who maintain articulation errors despite correction of VPD require speech therapy.[34] For children who receive surgical intervention of a structural deficit such as cleft palate, early intervention is recommended if stop oral consonants are not observed 6 to 8 weeks after surgery.[35] Phoneme-specific audible nasal air emissions can be present in children without VPD as well. Although appropriate referrals are important to rule out VPD, these children demonstrate an articulation disorder necessitating speech therapy as a primary means of treatment.

Articulation

Efficacy data regarding specific types of speech therapy techniques used to address articulation and resonance impairments in children with VPD are largely lacking. Correcting the placement and manner of articulation and adding additional phonemes to children's repertoires are primary goals of articulation therapy. Targets are selected on the basis of age appropriateness, impact on intelligibility, function, and stimulability. Careful evaluation of dentition to ensure that articulation errors are not a direct result of a structural problem also is required before initiation of therapy. The approach to articulation therapy does not vary significantly as a result of the presence or absence of VPD. However, glottal and nasal substitutions generally are considered atypical articulation disorders, so clinicians may have less experience in treating these types of substitutions. A generally recognized example of an articulation approach used to eliminate glottal stops involves repeating a stop plus vowel production first with a whisper and then gradually increase the voicing component.[36] Audible nasal air emissions that are phoneme-specific also are considered to be errors of articulation. Nasal air emissions generally occur during production of fricative, affricates, and sibilants. Clinicians frequently have the patient shape these sounds by increasing airflow during /t/ productions or use other voiceless stops with the same place of articulation as the targeted sound to establish correct productions. Nares-occluded oral productions of phonemes, syllables, words, and sentences also may be effective. Auditory, tactile, and visual training and feedback with respect to placement and manner of articulation as well as voicing components have demonstrated improvement in articulation of children with VPD as well.[37] Although some of the biofeedback techniques reported in the literature are not clinically relevant, they provide rationale for the use of auditory, visual, and tactile feedback during correct and incorrect productions of phonemes. Of note, compensatory articulation errors that are a result of VPD alone do not frequently occur with oral motor weakness. Therefore, oral motor exercises are not appropriate unless there is evidence of oral motor weakness in addition to VPD.

Resonance

It is unclear whether increasing strength or control of the muscles required for velopharyngeal closure by means of behavioral intervention is possible. Speech therapy generally is considered to be appropriate only when VPD is mild or inconsistently present, or if the affected child appears to fatigue throughout the day. Previous investigations of exercises to increase strength of the muscles needed for velopharyngeal closure have yielded poor results. Sucking, gagging, swallowing, and blowing exercises and electrical stimulation demonstrated no direct impact on improved velopharyngeal closure during speech tasks.[38-40] Attempts to train improved or more consistent velopharyngeal closure using speech therapy in children with mild hypernasality or intermittent closure rely heavily on auditory feedback. It is presumed that the ability to hear the difference between nasal and non-nasal productions is an important aspect of training production. Microphones, accelerometers, and tubing to assist with perception of airflow through the nose often are used. Resonance therapy and nasal occlusion with subsequent imitation of resonance without nares occluded are also commonly used to assist with auditory awareness and improve resonance. Visual feedback using the nasometer, which measures nasal and oral acoustic energy, is common instrumentation in many cleft palate and craniofacial settings. Some evidence supports its usefulness in reducing nasality with visual feedback.[14] However, long-term carryover has not been documented to the same degree.

Other forms of biofeedback, including Seescape, nasal stethoscope, and endoscopic feedback,[41,42] all have been used with some degree of success. Therapy techniques may include oral-motor awareness, continuous positive airway pressure (CPAP), and biofeedback techniques. Children with an inconsistent closure or those who on evaluation demonstrate minimal VPD may benefit from nasal CPAP. Nasal CPAP is used during speech tasks and resistance exercises performed to strengthen the velopharyngeal muscles. The exercises can be done at home. Although the reported results were variable, it may be helpful in some children for whom traditional therapy approaches do not result in significant improvement.[43]

Compensatory Strategies

Children who have undergone surgical repair of VPD but continue to demonstrate hypernasality often are referred for speech therapy to determine if altering speech production may improve speech to within socially acceptable limits. Strategies often include increasing breath support or loudness to increase sentence length, using increased jaw opening, and modifying pitch or breathiness of voice quality. Listener ratings of these changes either have not been studied in a systematic way or have yielded varied results.[44] Therefore, these therapy techniques generally are recommended on a trial basis.

Prosthetic Management

Prosthetic treatment has been used for many years and has been shown to be effective.[45] A palatal lift is created that pushes the palate up and back to contact the posterior pharyngeal wall (Fig. 187-5). If the palate is not too short, this maneuver will allow resolution of the VPD. Alternatively, an obturator (speech bulb prosthesis) is a round piece of acrylic that can be placed into the velopharynx so that with movement, the walls of the velopharynx will achieve closure as they contact the obturator (Fig. 187-6). "Weaning" from the obturator (bulb reduction therapy) subsequent to improved lateral wall and velar movement has been described.[46] Another study of clinical outcomes with the lift prosthesis did not seem to confirm this possibility.[47]

Prosthetic intervention is used in cases in which airway limitation is significant. The prosthesis can be removed at night to avoid obstructive apnea. It also is very useful in the case of stroke or central nervous system trauma[48] when there is a possibility of recovery. Older

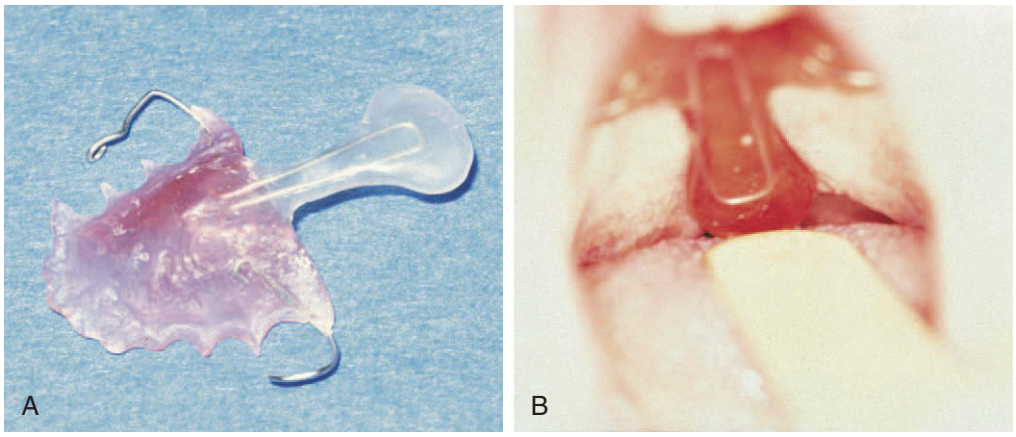

Figure 187-5. A palatal lift is shown out of the mouth **(A)** and in position **(B)**.

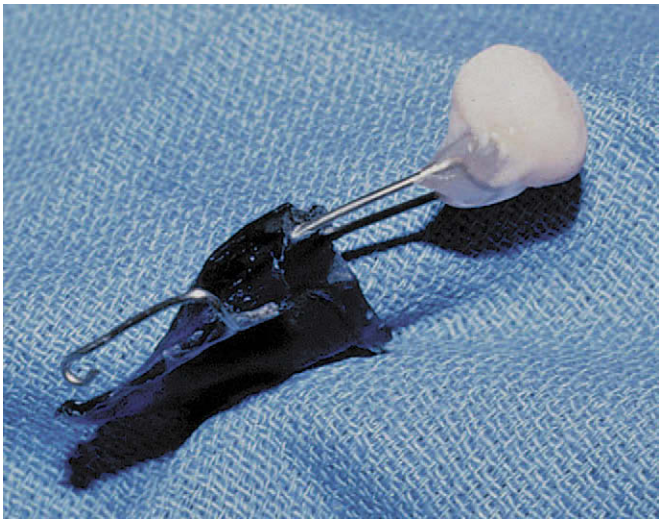

Figure 187-6. A palatal bulb obturator.

children and adults may be the most suitable candidates for this approach.

Prosthetic management has several limitations. First, an experienced prosthodontist is required for the fabrication, fitting, and maintenance of the appliance. Adequate maxillary dentition is mandatory, because the prosthesis is "hung" on the maxillary teeth. During the loss of deciduous teeth, keeping the prosthesis in place may not be possible. Similarly, during the rapid expansion of the maxilla in preparation for bone grafting, retention of the prosthesis is nearly impossible. The child must be cooperative with dental care. Finally, the prosthesis must be maintained with removal, cleaning, and repair. The inconvenience of this limits its widespread use and makes surgical options more desirable for long-term management in children.

Surgical Intervention

If a structural problem in velopharyngeal function exists, or speech therapy alone is ineffective, surgical intervention is a consideration. Options include intravelar veloplasty, Furlow double-opposing Z-plasty, sphincter pharyngoplasty, and superiorly based pharyngeal flap operations. The intravelar veloplasty and Furlow Z-plasty attempt to improve function by reorienting the levator sling. The (sphincter) pharyngoplasty borrows lateral wall tissue to obturate the lateral and posterior walls. The pharyngeal flap borrows tissue from the posterior wall to obturate the middle portion of the velopharynx.

Levator Repositioning

If the levator veli palatini muscle is oriented longitudinally, such as in a submucous cleft palate or after a palatoplasty, velar motion may be improved by reorienting the levator musculature. The traditional approach to this is an intravelar veloplasty. This operation dissects the levator muscles from their posterior attachment to the hard palate and nasal and oral mucosa to achieve a more anatomic transverse orientation. Although this is intuitively sensible, the results are not always satisfactory.[49] It has, however, been used with some success in "re-repair" of the palate if VPD follows a palatoplasty that did not include levator repositioning.[50]

The intravelar veloplasty can be done at the initial palate repair or as a secondary operation. An initial repair technique that can be slightly altered in revision surgery is described next.

After induction of general anesthesia and the securing of the endotracheal tube, a mouth gag is placed. This device secures the endotracheal tube against the tongue while retracting it out of the way with epinephrine. The greater palatine neurovascular bundle is injected with a small amount of local anesthetic. The palate will blanch, demonstrating a good local block. The soft palate is then additionally infiltrated to achieve further hemostasis.

The hard palatal flaps are elevated to the neurovascular bundle. Care is taken to dissect this without injury to the vascular supply. The lateral incision allows dissection around the hamulus. This maneuver will assist in freeing enough oral mucosa to allow closure.

The levator muscle inserts into the posterior border of the hard palate. This alignment makes the muscle nonfunctional. As the muscle is dissected from the posterior hard palate border, care is taken to avoid injuring the thinner nasal mucosa. The muscle is then freed from the oral mucosa and nasal mucosa. The dissection is best carried back to the hamulus and the levator followed toward the skull base. Debate is ongoing regarding the advantage of fracturing the hamulus to increase the mobility of the muscle bundle.

The palate is then closed in three layers. Nasal mucosa is closed with everting simple and mattress sutures from anterior to posterior. Absorbable sutures such as chromic are used. Uvular reapproximation, though not essential, is ideal. The muscle bundle often is attenuated. It is best closed with mattress sutures across the midline and may be tacked in this anatomic position. The oral mucosa is then closed as well.

Double-Opposing Z-plasty Palatoplasty

A current trend has been toward the use of the double-opposing Z-plasty originally described by Furlow (see Chapter 186).[38,51-54] This method reorients the levator while also thickening and lengthening the palate. The Furlow double-opposing Z-plasty also can be used as a primary closure, a repair of a submucous cleft palate, or a secondary procedure if the levators are longitudinally oriented. The Z-plasty is a well-known technique for lengthening a scar. The reorientation of the flaps also builds bulk in the posterior palate to aid contact of the posterior pharyngeal wall.

The Furlow double-opposing Z-plasty is done with the patient under general anesthesia. The mouth gag is used as well. After injection for hemostasis, as described earlier in the discussion of intravelar veloplasty, the four flaps are designed. The two myomucosal flaps are always posteriorly based and two mucosal flaps anteriorly based. A right-handed surgeon may find the elevation of the myomucosal flap on the patient's left more easily done, but this is not required.

If the palate is intact, it is divided in the midline. An incision is made on the left hemipalate, just posterior to the hard palate edge, leaving a small margin for ease of closure. This incision is carried through the muscle layer to the submucosal layer of the nasal mucosa. Care must be taken not to injure the thin nasal mucosa. The dissection is then carried posteriorly toward the free margin of the palate.

The oral mucosa is elevated from the muscle layer on the right hemipalate. This is based anteriorly. The incision is made just anterior to the free margin of the right hemipalate.

The right myomucosal flap is then developed by incising the muscle and nasal mucosa from the posterior edge of the right hard palate from medial to lateral. A cuff of tissue is left at the hard palate to facilitate closure.

The nasal mucosal flap on the left hemipalate is developed. An incision is made beneath the left myomucosal flap near the posterior edge of the soft palate toward the eustachian tube. This also creates a flap based anteriorly on the hard palate.

These four flaps are then repositioned to allow closure. The closure proceeds first with the nasal suture line repair, followed by the oral suture line closure. The left nasal mucosal flap is rotated across midline to the right hard palate margin. Everting sutures are tied with the knot toward the nose. The right myomucosal flap is then rotated to the left to insert into the left hemipalate. This maneuver brings the muscle bundle across the midline. The tension is not in the midline but lateral, reducing risk of fistula formation. The rotated flap is positioned so that the midline incision is now sewn to the posterior edge of the soft palate. The incision line that was at the hard palate is now sewn to the free edge of the nasal mucosal flap.

The oral mucosal flap from the right hemipalate is now rotated to the left, past the midline. The right oral mucosal flap is sutured to the incision at the posterior hard palate. The left myomucosal flap is

then rotated to the right across the midline. The once-medial edge will be sutured to the posterior soft palate edge. The muscular flaps thus overlap each other, which thickens the soft palate. The lateral incision will be closed to the free margin of the oral mucosal flap. The uvula is reapproximated.

Pharyngeal Flap

For years, the pharyngeal flap operation has been the mainstay of management for VPD when performed as a secondary procedure in patients with cleft palate. Many surgeons have excellent success with this operation.[29,55-59] Although both inferiorly and superiorly based flaps can be designed, the superiorly based flap is in more common use.[60] This flap places posterior wall tissue in the center of the velopharynx, leaving a lateral port on either side. With use of lateral port control with an appropriately sized catheter, airway problems are reduced.[58] Because of the midline obturation, the pharyngeal flap is ideal for a sagittal or circular pattern with good lateral wall motion. It may be altered as a secondary procedure to improve results.[61,62] Lateral wall motion is necessary for closure, but some evidence suggests that the lateral wall motion will improve after the procedure.[57]

After induction of general anesthesia and endotracheal intubation, the Dingman mouth gag is introduced. Palatal injection is performed as described earlier. The posterior pharyngeal wall is injected as well.

The flap is designed based on previously obtained endoscopic or videofluoroscopic results. The width and length will be key. Care must be taken to avoid elevating the flap too far into the hypopharynx, to reduce scarring and postoperative dysphagia.

Lateral incisions are made to the prevertebral fascia. The flap is undermined. Division in the inferior aspect can be left until the palate is opened. It is important to recognize that the flap will shrink once the inferior cut is made. Adequate length is important, but little advantage accrues to creation of an exceptionally long flap.

This procedure may be done using a palatal split technique, with the nasal mucosa used to cover the raw surface of the flap. Alternatively, the flap may be introduced into a bivalved palate. Flap width can vary because of the vagaries of scarring.

If the bivalve or fish-mouth technique is chosen, the palate is retracted to expose the nasal surface. An incision is made just anterior to the free margin on the nasal side. The oral mucosa is then dissected from the muscle layer through this incision, creating a pocket. The width of the pocket is based on the preoperative assessment on the needed width of the flap.

The superiorly based flap is then released from its inferior connection. The flap is inserted into the pocket so that the raw surface is in contact with the raw surface of the pocket. Sutures are brought from the oral surface of the palate through the pocket. These are then placed from the raw surface of the flap through the mucosa about 1 cm from the tip. The suture is then placed back through the mucosa of the flap and brought through the pocket to come out on the oral mucosal surface. As these sutures are tied, the flap pulls itself into the pocket, with raw surface to raw surface and mucosa to mucosa. Lateral port control is helpful. The mucosa also can be removed from the distal end of the pharyngeal flap so that the sutures can be placed at the distal end of the flap. The denuded flap is inserted into the pocket. This technique, in one report, yielded inconsistent results when compared with others.[30]

If the surgeon prefers, a palatal split approach can be used. The palate is divided in the midline. The hemipalate sections are retracted laterally. Back-cuts are made through the nasal mucosa at the posterior margin of the hard palate to elevate a laterally based nasal mucosal flap from the soft palate. The pharyngeal flap is sutured to the midline at the soft-hard palate junction and laterally to the mucosal edge of the back-cut. Lateral port control is maintained by the placement of catheters. The size of the port is determined by how far laterally the flap is sewn to the back cut. The laterally based nasal mucosal flaps are then sewn over the pharyngeal flap, to reduce scar contracture and narrowing of the flap. The nasal mucosal incision is closed in the midline. The cut edges of the muscular layer are reapproximated. The oral mucosa is then closed.

The posterior wall defect can be partially closed to assist in the postoperative healing, but can also be left open to heal secondarily. Excessive closure narrows the pharynx, which can cause airway obstruction and consequent sleep apnea.

Pharyngoplasty

The sphincter pharyngoplasty is commonly used for treatment of VPD.[6,63-67] This procedure is a popular choice because of a perceived decrease in risk of postoperative airway obstruction and a high percentage of coronal and circular closure patterns. Bilateral myomucosal flaps are elevated from the lateral pharyngeal wall to be inserted into an incision on the posterior nasopharyngeal wall at the level of greatest closure. This obturates the posterior and lateral portions of the velopharynx. Movement of the palate to the flap accomplishes closure.[66,67] Sphincter pharyngoplasty is ideally suited for a coronal closure but also is useful in the circular closure if the palate has reasonable motion. This procedure is called a sphincter operation because it was felt that active movement of the myomucosal flap was possible. Although active motion of the flap occasionally is seen, it is not constant.[66,67] There seems to be improved palatal motion after this procedure.[67] The width, length, and degree of overlap of the myomucosal flaps determine the "tightness." Alterations in these three factors can compensate to some degree for limitation of palatal motion seen preoperatively.

The sphincter pharyngoplasty preparation is similar to the previously discussed palatal operations. Because no incisions are made in the palate, injection for hemostasis is only in the lateral pharyngeal wall and posterior nasopharynx.

The palate is retracted with a uvula retractor or red rubber catheters. Preoperative endoscopy or speech videofluoroscopy allows estimation of the amount of obturation needed and the level of maximal palatal excursion. The width of the lateral myomucosal flaps can be altered and the position of the incision for nasopharyngeal insertion decided, as needed. Adjustability is an advantage of this procedure. Even unilateral sphincter pharyngoplasty may be used on occasion.

A posterior incision is made at the level of the maximal palatal excursion. The flap placed at this level will allow the most closure during speech. The incision is carried bilaterally to the posterior limb of the outlined lateral flap. It is not carried through the deep fascia.

The lateral flaps are superiorly based myomucosal flaps. They may include the palatopharyngeal muscle (posterior tonsillar pillar) but can be taken directly from the constrictors.

Many variations are available on the placement of the flaps. Rotation into the velopharynx and suturing to the horizontal incision are necessary. The posterior border of the left flap can be sutured to the superior border of the horizontal incision in the nasopharynx. The right flap is rotated so that the anterior border is sutured to the inferior border of the horizontal incision. The two flaps are then sutured together at the remaining free edge.

The degree of overlap will determine the tightness of the sphincter, the degree of obturation, and obstruction. If vigorous movement of the palate is seen preoperatively, a narrow flap can be taken and secured with less overlap. If little preoperative palatal motion is possible, a wider flap is harvested and the overlap should be maximal.

In the postoperative period, all of these procedures warrant concern related to airway obstruction.[56,68-70] Close monitoring of the patient through the immediate postoperative period for acute obstruction is necessary. Chronic obstruction can manifest as obstructive sleep apnea. The use of CPAP can be helpful to allow resolution of edema and scar maturation. Some children can then "outgrow" the obstruction over time as the dimensions of the pharynx increase with growth.

Posterior Wall Augmentation

In the child who has a very small posterior midline "gap" that causes VPD, augmentation of the posterior pharyngeal wall may be tried. Although many materials have been used, including hyaluronic acid,[71] fat,[72] Teflon,[73] Proplast,[74] and cartilage,[75] most have achieved limited long-term success. A recent animal study looked at the duration of injectable micronized acellular dermal matrix in a submucosal area. Even after only 30 days, little of the injected material remained.[76] Gray and colleagues reported lasting improvement using a "rolled" posterior

pharyngeal flap for autologous posterior wall augmentation.[77] In this procedure, a superiorly based pharyngeal flap is rolled or folded on itself and sutured to make a ridge in the posterior nasopharynx. Success may be variable, however: Durability of the obturation was not seen in a similar study using this technique.[78]

The autologous posterior wall augmentation uses the superiorly based pharyngeal flap. Lateral incisions are made, and the flap is elevated along the deep fascial plane. The flap is folded on itself. The distal end of the flap is secured at the base of the elevated flap into the deep fascia. This creates a mass effect on the posterior velopharyngeal wall. Preoperative endoscopy or speech videofluoroscopy can assist in determining the correct level for positioning the "rolled" flap. As in the pharyngeal flap operation, the posterior wall defect can be partially closed.

Choice of Surgical Intervention

Although basing selection of the surgical intervention on the gap seen at speech videofluoroscopy or endoscopy seems like a reasonable approach, alternative views have emerged. In one series, no difference was seen between superiorly and inferiorly based pharyngeal flaps.[79] A prospective multicenter study randomizing the patients to undergo either sphincter pharyngoplasty or a pharyngeal flap operation suggested no difference in outcomes.[63] Indeed, in centers that use pharyngeal flap operations as the mainstay of management for children with VPI, excellent results are obtained even though the most common closure pattern is coronal.[55] One protocol suggests that the initial decision be based on the orientation of the levators. A Furlow Z-plasty is done if they are suspected not to be horizontally placed. If that fails or if the orientation is normal in a child without a cleft deformity or if the cleft repair included this, a sphincter pharyngoplasty is used.[80]

Fortunately, most reported series do show very good results in the overwhelming majority of the patients. To that end, surgeons should consider maximizing competency in a particular technique and continuing to develop the skills for that technique. An important point is that although the velopharyngeal incompetence can be surgically eliminated, speech therapy may still be needed to correct the articulation errors, especially those that are maladaptive.

Conclusions

The diagnosis, assessment, and management of VPD involve a variety of diagnostic options, assessment tools, and management options. It is helpful for the otolaryngologist, speech-language pathologist, and other team members to take a "transdisciplinary" approach, in which each is thoroughly knowledgeable about the various disciplines involved in the care of children with these problems.[36] Identifying the need for speech therapy and the timely inclusion of surgical management, if needed, demand an understanding of the velopharyngeal mechanism and its relation to phonologic and articulation development, as well as awareness of the various surgical and prosthetic options and their short- and long-term consequences for the child.

CHAPTER ONE HUNDRED AND EIGHTY-EIGHT

Congenital Malformations of the Nose

Ravindhra G. Elluru

Christopher T. Wootten

Key Points

- Most congenital nasal lesions relate to developmental errors in one of three embryologic zones: (1) anterior neuropore; (2) central midface; (3) nasobuccal membrane.
- Encephaloceles, gliomas, and dermoids share a common embryologic origin and frequently manifest as midline nasal masses that require surgical management.
- Appropriate preoperative imaging with CT or MRI, or both, and use of careful intraoperative dissection techniques are required to determine whether a dermoid extends intracranially. In such cases, optimal management consists of a combined approach involving otolaryngology and neurosurgery.
- The most common congenital nasal disorders of the central midface relate to cleft lip deformities. The typical appearance of the nose features a flattened, retracted nostril and a broad nasal tip.
- Congenital nasal pyriform aperture stenosis is associated with holoprosencephaly and a central maxillary megaincisor in a majority of cases. Pituitary abnormalities are also common.
- Up to 30% of infants are born with nasolacrimal duct obstruction, but only those with nasal obstruction and feeding difficulties secondary to nasolacrimal duct cysts require marsupialization.
- Choanal atresia is a relatively common cause of congenital nasal obstruction and more frequently is unilateral in presentation.
- Choanal atresia without a bony component does not exist. Transnasal approaches are the most popular technique. Mucosa-sparing techniques are associated with the best outcomes.

Overview

Congenital malformations of the nose and paranasal sinuses are rare manifestations of disordered development located at the origin of the aerodigestive tract. Clinical presentations range from subtle cosmetic deformities to life-threatening acute upper airway obstruction and feeding difficulties in neonates. This chapter focuses on the most common congenital lesions in the nose and paranasal sinuses. These lesions are considered within the framework of possible developmental errors in specific anatomic zones: (1) errors at the anterior neuropore, (2) errors of the central midface, and (3) errors of the nasobuccal membrane. Mesodermal and germline malformations not unique to the nose and paranasal sinuses also are discussed.

Developmental Errors of the Anterior Neuropore

The anterior neuropore persists medial to the optic recesses in the third week of life, and around it the skull base develops as the frontal, ethmoidal, and nasal bones. Behind the nasal bones but in front of the nasal and septal cartilages lies a potential space, the prenasal space. The foramen caecum forms a defect in the anterior skull base at the apex of the prenasal space, where the cribriform plate ultimately condenses. This structure is closed by its fusion with the fonticulus frontalis, a fontanelle between the inferior aspect of the frontal bones and the developing nasal bones. During the third through the eighth weeks of development, a projection of dura extends through the foramen caecum, traverses the prenasal space, and apposes ectoderm at the tip of the nasal bones (the future rhinion). As the foramen closes, the dural diverticulum detaches from the overlying ectoderm and retracts into the cranium. Irrevocably apposed ectoderm may be pulled posterosuperiorly toward and even through the foramen caecum, giving rise to a dermoid fistula, cyst, or sinus. Faulty or premature closure of the foramen may enable persistence of neural tissue in the nasal cavity as isolated heterotopic glial tissue (glioma) or as a patent central nervous system (CNS) communication (meningocele or encephalocele) (Fig. 188-1). The latter can occur in a paramedian position, as a nasoethmoidal encephalocele, or, more laterally through a medial orbital wall defect, as a naso-orbital encephalocele. Basal encephaloceles herniate posterior to the cribriform plate. Similar errors may occur above the developing nasal bones at the fonticulus frontalis. Intracranial contents may herniate through the patent fonticulus frontalis until the eighth week. If the fonticulus also closes abnormally, the result may be persistence of an extranasal path, leading to nasofrontal meningoceles or encephaloceles or gliomas[1] (Fig. 188-2).

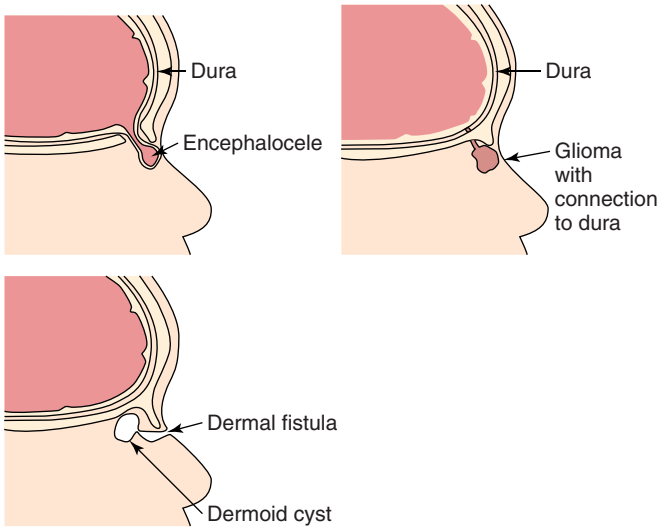

Figure 188-1. Schematic view of the common midline nasal masses.

Figure 188-2. Sincipital encephalocoele. A soft, bluish compressible mass protruding from the glabellar region.

Encephaloceles

An *encephalocele* is an extracranial herniation of cranial contents through a defect in the skull. When the encephalocele includes meninges only, it is termed a *meningocele*; if it includes both brain and meninges, it is termed a *meningoencephalocele*. Estimates of the incidence of these lesions vary considerably, ranging from 1 in 3000 to 1 in 30,000 live births in North America and Europe. The incidence in Asian populations is higher, with a reported incidence of 1 in 6000 live births. Encephaloceles have no familial tendency or gender predilection. Approximately 40% of affected patients have other associated anomalies.[2-4]

Encephaloceles are divided into occipital, sincipital, and basal types (Tables 188-1 and 188-2). Occipital encephaloceles will not be discussed in this chapter as they occur outside the nose. *Sincipital* encephaloceles account for 25% of all encephaloceles, and they are further classified according to their location. Nasofrontal encephaloceles manifest as glabellar masses, causing telecanthus and inferior displacement of the nasal bones. Nasoethmoidal lesions manifest as dorsal nasal masses, causing superior displacement of the nasal bones and inferior displacement of the alar cartilages. Naso-orbital lesions manifest as orbital masses, causing proptosis and visual changes.[1] The anatomic course of each of these sincipital encephalocele presentations is shown in Table 188-1. *Basal* encephaloceles are less common, arising

Table 188-1

Sincipital Encephaloceles

Type	Course	Clinical Features
Nasofrontal	Through bone defect between orbits and forward between nasal and frontal bones to the area superficial to the nasal bones	Glabellar mass Telecanthus Inferior displacement of nasal bones
Nasoethmoidal	Through foramen caecum deep to the nasal bones, turning superficially at the cephalic end of the upper lateral cartilage to expand superficial to the upper lateral cartilage	Mass on the nasal dorsum Superior displacement of nasal bones Inferior displacement of the alar cartilages
Naso-orbital	Through the foramen caecum deep to the nasal and frontal bones through a lateral defect in the medial orbital wall	Orbital mass Proptosis Visual changes

Table 188-2

Basal Encephaloceles

Type	Course	Clinical Features
Transethmoidal	Through the cribriform plate into the superior meatus medial to the middle turbinate	Most common type Nasal obstruction Hypertelorism Broad nasal vault Unilateral nasal mass
Sphenoethmoidal	Passes through a bony defect between the posterior ethmoid cells and sphenoid	Nasal obstruction Hypertelorism Broad nasal vault Unilateral nasal mass
Transsphenoidal	Through a patent craniopharyngeal canal into the nasopharynx	Nasopharyngeal mass Nasal obstruction Associated with cleft palate
Spheno-orbital	Through the superior orbital fissure and out the inferior orbital fissure into the sphenopalatine fossa	Unilateral exophthalmos Visual changes Diplopia

between the cribriform plate and the superior orbital fissure or posterior clinoid fissure and manifesting as an intranasal mass (Fig. 188-3). These masses may not manifest until later in childhood, when they cause nasal obstruction and drainage. Sincipital and basal encephaloceles appear as pulsatile, bluish compressible lesions that transilluminate. Classically, these lesions expand with crying, straining, or compression of the jugular veins.

On histopathologic analysis, sincipital and basal encephaloceles have a glial component, with astrocytes surrounded by collagen, submucosal glands, and sometimes nasal septal cartilage or calcification. When it is difficult to differentiate between gliomas and encephaloceles, the presence of ependymal tissue is consistent with an encephalocele.[5]

High-resolution computed tomography (CT) or magnetic resonance imaging (MRI) delineates encephaloceles and additionally helps to exclude associated anomalies such as agenesis of the corpus callosum and hydrocephalus.[5] CT outlines the bony cartilaginous defect, whereas MRI provides complementary information regarding the soft tissue characteristics of the mass (Fig. 188-4). MRI also differentiates meningoceles from meningoencephaloceles. Sagittal reconstructions and contrast enhancement are particularly advantageous for identifying an intracranial connection.

Once the diagnosis of encephalocele has been made, management is surgical. Most authorities advocate intervention in the first few months of life[2] to minimize the risk of meningitis and cosmetic deformity, but the risk of meningitis is not decreased with prophylactic antibiotics while surgery is being planned. Additionally, early intervention makes the identification of the intracranial connection technically easier and allows more complete repair of the dural defect.[2] Small lesions with minimal skull base defects may be managed endoscopically. Larger lesions require a combined approach with a craniotomy to resect condemned dura and cerebral tissue with concomitant endoscopic removal of the residual nasal tumor. The skull base defect can then be reconstructed using a pericranial flap or split-thickness calvarial bone graft.[5] The most commonly encountered postoperative complications are cerebrospinal fluid (CSF) leak, meningitis, and hydrocephalus. Postoperative neurologic function reflects the patient's preoperative performance. Encephalocele recurrence rates of 4% to10% have been reported.[6]

Gliomas

Gliomas consist of heterotopic glial tissue that lacks a patent CSF communication to the subarachnoid space; however, 5% to 20% of gliomas maintain a fibrous affiliation (see Fig. 188-1). Nasal gliomas are rare and show nonfamilial inheritance. They occur more commonly in males (in a ratio of 3:2). These benign masses manifest as extranasal (60%), intranasal (30%), or combined (10%) lesions.[7] *Extranasal* gliomas are smooth, firm, noncompressible masses that occur most commonly at the glabella, although they may arise along the side of the nose or the nasomaxillary suture line.[2] *Intranasal* gliomas are polypoid pale masses that may protrude from the nostril. The nasal fossa on the involved side may be obstructed. Intranasal gliomas most often arises from the lateral nasal wall near the middle turbinate and occasionally from the nasal septum.[7] Nasal gliomas rarely may extend into the orbit, frontal sinus, oral cavity, or nasopharynx. Because they lack a patent CSF connection, gliomas do not change in size with crying or straining and do not transilluminate.

Pathologically, gliomas are better termed nasal glial heterotopias, nasal cerebral heterotopias, or congenital nasal neuroectodermal tumors. Histologic analysis shows dysplastic, neuroglial, and fibrovascular tissue. Ependymal tissue is not found in gliomas, a distinction that allows differentiation from encephaloceles.

Diagnostic evaluation should include a CT scan to assess the bony anatomy of the skull base, an MRI study to accurately image soft tissue connections to the CNS, and nasal endoscopy to assess the location, origin, and extent of the nasal mass. As with encephaloceles, sagittal reconstructions and contrast enhancement are useful imaging adjuncts.

Proper management of gliomas requires surgical extirpation using a multidisciplinary approach involving otolaryngology and neurosurgery. Delaying intervention may lead to distortion of the septum or nasal bones, or infection. With cosmesis kept in mind, surgical access should provide exposure of the lesion and possible exploration of the skull base. For resection of extranasal gliomas, options include lateral rhinotomy, external rhinoplasty, transglabellar subcranial, bicoronal, and midline nasal approaches.[8] Except in the case of large glabellar lesions, the external rhinoplasty approach provides adequate surgical exposure while minimizing the use of facial incisions.[5] When a fibrous stalk is present that extends deep to the nasal bones toward the base of the skull, a nasal osteotomy is recommended to improve exposure. Following the stalk in its entirety is crucial in determining the possible presence of an intracranial extension. As a result of advancements in surgical instrumentation, image guidance, and surgical techniques, most intranasal gliomas can be removed endoscopically.[9,10] Reported recurrence rates are between 4% and 10%.[11]

Nasal Dermoids

Nasal dermoids are frontonasal inclusion cysts or tracts related to embryologic errors localized to the anterior neuropore. Congenital

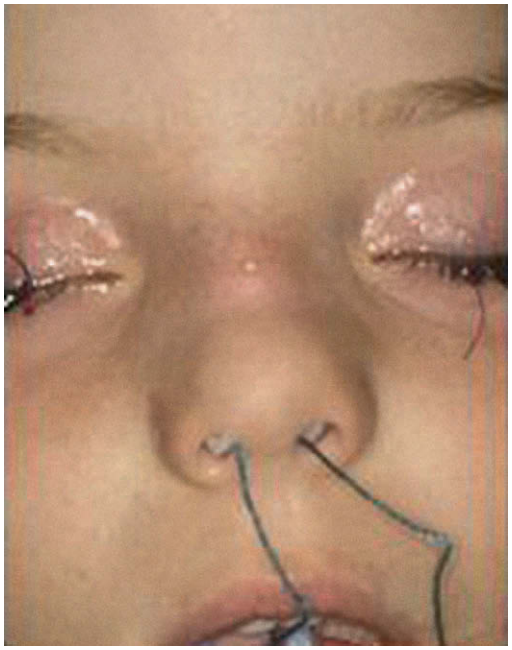

Figure 188-5. Nasal dermoid manifesting as a firm midline nasal swelling associated with a sinus opening.

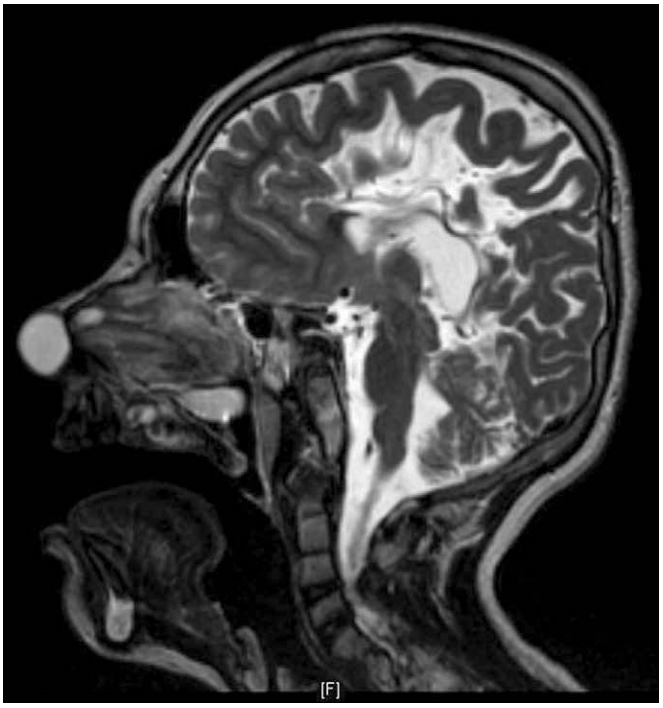

Figure 188-6. Sagittal magnetic resonance image of a nasal dermoid, evident as a region of signal hyperintensity in the anterior nasal septum as a hyperintense lesion.

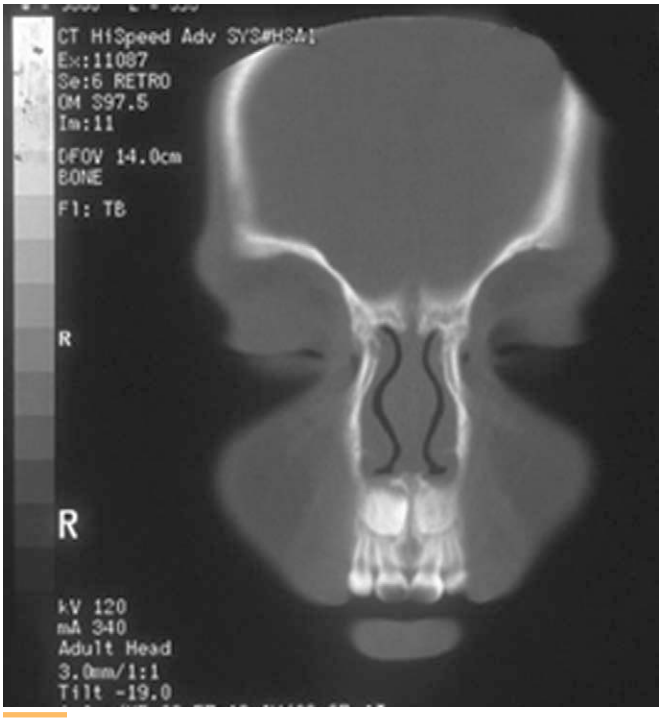

Figure 188-7. Coronal computed tomography scan showing a bifid crista galli and an enlarged foramen caecum.

midline nasal masses occur in 1 in 3000 to 1 in 40,000 live births, and dermoids are by far the most common.[12] Nasal dermoids account for 1% to 3% of all dermoids and approximately 10% to12% of head and neck dermoids. Most dermoid cysts occur sporadically, with a slight male preponderance,[13,14] although familial associations have been reported. Nasal dermoids may accompany aural atresia, pinna deformity, mental retardation, hydrocephalus, branchial arch anomalies, cleft lip and palate, hypertelorism, and hemifacial microsomia in 5% to 41% of presentations.[13]

Nasal dermoids usually manifest as a midline pit or mass. In approximately 50% of clinical presentations, a dimple is present at or near the rhinion, along with a widened nasal bridge; however, the true spectrum of disease includes cysts, sinuses, or fistulas that may occur anywhere along the embryologic line from the nasal tip into the cranial space. Mass lesions are firm, lobulated, and noncompressible and may be associated with a sinus opening (Fig. 188-5) with intermittent caseous discharge or infection. Although a protruding hair is seen in only a minority of patients, it is pathognomic for a nasal dermoid. A lesion within the nasal septum will cause nasal obstruction. Intracranial extension rates range from 4% to 45%.[13] Recurrent meningitis with typical skin flora may indicate an intracranial tract. Nasal dermoids do not enlarge with crying or straining and do not transilluminate.

Unlike teratomas, which contain all three embryonal germ layers, congenital dermoids contain only ectodermal and mesodermal embryonic elements. The latter include hair follicles, sebaceous glands, and sweat glands that are found in the wall of the cyst and thus differentiate these masses from simple epidermoid cysts. Keratin debris is another prominent feature on histologic examination, and dermoids also lack the glial features of encephaloceles and gliomas.

CT and MRI provide complementary information in the radiologic evaluation of nasal dermoids. Thin-slice (1 to 3 mm) CT scans with intravenous contrast are recommended to differentiate the dermoid from the surrounding nasal mucosa and to define the bony anatomy of the nose and anterior skull base (Fig. 188-6). Unique findings with intracranial dermoids include a bifid crista galli (Fig. 188-7) and an enlarged foramen caecum; a normal crista galli and foramen caecum may be used to exclude intracranial extension.[15] Multiplanar, thin-section contrast-enhanced MRI is used to depict the soft tissue anatomy of the anterior skull base, and contrast-enhanced MRI distinguishes the nonenhancing dermoid from enhancing lesions such as hemangiomas and teratomas. The neonatal crista galli does not contain marrow fat, so high signal intensity on T1-weighted images is suggestive of an intracranial dermoid.

As with other congenital anterior neuropore lesions, the management of nasal dermoids is surgical. Because aspiration, incision and drainage, curettage, and subtotal excision are associated with high recurrence rates, these management approaches generally are not advocated. Assessing the degree of intracranial extension is crucial, and in

patients with features suggestive of intracranial extension, a combined intracranial-extracranial approach should be planned with the participating neurosurgeon. Extracranial access should fulfill four criteria: (1) excellent access to the midline; (2) access to the base of the skull; (3) adequate exposure for reconstruction of the nasal dorsum; and (4) an acceptable scar.[16] Several different extracranial approaches have been described. The external rhinoplasty incision generally gives the best cosmetic result and is therefore the most widely used approach. This approach also gives access to the skull base and allows for exposure of the nasal dorsum; nevertheless, it provides limited access to lesions in the glabellar region. Alternative approaches include lateral rhinotomy and midline vertical incisions, both of which provide excellent access.[13] For lesions in the glabellar area without a sinus tract, a transglabellar subcranial approach, a paracanthal incision, or a bicoronal approach is an acceptable alternative. Glabellar lesions with a sinus opening require an elliptic incision to excise the ostium, despite the possibility of a widened scar.

For lesions that extend into the cranial cavity, a multidisciplinary effort is required to perform a frontal craniotomy. This usually is carried out through a coronal incision using a combined intracranial-extracranial approach with a large frontal craniotomy; however, anterior small window craniotomies have been described.[17] Sessions[18] has suggested that craniotomy may be avoided altogether and the tract sutureligated if it is devoid of epidermal and adnexal structures at the skull base. This information can be obtained by intraoperative frozen-section analysis of the tract. A number of investigators[13,15] agree with this approach. Other workers[19] have suggested that epidermal elements may be staggered along the tract and thus postulate that a single biopsy site may provide false-negative information regarding the presence of an intracranial extension of the dermoid tract. The overall recurrence rate after adequate excision is low; however, long-term follow-up is essential to diagnose the occasional late recurrence.

Developmental Errors of the Central Midface

Eruption of nasal pits into the choana, fusion of the palatal shelves, and growth of the nasal septum and soft palate coincide with the development of the lateral nasal wall and primitive sinus anatomy. For normal nasal and paranasal growth to occur, all of these rapid changes must take place with complete precision.[1]

Normal nasal development occurs between weeks 4 and 12 of life. During this time, neural crest cells migrate from their origin in the dorsal neural folds around the eye to form the first and second branchial arch–derived facial prominences surrounding the stomodeum. The stomodeum is surrounded by the frontonasal prominence superiorly, the maxillary processes laterally, and the mandibular processes inferiorly. The nasal placodes, which are two small thickenings in the frontonasal prominence, begin to burrow, forming nasal pits. This invagination process in the fifth week creates ridges of tissue around the pit; these are called the lateral nasal prominences laterally and the medial nasal prominences medially. Nasolacrimal duct development begins as a thickening of the ectoderm that becomes buried in the mesoderm of the nasal pits between the lateral nasal prominence and the maxillary process. This buried ectoderm canalizes from superiorly to inferiorly postnatally. The lateral and medial prominences finalize interaction with the developing maxillary process, creating the philtrum and medial lip (from the fused medial nasal prominences) and the lateral upper lip (from the maxillary prominences). The lateral nasal prominences form the nasal alae (Fig. 188-8).

Errors in central midface development underlie a host of congenital anomalies. Arhinia (congenital absence of the nose) may result from (1) abnormal migration of neural crest cells; (2) failure of fusion of the medial and lateral nasal processes; (3) overgrowth and premature fusion of the medial nasal processes; or (4) lack of resorption of the nasal epithelial plugs.[20] Similarly, polyrhinia probably results from incomplete development of the frontonasal process, which subsequently allows separation of the developing lateral portions of the nose.[1,21,22] The medial nasal processes and the septum continue to develop as scripted and are duplicated, thereby forming a "double nose."[1,2,11,23] Proboscis lateralis may result from mesodermal proliferation errors in the frontonasal and maxillary processes adjacent to the forming nasal pits. Epidermal breakdown then occurs, leaving the lateral nasal process sequestered as a tube arising in the frontonasal region. Also, because of this breakdown, the nasolacrimal duct is not formed.[1] Independent of proboscis lateralis, failure of the nasolacrimal ectodermal tract to canalize postnatally may result in formation of a nasolacrimal duct cyst in an otherwise normal patient.

Midline and paramedian fusion errors produce midfacial clefting. This may be isolated to the midface or occur as a part of cephalic clefting (Robert's syndrome) or holoprosencephaly. Errors in fusion of the medial nasal prominences with the medial aspect of the maxillary process produce a cleft lip, with its accompanying congenital nasal deformity. Finally, deficient development of the primary palate and bony overgrowth of the nasal process of the maxilla[24] are responsible for congenital nasal pyriform aperture stenosis. A developmental deficiency of the incisive os could explain the occurrence of a triangular plate, the narrow inferior portion of the nasal cavity, and the associated central maxillary mega-incisor, which is seen in 60% of cases[25] (Fig. 188-9). The term *holoprosencephaly* was introduced by DeMyer and coworkers to describe median facial anomalies and the brain morphology associated with these anomalies.[26] Holoprosencephaly is a failure of the embryonic forebrain to cleave sagittally into cerebral hemispheres, transversely into a diencephalon, and horizontally into olfactory and optic bulbs. This failure is associated with a spectrum of facial anomalies including (1) cyclopia (single eye and single orbit with arhinia and proboscis); (2) ethmocephaly (extreme hypertelorism, separate orbits, and arhinia; (3) cebocephaly (hypertelorism and proboscis-like nose without cleft lip); (4) median cleft lip (orbital hypertelorism and flat nose); and (5) median philtrum-premaxilla anlage (hypertelorism, bilateral cleft lip, and a median process representing the philtrum-maxilla anlage).

Complete Agenesis of the Nose (Arhinia)

Arhinia is part of the holoprosencephaly spectrum. This malformation is extremely rare, with approximately 30 cases described in the literature (Fig. 188-10). In the few reported cases, arhinia generally is sporadic in inheritance and may occur either as an isolated defect or in association with other facial and cerebral abnormalities.[27] Associations with genetic disorders such as trisomy 10, trisomy 13, and trisomy 21, as well as chromosome 9 inversion and translocation of chromosomes 3 and 12, also have been reported.[3,27,28]

The features of arhinia include absence of the external nose and nasal airways, hypoplasia of the maxilla, a small high-arched palate, and hypertelorism. Affected infants display respiratory distress and cyanosis associated with feeding. Older children may gulp food between breaths. Speech is characteristically hypernasal, and patients demonstrate evidence of hyposmia. Physical examination reveals an absence of the external nose, nasal septum, and sinuses. Rare associated abnormalities of the eye include anophthalmia and hypoplasia of the orbits.

Early management of arhinia focuses on nutrition. A cleft palate feeder or a gastrostomy tube is required. A prosthetic nose may be used until the child is older and can undergo definitive surgical repair. Vertical distraction osteogenesis of the midface has been reported to increase midfacial height, maximizing bone and soft tissue for later reconstruction.[29] Re-establishing the nasal passageway requires removing the incisors, creating an airway through the maxilla, and releasing the high-arched palate. The nasal passage is then lined with split-thickness skin grafts and maintained with long-term stenting. Restenosis is common, and serial dilations are required. Reconstruction of the external nose is a multistage procedure that requires the use of tissue expanders, bone, cartilage or prosthetic grafts, and local or regional skin flaps, with concomitant dacrocystorhinostomy to prevent recurrent conjunctivitis resulting from absence of the nasolacrimal ducts.[30]

Polyrhinia and Supernumerary Nostril

Polyrhinia (double nose) and supernumerary nostril (accessory nostril) are extremely rare anomalies, with only four reported cases of each.[21] These deformities may occur in isolation or in association with pseudohypertelorism. Patients with polyrhinia generally present with anterior (septal duplication, duplicated nasal passageways) and posterior (choanal atresia) nasal defects. The primary step in surgical

management is correction of the choanal atresia. The nasal deformity is later corrected by removing the medial portions of each nasal passage and anastomosing the lateral portions in the midline.[2] The result is a broad flat nose with a depression in the midline, which can be corrected later on by medial in-fracture of the nasal bones and additional rhinoplasty techniques.

Supernumerary nostril manifests with the external appearance of a small accessory nasal orifice with surrounding redundant soft tissue. The orifice may be lateral, medial or superior to the nose. With a true fistula, a discharge from this orifice may occur. Treatment entails excision of the supernumerary nostril and primary closure of the defect or closure with the assistance of local flaps.[21]

Proboscis Lateralis

Proboscis lateralis is a rare disorder that manifests as a tubular sleeve of skin attached to the inner canthus of the orbit and heminasal aplasia on the affected side (Fig. 188-11). This deformity is thought to be secondary to fusion of the maxillary process on the affected side with the contralateral developing nasal process. Approximately 30 cases have been reported in the recent literature. Proboscis lateralis is associated with other CNS abnormalities and congenital ocular lesions, such as microphthalmus, coloboma, and arachnoid cysts. The diagnosis is made by physical examination, nasal endoscopy, and CT scanning. Treatment is delayed until facial growth is complete, and a prosthetic device is worn until reconstructive efforts begin. Reconstruction involves the use of bone and cartilage grafts and surrounding skin, including the tube of anomalous lateral nasal skin. Restenosis is common, and serial dilations with stenting often are required.[2]

Craniofacial Clefts

Craniofacial clefts are exceedingly rare and generally are not encountered in routine clinical practice. The hallmarks of this disorder are ocular hypertelorism; a broad nasal root; lack of formation of the nasal tip; anterior cranium bifidum occultum; median clefting of the nose, lip, and palate; and unilateral orbital clefting or notching of the nasal ala.[1,31] DeMyer[32] noted an association among hypertelorism, cephalic anomalies, and mental deficiency. The Tessier classification of cranial clefts[23] is the most widely used. This classification is based on specific axes (0 to 14) along the face and cranium. Because the orbit is common to the face and cranium, it distinguishes cranial clefts (9 to 14) from facial clefts (0 to 8).

There is a large degree of variability in the severity of median nasal clefts. This deformity, also known as bifid nose and internasal dysplasia, can range from a simple median scar at the cephalic end of the nasal dorsum to a completely split nose, forming separate halves with independent medial nasal walls. Disparate associations have been reported in the literature. A median cleft lip is a frequent associated anomaly.[33] The airway usually is adequate despite the cosmetic appearance. Before surgical reconstruction, it is important to rule out a possible dermoid cyst or encephalocele within the nasal-septal area. Surgical reconstruction requires the cooperative efforts of a multidisciplinary team, and treatment outcomes depend largely on the severity of the midline dysraphia.

Lateral nasal clefts are rare anomalies that involve defects of the lateral nasal wall or ala. They range from scarlike lines in the ala to triangular defects extending into the inner canthal fold and affecting the nasolacrimal apparatus. As with median nasal clefts, lateral nasal clefts require surgical reconstruction using a multidisciplinary approach.

Cleft Lip Nasal Deformity

Cleft lip deformity is among the most common congenital abnormalities of the head and neck. A complete cleft lip extends into the floor of the nose, whereas an incomplete cleft extends only partway through the upper lip. Cleft lip deformity shows a male predilection. Overall, the incidence of cleft lip and palate, singly or in combination, is between 1 in 1000 and 1 in 4000 live births. One half of these demonstrate cleft lip and palate, whereas 20% involve cleft lip alone. The distribution of left, right, and bilateral cleft lip deformities is approximately 6:3:1.

All complete clefts and many incomplete clefts involve the nose. The most severe defects are those associated with a bilateral complete cleft. Children with a bilateral deformity have a flattened nasal tip and a shortened columella. They also may have bilateral maxillary hypoplasia and relative prognathism. Less severe deformity is seen in children with unilateral clefting. In these children, the nasal ala on the side of the cleft is more laterally based, giving the appearance of a flat, retracted nostril. The caudal septum also is displaced to the cleft side. The maxilla on the cleft side is hypoplastic, and the nasal tip has a bifid appearance.

Treatment options for nasal deformities associated with cleft lip include both primary and secondary rhinoplasty. Many surgeons undertake redraping of the skin–soft tissue envelope over the lower lateral cartilages at the time of initial cleft lip repair within the first year of life. The flattened appearance of the nostril may be corrected by anchoring the skin–soft tissue envelope more medially on the lower lateral cartilage. This correction also adds definition to the tip subunit. Later, during a second procedure, a laterally based chondrocutaneous sliding flap procedure is performed to reposition the alar base; this often is combined with a columellar strut or shield graft placement to project the foreshortened columella. The secondary operation often is divided into stages. Stage 1, performed at the ages of 4 to 6 years, aims at providing cosmetic improvement. Stage 2, performed at ages 8 to 12 years, follows orthodontic correction and has the goal of making available an optimal skeletal framework. More definitive rhinoplasty is delayed until skeletal growth is completed. Accordingly, it is performed at the ages of approximately 16 to 18 years.[34] Both open and closed rhinoplasty techniques have been used.

Congenital Nasal Pyriform Aperture Stenosis

Congenital nasal pyriform aperture stenosis (CNPAS) is a rare anomaly that occurs secondary to bony overgrowth of the nasal process of the maxilla and typically manifests in the first few months of life. The stenosis may occur in isolation, or the patient may present with a central mega-incisor and the holoprosencephaly spectrum of congenital midline lesions. Hypertelorism, a flat nasal bridge, and the central mega-incisor are clinical features of the premaxillary dysgenesis associated with holoprosencephaly. Pituitary disorders and dental and facial anomalies also are part of this spectrum.

The pyriform aperture is the narrowest part of the nasal cavity, and small changes in the cross-sectional area significantly affect airflow by increasing nasal airway resistance. Newborns present with symptoms

Figure 188-12. Congenital nasal pyriform aperture stenosis, as seen on anterior rhinoscopy.

Figure 188-13. Axial computed tomography scan showing pyriform aperture stenosis secondary to overgrowth of the nasal process of the maxilla, causing reduction in the width of the piriform aperture.

similar to those of choanal atresia, and failure to pass a nasopharyngeal catheter may result in a misdiagnosis of choanal atresia. In older infants and children, nasal obstructive symptoms may be triggered by an upper respiratory infection, which further compromises the already narrow airway.

The diagnosis of CNPAS is established by physical examination and is best confirmed by CT, which shows that the width of the pyriform aperture, the cross-sectional area of the nasal cavity, and the width of the choana all are reduced. By contrast, the height of the nasal cavity and cross-sectional area of the choana are not altered (Figs. 188-12 and 188-13). Belden and colleagues[35] found the most helpful CT measurement to be the width of the pyriform aperture, defined as the distance between the medial aspects of the maxillae at the level of the inferior meatus, as measured on images in the axial plane. These workers reported that the width was never greater than 8 mm in their CNPAS group and never less than 11 mm in their control group. It is prudent for patients with a central maxillary incisor to undergo further investigation, to include central imaging for evaluation of CNS malformations, chromosomal analysis, and pituitary function testing.[36]

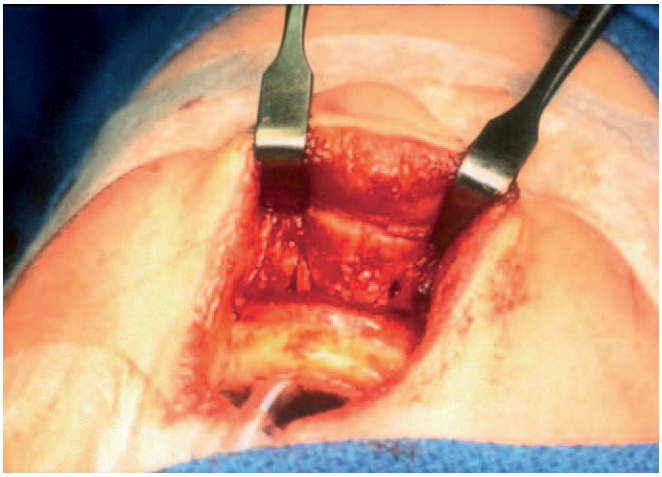

Figure 188-14. Sublabial approach to the piriform aperture. A gingivobuccal sulcus incision is made and a mucoperiosteal flap is raised to expose the piriform aperture.

Operative management is not always necessary for patients with CNPAS. Nonoperative management with nasal tubes and topical vasoconstrictive drops may be all that is required until growth results in increased nasal airway size. In patients who require surgery, repair is best accomplished through a sublabial approach, exposing the inferior and lateral pyriform aperture (Fig. 188-14). An otologic drill is used to widen the bony lateral and inferior margins. Brown and associates[24] recommend the use of nasal stents for up to 4 weeks.

Nasolacrimal Duct Cysts

Nasolacrimal duct cysts (dacrocystoceles) are uncommon abnormalities of the inferior meatus. These abnormalities may lead to nasal obstruction, respiratory distress, and epiphora. Although approximately 30% of all neonates have distal nasolacrimal duct obstruction at birth, formation of symptomatic cysts occurs only rarely in these children. The duct begins canalization at its lacrimal end and progresses inferiorly. In addition to producing nasal obstructive symptoms, the presence of a nasolacrimal duct cyst also makes neonates susceptible to aspiration and feeding difficulties. Infants with bilateral dacrocystoceles are the most severely affected. In most affected children, obstruction spontaneously resolves by 9 months of age.

The diagnosis of nasolacrimal duct cysts is made by anterior rhinoscopy or nasal endoscopy, which demonstrates a cystic mass in the inferior meatus (Fig. 188-15). This can be confirmed on a CT scan. The classic features evident on imaging are a dilated nasal lacrimal duct, an intranasal cyst, and cystic dilation of the lacrimal sac.[37]

Operative management is indicated for infants who have feeding problems, infection, or respiratory obstruction. The cyst is marsupialized endoscopically into the inferior meatus, opening the lesion with a curette or microsurgical débrider. This is best accomplished by a multidisciplinary team that includes an ophthalmologist, who may need to perform nasolacrimal duct probing and possible placement of nasolacrimal duct stents.

Developmental Errors of the Nasobuccal Membrane

During the third and fourth weeks of development, paramedian ectodermal nasal placodes appear. The nasal placodes, which are two small thickenings in the frontonasal process, begin to burrow, forming nasal pits. As these pits develop into the pouches of the nose and paranasal sinuses, the nasal pouches come to lie above the oral and buccal cavity. The nasobuccal membrane separates the nasal and oral or buccal spaces, and choanal atresia probably derives from failure of the nasobuccal membrane to rupture in the fifth and sixth weeks of development. An alternative theory suggests that abnormal migration of neural crest cells

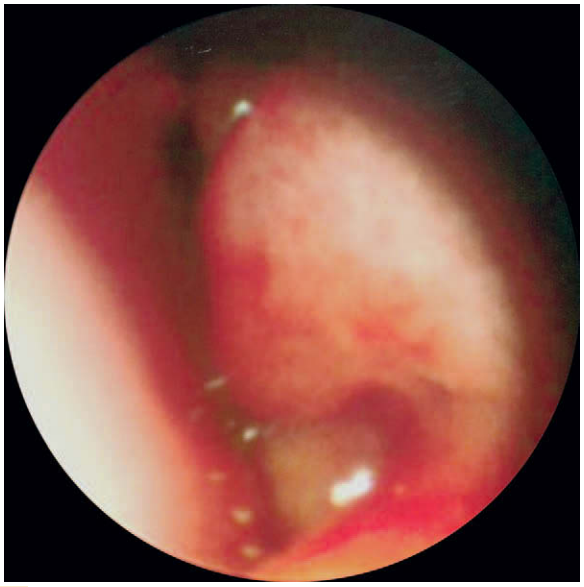

Figure 188-15. Left nasolacrimal duct cyst in the inferior meatus, as seen on anterior rhinoscopy.

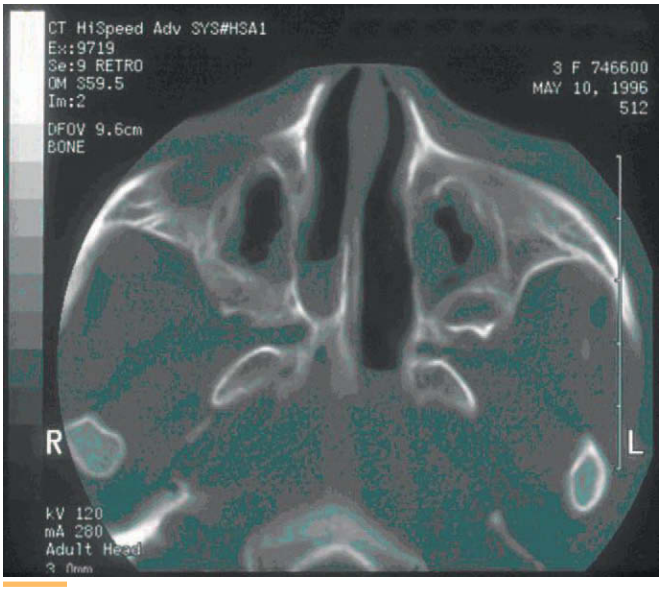

Figure 188-16. Axial computed tomography scan of unilateral choanal atresia, with a complete bony atretic plate and associated soft tissue.

results in choanal atresia. This theory is supported by the high incidence of choanal atresia in patients with mandibulofacial dysostosis (Treacher Collins syndrome), which is associated with abnormal neural crest migration.

Choanal Atresia

Choanal atresia occurs when the posterior nasal cavity fails to communicate with the nasopharynx.[1] This anomaly has a reported incidence ranging from 1 in 5000 to 1 in 8000 live births.[38] Up to two thirds of cases are unilateral, with atresia most commonly occurring on the right side.[1] Fifty percent of all patients with choanal atresia and up to 75% of patients with bilateral disease have other associated congenital anomalies.[2] These anomalies include CHARGE syndrome (*c*oloboma, *h*eart defects, *a*tretic choana, *r*etardation of growth and development, *g*enitourinary disorders, and *e*ar abnormalities); polydactyly; nasal, auricular, and palatal deformities; Crouzon's syndrome; craniosynostosis; microcephaly; hypoplasia of the orbit and midface; cleft palate; and hypertelorism.[39,40] The anatomic features that characterize choanal atresia include (1) a narrow nasal cavity; (2) lateral bony obstruction by the pterygoid plates; (3) medial obstruction caused by thickening of the vomer; and (4) membranous obstruction.[41-43] In a study conducted by Brown and associates,[41] the incidence of pure bony atresia was found to be 29%, whereas that of mixed bony-membranous atresia was 71%. No patients were found to have a purely membranous atresia.

The clinical presentation of choanal atresia varies between unilateral and bilateral disease. Patients with unilateral disease present later in life with rhinorrhea and nasal obstruction. On anterior rhinoscopy, the occluded nasal cavity is typically filled with thick, tenacious secretions. Patients with bilateral choanal atresia typically present as newborns with cyanotic events. An event begins with increasing efforts to breathe, tight mouth closure, and chest retractions followed by cyanosis. The cycle is broken by crying. A variant of bilateral choanal stenosis presents later in life with mouth breathing, recurrent sinusitis, chronic rhinorrhea, otitis media, failure to thrive, and defects of speech.

The diagnosis of choanal atresia is made clinically by failure to pass a 6F catheter through the nose into the nasopharynx (a distance of approximately 32 mm). CT is used to confirm the diagnosis and reveal the nature and thickness of the atresia.[44] Suctioning and pharmacologic vasoconstriction before imaging will improve resolution (Figs. 188-16 and 188-17). CT scanning also differentiates between complete atresia and stenosis. A diagnosis of choanal stenosis is made

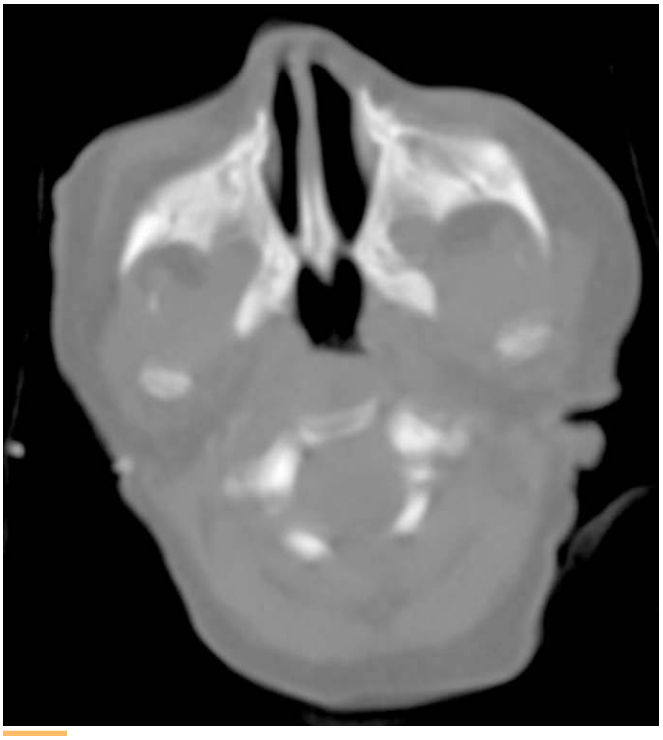

Figure 188-17. Axial computed tomography scan showing bilateral chonal atresia with soft tissue.

with recognition of a narrowed yet patent choana. Derkay and Grundfast[45] more specifically define this entity as a choanal space less than 6 mm across. This diagnosis should be confirmed by endoscopic evaluation (Fig. 188-18).

Unilateral atresia does not constitute an emergency. Treatment is delayed for several months, allowing for growth of the nose, which enhances the ease of surgery and reduces the risk of postoperative complications and restenosis. Bilateral atresia requires an initial intervention to establish an oropharyngeal or orotracheal airway and gastric feeding before definitive surgery. The timing of surgery is variable, and it may be preferable to wait several months until adequate facial growth has occurred (similar to the timing of cleft lip repair). In patients with

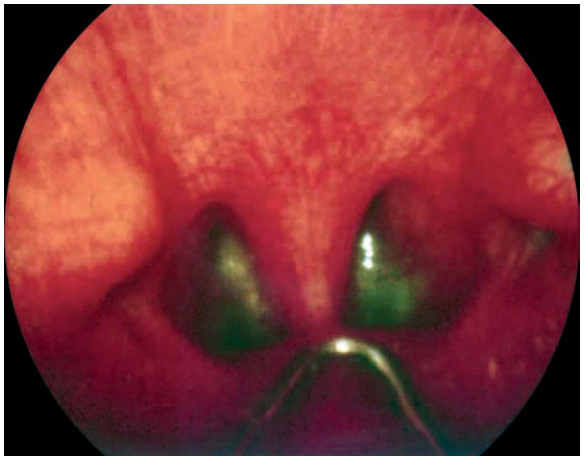

Figure 188-18. A view of bilateral choanal atresia through a 120-degree nasopharyngoscope.

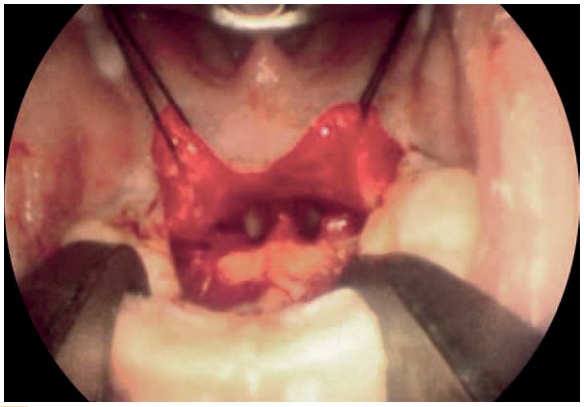

Figure 188-19. Transpalatal approach to choanal atresia repair. A pedicled hard palate mucoperiosteal flap based on the greater palatine artery is elevated to expose the choanae.

additional indications for tracheotomy, a surgical airway is obtained and definitive atresia repair is often delayed, allowing for facial growth. A shift has occurred in the surgical philosophy over the last few decades away from transpalatal (Fig. 188-19) and toward transnasal surgery. This shift can be attributed to reports citing a lower risk of dental and facial growth abnormalities associated with the latter approach. Most techniques begin the repair by perforating the atretic plate at its thinnest portion, using a urethral sound or suction instrument. A 0-degree transnasal endoscope or a 120-degree nasopharyngoscope is used for visualization (see Fig. 188-14). Subsequently, a backbiting forceps, a microsurgical débrider, a laser, and a drill are used as necessary to remove choanal soft tissue and bone. The posterior tip of the middle turbinate is a useful anatomic landmark. Restricting surgical maneuvers to remain inferior to this structure reduces the risk of intracranial injury.[46] The importance of stenting, as well as the use of fibroblast inhibitors (mitomycin C) and the preservation of mucosal flaps, remains controversial. Regardless of the techniques used, most studies[47,48] report significant recurrence rates, necessitating revision surgery. The lowest recurrence rates are seen in older children (with unilateral atresia), nonsyndromic patients, and patients who have undergone surgical procedures that minimize mucosal trauma.

Other Mesodermal and Germline Malformations

Mesodermally derived lesions such as hemangiomas and lipoblastomas may occur in the head and neck, although they rarely occur in the nose. These lesions present unique management challenges to the otolaryngologist or facial plastic surgeon. Similarly, germline malformations such as teratomas rarely localize to the nasopharynx. These foci may be remnants of normal embryologic structures that break off or fail to migrate along well-defined pathways to their normal destination.[49] The management of cutaneous hemangiomas follows principles detailed elsewhere in this text; the unique presentation and management of nasopharyngeal teratomas are described in this section.

Intranasal Hemangiomas

Infantile hemangiomas are discussed more fully elsewhere in this text. As suggested by Waner and colleagues, glucose transporter isoform 1 (GLUT1)-positive infantile hemangiomas have a predilection for embryonic fusion planes on the central face.[50] Thus, deep midface infantile hemangiomas may involve or distort the nasal lining. More typically, the intranasal hemangiomas described in the literature are lobular capillary hemangiomas and reparative cavernous hemangiomas. These noninfantile hemangiomas are GLUT1-negative and have been noted on the septum, the middle and inferior turbinates, and the lateral nasal wall.[51] These lesions frequently manifest with epistaxis and nasal obstruction. On examination, the hemangiomatous masses are friable, sessile or pedunculated, and reddish-purple in color. MRI shows high signal intensity on T2 sequences and enhancement with gadolinium on T1 sequences. CT may show associated bony remodeling. Whereas true infantile hemangiomas are amenable to both surgical and nonsurgical management, lobular capillary hemangiomas and cavernous lesions are treated by wide local excision of the lesion using endoscopic or open (midface degloving, open rhinoplasty, lateral rhinotomy) approaches.[51,52] Preoperative angioembolization has been described for larger lesions. The prognosis is excellent with complete excision.

Nasopharyngeal Teratomas

Teratomas are the most common germ cell tumors of childhood and are almost always benign. These lesions comprise representative tissues from each of the three embryonic germ layers (ectoderm, endoderm, and mesoderm) and generally contain tissues foreign to the anatomic site of origin. Teratomas occurring in infancy and early childhood generally are extragonadal, whereas those manifesting in older children more commonly occur in the ovary or testis.[53] Teratomas of the head and neck account for less than 5% of all teratomas. These rare neoplasms, which reportedly occur in 1 in 20,000 to 1 in 40,000 live births, may be located in the brain, orbit, oropharynx, nasopharynx, or cervical region.

Clinically, nasopharyngeal teratomas may be sessile or pedunculated and often protrude through the mouth. Anencephaly, hemicrania, and palatal fissures are associated with these lesions. The newborn usually presents with severe acute respiratory distress requiring endotracheal intubation or tracheotomy. In patients with smaller lesions, feeding difficulties may be the only presenting symptom.[54]

The diagnosis of congenital nasopharyngeal teratoma begins in utero. Maternal clinical characteristics may include polyhydramnios due to impaired swallowing and elevated α-fetoprotein levels. Larger lesions often are diagnosed by prenatal ultrasound examination. Such early detection enables planning for an EXIT (ex utero intrapartum treatment) procedure to secure the infant's airway before division of the maternal-fetal circulation. For lesions manifesting postnatally, fine needle aspiration may be used to assist in establishing the diagnosis.[54] Imaging is confirmatory. Lesions are seen as cystic and solid areas of fat density on CT and MRI (Fig. 188-20). Areas of bone and tooth formation may be present. Most nasopharyngeal teratomas are well encapsulated and demonstrate no intracranial connections.

The management of nasopharyngeal teratomas is surgical, and the approach depends greatly on the size of the lesion. Lesions can be excised through a transoral approach with or without endoscopic assistance. This approach may require splitting of the soft palate or palatal resection. Endoscopic assistance may obviate the need for palatal division or resection.[49] External approaches using a lateral rhinotomy incision or a transcervical incision also are used. If an intracranial component is present, a craniofacial approach is necessary. Outcomes generally are good, and α-fetoprotein levels are periodically measured to monitor for recurrence.

CHAPTER ONE HUNDRED AND EIGHTY-NINE

Pediatric Facial Fractures

Paul R. Krakovitz

Peter J. Koltai

Key Points

- After the first month of life, trauma is the number one cause of pediatric deaths and a major contributor to long-term morbidity.
- Nasal fractures in children are the most common fractures of the facial bones in this age group. Mandible fractures are the most common facial fractures in children requiring hospitalization.
- Pediatric facial fractures often are complicated by associated neurocranial injury.
- Owing to rapid changes in facial dimensions with growth, patterns of fractures differ significantly among various pediatric age groups and between children and adults.
- Fractures to the developing body and ramus of the mandible are less likely to cause growth disturbance.
- Fractures to the developing mandibular condyles and the midface often lead to developmental deformities.
- Rigid fixation with plates and screws is avoided in the management of pediatric fractures unless the original features cannot be restored by simpler, less invasive means. These materials should be used in short segments so that crossing more than one osseous suture line is avoided. Use of resorbable plating systems is confined to non–load-bearing bone.
- After septal hematoma initially is ruled out in the evaluation of a child with a nasal injury, reexamination 3 to 5 days later is indicated to allow time for the resolution of edema. An accurate diagnosis can then be made in regard to a displaced nasal fracture, which if present necessitates reduction. Occult nasoethmoidal fracture is suspected when the clinical findings include marked flattening of the nasal dorsum.
- With internal fixation of fractures of the mandible or maxilla in children younger than 13 years, an understanding of the position of unerupted tooth buds is crucial. In regard to the mandible, monocortical miniplates are drilled in the lowermost margin.
- Maxillomandibular fixation is limited to 2 to 3 weeks and is followed by 6 to 8 weeks of use of guiding elastic bands.
- Delayed periorbital hematoma suggests fracture of the orbital roof.
- With extensive fractures of the orbital floor or demonstrable muscle entrapment, early surgery is appropriate. With more isolated injuries, waiting 7 to 10 days may prevent an unnecessary operation.

After the first month of life, trauma is the number one cause of pediatric deaths and a major contributor to long-term morbidity.[1,2] Nearly 15,000 children die and 100,000 others are disabled worldwide each year from trauma resulting from motor vehicle crashes, sports injuries, falls, altercations, and abuse.[2] More than $15 billion is spent annually in the United States for the treatment of childhood injuries.[1,3] Despite this epidemic of injuries, facial fractures in children remain uncommon.

Reconstruction of pediatric facial fractures requires an understanding of craniofacial development and of the consequences of injury for future growth. The patterns of facial fracture differ significantly not only between adults and children but also among pediatric age groups. Although some of the treatment strategies for facial fractures in adults and children are similar, children need to be considered in a different management algorithm because the repair of bony injuries is best accomplished by techniques that may adversely affect craniofacial development. This dilemma renders the treatment of facial fractures in children controversial. It is not possible to resolve all of the issues related to treatment; however, a rational approach to treatment that yields consistently excellent results can be formulated.

Epidemiology

Pediatric maxillofacial injuries account for approximately 5% of all facial fractures, although the incidence is reported as being between 1.5% and 15%.[4-18] Children younger than 5 years of age account for only 0.9% to 1.2%, whereas those 6 to 14 years of age account for 4% to 6% of all cases of maxillofacial trauma.[19,20] Bamjee and colleagues[19] found that 7% of pediatric traumatic injuries occur in children younger than 6 years, whereas 70% befall those between 13 and 18 years of age, indicating the increased vulnerability of the maturing face as well as the greater risk-taking behavior of a growing child.

In children, males are more prone to maxillofacial fractures than females, with an overall ratio of 1.5:1 to 2.3:1.[18,21-24] In children younger than 8 years, no difference between genders has been noted.[25] With approaching adolescence and greater involvement in sports and violence, the male-to-female ratio approaches 4.5:1.[25] In South Africa,

male children are three times more likely to be involved in violence resulting in facial fractures; however, other types of injuries resulting in facial fractures are gender-neutral.[19] Nasal fractures are the most common fractures of the facial bones in children. Because most nasal fractures are treated in an office setting, precise statistics on their frequency are difficult to determine. Limited studies have reported the incidence to be between 45% and 60% of all facial fractures.[26,27]

Mandible fractures are the most common facial fractures in children requiring hospitalization. Depending on whether nasal fractures are included, mandible fractures account for between 5% and 50% of reported pediatric facial fractures.[1,16,21] The condyle is the most common site, accounting for 40% to 70% of mandibular fractures.[11,18,22,28] Mandibular body (0 to 20% of fractures, depending on the series), angle (3% to 17%), ramus (3% to 10%), and symphyseal fractures (2% to 30%) occur less frequently in young children.[9,12-14,22,25-27,29-37] As adolescence approaches, the incidence of fractures of the arch and body of the mandible reflects a more adult pattern.[38] Dentoalveolar fractures, like nasal fractures, often are treated in an office setting; hence, it is difficult to gauge their true frequency, which probably is higher than the 14% incidence reported in one large study.[29]

Complex facial fractures are rare in children. The literature shows a wide range of anatomic distribution. Reported incidence rates for orbital fractures range from 0.2% to 30%; for zygomatic complex fractures, 2.7% to 13.5%; and for Le Fort type fractures, 0 to 16%.[9,17,26,27,39,40] The sporadic distribution of midface injuries, especially among preadolescent children, highlights their uniqueness and emphasizes how limited a particular surgeon's experience can be with these complex injuries.

Associated injuries are a common feature of childhood maxillofacial trauma. In the pediatric age group, intracranial, intra-abdominal, and orthopedic injuries are associated with more severe types of facial fractures in 30% to 60% of the cases.[8,9,38,41] Temporal bone and soft tissue injuries also are commonly associated with facial fractures.[9] In young children, up to 86% of orbital roof fractures are associated with frontal skull fractures and concomitant intracranial injuries.[7,42] In 30% of orbital fractures, there are other associated facial injuries.[43] These statistics emphasize the importance of a complete initial assessment in children with facial trauma and highlight the dilemma of the timing of repair when medical instability conflicts with the limited period during which optimal reconstruction is best accomplished.

Etiology

In considering the cause of pediatric facial fractures, it is important to understand both the types of traumatic events that result in injury and the unique anatomic features of the child's face. These combined factors predispose children to patterns of injury that are different from those seen in adults.

Motor vehicle collisions constitute the main cause of serious pediatric facial trauma.[4-15,17,18] Fortunately, less than 1% of traffic accidents result in pediatric facial bone fractures.[44] The risk of injury is 1.6 times higher for children who are inappropriately restrained in the vehicle, and children seated in the front seat have nearly twice the risk of fracture as those sitting in the rear seat.[44] Air bags have been shown to decrease the mortality rate in the adult population; however, children younger than the age of 10 years have a 34% increased risk of dying in frontal crashes with air bag deployment.[45] The current recommendations for protection during motor vehicle travel by the American Academy of Pediatrics and the National Highway Traffic Safety Administration are use of child restraints for children weighing less than 40 lb, belt-positioning booster seats for children from 40 to 80 lb and up to 57 inches in height, and lap-shoulder belts for children weighing more than 80 lb and more than 57 inches tall, and placement of children younger than 13 years in the rear seat.[46-48]

Although a majority of serious pediatric facial fractures are incurred in motor vehicle collisions, childhood play is the most common cause of facial trauma (15% to 30%) when all forms of fractures are considered, including orbital, nasal, and dentoalveolar fractures.[49] Bicycle accidents remain an important cause of injury to children, and although wearing helmets has greatly reduced midfacial and intracranial injuries, the current designs of helmets do not protect against mandibular and dentoalveolar injury.[50-53] Other causes include falls (20% to 30%), aggravated assault (8% to 30%), and sports injuries (2% to 30%).* An uncommon cause of facial fracture is trauma from dog bites.[56,57] Isolated orbital fractures most commonly are seen in sports, with violence recognized as a significant risk among those 12 years and older.[43,58] Child abuse deserves special mention. Facial fractures, in particular, of the mandible, can be the result of child abuse.[8,14,33,59] It is important to consider the possibility of child abuse, especially in cases of facial injury among children younger than 5 years, because this is the age group at highest risk for battering.

Both social and anatomic differences account for the disparity in the incidence and in the nature of facial fractures between adults and children. Falls are frequent but generally occur from low heights and involve low speeds, so the likelihood of serious fractures is diminished. Children generally are in a more protected environment than adults that further reduces the risk of major injuries.

Understanding the difference in the patterns of fractures between children and adults requires familiarity with the development of the facial skeleton. At birth, the craniofacial ratio is 8:1, with the face located in a recessed position relative to a large skull. The cranium and forehead effectively shield the smaller lower and middle thirds of the face from injury. By the age of 2 years, the cranium has achieved 80% of its mature size. Facial growth also is rapid during this period, but it is only after the second year that facial growth outpaces cranial growth. Brain and ocular growth are near completion by age 7; however, facial growth continues into the second decade of life.[60,61] In adults, the craniofacial ratio is 2:1.[61,62] The consequence of the higher craniofacial ratio is that the cranium, especially the prominent forehead overhanging the face, absorbs the major portion of the impacting force. This accounts for the higher proportion of pediatric skull fractures relative to facial fractures and the rarity of serious midface fractures in young children, in whom the force necessary to cause major maxillary disruption often results in brain injury and death.[14,35]

Another resilient feature of young children is the makeup of the face with thick soft tissue, lack of sinus pneumatization, and elasticity of the bones. The greater proportion of cancellous to cortical bone explains the higher incidence of "greenstick" fractures in children.[63] The presence of unerupted and mixed dentition in the maxilla and mandible increases the resistance to fracture, although fractures can occur through developing tooth crypts. As the child enters adolescence and adulthood, the concomitant pneumatization of the paranasal sinuses, maturation of the dentition, hardening of bone, and thinning of the facial soft tissues, synchronized with higher-energy injuries associated with increased risk-taking behavior, all lead to a higher risk of fracture.[29,60,64-66]

Emergency Management

The first step in evaluating pediatric facial trauma is to follow the basic principles of trauma management. A primary survey must be made of the child's airway, breathing, and circulation. Airway-securing algorithms should be closely followed. In most cases of isolated facial trauma, careful posturing of the child is adequate. The oral cavity should be cleared of loose teeth and bone fragments, with suctioning of blood and secretions as necessary. In case of mandibular displacement, a midline traction suture on the tongue can help maintain a patent airway.

Orotracheal intubation is necessary in patients with concomitant cranial trauma, severe bleeding associated with midfacial fractures, or oropharyngeal obstruction and posterior retrusion of the mandible. Orotracheal intubation ideally is accomplished after the cervical spine is secured. Optimally, when oropharyngeal or laryngeal injuries are present, intubation is performed in the operating room with rigid instrumentation. "Crash" tracheotomy and particularly cricothyrotomy in the emergency department are ideally avoided in favor of orotracheal intubation. Once the airway is secured, elective controlled tracheotomy can be performed in the operating room when deemed necessary by the extent of injury. In one series of 73 patients with mandibular frac-

*References 12-14, 19, 21, 22, 25, 27, 32, 34, 36, 39, 54, 55.

tures, only one patient required airway control for obstruction; a tracheotomy was not necessary.[14] However, a controlled tracheotomy is a safe option in patients with panfacial fractures and associated major systemic trauma.[38]

Hypovolemic shock can result from the blood loss with injuries to the highly vascular face of a child. This blood loss may be a double threat if the bleeding is into the airway. Standard volume replacement practices should be implemented, along with transfusion of blood products as indicated.

The secondary survey of the head and neck is conducted in an orderly fashion, beginning with the neurologic assessment and proceeding to evaluation of the neck and cervical spine, inspection of the eyes, otoscopy, rhinoscopy, and finally, examination of the face and oral cavity.

Clinical and Physical Evaluation

If at all possible, an accurate history should be obtained, with the focus on the mechanism of injury as well as the energy and direction of the impact. An injury that appears inconsistent with the reported history should raise suspicion of child abuse.

Although cooperation may be limited in young children, the examination of the facial skeleton should begin with inspection followed by manual palpation in an orderly and systematic manner. Suggestive signs of facial fracture can include facial asymmetry, edema, ecchymosis, Battle's sign, "raccoon eyes," periorbital swelling, conjunctival chemosis, epistaxis, trismus, and malocclusion.

Bimanual examination of the facial skeleton begins over the zygomatic arches and systemically proceeds down the face. The examiner feels for asymmetry, tenderness, and crepitation. The forehead, malar eminences, orbital rims, and nasal bones are palpated. The premaxilla should be grasped with one hand and the head stabilized with the opposite hand to check midfacial stability. Further information can be obtained by intraoral digital examination of the maxillary buttresses.

The manual examination of the mandible begins with the palpation of the temporomandibular joints and the external auditory canals with opening and closing of the jaw. The entirety of the mandible is palpated both intraorally and extraorally. The oral examination includes inspection of the hard and soft palate, tongue, floor of the mouth, and dentition. The gingiva is closely examined for ecchymosis and lacerations; the occlusion is inspected.

A complete neurologic examination is important with evaluation of the level of consciousness (using the Glasgow Coma Scale) and of cranial nerve integrity. Particular attention to the sensory function of the fifth cranial nerve and the motor function of the seventh cranial nerve is essential. Ophthalmologic evaluation is important to rule out optic nerve injury, intraocular trauma, and ophthalmoplegia. This should include visual assessment (if possible), ophthalmoscopy, and tests for range of motion, diplopia, and pupillary reflexes. Forced duction testing should be performed with the patient under anesthesia whenever orbital trauma is suspected. The anterior external ear canal wall is inspected for lacerations from a condylar fracture; a hematotympanum may suggest a temporal bone fracture. Anterior rhinoscopy is valuable for evaluation for septal injury, septal hematoma, or cerebrospinal fluid (CSF) rhinorrhea.

Radiologic Examination

Computed tomography (CT) is invaluable in the evaluation of pediatric trauma. Axial and coronal cuts allow for a complete survey of the craniofacial, intracranial, orbital, and facial skeleton. Orbital injuries should be evaluated with 1.5- to 3.0-mm coronal and axial cuts. When the stability of the cervical spine is in question, and in the case of an uncooperative child, coronal cuts may be unobtainable. However, coronal reconstructions are universally available with the software of contemporary CT scanners, and these allow for appropriate preoperative assessment and surgical planning. Three-dimensional CT reconstructions also are routinely available to permit a more global understanding of the injury. Intraoperative findings generally correlate well with radiologic images.

The "gold standard" imaging study for displaying the mandible is the panoramic radiographic view (Panorex). This can be difficult to obtain in a multiply injured or uncooperative child. Alternatively, a plain film such as Towne's view is specific for the condyles. The lateral oblique view displays the condyle, coronoid, ramus, angle, and body. Intraoral projections can be helpful for symphyseal, parasymphyseal, and dentoalveolar fractures. In our experience, the axial CT scans of the mandible are the most useful for documenting mandible fractures in a multiply injured child and are best obtained when cranial and upper facial CT scanning is being performed.

Routine x-ray evaluation for isolated pediatric nasal trauma is rarely useful. Standard nasal radiographs frequently are inaccurate, especially in children whose nasal bones are not fully fused. However, when significant flattening or deformity of the nasal dorsum has occurred, both axial and coronal CT scans should be obtained.

Facial Growth and Trauma

Craniofacial bone growth is a complex process that is incompletely understood, and even less is known about the effects of trauma on this process.[67] See Chapter 184 for a detailed review of facial growth.

It is clear that facial growth is a complex process. What is unclear is the mechanism of control and coordination responsible for overall growth.[68] Practical concepts for the repair of facial fractures in children are based on the known effects of trauma in the growing face, as well as on an understanding of the operational mechanics of facial development (see Chapter 185, Craniofacial Surgery for Congenital and Acquired Deformities). The mandible appears to be generally resistant to abnormalities of growth as a result of trauma, unless its function is altered as a result of injury in or near the TMJ. Early return of mandibular mobility is desirable to facilitate the restorative bony changes that result from normal function.

The nose, nasoethmoidal complex, and maxilla are more prone to growth abnormalities resulting from trauma. This susceptibility probably stems from the minor restorative functional movement to which these bones are subject, the physiologic derangements that result from the fractures, the importance of the septum as a regional growth site, and the vulnerability of the multiple suture sites to scar formation. These factors suggest that basic tenets should be followed in the interfragmentary repair of pediatric fractures:

- Careful restoration of injured soft tissue, particularly the periosteum
- Close attention to septal injuries, with an emphasis on realignment rather than resection
- Reduction of fractures into their stable anatomic locations
- Correct realignment of suture lines
- Minimal periosteal elevation
- Three-dimensional, stable fixation of complex fractures
- Use of bone grafts in rigid fixation as a substrate for growth in areas of bone loss

Rigid Fixation

Controversy still exists over the use of rigid fixation in the developing face. See Chapter 184 for detailed discussion of rigid fixation in children.

With the current state of knowledge, plate fixation should be considered only for children with complex three-dimensional injuries that cannot be repaired by simpler means. Such caution is appropriate for several reasons: Access for plating often requires surgical trauma to facial soft tissues and extensive periosteal elevation, both important factors with potential for adverse alteration of facial growth. Bone is deposited at facial sutures as a result of tension fields across them. Plating across a suture line could potentially convert the sites to compressive fields, resulting in bony absorption. Plate and screw fixation also risks injury to maxillary tooth buds.

Nevertheless, with the recognition that each reconstructive technique has its strengths and its weaknesses, the use of rigid fixation is

Table 189-1

Physical Properties of the Common Monomeric Polymers Currently Used in Fabricating Bioresorbable Plates and Screws

			In Vivo Degradation Time

highly desirable in complex fractures in which the original features are difficult to restore. The alternative of no correction is unacceptable, and the use of interfragmentary wires requires tedious surgery and can lead to reconstruction of uncertain stability. As Rahn[69] has written, "Open reduction of a fracture may sometimes appear to be an aggressive approach. It can be justified when late reconstruction and secondary surgery is avoided. Thus an approach that appears initially to be more aggressive may be more conservative."

Permanent versus Resorbable Plating Systems

As noted, controversy is ongoing regarding the use of permanent plates and screws in the developing face. Although these techniques are excellent for fixation, leaving a metallic foreign body in a growing child has several drawbacks: Transcranial migration of metallic plates is a well-recognized problem.[70-72] Growth disturbances in both animal and human studies have been shown with use of permanent rigid fixation.[41,73-75] Metal hypersensitivity, potential for bone atrophy, interference with CT and MRI, allergy, and palpability all are potential problems with use of metallic plates. Accordingly, many surgeons routinely remove plates once the fracture line is well healed, especially in children.[76-80] However, others suggest that watchful waiting is appropriate and have found the need to remove plates for the aforementioned reasons in approxiamtely 8% of the pediatric population.[81] Of interest, in a rabbit study, Connelly and Smith[82] found that the removal of rigid plate fixation had a more deleterious effect on growth than if the rigid fixation was left in place. An alternative solution to this quandary is the use of absorbable plates and screws, the safety and efficacy of which have been shown by extensive animal research and subsequent use in craniofacial surgery and facial trauma reconstruction.[72,76,83-95] A study using resorbable copolymer in infant minipigs looked for local reaction as well as the complication of passive intraosseous translocation of plates. The investigators found the tissue reaction to be minimal and demonstrated that although the plates were embedded in the growing bone, this did not hinder degradation of the plates or screws.[95] Bioabsorbable plates are reasonable in cost and clinically safe. With experience in their application, resorbable systems are comparable in efficiency to metal plating systems.

The most commonly used craniofacial bioabsorbable materials are high-molecular-weight polyalphahydroxy acids: polylactic acid (PLA), polyglycolic acid (PGA), and polydioxanone (i.e., the suture material PDS) and their copolymers. Lactic acid has two enantiomeric forms: L-lactic acid (PLLA) and D-lactic acid (PDLLA). PLA and PGA are metabolized into carbon dioxide and water and are eliminated by respiration; the degradation products of PDS are excreted primarily in the urine.[93] The absorption occurs initially by hydrolysis and is completed by phagocytosis.[96] The physical properties of the polymers are outlined in Table 189-1.[90] Pure polymers have been shown to have disadvantages in strength, time to degradation, or local tissue reaction.[86,93,96] PGA has the best initial strength properties, equal to those of stainless steel.[97] PGA's mechanical properties are lost in 6 weeks, and resorption is complete within 1 year.[49,57] However, the use of pure PGA has resulted in adverse reactions in up to 60% of cases, including swelling, draining fistulas, and osteolysis.[98,99] In vivo sheep studies have shown that PLLA takes 5 years to resorb.[94] Reports on pure PLLA have demonstrated late tissue responses up to 4 years after implantation.[100]

Current resorbable plating systems take advantage of copolymers of PLA and PGA, which allow for variable duration of adequate mechanical strength and biodegradation time. LactoSorb was the first absorbable system approved by the U.S. Food and Drug Administration (FDA) in 1996, and at present there are five commercially available resorbable plating systems with different properties based on their individual polymer chemistry, as outlined in Table 189-2.[90] Because each plating manufacturer uses slightly different mixtures of copolymers, plate strength, absorption, and ease of handling will differ between the systems. Ideally, the plate used will retain full strength for 4 to 6 weeks, the time it takes for facial fractures to ossify.[101] The absorbable plates currently on the market maintain 60% to 90% of their strength through the 3-month mark.[96]

Complications with resorbable systems are comparable with results with metal plates, with the exception of the potential for long-term translocation with metal implants.[20,90,93,102-104] The most common adverse reactions are transient peri-implant edema and a high rate of temporary visibility or palpability of hardware, both of which resolve with time. Foreign body reaction in the surrounding tissue typically is minimal.[96] To date, the long-term studies on absorbable plating systems have exclusively used LactoSorb, which has a faster resorption time than some of the more recently released systems. Studies have shown that the available resorbable plating systems (1.5- and 2.0-mm screw diameters) provide flexural and tensile strength comparable with that of the microplate titanium systems (1.0- to 1.3-mm-diameter screws).[105] Definitive long-term studies in facial trauma have yet to conclude whether resorbable plates cause problems with growth restriction.

At this time, absorbable plates are not recommended for all types of pediatric facial fractures. As indicated by preliminary data on sagittal split osteotomy plated with absorbable systems, excellent results were obtained without the use of maxillomandibular fixation (MMF) in a 15-month follow-up study.[93] However, the use of absorbable plates in the mandible and "load-bearing" bone is still investigational in children, and long-term results are limited.[90,92] At this time, the indications for the use of absorbable systems in pediatric trauma are in non–load-bearing regions in the upper and middle thirds of the craniofacial skeleton.

From a practical point of view, the main difficulties we have found with use of resorbable plates are in complex midfacial fractures with

Table 189-2

Commercially Available Craniomaxillofacial Resorbable Plating Systems and Their Properties

System with Manufacturer and Date Introduced	Polymer Composition	In Vitro Time	
		Remaining Strength	Complete Resorption

marked comminution or "cornflaking" of the bone. In such cases, the relatively large size of the resorbable instrumentation (especially the screws) makes fixation of multiple small fragments awkward and often impracticable. For similar reasons, problems with use of these devices also are on the infraorbital rim and in the nasoethmoidal area. Further evolution of resorbable plates and screws toward smaller, more refined sizes should improve their practicability for the rare highly comminuted midfacial injuries.

Maxillomandibular Fixation

In decisions regarding techniques to achieve MMF, primary considerations include the age and development of the teeth. In children who lack teeth or in whom the poor retentive shape of the deciduous teeth makes the use of arch bars and interdental wiring impractical, alternative methods of MMF need to be considered. Fortunately, 2 to 3 weeks of mandibular immobilization in children younger than 12 years is adequate.[38,106]

One approach is the use of an overlay acrylic mandibular splint held in place by circum-mandibular and transnasal wires. The splint's occlusal surface is placed in normocentric relation to the maxilla, and immobilization is accomplished by suspending a wire from the piriform aperture and tightening it around the mandibular midline wire that is holding the splint to the mandible (Fig. 189-1).

An alternative technique that adds more interocclusal stability is the placement of resorbable screws in the symphysis at the inferior border as well as that of the zygoma. The monofilament suture is tied between the two screws, thus avoiding the need for a circum-mandibular suture. The use of this MMF method in teenagers and adults is not advised, owing to the higher forces generated by the masticatory muscles.[107]

In children between the ages of 2 and 5 years, the deciduous incisors have firm roots, and if the deciduous molars have formed, they can be used for cap splints or arch bars. In general after age 10, the development of permanent teeth provides for safe anchors.[29] However, children develop at different rates, and the strength of the teeth should be carefully examined before the placement of any type of MMF instrumentation.

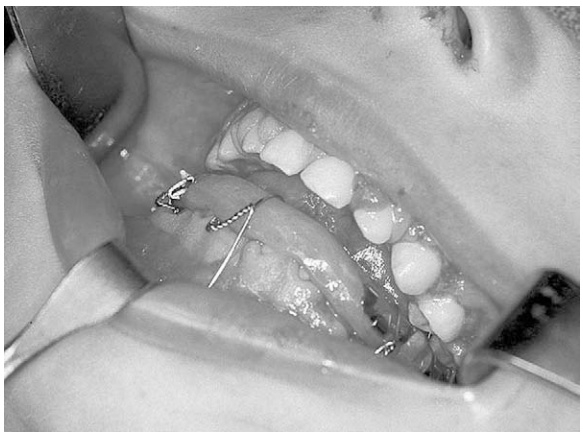

Figure 189-1. Circum-mandibular wires holding an acrylic splint in place in a 3-year-old child with a fracture of the body of the mandible, right side.

Surgical Approaches

Miniplate and microplate screw fixation systems have made open reduction with internal fixation (ORIF) the preferred method of treatment for midface fractures. The entire facial skeleton can be accessed and reconstructed using a combination of six incisions, which allows for rigid interfragmentary fixation of the entire midface[108] (Figs. 189-2 to 189-6). The *bicoronal* incision provides exposure of structures of the upper third of the face, including the zygomatic arches; lateral, medial, and superior orbital rims; and the nasoethmoidal region. The bicoronal

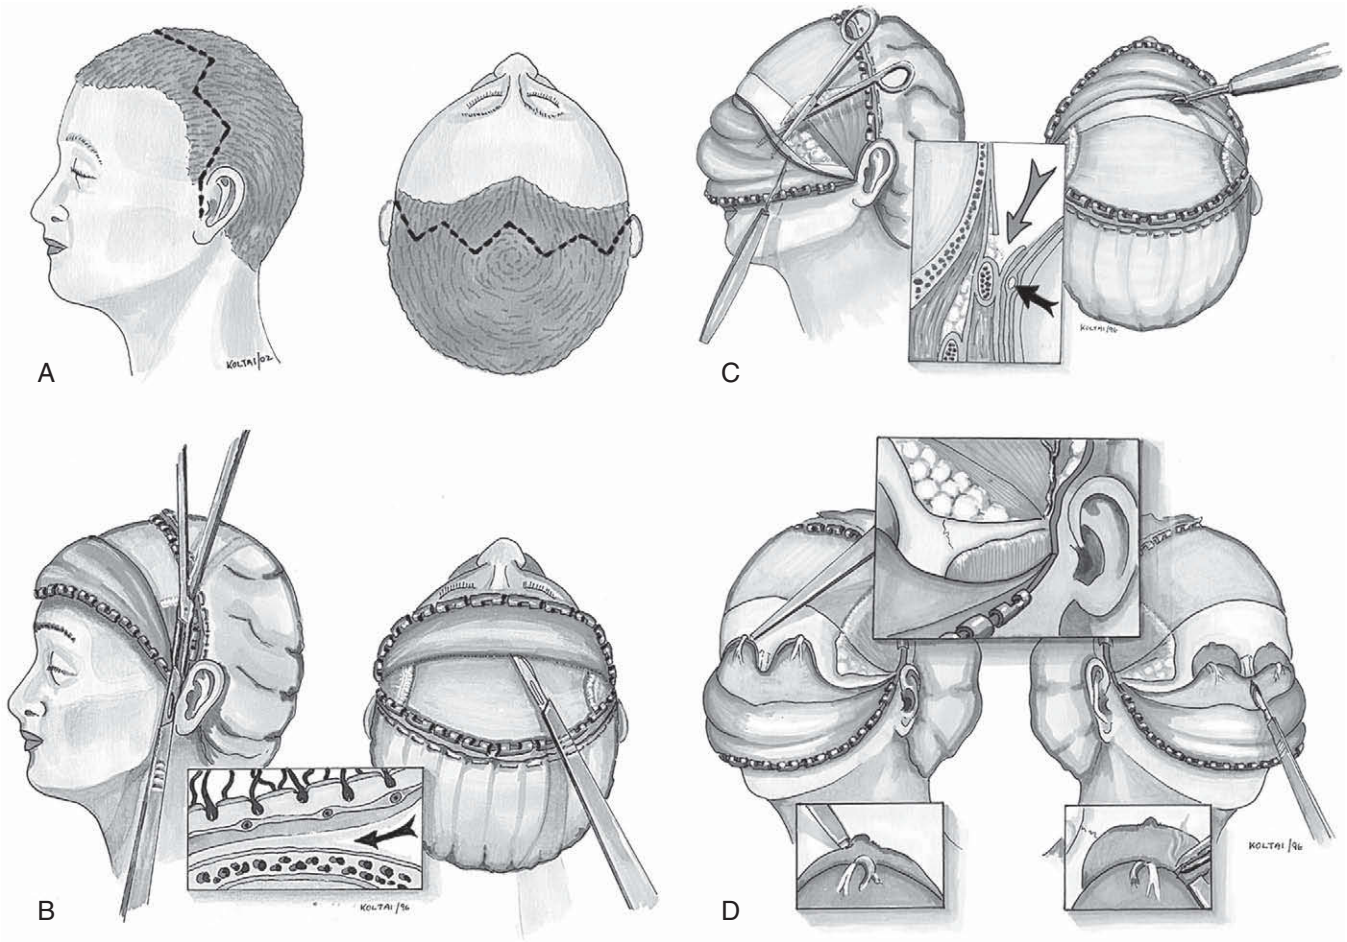

Figure 189-2. **A,** The incision line for coronal exposure begins in the preauricular crease above the tragus, enters the hairline above the attachment of the helix, and traverses the cranium 4 to 6 cm behind the hairline. The "stealth" modification of the traditional coronal incision leaves a broken-line, less visible scar. This technique also avoids parting of wetted hair along the incision line, a common postoperative complaint after repair using the traditional approach. **B,** The incision is carried down to the calvarial periosteum medially, which is contiguous with the deep temporal fascia laterally. The flap is elevated with a knife or blunt finger dissection in the subgaleal plane *(inset)*. Over the temporalis muscle, blunt dissection with a hemostat or scissor is used to develop the plane between the fascia and scalp. The scalp is incised over the instrument to prevent penetration of the deep temporal fascia, which will result in bleeding. **C,** Medially, the subgaleal dissection ends 2 cm above the supraorbital rims. The periosteum is incised, and dissection continues subperiosteally. Laterally, the temporal fat pad can be seen under the deep temporal fascia. The fascia is incised and dissection proceeds between the fascia and the fat pad, protecting the frontal branch of the facial nerve (*black arrow* on *inset*), which lies within the overlying temporoparietal fascia. **D,** The superior surface of the zygoma is exposed through sharp dissection of the periosteum, beginning at the temporal root of the arch *(upper inset)*. Medially, the supraorbital neurovascular bundle is released from its foramen using an osteotome or drill *(lower left inset)*. The medial orbit is exposed with blunt dissection and the anterior ethmoid neurovascular bundle, if still intact, is divided after bipolar cauterization *(lower right inset)*. A relaxing incision of the periosteum over the nasal dorsum allows for greater exposure. *(Reprinted with permission.)*

approach, which is subperiosteal over the cranium and subfascial over the temporalis muscle, permits access to the superior and medial orbital rims. Orbital roof and nasoethmoid exposure can be obtained by mobilizing the supraorbital neurovascular bundle. Detachment of the temporalis fascia from the lateral orbital rim and zygomatic arch reveals the bones of the entire upper face from the zygomatic root on one side completely around to the other. The exposure provides a means to realign and rigidly fix the frontozygomatic suture, the entire zygomatic arch, and the nasal bones. It also allows for harvesting of cranial bone grafts for orbital reconstruction and cantilever nasal reconstruction in complex nasoethmoid fractures. The inferior orbital rims and floor can be exposed by either a subciliary or transconjunctival incision. The medial orbit and apex can be exposed by a *transcaruncular* approach. The *gingivolabial sulcus* approach provides access to the entire maxilla, laterally to the malar bone and zygoma, anteriorly to the infraorbital nerve, and medially up to the lacrimal fossa. The exposure provides for the reestablishment of both the lateral zygomaticomaxillary buttress and the medial nasomaxillary buttress. The entire nasoethmoidal region can be exposed by a *midfacial degloving* incision.

The sequencing of procedures for repair of severe midfacial fractures, especially when the mandible is fractured, is important. Reestablishing occlusion by MMF and repair of the mandible establishes a solid base for upper face reconstruction. Different strategies with respect to the sequencing of maxillary fractures have evolved (Fig. 189-7). Traditionally, the external frame of the face is realigned, and then the work proceeds toward the central core. This approach emphasizes control of the facial width and projection, which is the function of the zygomatic arch.

Other reconstructive strategies emphasize the use of the anterior cranial base as a template for the midfacial reconstruction. This sequencing begins with reconstruction of the frontal bone to which the relations of the nasoethmoidal regions, orbit, and outer facial frame are reestablished. Reconstruction is then completed by connection of the midface to the occlusal unit at the Le Fort I level.

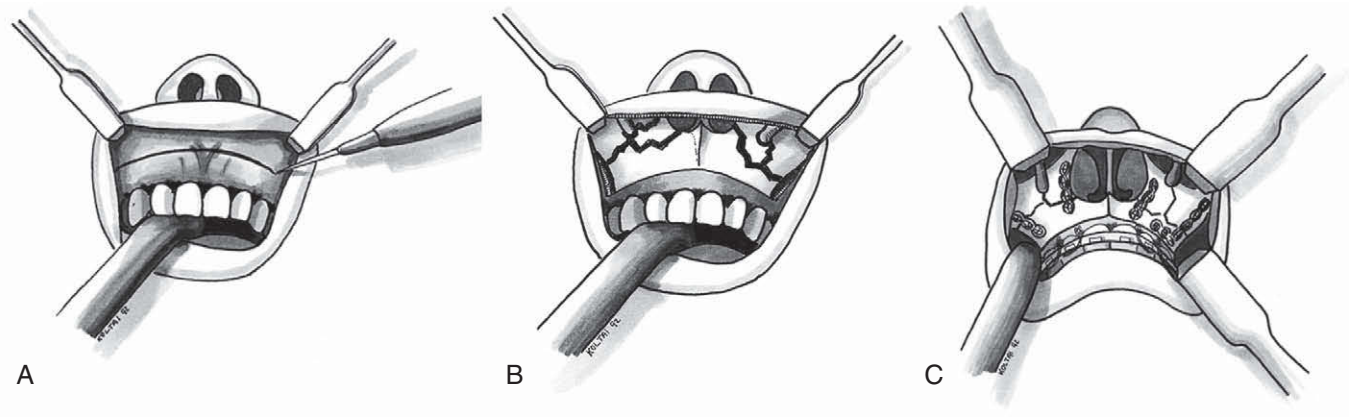

Figure 189-3. **A,** Using needle cautery, a maxillary gingivolabial sulcus incision is created, leaving a 3-mm cuff of tissue on the gingival side to facilitate closure. **B,** Fractures of the anterior and lateral buttresses have been exposed. **C,** The buttresses have been reduced and plated. *(Reprinted with permission.)*

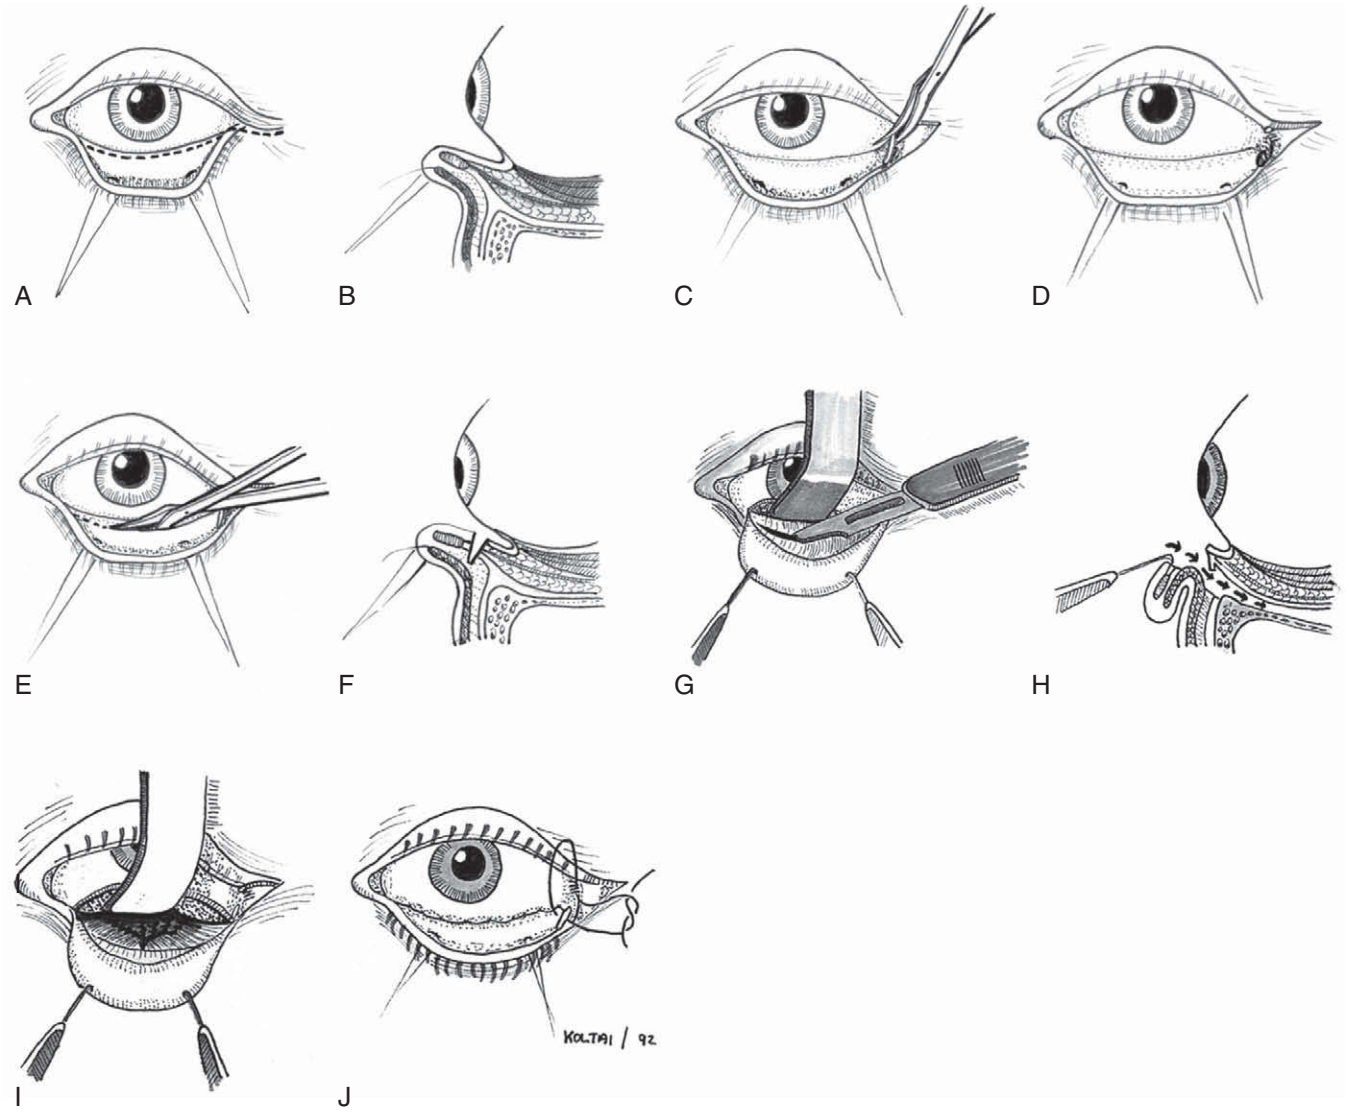

Figure 189-4. **A** to **F,** After traction, sutures are placed in the lower lid, and a lateral cantholysis is performed. Through the lateral canthotomy, sutures are introduced in the subconjunctival plane and blunt dissection proceeds inferior to the tarsal plate and medially up to, but not past, the lacrimal punctum. The conjunctiva is then incised below the tarsal plate **(E)**. The dissection can proceed in a preseptal or postseptal plane. **G** to **J,** The periosteum on the orbital rim is exposed and incised, allowing access to the floor. The procedure for closure consists of placement of running sutures of 6-0 chromic for the conjunctiva and 5-0 polydioxanone for repair of the cantholysis. *(Reprinted with permission.)*

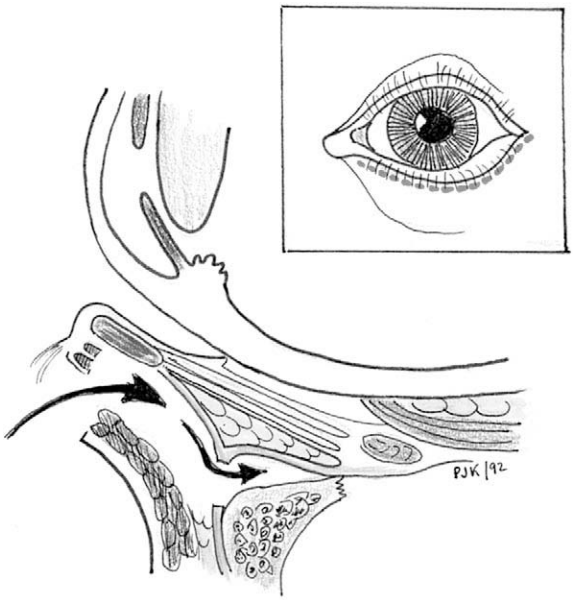

Figure 189-5. The subciliary incision is made 1 to 2 mm inferior to the lashes, through the skin and the orbicularis muscle. The plane of dissection is between the orbicularis muscle and the orbital septum. The periosteum is incised at the orbital rim, and the floor of the orbit is exposed. *(Reprinted with permission.)*

Our own approach to pediatric injuries is based on the recognition that the face is composed of component units connected by their associated buttresses and that the most prominent and most challenging aesthetic unit is the nasoethmoidal area. First, occlusion is established, and if necessary, the mandible is repaired. The central core is then reconstructed, followed by positioning of the orbits and the outer facial frame to the central core (Fig. 189-8).

Surgical Reconstruction

Fracture of the Mandible

Bicycle accidents, motor vehicle collisions, and falls are the most common source for mandibular fractures in children.[109] Greenstick injuries are more frequent in young children because of the presence of unerupted teeth, which increases density of bone, and a higher percentage of cancellous bone, which increases the elasticity.[110] Fractures through developing tooth crypts risk the maldevelopment as well as the devitalization of the respective teeth.[111]

The technical goal of repair in pediatric mandibular fractures is to restore the underlying bony architecture to its preinjury occlusion, tempered by the age-specific development of the mandible and the variable dentition. Before the age of 2 years, the eruption of the deciduous teeth is incomplete. From 2 to 5 years of age, the deciduous incisors and molars have firm roots. In children 5 and 9 years of age, resorption of the deciduous roots and incomplete eruption of the secondary dentition are characteristic. After 10 to 12 years of age, most children have a healthy complement of secondary dentition.

Complications of pediatric mandibular fractures include infection, nonunion, malunion, malocclusion, and TMJ dysfunction. Injuries to teeth in the fracture line account for 7% to 50% of all mandibular fractures.[18,112,113,] Post-traumatic ankylosis of the condyle is a rare but significant complication associated with injury in children younger than 3 years and those in whom MMF was prolonged.[122] One study showed a significant decrease in the vitality of teeth in proximity to fractures of the mandible treated by plates, which the investigators speculated was due to periosteal elevation and increased manipulation of bony fragments.[114] Several adult studies have shown an increased infection rate when teeth in the line of fracture are extracted during open repair.[115-119]

Condylar Fracture

Condylar fractures can be classified into three anatomic types. The first two are intracapsular and include crush-type fractures of the condylar head and high condylar fractures through the neck above the sigmoid notch. Before the age of 6 years, there is a preponderance of intracapsular fractures.[109] The third and most common type is a low or subcondylar fracture, often of the greenstick variety (Fig. 189-9). This fracture type is extracapsular and occurs from the sigmoid notch back toward the posterior ramus. The age discrepancy probably is related to anatomic development. When an injury occurs in a young child, the thickness of the condylar neck and the flexibility of the mandible direct the force toward the condylar head. Furthermore, children younger than 6 years are more likely to have other, systemic injuries concurrent with a mandible fracture.[14]

The condyle is an important site of mandibular growth, and controversy exists in the literature about the long-term issues surrounding preadolescent condylar fracture.[38] Lindahl and Hollender[120] showed that remodeling of the condyle after fracture resulted in normal anatomy in children aged 3 to 11 years but occurred to a lesser extent in adolescents and was minimal in adults. These findings have been the basis for the theory that younger children have fewer long-term problems.[10] However, more than one third of patients with arrested condylar development have a history of facial trauma.[121] Although most children heal without functional impairment,[122,124-126] multiple studies have demonstrated that between 5% and 20% of children with condylar fractures subsequently have some degree of functional or radiologic deformity.[13,16,32,122-124,127-129] Therefore, prolonged follow-up is mandatory, and orthodontia may be an important adjunct in the long-term management of condylar fractures.[38]

Clinical and experimental observations support a conservative, closed approach to the management of most pediatric condylar fractures. Although open surgical treatment is advocated by some experts, the primary decision is not whether to perform open reduction of the fracture but whether the child will need immobilization with MMF. Most unilateral and some bilateral condylar fractures will manifest with normal occlusion and mobility. A soft diet and movement exercises are all that is needed. Condylar fractures manifesting with an open bite, mandibular retrusion, or movement limitation are best treated with 2 to 3 weeks of immobilization. Early and persistent movement with an elastic jaw exerciser generally prevents the development of ankylosis and aids in restoring function (Fig. 189-10).

The indications for an open surgical approach to repair of pediatric condylar fractures are quite limited, and the procedure is reserved for the displacement of the condyle into the middle cranial fossa or interference with jaw mobility.[122] These circumstances are best approached with either a preauricular or submandibular approach, depending on the location of the fracture (Fig. 189-11).

Symphyseal and Parasymphyseal Fractures

Approximately one third of condylar fractures will have an associated symphyseal fracture.[109] With symphyseal and parasymphyseal fractures, the submental musculature exerts a downward and retrusive force, causing displacement of the fractured segments. These fractures with minimal to moderate displacement often can be realigned with careful manual manipulation of the patient under anesthesia and immobilized by the methods described for pediatric MMF.

The decision to treat with soft diet, MMF, or ORIF is best made on the basis of the degree of disruption in the fracture and the extent of occlusion change. The problem with MMF is that reducing the fracture on the side of the dentition (tension surface) often will result in distraction of the lower border (compression surface) of the mandible. To better reduce serious displacement, ORIF of the fragments is required. These midline areas are readily exposed using an intraoral approach. The lower border can then be reduced by wire fixation or by monocortical reconstruction with miniplates (Fig. 189-12). With both techniques, great care must be exercised in drill hole placement to prevent injury to the developing tooth buds (Fig. 189-13). Once preinjury occlusion has been established, a minor degree of osseous gap at the fracture site is of less consequence in the bony healing of pediatric mandibular fractures.[38] With both miniplate reconstruction and inter-

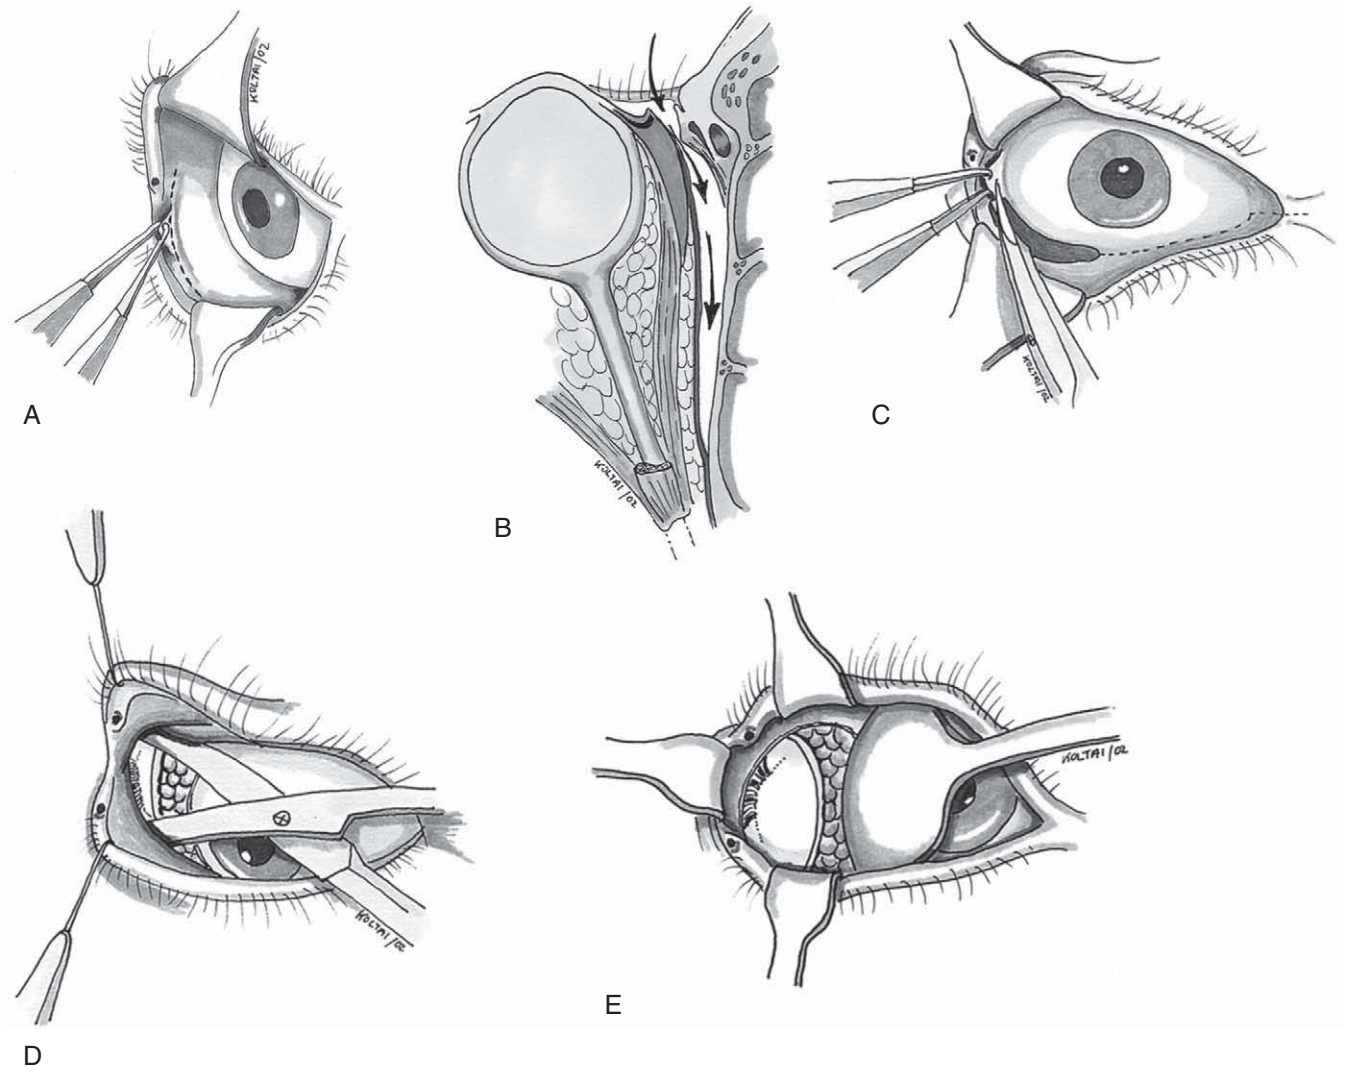

Figure 189-6. Transcaruncular approach. **A** and **B,** After retraction of the medial lid margins, the caruncle is incised along with the medial aspect of the superior and inferior conjunctival fornices. The incision can be continued into a transconjunctival approach with lateral canthotomy to expose the entire medial, inferior, and lateral orbit (*dotted line* in **A**). **C,** Blunt dissection in the plane between Horner's muscle medial and the orbital septum laterally is carried to the posterior lacrimal crest (*dotted line*). **D,** The periorbita is incised behind the posterior lacrimal crest; wide subperiosteal elevation exposed the medial orbital wall. **E,** Superior view of the orbit demonstrates the plane of dissection to gain wide exposure of the medial orbit to the apex. *(Reprinted with permission.)*

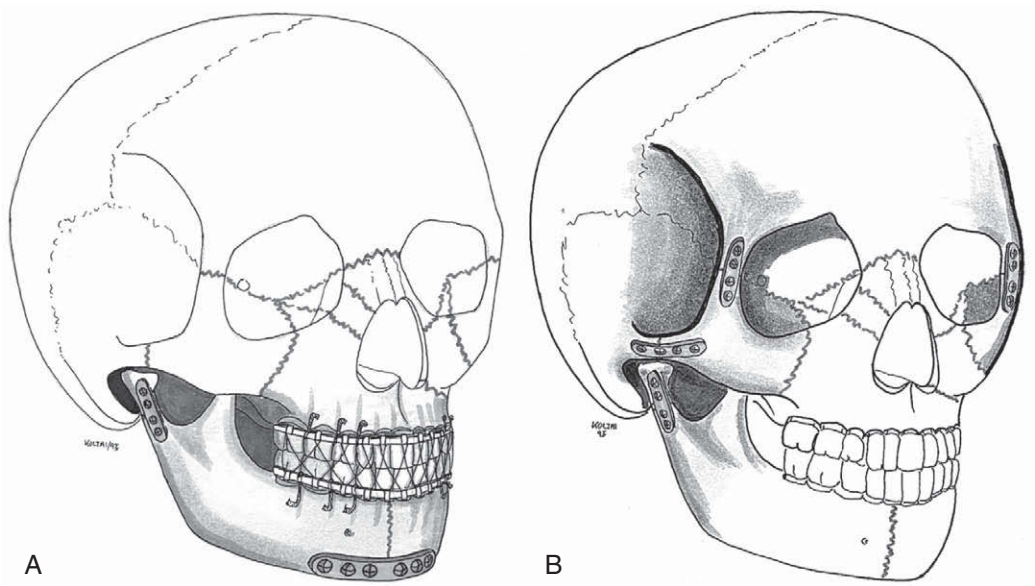

Figure 189-7. **A,** Bottom-up approach. Traditional sequencing begins with reconstruction of the occlusion and the mandible, which then serves as a template for the upper face. **B,** Outside-in approach. The outer facial frame is reconstructed with emphasis on the zygomatic arches, to narrow and project the face. *(Reprinted with permission.)*

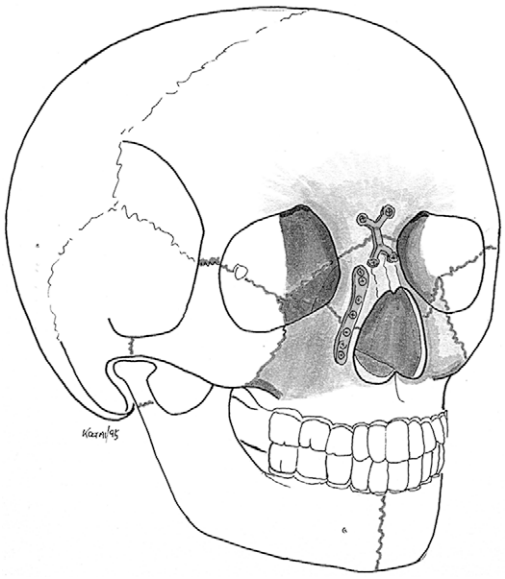

Figure 189-8. Inside-out approach. Reconstruction begins with the central core of the face, using the anterior skull base as the template, with the goal of improving the accuracy of the repair of the aesthetically most significant component of the face. *(Reprinted with permission.)*

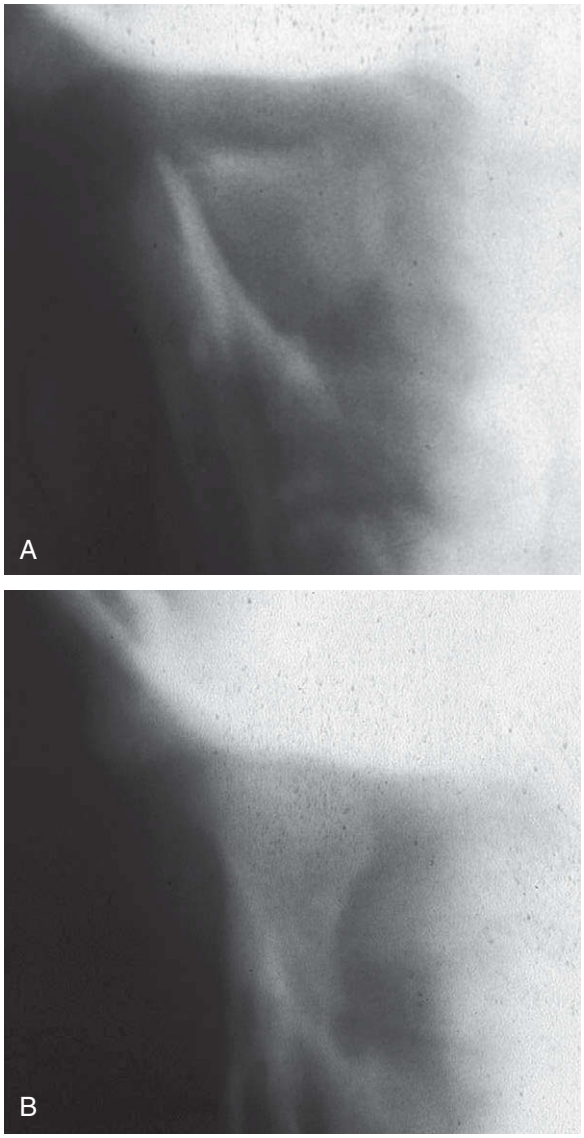

Figure 189-10. **A,** Polytomogram obtained in a 5-year-old child with a right subcondylar fracture, showing medial displacement of the condyle into the infratemporal fossa. The child was minimally symptomatic and treated only with analgesics, a soft diet, and range-of-motion exercises. **B,** Polytomogram obtained in the same child 6 months later, with the condyle restored to its normal position.

osseous wiring, a brief period of 2 to 3 weeks of MMF is required. In children with full, permanent dentition, the principles of bicortical, compression plate reduction are applicable.

Currently, absorbable plating systems in pediatric mandible fractures are not routinely used, nor are they FDA approved for this application.[90]

Angle and Body Fractures

Fractures of the body and angle frequently are monocortical greenstick fractures. Children with these injuries typically have normal occlusion and jaw movement. Treatment with soft diet, analgesics, and observation is appropriate. When the fracture components are displaced, treatment will depend on the availability of dentition, the directions of muscle pull, and the degree of distraction. For distracted body fractures, MMF with elastic traction usually is adequate. However, if misalignment of the lower border cannot be controlled in a conservative manner, then ORIF and the placement of monocortical miniplates will be necessary. The open reduction of posteriorly placed body fractures may require an external approach. However, the transcutaneous sleeve with improved plate holding instrumentation has made intraoral reduction technically simpler (Fig. 189-14).

Dentoalveolar Fracture

Falls and play accidents are the most common cause of dentoalveolar injury.[130,131] These fractures constitute dental emergencies because salvage of the traumatized bone segment and teeth requires prompt reimplantation. Isolated loss of the deciduous teeth without bone is not a problem; however, identification of tooth type, particularly during a period of mixed dentition, is difficult for practitioners unfamiliar with pediatric dentition. The maxillary incisors are the most commonly injured primary and permanent teeth, accounting for approximately 85% of dental injuries[130] (Fig. 189-15). Tooth luxation and concussion are more common in younger children, whereas crown fractures with dentin exposure are more common in children with permanent dentition.[131] Treatment is directed at arranging for immediate, definitive care of the child by a dentist. In the interim, the tooth is gently cleansed

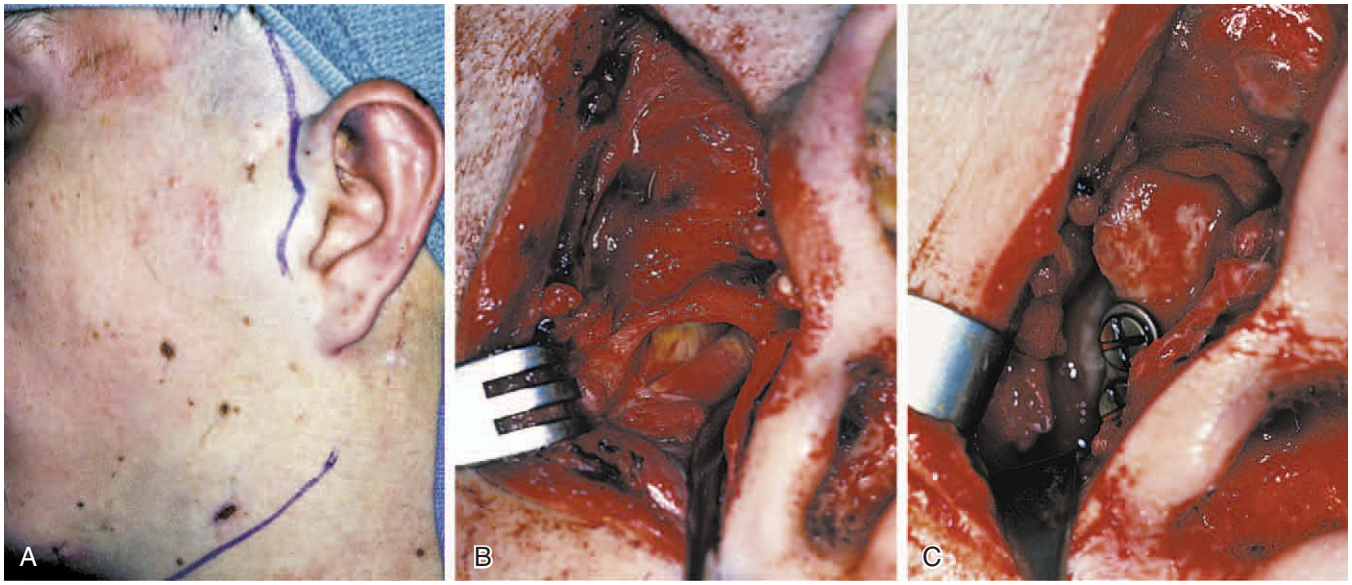

Figure 189-11. **A,** Surgical approach to a left subcondylar fracture in a 14-year-old adolescent male. **B,** Exposure of the temporomandibular joint with an empty glenoid fossa due to medial displacement of the condylar head. **C,** Open reduction and internal fixation of the condyle with titanium plates and screws.

with saline and handled by the crown. If possible, the tooth is replaced in the socket. However, if the child is uncooperative, then the tooth should be kept in saline-soaked gauze or a bowl of milk until a dentist can reimplant and stabilize the tooth. Every effort should be made to have the tooth reimplanted within 1 hour; beyond this time, tooth viability is less likely.

When an alveolar fracture is associated with a tooth fracture, treatment is more problematic. Tanaka and colleagues[15] found that dentoalveolar fractures were associated with the highest incidence of subsequent malocclusion among pediatric fractures. The problem often involves avulsed teeth, fractured roots, and displaced bone. Proper repositioning of the fragments can be very difficult, although reduction should be attempted. Prolonged periods of MMF often are required to maintain these fragments. Occasionally, stabilization with miniplates can be of some help if the bone is large enough to accept screw fixation and surgical space is adequate to avoid injuring healthy surrounding roots. A common outcome is loss of all of the components of a dentoalveolar fracture, despite aggressive measures.

Midface Fracture

Midface fractures in all age groups are described by the Le Fort classification. *Le Fort I fractures* separate the palate from the maxilla, extending through the floor of the nose, maxillary sinus, and the pterygoid plates. *Le Fort II fractures* separate the central midface from the cranium, extending through the pterygoid plates, along the lateral and anterior maxillary walls, the medial orbital wall, and the nasofrontal suture. *Le Fort III* fractures separate the entire face from the cranium extending through the zygomatic arch, frontozygomatic suture, lateral orbital wall, medial orbital wall, nasofrontal suture, septum, and the pterygoid plates.

Le Fort I fractures are rarely seen until approximately the age of 10 years, when the maxillary sinuses are well developed and the permanent teeth begin to descend.[132] In our experience, fractures in children rarely follow the typical Le Fort patterns of injury. Palatal fractures are more common in the pediatric midface injury due to incomplete fusion at the midline suture.[133] Manson[49] and Koltai[134] and their colleagues proposed a classification of midface fractures that is a simple and accurate preoperative tool. The classification, based on the energy of the impacting force, confirms that CT accurately defines the pattern of fracture and generally is the best guide for the extent and intensity of the reconstruction. Type I injuries are minimally displaced; type II fractures are moderately displaced, with some comminution; and type III fractures are severely displaced, with multiple comminution of the buttresses, resulting in a highly unstable injury that requires three-dimensional reconstruction and bone grafting.

Midface fractures in children are rare and manifest clinically with severe facial edema, prominent orbital ecchymosis, and malocclusion. Concomitant neurocranial injuries are frequent, because a force great enough to fracture the midface often will be transmitted intracranially. Axial and coronal CT scanning is indispensable for properly assessing the severity and degree of bony displacement and in developing a surgical plan. A team approach for care, including the expertise of pediatric intensivists, neurosurgeons, ophthalmologists, and anesthetists, is essential. Early operative intervention is ideal; however, this may not be possible owing to the medical condition of the child. Significant fracture displacement should be reduced within 10 days because of the high osteogenic potential of the periosteum and the growth centers; otherwise, rapid interfragmentary healing makes late correction difficult.[135] Acute reduction should be considered when fractures are accessible through open wounds.

The goals of therapy are to reestablish facial symmetry, appropriate occlusion, and normal three-dimensional proportions. Injuries with minimal or no displacement do not require correction. Active intervention is necessary when displacement has altered form or function (Fig. 189-16).

Zygomaticomalar Complex Fractures

Zygomaticomalar complex fractures correspond to the maxillary sinus pneumatization and are uncommon in children younger than 5 years. The frontozygomatic suture tends to be weak in children and easily displaced. Compared with those in adults, zygomaticomalar complex fractures in children tend to involve the lateral wall and orbital floor more extensively.[133,136] It is important to recognize orbital symptoms, including diplopia with ocular restriction and enophthalmos, signaling the possibility of an orbital floor fracture. Zygomaticomalar complex fractures can be classified by the patterns seen on CT scans, which generally correlate with the energy of the impacting force. Greenstick fracture with minimal displacement from the suture lines is typical with lower-force injuries. High-impact injuries lead to various degrees of disruption and comminution of the infraorbital rim, anterior

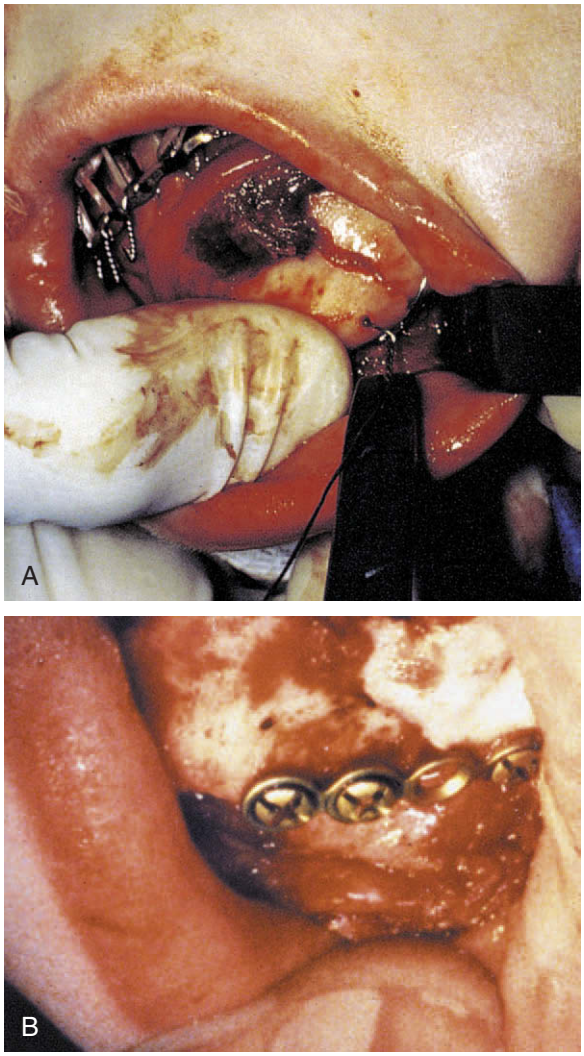

Figure 189-12. **A,** Basket-wire osteosynthesis of left parasymphyseal fracture in a 10-year-old boy. maxillary buttresses, and orbital wall and floor defects (Fig. 189-17). When the malar fragment has been laterally displaced, the fracture probably is unstable and will require fixation. The most severe injuries often are associated with Le Fort III fractures, again requiring rigid fixation.

The fracture typically involves the frontozygomatic suture, the infraorbital rim, the zygomaticomaxillary buttress, and the zygomatic arch, seen to be separated at the zygomaticotemporal suture. Minimally displaced fractures can be treated conservatively. A Gille's approach or transcutaneous bone hook can be used to reduce greenstick-type injuries, which frequently will not require internal fixation for stability. When simple reduction techniques result in unstable or nonanatomic reduction, ORIF is indicated.

Surgical correction involves adequate control of the frontozygomatic suture, the infraorbital rim, and the lateral buttresses. In most type I fractures, control of the infraorbital rim and the frontozygomatic suture can be accomplished with external palpation, and open visualization is necessary only for identification of the zygomaticomaxillary buttress through an intraoral gingivolabial sulcus incision. For type II fractures, open visualization can be accomplished through a brow, subciliary, or transconjunctival incision with lateral canthotomy, together with an upper buccal sulcus incision. For type III fractures for which significant reconstruction of the zygomatic arch also is required, a hemicoronal approach is necessary. Once exposure is achieved, most injuries can be reconstructed by one-point fixation of the zygomaticomaxillary buttress, or by two-point fixation with microplates at the frontozygomatic suture and infraorbital rim. Severe fractures will require three-point fixation of all of the buttresses. Zygomatic arch deformities usually can be repositioned by elevating through a brow or lateral canthotomy incision. When indicated, orbital floor exploration should be performed.

Nasal Fractures

The child's nose differs significantly from that of the adult. The soft, compliant cartilages that constitute the anterior projection of the nose bend easily during blunt trauma. The force causing the trauma is therefore dissipated across the maxilla and its buttresses, resulting in a broad area of edema. Rarely, the external cartilages can be dislocated from the bony framework. The septum is more rigid and thus likely to be fractured.

Several types of injury can affect the septum: Its perichondrial covering may become detached in response to the deformation of the cartilage during impact. This creates a potential space for the development of a septal hematoma. The septum also can be torn from its bony attachments or fractured in a vertical, horizontal, or stellate fashion. This can result in immediate or subsequent obstruction, delayed twisting deformities, and growth disturbances.

In young children, the nasal bones are rarely fractured because of minimal projection, but when they occur, fractures typically are of the greenstick type or occur along suture lines. When the blow is directly to the midline, an "open book" fracture can result, with central depression, lateral flaring, and splayed nasal bones over the frontal process (Fig. 189-18). With fractures of the nasal skeleton, a high index of suspicion should be maintained for more extensive but occult nasoethmoidal and orbital injuries. Fortunately, with isolated nasal fracture, growth retardation is rarely seen.[21,40]

The initial examination of a child with a suspected nasal fracture often is of limited value with regard to the external deformity because of edema. Several days may be required for the swelling to go down before the true extent of the deformity can be appreciated. However, immediate intranasal examination is essential to evaluate for septal injury, particularly septal hematoma. Nasal obstruction is the hallmark of septal hematoma and can be observed on anterior rhinoscopy as an obvious purple bulge on one side of the nose. The bulge is compressible but does not shrink with topical vasoconstriction. Septal hematoma is a serious complication and, left untreated, can result in a thick fibrotic and obstructive septum. The hematoma also can become infected, resulting in loss of cartilage and subsequent saddle nose deformity or septal perforation (Fig. 189-19). These injuries should be treated immediately with evacuation. In most cases this will require

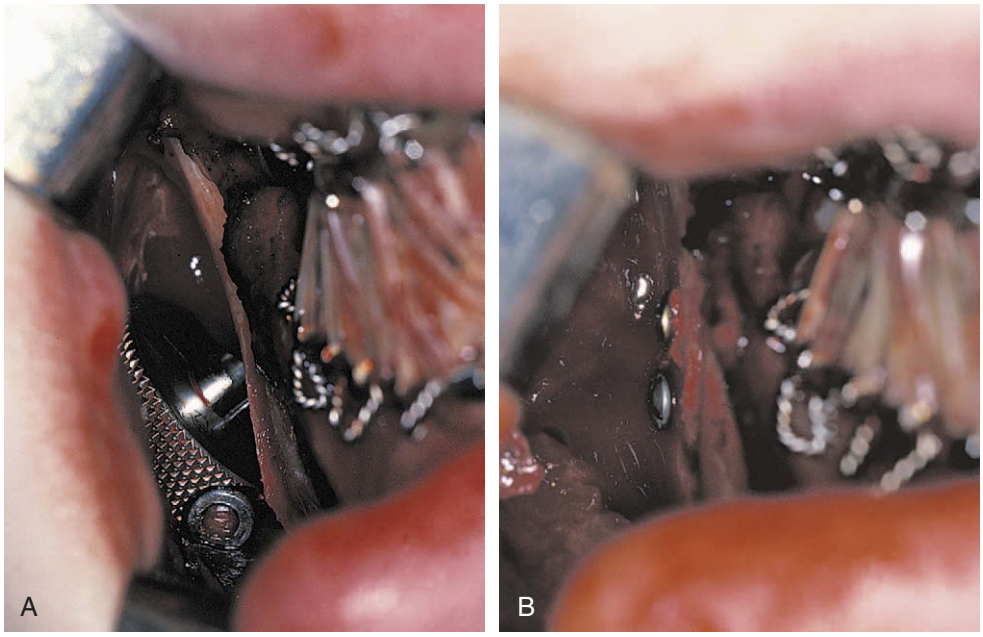

Figure 189-14. **A,** Transcutaneous instrumentation for intraoral reduction of a right-angle fracture in a 13-year-old girl. **B,** Open reduction and internal fixation of the fracture with lag screws.

general anesthesia. The use of a Killian septal incision allows for both drainage of the hematoma and investigation and suture reduction of any displaced septal fragments. After exploration has been completed, the mucoperichondrial leaflet is sewn back to the cartilage with a through-and-through suture. Septal splints and packing should be used for 2 to 3 days to prevent re-formation of the hematoma. Prophylactic oral antibiotics should be instituted. While the patient is under anesthesia, the bony nasal pyramid is examined, and if it is found to be dislocated, closed reduction can be accomplished.

If a septal hematoma has been ruled out and the possibility of nasal fracture is still a concern, the child is asked to return in 5 days, allowing time for the facial edema to subside. If a bony or septal fracture is present, resulting in a cosmetic deformity or a fixed nasal obstruction, then definitive surgical management is undertaken. Closed reduction of the bony fracture can be performed with intranasal instrumentation and bimanual external manipulation. Greenstick fractures may not always reduce into the desired position and sometimes require small osteotomies for proper alignment of the fragments. If significant dislocations are present or if the injury is more than 2 weeks old, open reduction may be necessary. The timing of open reduction is a subject of some debate; often, waiting is the best approach.

Newborn Nose

An occasional problem in newborn infants is an asymmetrical tip deformity. These infants typically have a flattened nasal tip off to one side, with the septum tilted in the same direction. The bony dorsum is invariably straight. Some controversy has arisen regarding whether this type of deformity is caused by birth trauma or by prolonged intrauterine positional pressure. Some surgeons advocate immediate surgical reduction of these deformities by straightening and relocating the septum.[137] In our experience, however, these deformities generally straighten over time despite lack of intervention, without late sequelae. The best approach with these children is to reassure the parents that the nose will straighten out in time. It is possible that such a displace-

ment can cause airway obstruction in a neonate who is an obligate nose breather, and in such cases, relocation of the septum is indicated.

Frontal Sinus Fracture

The frontal sinus is the last of the paranasal sinuses to develop in children and is therefore not prone to injury until adolescence. However, when fractures of the frontal sinus occur, 70% involve the posterior table, and the rate of CSF leak is 18%—nearly double that found in the adult population.[138] Management of pediatric frontal sinus fractures is similar to that of fractures in adults. When forehead deformity is present in a child with an anterior table fracture, it needs to be reduced (Fig. 189-20). The nasofrontal duct should be investigated both by direct visualization of the sinus floor and endoscopically. Posterior table fractures require open reconstruction, and severe comminution warrants neurosurgical consultation. Most posterior fractures are associated with anterior fractures, which can be repaired concurrently. The need for sinus obliteration is based on the same criteria as for adults. Long-term sequelae include CSF leak, intracranial abscess, and mucopyocele formation. It is important to maintain long-term follow-up with periodic imaging.

Fractures of the supraorbital rim can be treated as part of the neurosurgical repair and be approached either by extension of overlying laceration or through a coronal incision. Occasionally, a brow incision will be sufficient. Once frontal pneumatization has occurred, supraorbital rim fracture becomes more likely. Frontal sinus injury in this type of injury is common, and the approach is the same as for the adult.

Orbital Fracture

Injuries to the orbit and nasoethmoidal region can leave children with significant functional and cosmetic defects. The scope of these injuries is related to the magnitude of the force causing the injury and can vary, with injuries ranging from relatively minor fractures, such as "blowout" of the orbital floor, to complex fractures. Associated facial fractures occur in 30% of orbital fractures.[43]

Orbital fracture patterns in children tend to be age-specific. The two distinct factors in facial growth that affect the patterns of pediatric orbital fractures are craniofacial geometry and expansion and growth of the paranasal sinuses.[139] The ethmoid air cells steadily expand, reaching 70% of the interorbital width by the age of 7 years.[140] At birth, the maxillary sinus is medial to the globe, with the alveolar margin in close

Figure 189-21. Periorbital edema, ecchymoses, and subconjunctival hemorrhage are indicative of orbital injury in this 13-year-old boy with lateral orbital wall and orbital floor fractures.

Figure 189-22. Left orbital apex fracture resulting in blindness, ophthalmoplegia, and ptosis in a 14-year-old girl.

proximity to the inferior orbital rim. By age 7, the maxillary sinus has widened past the midpupillary line to occupy one half of the lateral nasal wall. Also at this age, the slowly expanding frontal sinus begins to reside above the supraorbital rim.[141] Before the age of 7 years, the large cranium is more vulnerable to trauma than the face.

There are two proposed mechanisms of orbital wall fractures.[142] The first mechanism, called the *bone conduction process*, stipulates that force applied to the orbital rim is transmitted to the walls, which then fracture.[143] The second mechanism, called the *hydraulic process*, stipulates that the force applied to the globe causes an increase in intraorbital pressure, which then results in fracture of the walls. Both mechanisms probably are operational, although bone conduction accounts for most fractures.

Suspected orbital trauma warrants an ophthalmologic evaluation. Periorbital edema, ecchymoses, and subconjunctival hemorrhage are indicative of orbital injury. Propagation of the orbital wall buckling deformation can result in optic nerve injury without apex fracture; accordingly, the first priority is an assessment of visual acuity.[156] The position of the globe, often obscured by edema, is inspected for exophthalmos, enophthalmos, and vertical dystopia. Intraocular pressures are measured. The extraocular musculature is tested for voluntary range of motion and, if necessary, with forced duction with the patient under anesthesia. Intercanthal distance and the length of the palpebral fissures are measured, and the locations of the medial canthal ligaments are identified. The rims are palpated for disruption. Cranial nerve V is tested for sensitivity (Fig. 189-21).

The orbit has three anatomically distinct regions classified by fracture patterns.[144] The *anterior* component is the hard bone of the orbital rim and is divided into three subsections. The first is the supraorbital rim, a portion of the frontal bone. Second is the infraorbital rim, which is part of the zygomaticomalar complex. The third is the medial rim, to which the medial canthal tendons attach, and is part of the nasoethmoidal complex. The *middle* component consists of the thin lamellae of bone forming the roof, the floor, and the medial and lateral walls. The *posterior* component consists of the orbital apex, including the orbital fissures and the optic canal.

Some orbital fractures in children can be treated successfully by traditional closed or limited open techniques. However, for the severe injuries that require open reduction with rigid internal fixation, the development of hidden extended incisions for complete exposure has been a major advance.

Orbital roof fractures rarely require repair. However, if ocular mobility has not improved within 7 to 10 days of injury, repair should be performed. Permanent exophthalmos, vertical dystopia, and encephaloceles can result from unattended fractures. Reconstruction is best accomplished using basicranial exposure or a combined neurosurgical-maxillofacial approach, with intracranial exposure of the orbital roof. Timing of these repairs is based on implementation of any necessary neurosurgical intervention.

Orbital Apex Fracture

Orbital apex injuries in children are exceedingly rare in clinical practice, probably because the force required is lethal.[4,12,17,40,110] Fractures of the apex usually are due to posterior extensions of complex craniofacial injuries. Blindness is the greatest concern, potentially occurring as a result of optic nerve injury and vascular injury to the ophthalmic artery. Loss of visual acuity and afferent pupil defect are the hallmark findings for an optic neuropathy. Initial treatment is with high-dose steroids. If visual acuity does not improve, optic nerve decompression should be considered using either a transsphenoidal, intracranial, or endoscopic approach. Injury to the neurovascular structures entering the superior orbital fissure can result in ophthalmoplegia, ptosis, and fifth nerve hypesthesia. Treatment is expectant, and long-term deficits are common[144] (Fig. 189-22).

Orbital Floor Fracture

Orbital floor fractures are the most common injuries of the middle component of the orbit.[145-148] In children, the occurrence of these injuries parallels the pneumatization of the maxillary sinus, and they generally are not seen before the age of 5 years. They occur as isolated blowout fractures or in conjunction with zygomaticomalar or Le Fort–type fractures.

Isolated orbital floor fractures typically present with diplopia, infraorbital hypoesthesia, periorbital ecchymosis, and edema. "Trapdoor" and "saucer" fractures are the two major types of blowout or orbital floor fractures seen in the pediatric population. Serious ocular injury with blowout fractures occurs in less than 5% of cases.[149,150]

The *trapdoor fracture* is a pure orbital floor fracture, linear in form and hinged medially, that allows herniation of orbital contents through the fracture and then entraps these herniated contents.[149,150] It usually is a consequence of low-velocity blunt trauma and is seen most commonly in the pediatric population, probably as the result of a greenstick fracture phenomenon.[151-153] The trapdoor fracture, also known as the white-eyed fracture, can be subtle on presentation. The degree of orbital edema tends to be relatively minor in trapdoor cases and insufficient to explain the significant reduction in supraduction motility.[7,151,154-158] Furthermore, the trapdoor fracture frequently is associated with nausea and vomiting.[58,151] Trapdoor fractures are believed to cause tissue ischemia and necrosis, particularly of the inferior rectus and oblique muscles.[7,154-158] Failure to relieve the pressure on the muscle results in persistent diplopia.[153] With lid edema, the diagnosis can be difficult. It is therefore imperative to maintain a high index of suspicion for trapdoor fractures. CT scans classically show a trapdoor fracture along the canal of the infraorbital nerve.[153] However, entrapment is a clinical diagnosis, so CT scanning should be used to aid in the diagnosis. Severe limitation on forced duction testing is diagnostic for these fractures[155,157] (Fig. 189-23).

The second type of orbital floor rupture is the *saucer fracture*, characterized by a depressed crack in the orbital floor, resulting in enophthalmos. These fractures are more likely to cause enophthalmos

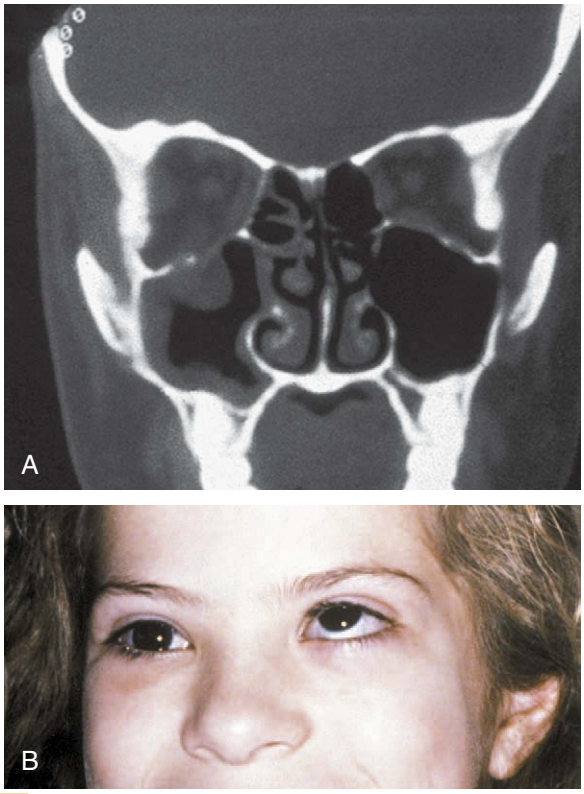

Figure 189-23. "Trapdoor" fracture of the right orbital floor in a 10-year-old child with entrapment of the inferior rectus muscle. **A,** CT scan demonstrating entrapment. **B,** Clinical photograph demonstrating the limitation of upward gaze on the right side. This problem resolved with exploration and freeing up of the entrapped muscle.

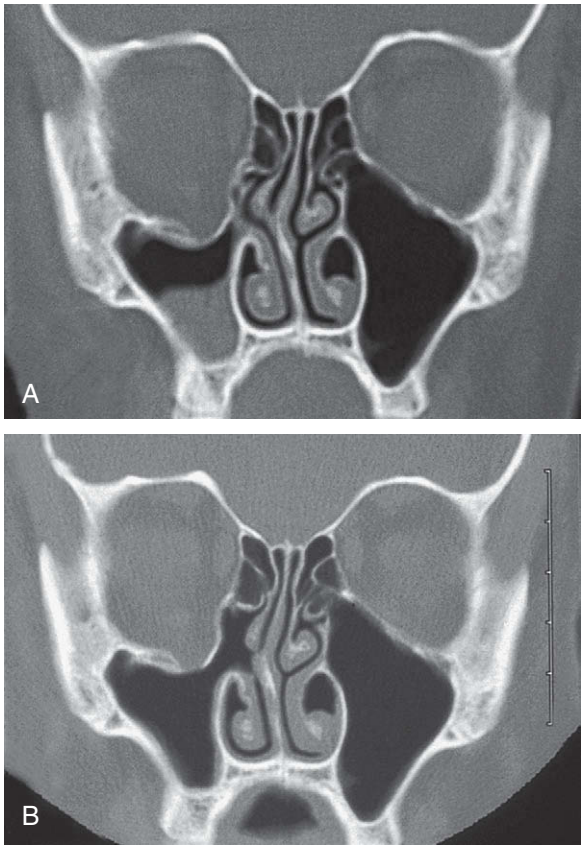

Figure 189-24. **A,** CT scan demonstrating unrecognized "saucer" fracture of the right orbital floor in a 15-year-old adolescent, causing obstruction of maxillary sinus outflow tract resulting in chronic maxillary sinusitis. **B,** Resolution of sinusitis after endoscopic maxillary antrostomy. Despite the obvious expansion of orbital volume noted on this coronal CT scan, the patient had only 1 mm of measurable enophthalmos and did not wish to have it repaired.

without significant duction deficits.[58] Because larger fractures tend not to impinge the muscle, they are less apt to cause muscle ischemia and can therefore be addressed after the resolution of edema (Fig. 189-24).

Differentiating between the two types of floor fractures is important, although management remains unnecessarily controversial. Relatively few studies evaluating the characteristics and management of internal orbital fractures in the pediatric population have been published. Putterman and colleagues popularized observation and a nonsurgical approach to all orbital blowout fractures, and for many years this was the trend in treatment.[159] However, failure to treat can lead to permanent gaze restriction, diplopia, and enophthalmos.[160,161] Accordingly, the practice of observation for all floor fractures has been challenged, with recognition of a role for surgery in some cases.

Indications for surgical intervention after an internal orbital fracture include significant (greater than 2 mm) enophthalmos, extraocular muscle restriction with positive results on forced duction testing (greater than 30 degrees), symptomatic diplopia, or CT findings of large orbital wall defect (involving more than 50% of the floor or orbital wall).[151,156,157,162,163] It is crucial that pseudoentrapment conditions such as orbital soft tissue swelling, extraocular muscle contusion, and cranial nerve injuries be distinguished from true muscular entrapment, because patients with the former conditions can be managed with observation only. The timing of surgery also is controversial. Patients with minimal diplopia, good ocular motility, absence of evidence of significant fracture or herniation on CT scans, and no significant enophthalmos can be managed by close observation over weeks.[164] However, some studies have demonstrated tight restriction of extraocular muscles. Patients with true muscle incarceration have an increased chance of ocular motility recovery with early intervention, preferably within 48 hours.[7,151,153-158,165,166]

The orbital floor can be exposed through a transconjunctival or subciliary approach. The orbital contents are gently teased back into the orbit, and bony fragments are reduced if possible. If a small defect or weakness persist, an implant of absorbable gelatin film (Gel-film) usually is adequate in children. Larger defects in children can be grafted with split calvarial bone.

Orbital Roof Fracture

Orbital roof fractures occur primarily in younger children, as a consequence of the proportionally larger cranium and the lack of frontal sinus pneumatization.[129,167] With aging, the orbital floor thins as the maxillary sinus enlarges. Consistent with maturation, the pattern of orbital fractures changes from roof fractures to the lower orbit around the age of 7 years.[8]

A history of a blow to the brow from a fall or blunt object associated with a late-developing periorbital hematoma should alert the clinician to the possibility of a roof fracture. Proptosis or dystopia can occur but may not be immediately evident (Fig. 189-25). In older children, orbital roof fractures occur as a component of more extensive craniofacial fractures, usually the result of high-velocity injuries. Up to 86% of all orbital roof fractures are associated with intracranial injury.[42,168] The orbit and globe rarely sustain long-term damage, so surgical repair is rarely necessary.[8] Fracture fragments that are displaced into the orbit will require combined intracranial and extracranial exploration with cranial bone graft reconstruction of the deficit to correct dystopia and exophthalmos and to prevent development of encephaloceles. Orbital encephaloceles have been reported as late sequelae, manifesting with vertical dystopia, axial proptosis, and pulsation of the globe.[26] Therefore, long-term follow-up with periodic imaging is important.

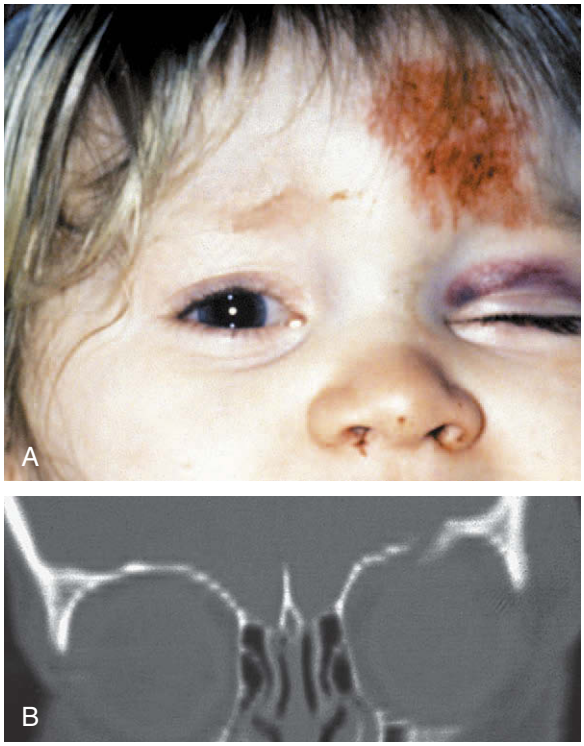

Figure 189-25. Left orbital roof fracture in a 3-year-old child from a blow to the left forehead. **A,** Note the upper eyelid hematoma. **B,** Coronal reconstruction CT scan shows the buckling of the orbital roof.

Lateral/Medial Orbital Wall

Pure fractures of the lateral and medial walls of the orbit are rare.[122,125,] When they do occur, orbital emphysema is commonly seen on CT scans. Surgical correction is necessary only for isolated injuries with nonresolving or fixed enophthalmos and entrapment within the ethmoid sinus. Surgical exposure can be accomplished using either a transcaruncular approach or through an external ethmoidectomy incision. The advantage of the transcaruncular approach is camouflage of the incision, with the small risk of medial fornix scarring[98,169,170] (Fig. 189-26).

Naso-orbitoethmoid Fractures

Fractures of the naso-orbitoethmoid (NOE) complex can vary in severity, ranging from minimal dislocations to highly comminuted compound fractures that extend into the surrounding frontal bone, orbits, and maxilla. The four-sided NOE fracture is anatomically defined by fractures of the nasofrontal suture, nasal bones, medial orbital rim, and infraorbital rim. This complex makes up the "central fragment" core of the midface.[144] Presence and degree of comminution of this core will determine the severity of the fracture and the complexity of surgery to achieve optimal cosmetic and functional results (Fig. 189-27).

CT scan is invaluable in the assessment of the NOE fracture. Evaluation of the medial canthal ligaments is mandatory and best performed with the patient under anesthesia by inserting a hemostat in the nose up toward the medial orbital rim (Fig. 189-28). Traumatic hypertelorism is evaluated by intercanthal distance, which is difficult owing to the lack of standard reference data and the great variation between males and females and among those of differing ethnic backgrounds. Nevertheless, the average intercanthal distance in children at the age of 3 years is approximately 25 mm; by age 12, it is 28 mm, and by adulthood, 30 mm.[140] An additional 5 mm of soft tissue widening above the age-adjusted average is suggestive of displaced fracture of the NOE complex, with 10 mm of displacement being diagnostic.

Most NOE fractures are best treated with ORIF. Although this is technically difficult, overcorrection of the NOE fracture is aesthetically superior to undercorrection.[171] Exposure is best obtained through preexisting lacerations or coronal incisions, with mobilization of the globes along the orbital roof to expose the nasal dorsum. The major fragments and the medial canthal ligaments are identified. Care is taken to preserve the attachment of the ligament to the bony insertion. To facilitate interfragmentary reduction and transnasal wiring, the central fragment is mobilized (Fig. 189-29).

Resetting the intercanthal distance is aesthetically the most important step for optimal results. Interorbital growth is nearly complete by the age of 8 years. It is crucial in children to set the intercanthal distance narrower than anticipated. In medial canthal reconstruction, a drill hole is made in the anterior lacrimal crest just above the insertion of the anterior limb of the tendon. A second drill hole is made in the posterior lacrimal crest just behind the insertion of the posterior limbs. Contralateral drill holes are made, and 28-gauge, stainless steel wire is passed transnasally between the two fragments and tightened in an effort to overcorrect the deformity. An alternative technique is to use a small screw as the anchor for the transnasal wires. Interfragmentary wiring is completed and, if the repair is unstable, further supported by plate fixation of the medial orbital rim[65,144] (Fig. 189-30).

The final step is reconstruction of the nasal dorsum, which often loses its support. A cantilever calvarial bone graft can be used to correct this deformity. It is best to place these grafts rigidly in hopes of limiting reabsorption. The tip of the graft should be deep to the upper border of the lower lateral cartilages (Fig. 189-31).

Direct injury to the lacrimal drainage system is uncommon in NOE fractures. Nevertheless, the lacrimal sac, duct, and canaliculi should be examined, and if injured, definitive repair with stents should be performed to prevent epiphora.

Conclusion

Children sustain severe maxillofacial injuries that require appropriate repair. The primary factor that distinguishes the management of pediatric fractures from that of adult fractures is facial growth. Trauma to the mandible is well compensated and growth disturbances are uncommon with appropriate treatment. Inadequate treatment of upper and midfacial injuries may result in serious alterations of facial growth. CT scanning, craniofacial exposure, bone grafting, and the advent of resorbable rigid fixation facilitate the reconstruction of the most complex three-dimensional disfigurements. These techniques have solid theoretic and practical applications in severe facial trauma.

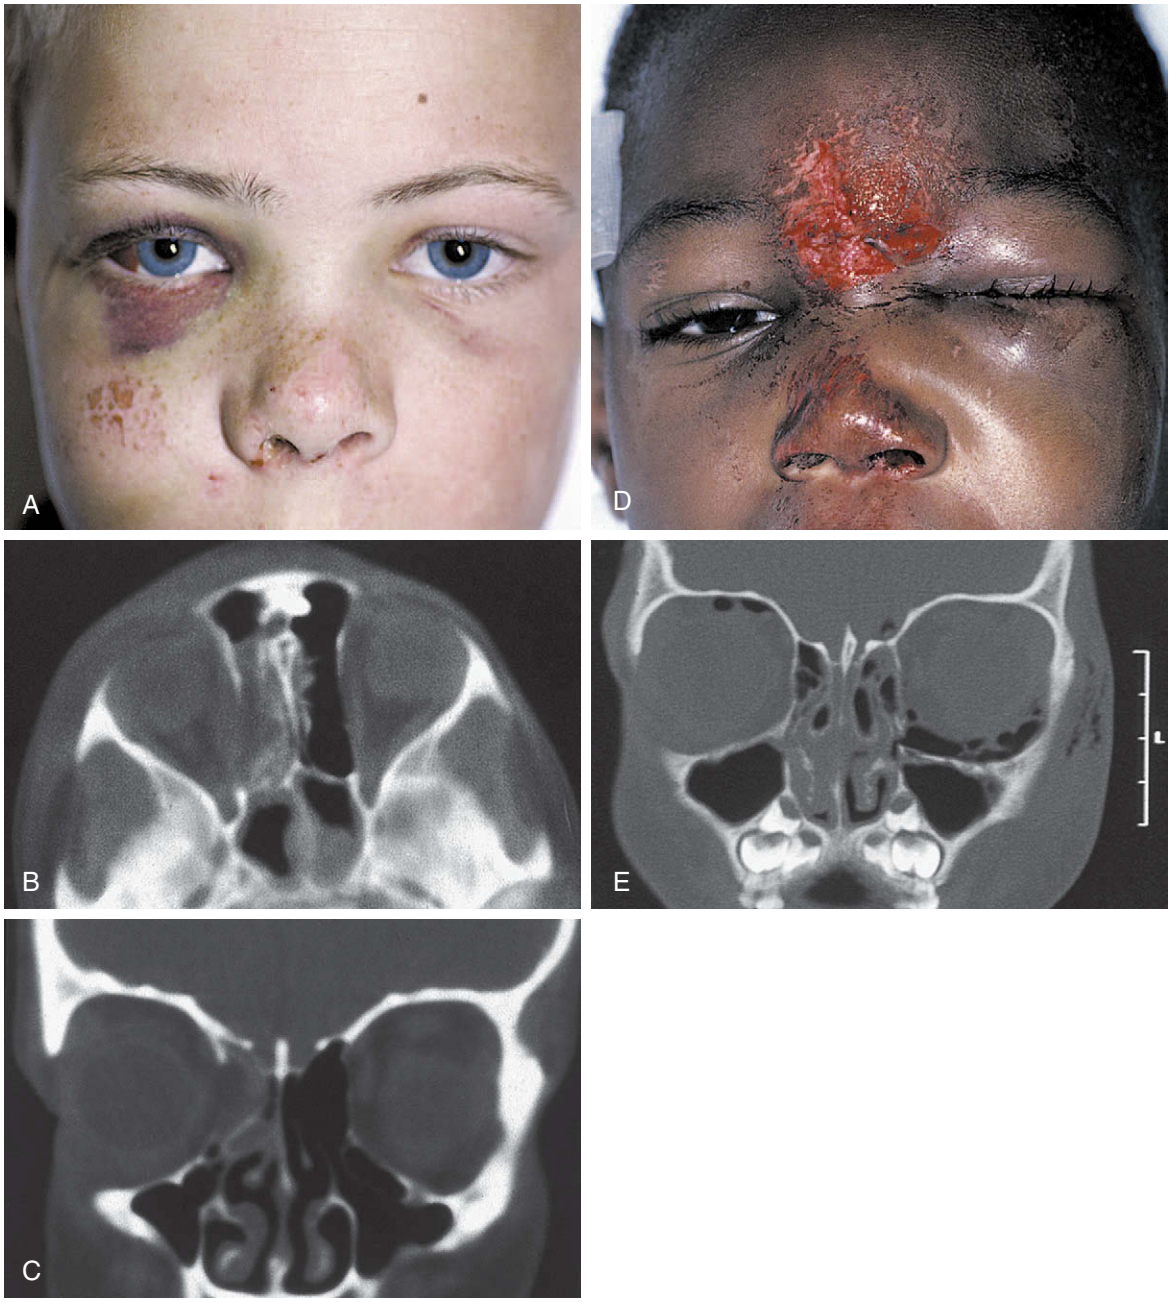

Figure 189-26. **A to C,** Right medial orbital wall fracture in a 9-year-old child. **A,** Note the lower eyelid and subconjunctival hematoma. **B** and **C,** Axial and coronal CT scans showing the medial displacement of the lamina papyracea. **D** and **E,** Nondisplaced bilateral medial orbital fractures in a 4-year-old child from a blow to the nasoethmoidal region and forehead. **D,** Clinical photograph. **E,** Coronal CT scan demonstrating orbital emphysema from the nondisplaced medial wall fractures. *(**B** and **C**, courtesy of Linda Brodsky, MD.)*

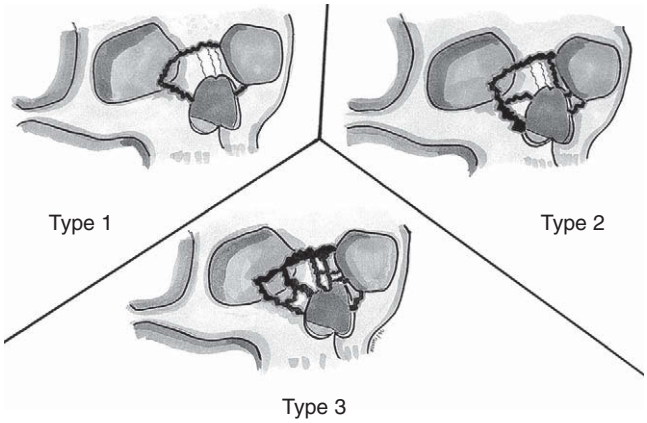

Figure 189-27. Classification of nasoethmoidal fractures. In type 1 fractures, the "central fragment" is intact as a single fragment of bone. In type 2 fractures, the central fragment is comminuted, but the fracture does not extend deep to the anterior lacrimal crest. In type 3 fractures, the comminution extends deep to the anterior lacrimal crest.

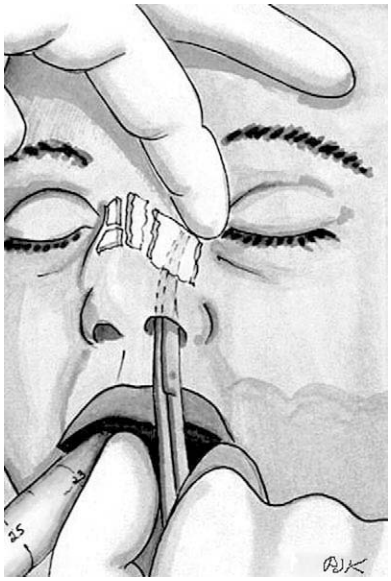

Figure 189-28. Bimanual test for medial canthal displacement. A hemostat is placed intranasally underneath the canthal bearing bone while the examiner's finger palpates the medial canthal tendon. The mobility of the canthal tendon-bearing fragment is an indication for medial canthopexy.

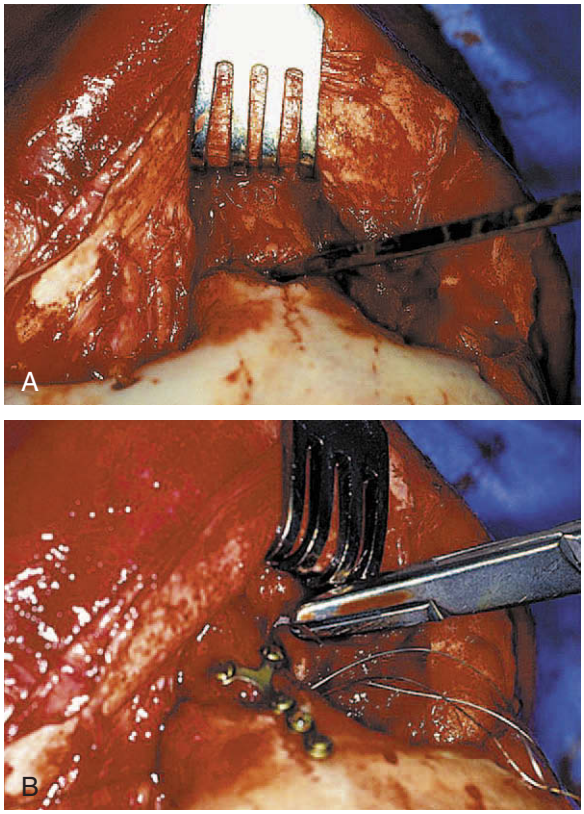

Figure 189-29. Repair of a nasoethmoidal fracture in a 3-year-old child was delayed for 3 weeks owing to concomitant neurocranial injuries, by which time the injury had begun to heal. **A,** At surgical repair, the fracture fragments required remobilization. **B,** Open reduction and internal fixation of the "central fragment" has been completed by suspension from the frontal bar by a "Y" plate. Medial canthopexy with transnasal wiring is demonstrated.

CHAPTER ONE HUNDRED AND NINETY

Early Detection and Diagnosis of Infant Hearing Impairment

Susan J. Norton

Prabhat K. Bhama

Jonathan A. Perkins

Key Points

General

- Hearing loss may lead to delayed language development and poor school performance.
- Universal newborn hearing screening allows for earlier detection and intervention in infants with hearing loss, which may result in improved language development in affected children.
- Estimated rates of congenital sensorineural hearing loss (SNHL) range from 1 per 1000 to 3 per 1000 live births, depending on the degree of hearing loss.

Principles and Techniques of Newborn Hearing Assessment

- Screening outcomes are either "pass" (no further testing indicated) or "refer" (infant is at risk for hearing loss and requires diagnostic hearing evaluation).
- The auditory brainstem response (ABR) measures action potential responses of the eighth cranial nerve to an auditory stimulus.
- Evoked otoacoustic emissions (EOAEs) measure sound waves generated by the outer hair cells of the cochlea after an auditory stimulus.
- Most newborns with hearing loss do not have obvious abnormalities on physical examination, but ophthalmologic examination is warranted in these patients because of the high incidence of ocular defects in patients with severe to profound hearing loss.
- A strong association between hearing loss and impaired vestibular function in infants and children has been documented.
- Newborns who fail initial hearing screening tests should undergo careful otomicroscopic examination, because middle and external auditory canal problems are a frequent cause of such results.
- Diagnostic audiology (or visual reinforcement audiometry for infants unable to understand verbal instruction) is indicated by the age of 3 months for all infants not passing a newborn hearing screening test.
- Standardized laboratory tests in infants failing initial screening are not necessary or cost effective.

History of Infant Hearing Screening

The importance of early identification of hearing loss has been recognized for many years.[1-3] Undetected hearing loss present from an early age can impede acquisition of speech, language, cognitive, and social-emotional development.

Joint Committee on Infant Hearing

The Joint Committee on Infant Hearing (JCIH), of which the American Academy of Otolaryngology–Head and Neck Surgery is a founding member, was established in 1969 with the goal of developing more accurate and efficient methods of identifying neonatal hearing impairment. In 1972, the JCIH recommended the use of a High-Risk Registry (HRR) to identify neonates at higher-than-normal risk for hearing loss. It recommended these infants be referred for audiologic testing within the first 2 months of life. In 1982,[4] 1990,[5] and 1994[6] the JCIH issued updated high-risk criteria. The 1994 HRR included family history of hereditary childhood sensorineural hearing loss, in utero infection (e.g., toxoplasmosis, other viral infections, rubella, cytomegalovirus infection, and herpes simplex [TORCH]), craniofacial anomalies, birth weight less than 1500 g, hyperbilirubinemia severe enough to necessitate an exchange transfusion, ototoxic medications including but not limited to use of aminoglycosides in multiple courses or in combination with loop diuretics, bacterial meningitis, Apgar scores of 0 to 4 at 1 minute or 0 to 6 at 5 minutes, mechanical ventilation lasting 5 days or more, and presence of stigmata or other findings associated with a syndrome known to include sensorineural or conductive hearing

loss. However, the JCIH recommended HRR use only if universal newborn hearing screening (UNHS) was unavailable. Only 2% to 5% of neonates with one or more risk factors exhibit a moderate to profound hearing loss. Conversely, 95% to 98% of neonates with one or more risk factors have normal hearing.[7] Furthermore, 50% of children with moderate to profound congenital hearing loss exhibit no risk factors for hearing loss.[8] This means that use of the HRR alone, as an indication for hearing testing, would leave at least 50% of infants with congenital hearing loss undiagnosed. In 2007, the JCIH recommended hearing screening for all newborns, with formal audiologic assessment in those who fail the initial screening test by 3 months of age, followed by intervention by 6 months of age for children with significant hearing loss.[9]

Delay in Identification

A significant delay exists in the identification and intervention of hearing impairment for infants without risk factors. For infants with mild to moderate hearing loss, a 1996 survey showed that parents of high-risk infants first suspected the loss when their infants were at a median age of 8 months. By contrast, the parents of infants without risk factors first suspected their infant had a hearing loss when the child was 15 months old.[10,11] Hearing loss was confirmed in infants without risk factors at 22 months of age, compared with 12 months of age for infants with risk factors, and infants were enrolled in intervention at 28 and 18 months, respectively. Ages of suspicion (7 to 8 months), diagnosis (12 to 13 months), and intervention (18 to 19 months) were essentially the same for infants with severe to profound hearing loss, regardless of whether risk factors were present. Recent retrospective studies indicate that infants with hearing loss enrolled in appropriate early intervention by 6 months of age incur significantly fewer delays than those who enroll after 6 months of age.[10,12] These findings are for children with all degrees of hearing loss, as well as for children with other handicapping conditions.

Universal Newborn Hearing Screening

In 1993, the National Institute for Deafness and Other Communicative Disorders (NIDCD) Consensus Conference on Early Identification of Hearing Loss recommended UNHS for infants within the first 3 months of life, preferably before hospital discharge.[13] Subsequently, several organizations and government agencies have endorsed UNHS as the best way to ensure early detection and habilitation of hearing loss. These groups include the Academy of Otolaryngology–Head and Neck Surgery, American Academy of Pediatrics, American Speech-Language-Hearing Association, American Academy of Audiology, and others. Despite considerable disagreement concerning the relative merits of specific measurement approaches for neonatal hearing screening and whether UNHS is even appropriate at this time,[14] universal newborn and infant hearing screening statutes have been passed in 41 states (legislation is pending in two states), and all states have implemented newborn hearing screening programs.[9] The goals of the U.S. Department of Health and Human Services' initiative Healthy People 2010 include UNHS by 1 month of age, diagnostic confirmation of hearing loss by 3 months of age, and enrollment in appropriate early intervention for children with hearing loss and their families by 6 months of age.[15] The Newborn Infant Hearing and Screening Intervention Act of 1999 provided funding to help states reach this goal. In 2008, the U.S. Preventive Services Task Force published a grade B recommendation to screen for hearing loss in all newborn infants.[16]

Prevalence of Sensorineural Hearing Loss in Children

Estimates of congenital sensorineural hearing loss (SNHL) vary, ranging from 1 per 1000 to 3 per 1000 live births, depending on the degree of hearing loss. Bilateral severe to profound hearing loss (70 dB HL or greater) occurs in 1 per 1000 live births. When the results of several studies are averaged, approximately 3 per 1000 infants have a hearing loss of 30 dB or greater.[17-21] The incidence of significant hearing loss is 10 times greater for infants with one or more risk factors than for those with no risk factors.

Progressive, late-onset, and acquired hearing loss in childhood is a continuing challenge. In its survey of deaf and hard-of-hearing school-aged children, Gallaudet Research Institute found a prevalence of significant hearing loss of 1.8% in children 3 to 17 years of age.[22] This figure is six times higher than the incidence of hearing loss in the neonatal period. Similarly, van Naarden and colleagues[23] reported that the average point prevalence of hearing losses 40 dB or greater increased with age from 0.67% at 3 years of age to 1.38% at 10 years of age. It is important that hearing, speech, and language development be monitored because of the occurrence of progressive, late-onset, and acquired hearing loss in early childhood.

Increase in Early Identification

In those states with UNHS, the average age of identification of congenital hearing loss has dramatically decreased. Rhode Island mandated UNHS in 1993. In 1998, Vohr and colleagues[24] reported that the average age at confirmation of permanent hearing loss in Rhode Island infants was 3 months. By contrast, in the absence of UNHS, the average age at diagnosis of permanent hearing loss in children was 31.25 months. In its 1999 Policy Statement, the American Academy of Pediatrics noted: "Reliance on physician observation and/or parental recognition has not been successful in the past in detecting significant hearing loss in the first year of life."[25] Long-term prospective studies of deaf and hard-of-hearing children identified through newborn hearing screening programs are needed to determine if in fact educational and vocational outcomes are significantly better for these children. A recently published controlled trial in the United Kingdom demonstrated that UNHS increased the proportion of 7- to 9-year-old children with permanent hearing loss who were identified before 6 months of age.[26] Strong data illustrating improved speech and language development from early interventions are lacking, but one controlled trial found that early detection of childhood hearing impairment leads to higher language scores (but not speech scores) in mid-childhood.[27]

Principles and Techniques of Newborn Hearing Assessment

Testing Protocols

The goal of newborn hearing screening is to identify those infants who need diagnostic hearing evaluations because they are at risk for significant hearing loss. With current technology, screening outcomes are either "pass" or "refer" (Fig. 190-1). "Pass" indicates the infant is not at risk for significant hearing loss and needs no further testing at this time. "Refer" indicates the infant is at risk for hearing loss and requires a diagnostic hearing evaluation. It is important to emphasize to parents and health care providers that "refer" does not mean that the baby has a hearing loss; this designation indicates only that the child has a greater risk of having hearing loss.

For many years, a primary barrier to UNHS was the lack of affordable, reliable, easy-to-use methodology. A hearing screening test has several requirements. First, the response being measured must be robust, specific to the peripheral auditory system, and present in all normal-hearing newborns. Second, the response criteria must be objective, based on scientific data, and applied consistently. Third, the measurement procedures must be noninvasive, rapid, reliable, and easy to use, with capability for separate testing of each ear. Behavioral methods do not meet these requirements. At present, one of two physiologic measures of auditory system status is used singly or in combination in most UNHS programs. Current technology uses automated protocols and pass-refer criteria. Such algorithms allow the use of less experienced testers, thereby reducing the cost of screening and removing some of the variability in test administration.

Auditory Brainstem Responses

The auditory brainstem response (ABR) is a series of scalp-recorded electrical potentials generated in the auditory nerve and brainstem during the first 10 to 20 ms after the onset of a transient stimulus. For the purposes of a hearing screening, responses typically are elicited by air-conducted clicks presented at a level that is thought to produce a response in ears with normal hearing and to produce no response in ears with

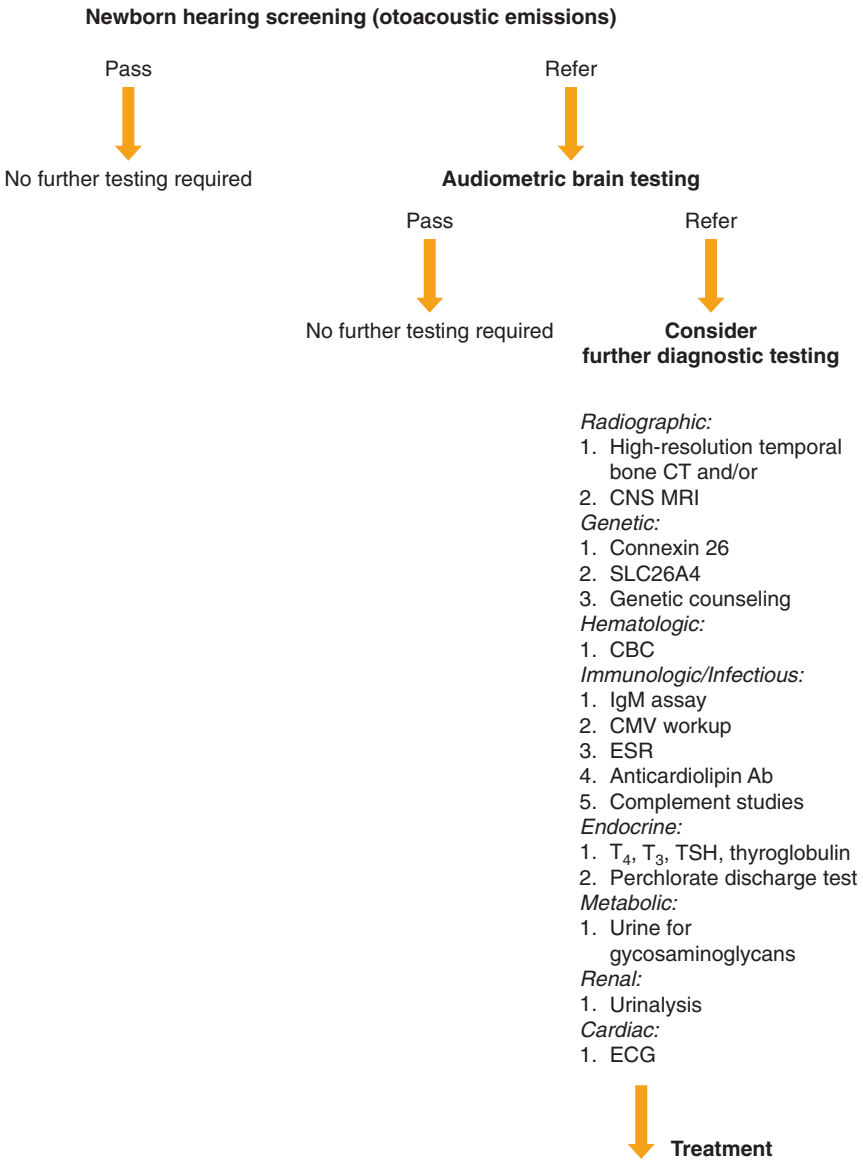

Figure 190-1. Algorithm for newborn hearing screening. Ab, antibody; CBC, complete blood count; CMV, cytomegalovirus; CNS, central nervous system; CT, computed tomography; ECG, electrocardiogram; ESR, erythrocyte sedimentation rate; IgM, immunoglobulin M; MRI, magnetic resonance imaging; T_3, triiodothyronine; T_4, thyroxine; TSH, thyroid-stimulating hormone.

hearing loss (30 to 35 dB normal hearing level [nHL]). Surface electrodes record the synchronized time-domain averaged response to the click.

In response to a click stimulus of known intensity, ABR latency and morphology are highly predictable for infants of a given age. This evoked potential is present in human neonates as early as 25 weeks of gestational age and is unaffected by sleep, attention, or sedation. ABR morphology changes rapidly with age during infancy because of maturation of the central nervous system (CNS). Therefore, it is important to use age-appropriate latency-intensity norms in judging the quality of ABR. ABR is affected by external and middle ear, cochlear, auditory nerve, and brainstem status. Middle ear disease or anomaly reduces the stimulus intensity, thus increasing the latency and decreasing the amplitude of the ABR. Cochlear abnormalities affect the quality and morphology of the ABR in many different ways. Response amplitude may be reduced, latency may be increased, or waveform morphology altered, depending on the degree and configuration of the hearing loss. Brief stimuli such as clicks have a broadband frequency spectrum. Click-evoked ABR is not frequency-specific. Any region of normal hearing can generate the response if there is sufficient energy in the stimulus at that frequency. ABR also is abnormal in the presence of eighth cranial nerve and lower brainstem abnormalities even if peripheral hearing loss is not present.

ABR has been used for many years to screen infants in the neonatal intensive care unit (NICU) before hospital discharge.[28-32] Recent advances have resulted in the development of automated ABR detection algorithms.[33-37] These systems replace the subjective impression of the tester as to the presence or absence of an ABR, with an objective statistical estimate of the likelihood or probability of a "response" distinct from the background "noise."

Evoked Otoacoustic Emissions

Evoked otoacoustic emissions (EOAEs) are also used widely for newborn hearing screening. EOAEs are acoustic signals generated by the cochlea in response to auditory stimulation. They are a physiologically vulnerable indicator of cochlear status, specifically outer hair cells. EOAE generation is independent of neural activity, so EOAE testing measures cochlear status independent of CNS status. Transient evoked otoacoustic emissions (TEOAEs) occur after a brief click stimulus.[38] TEOAEs provide information over a broad frequency range (approximately 500 to 6000 Hz). Distortion product otoacoustic emis-

sions (DPOAEs) occur in response to simultaneous presentation of two pure tones with the appropriate frequency and amplitude ratios and provide frequency-specific information across a broad range of frequencies.[39]

Almost immediately after the first otoacoustic emissions (OAEs) reports by Kemp and Ryan[40] and Kemp, several investigators suggested that one of the potentially most useful clinical applications of OAE is assessment of cochlear status in infants.[41,42] In theory, OAEs were thought to (1) take less time to measure than an ABR, because OAEs do not require electrode attachment, (2) provide information over a broader frequency range than click-evoked ABR, and (3) provide cochlear-specific information unaffected by neurologic pathology.

Data from several groups of investigators indicate that robust, broadband TEOAEs can be measured in neonatal ears in the absence of external or middle ear pathology.[40,43,44] Likewise, data indicate that DPOAEs are robust in neonates and infants.[45-49]

Concerns about OAE-based neonatal hearing screening include difficulty testing in noisy environments, and the effects of vernix and other debris in the ear canal, as well as collapsing ear canals during the first 24 hours after birth.

Comparison of Otoacoustic Emissions and Auditory Brainstem Responses

In summary, technologic advances now make it possible to assess auditory function in neonates and infants. These electrophysiologic and acoustic responses can be safely applied without reliance on a behavioral response. However, neither OAE nor ABR tests evaluate hearing or describe how a particular person will use available hearing. OAE and ABR are physiologic responses related to peripheral hearing status but constitute indirect measures of hearing.

To predict hearing status in children 8 to 12 months of age, a multicenter longitudinal study compared the accuracy of click-evoked ABRs, TEOAEs, and DPOAEs. The results indicated no significant differences among the three measures.[48] However, a recent study comparing two-step TEOAEs and ABRs found that ABR was more effective for UNHS because it yields fewer false-positive results and a lower referral rate compared with TEOAE, resulting in a smaller percentage of infants lost during follow-up.[50]

Typically, a simple pass-refer criterion is chosen for a screening tool. Many studies and these programs assume a priori that all infants who "passed" the screen had normal hearing. To determine the true accuracy of neonatal tests, however, it is necessary to follow all infants evaluated during the neonatal period, regardless of neonatal test outcome.[48] Because the true hearing status of those infants who pass the screening test is not known, true sensitivity cannot be calculated. Errors made among infants with normal hearing can be known because these false-positive results are evaluated with additional testing. The fact that the "passes" may include infants with hearing loss will have little or no influence on the true-negative rate or specificity of the test, because the vast majority of infants have normal hearing. However, the errors among ears with hearing loss (false-negative results) cannot be known if only those infants failing the newborn hearing test are followed. This is because misses are not followed up. Assigning a "pass" to even a small number of babies with hearing loss can have a large effect on test sensitivity because of the small total number of those with hearing loss.

The sensitivity and specificity of ABR, TEOAE, and DPOAE testing alone or in combination depend on the target degree of hearing loss, the test parameters, and response criteria. For example, Hyde and associates[51] reported ABR sensitivity of 98% and specificity of 96% if the average target hearing loss is 40 dB nHL at 2 and 4 kHz. If the target degree of hearing loss is 30 dB nHL, sensitivity and specificity were 100% and 91%, respectively. Norton and coworkers held specificity at 80% and determined sensitivity for TEOAE, DPOAE, and ABR alone and in combination for a target loss of 30 dB nHL. Sensitivity ranged from 80% to 90%. If those infants with known progressive hearing loss were excluded, sensitivity improved.[48]

Because it is impossible for hospital-based screening UNHS programs to follow all infants screened regardless of test outcome, it is important to remember that no test is perfect. Click-evoked ABR often misses hearing losses in which hearing is normal at some frequencies. For example, a baby with a low-frequency hearing loss with normal thresholds at 2000 Hz and above will pass an ABR screening test. Likewise, a baby with high-frequency hearing loss with normal hearing at lower frequencies may pass an ABR screen. High-frequency hearing losses are relatively common and may have significant effects on speech and language development.

OAE testing may miss inner hair cell and eighth cranial nerve hearing losses. OAEs are generated by the outer hair cells and are independent of neural status. Recently, there are concerns about auditory dyssynchrony,[52] defined as robust OAEs and abnormal or absent ABR. This is an extremely heterogeneous population whose behavioral hearing status ranges from normal hearing to profound hearing loss. Good incidence data of this disorder in the neonatal population are scarce.

Physicians and parents must include regular monitoring of hearing, speech, and language milestones even for those infants who pass a newborn hearing screening test whether it is TEAOE, DPOAE, or ABR.

Common UNHS protocols include OAE testing before discharge followed by an outpatient OAE re-screen for inpatient referrals, OAE inpatient screen and ABR re-screen, OAE and ABR inpatient screens, and ABR inpatient and ABR re-screens. Outpatient re-screens help minimize the number of infants referred for diagnostic audiologic testing and hence costs. Persistent re-screening is inappropriate. Infants should be referred for diagnostic follow-up evaluation after two failed screenings.

Some hospitals implement two-stage screening, in which OAE is used as the preliminary screening test. Infants failing this test are then screened with the automated ABR (AABR). Those who fail the AABR undergo more diagnostic testing to evaluate for permanent hearing loss, but infants who pass the AABR are not tested further. A multicenter evaluation of the two-stage screening revealed that many infants with hearing loss may be missed, because infants who pass only the AABR are not referred for further testing.[53]

Diagnosis and Treatment of Hearing Loss in Infants

History

In infants who fail hearing screening tests, a directed history to identify potential sources of hearing loss is appropriate.[54] A careful family history looking for hearing loss, ocular abnormalities, congenital cardiac problems in first- and second-degree relatives, and any associated syndromes is essential. Prenatal history for possible maternal infection (i.e., TORCH), gestational diabetes, and hypothyroidism can help direct the evaluation. Maternal use of alcohol should be sought, because fetal alcohol syndrome is associated with auditory dysfunction. Other maternal illnesses and social habits (e.g., drug use and smoking) should be sought. Risk factors for hearing loss in the perinatal period are well known, as discussed earlier in this chapter.[6,55]

Physical Examination

A majority of newborns with hearing loss do not have abnormal physical features.[56] Nevertheless, a complete physical examination is essential. Presence of abnormal iris color, skin tags, anterior cervical neck pits, goiter, cleft palate, skull shape, abnormal numbers of digits, areas of hypopigmentation, and café au lait spots are potential signs of a syndromic disorder. Such a diagnosis, such as Wardenburg's or branchio-oto-renal syndrome, may explain hearing loss identified through infant hearing screening. Alternatively, these physical signs may prompt careful follow-up investigation and imaging to identify progressive sensorineural hearing loss or conductive hearing loss, which may occur in neurofibromatosis or craniosynostosis. Pendred's syndrome may be associated with goiter development. Stickler's syndrome has characteristic eye and facial features, along with cleft palate. Patients suspected of having possible branchio-oto-renal syndrome need a renal ultrasound examination. Those patients identified with severe to profound sensorineural hearing loss and neurologic and ocular abnormalities should

have serial ophthalmologic evaluations to evaluate for retinitis pigmentosa. Electroretinography may uncover early forms of this abnormality, allowing early identification of Usher's syndrome. At this point the exact indications for this testing modality are unclear, but some investigators recommend electroretinography in all cases of undetermined bilateral severe to profound sensorineural hearing loss.[57] In any case, ophthalmologic examination is warranted, because up to one half of children with severe to profound hearing loss have ocular defects.[58]

Vestibular Function Assessment

When hearing loss is identified, careful attention to vestibular function is necessary.[59] A strong association exists between hearing loss and impaired vestibular function in infants and children. Neurologic and developmental milestones are important to record. Signs of peripheral vestibular dysfunction can occur with delayed motor development. Evaluation for the presence of nystagmus (i.e., spontaneous or head shaking type) can be done in infants. When nystagmus is present, further testing may be warranted.

Otomicroscopy

Infants who fail hearing screening tests should have careful middle and external auditory canal examinations with the otomicroscope, because a problem with the middle and external auditory canals is the most common source of failed initial hearing screening.[60] This type of examination allows careful cleaning of the ear canal and identification of external auditory canal stenosis or atresia.[61,62] Additionally, assessment of middle ear function may be possible with this method by assessing the thickness and character of the tympanic membrane, as well as its motion. In older children, tympanometry and pneumatic otoscopy by experienced examiners both measure middle ear status accurately, but in infancy (0 to 6 months of age) both measures can miss detection of middle ear effusions.[63]

Middle Ear Effusions

When persistent middle ear effusions are identified as a potential source of an abnormal hearing screening, observation is essential when there is no evidence of acute inflammation. The incidence of middle ear effusions in the first year of life is quite high and in infancy it is estimated to be as high 61%.[64] In our practice, we usually wait 2 to 3 months for spontaneous resolution of the middle ear effusion. If the effusion persists after that time, ABR testing is still performed to determine whether there is a response to sound. No clear guidelines for medical therapy have been developed for infants with persistent middle ear effusions. Oral steroid therapy can be given to clear the effusion, but in infancy the risks of this treatment must be weighed against its benefits.[65] If the child has acute otitis media, antibiotic therapy is necessary along with observation for effusion resolution. Tympanostomy tube insertion is done for persistent middle ear effusion. Usually the recommendations for treatment of persistent otitis media with effusion in children between 1 and 3 years of age as outlined in 1994 by the Agency for Health Care Policy and Research also are used in young infants.[66,67] However, no outcomes studies have been conducted to demonstrate the most effective therapy for middle ear effusions in children younger than 1 year of age.

Diagnostic Audiology

As mentioned earlier in this chapter, all infants not passing a newborn hearing screening should be referred for diagnostic audiology by 3 months of age. Diagnostic follow-up investigation for infants referred from newborn hearing screening programs should include threshold frequency–specific ABR and OAE testing. Frequency-specific ABR thresholds have good agreement with behavioral thresholds[68] and can be used to fit appropriate amplification and guide intervention. Air and bone conduction should both be evaluated using tone-pip ABR. A significant air-bone gap in ABR thresholds is indicative of external or middle ear pathology, just as with pure-tone audiometry. EOAE should always be obtained with ABR testing to rule out auditory neuropathy and other neural losses. Tympanometry using a probe-tone frequency of 1000 Hz or higher can provide information about middle ear status. In children younger than 4 months of corrected age, traditional tympanometry—using a 226-Hz probe tone—is invalid because of the characteristics of the neonatal ear canal.[69]

Visual Reinforcement Audiometry

Visual reinforcement audiometry (VRA) is a modification of standard audiometric testing, designed for infants who are unable to understand verbal instruction. In VRA, operant conditioning techniques are used to reward a natural orienting response of the infant by providing an enjoyable event to reinforce the likelihood of continued responses. An infant's natural response to sound is a head turn in the direction of the sound source. When that response is rewarded by the activation of a lighted, animated toy, the infant may continue to respond for a sufficient number of stimulus trials to obtain an audiogram.[70]

VRA thresholds for infants as young as 6 months of age have been shown to be within 10 dB of adult hearing thresholds. VRA thresholds have been shown to be comparable to thresholds obtained by play audiometry in children of preschool age.[71-74] Good agreement between VRA and tympanometry indicates that the method is sensitive enough to detect even slight threshold elevations, such as those due to middle ear effusion. VRA is not restricted to sound field testing. Numerous reports indicate that VRA testing can be done reliably under earphones. Infants born prematurely who have spent time in the NICU tend to perform better if testing is delayed until 6 to 8 months corrected age. By 12 months of age, infants have been shown to need fewer conditioning trials, be less variable in responses near threshold, and yield fewer false-positive responses in comparison with infants who are 6 months of age; however, older infants tend to reject earphones more frequently than younger ones.[73-76]

Ancillary Testing

Ancillary Laboratory Testing

No evidence shows that standardized batteries of laboratory tests in infants failing initial hearing screening are necessary or cost effective.[56] All testing in these infants should be directed by hearing testing results and patient age, history, and physical examination.[77] These tests usually exclude specific causes of hearing loss but on occasion can confirm a diagnosis. Routine blood chemistry and complete blood count are unhelpful in evaluating hearing loss in infancy. If there is a family history of hematologic disease, such as thalassemia or sickle cell disease, screening can be performed for these disorders.[78,79] Diseases with platelet abnormalities that usually appear later in life (e.g., Fechtner or Epstein-Barr syndrome) can be discovered.[80] Such diseases are associated with sensorineural hearing loss.[12,38] Similarly, Alport's syndrome can be suspected when laboratory evidence for renal dysfunction is present with hearing loss. Autoimmune-induced hearing loss can occur in children but is not routinely suspected in infants.[63] Metabolic disorders, such as mucopolysaccharidoses, are associated with both conductive and sensorineural hearing loss and should be tested for when assessment reveals a family history of metabolic disorders, with hearing loss or physical features consistent with this diagnosis.[81,82] When the family history includes syncopal episodes and hearing loss, an electrocardiogram should be obtained to look for evidence of Jervell and Lange-Nielsen syndrome.

Guidelines for Genetic Testing

Deafness in infancy is believed to be at least 50% genetic in origin, with the remaining 50% being acquired or of unknown etiology.[83] Of the cases of genetic deafness, 75% to 80% are autosomal recessive, 15% to 20% are autosomal dominant, and 1% to 2% are X-linked. A few patients acquire hearing loss through mitochondrial inheritance. Of note, newborn hearing screening does not identify progressive hearing loss, which does occur in preschool-aged children. It is estimated that 15% to 20% of young children identified with SNHL have progressive hearing loss. Among children with SNHL in infancy, chromosomal karyotyping is recommended for those with a maternal history of multiple miscarriages and an unrecognizable constellation of anomalies. Additionally, if there are any associated neurologic or cardiac defects, chromosomal karyotyping is essential. Rapid advances in

molecular genetics ensure that many new diagnostic methods for detection of the genetic basis for hearing loss will become available by the next decade.

Screening for Connexin 26 Mutation

In the late 1990s and early in the millennium, the autosomal recessive inheritance of hearing loss was linked to mutations at *GJB2*.[84,85] This gene codes for connexin 26 and is believed to be responsible for up to one half of all cases of autosomal recessive congenital hearing loss. The 35delG deletion is responsible for 70% of all connexin 26 mutations. The autosomal recessive non-syndromic hearing loss mutation in connexin 26 is known as DFNB1 (in genetic notation, the prefix DFNB signifies autosomal recessive hearing loss).[86] DFNB1 is associated with prelingual nonprogressive bilateral sensorineural hearing loss without evidence of temporal bone computed tomography (CT) anomalies or vestibular abnormalities. The hearing loss associated with this deletion can range from mild deficits to profound deafness. Considerable interfamilial variation in degree of hearing loss is recognized among affected families. Because the 35delG mutation involves a single base pair, screening tests for this deletion are available. It is estimated that the connexin 26 deletion is responsible for 50% of the cases of autosomal recessive sensorineural hearing loss.[87] Within this family of connexins, however, 60 different allele variations exist and therefore the hearing loss may not always be simply a result of the 35delG mutation.[88] When a child is born homozygous for the 35delG mutation, the chance of recurrence is 25%. The same chance of occurrence is present in a heterozygous patient. Siblings of affected persons have a 66% chance of carrying the deletion while having normal hearing.[89] Therefore, when testing for the 35DelG mutation is performed, genetic counseling should also be available.

Testing for Pendred's Syndrome

Genetic testing can be performed when Pendred's syndrome is suspected.[86] Pendred's syndrome represents 10% of the cases of syndromic hearing loss and is the most common cause of syndromic hearing loss. It is associated with a dilated vestibular aqueduct on temporal CT scanning.[90] Screening for mutations at *SCL26A4* (*DFNB4*) is done in the research setting.[85] Results of thyroid function tests usually are normal, with the exception of thyroglobulin levels, which can be elevated. The perchlorate discharge test is nonspecific and difficult to perform in young children.

Temporal Bone Imaging

Noncontrast temporal bone CT scanning is the imaging test most commonly used for all children with SNHL. Increasingly, T2-weighted MRI is being used as new techniques have enhanced its capability to delineate anatomy. (See also Chapter 191 in this text.) The timing of the imaging is debated and is beyond the scope of this chapter to discuss. It should definitely be performed at any age in all patients with progressive SNHL or craniofacial anomalies. These clinical signs are the best predictive factors for abnormalities within the temporal bone.[91] As mentioned earlier, the dilated vestibular aqueduct is associated with Pendred's syndrome.[92] A dilated vestibular aqueduct is defined as one with a diameter greater than 1.5 mm at its middle third or greater than 2.0 mm anywhere along its length. When a dilated duct is discovered, testing for Pendred's syndrome should be initiated, along with serial audiologic examinations to detect progressive hearing loss. Mondini dysplasia reflects abnormal development of the cochlea and is associated with both Pendred's and branchio-oto-renal syndromes.[93] Abnormalities of the semicircular canals also are seen on temporal bone imaging and are associated with a well-recognized constellation of manifestations: coloboma, heart defects, atresia choanae, retardation of growth and development, genitourinary problems, and ear abnormalities—the CHARGE association.[94] Superior semicircular canal dehiscence also can be identified radiographically and has been associated with conductive hearing loss in children, albeit in rare cases.[95]

Identification of internal auditory canal stenosis and possible eighth cranial nerve aplasia is associated with hereditary deafness. This X-linked form of deafness (DFN3) is associated with conductive loss at birth, followed by SNHL at a later age. Magnetic resonance imaging (MRI) scanning can be used to visualize the acoustic nerve, exclude aplasia, and rule out inner ear destruction secondary to infectious causes.[96] In cases in which infection or neoplasia is suspected, MRI with contrast is favored.[97] Accurate imaging of the seventh and eighth cranial nerve complex may be necessary before consideration for cochlear implantation.[98] Functional MRI scanning may help elucidate the exact nature of SNHL found in infancy.[99,100] Additionally, central auditory processing may be further clarified with this modality.[101] Because of its soft tissue detail,[102] some investigators feel that MRI should be performed in cases of pediatric unilateral or asymmetrical SNHL in which CT findings are negative, to rule out a CNS cause of hearing loss.[103] MRI also is indicated in patients who may have neurofibromatosis type 2. If CT results are negative but hearing loss is progressive, or if audiologic testing reveals a possible retrocochlear pathology, MRI also may be warranted.[104]

Screening for Maternally Transmitted Infection

Other laboratory evaluations may include specific immunoglobulin M (IgM) testing for suspected intrauterine infection. IgM does not cross the placenta and, if present in the infant's blood, may suggest congenital cytomegalovirus (CMV), syphilis, or rubella infection. Further testing to elucidate these potential sources of hearing loss may include cultures for CMV in blood, urine, or saliva. Congenital CMV infection is a frequent congenital infection that can have significant neurologic sequelae.[12] Hearing loss can be the only manifestation.[105] The virus persists in infected infants and can be detected in the first 3 months of life. When the virus is detected, early treatment may lessen the severity of neurologic sequelae. With congenital syphilis, the fluorescent treponemal antibody absorption (FTA-ABS) test indicates intrauterine transmission of syphilis.[106] Congenital toxoplasmosis is present in 0.6% of newborns. Hearing loss is present in 10% to 15% of these newborns and usually is associated with other abnormalities (i.e., chorioretinitis, intracerebral calcification, and microcephaly). Early identification of the potential for this infection suggests that treatment may reduce the level of hearing impairment. Herpes simplex type 2 usually is transmitted through contact with vaginal lesions at the time of delivery and is associated with a low incidence of hearing loss. On the other hand, herpes simplex type 1 is associated with hearing loss in transplacental transmission.[107] Detection of IgM antibodies to this virus raises this infection as a possible source of hearing loss. Congenital rubella can be detected through serologic testing. Although the incidence of this infection has significantly decreased in recent times, it still is present, particularly in underdeveloped countries, and hearing loss is estimated to be the only sign of this infection in 50% of cases.[83]

Intervention Strategies

Surgical Therapy for Conductive Hearing Loss

Newborns with conductive hearing loss most commonly have middle ear effusions. If the actual hearing threshold needs to be established, then tympanostomy tube insertion is necessary. Other types of surgery to correct conductive hearing loss are beyond the scope of this discussion and are not usually attempted in infancy.

Bone Conduction Amplification

Hearing aids should be considered for any child who demonstrates a permanent bilateral hearing loss—both conductive and sensorineural—exceeding 20 dB HL between 1000 and 4000 Hz.[108] Even children with minimal hearing losses are at risk for experiencing educational difficulty.[109,110] A bone conduction hearing aid is fitted when the child is unable to wear air conduction hearing aids as a result of atresia, stenotic ear canals, or recurrent draining middle ears. Bone-anchored hearing aids are not approved by the U.S. Food and Drug Administration (FDA) for children younger than 5 years of age.

Amplification

Hearing aids should be fitted as soon as possible after confirmation of a hearing loss. As infants are identified earlier as a result of UNHS, audiologists face many challenges in fitting hearing aids, including size

of the head and ear canal, poor head control, behavior, and rapid growth. Children younger than 7 years of age should be fitted with either behind the ear (BTE) hearing aids or bone conduction hearing aids.[108] Smaller styles of hearing aids, such as in the ear (ITE) and completely in canal (CIC) aids, are inappropriate for infants and young children whose ear canals are constantly increasing in size. Increasing ear canal size means that new ear molds must be made frequently to ensure proper amplification. ITE and CIC hearing aids would necessitate recasting, leaving the child without amplification during this process. Furthermore, ITE and CIC hearing aids pose a significant safety issue.

Hearing aid evaluation and selection involve determination of the appropriate circuitry and processing algorithm based on the child's degree, configuration, and type of hearing loss, plus the child's developmental needs and family resources. A selection and fitting technique designed for infants should be employed. The most widely used procedure involves measurement of the real-ear-to-coupler (RECD).[109-111] In addition, a technique such as the desired sensation level (DSL) method should be used to ensure audibility of the amplified speech, regardless of input level or vocal effort.[112,113]

Infants, particularly those with hearing losses of 55 dB and above, should be fitted with personal wireless frequency modulation (FM) systems to improve the speech-to-noise ratio. A receiver attaches to the child's hearing aid, and the caregiver wears a microphone and transmitter. Use of an FM system also reduces the feedback problems often encountered with infants, who have poor head control and mobility.

Regular follow-up appointments with the audiologist are critical for optimal fitting and usage of amplification devices for infants. Generally, infants are seen for follow-up appointments at least every 3 months during their first year. Ear molds may need to be remade even more frequently for some children. Other important considerations for children include tamper-resistant battery doors and controls, clips to secure the hearing aid to the child's clothing to prevent loss, listening tubes for parents, and extended warranties for loss and damage. Orientation for parents and other caregivers should include care and use of the hearing aid and FM system including wearing schedules, insertion, removal, storage, cleaning, and basic troubleshooting.

Sound field–aided testing often is used to confirm audibility. Aided testing provides information about how the child uses the signal provided by the hearing aid. That is, RECD and DSL are used to select, fit, and verify proper hearing aid function and audibility, whereas sound field testing provides information about how the child is using his or her hearing. Misleading information may be obtained in cases of severe to profound hearing loss or minimal hearing loss, or when nonlinear signal processing or digital noise reduction circuitry is used.[112]

Cochlear Implantation

A discussion of all aspects of cochlear implantation in children is beyond the scope of this chapter. Some general considerations are presented here.

When SNHL is identified and hearing aid amplification is applied with success, consideration for cochlear implantation is entertained. It is our practice to carefully evaluate each patient to establish candidacy for this procedure. As time has gone on, the indications for implantation have broadened and continue to evolve. Several studies indicate that the younger the age at which children with severe to profound hearing loss receive a cochlear implant, the better their auditory oral speech and language skills, and the more likely they are to be mainstreamed with their normal-hearing age peers. The FDA has approved cochlear implants for infants with profound hearing loss at 12 months of age and at 18 months of age for those with severe hearing loss. Increasingly, infants younger than 12 months of age are receiving cochlear implants. The key component of all treatment is identification of the type and extent of the hearing loss. Once this has been established, appropriate rehabilitative measures can be initiated, which eventually may include cochlear implantation. Several temporal bone abnormalities that may preclude this intervention are cochlear ossification and vestibular nerve aplasia. Enlarged vestibular aqueduct (EVA) syndrome has been thought to be a contraindication to implantation in the past, but not at present. Postmeningitic deafness is associated with cochlear ossification, and early implantation is recommended by some investigators to avoid the difficulties encountered when the cochlea is ossified. If the vestibular nerve is nonexistent, implantation will not help.

Early Intervention

Hearing loss in infants is primarily a communication problem, limiting the child's access to spoken language. Hearing loss happens to the family, not just the child. Providing the infant with full access to communication is the primary goal of early intervention. In addition to the use of assertive listening devices, parents learn to accommodate their baby's communication needs. The Individuals with Disabilities Education Act (IDEA) mandates early intervention services for children 0 to 3 years of age.[114] These programs are administered by individual states. Physicians should consult with local agencies to learn more about the services in their home state. Services for infants with hearing loss and families are generally home-based. There may be play groups and parent groups, but IDEA specifies that a majority of services be delivered in natural environments (i.e., where infants without disabilities are found). Because of the unique language and communication needs of deaf and hard of hearing (D/HOH) children, it is critical that services be provided by professionals with expertise in childhood hearing loss and early childhood education.

Historically, controversies in the education of D/HOH children have focused on communication methodology. Three broad categories exist: American Sign Language (ASL), simultaneous communication using spoken and signed English, and auditory-oral only. The history and nuances of this issue are beyond the scope of this discussion. Parents of children with hearing loss repeatedly stress that they want full unbiased access to information about their options, that they want to talk to other parents and not just to professionals, and that they are in charge of making decisions about their baby's communication needs.

CHAPTER ONE HUNDRED AND NINETY-ONE

Congenital Malformations of the Inner Ear

Robert K. Jackler

Key Points

- In congenital SNHL, approximately 20% of inner ears demonstrate a radiographically detectable abnormality.
- Many patterns of deformity appear to result from disturbance in the embryogenesis of the inner ear during the first trimester.
- Enlargement of the vestibular aqueduct is most common, followed in frequency by semicircular canal and cochlear deformities.
- The imaging patterns of cochlear anomaly include aplasia, hypoplasia, incomplete partition, and common cavity.
- Semicircular canals may be absent (aplastic) or deformed (dysplastic).
- The eighth nerve may be aplastic or hypoplastic, especially when the internal auditory canal is narrow.
- Congenital ear malformations may be a feature of syndromes such as Pendred's and Usher's syndromes, the CHARGE association, and various trisomies.
- High-resolution T2-weighted MRI is superior to CT because it shows the endolymphatic sac and eighth nerve.
- Hearing in milder deformities is variable but tends to worsen over time.
- Pseudoconductive hearing loss may be present, with a high risk for dead ear and occurrence of CSF "gusher" at stapes surgery.
- Predilection for stapes gusher, due to modiolar defects, may be inherited in an X-linked pattern.
- Head trauma may cause sudden decrease in hearing.
- May be associated with transotic CSF leak and recurrent meningitis.
- Surgery on the endolymphatic sac or middle ear windows has not been shown to improve or stabilize hearing.
- Cochlear implantation usually is successful but carries a heightened risk for CSF leak, meningitis, and facial twitch.

Development of the inner ear begins early in embryogenesis. By the end of the eighth week, the membranous labyrinth has assumed its characteristic convoluted shape.[1] Gradual ossification of the otic capsule develops around the membranous labyrinth and is essentially complete by birth.[2] Maturation of the sensory epithelium occurs long after formation of the membranous labyrinth, during the late second and early third trimesters. By weeks 26 to 28 of gestation, hair cell and auditory neural development are largely complete. Thus, the normal human fetus may be able to hear 2.5 to 3 months before birth.

Most inner ear malformations arise when formation of the membranous labyrinth is interrupted during the first trimester of pregnancy.[2] This interruption may be either a result of inborn genetic error or a consequence of a teratogenic exposure during the period of inner ear organogenesis between the fourth and eighth weeks of gestation. Genetic errors may be either dominant or recessive and may manifest as sensorineural hearing loss (SNHL) alone or be associated with any of a number of syndromes.[4] A partial list of syndromes associated with radiologically detectable inner ear malformation includes Pendred's, Usher's, Waardenburg's, Wildervanck's (cervico-oculoacoustic), branchio-oto-renal, and Alagille's sundromes.[5-8] Nonsyndromic familial inner ear malformations have also been described.[9,10] Teratogenic influences known to affect inner ear organogenesis include in utero viral infection (e.g., rubella, cytomegalovirus infection), chemical teratogens (e.g., thalidomide), and radiation exposure.[11] Abnormalities in otic capsule structure and deficiencies in the organ of Corti appear to arise as secondary effects of the earlier error in development of the membranous labyrinth. Derangement of the otic capsule ossification process alone does not appear to be a major mechanism in congenital hearing loss. Ossification of the labyrinthine lumen, however, is a common finding in early acquired deafness, typically arising as a consequence of meningitis.

Developmental damage to cochlear structure and function is not restricted to agents that cause gross structural malformations. Even in doses below those that would be ototoxic in the adult, aminoglycoside antibiotics administered in the animal equivalent of the human first trimester of pregnancy cause severe hearing loss in several species.[12] This time frame corresponds to the maturation of the outer hair cells and initiation of the cochlear potentials. Human studies also document this. In 35 of the infants delivered by 72 women who received streptomycin prophylaxis for tuberculosis during the first 4 months of pregnancy, auditory deficits ranging from minor high-frequency threshold elevations to severe bilateral SNHL were noted.[13]

The risk is not restricted to the first trimester. Even at low doses, slighter hearing losses were noted when aminoglycoside antibiotics were administered during the human equivalent of the last two trimesters of pregnancy, which has obvious implications for use of these drugs in pregnant women and in premature infants who have not yet reached functional cochlear maturity.

Congenital anomalies of the inner ear may be considered in two broad categories: malformations with pathologic changes limited to the

membranous labyrinth and malformations that involve both the osseous and membranous portions of the labyrinth. This division has been chosen because of its clinical relevance. Only patients with malformed otic capsules exhibit abnormalities on inner ear radiographs and therefore may be diagnosed during life. By inference, children with congenital SNHL and radiographically normal inner ears may be assumed to possess anomalies limited to the membranous labyrinth or neural pathways. Although several types of membranous deformities have been described, their classification is not yet of clinical use because differentiation requires histopathologic examination. Among the deformities that affect the otic capsule, a variety of morphologic patterns may be recognized radiographically, and classification may have prognostic and even therapeutic importance.

Incidence

Most children with congenital sensory hearing loss, with the possible exception of auditory neuropathy, would have detectable abnormalities in their inner ears if they could be examined histologically. Because most children with profound bilateral SNHL have radiographically normal inner ears, it can be inferred that malformations limited to the membranous labyrinth predominate. The incidence of malformations reported varies, depending on the hearing level of the study population, the sophistication of imaging used, and the definition of abnormality used by the observer. As a rule of thumb, approximately 20% of cases of congenital SNHL will demonstrate inner ear malformation with modern imaging technology. In a series of 234 children who had SNHL of varying degrees of severity, Reilly[14] found cochlear anomalies in only 4% of those evaluated by high-resolution computed tomography (CT). With improvements in CT imaging technology and greater awareness of inner ear deformities, Antonelli and colleagues found anomalies in 31% of 157 children with SNHL of variable degree.[15] In another CT study, anomalies were found in 17% of 185 ears of children with SNHL and none in the ears of 309 children without SNHL.[16] A large Korean study found 22% incidence of anomalies on radiologic imaging in 590 ears with profound SNHL.[17]

The incidence of deformities of the semicircular canals (SCCs) and inner ear aqueducts has been less well studied than that of cochlear deformities. In a series of patients with radiographically detectable malformations of the inner ear, the cochlea was involved in 76%, the semicircular canals were involved in 39%, and the vestibular aqueduct (VA) was affected in 32% of ears.[3] The total is more than 100%, because many cases demonstrate abnormalities of more than one portion of the inner ear. In recent years, a heightened awareness of VA enlargement, combined with the greater sensitivity of axial CT scans in demonstrating this deformity, has led to a substantial increase in its detection. The rapid accrual of cases by clinicians interested in inner ear malformations suggests that enlargement of the VA will ultimately prove to be the most common radiographically detectable inner ear anomaly.[6]

Among deaf children with radiographically normal inner ears, histopathologic studies indicate that cochleosaccular dysplasia (Scheibe's dysplasia) is by far the most common deformity.[18] Because of the paucity of pathologic specimens available for examination, it is impossible to estimate the relative frequency of the various membranous malformations.

Classification

The traditional nomenclature used to describe congenital anomalies of the inner ear involves a confusing array of eponyms that stem from the first reports of the various morphologic patterns, usually by 18th or 19th century authors. In this chapter, a descriptive classification system is used, along with the traditional eponymous terminology, to make this topic more logical, easier to learn, and more clinically relevant (Box 191-1). In membranous malformations, this classification is based on histopathologic changes in the inner ear; in combined osseous-membranous deformities, radiographic appearance is used to distinguish among the various entities.[3] Correct use of the terminology of pathoembryology is important, although these terms frequently are applied imprecisely in the earlier literature. Key terms are *aplasia* (complete lack of development), *hypoplasia* (incomplete development), and *dysplasia* (aberration in development). The classification scheme used in this chapter has proved to be of practical clinical use and has been employed in most published studies in recent years. Other classification schema that categorize observed anomalies have been proposed.[19]

Box 191-1

Classification of Congenital Inner Ear Malformations

Malformations Limited to the Membranous Labyrinth

- Complete membranous labyrinthine dysplasia
- Limited membranous labyrinthine dysplasia
  - Cochleosaccular dysplasia (Scheibe)
  - Cochlear basal turn dysplasia

Malformations of the Osseous and Membranous Labyrinth

- Complete labyrinthine aplasia (Michel)
- Cochlear anomalies
  - Cochlear aplasia
  - Cochlear hypoplasia
  - Incomplete partition (Mondini)
  - Common cavity
- Labyrinthine anomalies
  - Semicircular canal dysplasia
  - Semicircular canal aplasia
- Aqueductal anomalies
  - Enlargement of the vestibular aqueduct
  - Enlargement of the cochlear aqueduct
- Internal auditory canal anomalies
  - Narrow internal auditory canal
  - Wide internal auditory canal
- Eighth nerve anomalies
  - Hypoplasia
  - Aplasia

Malformations Limited to the Membranous Labyrinth

In malformations limited to the membranous labyrinth, which account for more than 90% of cases of congenital deafness, the bony labyrinth is normal.[20-23] In its most severe form, membranous dysplasia involves the entire labyrinth, including the cochlea, semicircular canals (SCCs), utricle, and saccule. A limited form of membranous labyrinthine dysplasia, involving only a portion of the inner ear, also has been described.

Complete Membranous Labyrinthine Dysplasia

Complete membranous labyrinthine dysplasia was first described by Siebenmann and Bing[24] and is extremely rare. It has been reported in association with cardioauditory (Jervell and Lange-Nielsen) and Usher syndromes.[25]

Limited Membranous Labyrinthine Dysplasia

Cochleosaccular Dysplasia (Scheibe's Dysplasia)

Incomplete development of the pars inferior is the most frequent histopathologic finding in congenital deafness. It was first described by Scheibe[26] and commonly is known as *cochleosaccular dysplasia*. The spectrum of pathologic findings in this anomaly, which is confined to the cochlea and the saccule, has been well described.[22,27-30] The organ of Corti is either partially or completely missing. The cochlear duct usually is collapsed, with Reissner's membrane adherent to the limbus. Less commonly, the duct is distended, presumably as a result of endolymphatic hydrops. The stria vascularis typically is degenerated and may contain colloidal inclusions. Schuknecht[31] described characteristic

strial changes consisting of aplasia alternating with regions of hyperplasia and gross deformity. Cochlear changes may be severe in the base turn and gradually lessen in intensity toward the apex, or they may be severe throughout. The saccule usually is collapsed and has degenerated sensory epithelium. In cochleosaccular dysplasia, the SCCs and utricle are normal. Auditory neuronal survival is variable but may remain normal into adulthood, at least in some cases. Cochleosaccular dysplasia also has been demonstrated in a number of animal species, including the deaf white cat, Dalmatian dogs, and various mouse mutants.[32]

Cochlear Basal Turn Dysplasia

Dysplasia limited to the basal turn of the cochlea may be related to familial high-frequency SNHL. No description of membranous labyrinthine dysplasia limited to the pars superior was found in an extensive review of the literature. This outcome is not surprising, because affected persons probably are minimally symptomatic. They would have normal hearing and presumably would have compensated for their congenital vestibular deficit.

Malformations of the Membranous and Osseous Labyrinth

Congenital anomalies of the inner ear that deform the otic capsule are of special interest to the clinician because they may be recognized and differentiated during life through radiographic imaging. As discussed previously, only approximately 20% of congenitally deaf people demonstrate radiographically anomalous inner ears. The clinical manifestations and natural history of these deformities are highly variable. Although some patients are deaf from birth, most maintain some residual hearing into adulthood. Slowly progressive deterioration of hearing during childhood, with eventual stabilization, is common. Sudden decrements in hearing are frequent and may appear to be spontaneous or may be triggered by head trauma, even minor in nature. Presumably, most of these cases are due either to internal fistulization secondary to membrane rupture within the cochlea, with admixture of perilymph and endolymph, or to external fistulization to the middle ear. Fluctuant hearing loss is unusual in these patients, and endolymphatic hydrops is an atypical finding. In some patients, hearing may be best preserved in very high frequencies (greater than 8000 Hz), which are not measured by conventional audiometry.[33] Residual ultra-audiometric hearing should be suspected in hearing-impaired children who manifest substantially better auditory function than would be predicted by pure tone results in the speech frequencies.[34] Occasionally, malformation of the inner ears may be associated with normal hearing.[35,36] This is especially the case for semicircular canal anomalies.[37] Vestibular symptoms, which occasionally are severe, are present in approximately 20% of patients.[3] Retardation of motor development has been documented in some children with malformed inner ears, particularly those in whom semicircular canals are absent.[38] A few patients experience vertigo when exposed to loud sounds—the so-called Tullio phenomenon.[39]

A wide variety of morphologic patterns of inner ear malformation has been observed radiographically and may involve the cochlea, SCCs, or vestibular aqueduct[3,40-45] (Fig. 191-1). Similar diversity has been observed on histologic analysis.[21,46-50] A majority of combined osseous and membranous malformations appears to arise from a premature arrest in the development of one or more components of the inner ear (Fig. 191-2). The strongest evidence for this theory comes from the resemblance of most malformed inner ears to the appearance of the inner ear during embryogenesis, particularly between the fourth and eighth weeks of gestation. As a general rule, the earlier the developmental arrest, the more severe the deformity and the worse the hearing will be.

Other anomalies cannot be explained by a premature arrest in development alone and appear to arise from an aberrant embryologic process. An example of this type of anomaly is a cochlea of normal length but abnormal size or coiling geometry.[46] In humans, the inner ear is of adult size at birth and shows strikingly little variation in size among individual patients. Pappas and colleagues[51] suggested that some children with congenital SNHL and apparently normal inner ear morphology on CT possess subtle abnormalities in the dimensions of inner ear structures. These investigators propose that such dimensional variations arise from a teratogenic insult during the second or third trimester, after the membranous labyrinth has formed but before it has reached adult size. Further study is needed to determine the clinical relevance of these observations.

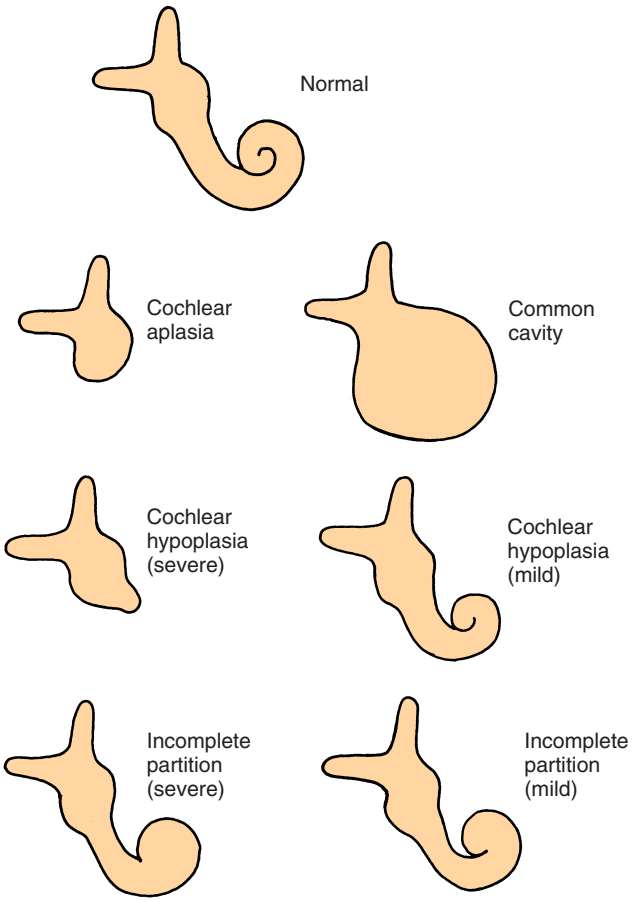

Figure 191-1. Cochlear malformations. Drawings were made from coronal computed tomography scans. *(From Jackler RK, Luxford WM, House WF. Congenital malformations of the inner ear: a classification based on embryogenesis.* Laryngoscope. *1987;97[Suppl 40]:2.)*

Whereas some inner ear malformations involve only one portion of the inner ear, many patients have a combination of anomalies involving more than one component. Between the fourth and fifth weeks of development, the spheric otocyst develops three buds that ultimately form the cochlea, SCCs, and VA (see Fig. 191-2). An inner ear malformation may be limited to one of these anlages, may involve a combination of two, or may even affect all three.

The frequent coexistence of deformities involving the cochlea, SCCs, and VA has several possible explanations: (1) the anomaly is genetically predetermined; (2) an insult to the embryo occurred before the fifth week; or (3) each of the buds was susceptible to some teratogenic influence at a later stage of development. A majority of inner ear malformations are bilateral and symmetrical. In cases in which radiographs detect an anomaly on only one side, the opposite "normal" inner ear has a hearing loss in approximately 50% of cases.[3]

Before the evolution of high-resolution imaging technology, clinicians and histopathologists alike tended to lump these malformations together under the term *Mondini's dysplasia*, after the first report by Carlo Mondini. We are indebted to the late Dr. Peter Phelps and Latin scholar Gordon Hartley for an English translation of Mondini's original article.[52] Before the Academy of Sciences of the University of Bologna, Mondini described the inner ear findings in a deaf 8-year-old boy who was struck on the foot by a wagon and later died of gangrene.[53]

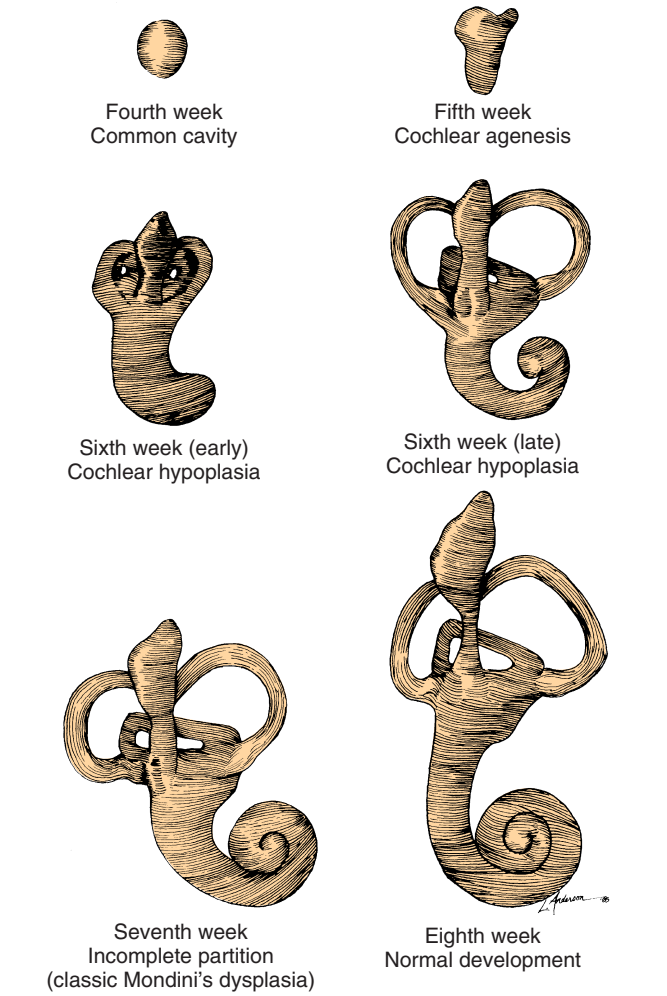

Figure 191-2. Embryogenesis of cochlear malformations. *(From Jackler RK, Luxford WM, House WF. Congenital malformations of the inner ear: a classification based on embryogenesis.* Laryngoscope. *1987;97(Suppl 40):2.)*

Table 191-1

Relative Incidence of Cochlear Malformations

Malformation	Incidence (%)
Incomplete partition (Mondini's dysplasia)	55
Common cavity	26
Cochlear hypoplasia	15
Cochlear aplasia	3
Complete labyrinthine aplasia (Michel's aplasia)	1

The cochlea possessed only 1.5 turns and had a hollow apical cavity. An enlarged vestibule and VA also were noted. This deformity is the most common form of cochlear anomaly (Table 191-1). Although numerous other distinct anatomic patterns of inner ear malformation are discernible radiographically and histologically, many workers continue to use the term Mondini's dysplasia to describe them all. To avoid a confusing and overly broad nomenclature system, this designation is best reserved for the particular subtype of cochlear malformation first described by Mondini, whether or not it is associated with other inner ear malformations.

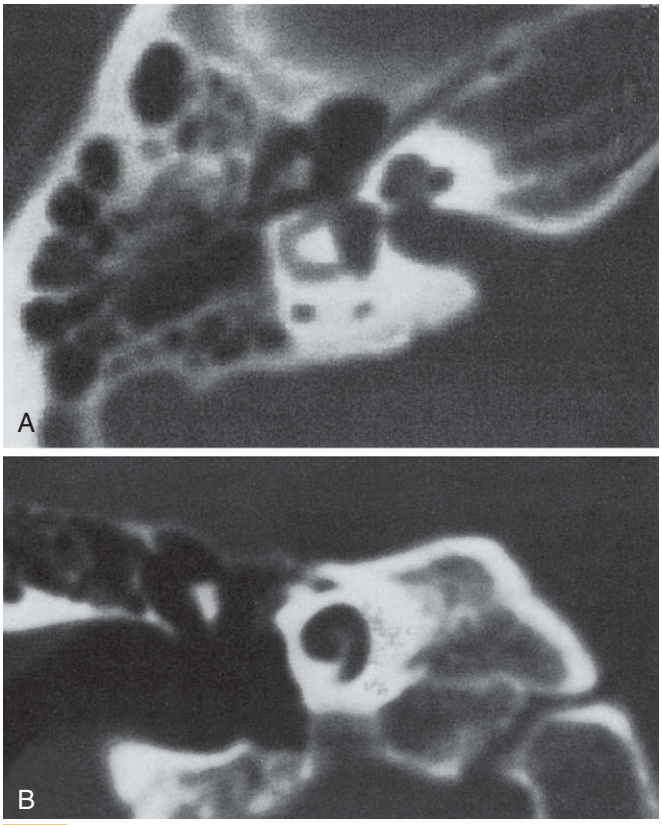

Figure 191-3. Radiographically normal inner ear as seen on axial (**A**) and coronal (**B**) high-resolution computed tomography scans. Note that the normal cochlea appears to have only 1.5 turns on the coronal scan, as a result of the oblique angle of section in relation to the axial scans of the modiolus.

Complete Labyrinthine Aplasia (Michel's Aplasia)

The most severe deformity of the membranous and osseous labyrinth, complete labyrinthine aplasia, was first described by Michel.[54] This malformation is exceedingly rare. Presumably, a developmental arrest occurs before the formation of an otic vesicle, resulting in a complete absence of inner ear structures. Complete labyrinthine aplasia has been reported in association with anencephaly and thalidomide exposure.[21,55] An association with external ear abnormalities also has been reported.[56] A purported case of Michel's aplasia actually described a cystic inner ear of the common cavity type.[57] This is but one example of the inaccurate use of traditional eponyms—a frequent occurrence in the literature. The incidence of complete labyrinthine aplasia is overestimated in the radiographic literature because it is confused with labyrinthine ossification. In the latter condition, which usually is acquired during life, a sizable and dense otic capsule is evident radiographically. In complete labyrinthine aplasia, the otic capsule is entirely absent[58] (Figs. 191-3 to 191-5). Such ears are, of course, uniformly deaf.

Cochlear Anomalies

Cochlear Aplasia

In cochlear aplasia the cochlea is completely absent, presumably as a result of an arrest in the development of the cochlear bud at the fifth week of gestation (see Fig. 191-1). This morphologic pattern is rare. Radiographically, only a vestibule and SCCs (usually deformed) are present. To differentiate this anomaly from labyrinthine ossification, it is necessary to assess the amount of otic capsule bone anterior to the internal auditory canal (IAC). In cochlear aplasia, the otic capsule is

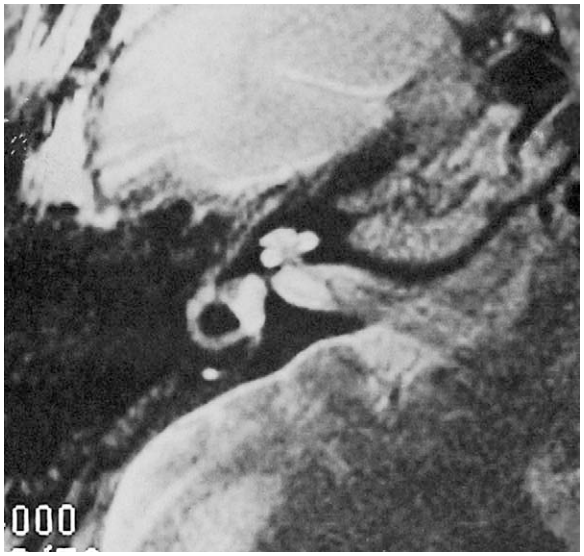

Figure 191-4. Axial high-resolution T2-weighted magnetic resonance image (fast spin echo) of a normal inner ear at the level of the mid- and apical cochlea and lateral semicircular canal. Note the internal detail of the cochlea, which includes visualization of the scalar partitions and the modiolus. The seventh and eighth cranial nerves can be seen in the internal auditory canal outlined by cerebrospinal fluid.

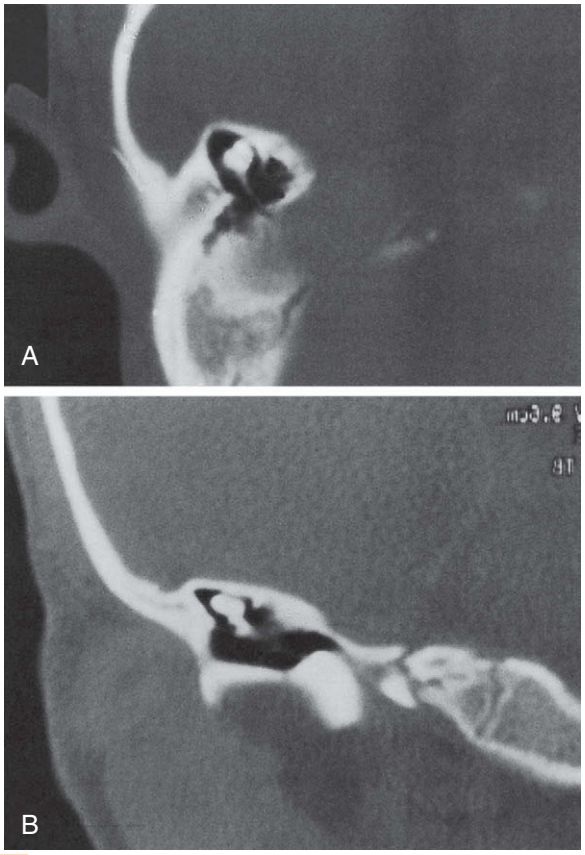

Figure 191-5. Complete labyrinthine aplasia as seen on axial (**A**) and coronal (**B**) computed tomography scans. Note the presence of an ear canal and middle ear but complete absence of the otic capsule. *(Courtesy of Joel Swartz, MD.)*

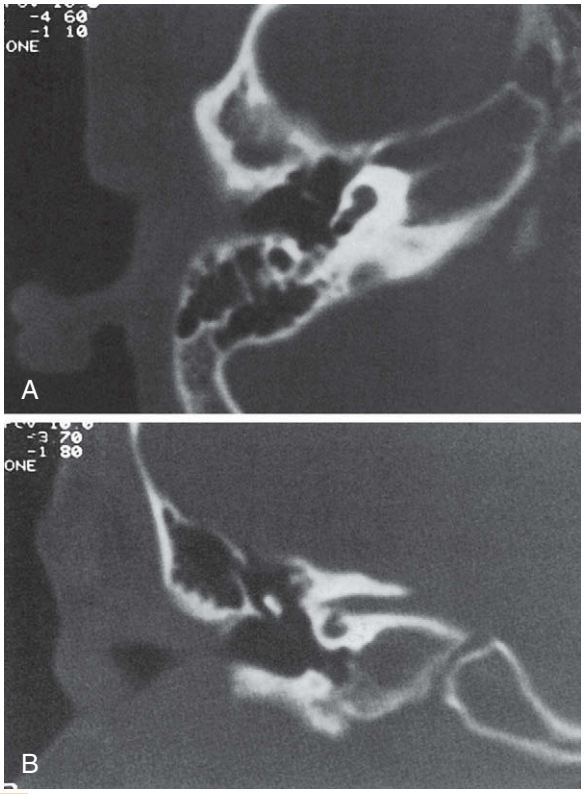

Figure 191-6. Cochlear hypoplasia as seen on axial (**A**) and coronal (**B**) computed tomography scans. The cochlea consists of only a small bud off the vestibule.

absent, whereas in osseous obliteration, it is dense and of normal dimensions. Ears with cochlear aplasia are devoid of auditory function.

Cochlear Hypoplasia

An arrest during the sixth week of gestation results in a hypoplastic cochlea consisting of a single turn or less. This deformity comprises approximately 15% of all cochlear anomalies. Radiographically, a small bud of variable length (usually 1 to 3 mm) protrudes from the vestibule (Fig. 191-6). The vestibule frequently is enlarged, with accompanying semicircular malformations in approximately one half of the cases. Small cochleas lacking a modiolus or other internal architecture have been described histologically.[27,50,59] Hearing is variable in these ears and may be remarkably good in view of the minute size of the cochlea. The variability of hearing presumably is accounted for by the degree of membranous labyrinthine development within the truncated cochlear lumen.

Incomplete Partition (Mondini)

Arrest at the seventh week of gestation yields a cochlea that has only 1.5 turns. This is the most common type of cochlear malformation, accounting for more than 50% of all such deformities. Radiographically, the cochlea is smaller than normal and partially or completely lacks an interscalar septum (Figs. 191-7 and 191-8). Although the cochlea usually measures 8 to 10 mm vertically, it is typically in the 5- to 6-mm range in incomplete partition deformity. Care must be exercised in counting the number of cochlear turns radiographically because this may be difficult to determine even using high-resolution CT. The radiographic diagnosis depends more on cochlear size and the absence of a scalar septum than on the number of cochlear turns perceived. Histologically, incomplete partition appears to be the radiographic correlate of classical Mondini's dysplasia (Fig. 191-9). In numerous reported cases, a small cochlea with 1.5 turns possessing an apical scala communis secondary to deficiency in the osseous spiral lamina has been described.[27,46,48] Sennaroglu and Saatci have subtyped the incomplete partition deformity into three variants[60] (Fig. 191-10).

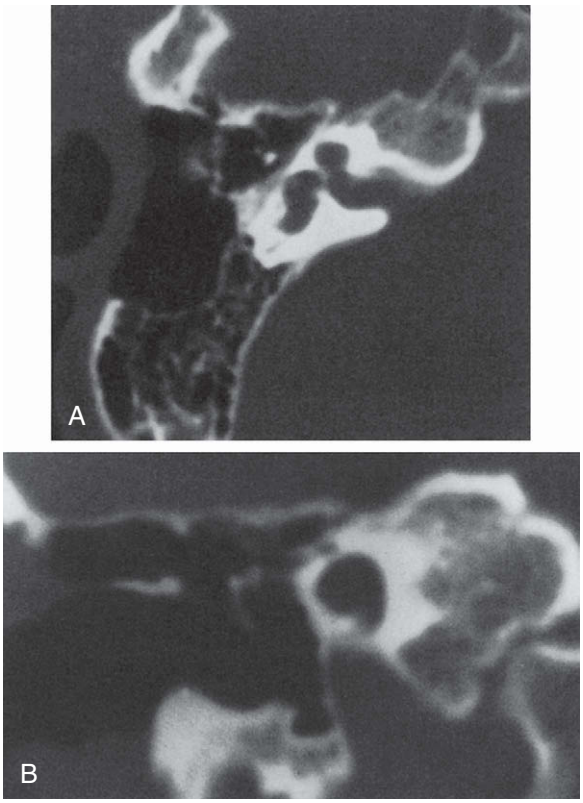

Figure 191-7. Incomplete partition as seen on axial (**A**) and coronal (**B**) computed tomography scans. Note the absence of an interscalar septum, which is more evident on the coronal scan.

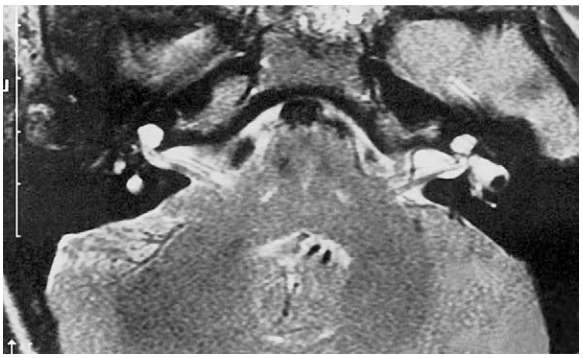

Figure 191-8. High-resolution T2-weighted magnetic resonance image (fast spin echo) of an incomplete partition deformity. Note the absence of intracochlear septation.

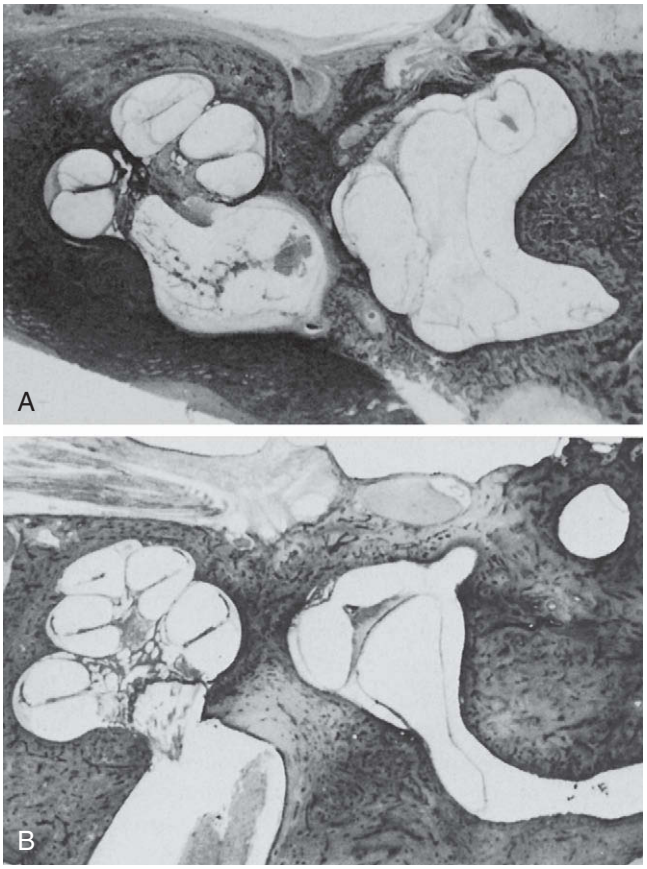

Figure 191-9. **A,** Photomicrograph of a malformed cochlea with the typical features of Mondini's dysplasia. The cochlea has 1.5 turns and an apical scala communis. **B,** Midmodiolar section through a normal cochlea for comparison. *(From Monsell EM, Jackler RK, Motta G, Linthicum FH Jr. Congenital malformations of the inner ear: histologic findings in five temporal bones.* Laryngoscope. *1987;97[Suppl 40]:18.)*

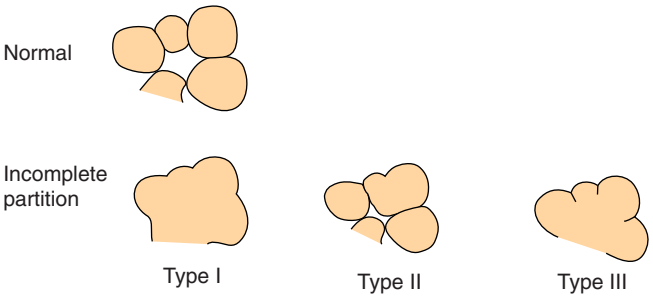

Figure 191-10. Subtypes of the incomplete partition deformity proposed by Sennaroglu and Saatci. *(From Sennaroglu L, Saatci I. Unpartitioned versus incompletely partitioned cochleae: radiologic differentiation.* Otol Neurotol. *2004;25:520.)*

Type I lacks the entire modiolus and interscalar septa and demonstrates a cystic appearance. Type II has a normal base turn but a cystic apex ("Mondini type"). Recently Sennaroglu has proposed a type III variant with deficient modiolus and partial interscalar septation at the cochlea's periphery (L. Sennaroglu, personal communication, 2007). Organ of Corti development is variable, as is the auditory neural population. As might be expected, auditory function also is variable, ranging from normal to profound SNHL. The mean hearing threshold (three-tone average) in a group of 41 ears with incomplete partition was 75 dB.[3] SCC deformities accompany incomplete partition of the cochlea in approximately 20% of cases.

Common Cavity

A deformed inner ear in which the cochlea and vestibule are confluent, forming an ovoid cystic space without internal architecture, may be explained by an arrest at the week 4 otocyst stage. Alternatively, this deformity may result from aberrant development at a later stage. An empty ovoid space typically longer in its horizontal dimension is seen radiographically. Although the size of the cyst may vary, it averages 7 mm vertically and 10 mm horizontally. It is quite easy to misdiagnose a dysplastic lateral SCC as a common cavity deformity. The key to differentiating between the two is that a common cavity cochlea lies predominantly anterior to the IAC on axial-plane CT, and a dysplastic vestibular system lies posterior to it. Histologically, an ovoid or spherical smooth-walled cystic cavity containing primordia of the membranous labyrinth has been described.[48,50,55] Sensory and supporting

cells may be differentiated into recognizable organs of Corti that are scattered peripherally around the walls of the cyst. Neural population usually is sparse or absent. Hearing is usually, but not invariably, poor.

Cochlear Hyperplasia

First reported in 2006, three temporal bones with a extra half apical turn have been described histologically.[61] Neither the clinical features nor the radiographic appearance of this anomaily has yet to be reported.

Labyrinthine Anomalies

Semicircular Canal Dysplasia

Dysplasia of the lateral SCC is a common type of inner ear malformation (Fig. 191-11). Approximately 40% of ears with a malformed cochlea will have an accompanying dysplasia of the lateral SCC.[3] Occasionally, dysplasia of the lateral SCC exists as the sole inner ear malformation. During the sixth week of development, the budding SCC normally forms a semicircular evagination from the vestibular anlage. The central portion of the pocket-shaped protrusion adheres, leaving a peripheral semicircular tube. When this central adhesion fails to occur, SCC dysplasia results (Fig. 191-12; see also Fig. 191-2). SCC dysplasia occasionally takes the form of a small bud, rather than the more common half-disk shape, presumably because of a slightly earlier timing of the developmental insult. The lateral SCC is deformed more often than the posterior or superior SCC, apparently because it forms earlier in embryogenesis. The typical radiographic appearance of SCC dysplasia is that of a short, broad cystic space confluent with the vestibule (Fig. 191-13).

Numerous histologic descriptions of SCC dysplasia exist in the literature.[46-50] The half-disk shaped cavity may contain a rudimentary crista ampullaris. The utricle and saccule may be distended, collapsed, or entirely absent. Caloric responses in SCC dysplasia are functionally absent or reduced in most cases, but a few may have normal responsiveness.[3] Ears with malformations limited to the vestibular system often have normal or near-normal hearing. When the cochlea also is abnormal, sensory hearing levels tend to be impaired, to a variable degree.[62] SCC dysplasia appears to have an association with conductive hearing loss, presumably because of inner ear micromechanical factors rather than stapes fixation.[63]

Semicircular Canal Aplasia

SCC aplasia is only one-fourth as common as SCC dysplasia.[3] It is usually associated with cochlear anomalies.[29] Presumably, SCC aplasia

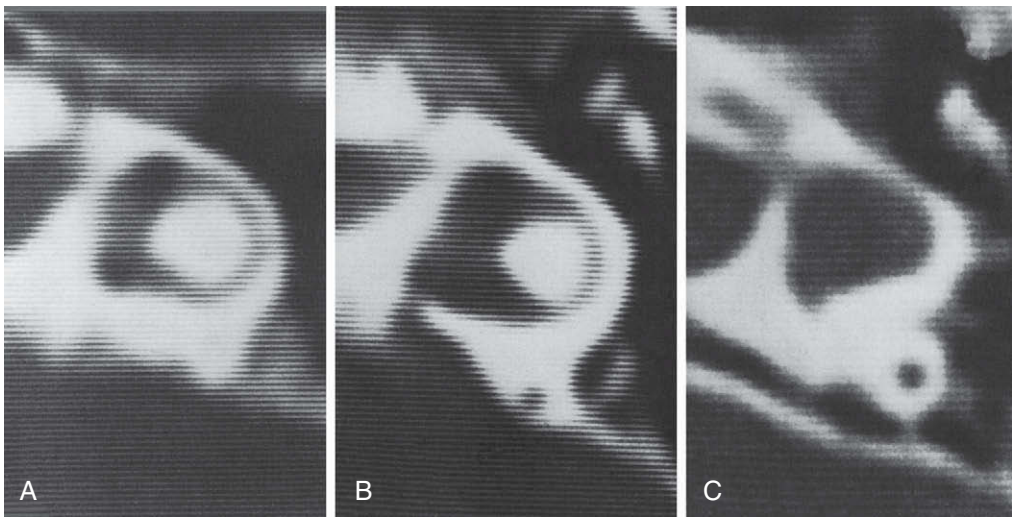

Figure 191-12. **A,** Lateral semicircular canal dysplasia as seen on an axial computed tomography scan. The normal appearance should be contrasted with that in mild, and severe dysplasia, in **B** and **C,** respectively. These images illustrate how semicircular canal dysplasia may arise from a failure of adhesion of the central region of the vestibular evagination during development. *(From Jackler RK, Luxford WM, House WF. Congenital malformations of the inner ear: a classification based on embryogenesis.* Laryngoscope. *1987;97[Suppl 40]:2.)*

arises from a failure in the development of the vestibular anlage before the sixth week of gestation. Most cases are syndromic, with a predominance of the CHARGE association (*c*oloboma, *h*eart defects, *a*tresia of the choanae, *r*etardation of growth and development, *g*enital, and *e*ar abnormalities or hearing loss).[64,65]

Malformations of the Vestibular and Cochlear Aqueducts

Enlargement of the Vestibular Aqueduct

Experience suggests that enlargement of the VA is the most common radiographically detectable malformation of the inner ear.[57,66-71] In earlier literature its incidence was underestimated, partly because of a lack of awareness but mostly because enlargement of the VA could be visualized only by lateral polytomography at a time when most studies were confined to the anteroposterior plane. The advent of high-resolution CT in the axial plane has made assessment of the VA much easier. The diameter of a normal VA, when measured halfway between the common crus and its external aperture, is between 0.4 and 1 mm. Enlargement of the VA is diagnosed when its diameter exceeds 2 mm, although enlarged VAs may exceed 6 mm in width. Whereas the VA is well visualized on axial CT (Fig. 191-14), the dilated endolymphatic sac is better seen with T2-weighted magnetic resonance imaging (MRI)[72,73] (Fig. 191-15). The sac often is seen to be enormously enlarged on MRI, sometimes measuring 2 cm or more in diameter.[74] In many cases, VA enlargement accompanies malformation of the cochlea or SCC. It also may be the sole radiographically detectable abnormality of the inner ear in a child with hearing loss. This condition is commonly referred to as the large VA syndrome, after Valvassori and Clemis's first descriptions.[75,76]

The VA derives from a diverticulum formed in the wall of the otocyst during the fifth week of gestation. It begins as a short, broad pouch but gradually elongates and thins until it achieves its characteristic J shape of adulthood (see Fig. 191-2). A premature arrest in development would be expected to produce a VA that is abnormally short and broad. However, an increasing body of evidence suggests that VA enlargement does not stem from an early arrest of sac development, but rather is an acquired deformity. Histologically, the sac and aqueduct are thin-walled and lack both vascularity and the rugose features thought to be important for physiologic function. Three observations suggest that a large VA stems from an abnormal communication between the subarachnoid space and the fluid chambers of the inner ear. The bone surrounding the VA may show signs of erosion, a finding that is inconsistent with a stable congenital deformity.[77] Serial MR images show variability in both the size and signal characteristics of the enlarged sac.[78] Presence of cerebrospinal fluid (CSF) under pressure,

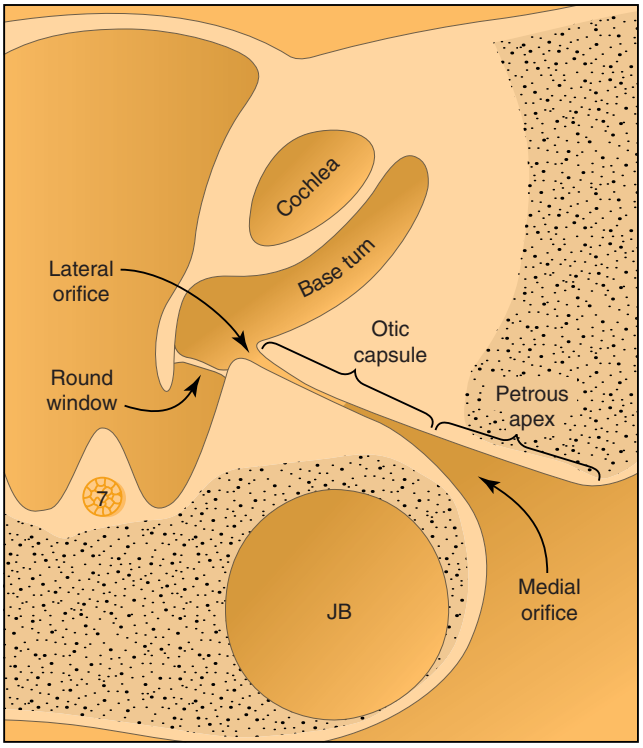

Figure 191-17. Illustration of the cochlear aqueduct in the axial plane. The diameter of the medial orifice is highly variable but often is wide (as depicted here) in normal-hearing persons. By contrast, the otic capsule portion typically is very narrow in both healthy and congenitally deaf persons. *(Adapted from Jackler RK, Hwang PH. Enlargement of the cochlear aqueduct: fact or fiction?* Otolaryngol Head Neck Surg. *1993;109:14.)*

with consequent "gusher," within the inner ear has been observed in ears with large VAs during both cochlear implantation and stapedectomy.[31,79] Furthermore, the existence of abnormal CSF in the inner ear pathway frequently has been observed with CT or MRI. This anomaly typically consists of a defect of the cochlear modiolus at the distal end of the IAC.[12,73] For CSF to become confluent with the endolymphatic space, the CSF fistula (subarachnoid space to perilymph compartment) must be accompanied by a second fistula joining the endolymph and perilymph spaces.

The large VA syndrome typically is bilateral. Affected children usually are born with normal or mildly impaired hearing that gradually deteriorates through childhood into adolescence and early adulthood. Hearing levels are variable, although at least 40% eventually develop profound SNHL.[80] As with other inner ear malformations, there is a tendency to suffer sudden decrements of hearing, particularly after head trauma. Conductive hearing loss may be present but is likely to be from intracochlear micromechanical disturbances rather than from impairment of ossicular mobility. Stapes surgery is best avoided because of the risk of CSF otorrhea.[79] Vestibular complaints in these patients have frequently been reported.[81,82] Large VA syndrome has been observed to occur in familial clusters.[10]

Surgical manipulation of the endolymphatic sac has been attempted in patients with large VAs. In a sizable series of shunt procedures, there was a high incidence of postoperative hearing loss.[67] Furthermore, a comparison of the operated and contralateral unoperated ears revealed no evidence of hearing stabilization after surgery. Recently, surgical obliteration of the enlarged endolymphatic sac with muscle and fascia has been advocated.[83] Results in a multicenter study indicated that the procedure not only lacks efficacy but actually injures one half of the operated ears.[84] Cochlear implantation has been quite successful in both adults and children with large VAs.[85,86]

Enlargement of the Cochlear Aqueduct

Enlargement of the cochlear aqueduct (CA) frequently is mentioned in the otologic literature because of its purported association with stapedectomy gusher and transotic CSF leak. Despite an active interest in the field and an extensive review of published radiographic images, I have never seen a radiograph that convincingly demonstrated CA enlargement.[87] Most cases presented as enlargement of the CA are misinterpretations of the wide internal funnel that opens into the posterior fossa.[88,89] In healthy subjects, the radiographic diameter of this aperture averages 3 to 4 mm but ranges from radiographically invisible to more than 10 mm[46,90-92] (Figs. 191-16 and 191-17). For enlargement of the CA to be diagnosed radiographically, the intraosseous portion coursing toward the vestibule must be enlarged beyond 1 mm, the practical resolution limit of contemporary CT scanners. If criteria analogous to those for enlargement of the VA are used, then an enlarged CA must have a diameter exceeding 2 mm throughout its course between the inner ear and the posterior fossa.

The preponderance of evidence suggests that the human CA usually is functionally patent.[92-94] In most persons, however, it can neither transmit sudden large pressure changes to the inner ear nor allow free flow of spinal fluid in any significant quantity (e.g., with outflow of perilymphatic fluid from perilymphatic fistula or an open vestibule). This observation reflects two anatomic features of the aqueduct: a narrow diameter of the bony channel and the presence of a fibrous tissue meshwork occupying and baffling the lumen. Schuknecht and Reisser[95] evaluated more than 1400 temporal bones in the Massachusetts Eye and Ear Infirmary collection and found no CA that exceeded 0.2 mm at its narrowest point. This series included 29 congenitally malformed inner ears. Of note, the CA was absent or nonpatent in 21 of these dysmorphic ears.

Some persons have less than normal or no fibrous tissue within the lumen, and the bony diameter is wider than normal. An opportunity may then exist for free flow of CSF from the oval window through the CA. According to Poiseuille's law, fluid flow through a tube varies with the fourth power of the radius, suggesting the possibility of free flow in an individual with a large-diameter unimpeded channel, as discussed by Allen.[96] Several histologic studies of congenital inner ear malformations have detected slightly larger CAs, particularly at their lateral orifice at the vestibule.[24,49] Even in these malformed inner ears, however, the aqueduct diameter remained well in the submillimeter range. From a clinical standpoint, a CA less than 1 mm in diameter is undetectable radiographically. Despite the theoretical possibility that a widely patent CA may cause a stapedectomy gusher, abnormal connections between the IAC and the vestibule appear to be etiologic in a majority of cases.[9,89,97,98]

Figure 191-18. Axial computed tomography scan of a bulbous internal auditory canal (IAC). Note the minimal separation between the lateral end of the IAC from the vestibule *(arrowheads)*. Such an ear may be prone to spontaneous cerebrospinal fluid leakage and to "gusher" during stapes surgery.

Figure 191-19. A pathologically narrow internal auditory canal (IAC) as seen on an axial computed tomography scan *(arrowheads)*. When the IAC is less than 3 mm in diameter, incomplete auditory nerve development is probable.

Developmental Anomalies of the Internal Auditory Canal

Wide Internal Auditory Canal

Unlike congenital narrowness of the IAC, a congenitally large canal may be an incidental finding in healthy individuals (Fig. 191-18). When a large IAC (larger than 10 mm in diameter) accompanies a malformation of the inner ear, it does not, as an independent variable, correlate with the level of hearing.[3] One report suggests that a wide IAC may be correlated with hearing loss.[99] The primary importance of detecting enlargement of the IAC is its association with spontaneous CSF leak and the occurrence of gusher during stapes surgery.[97] Because hearing after stapedectomy complicated by CSF gusher (often erroneously called "perilymph gusher") frequently is poor, a CT scan should be obtained before stapedectomy to address congenital fixation is undertaken. Dilation of the IAC, especially when the partition between the lateral end of the canal and inner ear appears deficient, should contraindicate stapedectomy.

Narrow Internal Auditory Canal

A narrow IAC may indicate a failure of eighth cranial nerve development. When a patient has normal facial function and an IAC less than 3 mm in diameter, it is likely that the bony canal transmits only the facial nerve (Fig. 191-19). A narrow IAC may accompany inner ear malformations or may be the sole radiographically detectable anomaly in a deaf child. A narrow IAC has been considered a relative contraindication to cochlear implantation, because it suggests that the eighth nerve may be insufficiently developed to conduct an auditory signal.[50] After cochlear implantation, some patients with narrow IACs have experienced facial pain and twitching without useful auditory sensation.

Anomalies of the Eighth Nerve

Hypoplasia and aplasia of the eighth nerve are often, but not inevitably, associated with congenital narrowness or even absence of the IAC. Similarly, although eighth nerve maldevelopment frequently accompanies malformation of the inner ear, the presence of a normal cochlea and semicircular canals does not guarantee normal development of the audiovestibular nerve.[100] High-resolution, thin-section MRI with T2-weighted sequences currently is the best means of assessing the fine anatomy of the eighth nerve in the IAC.[101,102] Such a study is warranted before cochlear implantation when the bony IAC is narrow on the CT scan, with severe types of inner ear malformation, and in syndromes known to be associated with maldevelopment of the eighth nerve (e.g., the CHARGE association, Möbius's syndrome).[103] Unilateral cochlear nerve aplasia, sometimes familial, is increasingly recognized as an important cause of congenital unilateral profound SNHL.[104,105] The internal auditory canal frequently is normal.[106] Increasingly refined MR techniques may reveal hypoplasia of the auditory nerve as more common than previously recognized.[107]

Syndromic Correlations and Familial Patterns

Inner ear malformations have been described in an increasing number of recognized syndromes associated with SNHL. Some of the more common examples are reviewed briefly next.

In Waardenburg's syndrome type I, absence of all three semicircular canals (17%) and cochlear hypoplasia (8%) have been reported.[108] In Waardenburg's syndrome type II, maldevelopment of the posterior semicircular canal has been described.[109] Semicircular canal agenesis or hypoplasia also has been noted in CHARGE syndrome.[110,111] In branchio-oto-renal syndrome, hypoplasia of the cochlea, sometimes accompanied by large VA, has been reported.[7,112,113] In Pendred's syndrome, large VA is a common feature, sometimes accompanied by modiolar deficiency.[114,115] Otic capsule anomalies also have been described in trisomy E and Usher's syndrome.[5,8] Down syndrome (trisomy 21) is associated with semicircular canal dysplasia and a variety of other inner ear malformations.[116]

Nonsyndromic familial patterns of inner ear malformation also have been identified.[9,10] An autosomal recessive pattern of Mondini's dysplasia has been reported.[117] In familial Mondini's dysplasia, genetic analysis has identified a deletion in locus DFN3.[118] Inherited complete labyrinthine aplasia (Michel's aplasia) has been described with a probable autosomal recessive inheritance pattern.[119] Familial lateral semicircular canal malformation has been described in association with anomalies of the external and middle ear.[120] Nonsyndromic familial occurrence of large VA has been associated with the Pendred gene.[121]

Cerebrospinal Fluid Leakage and Meningitis

Congenitally malformed inner ears may be a source of CSF otorhinorrhea.[122,123] For CSF leakage to occur, two abnormal connections must be present: one between the subarachnoid space and the inner ear and a second between the inner ear and middle ear. The most common pathologic interconnection between the subarachnoid space and the inner ear is through the fundus of the IAC. Histologically, large defects in the modiolar end of the IAC have been shown to exist in 10% of dysplastic ears.[95] Leakage may occur less often around the facial nerve at the lateral end of the IAC[124-126] (Fig. 191-20). The junction between the IAC and the inner ear may be evaluated with CT (Figs. 191-21 and 191-22). A well-defined bony plate normally partitions the distal IAC from the labyrinthine lumen. In a number of well-documented

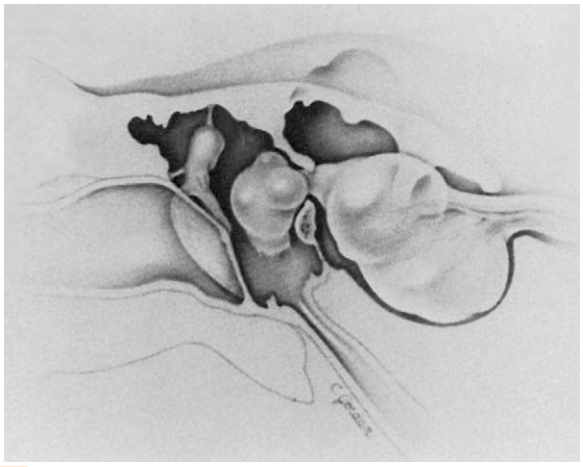

Figure 191-23. Drawing of a dural hernia protruding through the oval window in a child with cochlear hypoplasia, chronic cerebrospinal fluid leakage, and recurrent meningitis. *(From Herther C, Schindler RA. Mondini's dysplasia with recurrent meningitis.* Laryngoscope. *1985;95:655.)*

cases of CSF leakage, radiopaque contrast placed into the cerebellopontine angle cistern could be traced through the IAC into the inner ear.[122,124,127-129] The propensity of a dysplastic inner ear to leak CSF depends on its morphologic type. The common cavity deformity appears to be at particularly high risk. By contrast, Phelps and coworkers[130,131] maintain that the incomplete partition deformity (Mondini's dysplasia) is not associated with a heightened risk of CSF leakage. In ears with CSF fistulas, the SCCs usually are severely deformed. Although enlargement of the VA is a sign that CSF pressure is present within the inner ear, it does not necessarily imply the existence of an external leak into the middle ear. Rarely, transotic CSF leakage may be accompanied by a second congenital fistula in the anterior skull base.[132]

A second potential pathway between the subarachnoid space and the inner ear is the CA. As discussed previously in this chapter, there is little evidence to suggest that this pathway is a source of vigorous CSF leakage. In one published report, a CT metrizamide cisternogram was said to demonstrate a large CSF leak occurring through the CA; however, the published image showed the defect to be far anterior and superior to the region of the CA.[122]

A direct route between the subarachnoid space and middle ear, bypassing the inner ear, may exist in rare cases. Hyrtl's fissure, a congenital cleft that runs between the hypotympanum and posterior cranial fossa passing in proximity to the jugular bulb, has been reported to be a source of CSF leakage.[125] It is interesting that a diligent search of the historical literature has failed to find a publication on this subject by Hyrtl, despite his long eponymic association with this deformity.[133] In the interest of clarity, the descriptive term *tympanomeningeal fissure* is preferable.

The pathologic interconnection between the inner ear and middle ear most frequently is at the oval window. Numerous reports have described defects in the central portion of the footplate with a protruding membrane, most probably arachnoid[123,124,134-137] (Fig. 191-23). In other cases the defect is adjacent to the footplate, particularly just

anterior to it. Much less frequently, leakage may occur through the round window or a fissure on the promontory.[123] Schuknecht and Reisser[95] evaluated the oval and round windows in 29 ears with congenital malformations of the inner ear. On histologic examination, the stapes were absent in 4, fixed in 6, and normal in 15 cases. In 4 cases the footplates were noted to have defects that were bridged by thin membranes only. The round windows were normal in 28 cases and abnormal in only 1 (bony closure). No deficiencies in the round window membranes were noted.

The primary clinical importance of CSF leakage is the risk of meningitis. There have been numerous reports of meningitis complicating congenital malformation of the inner ear.[122-124,134,136-138] Recurrent bouts of meningitis are typical, and recognition of the inner ear as the source frequently comes only after several episodes have occurred. Acute otitis media appears to be the bacterial source in most cases. All children with recurrent meningitis without an obvious cause should undergo CT of the inner ear to exclude inner ear malformation.[139] Even children with a single episode of meningitis should have a postrecovery audiogram followed by CT if unilateral or bilateral SNHL is discovered. The causative organisms in a review of 24 reported cases have been *Streptococcus pneumoniae* (in 71% of the cases), *Haemophilus influenzae* (in 33%), and β-hemolytic streptococci (in 8%). The total exceeds 100% because of the incidence of polymicrobial infection.

Surgical closure of transotic CSF leakage may be attempted at four anatomic levels: (1) the posterior cranial fossa; (2) the dysplastic inner ear; (3) the middle ear windows; and (4) the eustachian tube. In an ear with residual hearing, tympanotomy and overlay grafting of the site of leakage with a connective tissue graft is indicated as a first attempt. Unfortunately, recurrent leakage is common. When this technique fails and a useful amount of hearing persists, posterior fossa craniotomy with placement of a muscle plug in the IAC or connective tissue graft over the fistulous tract may prove to be successful and spare hearing.[122] When the hearing is poor, a direct approach to the dysplastic inner ear is indicated. After tympanotomy and removal of the footplate, an oversized piece of muscle may be used to obliterate the vestibule.[18,25,123,140] If the anatomy is unfavorable for this maneuver, a postauricular translabyrinthine approach to the IAC should prove to be effective. Farrior and Endicott[141] proposed a hypotympanic approach to ablation of the CA. However, this aqueduct has never been convincingly demonstrated to cause a high-volume CSF leak. The final option, closure of the eustachian tube, is not a good choice for children. After this procedure, the anomalous CSF pathway is still open to the middle ear—a disadvantageous situation at an age when acute otitis media is common. Subsequent to the repair of any CSF leakage, the patient is placed on bed rest with the head elevated 30 degrees for several days. Acetazolamide (Diamox) is administered to reduce CSF production, and fluids are restricted. Placement of a lumbar drain is a useful adjunctive measure, although it may be difficult to insert and maintain in young children.[90]

X-Linked Stapes Gusher Syndrome

A form of hereditary mixed conductive and sensory hearing loss associated with CSF gusher during stapes surgery has recently been described.[142] Inherited hearing loss follows an X-linked pattern.[143] The characteristic inner ear deformity may be seen radiographically.[144,145] On CT, the cochlear modiolus is deficient and the lateral portion of the IAC often is bulbous (see Fig. 191-21). These observations provide strong evidence that the abnormal interconnection between the subarachnoid space and the inner ear is by way of the lateral terminus of the IAC. The labyrinthine segment of the fallopian canal may be dilated. In the vestibular system, the posterior semicircular canal often is deformed, and the VA may be enlarged.

The occurrence of stapes fixation in X-linked gusher syndrome is questionable. It has been proposed that the observed air-bone gap may be accounted for by alteration in cochlear micromechanics rather than dysfunction of the conducting system.[146] Results of acoustic reflex testing and auditory evoked responses are more consistent with a pure sensory hearing loss than a mixed form. The outcome of stapes surgery in these patients usually is poor, with anacusis in the operated ear a frequent result. When surgery is contemplated for a congenital conductive hearing loss, preoperative imaging is advisable to screen for inner ear malformation.

Perilymphatic Fistula

In contrast with CSF leakage, a perilymphatic fistula requires only one abnormal pathway: an interconnection of the inner ear with the tympanic cavity. In all probability, perilymph fistula and CSF leak are part of a spectrum of related disturbances of inner ear fluid homeostasis. Although separation of the two topics may be artificial pathophysiologically, it can be justified by the different clinical settings of the two problems. With CSF leakage, the cardinal clinical issues are gross fluid leakage and recurrent meningitis; with perilymph fistulization, sudden or progressive hearing loss and vertigo are the primary manifestations.

Much controversy surrounds the diagnosis and management of perilymphatic fistula in children. The candidate group for exploratory tympanotomy consists of children with progressive or sudden SNHL. CT of the inner ear may demonstrate pneumolabyrinth, although this finding is rare (Fig. 191-24). Conservative surgeons have advocated exploration only in children with radiographically abnormal inner ears who have a clear antecedent event of head trauma or barometric pressure change.[147] Other workers have espoused the notion of surgical exploration in all children with unexplained SNHL.[14,148,149] Great variability exists in the number of fistulas "confirmed" at surgery. Pappas and colleagues[147] found only 4 fistulas in 36 ears (11%) explored for progressive SNHL during childhood. Of note, 50% of these ears had radiographically malformed inner ears. By contrast, Parnes and McCabe[148] found fistulas in 20 of 26 children's ears (77%), only 6 of whom had inner ear anomalies radiographically. A high incidence of fistulas among children with sensory hearing loss (64%), both with and without inner ear malformation, has been reported.[150,151] Furthermore, one group of investigators claim to have objective verification of the presence of perilymph in the middle ear through evaluation of β_2-transferrin levels in surgical aspirates.[152] An important point is that considerable doubt exists regarding whether this test is valid. A recent study in which perilymph samples were directly obtained during either stapedectomy or cochlear implant surgery failed to detect β_2-transferrin in this fluid.[153]

In exploration of a perilymph fistula, it is important to perform provocative maneuvers to render subtle perilymph flows more visible. Such maneuvers include performing a Valsalva maneuver, using the Trendelenburg position, and compressing the jugular veins. Many surgeons are either missing subtle or intermittent perilymphatic fistulas during explorations or overdiagnosing them by misinterpreting middle ear secretions or local anesthetic as perilymph. Attempts to make a

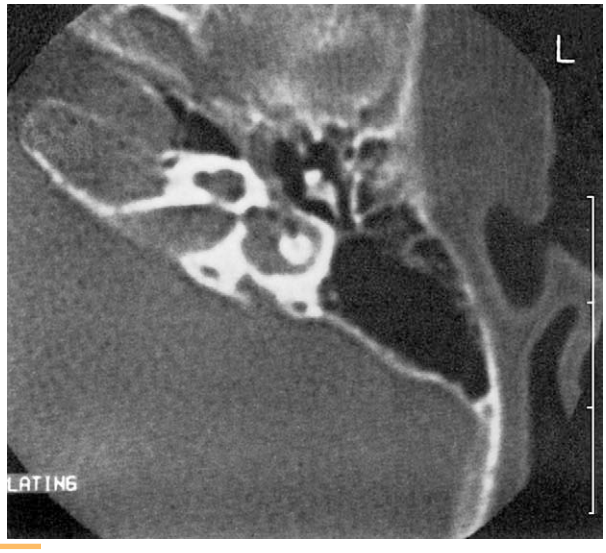

Figure 191-24. Air bubbles in the inner ear (pneumolabyrinth) in a congenitally deaf child with a perilymphatic fistula.

practical biochemical test for the presence of perilymph or CSF in the middle ear—through either assay of β_2-transferrin or intrathecal fluorescein administration—have not yet proved useful.[154,155] Most surgeons patch both oval and round windows with connective tissue whether or not a perilymphatic fistula was identified during exploration.

Rather than dwell on the controversy about how many fistulas are found, the critical observer should judge the effectiveness of the therapeutic intervention by analyzing its outcome relative to the natural history of the disease. In this regard, results of perilymphatic fistula exploration in children have been disappointing. In one series of 36 patients, hearing was better in 3, unchanged in 21, and worse in 12.[147] Similar results have been obtained in other childhood perilymphatic fistula series. It would be difficult to argue that these data represent a significant improvement over the natural history of the inner ear disease. Congenital progressive SNHL often is characterized by long periods of stability interspersed with periods of rapid deterioration. Even a relative improvement in hearing may occur after an episode of sudden loss. It is apparent that most children with sudden or progressive SNHL have suffered from cochlear diseases other than perilymphatic fistula. Examples are hereditary progressive loss, viral labyrinthitis (e.g., measles, mumps, cytomegalovirus), autoimmune inner ear disease (e.g., Cogan's syndrome), and endolymphatic hydrops. Even in the most suggestive clinical situation—sudden loss triggered by head trauma in a child with radiographically malformed inner ears—only a minority of patients demonstrate oval or round window fistulization. Many of these children probably lose hearing as a result of internal fistulization between the endolymphatic and perilymphatic space because of deficiencies of the osseous spiral lamina, rather than because of external fistulization to the middle ear. A minority of children with sudden or progressive SNHL have prominent vestibular symptoms. Results of perilymphatic fistula repair in the relief of vertigo have been quite good, although spontaneous recovery from vestibulopathy is common in this age group.

Inner Ear Malformations in Congenital Aural Atresia

Development of the external and middle ears is embryologically distinct from that of the inner ear. Anomalies of the lateral portion of the temporal bone typically result from derangement of the first or second branchial arches. Despite their embryologic separateness, congenital aural atresia may coexist with malformation of the inner ear.[156] In one study of patients with atresia, 12% (8 of 66) had a radiographically detectable inner ear abnormality.[157] In this group, SCC abnormalities were most common, including some ears with normal bone-conduction hearing. Cochlear anomalies were present in 5% (3 of 66) of these patients, all of whom had poor bone conduction hearing. It is an embryologic enigma that one patient with unilateral atresia had a malformed inner ear only on the contralateral side. In another polytomographic study of atretic ears, 8% (4 of 48) had SCC anomalies, and 2% (1 of 48) had a deformed cochlea.[158] As indicated by a comprehensive review of the relevant literature, approximately 5% of patients with atresia have cochlear deformities, whereas 10% have malformed SCCs. As a general rule, surgical reconstruction of atretic ears should not be attempted when they are associated with malformation of the inner ear. The deformed cochlea is more vulnerable to injury from vibratory trauma, and the risk of inducing a sensory hearing loss is increased. This surgery also carries a heightened risk of CSF leakage.

Imaging

During the 1980s and 1990s, CT was the gold standard imaging modality for investigation of patients suspected of having an inner ear malformation. In the early 21st century, new MRI techniques are capable of producing images superior to those obtained with CT. In contrast to CT, which depicts otic capsule bone, MRI displays inner ear morphology by imaging inner ear fluids. High-resolution, thin-section, T2-weighted sequences (e.g., fast-spin echo) provide exquisite detail of inner ear anatomy (see Fig. 191-4).[159] MRI is superior to CT in a number of ways. MRI can distinguish between a cochlea filled with fluid and one occluded by soft tissue. CT is unable to make this distinction—an observation of great importance in assessing scala tympani patency before cochlear implantation. MRI provides more information about large VAs than that provided by CT.[72,73,160] It displays not only the dilated osseous canal but also the dimensions of the often impressively expanded endolymphatic sac. Direct visualization of the eighth nerve in the IAC, where it appears as a linear filling defect outlined by CSF, is yet another advantage of MRI. This capability is important in certain severe deformities in which neural agenesis may be found. Three-dimensional renderings of inner ear malformations have been produced using both CT and MRI.[161,162]

In assessing images for possible inner ear malformation, it is important to measure the size of structures and not merely look for anomalous patterns. Normative data of inner ear dimension have been published to aid in this determination.[163] Quantitative measurement has been shown to increase diagnositc yield in cochlear hypoplasia (less than 4.4 mm cochlear height on coronal images) and semicircular canal dysplasia (bony island width on axial projection) even for experienced neuroradiologists.[164]

In addition to inner ear malformation, numerous causes of acute and chronic SNHL in children are recognized. Whereas either CT or MRI findings would be normal in the great majority of these, a few disorders can be visualized only by MRI. The obvious category is lesions of the cerebellopontine angle (e.g., tumors) and brainstem (e.g., adrenoleukodystrophy). On noncontrast T1-weighted MRI, acute hemorrhage results in hyperintensity of the inner ear. On gadolinium-enhanced studies, acute inflammation (e.g., viral infection) results in high signal intensity in the inner ear or along the course of the eighth nerve.

When selecting MRI as an imaging study to screen for inner ear malformation, it is important for the physician to be aware that standard MRI protocols designed to screen for central nervous system abnormalities provide only limited information concerning the inner ear. To be useful in screening for inner ear anomalies, specially designed protocols are needed.[159] One disadvantage of MRI is the difficulty young children have in tolerating the confined spaces of the magnet. In addition, fast-spin echo MRI requires considerably longer scan time than does CT. Whereas simple sedation usually is sufficient for CT, acquiring high-quality magnetic resonance images may require use of general anesthesia in pediatric patients. Accordingly, despite the numerous advantages of MRI (including the absence of ionizing radiation), CT is the pediatric examination of choice in many centers for this important practical reason.

Evaluation and Management

High-resolution CT or MRI of the inner ears is recommended for all children with suspected congenital malformation of the inner ear, including those with otherwise unexplained SNHL, regardless of whether it has existed from birth or occurred later. Scans usually are obtained when hearing impairment is first recognized. Use of thin slices of 1- or 1.5-mm thickness with 0.5-mm overlap will adequately image the minute inner ear structures.[59] If only one plane of view is to be obtained, the axial orientation is preferred because it provides superior images of the VA, a frequently malformed structure that is difficult to visualize on coronal scans. When possible, both axial and coronal views should be obtained, because certain subtle deformities, such as deficiency of the interscalar septum, are best seen in the coronal orientation. It is important to examine thoroughly all portions of the inner ear, because anomalies frequently are multiple (Fig. 191-25).

No medical or surgical therapy has been shown to prevent the progressive hearing loss associated with congenital malformation of the inner ear. After a sudden decrease in hearing, a short course of an oral corticosteroid (e.g., prednisone) is administered. Although no studies have assessed the efficacy of corticosteroids in children with inner ear deformities, studies of idiopathic sudden SNHL in adults suggest some benefit. Furthermore, autoimmune mechanisms may play a role in a few children with rapid hearing deterioration, a possibility that justifies a therapeutic trial. Of course, many patients experience spontaneous partial recovery after sudden losses, even without therapeutic intervention.

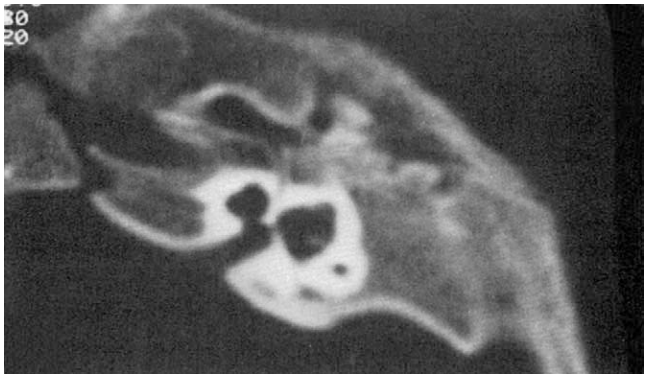

Figure 191-25. Axial computed tomography scan demonstrating a cochlear deformity (incomplete partition) as well as dysplasia of the lateral semicircular canal. Many congenitally malformed inner ears have abnormalities in more than one portion of the inner ear.

Few patients with congenitally malformed inner ears have a fluctuating pattern of hearing loss suggestive of endolymphatic hydrops. When fluctuations are encountered, however, a low-salt diet and diuretics are prescribed. Surgical intervention is indicated in a few well-defined circumstances. Obviously, CSF leakage and meningitis require intervention. Exploration for perilymphatic fistula is reserved for patients with radiographically abnormal inner ears who have suffered a sudden hearing deterioration temporally related to a precipitating event such as head trauma, rapid barometric pressure change, vigorous exercise, or sneezing. As discussed previously, even in these patients, only a minority have a fistula, and those who do frequently continue to lose hearing despite repair. House[165] and later others advocated endolymphatic sac surgery for congenital malformations of the inner ear[166-168]; however, a careful analysis of the outcome in a large series revealed no benefit of this surgery in terms of hearing stabilization.[169] In fact, nearly 30% of the patients suffered significant postoperative hearing deterioration. Patients with large VAs appear to be at particularly high risk for poor outcome after sac surgery. Surgical obliteration of the endolymphatic sac with muscle and fascia has been advocated in patients with enlargement of the VA.[83] Unfortunately, a multicenter study showed that this procedure not only fails to stabilize hearing but is associated with a 50% rate of sensorineural hearing deterioration.[84]

Preventive measures are important in the management of patients with congenitally malformed inner ears. The risk of CSF leakage may be estimated by CT or MRI of the inner ear. Anatomic features of concern include a wide IAC, deficient partitioning between the IAC and inner ear, and enlargement of the vestibule in the horizontal plane. Parents should be made aware of the risk of meningitis and instructed in recognizing its early symptoms and signs. Because most episodes of meningitis associated with inner ear malformation are pneumococcal, use of the pneumococcal vaccine is recommended.[170] Children with malformed inner ears should avoid head trauma and rapid barometric pressure changes, because these risk provoking a sudden hearing loss or even CSF leakage. Activities such as contact sports and scuba diving are discouraged. Finally, establishing a prognosis for future auditory function in a hearing-impaired child serves as a guide for educational and rehabilitative efforts. Recognizing an inner ear malformation on CT may be helpful, because certain morphologic patterns have more favorable prognoses than others.

Cochlear Implantation

Electrical stimulation of the auditory nerve has proved useful in many forms of sensory deafness, including those associated with congenital malformations of the inner ear. The fundamental premise of cochlear implantation is that some of the cochlear neural population survive despite the absence of hair cells. In congenital malformations of the inner ear, the auditory nerve population typically is less than with other forms of sensory deafness. The normal human spiral ganglion cell count usually is 25,000 to 35,000. In eight congenitally dysplastic ears, Schmidt[171] reported cell counts ranging from 7677 to 16,110, with an average of only 11,478. By contrast, ears with profound sensory hearing loss from ototoxicity, otosclerosis, or mechanisms of sudden loss have ganglion cell populations in the range of 18,000 to 22,000. This observation suggests that malformed inner ears could be electrically stimulated but that improvements in speech discrimination would fall below average for the deaf population at large. A narrow IAC on pre-implantation CT (less than 3 mm in diameter) is a strongly adverse predictor of neural survival.[23]

Cochlear implantation in deformities that involve both the membranous and osseous labyrinth raises several special considerations. Cochlear implantation in malformations limited to the membranous labyrinth is equivalent to implantation in the prelingually deaf child (see Chapter 159). Results of implantation with short, single-channel devices in patients with cochlear hypoplasia, common cavity, and incomplete partition deformities appear in the literature.[36,172,173] In successful cases, sound detection levels are similar to those in other prelingually deaf children.[174,175] Implantation of deformed cochleas with multichannel devices also has proved to be valuable in a majority of cases but is associated with a higher rate of complications.[31,176-179] Performance varies widely and appears, on average, to be somewhat below that realized in most other forms of deafness. The design of multichannel electrodes makes certain assumptions about the geometry of the scala tympani that affect the anticipated orientation of stimulating electrodes to neural elements. Although standard electrodes are not optimized for dysplastic cochleae, fabrication of custom electrodes for each malformed cochlea is not feasible with current technology. The degree of electrode insertion varies, in large part because of variability in size and geometry of the deformed cochlea.[180] Only partial insertion may be realized, particularly in hypoplastic cochleas, whereas complete insertion is more common with milder deformities such as incomplete partition.

One complication of unpredictable electrode positioning is stimulation of the facial nerve at current levels lower than the threshold for auditory perception. Cross-stimulation of the facial nerve has been reported with both single-channel and multichannel designs and has prevented some patients from using the device. Multichannel systems have a distinct advantage in this regard because the offending electrode pair or pairs may be programmed out of the stimulation map, thereby preserving the ability to provide auditory stimulation. The presence of a dysplastic inner ear may be a warning that the facial nerve is malpositioned.[181] An anomalous facial nerve course has been reported to occur in 16% of malformed inner ears.[176] In one patient with cochlear hypoplasia, an anomalous facial nerve was injured immediately above the round window niche, a highly vulnerable location during implant surgery.[31] Use of electrophysiologic facial nerve monitoring during implantation in patients with malformed inner ears is advisable. It also is possible for a persistent stapedial artery to traverse the round window region, thereby precluding implantation.[182]

Another complication of implantation in malformed cochleas is facial twitching consequent to inadvertent penetration of the IAC by the electrode.[179] When such a malpositioned electrode is activated, vigorous facial twitching may occur at an extremely low stimulation threshold. To avoid this complication, post-implantation CT is advisable before stimulation is undertaken to assess electrode position after implantation in a malformed cochlea.

CSF leak also has been a frequent complication during implantation of the malformed cochlea, occurring with an incidence of approximately 40%.[176] The leak typically is evident immediately on opening the round window and presumably occurs as a result of deficiencies in the partition between the modiolus and the dural envelope at the lateral end of the IAC. Leaks have been successfully handled by packing connective tissue around the electrode, but temporary CSF diversion may be required to obtain a lasting seal.[183] Multichannel cochlear implants, especially certain varieties designed to approximate the modiolus, have been associated with an increased long-term incidence of meningitis.[184] The incidence may well be higher in patients with malformed inner ears.[185]

CHAPTER ONE HUNDRED AND NINETY-TWO

Microtia Reconstruction

Craig S. Murakami

Vito C. Quatela

Kathleen C. Y. Sie

Joseph Shvidler

Key Points

- The auricle is formed from the branchial arches starting at approximately 5 weeks of gestation.
- The auricle grows rapidly in the first 3 years of life and then grows more slowly until approximately 13 years of age for boys and 12 years of age for girls. Normal adult ear height ranges from 5.5 to 6.5 cm.
- The etiology of microtia most commonly is sporadic, possibly as the result of a vascular injury in the distribution of the stapedial artery. Other causes include teratogenic exposures and syndromic associations.
- Type I microtia is used to designate ears with mild deformity. Type II includes ears that have all major structures present to some degree. Type III deformities have few or no recognizable landmarks of the auricle, although the lobule usually is present and positioned anteriorly. Anotia is the complete absence of auricle and lobule.
- Options for microtia management include observation, prosthetic management, and reconstruction with autologous rib graft or Medpor implant with temporoparietal fascial flap.
- Observation is recommended until the child is at least 5 to 8 years old. This allows both growth of the donor rib cartilage and development of the contralateral normal ear. In general, microtia repair should precede atresia repair.

Microtia occurs with an overall frequency of approximately 1 to 3 cases per 10,000 population,[1] although certain ethnic groups, such as Navaho Indians in Mexico and the Japanese, may have higher incidence of microtia.[2] Microtia deformities appear to be more common on the right side and affect boys more often than girls at roughly a 2.5:1 ratio; unilateral cases outnumber bilateral cases by 4:1. Surgical management of microtia remains one of the greatest reconstructive challenges for an otolaryngologist.[3-6] Auricular reconstruction of the microtia deformity is a complex and labor-intensive process that requires careful preoperative planning, surgical skill, and artistry. This chapter provides a basic overview of clinical issues in children with microtia and reconstruction with autologus rib cartilage. Discussion of aural atresia is presented elsewhere.

Embryology

The inner ear begins as the otic placode at approximately the third week of gestation, and it then forms into the otic pit and otic cyst. The external ear begins to form in the fifth week of gestation. The auricle begins as six small buds of mesenchyme, classically known as the hillocks of His, surrounding the dorsal end of the first branchial cleft.[7-10] On either side of the first branchial cleft are the first (mandibular) and second (hyoid) branchial arches. Hillocks 1 through 3 arise from the first branchial arch, and hillocks 4 through 6 arise from the second branchial arch. Conventional teaching holds that the first hillock forms the tragus, the second and third form the helix, the fourth and fifth form the antihelix, and the sixth forms the antitragus. The majority of the central ear is derived from hillocks 4 and 5, and the lobule appears to be one of the last parts of the ear to develop (Fig. 192-1). It has been estimated that the hyoid arch forms about 85% of the auricle.[5] The exact embryology of each of these hillocks remains unclear. The position of the auricular complex begins at the anterior neck region. As the mandible develops during gestational weeks 8 through 12, the auricular complex moves in dorsal and cephalic directions. The etiology of microtia remains unknown in most cases, although the inciting event that arrests development of the ear must occur during the first trimester, and may be related to abnormal neural crest cell migration.

Known teratogens, such as the retinoic acid derivative isotretinoin (Accutane; Roche, Nutley, New Jersey), can produce forms of microtia in conjunction with craniofacial, cardiac, thymic, and CNS anomalies, a condition commonly known as retinoic embryopathy.[11] Thalidomide and mycophenolate mofetil also have been reported to be associated with microtia.[12,13] Microtia is associated with other anomalies about 50% of the time. Microtia is most commonly associated with other regional anomalies related to the first and second branchial arches, i.e., facioauriculovertebral syndrome. Within the facioauriculovertebral spectrum are malformations and syndromes that affect the first and second branchial arch derivatives, such as Goldenhar's syndrome (preauricular nodes, epibulbar dermoids, mandibular hypoplasia), hemifacial microsomia,[14] and oculoauricular vertebral dysplasia (microtia, cervical spine anomalies, and epibulbar dermoids).[15,16] It may be that Goldenhar's syndrome, hemifacial microsomia, oculoauriculovertebral dysplasia, and microtia are simply variants of the same entity.[4] Microtia also may be seen in syndromes such as Treacher Collins syndrome, which has an autosomal dominant inheritance pattern.

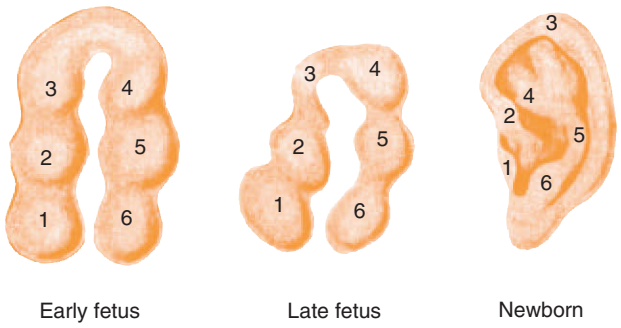

Figure 192-1. Embryonic development. The ear develops from six hillocks of His. Hillocks 1 through 3 are from the first branchial arch, and hillocks 4 to 6 are from the second branchial arch. Hillock 1 forms the tragus, hillock 2 forms the root of the helix, and hillock 6 forms the antitragus. Hillocks 2 through 5 appear to form the helix and antihelix.

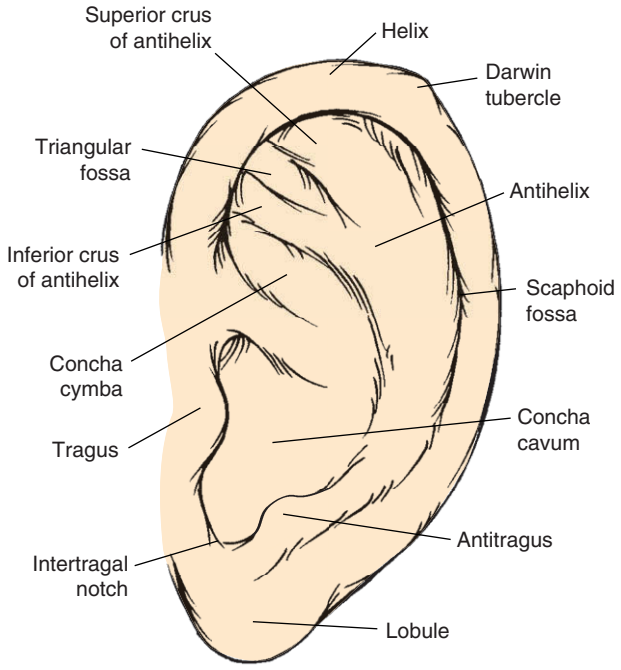

Figure 192-2. Normal anatomic landmarks of the ear.

Ear Anatomy

The anatomic contour of the normal ear must first be reviewed in order to understand the nature and extent of microtic ear deformities (Fig. 192-2). The auricle is an aesthetic sculpture of complex convexities, concavities, and curved lines such as the helix and the antihelix, which are smooth and uninterrupted. The elastic cartilage framework of the auricle is usually pliable yet structurally strong and extraordinarily resistant to trauma. The skin of the ear is fibrofatty and loose over the lobule and the margin of the helix but thin and fixed over the remaining cartilage framework.

Normal adult ear height ranges from 5.5 to 6.5 cm, which is typically attained by 13 years of age in boys and 12 years of age in girls. The ear goes through rapid growth between 2 and 3 years of age and reaches 95% of its adult size by about age 5. Thereafter it grows at a modest rate until it reaches its adult size during early teenage years. The horizontal width of the ear is achieved at a much earlier age. Protrusion of the ear from the surface of the mastoid should be 1.5 to 2.0 cm, thereby creating an angle between 15 and 20 degrees.[17] The superior margin of the helix is at the level of the tail of the eyebrow in 85% of people. Because the tail of the eyebrow is also quite variable, the level of the upper eyelid also may be used as a landmark if the patient has bilateral microtia.[18] The ear inclination is the angle formed by the vertical axis of the face and the longitudinal axis of the ear with the patient in the Frankfort horizontal position. This is approximately 24.8 degrees, with a standard deviation of 6.2 degrees.[19] Therefore, the longitudinal axis of the ear is not quite parallel with the dorsum of the nose (as is commonly thought), because the ear is in a slightly more vertical orientation.

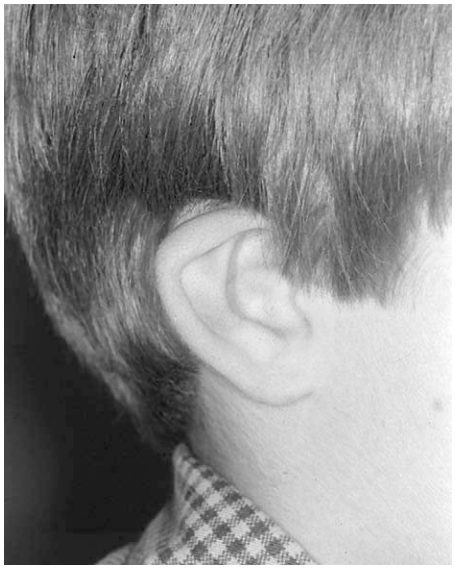

Figure 192-3. Type I microtia. A constricted ear with minimal tissue deficiency.

Microtia

Microtia deformities come in various shapes and sizes, and unfortunately, there is currently no universal, precise, and accurate classification scheme that is clinically useful. Classification schemes are further complicated if the status of the external auditory canal (EAC) and middle ear contents and the presence or absence of an associated syndrome are included.[5,20] Classification usually is simplified by evaluating the external auricular deformities alone. Perhaps *dysplasia* is a better term than *microtia* to use in describing ear deformities. Dysplasia deformities typically are divided into three broad and simple categories that have a great deal of overlap.[21] *Type I* (Fig. 192-3) is used to designate ears with mild deformity. All major structures are present to some degree, and reconstruction does not require additional tissue. *Type II* (atypical microtia) dysplasia (Fig. 192-4A to C) includes ears that have all major structures present to some degree. There is a deficiency of tissue, and surgical correction requires the addition of cartilage and skin. Mini-ear and severe cup-ear deformities are included in this category. The external auditory meatus is present, but it may demonstrate some degree of stenosis. *Type III* (classic microtia) dysplasia (Fig. 192-5A to C) deformities have few or no recognizable landmarks of the auricle, although the lobule usually is present and positioned anteriorly (see Fig. 192-16). *Anotia* is the complete absence of auricle and lobule. Reconstructive surgeons may find it more useful to simply note the status of the helix and antihelix, the conchal bowl, the lobule, the tragus, and the EAC, because these landmarks dictate the stages of ear reconstruction and the degree of surgical difficulty.

Evaluation

Children with microtia typically present to an otolaryngologist early during infancy because of the visible anomaly and parental concerns related to the child's hearing. The parents are usually concerned with the short- and long-term effects of monaural hearing on the child's speech development and the possibility of learning disabilities. Physical examination should focus on the mandibular shape and excursion, mouth, maxilla, eyes, and neck to rule out mandibular asym-

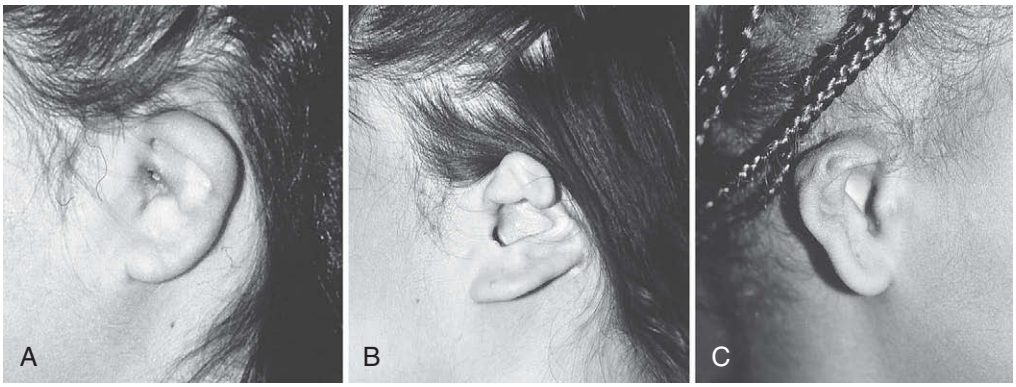

Figure 192-4. Type II microtia. **A,** A patient with type II microtia demonstrating a slight deformity with a small helix and missing antihelix. This patient also demonstrated canal stenosis. **B,** More extensive loss of the helix and antihelix, with a relatively normal canal and conchal cavum. **C,** A patient with loss of the superior crus of the antihelix and a constricted helix.

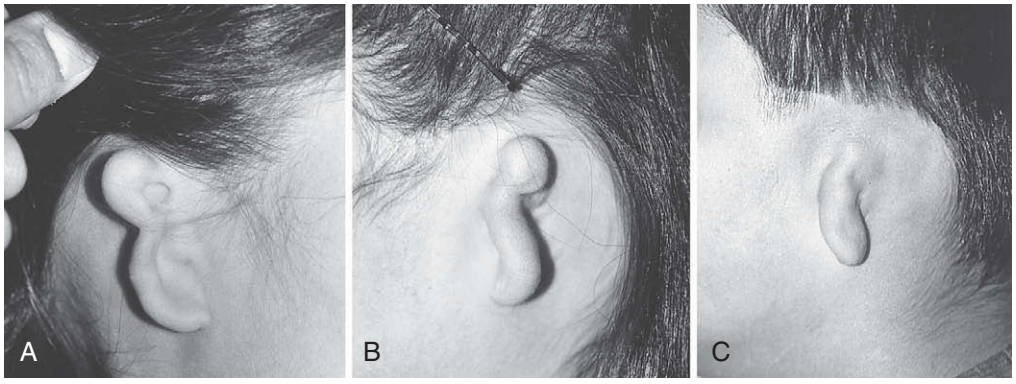

Figure 192-5. Type III microtia. **A** and **B,** Ears with moderate deformity and a few remaining visible landmarks of the helix. **C,** No recognizable landmarks of the auricle or canal are apparent, but the lobule is preserved.

metry, maxillary asymmetry, epibulbar dermoids, coloboma, and vertebral anomalies, which may indicate that the microtia is part of a syndrome.

Although patients with microtia typically have normal hearing in the contralateral ear, all patients with unilateral microtia should have age-appropriate hearing assessment. Hearing should continue to be monitored and eustachian tube dysfunction in the patent ear should be treated. Radiologic evaluation should include high-resolution computed tomography (CT) scan of the temporal bones to assess degree of atresia; cervical spine films to rule out vertebral anomalies; renal ultrasound to rule out congenital renal malformations; and panoramic (Panorex) films to assess the status of the mandible. If multiple anomalies are found, the child is referred to a multidisciplinary craniofacial team for more comprehensive evaluation.

Planning

Early evaluation by an otologist who is familiar with aural atresia is generally recommended. In most cases of unilateral microtia with aural atresia and a contralateral normal-hearing ear, canal reconstruction is controversial because speech development is expected to be normal. However, children with unilateral hearing loss predictably will have difficulties with sound localization and speech discrimination in a noisy setting. Careful review of the middle ear status, ossicular mass, position of the facial nerve, formation of the cochlea, and vestibular structures on CT scan helps the otologic surgeon determine candidacy for atresia repair.

If the patient is considered to be a favorable candidate, atresia repair should be performed after completion of microtia reconstruction. Patients with bilateral microtia and normal bone conduction thresholds may benefit from bone conduction hearing aids. Bone-anchored hearing aids may be considered in children older than 5 years of age.

With regard to the pinna, the patient and family are presented with three options: observation; prosthetic management, either adhesive- or implant-retained; and reconstructive options including staged reconstruction with autologous rib graft, and reconstruction with linear high-density polyethylene (Medpor) surgical implant material and temporoparietal fascial flap. Generally, observation is recommended until the child is at least 5 to 8 years old. This allows both growth of the donor rib cartilage and development of the contralateral normal ear, which will act as a template for the microtic side. Waiting until the child is older may reduce the risk of the development of a thoracic deformity as a result of harvesting of cartilaginous rib graft, although we feel this risk is minimal.[22] Finally, waiting until the child is school-aged allows the child to participate in these important decisions. We feel that it is important for the child to understand the options and participate in the decision making. The general health of the child is assessed, with particular attention paid to growth, maturation, and lung function. It is important to assess lung function, because the risk of pneumothorax and postoperative atelectasis and pneumonia is significant. This assessment usually is performed by the child's pediatrician. It is important to question the child about his or her personal concerns and to inquire about the effects of the microtia on social interaction with friends and classmates. Each child and parent will have different concerns that should be explored preoperatively.

During the planning stage of reconstruction, the surgical benefits, risks, and alternatives are discussed with the patient and the parents (Table 192-1). Complications such as infection, bleeding, scarring, graft loss, displacement or resorption, asymmetry, and pneumothorax should be discussed in detail. The possibility of a less-than-optimal aesthetic result also is discussed, and the expectations of the patient, parents, and surgeon must be realistic and clearly defined. Providing postoperative photographs of previous patients often is

Table 192-1

Overview of Treatment Options for Microtia

Treatment	Details	Advantage(s)	Disadvantages
Observation		No risk	Cosmesis Psychosocial issues
Prosthesis	Adhesive retained	Appearance	More difficult to incorporate atresia repair Requires removal of prosthesis at night and replacement in the morning Cost of prosthesis and maintenance
	Implant retained	Secure retention Appearance	Requires two surgical procedures that include removal of the microtic remnant Daily maintenance of implant site Appearance of implant site Cost of prosthesis and maintenance Eliminates possibility of reconstruction in the future
Reconstruction	Autogenous rib	Autogenous tissue Minimum maintenance More easily accommodates atresia repair	Appearance Donor site morbidity Multiple surgical procedures
	Medpor	Less donor site morbidity Less variability in carving	Foreign body More challenging to do atresia repair Increased risk of exposure of the framework

helpful to patients if the pictures depict a realistic result of a similar deformity.

One alternative for older children or adults may be the use of an auricular prosthesis. In some institutions, placement of a permanent auricular prosthesis with osseointegrated implants is recommended as the primary management modality. The aesthetic appearance often is excellent. However, most reconstructive surgeons discourage the use of osseointegrated implants for younger patients as a primary modality for several reasons: The implant sites will require daily care to maintain the health of the soft tissue surrounding the percutaneous osseointegrated implants. The prosthesis needs to be removed at night and replaced in the morning. The patient may unnecessarily avoid situations that may accidentally dislodge the ear and cause embarrassment. The placement of the osseointegrated implants requires removal of the soft tissue with skin grafting to bone to create nonmobile skin surrounding the posts. This eliminates the possibility of reconstructive surgery in the future. Furthermore, the prostheses are expensive and often not covered by third-party payers, leaving the patient at risk for having the osseointegrated implants in place without a prosthesis to wear in the future.

Finally, other materials for auricular reconstruction should be mentioned as part of a thorough informed consent, even if your institution may not offer these types of reconstructions. Implantable materials such as Medpor are used as alternatives to autogenous cartilage. Use of synthetic frameworks eliminates the need to harvest and carve the rib. However, the likelihood of extrusion and the lifelong risk of infections may outweigh their benefit. Stem cell technology is still emerging, and stem cell–derived implants may someday replace the need for rib graft harvesting. To date, no reliable cartilage implant created from stem cells is available.

Autogenous Costochondral Reconstruction

The use of rib cartilage in auricular reconstruction was pioneered by Tanzer[23] and refined by the meticulous work and accomplishments of Brent.[24,25] Reconstruction using the standard rib-grafting technique requires three to four stages, each separated by 2 to 6 months, beginning when the patient is approximately 6 to 8 years old.

The surgeon must develop carving and sculpting skills before undertaking a microtia reconstruction on a patient. For obvious reasons, fresh cadaveric rib cartilage is the best material with which to practice carving and harvesting grafts. If this cannot be obtained, carving the basic auricular framework can be practiced using soap or potatoes.

The surgical procedure described next is appropriate for reconstruction in patients with the most common class III dysplasia, or "peanut" ear.

Classic Microtia Reconstruction

Stage I: Cartilage Implantation

The first stage of microtia reconstruction is undoubtedly the most tedious and crucial of the entire process.[24] One of the most important objectives during the first stage is to place the auricular framework in a position that achieves the best symmetry for the patient's face. Placement of the reconstructed ear is determined by the position of the normal ear, and we do not alter this position to accommodate future reconstruction of the canal atresia or a low-lying hairline. If the hairline is low, the initial ear reconstruction is destined to have hair along the helix that will require depilation or excision at a later date. Preoperative tissue expansion to increase the amount of non–hair-bearing skin is not recommended, because the expanded skin capsule does not contour well over the implanted cartilaginous framework.

Three templates are made using radiographic film: a positioning template, a sizing template, and a carving template. The positioning template is made by carefully tracing the contour of the normal ear. It has the outline of the normal ear, with the landmarks of the lateral palpebral fissure and the lateral oral commissure for reference points. The landmarks are etched onto the radiographic film with an 18-gauge needle or scalpel to avoid losing these reference points (Fig. 192-6). The distance from the lateral palpebral fissure to the root of the helix is also measured on the template and should approximate 6.5 cm, or the length of the normal ear. The sizing template, which is a tracing of the entire ear, is used to test the size of the skin pocket in which the cartilaginous framework is placed. The carving template is drawn from the sizing template to include the landmarks of the antihelix, the triangular fossa, the scaphoid fossa, the medial aspect of the helix, and the antitragus. It is drawn 1 to 2 mm smaller than the sizing template to compensate for the thickness of the overlying skin. It is also used to determine the best donor site during rib harvesting and as a template

for sculpting the cartilaginous framework. After the landmarks are permanently etched, the templates are autoclaved. The entire head and neck region is prepared so that the contralateral normal side can be easily visualized to evaluate symmetry. The eyes and mouth are covered with a transparent drape to allow visualization of the lateral palpebral fissure and the lateral commissure and to facilitate placement using the positioning template. The recipient ear site is injected with lidocaine with epinephrine to assist with hemostasis, and the incision is drawn along the anterior and superior margin of the rudimentary lobule. The contralateral side of the chest is prepared, because the contralateral rib graft has better contour characteristics. The chest incision is drawn just superior to the margin of the rib cage.

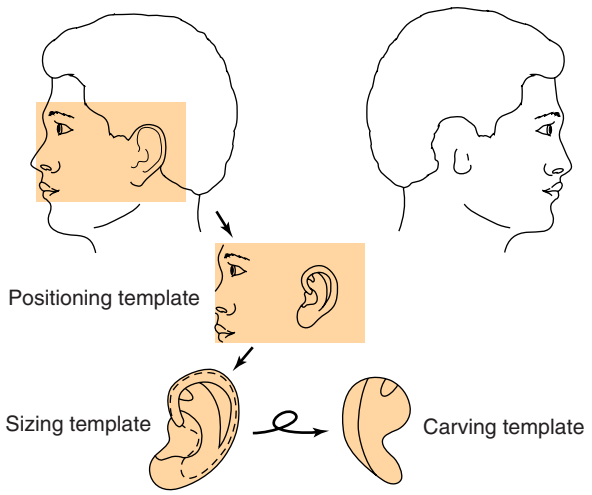

Figure 192-6. Templates for reconstruction. The positioning template, which is drawn with reference landmarks, is used to create the sizing and carving templates. The sizing template is drawn to match the exact size of the normal ear. The carving template is slightly smaller than the sizing template to compensate for the thickness of the skin flap.

We generally use two surgical teams to reduce operating time. The donor site incision is made on the contralateral side of the chest, and the inferior margin of the rib cage is exposed. We have refined a minimally invasive technique, using a 2-cm skin incision (Fig. 192-7A). Two cartilaginous segments are required: a segment of free-floating cartilage to create the helical rim and a portion of synchondrosis to create the auricular framework.

The floating eighth rib is isolated, and dissection is continued posterolaterally to the bony-cartilaginous junction. Ideally this segment is 8 to 9 cm in length. Then the synchondrosis, usually between sixth and seventh ribs, is exposed. The carving template is used to determine the best donor site for the synchondrosis (see Fig. 192-7B to D). The rib cartilage is harvested with the superficial perichondrium intact. After removal of both segments, the donor site is checked for violation of the pleura. The chest wound is filled with saline and the anesthesiologist is asked to deliver positive-pressure ventilation to sustain a pressure of 40 cm H_2O. If a defect in the pleura is identified, a red rubber catheter is introduced into the pleural space and placed on continuous suction. The catheter is removed during positive-pressure ventilation, and the wound is closed with an airtight closure. A suction drain is placed in the subcutaneous space after closure of the rectus muscle. Intercostal bupivacaine blocks are placed at the end of the procedure to reduce postoperative pain.

All incision planning should take into consideration future stages of reconstruction. The recipient incision is made vertically along the anterosuperior margin of the lobule. This incision site will be used for the second-stage lobule transfer. The rudimentary cartilage segment is meticulously removed, with great care taken to avoid perforating or traumatizing the skin flap. The recipient pocket is elevated over the

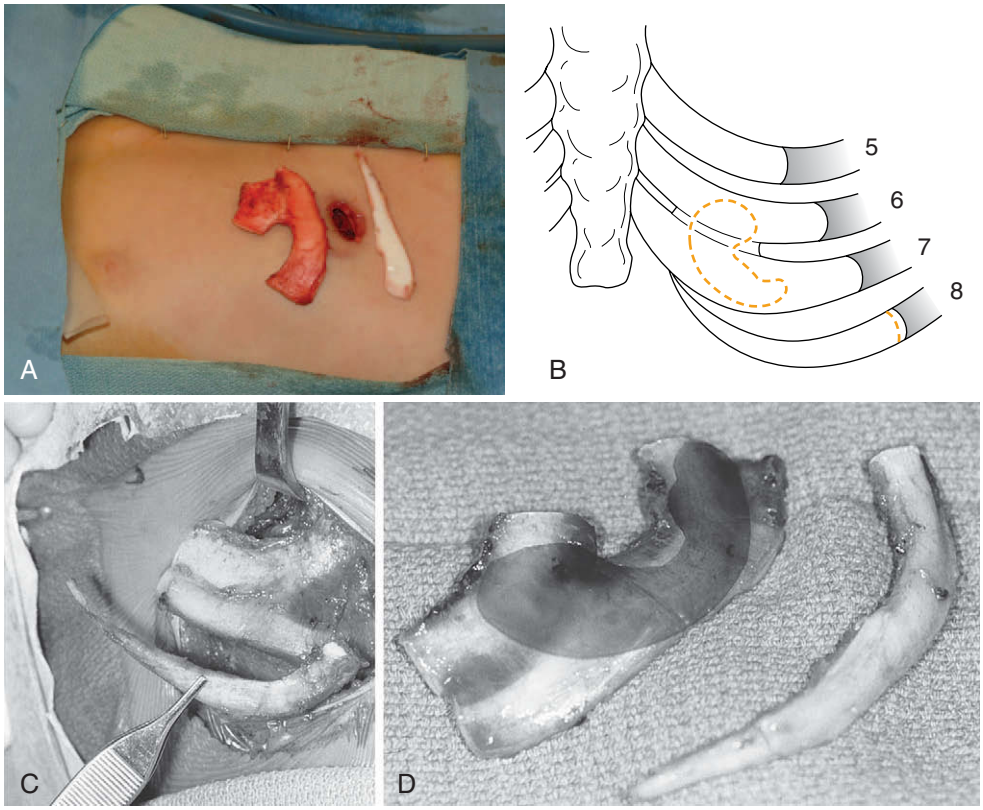

Figure 192-7. The donor site. **A,** A minimally invasive 2-cm incision is used to harvest rib segments. **B** to **D,** The contralateral chest is chosen for the donor site. The sixth, seventh, and eighth ribs and the synchondrosis between the sixth and seventh ribs are depicted. (The longer incision depicted in **C** is rarely necessary.) The donor sites of the auricular framework and the helical rim are indicated.

mastoid in a subcutaneous plane. The flap is thinned to a uniform thickness. In the hair-bearing region, the skin is thicker, because it becomes continuous with the scalp and contains a layer of galea. Dissection must be superficial to this layer of galea so that the flap remains uniformly thin and pliable. The sizing template is used to ensure that the pocket is large enough to accommodate the framework. The sizing template reduces the number of times that the reconstructed cartilage framework is transferred in and out of the pocket while adjustments are made; this helps reduce the amount of unnecessary handling and the risk of fracturing the framework.

The framework and helix are carved using Nos. 10, 11, and 15 scalpel blades. The 6700 Beaver blade can also be used (Fig. 192-8). As much perichondrium as possible is left intact over the lateral surface to enhance revascularization and tissue fixation. Suture or wire fixation is needed occasionally to reinforce the synchondrosis and to provide additional support to the framework. Additional cartilage grafts can be sutured to the posterior surface of the synchondrosis for more rigidity. The helix is carved from the eighth rib using the thicker part of the graft for the root of the helix and the thin distal tip of the graft for the caudal helix. The graft is carefully thinned until it is pliable enough to bend around the framework, and it is sutured into position with 4-0 clear nylon sutures. Additional thinning of the scaphoid and triangular fossa can be done after the helix is adequately fixated (Fig. 192-9A to C).

The reconstructed framework with attached helix is then placed into the pocket in a rotational manner, beginning with the root of the helix and then rotating the framework clockwise for the right side and counterclockwise for the left. If the pocket is excessively tight and the overlying skin remains blanched with poor vascular refill, the implant is removed and the pocket enlarged. After the graft is properly positioned, a small round suction drain is placed deep to the framework and brought out through the skin in the hairline. After the wound is sealed, the skin should conform to the framework, and the details of the helix and antihelix should be clearly visible (Fig. 192-10). The concavities of the ear are packed with petroleum gauze and secured with 4-0 chromic bolster sutures. A Glasscock dressing is applied using fluffed gauze to avoid unnecessary pressure. The drains are placed on intermediate suction. One of us (CSM) prefers continuous suction for 24 hours before placing the drains on bulb suction; another (VQ) recommends the continuous use of butterfly drains connected to vacuum-sealed red rubber–topped tubes.

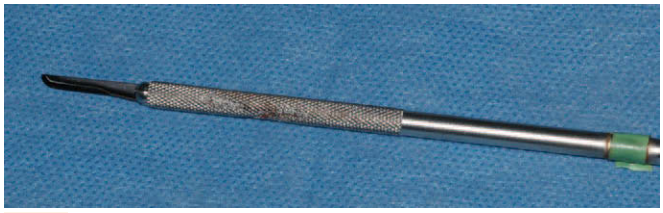

Figure 192-8. A 6700 Beaver blade is used to carve the framework.

A chest radiograph is obtained in the recovery room to rule out the possibility of pneumothorax. These patients are admitted for 48 hours for pain control, and intravenous antibiotics. The chest drain is removed on the first postoperative day, and the ear drain is removed after 2 to 3 days when there is little or no drainage. The vascularity of the skin overlying the helix is inspected on a regular basis, and the mastoid dressing is removed at 24 to 48 hours. A Glasscock dressing is then applied for the next 2 weeks to protect the ear. The patient must refrain from strenuous activity for 4 to 6 weeks, and the patient is not allowed to participate in contact sports for 1 month to avoid injuring the donor rib site.

Stage II: Lobule Transfer

The second surgery is performed 2 to 3 months after the first stage. A transposition flap is designed to move the vertically oriented lobule to the tail of the framework. After the incisions are made, a pocket is created within the lobule to accommodate the tail of the framework. The tail is elevated from the mastoid cortex so that the lobule can be wrapped around the posteroinferior margin of the cartilage framework. Care is taken to evert the wound margins in an attempt to avoid a stepoff at the junction of the lobule and framework. One to two Z-plasties are performed across the transverse portion of the incision (Fig. 192-11A to F).

Stage III: Creation of Postauricular Sulcus

This procedure is performed approximately 3 months after stage II (Fig. 192-12A to D). An incision is made around the helical rim. However, if there is hair on the helix, the incision is made slightly lower on its lateral surface to minimize the hair-bearing skin over the framework. The non–hair-bearing auricular skin is advanced 2 to 3 mm superiorly over the helical rim, and absorbable tacking sutures are placed between the subcutaneous tissue and the cartilaginous framework. The ear is released by dissecting into the postauricular sulcus and leaving the perichondrium intact to protect the cartilage graft. The postauricular skin over the mastoid is undermined and advanced into the postauricular sulcus, to help project the ear laterally away from the mastoid. After the postauricular skin is advanced and secured, the remaining defect is measured. It usually measures approximately $4 \times 8\,cm^2$. An elliptical thick split-thickness graft is harvested freehand from the left groin. The donor site is closed primarily. The graft is secured into the newly created postauricular sulcus with 5-0 chromic sutures. A bolster is secured into the sulcus with a 4-0 nylon. The ear is covered with a Glasscock dressing for protection for 1 to 2 weeks. The bolster is removed after 5 to 7 days, and the skin graft is kept moist for 2 to 3 weeks.

For some patients, the contralateral ear is prominent, contributing to the asymmetrical appearance of the ears. Otoplasty of the normally formed ear can be combined with this procedure, and the skin excised for the otoplasty can be used for grafting of the newly created postauricular sulcus of the microtic ear.

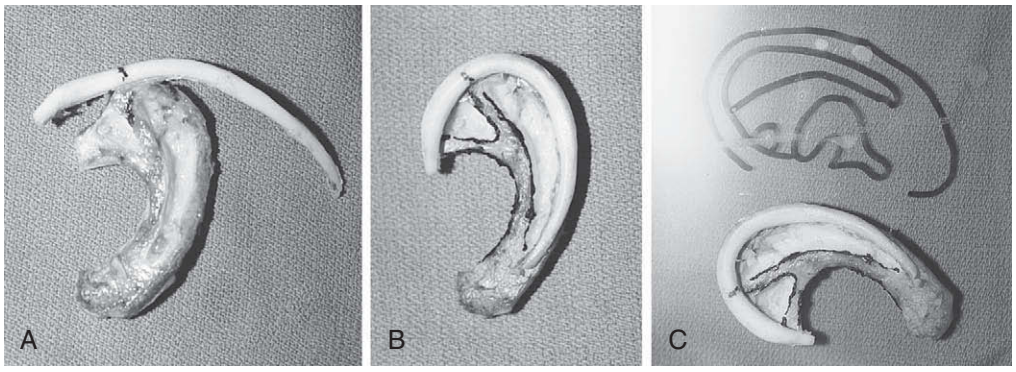

Figure 192-9. Construction of the implant. **A,** The framework is carved from the sixth and seventh ribs. The helix is carved from the eighth rib and is bent gently around the framework. **B,** The helix is secured with 4-0 clear nylon or wire. **C,** The implant is compared with the template.

Figure 192-10. Placement of the implant. The implant is placed into the pocket and positioned using the positioning template. One drain is placed over the surface of the implant as one is placed deep to the implant. The drains are then placed on suction. Note the contouring of the skin over the cartilaginous framework, with the drain traversing over the antihelix and into the scaphoid fossa.

Stage IV: Tragus Reconstruction

The fourth stage of reconstruction is to form a tragus and conchal bowl. If the conchal bowl is well defined, a composite graft can be used to reconstruct the tragus. An elliptical composite graft is removed from the concha cymba of the contralateral ear. An incision is made along the posterior border of the future tragus, and the composite graft is placed on the posterior surface to give the tragus some projection. The shadowing effect gives the illusion of an external auditory meatus. If the conchal bowl is not defined, an incision is made along the posterior border of the future conchal bowl, and an anterior-based cutaneous circular flap is created. The conchal bowl is then debulked of scar tissue and any rudimentary skin and cartilage that might remain. Because of facial nerve anomalies, a facial nerve monitor is recommended. The flap is folded onto itself to create a tragus that is then reinforced with a small piece of auricular or rib cartilage, and the surface of the conchal bowl is covered with a small skin graft (Fig. 192-13A to C). The bolster is removed in 3 to 5 days. Occasionally, an additional operation is needed to further elevate the reconstructed ear away from the mastoid using grafts of cartilage implanted medial to the framework.

Atypical Microtia Repair

Second-degree dysplasia or atypical microtia presents a more difficult surgical challenge. As previously discussed, many components of the auricular structure are recognizable, but there is a distinct tissue deficiency that necessitates the transportation of cartilage and skin. The additional structure often eliminates the necessity for complete framework insertion. When the vertical height difference between the two ears is greater than 20 mm, consideration is given to using a rib framework. When the difference is less than 20 mm, the result is achieved by

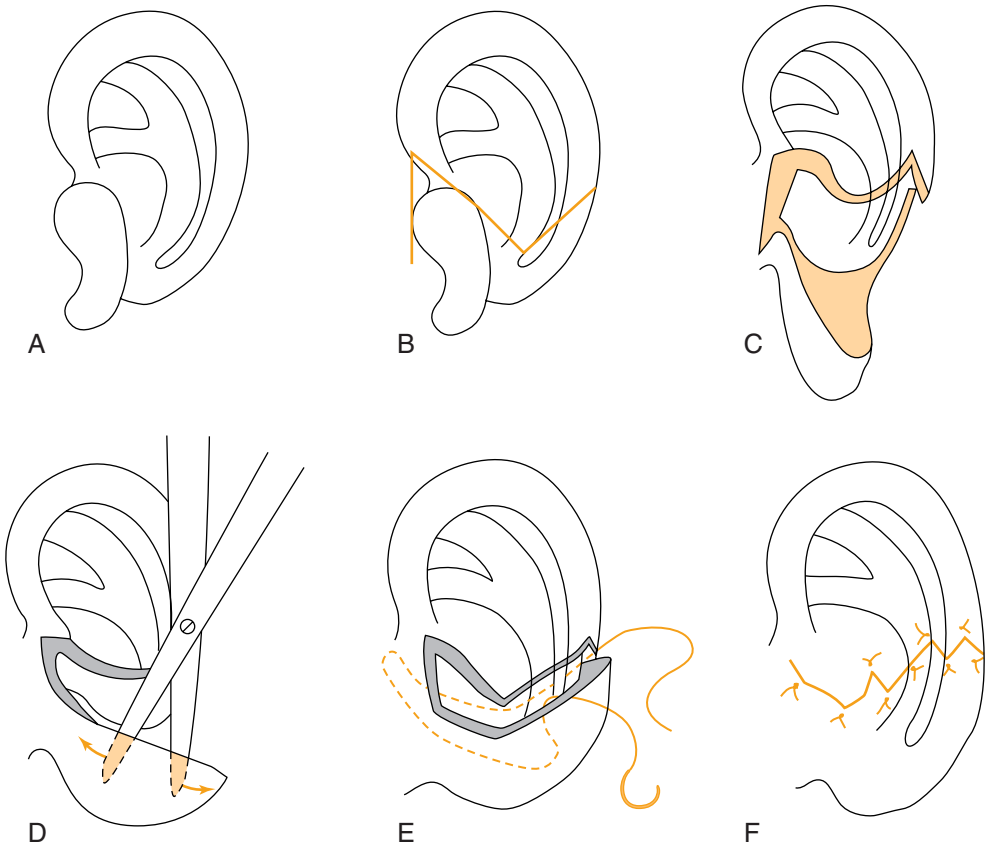

Figure 192-11. Stage II lobule transfer. **A,** Preoperatively, the lobule is noted to be malpositioned anteriorly. **B,** A lobule transposition flap incision is drawn. **C,** Lobule is elevated and posteroinferior margin of the framework is dissected out. **D,** A pocket is dissected within the lobule, and the lobule is transposed over the posteroinferior margin of the graft. **E,** Suture is placed from the pocket in the lobule to mastoid periosteum in order to reduce the flare of the lobule. **F,** Several mini Z-plasties are created along the incision to break up the scar and prevent contracture. Incisions are closed with mattress sutures.

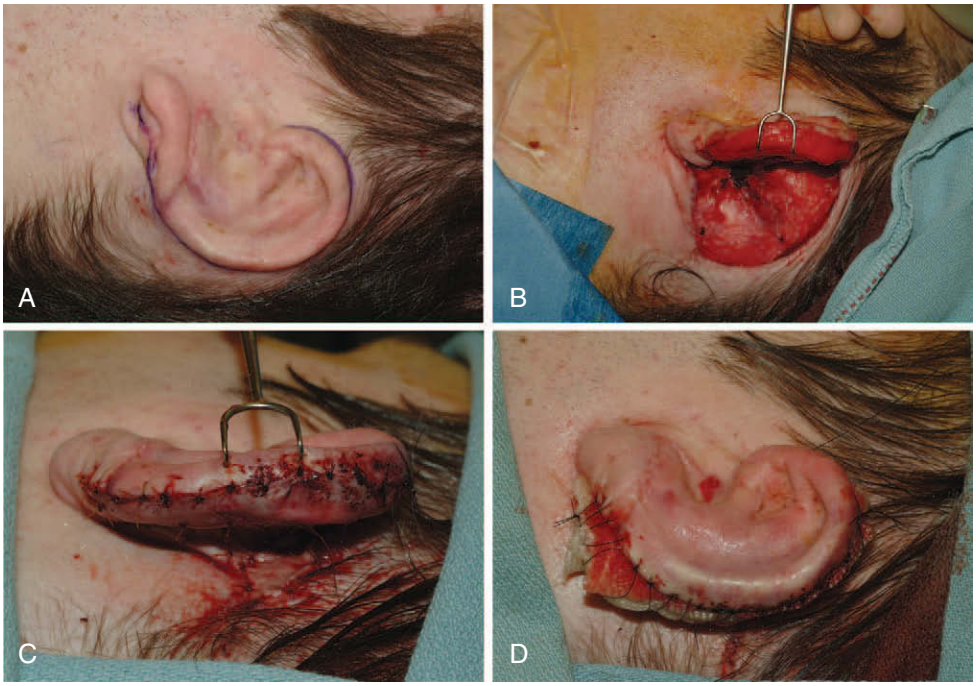

Figure 192-12. Stage III skin grafting. **A,** Before the procedure. **B,** Release of the skin, leaving the perichondrium intact. Dissection is carried into the postauricular sulcus, and postauricular skin is advanced. **C,** Skin graft in place. **D,** Skin graft secured with a soft bolster.

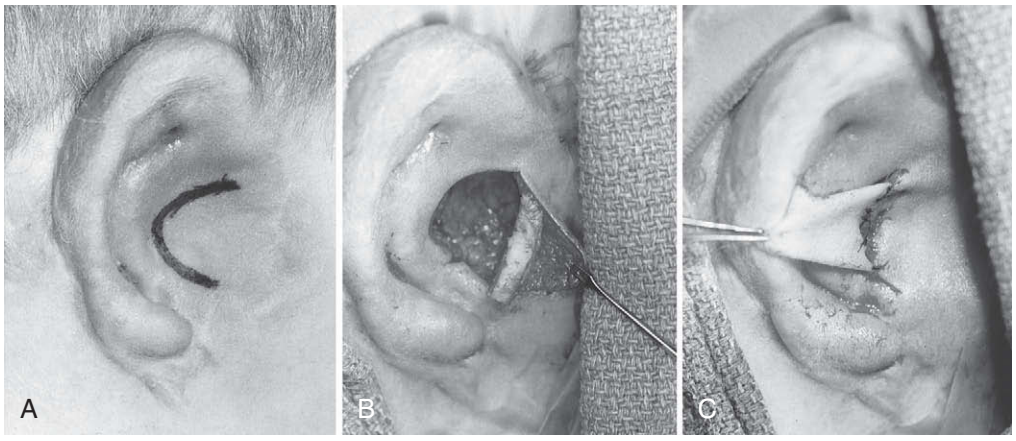

Figure 192-13. Stage IV tragus reconstruction. **A,** In bilateral microtia, tragal reconstruction is more difficult, because both ears are reconstructed; thus, normal concha cymba is not available for composite grafting. A longer flap must be elevated to provide both medial and lateral tragal lining. **B,** A free cartilage graft is placed to prevent contraction and is lined by the skin flap. **C,** The conchal bowl is deepened and lined with a skin graft. *(From Quatela VC, Goldman ND. Microtia repair.* Facial Plast Surg. 1995;11:257. Used with permission.)

expanding the existing structure; this is done by a combination of unfurling, uncupping, and increasing the vertical height with the use of cartilage composite grafts (Fig. 192-14A to H).[26] The helical root can also be advanced in a V-Y fashion into the helix to help augment the vertical height. Unlike classic microtia reconstruction, the use of vestigial remnants as a main framework does not lead to consistent results. Figure 192-15A to F shows a child with atypical microtia with an undeveloped lobule that was reconstructed by placing a cartilage implant that was harvested from the contralateral conchal bowl. This reconstruction was followed by a staged skin graft with an advancement flap of postauricular skin.

Complications

Major complications are rare. However, seemingly minor complications may lead to loss of the graft if they are not treated expeditiously. Immediate postoperative complications include pneumothorax and hematoma formation. Short-term complications include skin flap necrosis and infection. If a graft becomes exposed postoperatively secondary to breakdown of the overlying skin flap, the patient is placed on antibiotics that provide coverage for *Staphylococcus* and *Pseudomonas* infections, and the exposed site is covered with moist continuous dressings. If the exposure is small (1 to 2 mm) and the perichondrium is intact, the wound may granulate with local wound care. If the perichondrium is gone and the cartilage exposed, the framework may become devitalized, desiccated, and infected. Early coverage of the site with a local flap or a temporoparietal fascia flap with an overlying skin graft should be considered. Prolonged antibiotic therapy after flap coverage is necessary to avoid progression of the infection and eventual collapse and resorption of the graft.

Minor complications include malpositioning, scar contracture or hypertrophy, and poor contouring. Generally, problems with scar formation and poor contouring resolve with time if the cartilage has not

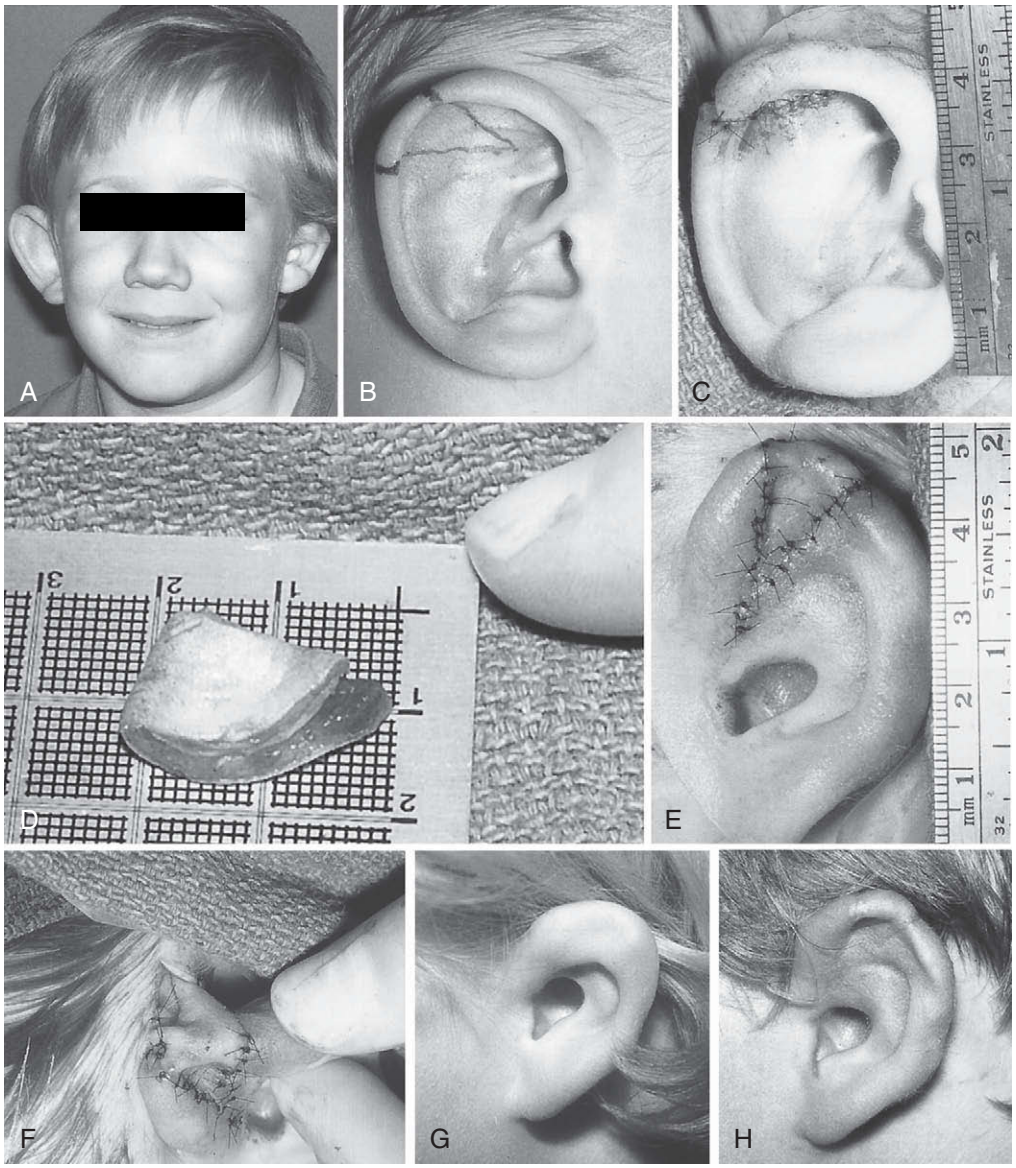

Figure 192-14. Atypical microtia reconstruction. **A,** A congenital defect of the ear with more than 20 mm of vertical height than in the contralateral healthy ear. **B,** The donor site composite graft is harvested to equal to one-half the size of the recipient defect, thereby reducing the disparity. The donor site is closed primarily, with the only resultant deformity being shortened vertical height, which is desirable in this patient's ear. **C,** The donor ear is shortened by 1 cm but retains good form. **D,** The composite graft. **E,** The composite graft sutured into position; vertical height is increased by approximately 1 cm. **F,** Epithelium is removed from the medial aspect of the composite graft, and the graft placed into a postauricular subcutaneous pocket. The medial skin is still attached at the rim as a hinge flap. The medial perichondrium is in contact with the retroauricular soft tissue; this will ensure maximum recipient contact for graft survival. Release is accomplished 2 weeks later, using the hinge flap skin for medial resurfacing. **G,** Before surgery. **H,** The final result at 1 year.

Figure 192-16. **A,** Type III microtia with anteriorly positioned lobule. **B** to **F,** At 2 years after completion of microtia reconstruction. Note the height symmetry and angle of the auricle in relation to Frankfurt horizontal plane.

become infected or undergone resorption. Minor scar revisions may be necessary when indicated, and the surgeon should be careful not to expose the cartilage graft. Problems with malposition are usually minor if proper template techniques were used, and they are commonly related to preexisting lobule asymmetry or generalized facial asymmetry caused by hemifacial microsomia. Major malposition problems are usually related to poor preoperative planning.

Conclusions

Managing patients with microtia can be a rewarding experience for both the patient and the surgeon if proper training, preparation, and planning are done. Each patient and each ear deformity are unique, thus making the management of these patients a humbling, challenging, and perpetually stimulating problem. In many respects, microtia surgery is similar to rhinoplasty, in which the surgeon continually strives to achieve the elusive "perfect" aesthetic and functional result through meticulous planning and attention to detail.

CHAPTER ONE HUNDRED AND NINETY-THREE

Reconstruction of the Auditory Canal and Tympanum

Antonio De la Cruz

Karen B. Teufert

Key Points

- Atresiaplasty aims to create a patent, skin-lined external auditory canal and to achieve a postoperative air-bone gap within 20 to 30 dB.
- In bilateral or unilateral cases of congenital atresia, auricular reconstruction and atresiaplasty are recommended at 6 years of age. Reconstruction with porous high-density polyethylene (Medpor) can be done at an earlier age. In unilateral cases, atresiaplasty is indicated only in minor deformities.
- The microtia repair is performed first because of the need for an excellent blood supply to cover the autologous rib graft, and the hearing restoration surgery is performed 2 months after the last step of the microtia repair.
- There are two requirements for planning surgery in congenital aural atresia: radiographic three-dimensional evaluation of the temporal bone and audiometric evidence of cochlear function.
- The following four anatomic parameters as seen radiographically are crucial for surgical planning: the status of the inner ear, the extent of pneumatization of the mastoid, the course of the facial nerve (both the relationship of the horizontal segment to the oval window and the location of the mastoid segment), and the presence of the oval window and stapes footplate.
- Ideal surgical candidates display a well-developed mastoid and a good oval window/footplate–facial nerve relationship.
- Ossicular reconstruction with the patient's own ossicular chain is preferred to the use of a prosthesis.
- Complications of atresiaplasty include lateralization of the tympanic membrane, stenosis of the meatus, sensorineural hearing loss, and facial nerve palsy.
- Graft lateralization is the most common delayed cause of a poor hearing outcome, usually occurring in the first 12 months after surgery.
- Polymeric silicone sheets, hydroxylated polyvinyl acetate wicks, absorbable gelatin film disks, and tabs in the fascia graft have helped lower the incidence of tympanic membrane lateralization by keeping the tympanic membrane graft in position.
- The incidence of stenosis has been significantly reduced with the use of one-piece split-thickness skin grafts covering all exposed bone, and polymeric silicone sheets and hydroxylated polyvinyl acetate wicks in the external auditory canal.
- It is important that drilling on the ossicular chain be minimized when it is dissected away from the atretic bone to reduce the risk of noise-induced sensorineural hearing loss.
- Intraoperative facial nerve monitoring is essential in all cases because there are often no clearly identifiable landmarks in atretic ears.
- Bone-anchored hearing aids are an alternative to atresiaplasty for rehabilitation of hearing loss resulting from congenital aural atresia, particularly in patients who are not good candidates for surgery.

Congenital aural atresia (CAA) represents aplasia or hypoplasia of the external auditory canal (EAC) resulting from failed or aborted development and is often associated with other malformations of the temporal bone, including external, middle, and inner ear deformities. CAA is unilateral more often than bilateral (occurring at a ratio of 3:1), preferentially affects males and the right side, and occurs in 1 in 10,000 to 1 in 20,000 live births.[1] Bony atresia occurs more frequently than membranous atresia. Fusion of the malleus and incus is the most common associated middle ear deformity, whereas the stapes footplate is usually normal.[2] Microtia is common in patients with CAA, and generally the severity of the external deformity correlates with the extent of middle ear deformity.[3-5] As opposed to middle ear malformations, the incidence of inner ear abnormalities in patients with CAA is relatively low, reflecting the earlier and independent embryonic development of the inner ear. The facial nerve typically lies in a normal position but may be displaced anteriorly and laterally in the vertical segment. Atresiaplasty aims to create a patent, skin-lined EAC and to achieve a postoperative air-bone gap within 20 to 30 dB. Surgical success depends on the appropriate selection of candidates for surgery and on proficient application of all modern tympanoplasty techniques,

including meatoplasty, canalplasty, tympanic membrane grafting, and ossicular reconstruction.

Embryology

Knowledge of normal ear development aids understanding of the potential combinations of malformations possible in ears with CAA. This understanding helps physicians select appropriate surgical candidates and avoid complications during surgery. Because the inner ear, middle ear, and external ear develop independently, deformity of one does not necessitate deformity of another. Fortunately, inner ear structure and function are usually normal in ears with outer and middle ear abnormalities.[6]

The external auditory meatus develops from the first branchial groove. During the second month, a solid core of epithelium extends inward from the primary meatus to the primitive tympanic cavity forming the meatal plate.[7,8] During the 21st week, this core resorbs and canalizes, forming the precursor to the EAC. Failure of resorption and canalization accounts for most cases of CAA. Subsequent posterior and inferior development carries the middle ear and facial nerve to their normal locations. By the end of the third gestational month, the primitive auricle has formed from six hillocks derived from the first and second branchial arches.

The eustachian tube, tympanic cavity, and mastoid air cells derive from the first branchial pouch, and the tympanic membrane forms from the plaque of tissue where this pouch meets the epithelium of the EAC.[7,8] Pneumatization of the middle ear and mastoid occurs late in fetal development, is usually present by birth, and continues to expand postnatally. Meckel's cartilage (first branchial arch) gives rise to the neck and head of the malleus and the body of the incus, whereas Reichert's cartilage (second branchial arch) forms the long processes of the malleus and incus as well as the stapes superstructure. The stapes footplate has a dual embryologic origin, developing from the second arch and from the otic capsule. The ossicles achieve their final shape by the fourth month and are covered with a mucous membrane from the expanding tympanic cavity by the end of the seventh to eighth month.

The facial nerve is the nerve of the second branchial arch. Its general course is established by the end of the embryonic period; however, its ultimate intraosseous course depends on later bony expansion of the tympanic ring and cavity.[9] The auditory placode on the lateral surface of the hindbrain gives rise to the membranous inner ear during the third to the sixth week. The surrounding mesenchyme transforms into the bony otic capsule.

Classification Systems

In atresiaplasty, surgery classification systems that help in the identification of best candidates and in comparison of outcome and multiple schemes have been developed. The De la Cruz classification divides abnormalities into "minor" and "major" categories (Box 193-1).[2] The clinical importance of this classification is that surgery in cases of minor malformations has a good possibility of yielding serviceable hearing, whereas cases of major malformations are best treated with the bone-anchored hearing aid (BAHA) system.

The point-grading system for preoperative assessment of the best candidates for hearing improvement developed by Jahrsdoerfer and colleagues[10] assigns points on the basis of preoperative temporal bone CT scan findings of mastoid pneumatization, presence of the oval and round windows, facial nerve course, status of the ossicles and mesotympanum, and presence of the stapes, as well as on the external appearance (Table 193-1). Each parameter receives 1 point except for the presence of the stapes, which receives 2 points. A score of 8 or higher predicts the best chance of surgical success (greater than 80% success). A score of 7 implies a fair result, a score of 6, a marginal result; and a score less than 6 indicates that the patient would have poor results from atresiaplasty.

Ishimoto and colleagues[11] evaluated the relationship between hearing level and temporal bone abnormalities in patients with microtia, using the Jahrsdoerfer scoring system and high-resolution CT (HRCT) scans of the temporal bone.[11] The hearing level in microtic ears best correlated with the formation of oval/round windows and ossicular development but not with the degree of middle ear aeration, facial nerve aberration, or severity of microtia.

Box 193-1

De la Cruz Classification of Congenital Aural Atresia

Minor Malformations

- Normal mastoid pneumatization
- Normal oval window footplate
- Good facial nerve–footplate relationship
- Normal inner ear

Major Malformations

- Poor pneumatization
- Abnormality or absence of oval window/footplate
- Abnormal course of the facial nerve
- Abnormalities of the inner ear

Adapted from De la Cruz A, Linthicum FH Jr, Luxford WM. Congenital atresia of the external auditory canal. *Laryngoscope*. 1985;95:421-427.

Table 193-1

Jahrsdoerfer Grading System of Candidacy for Atresiaplasty

Parameter	Points
Stapes present	2
Oval window open	1
Middle ear space	1
Facial nerve normal	1
Malleus-incus complex present	1
Mastoid well pneumatized	1
Incus-stapes connection	1
Round window normal	1
Appearance of external ear	1
Total available points	10

Total Score	Type of Candidate
10	Excellent
9	Very good
8	Good
7	Fair
6	Marginal
≤5	Poor

Modified from Jahrsdoerfer RA, Yeakley JW, Aguilar EA, Cole RR, Gray LC. Grading system for the selection of patients with congenital aural atresia. *Am J Otol.* 1992;13:6-12.

Other classifications systems have been developed by Altmann,[12] Chiossone,[13] and Schuknecht.[14] Congenital cholesteatoma occurs in 14% of patients with CAA and is not included in any of the grading systems because these systems are used only for predicting hearing results in patients undergoing elective procedures.

Initial Evaluation

Several issues should be addressed in infants presented with CAA. In addition to the malformations of the temporal bone, other congenital abnormalities may be present and should be excluded. Evaluation of auditory function with auditory brainstem response (ABR) audiometry should be performed during the first few days of life in patients with either unilateral or bilateral atresia, because ipsilateral and contralateral inner ear abnormalities may be associated with CAA. Occasionally, a patient with unilateral atresia has a total sensorineural hearing loss (SNHL) on the side of the normal-looking ear. To maximize speech and language development, proper hearing amplification must begin promptly. For the patient with bilateral CAA, a bone conduction hearing aid should be applied as soon as possible, ideally at 3 or 4 weeks of age. Hearing amplification is not necessary in the patient with unilateral atresia if hearing is normal in the contralateral ear.

Parents of a child with sporadic, nonsyndromic CAA are counseled that the possibility of CAA in their subsequent children is no greater than that for the general population. Options regarding future auricular reconstruction are also reviewed with the parents, and the need for proper hearing rehabilitation is stressed. Early enrollment in special education enhances speech and language development. Children with CAA in association with other syndromes (e.g., hemifacial microsomia, Treacher Collins or Crouzon's syndrome, Pierre Robin sequence) are poor surgical candidates for whom long-term bone-conduction aids or BAHAs offer the best rehabilitation.

The two requirements for elective atresiaplasty are (1) audiometric evidence of cochlear function and (2) radiographic three-dimensional evaluation of the temporal bone. As noted, audiometric evaluation should occur within the first few days of life; however, radiologic evaluation with HRCT of the temporal bone is deferred until age 5 or 6 years. A patient with CAA may experience an infected or draining ear or acute facial palsy with or without a congenital cholesteatoma. In such a case, resolution of the infection and removal of the cholesteatoma, if present, take priority, and HRCT scanning may be indicated before age 5 or 6 years.

Timing of Ear Reconstructive Surgery

Auricular reconstruction precedes hearing restoration surgery by at least 2 months to optimize the blood supply for the autologous rib graft and complex flaps.[15] For patients with binaural or unilateral atresia, microtia repair and atresiaplasty are recommended at 6 years of age. By this age, mastoid pneumatization is complete and the costal cartilage has developed sufficiently for auricular reconstruction. Auricular defects can be rehabilitated with an osseointegrated percutaneous mastoid implant prosthesis, with or without bone-conduction aids such as a BAHA.[16] Alloplastic materials have been used for microtia repair in the past, but a high risk of extrusion is associated with their use. However, new materials, such as porous high-density polyethylene (Medpor), seem to be very well tolerated.[17,18] Medpor reconstruction can be done before or after atresiaplasty because intact blood supply is not indispensable to its success.

In unilateral cases, atresiaplasty surgery may be indicated in a patient who has "minor" unilateral atresia with normal middle ear, ossicles, and facial nerve and excellent pneumatization. In such a patient, atresiaplasty may be offered in childhood with the parents' consent. An adult with unilateral atresia commonly requests atresiaplasty when presbycusis develops in the normal ear.

Preoperative Evaluation and Patient Counseling

Palpation of the mastoid tip, suprameatal spine of Henle (if present), condyle, and zygomatic arch provides a reasonable clinical estimate of the size of the mastoid. This is a useful measure because the new ear canal will be created at the expense of the mastoid air-cell system. The preoperative imaging study is HRCT of the temporal bone in both axial and coronal planes (Fig. 193-1). The surgeon and the radiologist should both review the HRCT scans. Particular attention is given to the following elements, which are the most critical for surgical planning: (1) the status of the inner ear, (2) the extent of temporal bone pneumatization, (3) the course of the facial nerve, with emphasis on the relationship of the horizontal portion to the footplate and the location of the mastoid segment, and (4) the presence of the oval window and stapes footplate. The ideal surgical candidate displays a well-developed mastoid and a good oval window/footplate–facial nerve relationship. In addition to the elements mentioned, HRCT also delineates the thickness and form of the atretic bone, the soft tissue contribution to the atresia, the size and status of the middle ear cavity, and the presence or absence of congenital cholesteatoma. These factors are less critical for the repair.

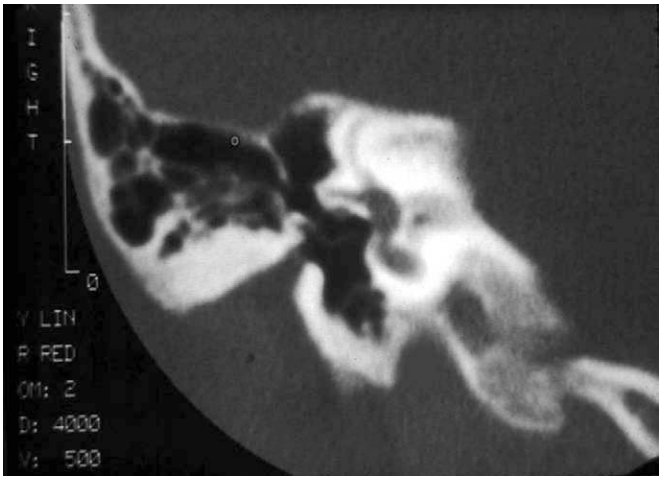

Figure 193-1. Congenital aural atresia, right ear. Coronal high-resolution computed tomography demonstrates atretic external auditory canal and normally developed mastoid system, with normal inner ear.

Poor pneumatization is the most common cause of inoperability in CAA. Fortunately, the majority of patients have normal pneumatization. A facial nerve overlying the oval window may prevent ossicular reconstruction and hearing improvement. If the oval window is absent, it is possible to fenestrate the lateral semicircular canal to improve hearing. However, hearing results are generally poorer in such cases and there is increased risk of SNHL. Patients with these findings are usually best rehabilitated with hearing amplification. Atresiaplasty carries potential for facial nerve injury. The nerve often lies more laterally than usual and may assume a more acute angle than its usual 90 to 120 degrees at the mastoid genu (Fig. 193-2). Even in patients in whom the facial nerve follows a normal course, the distances between the nerve and the temporomandibular joint and between the nerve and the posterior wall of the tympanic cavity are significantly reduced.

Preoperative patient and parent counseling carefully considers reasonably expected surgical results and the potential risks and complications.[19-25] Patients who have minor malformations or a score of 8 or better on the Jahrsdoerfer grading scale are given a greater than 80% chance of significant hearing improvement. Of surgical patients, we find that 50% achieve a long-term postoperative air-bone gap of 30 dB or less.[26] The risk of graft lateralization is less than 4%, the risk of high-tone SNHL is approximately 7%, and the risk of facial nerve palsy is less than 1%. Other risks and complications are comparable to those for other tympanomastoidectomy procedures. Patients and parents are reminded that frequent postoperative visits are critical in the early postoperative period and that a split-thickness skin graft will be taken from the low abdomen to line the new ear canal.

Surgical Approach

Although three approaches to drilling the new ear canal have been described, we have used only an anterior approach for the past 25 years,

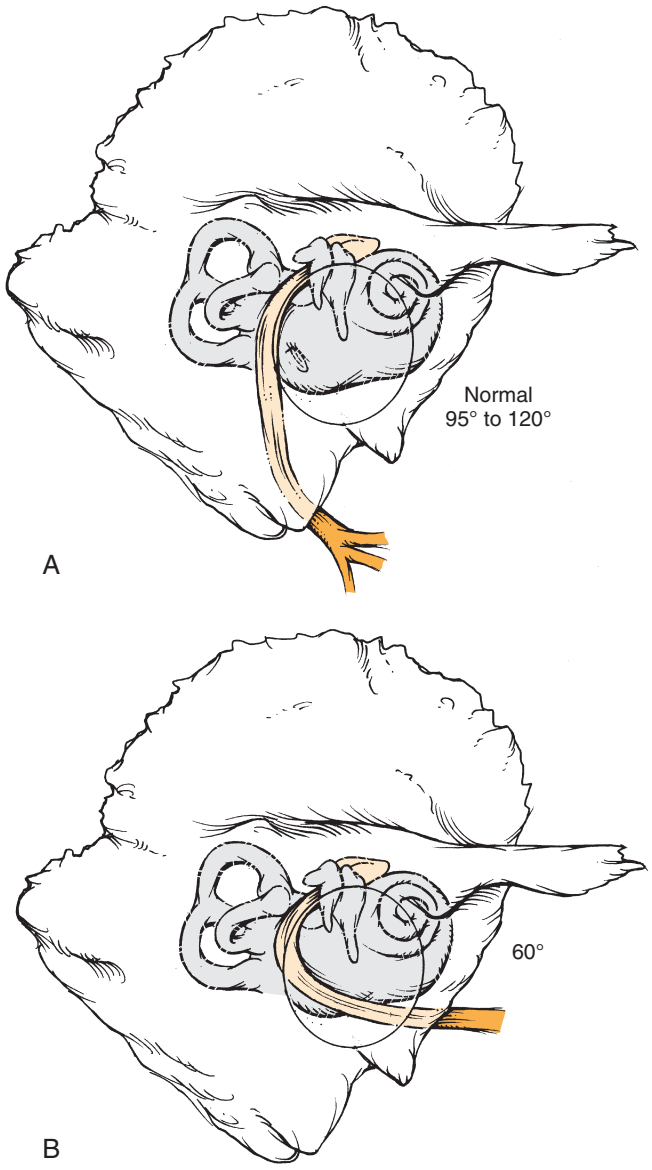

Figure 193-2. The facial nerve in congenital aural atresia. **A,** Normal intratemporal facial nerve anatomy. **B,** Intratemporal facial nerve anatomy in congenital aural atresia. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

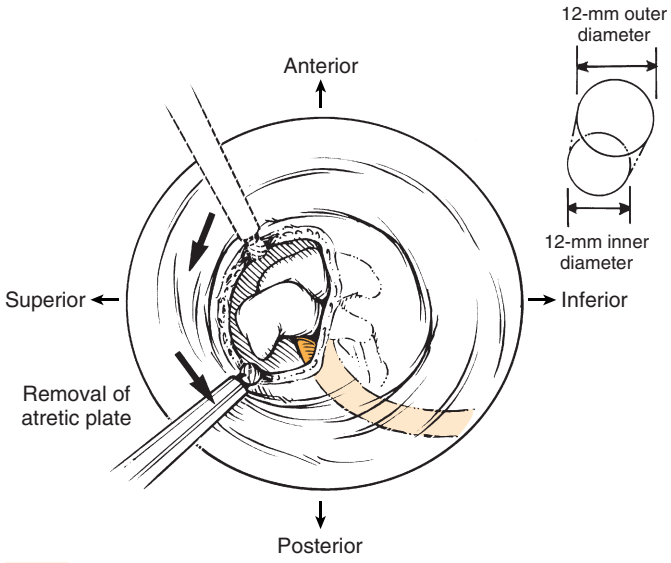

Figure 193-4. Anterior approach: Removal of atretic plate and adhesions, exposing the ossicles, and drilling for the new ear canal. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

and only this standard approach is described here.[27] Under general endotracheal anesthesia, the patient is placed in the otologic position with the head turned away. Facial nerve monitoring electrodes are placed, and muscle relaxants are avoided. The postauricular area is shaved, and the auricle and postauricular area are prepared with povidone-iodine and then draped. The lower abdomen is similarly prepared for the skin graft donor site.

The approach in all cases is through a postauricular incision. In patients with prior auricular reconstruction, care is taken not to expose the grafted costal cartilage. A T-shaped incision is made in the periosteum, and the subcutaneous tissue and periosteum are elevated anteriorly to allow identification of the glenoid fossa (Fig. 193-3). The temporomandibular joint space is gently explored to ensure that an anomalous facial nerve or tympanic bone remnant is not lying within it. Temporalis fascia is harvested and dried.

If a remnant of tympanic bone is present, drilling for the new ear canal begins at the cribriform area. If no such remnant exists, drilling of a 12-mm cylindrical canal begins at the level of the linea temporalis, just posterior to the glenoid fossa. Dissection proceeds anteriorly and medially, taking into consideration the lack of landmarks in atretic bone. The middle fossa plate is identified and followed to the epitympanum, where the fused malleus head–incus body mass is identified (Fig. 193-4). Care is taken to avoid exposure of the temporomandibular joint space or to avoid opening an excessive number of mastoid air cells. A radical mastoidectomy–like approach is to be avoided. Once the ossicular mass is identified, the atretic bone is removed with diamond micro-drills and curettes to completely expose the ossicles (Fig. 193-5A). It is important to minimize drilling on the ossicular mass because transmission of high-speed drill energy to the inner ear may result in high-tone SNHL. An argon laser is used to free the malleus-incus complex from its soft tissue attachments to reduce potential drill trauma to the inner ear. The ossicular mass in the epitympanum is meticulously dissected free of the atresia plate and left intact. Although the temporomandibular joint often limits anterior dissection, particular effort is made to try to create a space of 2 mm or greater

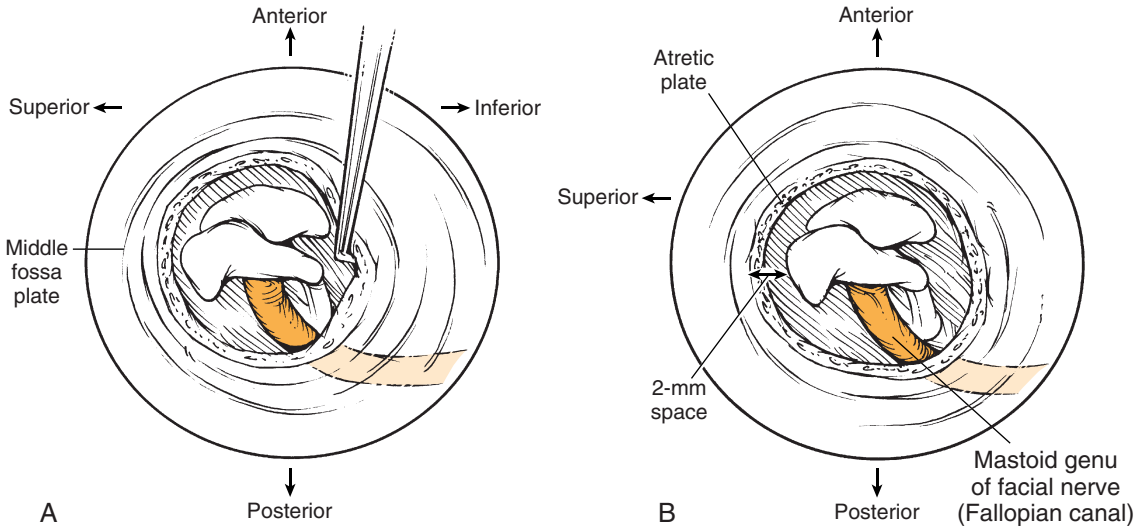

Figure 193-5. **A** and **B,** Anterior approach: The ossicular mass is dissected free of the atretic plate, and a 2-mm space is created around the ossicles. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

anterior to the ossicular mass (Fig. 193-5B). The horizontal facial nerve always lies medial to the ossicular mass. During dissection of the inferior and posterior aspects of the canal, an aberrant facial nerve may be encountered as it passes laterally through the atretic bone. Drilling for the new ear canal continues until it measures about 12 mm. This circumference is most difficult to achieve medially, where the facial nerve, temporomandibular joint capsule, and middle fossa plate limit larger exposure.

Reconstruction with the patient's own ossicular chain is performed in almost all cases, even if the ossicular chain is deformed. Therefore, if the ossicular chain is intact, it is left in place and used for ossicular reconstruction. When this is not possible, a total or partial ossicular reconstruction prosthesis to either a mobile footplate or the stapes head is used for reconstruction. If access to the oval window footplate is impossible because a dehiscent facial nerve obliterates the window, hearing restoration can be accomplished with the use of a BAHA.[28-30]

Drilling continues to create an external auditory canal. It must be one-and-one-third times the size of a normal canal (12 mm vs. 9 mm) to allow for contracture healing in the postoperative period. During creation of the external auditory canal, care is taken not to enter the temporomandibular joint or unnecessarily open mastoid cells.

A dermatome is used to obtain a 0.008-inch thick, 6 × 6-cm split-thickness skin graft (STSG) from the hypogastrium. Pressure with a gauze sponge wet-soaked in 1% lidocaine with epinephrine 1 : 100,000 and thrombin solution aids hemostasis of the donor site. When dry, the donor site is dressed with a sterile wound dressing such as a Tegaderm dressing (3M, St. Paul, MN). This step reduces most of the pain associated with other methods of donor site care. One edge of the skin graft is cut in a zigzag fashion to create four or five triangular points (Fig. 193-6). To facilitate inspection of the skin graft in the final stages of the procedure, the tips of each point and the two corners on the opposite edge are colored with a skin marker.

The dried temporalis fascia is trimmed to size, ideally a 20 × 15-mm oval, and a small (4-mm) "tab" is cut into the anterior-inferior aspect of the graft in an attempt to prevent lateralization. (Lateralization is the most common delayed cause of a poor hearing outcome, usually occurring in the first 12 months after surgery. Once the graft starts lateralizing, it pulls away from the ossicles, and the original good hearing results slowly deteriorate.) Thirty minutes before grafting begins, nitrous oxide administration is discontinued. The fascia is placed over the ossicular chain medial to the malleus, if present, or over the cartilage that covers the prosthesis (Fig. 193-7). The tab of the graft is placed medially into the protympanum to help prevent lateralization of the new eardrum.

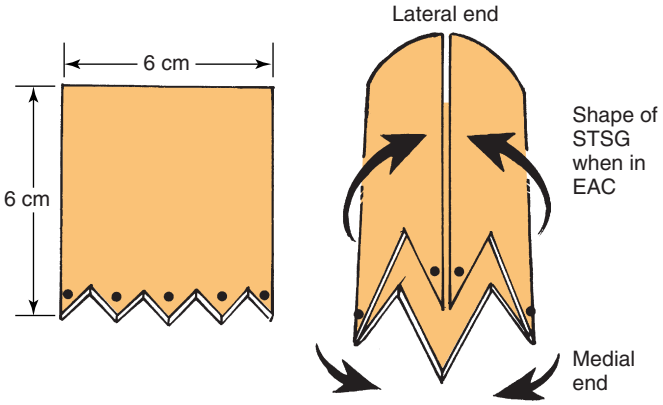

Figure 193-6. Split-thickness skin graft (STSG) used to line new external auditory canal (EAC). *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

Next, the new ear canal is circumferentially lined with the STSG so that all the bone is completely covered (Fig. 193-8). The triangular corners of the skin graft are placed medially and partially overlap the fascia. The previous coloring of the points helps ensure that no skin lies folded on itself and that the entire width of the graft is used. A single layer of antibiotic-soaked absorbable gelatin sponge (Gelfoam; Pfizer Inc, New York) holds the fascia and skin graft in place. To reproduce the anterior tympanomeatal angle, a disk of absorbable gelatin film (Gelfilm; Pfizer Inc) is placed over the fascia and skin graft. After the fascia and skin graft are in proper position, three 0.020-inch polymeric silicone (Silastic; Dow Corning Corporation, Midland, MI) strips are placed to line the skin (Fig. 193-9). This step helps prevent adhesions between the skin graft and the ear canal packing and ensures good contact between the skin graft and ear canal bone. A 9 × 15-mm hydroxylated polyvinyl acetate sponge wick (Merocel; Medtronic USA, Inc., Jacksonville, FL) is placed in the bony canal.

A 12-mm meatus is created, with the anticipation that a third of its diameter will diminish through normal healing. Before the meatoplasty is begun, the ear is turned back and the periosteum is brought back in place with one absorbable suture at the superior level of the new ear canal. This maneuver stabilizes the pinna and helps ensure that the meatus is at the same level as the new ear canal. Skin, subcutaneous tissue, and cartilage are removed in a 12-mm-diameter core over the new meatus. An attempt is made to avoid exposing the grafted cartilage

or other materials used for auricular reconstruction. The lateral edge of the STSG is brought through the meatoplasty, and the lateral portion of the new ear canal and the meatus are packed with a large 15 × 25-mm Ambrus Merocel Ear Wick (Medtronic Xomed Surgical Products, Jacksonville, Fla.). This packing applies diffuse pressure over the entire lateral skin graft and widely packs the meatoplasty. Five tacking sutures of 5-0 Ti-Cron (Covidien, Mansfield, MA) attach the lateral edge of the skin graft circumferentially to the meatal skin. Finally, 6-0 fast-absorbing plain gut is used in a running manner between each Ti-Cron sutures (Fig. 193-10). The periosteum is sutured back into position. The postauricular incision is closed using absorbable sutures (3-0 polyglactin 910 [Vicryl; Ethicon, Inc, Somerville, NJ]). Steri-Strip surgical skin closures (3M) cover the incision, a mastoid dressing is applied, anesthesia is reversed, monitoring equipment is removed, and the patient leaves the operating room.

Silastic sheets and Merocel wicks have helped decrease both the incidence of TM lateralization by keeping the TM graft in position and the incidence of postoperative EAC stenosis by covering all exposed areas of bone that may cause granulation tissue formation.[26] The Merocel wicks that are now available in many sizes for canal stenting help prevent postoperative infection and granulation tissue by allowing administration of topical antibiotic medication to the entire external auditory canal.

Postoperative Care

The mastoid dressing is removed on the first postoperative day. The Tegaderm dressing remains over the STSG donor site for at least 3 weeks to allow epithelialization to occur under the plastic. The patient is seen 1 week after surgery, at which time the tacking Ti-Cron sutures at the meatus and the postauricular Steri-Strips are removed. Any dried blood or crusting on the lateral end of the meatus pack should be trimmed. The postauricular site can now be washed, but water precautions continue for the ear canal. We continue to see the patient on a weekly basis. At 2 weeks, the Merocel packs and Silastic sheet are removed, and the meatus is repacked with antibiotic-soaked Gelfoam. At this point, the patient or parent(s) should apply antibiotic suspension to the packing in the ear canal twice a day for 8 to 12 weeks. Usually by 3 weeks, the abdominal donor site has completed the initial re-epithelialization, and the Tegaderm dressing may be removed.

By 6 to 8 weeks postoperatively, nearly all of the Gelfoam is usually gone and the canal is healing well. The first postoperative

audiogram is obtained at that time, and audiography is repeated in 6 months, in 1 year, and yearly thereafter.

Avoidance of Complications

Complications of atresiaplasty include lateralization of the tympanic membrane in 3.4% of patients, stenosis of the meatus in 3.8%, high-tone SNHL in 7.5%, and facial nerve palsy in less than 1%.[26,31] Other investigators have reported meatal stenosis in 7% and tympanic membrane lateralization in 18% of their cases.[32] Attention to intraoperative measures helps minimize graft lateralization: Nitrous oxide should be discontinued 30 minutes before grafting. The graft should be anchored medially to the malleus and the tab should be placed into the protympanum. Use of an accurately sized Gelfilm disk attempts to recreate an anterior tympanomeatal angle and keeps the graft in position. Silastic sheets and Merocel wicks placed in the EAC also help minimize the incidence of graft lateralization. The patient must be followed carefully for at least 24 months, because lateralization has been known to occur up to 12 months postoperatively.

The incidence of stenosis has been significantly reduced with the use of one-piece STSGs covering all exposed bone, and Silastic sheets and Merocel wicks in the EAC.[26] Of equal importance to surgical

technique are consistent postoperative follow-up and office care. Patients or their parents should understand beforehand that they must strictly follow the postoperative instructions and that they must keep all scheduled postoperative visits. We check the circumference of the pack each week to ensure that there is no ingrowth of grafted skin into the pack. If the meatus appears to be narrowing, usually at the third month, it should be dilated every 2 weeks and restented with the large Merocel wick for several months to 2 years. This measure usually avoids the need for reoperation. Early identification and treatment of infection are also necessary to prevent graft failure and canal stenosis.

High-tone SNHL occurs in up to 7.5% of cases.[26,31] To reduce the risk of noise-induced hearing loss, it is critical to minimize drilling on the ossicular chain while it is being dissected away from the atretic bone, but noise transmission during creation of the ear canal cannot be completely avoided. Use of the laser helps minimize manipulation when the surgeon is trying to free the malleus-incus complex from the atretic plate. With better imaging techniques, oval window problems can be identified preoperatively, and problems of SNHL due to oval window drill-out are avoided. Likewise, patients with computed tomography evidence of severe malformations are likely to have poor surgical results and so are best fitted with conventional bone-conduction hearing aids or BAHAs instead.

Intraoperative facial nerve monitoring is essential in all cases because there are often no clearly identifiable landmarks in atretic ears. If the monitor is off transiently because of the use of electrocautery, the surgeon can monitor the facial nerve manually by placing a hand on the patient's face. It is also important to remember that in a poorly pneumatized temporal bone, the otic capsule may be difficult to distinguish, and care must be taken to avoid "blue lining" (or worse) of the semicircular canals.

Surgical Alternatives to Atresiaplasty

BAHAs provide a good alternative to atresiaplasty for rehabilitation of hearing loss resulting from CAA.[28,33] BAHAs are especially suitable for patients with bilateral CAA and who, because of the severity of the malformations, would have poor results with atresiaplasty. The BAHA is a better alternative than a conventional bone hearing aid. Conventional bone hearing aids have the following drawbacks: discomfort because of constant pressure from the steel spring, worse sound quality because of higher-frequency attenuation by the skin, and poor aesthetics and insecure positioning of the device. The BAHA works without pressure on the skin and provides direct bone transmission without air interface.

Surgery for the BAHA can be performed under local or general anesthesia and is a one-stage procedure. To implant the BAHA, a small titanium abutment is implanted behind the ear, where it osseointegrates to the mastoid bone. After a 3-month healing period the BAHA processor can then be connected.

Audiologic indications for the BAHA include a pure-tone average bone-conduction threshold better than or equal to a 45-dB hearing level (average of 500, 1000, 2000, and 3000 Hz). A maximum speech discrimination score better than 60% for use of the PB word lists is recommended. From an audiologic point of view, the side with the better cochlear function (the better bone-conduction threshold) should be used. Patients with a bone-conduction threshold of 25 to 45 dB hearing level will be expected to improve but may not achieve levels in the normal range. Patients with a bone-conduction threshold of less than 25 dB hearing level can be expected to experience hearing improvements that restore hearing levels to normal ranges. Patients must be able to maintain the abutment/skin interface of the BAHA. Careful consideration must be given to the patient's psychological, physical, emotional, and developmental capabilities to maintain hygiene. Titanium implants can be installed in most patients because allergy to titanium is extremely rare. Alternative treatments should be considered for patients with a disease state that might jeopardize osseointegration.

In general, we do not recommend implantable hearing aids in young children, because the surgical scars may preclude any future microtia repair. However, the BAHA titanium implant is ideally placed 5 to 6 cm behind and 3 cm above the ear canal in a hair-bearing area. This placement seems to allow for the possibility of future microtia repair that would transplant costal cartilage to an area with unscarred skin. On the other hand, the titanium implants for a bone-anchored ear epithesis are ideally placed 18 to 20 mm behind the (future) ear canal. This site would interfere with the skin of a future auricle, if reconstruction is contemplated.

Summary

The treatment of congenital aural atresia represents a challenging, complex problem. Early identification, appropriate hearing amplification, and speech and language therapy are crucial in patients with bilateral disease. Surgical coordination with the auricular reconstruction surgeon allows for the best aesthetic and functional success. Strict radiologic and clinical criteria are necessary to appropriately identify atresiaplasty candidates. Classification of patients into those with minor and major malformations provides prognosis for hearing improvement and potential risks of surgery. A thorough understanding of the embryologic development of the ear and adherence to the surgical principles of tympanoplasty, canalplasty, and facial nerve surgery enable optimal and safe hearing restoration. Maintenance of good initial surgical results and avoidance of late complications requires diligent postoperative office care. BAHAs provide a good alternative for patients in whom atresiaplasty results would be poor.

CHAPTER ONE HUNDRED AND NINETY-FOUR

Acute Otitis Media and Otitis Media with Effusion

Margaretha L. Casselbrant

Ellen M. Mandel

Key Points

- The presence or absence of signs and symptoms and findings on the otoscopic examination provide the basis for diagnosis of the different types of otitis media.
- Proper treatment depends on differentiation between acute otitis media and otitis media with effusion.
- The highest incidence of otitis media occurs between the ages of 6 and 11 months and decreases with age. Risk factors include both host and environmental factors.
- Prevention of disease through use of vaccines and risk factor reduction is desirable.
- For children 2 years of age or older with nonsevere acute otitis media, published guidelines have given the option of observing rather than treating with antibiotics immediately.
- Antihistamines and steroids are ineffective for the treatment of otitis media.
- Tympanostomy tube insertion is effective in reducing recurrent episodes of otitis media and persistent middle ear effusion.
- Adenoidectomy *is not* recommended for the initial surgical treatment of otitis media unless nasal obstruction is present but *is* recommended for children in whom a repeat surgical procedure is needed.
- Careful follow-up is needed to identify complications and sequelae of otitis media as well as of its treatment.

Otitis media is not only a disease of modern times. It has been a major health problem in many societies. In the 8th century, the most common approach to healing was water from wells named after various saints.[1] Otitis media is in general a childhood disease, and in most children it resolves with anatomic and physiologic changes with growth. Until the condition has resolved, it may affect balance, hearing, and speech and language development and cause poor school performance. This disease affects not only the child but the whole family, from an economic as well as a societal standpoint. It is more than the cost for medicine or visits to the doctors; passing sleepless nights due to a crying child, having to take off from work to stay home with the child, and taking the child to the doctors can be very stressful for the family. The cost for medical and surgical therapy for otitis media in children 5 years of age or younger is estimated at $5 billion annually in the United States.[2]

Diagnosis

Definition/Symptoms and Signs

Although considered to constitute a continuum of disease, otitis media can be subclassified into *acute otitis media* (AOM) and *otitis media with effusion* (OME) on the basis of signs and symptoms. Because the treatments for AOM and for OME differ, it is important to accurately diagnose the two conditions. AOM generally is characterized by rapid onset of signs and symptoms of inflammation in the middle ear accompanied by middle ear effusion (MEE). Signs of inflammation include bulging or fullness of the tympanic membrane (TM), erythema of the TM, and acute perforation of the TM with otorrhea. Symptoms include otalgia, irritability, and fever. OME, on the other hand, is defined as MEE without signs and symptoms of acute inflammation as found in AOM.

Physical Examination

In addition to the examination of the ears, a proper head and neck examination is invaluable, because it may identify conditions that may predispose the patient to otitis media. Facial features should be assessed for craniofacial anomalies such as those of Down syndrome and Treacher Collins syndrome, because they are associated with increased incidence of otitis media. Examination of the oropharynx may show a bifid uvula or a cleft palate. Hypernasality indicates velopharyngeal insufficiency, whereas hyponasality may be caused by obstructing adenoids or nasal obstruction due to nasal polyposis or deviated septum.

Pneumatic otoscopy is the primary diagnostic tool to evaluate the status of the middle ear, because it allows assessment of the TM and its mobility. The normal TM is translucent and concave and moves briskly with application of positive and negative pressure. A visible landmark is the handle (manubrium) of the malleus, which is attached to the TM, with the umbo in the center of the TM. To adequately visualize the TM, the external ear canal must be cleared of cerumen and debris. The assessment of the TM should note *position*, *color*, *degree of translucency*, and *mobility*. To ascertain the mobility of the TM, a good airtight seal must be obtained between the speculum and the ear canal. The largest speculum that fits comfortably should be used. A bulb through which air is puffed should be attached to the otoscope, allowing for visualization of TM mobility. Reduced or no mobility of

the TM indicates loss of compliance of the TM, either as a result of effusion in the middle ear or from increased stiffness due to scarring or increased thickness of the TM. Total absence of mobility of the TM may also be due to an opening in the TM either as a perforation or a patent tympanostomy tube. Other features, such as fluid levels or bubbles, may be more easily discerned with movement of the TM. The position of the TM ranges from severely retracted to bulging. Mild to moderate retraction indicates negative pressure, MEE, or both, whereas a severely retracted TM usually is associated with effusion. Fullness and bulging of the TM are caused by increased pressure or fluid, or both, in the middle ear. Opacification of the TM may be caused by thickening or scarring or presence of MEE. A red but translucent TM is a typical finding in a crying or sneezing infant, secondary to engorgement of blood vessels in the TM. On the other hand, a "red" TM that is full or bulging often is a sign of AOM. A pink, gray, yellow, or blue retracted TM with reduced or no mobility usually is seen with OME. Myringitis is inflammation of the TM without fluid in the middle ear. Use of an operating microscope may clarify features seen on otoscopy, and visualization of scarring and atrophy of the TM may be enhanced.

Immittance Testing (Tympanometry)

Immittance testing is an excellent adjunct to the assessment of middle ear status and the management of otitis media. When otoscopic evaluation is inconclusive or difficult to perform, tympanometry can be very useful in evaluating ear disease in children older than 6 months of age. It is easy to perform and most often is well accepted by the patient. It has been used for school screening as well as in pediatricians' offices. It also is valuable for documentation of middle ear status over time with repeat testing. A small probe, which emits a tone, is placed in the ear canal with an airtight seal. The tympanogram is obtained by plotting the immittance (acoustic energy of the reflected tone) of the middle ear as a function of the pressure in the external ear canal, which varies, ranging from −400 to +200 daPa (decapascals). The instrument provides measures such as peak compensated (static) admittance, tympanometric peak pressure, acoustic reflex, and tympanometric width (TW) (a measure of gradient). The following set of criteria uses TW to categorize middle ear status[3]:

TW less than 150 daPa = no OME

TW greater than 350 daPa = OME

TW 150-350 daPa = presence or absence of OME is determined by otoscopy

A flat or rounded pattern (TW greater than 350 daPa) with a small ear canal volume indicates MEE, whereas a flat pattern with a large ear canal volume suggests a perforation or a patent tympanostomy tube. In a normal air-filled middle ear with equal pressure on both sides of the TM, the peak pressure of the tympanogram is 0 daPa. Algorithms have been developed to determine the presence or absence of MEE, some combining pneumatic otoscopy and tympanometry. Other methods of ascertaining middle ear status have been investigated, including spectral gradient acoustic reflectometry[4,5] and ultrasound evaluation,[6] but they have been found to have limitations, although they may be useful for screening.

Audiometry

MEE usually results in a mild to moderate conductive hearing loss. The assessment of hearing is essential to management, because hearing impairment can predispose the affected child to delays in speech and language development and may later affect school performance. Audiometry should be used to determine specific management strategies, with a more aggressive approach considered in children with significant hearing impairment.

Behavioral audiometry requires cooperation of the child with the examination and the test is adapted to the age of the child. *Visual reinforcement audiometry* is used for children 6 months to 2 years of age and involves presentation of a sound stimulus in the sound field with observation of the child's conditioned head turn response. This reaction is rewarded with a visual reinforcement such as an animated toy. *Play audiometry*, for children older than 2 years, is similar to *conventional audiometry* (for children over 5 years of age), but the child places toys in a bucket rather than raising a hand to acknowledge hearing the sound. Hearing thresholds in the sound field or ear-specific are determined at 0.25, 0.5, 1, 2, 4, and 8 kHz, depending on the age of the child.

Auditory brainstem audiometry (ABR) and *transitory otoacoustic emissions* (TOAE) are excellent methods for testing children who do not cooperate with behavioral hearing evaluation because of very young age or developmental delay. Except for infants, sedation or general anesthesia is usually necessary for ABR testing in younger children. Three electrodes are placed (forehead and each mastoid process) to record the response to clicks of 2000 to 4000 Hz or pure tone burst. The ABR consists of five to seven vertex-positive waves. Waves I to III presumably reflect activity of the auditory centers in the eighth nerve fibers and pons, waves IV and V reflect auditory centers in mid- to rostral pons and caudal midbrain, respectively; activity from waves VI and VII is less certain. The ABR reflects auditory neural electrical responses that are adequately correlated to behavioral hearing thresholds. However, a normal response on the ABR suggests only that the auditory system up to the midbrain level is responsive to the stimulus employed. Thus, it does not guarantee normal hearing.

Otoacoustic emissions (OAE) testing measures cochlear function (outer hair cells) and is a means of objective assessment of auditory function. It commonly is used for newborn hearing screening because it is fast and easy to perform. It is excellent for testing children who do not cooperate with behavioral testing. MEE may confound the results. Therefore, if the OAEs are absent, immittance testing should be performed to assess the middle ear. For children who "fail" OAE testing, follow-up audiologic testing must be done to assess type and degree of hearing loss.

Pathophysiology and Pathogenesis

The pathophysiology of otitis media is multifactorial, with various overlapping factors (Fig. 194-1).

Eustachian Tube Function

The eustachian tube in the infant is shorter, wider, and more horizontal than in the adult, which accounts for the high rate of otitis media in infants and children. By the age of 7 years, when the tube has a more

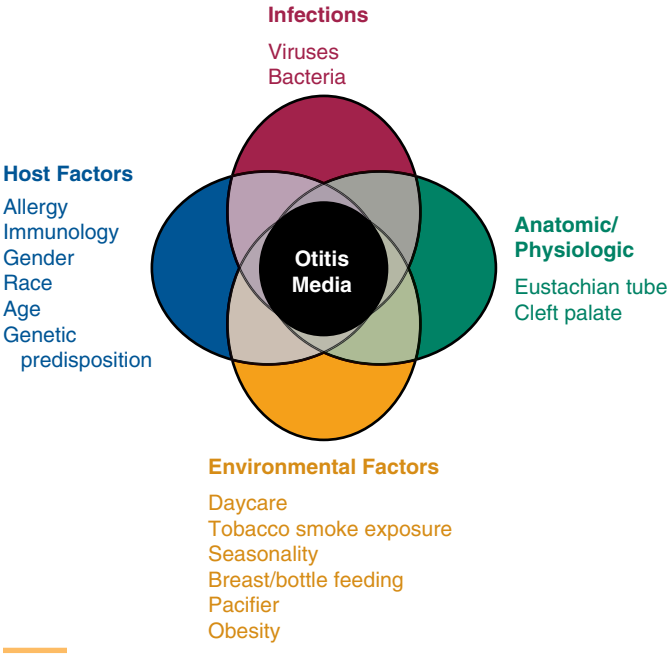

Figure 194-1. Various factors interact in the pathogenesis of otitis media.

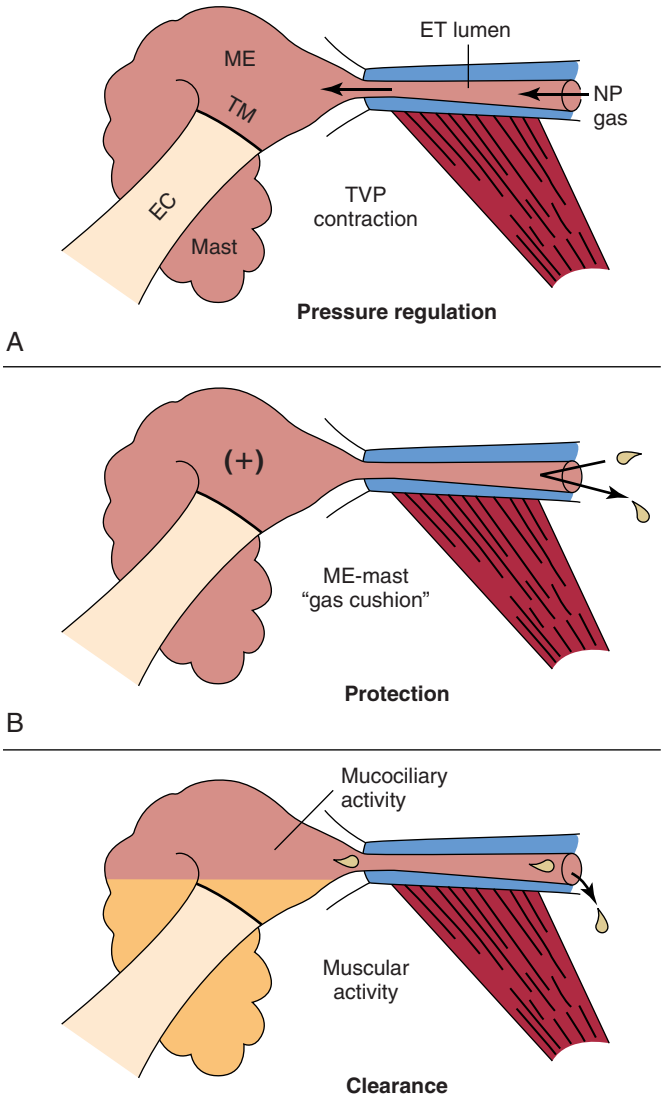

Figure 194-2. Functions of the eustachian tube (ET)-middle ear (ME)-mastoid (mast) gas cell system. **A,** Pressure regulation function is related to active dilation of the tube by contraction of the tensor veli palatini muscle (TVP). **B,** Protective function is dependent in part on an intact middle ear and mastoid gas cells to maintain a gas cushion. **C,** Clearance function is enhanced by mucociliary activity and muscular activity during tubal closing. EC, external canal; NP, nasopharynx; TM, tympanic membrane. *(Adapted from Bluestone CD.* Eustachian Tube: Structure, Function, Role in Otitis Media. *Hamilton, Ont: BC Decker; 2005:51.)*

adult configuration, the prevalence of otitis media is low.[7] The three physiologic functions of the eustachian tube are (1) *pressure regulation* (ventilation), (2) *protection*, and (3) *clearance* (drainage). Of these three functions, pressure regulation is the most important[8] (Fig. 194-2). Middle ear pressure is equilibrated to atmospheric pressure through active intermittent openings of the eustachian tube caused by contraction of the tensor veli palatini muscle during swallowing, jaw movements, and yawning. If active function is impaired, negative pressure will develop in the middle ear. Pressure regulation can be impaired by failure of the opening mechanism (*functional obstruction*) or anatomic (*mechanical*) obstruction. Using a pressure chamber, Bylander and associates evaluated eustachian tube function in children and adults who were considered otologically normal with intact TMs.[9] Although only 5% of the adults were not able to equilibrate negative middle ear pressure, as many as 35.8% of the children could not equilibrate negative pressure. Children 3 to 6 years of age performed worse than children 7 to 12 years of age. These studies indicate that in even apparently otologically normal children eustachian tube function is worse than in adults, but it does improve with age. The improvement in the eustachian tube function parallels the decrease in the incidence of otitis media. Stenström and colleagues tested eustachian tube function in 50 otitis-prone children and 49 children with no history of AOM (control group) using a pressure chamber.[10] The otitis-prone children had significantly poorer active tubal function than the normal control subjects, suggesting that recurrent AOM is the result of functional obstruction of the eustachian tube.

In ears with normal eustachian tube function, the eustachian tube is collapsed when at rest. This arrangement protects the middle ear from nasopharyngeal sound pressure and reflux of secretions from the nasopharynx.

The clearance of secretions produced within the middle ear into the nasopharynx is provided via the mucociliary system and through the "pumping action" of the eustachian tube during closing. The passive closing of the tube is initiated at the middle ear end of the eustachian tube and progresses toward the nasopharyngeal end, facilitating removal of the secretions.

Infection

Bacteriology

Before the year 2000, studies in the United States reported that *Streptococcus pneumoniae* was the single most common bacterial pathogen in AOM, followed by *Haemophilus influenzae* and *Moraxella catarrhalis*; *Streptococcus pyogenes* and other miscellaneous bacteria accounted for just a few cases. From ears with chronic OME, *H. influenzae* was the single most common pathogen, with *S. pneumoniae*, *M. catarrhalis*, and other bacteria accounting for a small percentage of cases each. Data obtained during the 1980s from a single institution is shown in Figure 194-3.[11] There was great hope that the introduction and subsequent use of the heptavalent conjugated pneumococcal vaccine (PCV7) for infants and young children, licensed in the United States in 2000, would lead to a substantial decrease in AOM. However, data from vaccine trials conducted in California[12] and Finland[13] revealed only a 7.8% and a 6% relative risk reduction, respectively, in AOM. Casey and Pichichero examined the experience of children in a suburban Rochester, New York, practice in the years 2001 to 2003 (after the introduction of PCV7) compared with the years 1995 to 2000 and reported a 24% decrease in persistent AOM and AOM treatment failures.[14] These investigators also reported a decrease in recovery of *S. pneumoniae* from the ears of such children and an increase in *H. influenzae*. McEllistrem and coworkers looked at middle ear cultures obtained between 1999 and 2002 at five institutions.[15] They reported that the percentage of AOM episodes due to non-PCV7 serogroups increased after 2000, from 12% in 1999 to 32% in 2002, and the nonvaccine serotypes were more frequent in those who received more than one dose of vaccine. The frequency of penicillin nonsusceptible strains in the vaccine and nonvaccine serotypes remained unchanged.

Nasopharyngeal carriage also was examined. Pelton and associates enrolled 275 infants and children 2 to 24 months of age in a surveillance study in which nasopharyngeal swabs or nasal washes were obtained at all well-child visits and at visits for AOM.[16] From 2000 to 2003, these workers noted a decrease in vaccine serotypes with an increase in nonvaccine serotypes. Tracking antimicrobial susceptibility, they found that the MIC50 and the MIC90 for amoxicillin were stable until the 6-month period from October 2002 to March 2003, when they both increased significantly. Jacobs and associates examined the nasopharyngeal flora in children undergoing tympanostomy tube placement in March 2004 to March 2005 and also found a decrease in vaccine serotypes with a concomitant increase in nonvaccine serotypes, many of which were antibiotic-resistant strains.[17]

These data point to a changing bacteriology and the need for continued surveillance. A remarkable decrease in serious disease has occurred with the use of the newer pneumococcal vaccines, but the impact on otitis media continues to evolve.

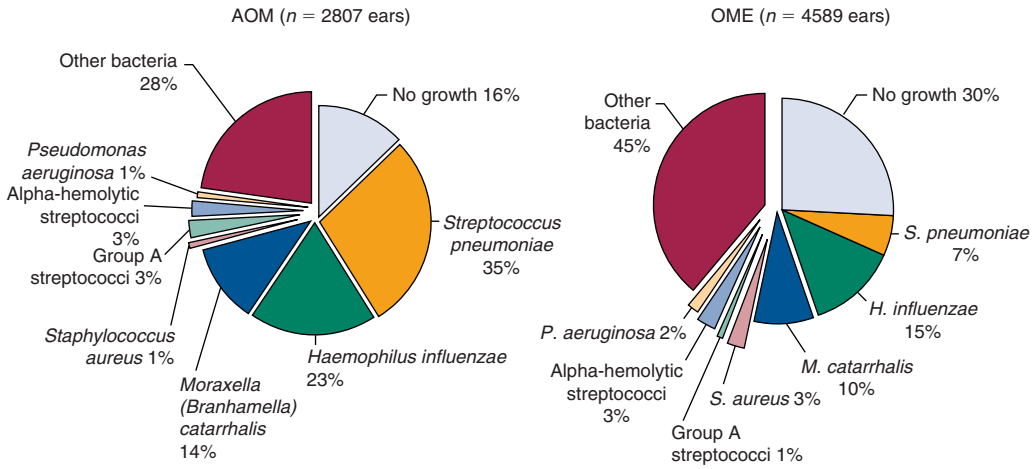

Figure 194-3. Comparison of distribution of isolates in 2807 effusions from patients with acute otitis media (AOM) and 4589 effusions from patients with otitis media with effusion (OME) at the Pittsburgh Otitis Media Research Center, 1980 to 1989. Total percentages are greater than 100% because of multiple organisms. *(Adapted from Bluestone CD, Klein JO.* Otitis Media in Infants and Children. *4th ed. Hamilton, Ont: BC Decker; 2007:103.)*

Biofilms

Bacterial biofilms are sessile communities of interacting bacteria attached to a surface and encased in a protective matrix of exopolysaccharides rather than living in a motile "planktonic" or free-floating state. The exopolysaccharide matrix provides protection from phagocytosis and other host defense mechanisms due to lack of accessibility by immunoglobulins and complement. The reduced metabolic rate of bacteria in the biofilm renders them resistant to antimicrobial treatment. The bacterial community relies on a complex intracellular communication system that provides for organized growth characteristics known as "quorum sensing." Biofilms have been known to exist on hard surfaces such as metal pipes or teeth. However, recent animal and human studies have suggested that biofilms can also be isolated from the middle ear. Post and coworkers, using polymerase chain reaction (PCR) methodology, found evidence of bacteria in 48% of culture-negative MEE specimens from children undergoing tympanostomy tube insertion for chronic OME.[18] Hall-Stoodley and colleagues obtained confocal laser scanning microscopy images from the middle ear mucosa of 26 children scheduled for tympanostomy tube insertion for recurrent or persistent otitis media and 8 control subjects (3 children and 5 adults) who underwent cochlear implantation.[19] Generic stains and species-specific probes for *H. influenzae*, *S. pneumoniae*, and *M. catarrhalis* were used to evaluate biofilm morphology. Mucosal biofilms were visualized in 92% of the mucosa from children with chronic and recurrent otitis media but were not observed in any of the 8 control subjects. The investigators suggested that the findings supported the hypothesis that chronic middle ear disease is biofilm-related. Biofilms also have been identified in the nasopharynx of children with otitis media, and it was suggested that the biofilm may act as a reservoir for bacterial pathogens resistant to antibiotics. The mechanical débridement of the nasopharyngeal biofilms may explain the observed clinical benefit associated with adenoidectomy in subsets of pediatric patients.[20]

Viruses

Until the introduction of PCR, viruses were not considered a major factor in the etiology of otitis media, probably because of the technical difficulties in isolating the viruses. Using PCR techniques, however, it has been possible to identify respiratory syncytial virus (RSV), influenzavirus, adenovirus, parainfluenza virus, and rhinoviruses in MEE.[21,22] There is strong evidence that viruses have a crucial role in the development of AOM.[22] In a majority of children, viral infection of the upper respiratory tract mucosa initiates the whole cascade of events that finally leads to the development of AOM, and AOM may be regarded as a complication of a preceding or concomitant viral infection. In a study of 60 children (in 24 families) who were followed from October 2003 through April 2004 by daily parental recording of illness signs, weekly pneumatic otoscopy and viral PCR analysis of nasal secretions collected during "colds" or when MEE was noted, or from enrolled siblings without these conditions, one or more viruses were identified from 73% of secretions collected during a cold but only 18% collected at a time without a cold.[23] Of 93 episodes of otitis media, 70% occurred during a cold, and nasal secretions from 77% of children at the time of these episodes were positive for virus.

Allergy and Immunology

Even though allergy is considered in the pathogenesis of otitis media, the causal mechanism is not understood, and well-controlled studies to prove the efficacy of anti-allergic medication in the treatment of OM are lacking. Several mechanisms by which allergy may cause otitis media have been suggested: (1) the middle ear is a "shock organ" (target); (2) allergy may induce inflammatory swelling of the eustachian tube mucosa; (3) allergies produce inflammatory obstruction of the nose; and (4) bacteria-laden allergic nasopharyngeal secretions may be aspirated into the middle ear. The last three mechanisms involve an association between allergy and abnormal eustachian tube function. Prospective studies have reported a relationship between upper respiratory tract allergy and eustachian tube obstruction in a series of provocative, intranasal allergen–inhalation challenge studies.[24]

Recent studies focus on the analysis of the inflammatory markers in MEE to determine the role of allergy. Both TH1 and TH2 inflammatory patterns in helper T cells have been found in OME. TH1 cytokines antagonize allergic inflammation and play a key part in the defense against viruses and intracellular pathogens, whereas TH2 cytokines promote IgE production, eosinophil growth, and mucus production.[25] The chemoattractant cytokine RANTES (*r*egulated upon *a*ctivation, normal *T* cell–*e*xpressed and *s*ecreted) and eosinophilic cationic protein (ECP), signs of a TH2 process, were assessed in MEE samples from 25 children with allergy and 20 nonallergic children who were 5 to 11 years old at the time of tympanostomy tube insertion.[26] RANTES and ECP levels were significantly higher in the MEE samples from children with allergy than in children without allergy ($P < 0.01$ and < 0.05, respectively). A positive correlation also was found between RANTES and ECP in MEE ($P < 0.01$) in children with allergy, which suggests that allergy is a contributing factor in the pathogenesis of otitis media.

Children with major immune deficiencies may have recurrent otitis media as part of their overall clinical picture, but most otitis-prone children may have only a subtle immunologic abnormality that predisposes them to recurrent infections.[27] The three major pathogens of otitis media—*S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*—frequently colonize the nasopharynx. There are many strains of these

organisms, and among the different strains are heterologous surface (strain specific) antigens and conserved antigens. Conserved antigens induce broadly protective antibodies while strain-specific antigens induce limited protection. Otitis-prone children may display strain-specific immunity but fail to develop a broadly protective antibody response, which makes them susceptible to recurrent and persistent otitis media.[28]

Recurrence of bilateral OME after tympanostomy tube insertion was more likely in children with poor eustachian tube function and low IgA or low IgG2 and decreased levels of mannose-binding lectin than in children with poor tubal function and high IgA and IgG2 measured at the time of tube insertion.[29] This suggests that an interaction between various immune factors may increase the risk for the development of otitis media.

Gastroesophageal Reflux

In 2002 Tasker and associates reported finding pepsin/pepsinogen, using enzyme-linked immunosorbent assays, in 90.8% of 65 MEE samples obtained at the time of myringotomy in children.[30] The pepsin-pepsinogen levels ranged from 0.8 to 213.9 µg/mL, which is 1000 times higher than serum levels. He and colleagues, using a sensitive and specific pepsin assay, detected pepsin activity in 14.4% of 152 subjects undergoing tympanostomy tube insertion.[31] The levels of pepsin ranged from 13 to 687 ng/mL. Crapko and associates also identified pepsin activity in the middle ear fluid in 60% of 20 subjects also undergoing tympanostomy tube insertion.[32] In this group of children the pepsin levels ranged from 80 to 1000 ng/mL. The latter studies have shown that pepsin is identified less frequently and at lower levels of pepsin, which may be due to differences in methodology. However, it may be concluded from these studies that gastroesophageal reflux may be a causative factor in otitis media, with a potential role for antireflux therapy in the treatment of otitis media in some children, but adequate controlled trials have not been done.

Epidemiology

Incidence and Prevalence

Otitis media is considered a worldwide pediatric health care problem. The Early Childhood Study—Birth Cohort (ECLS—B), a nationally representative longitudinal study of more than 8000 children born in 2001, showed that otitis media was diagnosed in 39% of children by 9 months and 62% of children by 2 years of age.[33] Although the highest incidence of otitis media is in young children, it also occurs in older children, adolescents, and adults. The Oslo Birth Cohort enrolling infants born in a 15-month period in 1992 to 1993 found that 13% of 10-year-olds had at least one episode of otitis media in the previous 12 months.[34] Approximately 3% to 15% of patients with otitis media referred to otolaryngology clinics are adults.[35]

Acute Otitis Media

Most children experience at least one episode of AOM during their childhood. The cumulative incidence of the first episode of AOM based on studies from various countries ranges from 19% to 62% by age 1 year and 50% to 84% by 3 years of age[36-42] (Fig. 194-4). In a majority of these studies, the peak incidence of AOM was during the first 6 to 12 months of life.[39] The incidence decreases with age, and by the age of 7 years, few children experience episodes of AOM. Recurrent episodes of AOM are common in young children. By 6 months of age, 20% have had two or more episodes.[43] Occurrence of three or more episodes of AOM by the ages of 1, 3, 5, and 7 years has been documented in 10% to 19%, 50%, 65%, and 75% of children, respectively.[39] Occurrence of six or more episodes of AOM was documented in 39% of children by the age of 7 years.

Otitis Media with Effusion

It may be difficult to determine the "true" incidence of OME because, by definition, OME is asymptomatic. Furthermore, most screening studies determine the presence of MEE without differentiating between AOM and OME. Also, a short time between observations is needed for precise assessment of the onset and time to resolution of each new episode of OME, because approximately 65% of OME episodes in children 2 to 7 years of age resolve within 1 month.[44] Monthly examinations with otoscopy and tympanometry in 2- to 6-year-old children in a day care center in Pittsburgh revealed MEE at least once in 53% to 61% of the children. Lous and Fiellau-Nikolajsen found an incidence of MEE of 26% in 7-year-old children followed monthly for 1 year using tympanometry.[45]

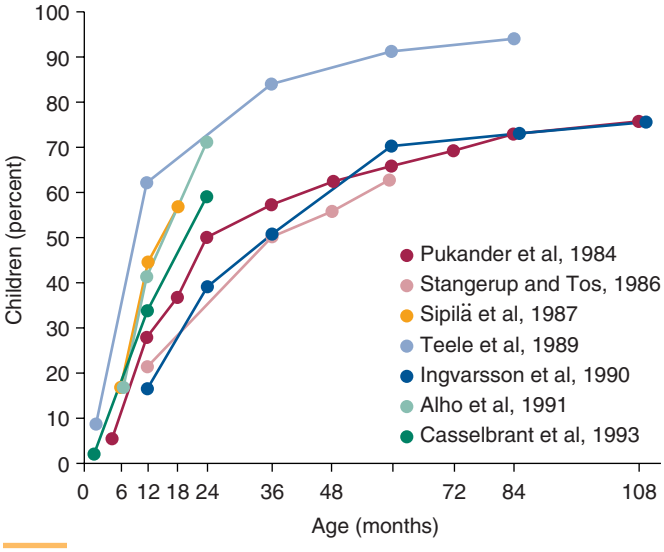

Figure 194-4. Cumulative incidence of first episode of acute otitis media. *(Reproduced from Casselbrant ML, Mandel EM. Epidemiology. In: Rosenfeld RM, Bluestone CD, eds.* Evidence-Based Otitis Media. *2nd ed. Hamilton, Ont: BC Decker; 2003:147.)*

The point prevalence of MEE from different countries shows a wide variation, depending on the age of the child, season of the year, and type of assessment. Thus, it must be emphasized that comparison of outcomes between studies will require careful evaluation of study methodology, as well as caution in drawing conclusions. However, nearly all children had experienced at least one episode by the age of 3 years.[46]

Trend over Time

Even though otitis media remains a major problem in the United States, several recent studies point to a trend toward reduction in the burden of otitis media. Grijalva and associates compared the national rates of outpatient visits for pneumonia and otitis media in children in 1994 to 1999 to those in 2002 to 2003 using the National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey.[47] The results showed that otitis media visit rates declined by 20% in children younger than 2 years of age while there was no significant decrease in outpatient visit rates for pneumonia or other respiratory infections in children in this same age group. The second study compared the risk of developing frequent otitis media or having tympanostomy tubes inserted in four birth cohorts (1998 to 1999, 1999 to 2000, 2000 to 2001, and 2001 to 2002).[48] The study population included all children at birth in TennCare or selected upstate New York commercial insurance plans as of July 1998 and followed them for 5 years. When comparing the 2000-2001 cohort to the 1998-1999 cohort frequent otitis media declined by 17% and 28% and tympanostomy tube insertion declined by 16% and 23% for Tennessee and New York cohorts, respectively. The decline may be the result of infant immunization, catch-up doses in older children, and herd immunity after introduction of the heptavalent pneumococcal conjugate vaccine in the United States in 2000. In a comparison of the 2000 to 2001 and 2001 to 2002 birth cohorts, frequent otitis media and tympanostomy tubes remained stable in New York but increased in Tennessee. The investigators attributed this to several possible factors including increase in disease due to nonvaccine serotypes and change in medical care utilization.

A decline in the incidence of otitis media also has been reported from several European countries. Kvaerner conducted a study in Norway of hospital admissions for AOM from 1999 to 2005 among children aged 7 years or younger.[49] Hospitalization for AOM was less frequent but the incidence of acute mastoiditis remained stable at approximately 6 per 100,000 children over time. The consultation rates to the general physicians in the Netherlands for otitis media during 1995 to 2003 in children from birth to 13 years of age were assessed using the research database of the Netherlands University Medical Center Utrecht Primary Care Network.[50] The overall consultation rates decreased by 9% for AOM and 34% for OME. In children aged 2 to 6 years and those aged 6 to 13 years, the rate of AOM declined by 15% and 40%, respectively; the rates of OME declined by 41% and 48%, respectively. In children younger than 2 years of age, however, the rates of AOM and OME increased by 46% and 66%.

Data from the General Practitioner Database in the United Kingdom were analyzed for events classified as AOM or "glue ear" in the years 1991 to 2001.[51] Total consultations for AOM and glue ear in children aged 2 to 13 years had changed from 105.3 to 34.7 and 15.2 to 16.7 per 1000 per year, respectively.

Further surveillance is needed. As noted previously, disease rates must continue to be monitored to determine the effects of vaccines and changes in treatment on the epidemiology of otitis media.

Risk Factors

Risk factors can be host-related (age, gender, race, prematurity, allergy, immunocompetence, cleft palate and craniofacial abnormalities, genetic predisposition) as well as environmental (upper respiratory infections, seasonality, day care, siblings, tobacco smoke exposure, breastfeeding, socioeconomic status, pacifier use, and obesity) and are considered important in the occurrence, recurrence, and persistence of middle ear disease.

Host-Related Factors

Age

The highest incidence of AOM is between 6 and 11 months of age,[39] and onset of the first episode of AOM before 6 months[39] or 12 months of age is a powerful predictor of recurrence.[52] The risk of persistent MEE after an episode of AOM is inversely correlated with age,[39] and children who experience their first episode of MEE before 2 months of age are at a higher risk for persistent fluid during their first year of life than are children who have their first episode later.[53]

Sex

Most investigators have reported no apparent sex-based difference in the incidence of OME.[46] Paradise and coworkers, in a study involving more than 2000 infants, found males had more time with MEE, although the difference was not large.[54] Some studies have found a significantly higher incidence of AOM in males as well as more recurrent episodes than in females, but others have not found this.[46]

Race

Earlier studies have suggested a lower incidence of otitis media in African-American children than in white children. More recent studies in which the children were followed prospectively from infancy to age 2 years with routine examinations of the ears every 6 weeks showed no difference between the African-American and white children in their experience with otitis media.[54,55] A third study, part of an American population-based sample survey evaluating schoolchildren 6 to 10 years of age with tympanometry, reported no difference between African-American and white children. However, the prevalence of OME was significantly higher in Hispanic children compared with white children.[56] In another study of more than 11,000 infants followed only from the ages of 1 through 6 months at two urban and one suburban location in the United States, non-Hispanic white children had significantly higher rates of otitis media after multivariant adjustment than non-Hispanic black or Asian children. There was no difference between Hispanic and non-Hispanic children.[57]

Prematurity

Some studies have shown a possible association between low birth weight and prematurity and otitis media, but others have not. In many of these studies, however, the sample sizes have been relatively small. A recent study analyzing data from more than 10,000 births showed some relationship between very low birth weight (less than 1500 g) and frequent otitis media, but no increased risk was found for recurrent otitis media and moderately low birth weight (1500 to 2499 g). In a prospective cohort study of 136 children treated with tympanostomy tubes, a positive but nonsignificant association was documented between low birth weight or low gestational age or history of incubator care and recurrent OME.[58]

Allergy

There is still controversy regarding the role of allergy in the pathogenesis of otitis media. Allergy is a common problem in children, occurring at a time when respiratory infections and otitis media are common. Most, but not all, of the epidemiologic studies have supported an association. Pukander and Karma followed 707 children with AOM and found that in children with atopic manifestations, persistence of MEE for 2 months or longer was more common than in children without allergy.[59] In another study, however, atopic diathesis was not found to predispose affected children to the development of AOM.[60] The Japanese investigators Tomonaga and associates determined that allergic rhinitis was present in 50% of 259 patients (mean age of 6 years) in whom OME had been diagnosed, and OME was present in 21% of 605 patients (mean age of 9 years) in whom allergic rhinitis had been diagnosed.[61] Among 108 children 5 to 8 years of age (mean age of 6 years) in whom neither condition had been diagnosed, the occurrence rates for allergic rhinitis, OME, and both of these conditions were 17%, 6%, and 2%, respectively. Another investigative group (Kraemer and coworkers) compared risk factors for persistent MEE among 76 children hospitalized for bilateral myringotomy with tube insertion (M&T) and 76 control subjects matched by age, gender, and season of admission for a general surgical procedure.[62] Results showed a nearly fourfold increase in the risk of persistent MEE in children who had atopic symptoms for more than 15 days per month. In another study, Bernstein and Reisman determined the allergy status of a group of 200 children who had undergone one or more M&T procedures.[63] These workers diagnosed allergy in 23% of the entire group but found that the frequency was 35% among the 88 children with multiple myringotomies with tube insertions. The frequency of allergy in these patients was higher than that reported for children of similar age in the general population. The foregoing studies generally found a higher frequency of OME in allergic children than in age-matched nonallergic children, as well as higher frequencies of allergy in children with OME than in children without OME.

Immunocompetence

Children with recurrent otitis media as well as other recurrent infections may have a defect in the immune system such as a defect in phagocyte function, humoral immunity, local immunity, or other immune defects.[8] Children infected with the human immunodeficiency virus (HIV) demonstrate a significantly higher recurrence rate than in normal children or children who have seroconverted.[64]

Cleft Palate/Craniofacial Abnormality

Otitis media is considered "universal" in infants younger than 2 years of age with unrepaired cleft palate.[65] After surgical repair of the palate, the occurrence of otitis media is reduced, probably because of improvement in eustachian tube function. However, many children continue to have problems up into the teens. Otitis media also is common in children with other craniofacial abnormalities or Down syndrome, also due to anatomic or functional eustachian tube abnormalities.[66] In children with Down syndrome, low resistance of the tube, in addition to poor active eustachian tube function, predisposes them to reflux of nasal secretions into the middle ear.[67]

Genetic Predisposition

The frequency of the occurrence of one episode of otitis media is so high that a genetic predisposition is highly unlikely. However, a pre-

disposition to recurrent episodes of otitis media and chronic MEE may have a significant genetic component. The etiology of otitis media is multifactorial, involving environmental as well as genetic factors. A large number of genes may be involved, each contributing to a particular increase in disease risk.

Twin and triplet studies have been used to assess the heritability of otitis media. Two retrospective studies using questionnaires have been published. The first study, using 2750 Norwegian twin pairs, estimated the heritability at 0.74 in females and 0.45 in males.[68] In the second study, the estimated heritability was, on average, 0.57 at the ages of 2, 3, and 4 years.[69] In a prospective twin-triplet study from Pittsburgh with monthly assessments of middle ear status, the heritability estimate for otitis media at age 2 years was 0.79 in females and 0.64 in males.[70] Heritability is a population statistic used to ascertain if a trait is heritable, and linkage and association studies may identify genetic regions or specific genes influencing the particular trait or disease. Daly and coworkers, using genome-wide linkage analysis, have suggested that chromosomal regions on 19q and 10q contain genes contributing to the susceptibility to chronic OME or recurrent AOM.[71] Subsequent fine mapping of both regions further strengthened the evidence for this linkage.[72] In addition, evidence for an association between polymorphisms in *FBXO11*, the human homolog of a mouse model gene for chronic otitis media, and chronic OME/recurrent AOM (COME/ROM) has been reported.[73]

Environmental Factors

A study was conducted to assess the variation in environmental risk factors for otitis media across Western countries, including European countries, the United States, Canada, and Australia.[74] The main risk factors for otitis media were day care atendance, number of siblings, tobacco smoke exposure, breastfeeding, birth weight, socioeconomic status, and air pollution. However, the results indicated large variations in rates across the various countries: day care at ages 1 to 3 years: Sweden 75% versus Italy 6%; breastfed at 6 months: Norway 80% versus Poland 6%; and women smoking: Germany, France, and Norway 30% to 40% versus Portugal less than 10%.

Upper Respiratory Infection/Seasonality

Both epidemiologic evidence and clinical experience strongly suggest that otitis media frequently is a complication of an upper respiratory infection (URI). The incidence of AOM is highest during the fall and winter months and lowest during spring and summer months, which parallels the incidence of URI.[44] This correlation supports the hypothesis that an episode of URI plays an important role in the etiology of otitis media. Rhinovirus, RSV, adenovirus, and coronavirus have been detected in MEE during episodes of AOM.[21,75] Upper respiratory tract infections with RSV, influenzavirus, and adenovirus often precede an episode of AOM.[22] In a prospective study of Finnish children, 54% of ensuing AOM episodes were diagnosed by day 4 after the onset of URI symptoms.[76]

Day Care/Home Care/Siblings

Almost universally, day care center attendance remains a very important risk factor for development of otitis media. For example, prevalence of high negative ME pressure and flat tympanograms (type B), indicative of MEE, have been shown to be highest in children cared for in day care centers with many children, intermediate in children in family day care with fewer children, and lowest in children cared for at home.[77] Children attending day care centers also have been shown to be more likely to have tympanostomy tubes inserted than children cared for at home.[78]

Birth order has been shown to be associated with episodes of otitis media and percentage of time with MEE.[55] First-born children had a lower rate of episodes of AOM and less time with MEE during the first 2 years of life than children with older siblings. Also, having more than one sibling was significantly related to early onset of otitis media.[59]

The increased morbidity among children in day care centers and in children with older siblings may be related to the greater opportunity for exposure to viral URI, which may cause eustachian tube dysfunction, leading to the development of otitis media.

Tobacco Smoke Exposure

An association between otitis media and passive exposure to smoking has been reported by many investigators while others have not been able to demonstrate such an association. In most studies the information regarding smoke exposure has been obtained from the parents. A few recent studies have measured cotinine, a metabolite of nicotine, in blood, urine, or saliva of the child and have been able to more accurately determine the association between otitis media and smoke exposure.[43,79] More information about the pathogenesis and duration and intensity of exposure is needed to clarify this association. Two recent studies have shown an association between middle ear status and parental smoking. In children exposed to parental smoking, tympanostomy tubes stayed in place for 59 weeks, compared with 86 weeks in children who were not exposed to smoking.[80] Also, myringosclerosis was more prevalent in children with two smoking parents compared with those with no smoking parents (64% versus 20%) and maternal smoking was associated with a highly increased risk of recurrent otitis media after insertion of tympanostomy tubes.[81]

Breastfeeding/Bottle Feeding

Currently, most national and international authorities, including the American Academy of Pediatrics and the American Academy of Family Physicians, the World Health Organization (WHO), and the United Nations Children's Fund, recommend 6 months of exclusive breastfeeding. In 2004, Kramer and Kakuma published a comprehensive review of the world literature to determine health benefits of exclusive breastfeeding for 6 months compared with 3 to 4 months.[82] They reported a decrease in the risk for gastrointestinal infection even in developed areas. It had not been shown previously that exclusive breastfeeding for 6 months or longer compared with 4 to less than 6 months in the United States provided greater protection against respiratory infections. Therefore, a secondary analysis of data from the National Health and Nutrition Examination Survey III, a population-based cross-sectional home survey conducted from 1988 to 1994, was undertaken.[83] After adjustment for demographic variables, child care, and smoke exposure, the data revealed statistically significant increased risk for both pneumonia (odds ratio [OR]: 4.27; 95% confidence interval [CI]: 1.27-14.35) and three or more episodes of otitis media (OR: 1.95; 95% CI: 1.06-3.59) in those children breastfed 4 to less than 6 months. These findings further support the current recommendations that infants receive breast milk exclusively during the first 6 months of life.

Socioeconomic Status

Socioeconomic status and access to health care are factors that may affect the incidence of otitis media. It has been generally thought that otitis media is more common among persons in the lower socioeconomic strata as a result of poor sanitary conditions and crowding. Paradise and colleagues followed 2253 infants for 2 years in the United States and found an inverse relationship between the cumulative proportion of days with MEE and socioeconomic status.[84] However, many studies have not revealed any correlation between socioeconomic status of the child's family and the incidence of MEE.

Pacifier Use

Niemelä and associates reported that pacifier use increased the annual incidence of AOM and calculated that pacifier use was responsible for 25% of AOM episodes in children younger than 3 years.[85] They reported the results of an intervention trial in which parents in various well-baby clinics were taught that pacifier use was harmful and should be limited, and parents in other clinics were not provided with this information. This led to a 29% decrease in AOM in the group provided with pacifier information. Pacifier use has been theorized to contribute to the development of otitis media, possibly due to the sucking action of the child propelling nasopharyngeal secretions into the middle ear or by the pacifier acting as a fomite. However, Brook and Gober cultured the surface of pacifiers from children with AOM but found no pathogens typical of AOM.[86] The role of pacifier use in AOM remains unclear.

Obesity

Recent studies have indicated a possible association between otitis media and body mass index (BMI). Tympanostomy tube insertion and overweight were studied in two cohorts of children followed from birth to 2 years of age.[87] Weight-for-length and BMI-for-age were calculated using well-child visit data. In the cohort of predominantly white children, a history of tympanostomy tube insertion significantly predicted risk of BMI index beyond the 85th percentile at the age of 2 years. In the other cohort of American Indian children, a history of recurrent AOM increased the likelihood of weight-for-length index beyond the 95th percentile. Further studies are needed to clarify the association.

Prevention of Disease

Prevention and modification of risk factors and vaccine development are two recommended strategies for the prevention of disease.

Management of Environmental Factors

Promotion of breastfeeding in the first 6 months of life, avoidance of supine bottle feeding and pacifier use, and elimination of passive tobacco smoke may be helpful in reducing the risk of development of otitis media. Alteration of child care arrangements such that the child is exposed to fewer children may also be of benefit.

Vaccines

The three most common bacteria isolated from the middle ear are *S. pneumoniae*, *H. influenzae* and *M. catarrhalis*. At present, the *S. pneumoniae* vaccines (Pneumovax and Prevnar) are the only bacterial vaccines available for otitis media. Although respiratory viruses, such as RSV, influenzavirus, adenovirus, parainfluenza virus, and rhinovirus, have been isolated in MEE using PCR, influenza vaccine is the only available recommended viral vaccine today that may have an impact on otitis media.

Bacterial Vaccines

Streptococcus pneumoniae *Vaccine*

Pneumovax is a 23-valent polysaccharide vaccine that is not efficacious in children 2 years or younger because of poor antigen production in this age group. Prevnar is a conjugated vaccine in which pneumococcal polysaccharides are conjugated to a nontoxic mutant of diphtheria toxin. The 7-valent vaccine (PCV7), which includes serotypes 4, 6B, 9V, 14,18C, 19F, and 23F, was licensed for use in the United States in 2000 and recommended for use in children younger than 6 years of age by the American Academy of Pediatrics.[88] Infants are immunized at the ages of 2, 4, 6, and 12 to 15 months. For previously unimmunized children 7 to 23 months of age, a reduced number of doses is recommended, and for children 24 to 59 months of age and children at high risk at any age, two doses of PCV7 and one dose of the 23-valent vaccine are recommended.

The efficacy for AOM of the conjugated vaccine has been evaluated in several randomized clinical trials. The trial from Northern California Kaiser Permanente enrolling 37,868 children randomly assigned to either pneumococcal conjugate vaccine or a meningococcal type C conjugate vaccine and followed prospectively, reported an overall reduction of episodes of otitis media of 7%.[12] However, children with recurrent otitis media benefited from the vaccine with a reduction in otitis media episodes ranging from 9.3% to 22.8%, increasing as the frequency of episodes of AOM increased. In addition, immunized children were 20.1% less likely to require tube placement than control subjects. The PCV7 vaccine demonstrated a much higher efficacy (greater than 80%) in reducing invasive pneumococcal disease than in reducing the burden of otitis media. Additional follow-up of the study subjects continued to demonstrate a modest amount of protection against episodes of AOM and need for tympanostomy tube insertion.[89] In a Finnish study of 1662 children randomized to receive either PCV7 vaccine or a hepatitis B vaccine, with follow-up to the age of 24 months, a bacterial diagnosis was made based on a culture of the middle ear fluid, in addition to the clinical assessment of episodes of AOM.[13] The vaccine reduced the number of AOM episodes from any cause by 6%, the number of culture-confirmed pneumococcal episodes by 34%, and the number of episodes due to the vaccine serotypes by 57%. The number of episodes attributed to serotypes that were cross-reactive with those in the vaccine was reduced by 51%, whereas the number of episodes due to all other serotypes increased by 33%. The modest response in reducing number of episodes of AOM was due to a decrease in vaccine efficacy against serotype-specific infections as well as an increase in AOM episodes due to nonvaccine serotypes. A second trial was conducted in Finland using a 7-valent pneumococcal polysaccharide–meningococcal outer membrane protein complex conjugate vaccine (PncOMPC) in 1666 children who were followed for 24 months.[90] This trial showed no reduction in overall number of AOM episodes. The reduction in number of AOM episodes due to any culture-confirmed pneumococci was 25% and to vaccine serotype pneumococci, 56%—results similar to those with the PCV7. This vaccine failed to show protection against cross-reactive serotypes. An increased rate of carriage of nonvaccine serotypes was noted among infants vaccinated with the pneumococcal conjugate vaccine.

With use of the vaccine, pneumococcal colonization in the nasopharynx has changed as the vaccine has caused a reduction in the carriage rate of vaccine serotypes and replacement with nonvaccine serotypes.[17,91] It should be noted that a reduction in nasopharyngeal carriage of vaccine serotypes and an increase in nonvaccine serotypes has also been seen in children younger than 7 months of age.[16]

In the United States and Finland, the initial immunization with PCV7 is at age 2 months based on the results from the clinical trials. However, the question of whether or not the results obtained in the Finnish and U.S. trials could be extrapolated to older children who already had a history of recurrent episodes of AOM was addressed by Dutch and Belgian trials.[92,93] Seventy-eight and 383 children with documented histories of recurrent AOM were enrolled in the Belgian and Dutch studies, respectively. In both trials children between 1 and 7 years old were immunized at entry with PCV7 followed by a booster immunization with a 23-valent pneumococcal polysaccharide vaccine 7 months later and followed up for a total of 18 months in the Dutch trial and 26 months in the Belgian trial. The results from these two studies did not lend any support to the use of pneumococcal conjugate vaccine to prevent AOM in previously unvaccinated toddlers and children with a history of recurrent AOM. The differences in outcome between the studies in older children and those in healthy infants may be caused by differences in age at immunization. In the infant studies the PCV7 immunization may prevent or delay nasopharyngeal colonization of the most frequent pneumococcal serotypes and consequently delay pneumococcal episodes of AOM until a later age. In older children, who already are carriers of pneumococci, there is rapid replacement of pneumococcal vaccine serotypes with nonvaccine serotypes.

An 11-valent polysaccharide pneumococcal serotype vaccine conjugated to *H. influenzae*–derived protein D was evaluated in a clinical trial conducted in the Czech Republic enrolling a total of 4968 children, who were followed to the end of the second year of life.[94] Middle ear fluid was cultured when episodes of AOM were diagnosed. The vaccine reduced the overall incidence of AOM episodes by 33.6%. Vaccine efficacy was 57.6% for episodes of AOM caused by pneumococcal serotypes included in the vaccine and 66% for vaccine-related cross-reactive pneumococcal serotypes. There was no significant change in number of AOM episodes due to other nonvaccine serotypes. Of great interest is that there was 35.3% efficacy against AOM episodes caused by nontypeable *H. influenzae*. These results indicate that using the *H. influenzae*–derived protein D as a protein for conjugation of pneumococcal polysaccharides not only allowed for protection against pneumococcal otitis, but also against otitis media due to nontypeable *H. influenzae*. The use of the *H. influenzae*–derived protein D and the two additional pneumococcal serotypes probably explains the 33.6% reduction in numbers of all types of AOM episodes by the vaccine, which is significantly better than in the previously mentioned trials.[12,13]

Maternal Immunization

Infants immunized with PCV7 are unlikely to elicit protective serum antibody concentrations during the first 4 to 6 months of life, when

recurrent AOM begins. Maternal immunization with pneumococcal vaccine is another approach that is currently being studied in animals as well as in humans.[95,96] A randomized clinical trial was conducted to evaluate the immunogenocity and reactogenicity of the 23-valent pneumococcal polysaccharide vaccine among pregnant women in the Philippines. A significant rise in antibody to polysaccharides varying from 3.3- to 9.1-fold for individual serotypes between pre- and postvaccination was seen in the immunized mothers relative to that in the control subjects. The level of polysaccharide-specific antibody in cord blood was also significantly higher in the immunized group, indicating transfer from mother to infant to provide enhanced protection. Adverse reactions were mild and required no treatment. Healy and Baker, reviewing the subject of maternal vaccination, found strong evidence that maternal immunization would be a feasible approach, particularly for providing early protection to children at high risk.[97] The main concerns with maternal immunization appear to be the fear of risk of birth defects.

Haemophilus influenzae *Vaccine*

Because nontypeable *H. influenzae* is the second most common bacterial pathogen isolated from middle ear fluid in AOM, much effort has been channeled into developing an effective vaccine. Many different approaches using animal models have been used to develop vaccine antigens for nontypeable *H. influenzae*–induced otitis media, including the following proteins: outer membrane protein (OMP) P5, 26, P2, P6, Htr protein, protein D, phosphorylcholine (ChoP), detoxified lipo-oligosaccharides (dLOSs), and type 1V Pili. For the first time, however, it was possible to demonstrate an effective *H. influenzae* antigen for otitis media in a clinical trial using an 11-valent vaccine with the pneumococcal capsular polysaccharides conjugated to protein D, an outer membrane protein of *H. influenzae*, as previously mentioned.[94] Although the efficacy was only 35.3%, the results indicate that it would be feasible to develop an effective vaccine for *H. influenzae*.

Moraxella catarrhalis *Vaccine*

Moraxella catarrhalis is considered the third most common bacterial pathogen isolated from the middle ear. Although the frequency of *M. catarrhalis* infections has previously been rather modest, recent studies have indicated that the frequency of nasopharyngeal colonization with *M. catarrhalis* in children with otitis media increased with the widespread use of the pneumococcal conjugate vaccine.[98] Therefore, for the greatest impact on reducing otitis media episodes, the development of a vaccine that contains *M. catarrhalis*, as well as *S. pneumoniae* and *H. influenzae* antigens, is necessary. Very little progress has been made in defining the protective immune response in *M. catarrhalis*. However, recently, protective immune responses to *M. catarrhalis* in adults with chronic obstructive pulmonary disease have been identified.[99,100] Candidate *M. catarrhalis* vaccine antigens that have been shown to induce potentially protective responses include outer membrane protein OlpA, CopB, filamentous hemagglutinin (FHA-like protein), and lipo-oligosaccharides (LOSs).

Viral Vaccines

Based on evidence regarding the role of viruses in the pathogenesis of AOM, the development of viral vaccines should be strongly promoted.[22] It should be recognized that bacterial vaccines only prevent the bacterial complications of a viral infection, while viral vaccines act at an earlier stage in the pathogenesis of AOM. Thus, viral vaccines have the potential to prevent viral upper respiratory infections, thereby potentially preventing the development of AOM as a complication of bacterial colonization of the nasopharynx.

Influenza Vaccine

The only commercially available viral vaccine today used for prevention of otitis media is the influenza vaccine, which is recommended for all children 6 to 59 months of age and older children with high-risk conditions by the American Academy of Pediatrics.[101] Currently, two types of influenza vaccine are available. Trivalent inactivated influenza vaccine (TIV) contains killed viruses and is given intramuscularly to children 6 months and older and adults. Live-attenuated influenza vaccine (LAIV) contains live virus, is given intranasally, and currently is licensed by the U.S. Food and Drug Administration (FDA) for healthy persons 2 through 49 years of age.

A prospective study in children 13 years or younger was conducted during two respiratory seasons in Finland.[102] The average annual rate of influenza was highest (179 cases/1000 children) among children younger than 3 years of age. AOM developed as a complication of influenza in 39.7% of children younger than 3 years. For every 100 influenza-infected children younger than 3 years, there were 195 days of parental loss of work (mean 3.2 days). The investigators concluded that vaccination of children younger than 3 years of age may be beneficial for reducing the direct and indirect costs of childhood AOM.

Two recent clinical trials have addressed the efficacy of inactivated influenza vaccine in preventing otitis media. Hoberman and coworkers conducted a randomized double-blind, placebo controlled 2-year clinical trial in 786 children 6 to 24 months of age in Pittsburgh, Pennsylvania.[103] The investigators did not identify any significant reduction in the burden of AOM from administration of inactivated trivalent influenza vaccine. However, in the first year of the study, the efficacy of the vaccine against culture-confirmed influenza was 66%, whereas in the second year of the study the efficacy was −7%. The low efficacy rate in the second year may be explained by the fact that the attack rate of influenza virus in the second year did not reach epidemic proportions, in contrast with the first year (3.3% versus 15.9% in the placebo group). The second study was single-blinded and evaluated the efficacy of inactivated influenza vaccine in preventing otitis media. The study was carried out in 119 children 6 to 60 months of age attending day care in Turkey. Efficacy rates for the vaccine against AOM, OME, and otitis media were 51%, 18%, and 18%, respectively.[104]

A multicenter study enrolled and randomly assigned 8475 children 6 to 59 months of age in a double-blind fashion to intranasal trivalent live-attenuated influenza vaccine or trivalent inactivated influenza vaccine intramuscularly to assess the efficacy and safety of the vaccines.[105] The live-attenuated vaccine was overall superior to the inactivated vaccine in preventing influenza episodes. There were 54.9% fewer cases of culture-confirmed influenza episodes in the group that received the live-attenuated vaccine ($P < 0.001$). The superior efficacy of the live-attenuated vaccine was observed for both antigenically well-matched and drifted viruses. Rates of wheezing and hospitalization were higher in the youngest children who received the live-attenuated vaccine than in those given the inactivated vaccine. In 2007 the FDA approved the use of this vaccine for children 2 years of age and older without a history of recurrent wheezing or asthma. Additional studies to assess the safety of the vaccine in the youngest children need to be done.

Respiratory Syncytial Virus Vaccine

The seriousness of RSV infection in infants and children and the need for an RSV vaccine are widely recognized. In addition to causing lower airway infections, the RSV virus is one of the major viruses contributing to the development of AOM.[75] Only live-attenuated vaccines have been investigated. Karron and associates developed a recombinant live-attenuated RSV vaccine that was attenuated in RSV-seropositive children and was well tolerated and immunogenic in RSV-seronegative children.[106] Further studies are needed to assess the clinical efficacy.

An alternative approach to preventing RSV infection is maternal immunization. Munoz and colleagues conducted a study to assess safety and immunogenicity of an RSV purified fusion protein 2 (PFP-2) subunit vaccine in 35 pregnant women in their third trimester and the effect on the offspring.[107] The infants were followed during their first RSV season. Seventy-five percent of the immunized infants had a response to the PFP-2 by Western blot analysis, compared with none of the control subjects. The transplacental transfer of vaccine-induced maternal antibodies was efficient, and no increase in frequency or severity of respiratory tract infections was observed in the immunized infants. The infants were born healthy, and no adverse events related to maternal immunization were documented.

Treatment

The treatment of otitis media involves medical and surgical therapies.

Acute Otitis Media

Observation

In an effort to reduce antibiotic use and stem increasing bacterial resistance, observation without use of antibiotics is listed as an option for selected children with AOM in the guidelines document published by the American Academy of Pediatrics and American Academy of Family Physicians in 2004.[108] Children for whom this is an option are to be selected on the basis of diagnostic certainty, age, illness severity, and access to medical care. Severe disease is defined as moderate to severe otalgia, fever with temperatures higher than 39° C (102° F) orally or 39.5° C rectally, or a toxic-appearing child. Children younger than 6 months of age should be treated with antibiotics regardless; children 6 to 23 months, if the illness is nonsevere, may be observed if the diagnosis is uncertain, but if AOM is certain or severe, the child should be treated with antibiotics; children 24 months or older may be watched if the diagnosis is uncertain or disease is nonsevere but treated if AOM is severe.

Already a popular method of management in several countries outside the United States, observation, or "watchful waiting," is predicated on the results of several earlier studies showing a high spontaneous cure rate for AOM.[109-114] Wald, however, cited problems with the earlier studies: The definition of AOM used in the various studies may have allowed for the inclusion of subjects with asymptomatic OME; children younger than 2 years of age were not included in some studies and were underrepresented in others; the sickest children often were not selected for these studies; and the antibiotic selected may have been inappropriate and the doses used were often insufficient, all of which would make the efficacy of antimicrobial treatment appear lower.[115] A meta-analysis of studies of AOM with an observation group found that children younger than 2 years of age and those with bilateral AOM were more likely to have prolonged symptoms when not given antimicrobial treatment.[116]

Nonetheless, the practice of not treating AOM immediately with antibiotics, often giving a "backup" prescription in case of persistence of symptoms, is undergoing further scrutiny in this country and elsewhere. McCormick and associates reported their randomized trial of immediate antibiotics plus symptom medication versus symptom medication only in 223 subjects with "nonsevere" AOM, of whom 57% were younger than 2 years of age.[117] At day 12, 69% of TMs and 25% of tympanograms were considered to be normal in the antibiotic group, compared with 51% of TMs and 10% of the tympanograms in the nontreated group; 66% of the watchful-waiting group completed the study without antibiotics. Nasopharyngeal cultures at day 12 of the study revealed that *S. pneumoniae* was eradicated in most of the antibiotic-treated subjects, but the strains that were cultured were more likely to be antibiotic-resistant. Parental satisfaction with the assigned "treatment" was the same in both groups. Spiro and associates randomly assigned children 6 months to 12 years of age diagnosed with AOM (definition left to discretion of physician) to receive either immediate antibiotic treatment or a "wait-and-see" prescription, to be filled if the child was not improving or was worse at 48 hours.[118] In this study, performed in an emergency department population, the mean age of subjects was 3.2 years; approximately 84% had unilateral AOM. The investigators found that 62% of the group given instructions to delay filling the prescription did not fill the prescription, compared with 13% given the instructions to start the medication immediately ($P < 0.001$). The presence of fever or otalgia was associated with filling the prescription.

Vernacchio and coworkers surveyed physicians in a national practice-based pediatric research network regarding their preferred management of AOM.[119] Despite the studies showing that the use of observation or delayed prescribing may allow for spontaneous recovery in many children and the option of observation was offered in the AOM guidelines, they found that although 83% considered observation a "reasonable option," it was used only in a median of 15% of cases.

Medical Treatment

Antibiotics

Many antibiotics are available, but according to American Academy of Pediatrics–American Academy of Family Physicians guidelines,[108] amoxicillin is still the first-line antibiotic for non-severe episodes of AOM and, at 90 mg/kg per day in two divided doses, is recommended to provide coverage for *S. pneumoniae*, including resistant strains. For severe episodes of AOM, amoxicillin–clavulanic acid (amoxicillin 90 mg/kg per day and clavulanic acid 6.4 mg/kg per day in two divided doses) is recommended and will provide coverage for beta-lactamase–producing *H. influenzae* and *M. catarrhalis*. According to these guidelines, cephalosporins should be considered as accepted first-line treatment only for patients with penicillin allergy. Macrolides should be prescribed for patients with penicillin and cephalosporin allergies. Treatment failure is defined as persistence or recurrence of symptoms and signs 48 to 72 hours after institution of initial treatment. In such cases, the diagnosis should then be reassessed and antibiotics started if not given previously or changed to a broader-spectrum agent if antibiotics were previously prescribed (amoxicillin–clavulanic acid if amoxicillin failed to produce improvement and ceftriaxone for 3 days if amoxicillin–clavulanic acid was not effective). Tympanocentesis should always be considered if the child does not respond to the antibiotic treatment, in order to identify the bacteria in the MEE and to select an appropriate antibiotic.

Duration of Treatment

Ten days of antibiotic treatment has been the standard, but in an effort to reduce cost and the incidence of antibiotic resistance, the efficacy of shorter courses has been investigated. Studies have found the 10-day course has resulted in fewer early treatment failures in younger children,[8] in children recently treated for AOM,[120] and in those presenting with spontaneous perforation of the TM,[121] compared with a 5-day course. The recent U.S. guidelines recommend the standard 10-day course of therapy for younger children and for children with severe disease, and for those 6 years of age and older with mild to moderate disease, a 5- to 7-day course may be used.[108] Several short courses of antibiotics have been approved by the FDA for use in AOM. Cefpodoxime proxetil and cefdinir have been approved for a 5-day course; azithromycin may be given for 1-, 3-, and 5-day courses; one dose of IM ceftriaxone may be given, although results for penicillin-resistant *S. pneumoniae* are better with a 3-day course.[122]

Longer courses of antibiotics have also been proposed. In a randomized, double-blind trial of 10 days of amoxicillin versus 20 days of amoxicillin or 10 days of amoxicillin with an additional 10 days of amoxicillin-clavulanate, no advantage in treatment failure or duration of MEE was found with the longer courses.[123]

Decongestants/Antihistamines

A meta-analysis of studies of decongestant-antihistamine preparations for AOM found no benefit of these agents for early cure, symptom resolution, or prevention of surgery or complications. Although some benefit of the combination was found in number of subjects with persistent AOM at the 2-week endpoint, the 5- to 8-fold risk of side effects, along with the fact that finding benefit was inversely correlated with study quality, led the authors to not recommend the routine use of decongestant-antihistamine agents for AOM.[124] In 1994, Chonmaitree and associates reported increased levels of histamine in middle ear fluid from children with AOM and speculated that antihistamine may be clinically beneficial in reducing inflammation.[125] However, in a recent trial for AOM, antihistamine administered with an antibiotic did not result in improved clinical outcome and prolonged the duration of effusion.[126] At this point, neither decongestants or antihistamines, nor their combinations, are recommended for the treatment of AOM.

Steroids

Studies in rats suggested that steroid given with antibiotic reduced inflammatory changes in the middle ear mucosa to a greater extent than treatment with antibiotic alone.[127] McCormick and coworkers found no reduction in histamine or leukotriene B4 in children treated with

oral antibiotic and steroid compared with children receiving antibiotic alone but did find a lower rate of treatment failure during the first 2 weeks and a shorter duration for MEE in those treated with steroids.[128] When a larger sample of subjects was studied, however, the same group of workers found that corticosteroid (2 mg/kg given for 5 days) administered with antibiotic did not provide any improvement in clinical outcome.[126]

Recurrent Acute Otitis Media

Antibiotic Prophylaxis

Many studies have examined the efficacy of antibiotics in preventing AOM in children with frequently recurrent episodes. Many antibiotics have been studied, particularly amoxicillin and sulfisoxazole, used at one-half of their recommended daily dose and given once per day for months. Studies generally have concluded that antimicrobials are effective in preventing disease.[129] This method of managing children with recurrent AOM is not recommended, however, because of the potential for increasing resistant organisms. Rather than daily medicine given for months at a time, treating intermittently at the time of upper respiratory tract symptoms has been tried, but efficacy is less than with continuous medication.[130]

Surgical Treatment

Myringotomy/Tympanocentesis

For episodes of AOM, a myringotomy or tympanocentesis is helpful for relief of pain and allows samples to be obtained for culture to identify the pathogen and to guide in the selection of antibiotics, but provides no advantage in duration of effusion or recurrence of episodes of AOM.[111]

Myringotomy with Tympanostomy Tube Insertion

When preventive and medical treatments for recurrent AOM have failed, tympanostomy tube insertion is recommended. Two recent randomized studies have assessed the efficacy of tympanostomy tube insertion for recurrent AOM. A randomized clinical trial to evaluate the efficacy of myringotomy with tympanostomy tube insertion (M&T) versus sulfisoxazole prophylaxis versus placebo enrolled 65 children 4 years or younger with recurrent AOM and followed them for 6 months or longer.[131] Treatment failure was defined as two episodes of AOM or otorrhea in less than 3 months. Five of 22 children in the M&T group experienced treatment failure, compared with 12 of 20 children in the placebo group ($P = 0.02$) and 8 of 21 children in the prophylaxis group. In a similar study to determine the efficacy of amoxicillin prophylaxis versus M&T versus placebo, 264 children 7 to 35 months of age with recurrent AOM were randomized to one of the three treatment arms and followed for 2 years.[132] The average proportion of time with OM (AOM or otorrhea) was 10% in the amoxicillin, 15% in the placebo, and 6.6% in the tube groups (placebo versus tube; $P < 0.001$). Rates of new episodes of any type per child was 0.6 in the amoxicillin, 1.08 in the placebo, and 1.02 in the tube groups (amoxicillin versus placebo; $P < 0.001$). The low rate of new episodes must be viewed in light of the fact that the study subjects proved not to be at as high risk for AOM as had been anticipated. However, in comparison with children who received placebo, children with tympanostomy tubes spent less time with OM. It should be kept in mind that episodes of otorrhea with tympanostomy tubes usually are less severe, without fever and otalgia, and in most cases resolve with ototopical drops and do not require oral antibiotics.

For children with recurrent episodes of AOM, usually defined as three or more episodes of AOM in 6 months or four or more episodes in 12 months, insertion of tympanostomy tubes is an option.

Adenoidectomy with and without Tonsillectomy

Two parallel randomized clinical trials compared the efficacy of adenoidectomy and adenotonsillectomy in 461 children 3 to 15 years of age with persistent or recurrent otitis media who had not previously undergone tympanostomy tube placement.[133] Children without recurrent throat infections were randomized to undergo adenoidectomy, adenotonsillectomy, or no surgery (no adenoidectomy or adenotonsillectomy), and children with recurrent throat infections, to undergo adenotonsillectomy or no surgery. A majority of children (91%) had a history of recurrent AOM. The benefit of surgery in both trials was modest and limited mainly to the first follow-up year. The largest difference was in the three-way trial between adenotonsillectomy and no surgery, with a mean annual AOM rate of 1.4 versus 2.1 ($P < 0.001$) and mean estimated percentage of time with otitis media of 18.6% versus 29.9% ($P = 0.002$). Based on the short-term efficacy of adenoidectomy and adenotonsillectomy as well as the morbidity rate and cost of these procedures, it was suggested that neither should be considered as the initial surgical procedure.

In a randomized clinical trial assessing the efficacy of adenoidectomy versus placebo versus long-term antimicrobial prophylaxis in preventing episodes of recurrent AOM, 180 children 10 to 24 months of age were enrolled and followed for 24 months. No significant difference was observed between the groups in the numbers of episodes of AOM, visits to doctors, antibiotic prescriptions, and days with symptoms of respiratory infection. The investigators concluded that adenoidectomy cannot be recommended as the primary treatment in this age group.[134]

Hammarén-Malmi and colleagues conducted a clinical trial in children 12 to 48 months of age with recurrent AOM (three or more episodes in 6 months or five or more episodes in 12 months) to evaluate the efficacy of adenoidectomy in children receiving tympanostomy tubes.[81] The children were randomized to undergo tympanostomy tube insertion (i.e., bilateral myringotomy with tube insertion) with or without adenoidectomy. During the follow-up period of 12 months, the mean number of AOM episodes was 1.7 for children in the adenoidectomy plus tube insertion group, compared with 1.4 in children in the tube insertion–only group. Adenoidectomy at time of tympanostomy tube insertion does not significantly reduce the incidence of AOM in otitis-prone children younger than 4 years of age.

Adenoidectomy may provide modest improvement in children with recurrent AOM but is not recommended as a first-line procedure unless indicated for airway obstruction. Tonsillectomy, in conjunction with adenoidectomy, provides no significant advantage over adenoidectomy alone, and the risks outweigh the benefits.

Otitis Media with Effusion

Observation

For children not at risk for speech and language or learning disabilities, "watchful waiting" may be appropriate. Hearing testing should be done if MEE persists for 3 months or longer or at any time that language delay, learning difficulties or significant hearing loss is suspected. If the average hearing level is below 20 dB, watchful waiting is suggested, but if it is greater than 40 dB in the better ear, surgery is recommended. For children with hearing levels in the better ear between 21 and 39 dB, management is based on the duration of effusion and severity of symptoms. For children not at risk, examination at 3- to 6-month intervals until the fluid has resolved, hearing loss, language, or learning delays are identified or there are suspected structural abnormalities of the ear drum, is recommended.[108]

Medical Treatment

Decongestant/Antihistamine

Decongestant with or without antihistamine was a popular treatment for OME, but clinical trials found no efficacy of these medications.[135-138] In studies of OME at the Children's Hospital of Pittsburgh, no efficacy was found for an oral decongestant-antihistamine combination given either alone[139] or with an antimicrobial agent.[140]

Antibiotics

Antibiotics came into prominence as treatment for OME toward the end of the 1970s and beginning of the 1980s, when studies showed the ineffectiveness of decongestant-antihistamine combinations. In addition, although effusions were thought to be sterile, studies showed that specimens from asymptomatic children with MEE contained bacte-

ria.[11,141] Mandel and associates reported the results of their double-blind, randomized trial in which 518 children with OME of varying durations were divided into three treatment groups: (1) amoxicillin (40 mg/kg/day) for 14 days plus a decongestant/antihistamine combination for 28 days; (2) amoxicillin for 14 days plus placebo for decongestant/antihistamine for 28 days, or (3) placebo for both amoxicillin and decongestant/antihistamine.[140] At 4 weeks, the rate of resolution of MEE was twice as high in those treated with amoxicillin, with or without a decongestant-antihistamine agent, as those who received placebo (percentages of effusion-free: 31.6%, 28.8%, and 14.1% in the amoxicillin plus decongestant-antihistamine, amoxicillin alone, and placebo groups, respectively); the addition of the decongestant-antihistamine made no difference. Recurrence of effusion occurred in most subjects within 3 months after completion of treatment. Other antibiotics, including amoxicillin-clavulanate, ceftibuten, and penicillin, have been tested in clinical trials to determine whether all antibiotics had the same efficacy, but none has been clearly shown to have any long-term advantage over the others.[142-144] Mandel and associates compared the efficacies of cefaclor and erythromycin-sulfisoxazole to that of amoxicillin.[145] Besides not being better than placebo, cefaclor and erythromycin-sulfisoxazole showed no increased efficacy at 2 and 4 weeks after starting treatment compared with amoxicillin. Antibiotic used in prophylactic doses (generally half the total daily dose used for AOM, given once daily for months) has also been examined in the treatment of OME, but its efficacy is linked more to preventing AOM than treating OME.[146] Despite short-term efficacy, antibiotics are not recommended for routine treatment of OME, due to lack of long-term efficacy, the high spontaneous cure rate, and concern about overuse of antibiotics.[129,147]

Steroids

Theoretically, glucocorticoids should be efficacious in the treatment of OME: Anti-inflammatory properties are due to inhibition of phospholipase A_2, which then inhibits formation of arachidonic acid and the subsequent synthesis of inflammatory mediators; up-regulation of transepithelial sodium transport promotes fluid removal from the middle ear; and decreasing mucin production by suppressing MUC5AC.[148] In clinical trials, systemic steroids have demonstrated an advantage over placebo in resolving MEE, but owing to the high recurrence rate after treatment, steroids are not recommended for long-term management.[149]

Because of the side effects with use of systemic steroid, especially for prolonged courses of treatment, other routes of administration have been investigated. Tracy and colleagues used prophylactic antibiotics with and without (both an untreated group and a placebo group) intranasal beclomethasone to treat 59 children with chronic OME and recurrent AOM.[150] Although all groups improved initially, no difference in OME resolution was observed by the 12-week visit. Cengel and Akyol found, in a nonblinded, randomized (every other subject assigned to active treatment with nasal mometasone spray for 6 weeks, with the remaining subjects assigned to no treatment) study of patients with documented MEE of at least 3 months' duration, 42.2% of treated subjects resolved at 6 weeks, compared with 14.5% of untreated subjects ($P < 0.001$); no long-term follow-up was reported.[151]

Autoinflation

Popularized by Politzer more than 100 years ago, devices to insufflate air through the eustachian tube have been tried for the treatment of OME. However, studies using a number of devices have failed to show consistent efficacy,[152-155] so autoinflation is not recommended for routine use at this time. In their meta-analysis, Perera and associates concluded that because of its low cost and absence of adverse effects, autoinflation might be considered for use while awaiting spontaneous resolution of the effusion.[155]

Surgical Treatment

Myringotomy

Myringotomy alone has been shown to be ineffective for long-term management and is not recommended for chronic OME.[156,157] Laser-assisted myringotomy has been described as an alternative to the standard myringotomy in children with chronic OME, and the procedure can be done using local anesthesia and is considered safe. However, the mean time to closure of the perforation is only 2 to 3 weeks.[158,159]

Myringotomy with Tympanostomy Tube Insertion

In children with persistent MEE, the decision of whether to insert tympanostomy tubes is based on the child's hearing status and risk for developmental problems. Several randomized clinical trials have demonstrated evidence-based indications for the use of tympanostomy tube insertion for chronic OME.

The efficacy of M&T for the management of OME has been the subject of many studies. Mandel and coworkers reported the results of a 3-year clinical trial of 109 children, 7 months to 12 years of age, with OME of 2 months' duration or longer who were unresponsive to medical management and who were randomly assigned to receive myringotomy alone, M&T, or no surgery.[160] During the first year, over 50% of subjects in the myringotomy-only and the no surgery groups met preset treatment failure criteria and underwent M&T. A second study designed to correct some of the design flaws of the first study and to extend the time until treatment failure involved 111 children with OME for at least 2 months and whose pure-tone averages bilaterally were 35 dB or less.[157] This study also found high rates of treatment failure in children in the myringotomy-only group (70%) and the no surgery group (56%). The percentages of time with MEE during the first year in the myringotomy-only, M&T, and no surgery groups were 61%, 17%, and 64%, respectively ($P < 0.001$). From these studies, it was concluded that myringotomy offered no advantage over no surgery in regard to percentage of time with effusion, number of AOM episodes, and number of repeat surgical procedures, and M&T provided more disease-free time and better hearing than myringotomy only or no surgery.

Gates and associates studied the effects of various surgical treatments in children 4 to 8 years of age with chronic OME; 127 children were randomly assigned to undergo myringotomy and 150 were assigned to undergo M&T.[156] Compared with myringotomy only, M&T provided less time with effusion and more time with better hearing, and necessitated fewer surgical retreatments.

The previously mentioned studies[157,160] were performed at a time when it was considered "unethical" to allow a child to have MEE for more than 2 to 3 months because of the associated hearing loss and the possible detrimental effects on speech and language development. A more recent study by Paradise and colleagues randomly assigned 429 children younger than 3 years of age with persistent or recurrent OME either to prompt M&T or to M&T up to 9 months later.[84] Eighty-five percent of children in the promptly treated group and 41% of children in the late treatment group had undergone M&T by 6 years of age. On developmental testing at 6 years, there were no significant differences between the groups on 30 measures. Of interest, in both the randomized clinical trial and in children randomly selected from those followed in the study but who did not meet criteria for randomization, sociodemographic variables seemed to be the most important factors influencing developmental outcomes.

Adenoidectomy

A study by Maw enrolling children 2 to 11 years of age with chronic OME showed that adenoidectomy alone and M&T alone provided better results than no surgery, but the combination of the two surgical procedures provided better results than either alone.[161] The addition of tonsillectomy to adenoidectomy provided no additional benefit for middle ear fluid resolution. In the previously discussed study by Gates and associates,[156] the children randomly assigned to the adenoidectomy-myringotomy and the adenoidectomy-M&T groups both had a lower percentage of time with effusion than those who received M&T alone. Thus, on the basis of these results, Gates and associates recommended adenoidectomy-myringotomy as the first-line procedure.[156]

Paradise and colleagues studied 213 children 1 to 15 years old with recurrent AOM or OME who had previously had M&T.[162] Children were randomly assigned to undergo adenoidectomy or no ade-

noidectomy; M&T was also performed at the same time for specific indications. Among the 99 subjects who were randomized, a significant reduction in time with otitis media during the first 2 years was observed in the children who underwent adenoidectomy, in comparison with those who did not. For the remaining children, whose parents chose not to allow random assignment, the results favored adenoidectomy over no adenoidectomy.

A clinical trial enrolling 98 children ranging in age from 24 to 47 months who had bilateral OME for 3 months or longer, or unilateral OME for 6 months or longer, or recurrence of effusion after extrusion of previously placed tympanostomy tubes, randomized the subjects to undergo M&T versus adenoidectomy and myringotomy with and without insertion of tubes.[163] Adenoidectomy with M&T provided no advantage over M&T alone (11.9% versus 18.1%; $P = 0.12$) in regard to mean percentage of time with MEE during the 18-month follow-up period. However, the mean percentage of time with MEE in the adenoidectomy-myringotomy alone group (35.7%) was significantly higher than in both the M&T and the adenoidectomy-M&T groups ($P < 0.001$ and $P = 0.003$, respectively). Also, in the adenoidectomy plus myringotomy group, 25% of the children subsequently needed an additional procedure (M&T), compared with less than 10% in the two groups with initial M&T.

Several retrospective studies have looked at the efficacy of adenoidectomy in addition to M&T. Boston and associates evaluated risk factors for additional tube insertion in 2121 patients undergoing bilateral M&T.[164] In 19.9% of the children, two or more tube insertions were performed. After the initial tube insertion, as many as 45.1% of the patients needed an additional surgical procedure (tube insertion, adenoidectomy, or tonsillectomy with or without adenoidectomy). Patients younger than 18 months at the initial procedure were significantly more likely to have a second procedure (26.3% versus 15.9%; $P < 0.001$). Adenoidectomy was performed at the time of the initial tube insertion in 527 patients (24.5%). This reduced the probability of needing a second set of tubes (0.08 versus 0.24; $P < 0.001$). Also, the probability of needing a third set of tubes was reduced when adenoidectomy was performed at or before placement of the second set of tubes (0.15 versus 0.40; $P < 0.001$). The presence of craniofacial abnormalities and a family history of adenoidectomy, tonsillectomy, or tube insertion increased the likelihood of need for subsequent tube insertions ($P < 0.001$). Sex and race were not risk factors for subsequent tube insertion.[164]

Another retrospective study evaluated the effect of adjuvant adenoidectomy or adenotonsillectomy at time of tympanostomy tube insertion on the rate of reinsertion of tubes and re-hospitalization for otitis media–related conditions in 37,316 Canadian children (≤19 years) for whom tube insertion was their first surgical procedure.[165] Compared with tube insertion alone, adenoidectomy was associated with a reduction in the likelihood of reinsertion of tubes (relative risk [RR]: 0.5; 95% CI: 0.5-0.6; $P < 0.001$), as was adenotonsillectomy (RR: 0.5; 95% CI: 0.5-0.6; $P < 0.001$). Performing adenoidectomy or adenotonsillectomy at the time of the initial tympanostomy tube insertion substantially reduced the likelihood of additional hospitalization and operations related to otitis media among children 2 years of age or older.

A third large retrospective study assessing the benefits of adjuvant pharyngeal surgery (adenoidectomy, adenotonsillectomy and tonsillectomy) at the time of tympanostomy tube insertion examined the records of 51,373 children less than 10 years of age.[166] Twenty-nine percent of the children had pharyngeal surgery at the time of the first tube insertion. The study authors concluded that having adenoidectomy or adenotonsillectomy at the time of first or subsequent tube insertion was associated with reduced risk of further tube insertion.

Guidelines

In 2004 a revised Clinical Practical Guidelines for OME was published jointly by the American Academy of Family Physicians, the American Academy of Otolaryngology–Head and Neck Surgery, and the American Academy of Pediatrics.[108] The guidelines were evidence-based, and the quality of the evidence was assessed. The recommendations reflected the quality of the evidence and the balance between benefit and harm that is anticipated when recommendations are followed. The guidelines apply to children 2 months through 12 years of age with and without developmental disabilities or underlying conditions that predispose to OME and its sequelae. The decision regarding surgery for OME depends largely on hearing status, associated symptoms, the child's developmental risk, and the anticipated chance of timely spontaneous resolution of the effusion. Surgical candidates are children with (1) OME lasting 4 months or longer with persistent hearing loss or other signs or symptoms; (2) recurrent or persistent OME associated with increased risk of developmental problems regardless of hearing status; and (3) OME and structural damage to the TM or middle ear.

Tympanostomy tube insertion is the initial preferred procedure. Adenoidectomy should not be performed except for a specific indication (i.e., nasal obstruction, chronic adenoiditis). Repeat surgery consists of adenoidectomy plus myringotomy with or without tympanostomy tube insertion. Tonsillectomy alone or myringotomy alone should not be used to treat OME.

Quality of Life Assessment

The first validated quality of life (QOL) outcome study for otitis media used the OM-6 instrument developed by Rosenfeld and associates, representing six domains: physical stress, hearing loss, speech impairment, emotional distress, activity limitation, and caregivers' concerns.[167] Large, moderate, and small improvements after tympanostomy tube insertion were documented in 56%, 15%, and 8% of children, respectively, using this instrument.[168] Trivial changes were noticed in 17% of children and 4% of children had a poor outcome after tube insertion. The results indicate that tympanostomy tube insertion produces large short-term improvement in QOL for most children.

A QOL outcome study assessed the parents' appreciation of their child's general condition using the OM-6 scale before, after, and retrospectively before tube insertion in a group of Dutch children 12 to 36 months of age.[169] The results from the retrospective assessment of the child's general condition prior to tube insertion indicated that the parents underestimated the effects of otitis media before surgery. In particular, after tube insertion, parents were able to appreciate the extent of presurgical hearing loss.

Surgical Issues

Tympanostomy Tube Placement

Rationale

Myringotomy and tympanostomy tube insertion is currently the most common surgical procedure in children that requires general anesthesia. Insertion of a tympanostomy tube promotes ventilation of the middle ear and drainage through both the eustachian tube and the tympanostomy tube. Also the aeration of the middle ear may promote normalization of the middle ear mucosa. The removal of MEE restores the conductive hearing loss. However, reflux of nasopharyngeal secretions may occur in an ear with a tympanostomy tube, causing otorrhea due to loss of the middle ear air cushion effect.

Procedure

In most children insertion of tympanostomy tubes is performed under general mask anesthesia. In older children who are cooperative tympanostomy tube insertion could be performed using topical anesthesia such as phenol or lidocaine delivered by iontophoresis.

The procedure should be performed using a binocular operating microscope. After satisfactory removal of cerumen and debris the entire TM should be inspected to rule out any abnormalities. The myringotomy incision is performed in the anterior-superior or anterior-inferior quadrant of the pars tensa. A radial incision is made small enough to prevent premature tube extrusion but large enough that the tube can be easily inserted using an alligator forceps. If MEE is present, it should be aspirated. When the effusion is purulent or mucopurulent, it should be aspirated into a Juhn trap or Alden-Senturia trap and sent for culture (Fig. 194-5). If the MEE is too thick to be aspirated through the myringotomy incision with a large suction tip, a counterincision is

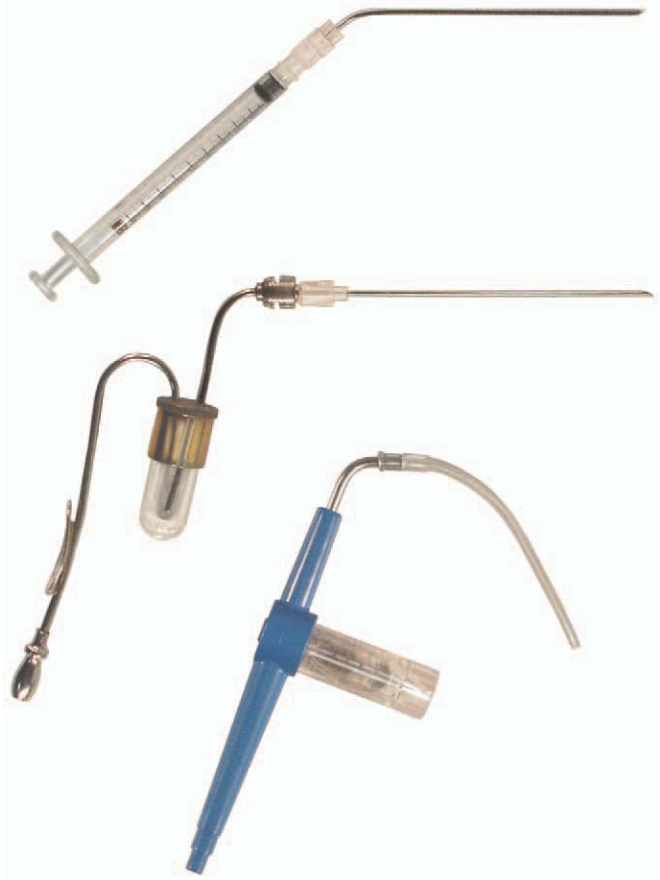

Figure 194-5. Collection vehicles for aspiration of middle ear effusions. *Top to bottom*: Syringe with spinal needle; Alden Senturia trap; Juhn Tym-Tap.

made in the inferior part of the tympanic membrane or sterile saline is placed in the canal or through the myringotomy to enhance the aspiration of the viscous fluid. There is still controversy regarding the best place to insert the tympanostomy tube. The anterosuperior quadrant is associated with a longer clincial tube life; however, a persistent perforation in that area is somewhat more difficult to repair.

Selection of Tympanostomy Tubes and Indications

Many different tympanostomy tubes have been developed, but most tympanostomy tubes are variations of the grommet or the T-tube. The duration of time before extrusion is shorter for grommet tubes than for T-tubes. Weigel and associates performed a randomized prospective trial of four different types of tympanostomy tubes in 75 children.[170] During the first 2 years, 93% of Shepard tubes, 80% of Armstrong tubes, 66% of Reuter-Bobbin tubes, and 31% of Goode T-tubes had extruded. In studies from Pittsburgh, the clinical life of the Armstrong-type tube was approximately 1 year; 50% had extruded by 12 months, and 75% by 18 months.[157] The time to extrusion is a function of the size, shape of the medial flange, absence of a lateral flange, and the material of the tube. Also, the coating of the tube may affect the time to extrusion, because it may prevent infections.[171,172]

In a young child with a history of recurrent or persistent otitis media, a tympanostomy tube that remains in place for at least a year is preferable. If the child has recurrent otitis media after the tubes have become nonfunctional or extruded, a similar type of tube should be recommended. Grommets with shorter duration are recommended in older children, who may not continue to have problems after the then current season. T-tubes or long-term tubes are recommended for older children with persistent problems due to poor eustachian tube function. These tubes also are recommended for children who have an atrophic TM after going through multiple sets of tympanostomy tubes, because a regular grommet tube may be very quickly extruded.

Perioperative and Postoperative Ototopical Drops

In an effort to reduce early postoperative otorrhea and tube blockage, use of ototopical antimicrobial drops at the time of surgery has been recommended, especially if MEE is present.[173,174] Only FDA-approved ototopical agents such as ofloxacin (Floxin) and ciprofloxacin (Ciprodex) should be considered.

Postsurgical Follow-up

All patients should return for a follow-up visit a few weeks after the surgery for an otoscopic examination to assess the status of the tympanostomy tube. Patients with a hearing loss documented preoperatively should have a repeat hearing evaluation postoperatively. Patients who did not have a preoperative hearing test should be examined postoperatively to document that the hearing is normal. Patients usually are evaluated 6 to 12 months after the insertion of the tubes and every 6 months thereafter, or when problems occur, to assess the status of the tubes and the TM.

Complications and Sequelae

Otorrhea

Otorrhea through a tube or perforation is a common problem after tympanostomy tube insertion and has been recorded in as many as 50% of children with tympanostomy tubes.[175] Transient otorrhea occurred in the postoperative period in 16% (range, 8.8 to 42.0) and later in 26% (range, 4.3 to 68.2) of patients; recurrent otorrhea occurred in 7.4% (range, 0.7 to 19.6), and chronic otorrhea in 3.4% (range, 1.4 to 9.9) of patients.[176] If untreated, acute otorrhea can develop into chronic suppurative otitis media. Pathogens typical of AOM (*S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and *S. pyogenes*) were found in 42% and *P. aeruginosa* and *S. aureus* in 44% of all episodes of acute otorrhea in 246 children with tympanostomy tubes followed prospectively.[175] The typical AOM pathogens were more common in children under 6 years of age than in older children (50% versus 4.4%; $P < 0.001$). *P. aeruginosa* was more common in children 6 years of age or older than in the younger children (43.5% versus 20.5%; $P = 0.052$). Roland and colleagues obtained 1309 isolates from 956 acutely draining ears and identified *S. pneumoniae* in 17%, *H. influenzae* in 18%, *S. aureus* in 13%, *P. aeruginosa* in 12%, and fungus in 5%.[177] Several clinical trials have demonstrated that ototopical agents such as ofloxacin otic solution and ciprofloxacin-dexamethasone otic suspension are effective when acute otorrhea occurs through a tympanostomy tube or perforation, even when no systemic antibiotic is given.[178] In a child who has severe systemic symptoms, a systemic antibiotic should be added. The ciprofloxacin-dexamethasone combination has been shown to be superior to ofloxacin in resolving granulation tissue.[179] The use of other ototopical agents in ears with a nonintact TM has not been approved by the FDA, because they can be ototoxic, especially those that contain aminoglycoside. If the drainage does not resolve in 7 to 10 days, suctioning of the ear canal should be performed and a culture specimen from the opening of the tube should be obtained to determine the causative pathogen. If yeast is the predominant organism, treatment with a topical antifungal drop such as clotrimazole should be initiated. Repeated aural toilet is a very important part of the treatment. Compliance with a regimen of frequent suctioning may be difficult for both the child and the parent, however. If aural toilet and topical treatment fail to produce improvement and the organisms are not sensitive to oral antibiotics, then intravenous antibiotics, removal of the tube(s), or simple mastoidectomy should be considered. CT scan of the temporal bones should be obtained before possible mastoidectomy, to look for complications such as coalescent mastoiditis. In older children with recurrent episodes of otorrhea, removal of the tubes is the treatment of choice, because in these children the eustachian tube may have matured and secretion from the nasopharynx may be refluxing into the middle ear. Also, the tube occasionally may act as a foreign body, causing a foreign body reaction with granulation tissue formation and infections.

Recently, biofilms were identified on a tympanostomy tube removed from a child with a chronic draining ear.[180]

Tympanosclerosis, Atrophy, and Retraction Pockets

A meta-analysis reviewing 134 articles estimated the incidence of TM sequelae after tube extrusion and reported that tympanosclerosis occurred in 32% (range, 7.2 to 64.3), focal atrophy in 25% (range, 1.6 to 75.0), and retraction pockets in 3.1% (range, 0 to 22.7) of ears.[176] The type of tube (short-term versus long-term) had no significant impact on these rates.

The sequelae of tympanostomy tube insertion in children with chronic OME followed for 8 years was reported by Daly and associates.[181] One hundred thirty-eight children (275 ears) followed for 3 years and 84 of these children (167 ears) followed for 8 years were evaluated in regard to TM myringosclerosis, atrophy, retraction pockets or perforations, hearing loss, and static admittance. In general, the annual incidence of sequelae was greater at the 4- to 5-year follow-up than at the 6- to 8-year follow-up. Although atrophy developed in 67% of the ears, myringosclerosis in 40%, and perforation in 3% between the 3- and 8-year follow-up evaluations, the annual risk of new sequelae declined considerably throughout the 3- to 8-year follow-up period for most sequelae studied. However, atrophy and pars tensa or pars flaccida retraction were present in 55% of ears at the 8-year follow-up evaluation, which may put children at risk for continuing middle ear problems during adolescence and adulthood. These results support the need for long-term follow-up in selected patients.

In reporting the incidence of TM abnormalities in children in the previously cited trial[84] of prompt versus delayed tube insertion, Johnston and associates noted that in children who underwent intubation, segmental atrophy and tympanosclerosis at age 5 years were more common than in children who did not receive tubes.[182] These workers found no significant relationship between hearing levels at 6 years of age and the presence or type of TM abnormalities.

Persistent Perforation

The incidence of persistent perforation after extrusion of tympanostomy tubes has been estimated at 4.8% (for short-term tubes, 2.2% [range, 0 to 12.3%]; for long-term tubes, 16.6% [range, 0 to 47.0%]).[176] Also, long-term tubes increased the relative risk of perforation by 3.5 (95% CI: 2.6 to 4.9) over that for short-term tubes. The perforations caused by tympanostomy tubes usually are small; consequently, hearing loss is very mild. The perforations are easily managed with a simple fat graft or surgical gel (Gelfoam), paper patch, or Steri-strip myringoplasty. Sckolnick and associates recently found that the success rate with Gelfoam myringoplasty was higher than with fat graft or paper patch.[183] Before closing the perforation, it is important to ensure that eustachian tube function is good; otherwise, there is a risk of nonclosure or reaccumulation of fluid in the middle ear. As a rule, the TM in the opposite ear should be intact and free of infection for 1 year.

Cholesteatoma

For all types of tubes, the combined incidence of cholesteatoma is 0.7%, but for short-term tubes, the incidence is 0.8% (range, 0 to 6.5) and for long-term tubes 1.4% (range, 0 to 3.0).[176] Any of several mechanisms may be responsible for the development of cholesteatomas. Tympanostomy tubes may be inserted to prevent the development of cholesteatoma in a retraction pocket. However, cholest atoma may result from ingrowth or transplantation of keratinized epithelium into the middle ear cleft around a tympanostomy tube. Also, an intratympanic cholesteatoma may develop after surgical manipulation of the TM. Patients with tympanostomy tubes require regular follow-up during the time the tubes are in place and after extrusion to assess the TM and middle ear for cholesteatoma development.

Early Extrusion

Premature extrusion of tubes occurs in approximately 3.9% of ears.[176] This is most likely due to infection in the middle ear that pushes the tube into the external ear canal. The tube may not have been properly inserted, especially if the TM is thickened owing to an infection at the time of tube insertion. An atrophic TM also may allow early tube extrusion.

Tube Blockage

The lumen of the tympanostomy tube may become obstructed from dried blood or mucus, granulation tissue or a polyp caused by infections in the middle ear. The incidence of plugging of the tube is 6.9% (range, 0 to 37.3) of ears.[176] The tube sometimes can be unplugged using a pick, suction, a Rosen needle or ototopical drops for 10 to 14 days. If the blockage cannot be resolved but the middle ear is effusion-free with normal middle ear pressure, the tube can be left in place and watched until extrusion. On the other hand, if fluid has accumulated in the middle ear or recurrent infections continue, replacement of the tube may be indicated.

Tube Displacement into the Middle Ear

The incidence of displacement of a tympanostomy tube into the middle ear is 0.5% (range, 0 to 1.3).[176] It occurs most commonly at the time of surgery, but it can also be seen later due to infection or trauma, which is very rare. If the tube is displaced into the middle ear during surgery, attempts should be made to retrieve the tube at the time of surgery. However, if a tube is visualized behind an intact TM, risks versus benefits have to be assessed, because a child would require general anesthesia and an incision of the TM to retrieve the tube. A tympanostomy tube displaced behind an intact TM rarely causes problems.

Retained Tympanostomy Tubes

A tympanostomy tube usually is not removed surgically, because most tubes extrude spontaneously. In some children, however, the tube remains in place in the TM and has to be removed surgically. Indications for removing a tympanostomy tube include the following clinical scenarios:

- Retention of one tube after extrusion of the other tube if the middle ear has been free of disease for 1 year or longer in a child 5 to 6 years old or older
- Bilateral retained tubes in an older child with good eustachian tube function
- Chronic or recurrent episodes of otorrhea that are not able to be managed medically, especially in an older child who previously has not had recurrent episodes of otorrhea, because this could be a sign of reflux of secretions from the nasopharynx due to maturation of the eustachian tube
- Blockage of a tympanostomy tube that has become embedded in granulation tissue

In children, most retained grommet, short-term tubes usually are removed with the patient under general anesthesia. After the tube has been removed, a paper patch or Gelfoam myringoplasty is performed. Soft long-term T-tubes may be removed in the office in older cooperative children. In these children, follow-up is esssential to see if the perforation closes spontaneously or requires myringoplasty.

Water Precautions

Several studies have been published, including two meta-analyses[184,185] demonstrating no increase in episodes of otorrhea in patients with tympanostomy tubes not using water precautions over the number of episodes of otorrhea in those using water precautions. In a clinical trial to assess the need for water precautions after insertion of tympanostomy tubes, 201 children, 6 months to 6 years of age, were randomized to swimming and bathing with and without ear plugs and evaluated monthly for 1 year and whenever an episode of otorrhea occurred.[186] At least one episode of otorrhea was documented in 47% of children who used ear plugs, compared with 56% in children with no ear plugs ($P = 0.21$). The mean rate of otorrhea per month for children who used ear plugs was 0.07, versus 0.10 for children not using ear plugs ($P = 0.05$). Although children who do not use ear plugs have a higher inci-

dence of episodes of otorrhea, the clinical impact of using ear plugs is small, and their use should be individualized, rather than recommended on a routine basis.

A clinical survey was conducted in the Pacific Northwest to determine the recommendations given to parents and patients regarding water precautions for swimming with tympanostomy tubes.[187] A total of 263 physicians returned the survey (23.5% response rate). As indicated by the survey findings, most primary care physicians (83%) and approximately one half of the otolaryngologists (47%) still recommend water precautions for swimming with tympanostomy tubes.

Adenoidectomy

Rationale for Adenoidectomy

The rationale for removal of the adenoids in children with otitis media is that the enlargement of the adenoids may cause obstruction of the nasopharynx and blockage of the eustachian tube, preventing ventilation of the middle ear–mastoid system.[188] Also, the adenoid tissue in children with otitis media has been found to have increased bacterial colonization, which may predispose to recurrent infections.[189] Coticchia and associates have demonstrated that the adenoids are covered with biofilm, which may act as a reservoir for bacteria causing middle ear disease.[20] This may explain the clinical improvement obtained after mechanical débridement of the adenoids. The effect of adenoidectomy for children with otitis media is independent of the size of the adenoids.[156,162]

Procedure

Adenoidectomy requires general anesthesia accomplished by either endotracheal intubation or laryngeal mask anesthesia (LMA) and is performed using many different techniques, including curettage, electocautery, microsurgical débridement, or coblation to remove the midline adenoid tissue. The adenoidectomy is completed when the choanae are completely opened and the nasopharynx has a smooth, level contour. Care should be taken to avoid injury to the torus tubarius, which may potentially result in stenosis and eustachian tube dysfunction. In children with submucous cleft palate without airway obstruction, adenoidectomy is not recommended for otitis media because of the risk of velopharyngeal insufficiency. If obstruction exists, partial superior adenoidectomy should be performed, leaving an inferior strip of adenoid tissue for palate closure. Other complications include bleeding, respiratory distress, and atlantoaxial subluxation, which are rare.

Complications and Sequelae of Otitis Media

Complications and sequelae of otitis media are *intratemporal* (extracranial, i.e., temporal bone or neck) or *intracranial* (within the cranial cavity). The intracranial complications are rare in developed countries but are still common in developing nations.

A judicious approach to the use of antimicrobial therapy, including observation without antimicrobials for AOM, has been promoted by guidelines in many different countries owing to the development of increased bacterial resistance to the most common antibiotics. However, delaying antimicrobial therapy may increase the risk for development of complications. Schilder and coworkers compared the national prescription rate of antibiotics for AOM and the national incidence rate of acute mastoiditis across countries.[190] The study showed a slightly higher incidence rate of acute mastoiditis in children (i.e., approximately 4 per 100,000 person–years) in the Netherlands, where only 31% of patients with AOM receive antibiotics, as compared with 2 per 100,000 person-years in the United States, where almost all cases of AOM are treated with antibiotics. More recent studies have shown that use of antibiotics to treat AOM in children may not influence the subsequent development of acute mastoiditis.[191] Also, there is no difference in the proportion of pediatric mastoiditis caused by *S. pneumoniae* in the preconjugated pneumococcal vaccine era versus the postvaccine era.[192]

Intratemporal Complications

The intratemporal complications of otitis media include hearing loss, vestibular and balance problems, acute perforation of the TM, mastoiditis, petrositis, labyrinthitis, and facial paralysis. The intratemporal sequelae include chronic suppurative otitis media, atelectatsis of the middle ear, adhesive otitis media, cholesteatoma, cholesterol granuloma, tympanosclerosis, and ossicular discontinuity and fixation with hearing loss.

Hearing Loss and Balance Problems

Most children with MEE have hearing loss that can be fluctuating or persistent. It usually is a mild to moderate conductive loss averaging between 20 and 30 dB.[193] Rarely, a permanent sensorineural hearing loss may result from AOM or OME, possibly as a result of spread of the infection through the round or oval window or a suppurative complication. Behavioral hearing thresholds in the high frequencies (12 to 20 kHz) are significantly higher in children with a history of otitis media when the middle ear was effusion free.[194]

During an episode with MEE, balance and vestibular function seem to deteriorate, and when the effusion resolves or tympanostomy tubes are inserted, these functions improve.[55] Also, children with otitis media may be more visually dependent as a result of the deterioration of vestibular function causing excessive reliance on other nonvestibular sensory cues to maintain balance.[195] Children may have delayed development of motor coordination skills, such as walking or manipulating their environment; the resultant "clumsiness" may make them more accident-prone. Stenström and Ingvarsson reported that Swedish otitis-prone children were seen more often in the orthopedic and general surgery departments compared with children who were not otitis-prone.[196]

Speech-Language and Child Development

Many studies have investigated the association between otitis media and child development. Some studies have found an association, whereas others have failed to do so. In a recent article, Paradise and coworkers reported that there was no difference between children with otitis media with early versus late tympanostomy tube insertion with regard to hearing, speech-language, and developmental testing.[197] As indicated in the OME Guidelines,[108] however, it is recommended that children with OME undergo hearing testing every 3 to 6 months and be assessed for tympanostomy tube placement if they are at risk for any developmental difficulties due to otitis media, such as significant speech delay.

Mastoiditis

Mastoiditis remains the most common suppurative complication of AOM. Mastoiditis without periosteitis or osteitis most likely represents a continuation of the middle ear inflammation as the mastoid air cell system is in continuity with the middle ear. In acute mastoiditis with periosteitis the infection has spread to the periosteum covering the mastoid process. The spread from the mastoid cells to the periosteum usually is through the mastoid emissary veins. In acute mastoiditis with osteitis with and without subperiosteal abscess the infection can cause destruction of the mastoid cells, leading to "coalescence" of the cells (i.e., mastoid empyema), and present as a subperiosteal abscess. The infection also may spread medially to the petrous bone (petrositis), the labyrinth (labyrinthitis), and neck (Bezold's abscess) and involve the facial nerve or extend into the intracranial cavity.

The diagnosis is made by physical examination and imaging studies such as CT scans and MRI. In the early stage, there are no specific signs and symptoms of mastoid infection with later progression to erythema and tenderness over the mastoid area, to edema or a subperiosteal abscess with displacement of the pinna inferiorly and anteriorly and obliteration of the postauricular crease. The CT scan in the early stage most frequently shows a cloudy mastoid; the inflammatory process may progress and develop into osteitis, with destruction of mastoid bone. Mastoiditis with and without periosteitis often responds to medical treatment and tympanocentesis or tympanostomy tube insertion, whereas mastoiditis with osteitis and bone destruction usually requires cortical mastoidectomy.

Intracranial Complications

The middle ear and the mastoid air cell system are close to the intracranial cavity, and infection can spread to the intracranial structures. Suppurative intracranial complications due to AOM include meningi-

tis, epidural abscess, subdural empyema, focal otitic encephalitis, brain abscess, lateral sinus thrombosis, and otic hydrocephalus. These are serious conditions and potentially life-threatening. The signs and symptoms are persistent headache, lethargy, malaise, irritability, severe otalgia, fever, and nausea and vomiting, as well as signs of intracranial complications including stiff neck, focal seizures, ataxia, blurred vision, papilledema, diplopia, hemiplegia, aphasia, dysdiadochokinesia, intention tremor, cranial nerve deficits other than of the facial nerve, dysmetria, and hemianopia. Any child with an intracranial infection such as meningitis or brain abscess should be evaluated for middle ear disease.

Meningitis

Hematogenous spread is the most common route of spread of infection from the middle ear to the meninges. It also may occur by direct extension through a preformed pathway or retrograde thrombophlebitis. Meningitis as a complication of otitis media is treated with high doses of broad-spectrum antibiotics; the dose is then adjusted according to the cerebrospinal fluid (CSF) culture results. Tympanocentesis or tympanostomy tube insertion should be done urgently to obtain material for culture to identify the causative agent of the otitis media. Surgery such as cortical mastoidectomy or tympanomastoidectomy may be necessary when the patient is stabilized.

Subdural Abscess and Subdural Empyema

Subdural abscess usually results when cholesteatoma or infection destroys bone next to the dura and there is an accumulation of granulation tissue and purulent material. A subdural empyema is an accumulation of purulent material between the dura and the arachnoid membrane. Treatment consists of broad-spectum antibiotics as well as surgical drainage by a neurosurgeon and otolaryngologist.

Brain Abscess

An otogenic brain abscess can develop directly from an acute or chronic middle ear infection or from the development of an adjacent infection such as a lateral sinus thrombophlebitis, petrositis or meningitis. The diagnosis is based on presence of clinical signs and symptoms and on CT and MRI findings. The CSF may be culture-negative if the abscess is deep. Treatment includes broad-spectrum antimicrobial agents and surgical treatment of the primary focus. Treatment for the brain abscess may consist of only long-term parenteral antibiotic therapy.

Lateral Sinus Thrombosis

Lateral and sigmoid sinus thrombophlebitis arises from an adjacent mastoid infection in contact with the sinus wall through inflammation of the adventitia and is followed by penetration of the venous wall. A thrombus is formed after the infection has spread to the intima; the mural thrombus may become infected and may occlude the lumen. Embolization of the thrombus may cause additional disease. Treatment includes parenteral broad-spectum antimicrobial agents; anticoagulants are recommended by some experts, but consensus is lacking on this issue. Surgical treatment may include tympanostomy tube insertion alone or with tympanomastoidectomy. There is also controversy regarding opening the lateral sinus and removing the thrombus or ligating the jugular vein in the neck if the patient experiences repeated episodes of formation of septic emboli.

CHAPTER ONE HUNDRED AND NINETY-FIVE

Pediatric Chronic Sinusitis

Rodney P. Lusk

Key Points

- Pediatric sinusitis is of primarily infectious origin secondary to immaturity of the immune system and small developing sinuses.
- Allergy, immunodeficiency, and GERD may be important associated diseases.
- Imaging is not required for medical management in children. Plain films are not useful in children. CT scans should be obtained only if ethmoidectomy is being contemplated.
- Medical management consists primarily of parental education regarding the frequency of upper respiratory tract infections and medical management but also may include broad-spectrum oral antibiotics as indicated, topical nasal steroid sprays if the patient is allergic, and appropriate management of GERD.
- Surgical management is considered in patients in whom medical management has failed and who have infections outside the norm. Options include endoscopic anterior ethmoidectomy and conservative maxillary antrostomy, adenoidectomy (to rid the nasopharynx of possible contamination secondary to biofilms), and rarely, sphenoidotomy.
- Surgical intervention has not been shown to interrupt facial growth in children and, in appropriately selected patients, is very successful.

The diagnosis of acute and chronic sinusitis is a common primarily clinical diagnosis. It is associated with significant morbidity. In a quality of life assessment, Cunningham[1] and colleagues found that sinusitis had a more significant impact on children and their families than asthma, juvenile rheumatoid arthritis, and other chronic disorders.

Pediatric sinusitis is estimated to complicate approximately 5% to 10% of upper respiratory infections in early childhood.[2] Because children average six to eight upper respiratory illnesses per year, sinusitis is a very common problem.

Etiology

Age is clearly one of the most significant etiologic factors in pediatric sinusitis.[3] Because of their immature immune system, children are more likely to develop upper respiratory tract viral infections and associated acute sinusitis. A strong association has been recognized between sinusitis and respiratory viral infections. Viral infections are thought to cause significant ciliary dysfunction by decreasing the ciliary beat frequency or destroying the ciliary blanket.[4] These changes result in inflammation and edema that obstructs the ostium and increases the chance of establishing a bacterial infection of the sinuses. The ciliary dysfunction and edema will interrupt the drainage in the osteomeatal complex, predisposing the patient to the development of acute and possibly chronic sinusitis. As the ciliary function improves, the sinuses clear and the infection resolves in 80% of patients. The role of allergy in chronic sinusitis remains controversial. Rachelefsky[5] and coworkers[6] were the first to point out an association between allergic symptoms and sinusitis in children. The allergic reaction also will be associated with edema, and the same pathophysiology may be present. Huang[7] studied this issue for 5 years in children with perennial allergic rhinitis (PAR) and seasonal allergic rhinitis (SAR). Huang found that the prevalence of sinusitis was significantly higher among patients with PAR than among those with SAR, regardless of age or season. The patients with mold allergy PAR had a higher risk than those with nonmold allergies. Huang concluded that mold allergy is an important risk factor for sinusitis.

According to Ponikau and colleagues,[8] allergic fungal sinusitis may be an important factor in polypoid disease in adults. A strong correlation does appear to exist between the allergic response and fungal infections in some patients. The presentation of pediatric patients with allergic fungal sinusitis is different from that of adults. Children have more malleable bones and therefore incur a higher incidence of obvious abnormalities of their facial skeletons. Obstruction and the disease appear to be more unilateral.

The incidence of sinusitis and that of seasonal allergic symptoms do not, however, show a high degree of correlation. Numerous studies show that approximately 50% of children with sinusitis also have allergies; however, cause and effect have not been definitively demonstrated. A long-standing association among asthma, allergies, and chronic sinusitis is recognized. Dixon and associates[9] found a strong correlation between asthmatics and patients with rhinitis or sinusitis. In a recent study, Riccio and coworkers[10] found that allergic asthmatic children with chronic rhinosinusitis have a typical Th2 cytokine pattern. Nonallergic asthmatic children share a similar pattern. Riccio's group postulated that these findings suggest the existence of a common pathophysiologic mechanism shared by upper and lower airways, consistent with the concept of unified airway disease. This concept of unified airway disease has been increasingly recognized.[11]

Gastroesophageal reflux disease (GERD) may be associated with chronic sinusitis.[9] The incidence of GERD in children is not known, but Bothwell and associates are convinced that GERD is present in a majority of children with chronic sinusitis and effective treatment of the reflux can prevent sinus surgery.[12] Chambers and colleagues[13] found that GERD was the only reliable historical symptom that predicted a bad outcome in adults. There is, however, conflicting information in the literature. Suskind and coworkers[14] studied patients undergoing

antireflux surgery and who had failed medical management. In this very young group of patients (younger than 2 years), only two patients (14%) had severe chronic sinusitis and otitis media. Yellon and colleagues[15] also found an incidence of sinusitis in only 10% of patients with esophagitis proved by biopsy. These two studies lead one to conclude that sinusitis is not associated with GERD. Without a doubt, some children have sinusitis associated with GERD. Reflux may be intermittent and cannot be identified with a 24-hour pH probe study. If present, the GERD should be treated with a proton pump inhibitor, which could possibly prevent the need for surgery. Some investigators have recommended empirical therapy with a proton pump inhibitor before proceeding with surgical management.[16]

Without a doubt, the bacteria causing sinusitis are becoming more resistant to antibiotics, especially *Streptococcus pneumoniae*, which has made medical management of chronic sinusitis more difficult. The aerobic pathogens in pediatric chronic sinusitis include bacteria typical of acute sinusitis and organisms more characteristic of chronic disease, such as *Staphylococcus aureus*. These resistant strains have a significant effect on the usefulness of available antibiotic regimens for medical management.

Imaging

It is now clear that plain films do not adequately image the pediatric sinuses.[17] In the setting of acute sinusitis, Gwaltney and associates[18] showed a high incidence of opacification of the anterior ethmoid and maxillary sinuses with acute rhinovirus infections. For assessing the status of sinuses, the coronal CT study remains the imaging method of choice. Plain films do not reveal the true status of sinusitis in children.[19] In general, sinusitis is a clinical diagnosis, and radiographic imaging is not necessary in children for confirmation. This is in contrast with adults, for whom most otolaryngologists (73%) feel that a CT scan is required to confirm the diagnosis.[20] CT scans should be obtained when both the parents and the surgeon feel that surgical intervention is warranted. The CT scan is used primarily to look for anatomic abnormalities that would increase the risk of surgical complications and to help document the presence of disease. The CT scan should be obtained after a trial of maximum medical management that would include broad-spectrum antibiotics and topical nasal steroid sprays for at least 3 to 4 weeks. The CT scan should be obtained at the end of this course of management. It is difficult to assess the meaning of positive findings on a CT scan that has been obtained without prior medical management. It also is important to avoid being forced by an anxious or frustrated parent into operating on a child whose CT scan shows minimal disease. The best way to prevent this is to warn the parents, before obtaining the CT scan, that a small amount of disease does not necessarily require surgical intervention.

Treatment

Irrigation of the nose has been found to be efficatious; however, in the child, compliance can be a significant issue. Irrigation with saline has been found to be as effective as use of topical vasoconstrictors.[21] If the child can cooperate, irrigations should be included as a primary modality.

In general, cultures of the nasal cavity have not been readily used in the pediatric population. In fact, many laboratories will not run routine cultures of the nose. The literature is mixed regarding the efficacy of directed cultures. Jiang and coworkers[22,23] have shown that the bacteriology of the middle meatus was different from that found in the ethmoid bulla. They therefore concluded that the bacteriologic findings in the middle meatus may not reflect the real bacteriology in chronic sinusitis. Other studies have shown that bacteriologic findings in the middle meatus have a high correlation with antral punctures.[24] In the cooperative patient, endoscopically directed cultures of the middle meatus may be very useful, particularly in communities with increased resistance. If the patient is uncooperative, then broad-spectrum antibiotics would be appropriate.

Medical Management

Because antibacterial therapy most often is empirically chosen to treat the disorder, knowledge of the typical etiologic agents, as well as awareness of the antibacterial susceptibility profiles in a given community, is of paramount importance.

Much is unknown about antibiotic therapy and chronic sinusitis. Recent advances, however, include recognition of the importance of nontypable *Haemophilus influenzae* unresponsive to first-generation cephalosporins and of tetracycline-resistant gram-positive cocci and the increasing emergence of beta-lactamase–positive respiratory pathogens such as *H. influenzae* and *Moraxella catarrhalis*. These realities now mandate the more conservative use of antibiotics in upper respiratory tract infections and the use of newer therapeutic agents for acute and chronic sinusitis.

One subject on which most authors have agreed in recent publications on pediatric sinusitis is that patient expectations for antibotic usage need to be altered. Currently, antibiotics often are used to treat viral upper respiratory tract infections, even though they usually are ineffective. This frequent inappropriate antibiotic use contributes to the emergence of drug-resistant bacterial pathogens. It is frequently difficult to assess whether the infection is viral or has been complicated by a bacterial infection and would subsequently improve with antibiotic therapy. Reviews in the literature emphasize the need for primary medical, not surgical, management of sinusitis. In the most resistant cases, however, surgery can have a significant therapeutic role, as outlined later in this chapter.

Chronic sinusitis is best treated with broader spectrum antibiotics. For the most resistant strains of pneumococci, File and colleagues[25] found the newer form of amoxicillin-clavulanate (2000 mg-125 mg) and the fluoroquinolones[26] to be highly active against these cultured isolates from patients with community-acquired respiratory tract infection. These drugs, however, should be saved for the most resistant infections.

There are proponents of the use of long-term, low-dose therapy with erythromycin in patients who do not respond to aggressive medical management.[27] Don and associates have recommended intravenous antibiotic therapy as an alternative to endoscopic sinus surgery.[28] They believed this was warranted because of the risk of interference with facial skeletal growth and complications of endoscopic sinus surgery. Conclusive evidence now shows that endoscopic sinus surgery does not interfere with facial growth,[29] and the risks of endoscopic sinus surgery are small. Don and associates[28] found that 89% of the patients had complete resolution of symptoms after intravenous therapy with selective adenoidectomy; the remaining 11% failed to respond to intravenous therapy and required endoscopic surgery. In this study, the criteria for performing selective adenoidectomy are not clear, and significant complications were reported with intravenous therapy as well. Intravenous therapy is, however, a potential modality of therapy in resistant cases and can be used for complications of acute or chronic sinusitis.

Some investigators have recommended topical aerosolized antibiotics, but others have found them to be ineffective.[12] At this time, a firm recommendation about the use of topical aerosolized antibiotics cannot be made.

Prospective studies are lacking in the use of antihistamines and decongestants. In theory, decongestants would decrease the amount of edema and open the ostia. Topical steroids have been shown to decrease edema within 2 weeks and may be of modest benefit. Topical steroids have been shown to be safe and not to interrupt growth.[30]

Some investigators have used intravenous immune globulin (IVIG) to treat patients who do not have immune deficiencies but have chronic sinusitis.[31] They concluded that IVIG was successful in improving the medical management of chronic sinusitis. They also thought the mechanisms by which IVIG may be helpful are probably not based on the concept of immune replacement therapy, but more likely as an immune or inflammatory modulating agent.

Surgical Management

There is little doubt that chronic sinusitis–like symptoms occur in children with large obstructive adenoid pads (Fig. 195-1). If the obstructive adenoid pad is not removed, the nasal cavity cannot become healthy. Several studies indicate that adenoidectomy improves the signs and symptoms of sinusitis.[32,33] The efficacy of the treatment

Figure 195-1. Endoscopic view of enlarged adenoid pad causing nasal obstruction and symptoms compatible with obstructive sleep apnea (OSA).

Figure 195-2. Endoscopic view of mucosa intact over the lamina papyracea and basal lamella.

appears to be independent of the size of the adenoid pad. Recently, biofilms have been discovered covering the adenoid tissue in children with chronic sinusitis.[34,35] Such biofilms may constitute a repository for bacterial seeding of the middle meatus; this theory is supported by the efficacy of adenoidectomy regardless of the size of the adenoid pad. Certainly more work needs to be performed in this area before a firm correlation can be established. Good prospective studies assessing the efficacy of adenoidectomy in well-documented cases of sinusitis have yet to be performed. Overall, adenoidectomy can be expected to help relieve the symptoms of chronic sinusitis in approximately 50% of patients. A majority of pediatric otolaryngologists perform an adenoidectomy as the initial step in surgical management of chronic sinusitis.[36]

Some investigators believe that endoscopic surgery is rarely indicated. Endoscopic sinus surgery has become, however, a primary method of surgical therapy for chronic sinusitis after adenoidectomy. The indications for endoscopic sinus surgery remain controversial. The Consensus Panel[37] preferred to divide its indications into absolute and possible indications:

Absolute indications include (1) complete nasal airway obstruction in cystic fibrosis due to massive polyposis or closure of the nose by medialization of the lateral nasal wall; (2) antrochoanal polyp; (3) intracranial complications; (4) mucoceles and mucopyoceles; (5) orbital abscess; (6) traumatic injury to the optic canal; (7) dacryocystorhinitis due to sinusitis and resistant to medical treatment; (8) fungal sinusitis; (9) some meningoencephaloceles; and (10) some neoplasms.

Relative or possible indications, which are present in the vast majority of patients, include chronic rhinosinusitis that persists despite optimal medical management and after the exclusion of any systemic disease. Optimal management includes 4 to 6 weeks of adequate broad-spectrum antibiotics and treatment of any concomitant diseases.

According to the Consensus Panel,[37] only a small fraction of all children suffering from chronic sinusitis will require functional endoscopic sinus surgery (FESS), but these children account for a majority of surgical patients, and the procedure has gained popularity. Reported success rates, defined mainly on the basis of improvement over preoperative symptoms, have been encouraging and ranged between 71% and 93%. Hebert and Bent[38] performed a meta-analysis that revealed a success rate of 88.4% with surgical management in children in whom medical management had failed to effect improvement. With more experience, many surgeons have modified their techniques to be less aggressive, with the aim of preservation of mucosa. Advances in instrumentation, including the advent of the microsurgical débrider and sharp through-biting instruments, also have contributed to realization of this goal. It is now possible to preserve mucosa over the lamina papyracea, middle turbinate, and basal lamella (Fig. 195-2). Extensive sphenoethmoidectomy usually is not justified in children unless they have symptomatic polyps secondary to cystic fibrosis or allergic fungal sinusitis (Fig. 195-3).

Most surgeons perform a limited procedure that involves an anterior ethmoidectomy and maxillary antrostomy.[36] The size of the maxillary antrostomy continues to be controversial. Many surgeons have become more conservative in the size of their antrostomy. The mucosa in the area of the root of the middle turbinate should not be removed. It is important to leave mucosa in this area to prevent scarring in the frontal recess. If the ostium can be seen with a 30-degree telescope, then it does not need to be enlarged. If, however, there is evidence of a polypoid mucosa in the ostium or if it is edematous and can only be identified with a seeker, then it may be enlarged posteriorly into the fontanelle, with through-biting instruments. On occasion, usually less than 30% of the time, the posterior ethmoid sinuses will need to be entered. In unusual circumstances, less than 10% of the time, the sphenoid sinus or frontal sinuses will need to be entered. The frontal recess in children is the source of the frontal sinuses, and frontal sinuses are not developed in children. Therefore, instrumentation of this area should be performed very carefully.

When the procedure was originally performed, a second-look operation that included cleaning of the cavity was believed to be necessary. In the pediatric population, this meant a second general anesthetic procedure. Ramadan[39] found that treatment with intravenous dexamethasone during endoscopic sinus surgery was safe and was helpful in reducing scarring and swelling noted during the second-look procedure. Use of corticosteroids was particularly helpful in children with asthma, lower CT scores, no exposure to smoking, and older than 6 years of age. Walner and associates[40] found that avoiding a second look did not increase the incidence of revision surgery. Fakhri and coworkers[41] concluded that second-look endoscopy did not decrease the incidence of revision surgery; therefore, the second look was of no benefit after routine FESS. It has now become more common practice to use some type of absorbable stenting material in children, to omit the second look. Most surgeons do not perform a second-look operation.[36]

Many areas of surgical management of sinusitis need further investigation but none is more important than the impact on facial growth. In two studies in animal models, piglets showed interruption of facial growth on the side of endoscopic surgery, but the animals clinically did not show evidence of abnormal growth.[42,43] Lund and associates[44] have

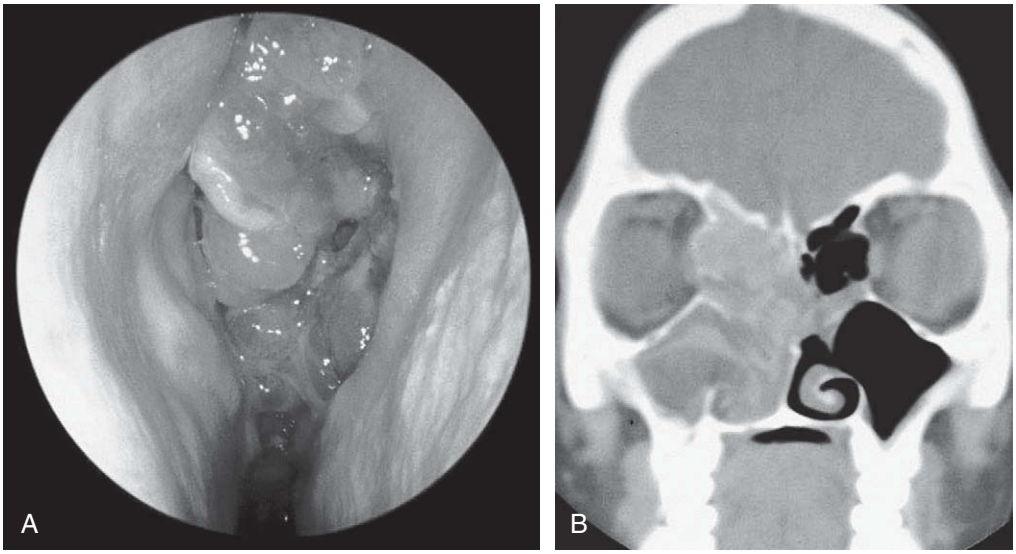

Figure 195-3. **A,** Endoscopic view of polyps secondary to fungal sinusitis. **B,** Computed tomography scan of a patient with fungal sinusitis.

evidence that very aggressive surgical management of midface lesions is not associated with interruption of facial growth. Wolf and colleagues[45] did not note any evidence of interruption of facial growth. However, these two studies did not perform accurate measurements of the facial skeleton.

Bothwell and associatess[29] sought to determine whether FESS performed in children with chronic rhinosinusitis alters facial growth. They evaluated 67 children with a mean age of 3.1 years at presentation. The patients were evaluated for facial growth 10 years later, at a mean age of 13.2 years. In this series, 46 children underwent FESS and 21 children did not undergo FESS and acted as a control group. Quantitative anthropomorphic analysis was performed using 12 standard facial measurements on both groups. A facial plastic surgery expert performed blinded qualitative facial analysis on standardized photographs. Both quantitative and qualitative analyses showed no trends or statistical significance in changes of facial growth between children who underwent FESS and those who had chronic sinusitis but did not undergo FESS. The data also showed no deviations, or trends toward deviation, from the standard norms in children. Bothwell's investigators concluded that evidence for an adverse effect of FESS on facial growth in children was lacking.

Large clinical studies are necessary to further elucidate the pathophysiology and medical and surgical management of chronic sinusitis. These studies will be difficult to perform because of the large numbers required.

CHAPTER ONE HUNDRED AND NINETY-SIX

Pharyngitis and Adenotonsillar Disease

W. Peyton Shirley

Audie L. Woolley

Brian J. Wiatrak

Key Points

- An understanding of the anatomy, embryology, and physiology of Waldeyer's ring is important to learning how to diagnose and treat disease in this region.
- The physician must be familiar with and be able to diagnose a wide range of infections that may be seen in Waldeyer's ring. Once the diagnosis is made, the physician needs to know the treatment options and the potential complications that may result from pharyngitis and adenotonsillar disease.
- Adenotonsillar hypertrophy is a common cause of upper airway obstruction in children that has a wide range of clinical manifestations and complications. Newer research suggests that upper airway obstruction potentially leads not only to harmful physiologic alterations but also to pathologic changes in behavior and neurocognitive development.
- Proper preoperative assessment is crucial. A good history and thorough physical examination are the most important part of appropriate treatment of adenotonsillar disease. The physician must be familiar with and know how to optimally use all the available diagnostic tests and procedures. Finally, the surgeon must have a thorough understanding of the proper indications for adenotonsillectomy.
- Many techniques have been and continue to be used to perform adenotonsillectomy. The physician must have knowledge of all the surgical options available and must make an informed choice about the method. Whatever technique is chosen, careful surgical technique is important as well as an awareness of potential complications. The surgeon must be able to handle the potential complications but, more important, know how to avoid them.

Infectious and inflammatory diseases involving the pharynx, tonsils, and adenoids account for a significant proportion of childhood illnesses and pediatric health care expenditures. They often result in two of the most common surgical procedures of childhood, tonsillectomy and adenoidectomy (Fig. 196-1). Clinical research has now helped illuminate this vast area of pediatric otolaryngology, including the effects of adenotonsillar hypertrophy on obstructive sleep apnea and the many possible sequelae of obstructive sleep apnea, the microbiologic flora of the tonsils and adenoids and their role in chronic adenotonsillar hypertrophy, the relationship between adenotonsillar hypertrophy and craniofacial growth, and new techniques for adenotonsillectomy with improved management of perioperative morbidity. This chapter reviews the current understanding of pharyngitis and adenotonsillar disease processes.

History

Celsus was the first to report removal of the tonsils.[1] Describing his surgical technique, Celsus indicated that "the tonsils are loosened by scraping around them and then torn out."[1] Hemostasis was obtained using a vinegar mouthwash and painting the tonsillar fossa with a medication to reduce bleeding.[2] Aëtius of Amida on the Tigris described a technique for tonsillectomy in the first half of the sixth century, in which a hook was used to snare the tonsil and a knife was used for amputation. He warned of the severe dangers of hemorrhage when excision was too deep.[3] Subsequent surgical techniques were described by Paul of Aegina in 625, and Physick described a forceps to facilitate extirpation of the tonsil, which became the forerunner of the modern tonsil guillotine.[1,4] Mackenzie improved on the Physick tonsillotome and popularized its use for surgery of the tonsils in the late nineteenth century.[5]

The adenoids were first described by the Danish physician Meyer. In his 1868 paper "Adenoid vegetations in the nasopharyngeal cavity," Meyer described in detail his technique of posterior rhinoscopy to diagnose adenoid hypertrophy and recommended removal of adenoid tissue with the aid of a ring knife.[6] In 1885, Gottstein described the first adenoid curette.[6]

Crowe and colleagues[7] reviewed 1000 consecutive tonsillectomies performed between 1911 and 1917. In the study "Relation of tonsillar and nasopharyngeal infection to general systemic disorders," they provided a detailed description of a meticulous surgical technique by sharp dissection and described using the Crowe-Davis mouth gag. The low complication rate they described compares favorably with rates in modern reports of tonsillectomy.

Anatomy

Waldeyer's Ring

Together, the lingual tonsils anteriorly, the palatine tonsils laterally, and the pharyngeal tonsils (adenoids) posterosuperiorly form a ring of lymphoid or adenoid tissue around the upper end of the pharynx known as Waldeyer's tonsillar ring. All the structures of Waldeyer's ring have similar histology and, presumably, similar functions.

Palatine Tonsil

The palatine tonsil represents the largest accumulation of lymphoid tissue in Waldeyer's ring and, in contrast to the lingual and pharyngeal tonsils, constitutes a compact body with a definite thin capsule on its deep surface.[8] Tonsillar crypts, blind tubules from the epithelium on the surface of the tonsil that are lined with stratified squamous epithelium, extend deep into this tissue.

The tonsillar capsule is a specialized portion of the pharyngobasilar fascia that covers the surface of the tonsil and extends into it to form septa that conduct the nerves and vessels.[8] The tonsil is not, therefore, easily separated from its capsule, but the capsule is united largely by loose connective tissue to the pharyngeal muscles. One can easily dissect the tonsil from its normal position by separating the capsule from the muscle through this loose connective tissue.

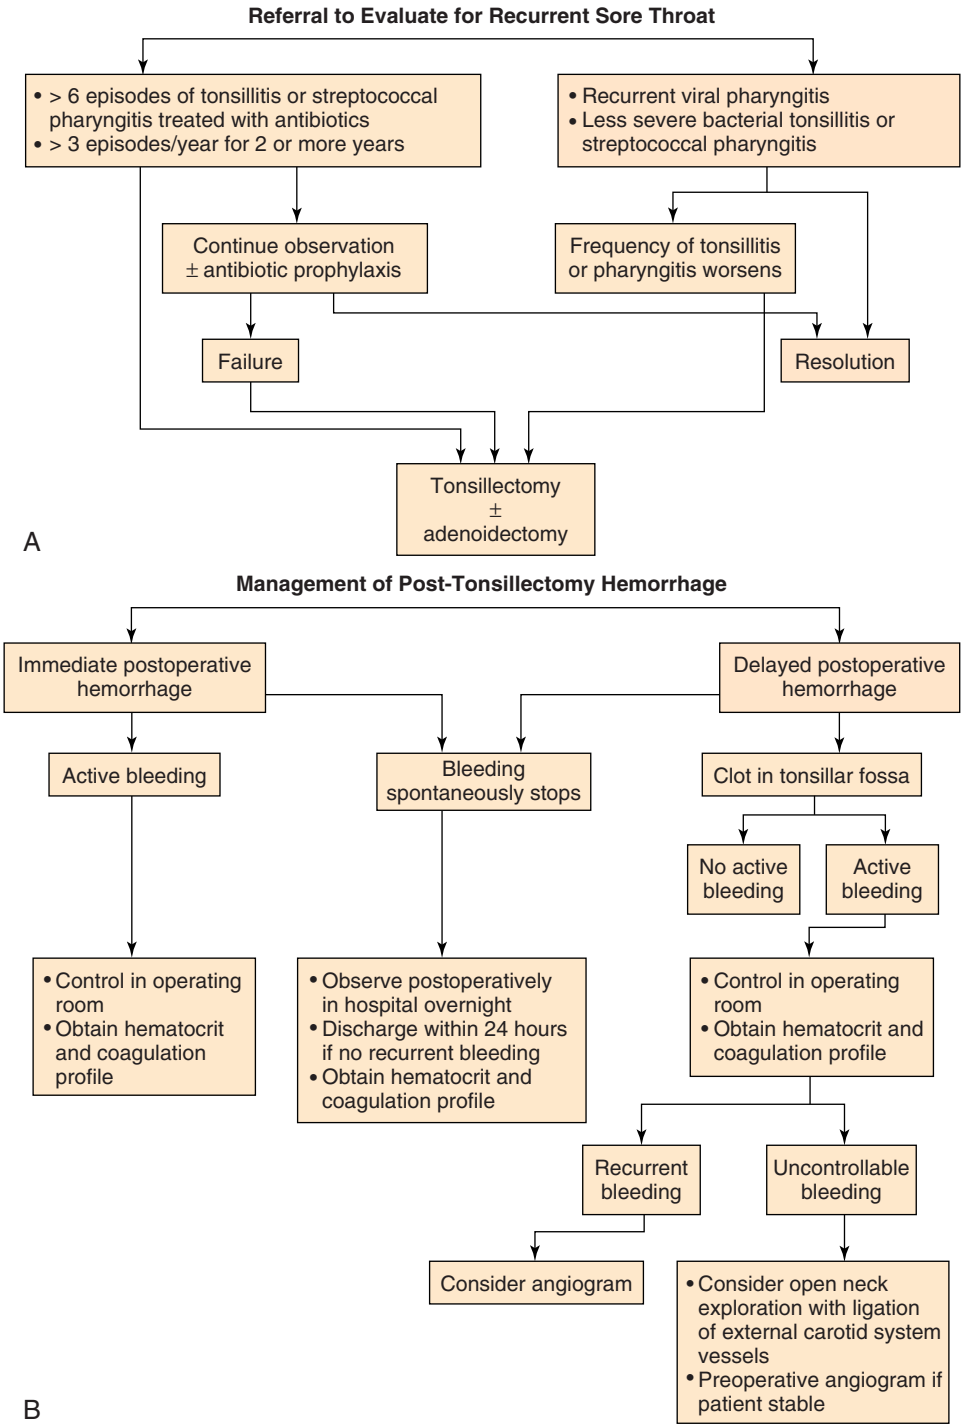

Figure 196-1. Management algorithms for pediatric pharyngitis and adenotonsillar disease. **A,** Algorithm for evaluation of a patient referred for recurrent sore throat. **B,** Algorithm for management of post-tonsillectomy hemorrhage. *Continued*

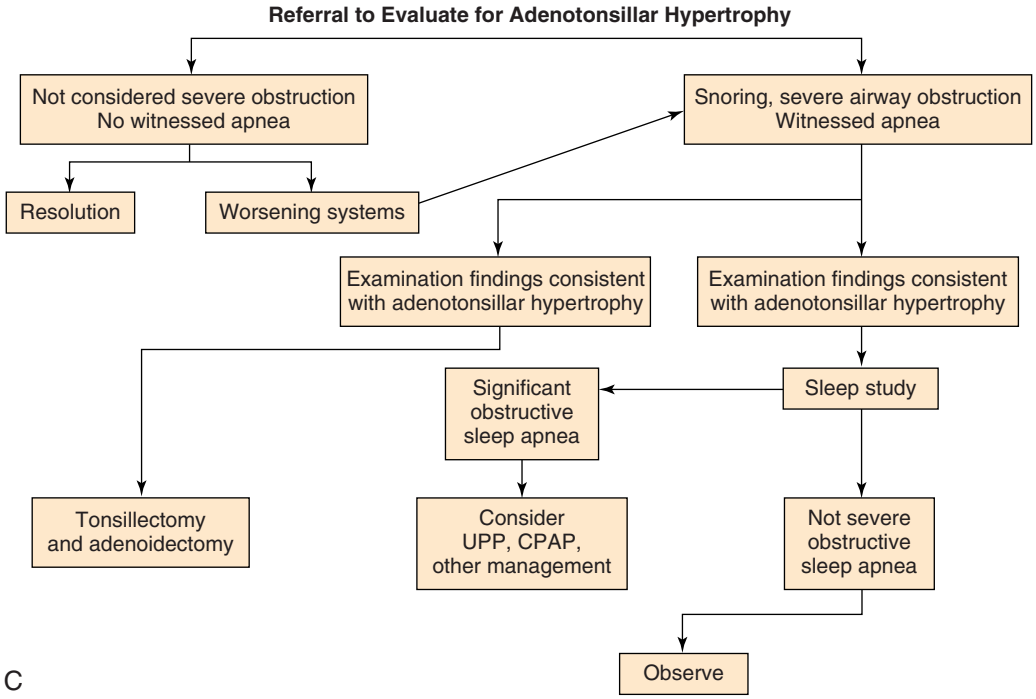

Figure 196-1, cont'd. **C,** Algorithm for evaluation of a patient referred for adenotonsillar hypertrophy.

The tonsillar fossa is composed of three muscles: the palatoglossus muscle, which forms the anterior pillar; the palatopharyngeal muscle, which is the posterior pillar; and the superior constrictor muscle of the pharynx, which forms the larger part of the tonsillar bed.[8] The muscular wall is thin, and immediately against it on the outer wall of the pharynx is the glossopharyngeal nerve. This nerve can be easily injured if the tonsillar bed is violated, and not uncommonly the nerve is temporarily affected by edema after tonsillectomy, which produces both a transitory loss of taste over the posterior third of the tongue and referred otalgia.

The arterial blood supply of the tonsil enters primarily at the lower pole, with branches also at the upper pole. There are typically three arteries at the lower pole: the tonsillar branch of the dorsal lingual artery anteriorly, the ascending palatine artery (a branch of the facial artery) posteriorly, and the tonsillar branch of the facial artery between them that enters the lower aspect of the tonsillar bed.[8] At the upper pole of the tonsil, the ascending pharyngeal artery enters posteriorly, and the lesser palatine artery enters on the anterior surface. The tonsillar branch of the facial artery is the largest. Venous blood drains through a peritonsillar plexus about the capsule.[8] The plexus drains into the lingual and pharyngeal veins, which in turn drain into the internal jugular vein.

The nerve supply of the tonsillar region is through the tonsillar branches of the glossopharyngeal nerve about the lower pole of the tonsil and through the descending branches of the lesser palatine nerves, which course through the pterygopalatine ganglion.[8] The cause of referred otalgia with tonsillitis is through the tympanic branch of the glossopharyngeal nerve. Efferent lymphatic drainage courses through the upper deep cervical lymph nodes, especially the jugulodigastric or tonsillar node located behind the angle of the mandible.[8]

Adenoids

The adenoid or pharyngeal tonsils form the central part of the ring of lymphoid tissue surrounding the oropharyngeal isthmus. The adenoid is composed of lymphoid tissue, with its apex pointed toward the nasal septum and its base toward the roof and posterior wall of the nasopharynx. The adenoid is covered by a pseudostratified ciliated columnar epithelium that is plicated to form numerous surface folds. The adenoid develops as a midline structure by the fusion of two lateral primordia that become visible during early fetal life, are fully developed during the seventh month of gestation, and continue to grow until the fifth year of life, often causing some airway obstruction.[6,9] Thereafter, the adenoid gradually atrophies, the nasopharynx grows, and the airway improves.[10]

The blood supply and drainage are from the ascending pharyngeal artery, the ascending palatine artery, the pharyngeal branch of the maxillary artery, the artery of the pterygoid canal, and contributing branches from the tonsillar branch of the facial artery.[9] Venous drainage is to the pharyngeal plexus, which communicates with the pterygoid plexus and then drains into the internal jugular and facial veins. The nerve supply is from the pharyngeal plexus. The efferent lymphatic drainage of the adenoids is to the retropharyngeal and pharyngomaxillary space lymph nodes.[9]

Immunology of the Adenoids and Tonsils

The adenoids and tonsils are predominantly B-cell organs; B cells account for 50% to 65% of all adenoid and tonsillar lymphocytes.[11] Approximately 40% of adenoid and tonsillar lymphocytes are T cells, and 3% are mature plasma cells. Conversely, 70% of the lymphocytes in peripheral blood are T cells.[12] The immunoreactive lymphoid cells of the adenoids and tonsils are found in four distinct areas: the reticular cell epithelium, the extrafollicular area, the mantle zone of the lymphoid follicle, and the germinal center of the lymphoid follicle.[11]

Ample evidence shows that the adenoids and tonsils are involved in inducing secretory immunity and regulating secretory immunoglobulin production. They contain a system of channels covered by specialized endothelium that can mediate antigen uptake much like Peyer's patches of epithelium in the bowel.[13] Both the adenoids and tonsils are favorably located to mediate immunologic protection of the upper aerodigestive tract as they are exposed to airborne antigens. Both organs, specifically the tonsils, are particularly designed for direct transport of foreign material from the exterior to the lymphoid cells.[11] This is in contrast to lymph nodes, which depend on antigenic delivery through afferent lymphatics. The tonsillar crypts are covered by stratified squamous epithelium. There are 10 to 30 of these crypts in the tonsils, and they are ideally suited to trapping foreign material and transporting it to the lymphoid follicles.[11]

The tonsils and adenoids rank among the secondary lymphatic organs. Intratonsillar defense mechanisms eliminate weak antigenic

signals. Only when additional higher antigenic concentrations are presented does proliferation of antigen-sensitive B cells occur in the germinal centers.[11] Low antigen doses effect the differentiation of lymphocytes to plasma cells, whereas high antigen doses produce B-cell proliferation. The generation of B cells in the germinal centers of the tonsils is considered by Siegel to be one of the most essential tonsillar functions.[14]

Immunoglobulins (Igs) produced by the adenoid include IgG, IgA, IgM, and IgD.[11] IgG appears to pass into the nasopharyngeal lumen by passive diffusion.[11] The tonsil produces antibodies locally as well as B cells, which migrate to other sites around the pharynx and periglandular lymphoid tissues to produce antibodies.

T-cell functions, such as interferon-γ production and, presumably, production of other important lymphokines, have been shown to be present in tonsils and adenoids.[11] The role played by tonsillar and adenoid T cells in tumor response is still unknown.

The human tonsils are immunologically most active between ages 4 and 10 years. Involution of the tonsils begins after puberty, resulting in a decrease of the B-cell population and a relative increase in the ratio of T to B cells.[11,15] Although the overall Ig-producing function is affected, considerable B-cell activity is still seen in clinically healthy tonsils even at age 80 years.[16] The situation is different in disease-associated changes, such as when recurrent tonsillitis and adenoid hyperplasia are observed. Inflammation of the reticular crypt epithelium results in shedding of immunologically active cells and decreasing antigen transport function with subsequent replacement by stratified squamous epithelium.[17] These changes lead to reduced activation of the local B-cell system, decreased antibody production, and an overall reduction in density of the B-cell and germinal centers in extrafollicular areas.[17] In contrast to recurrent tonsillitis, the changes are less pronounced in adenoid hyperplasia, in which the immunoregulatory conditions necessary for maintenance of the B-cell population are well preserved. The reason is most likely that the reticular epithelium is less affected in inflammation of adenoids than of tonsils.

Reports conflict regarding the immunologic consequences of tonsillectomy and adenoidectomy, yet it is clear that no major immunologic deficiencies result from these procedures.[16,18] Ogra[19] showed a three- to fourfold drop in titers in children previously immunized with live poliovirus vaccine. Attempts to vaccinate seronegative children subjected to tonsillectomy and adenoidectomy have resulted in delayed and lowered nasopharyngeal secretory immune responses as measured by IgA antibodies to the poliovirus.[19] Fortunately, poliovirus epidemics are no longer an annual threat. Serum IgA levels in patients who had undergone tonsillectomy were lower than in age-matched controls, but this immunologic change did not appear to be clinically significant. Some studies actually point to improved immunologic activity after tonsillectomy. One study showed better neutrophil chemotaxis after tonsillectomy, and another demonstrated increased IgG and IgM production, possibly as a result of unblocking of the suppression that the immune system was subject to before tonsillectomy.[20,21] One large study, with a cohort of 1328 children, showed no higher incidence of atopic disease (asthma, allergic rhinitis, and eczema) in children who had adenotonsillectomy prior to age 8 than in those who had not undergone surgery.[22]

It is clear that the adenoids and tonsils are active immunologic organs that generally reinforce the mucosal immunity of the entire upper aerodigestive tract. The immunologic role of these organs should be considered before a patient undergoes adenoidectomy or tonsillectomy; nonetheless, clinical consideration still forms the actual basis of surgery.

Bacteriology

Establishment of normal flora in the upper respiratory tract begins at birth. *Actinomyces*, *Fusobacterium*, and *Nocardia* are acquired by age 6 to 8 months.[23] Subsequently, *Bacteroides*, *Leptotrichia*, *Propionibacterium*, and *Candida* are also established as part of the oral flora.[24] *Fusobacterium* populations reach high numbers after dentition and reach maximal numbers at 1 year of age.[23] The ratio of anaerobic to aerobic bacteria in saliva is approximately 10:1,[24] because of variations in oxygen concentration throughout the oral cavity.

Healthy children up to 5 years of age can harbor known aerobic pathogens. Ingvarsson and colleagues[24] reported that *Streptococcus pneumoniae* was recovered in 19% of healthy children, *Haemophilus influenzae* in 13%, group A *Streptococcus* in 5%, and *Moraxella (Branhamella) catarrhalis* in 36%. The frequency of pathogens decreases with age, possibly because of greater immunity. Changes in the pharyngeal bacteria flora noted during viral illnesses are thought to be a result of the increased adherence of *Staphylococcus aureus* as well as gram-negative enteric organisms.[25] Oral pharyngeal colonization during illness-free periods was found to vary from 12% to 18% for gram-negative enteric organisms and from 5% to 14% for *S. aureus*.[26] During an episode of viral upper respiratory tract infection, the colonization rates for gram-negative organisms and *S. aureus* increased to 60% and 43%, respectively.

Brodsky and Koch[27] found substantive differences between the types and numbers of aerobic bacteria found in nondiseased and diseased adenoids. The core samples of normal adenoids showed that 75% of children who were relatively free of upper respiratory disease, otitis media, and symptoms of adenoid obstruction had either no bacterial growth on culture or bacteria that are considered part of the normal flora and not pathogenic. Core samples in adenoids of only 45% of children who had chronic adenoid infection and 39% who had obstructive adenoid hypertrophy had no bacteria growth or only normal flora; the bacteria found in these children were more likely to be β-lactamase producers.

Infections of Waldeyer's Ring

Many organisms can induce inflammation of Waldeyer's ring. These include aerobic as well as anaerobic bacteria, viruses, yeasts, and parasites. Some of the infectious organisms are part of the normal oral pharyngeal flora, and others are external pathogens. Because the oropharynx is colonized by many organisms, most infections of Waldeyer's ring are polymicrobial. These organisms work synergistically and can be demonstrated in mixed aerobic and anaerobic infections.[28]

Another feature of mixed infections is the ability of organisms resistant to an antimicrobial agent to protect an organism susceptible to that agent by the production of an antibiotic-degrading enzyme that is secreted into the tissues.[29] Because of the polymicrobial nature of most infections around Waldeyer's ring, it is often difficult to interpret data derived from clinical samples obtained from mucosal surfaces and to differentiate between organisms that are colonized and those that are invaders.

Viruses

The classic "common cold" is the most frequent cause of otolaryngologic infection in children. A multitude of offending viral pathogens have been implicated in causing pharyngitis, including rhinovirus, influenzavirus, parainfluenza virus, adenovirus, coxsackievirus, echovirus, reovirus, and respiratory syncytial virus. Viral pharyngitis is usually mild in manifestations, with patients complaining of a sore throat and dysphagia. Most patients have a fever with erythema of the pharyngeal mucosa. The tonsils may be enlarged but frequently there is no associated exudate.

Herpangina caused by coxsackievirus is characterized by small vesicles with erythematous bases that become ulcers and are spread over the anterior pillar tonsils, palate, and posterior pharynx (Fig. 196-2). Herpes simplex virus commonly causes the well-known "cold sore." This virus can also cause exudative or nonexudative pharyngitis, mainly in older children and young adults. In younger children, the herpesvirus may induce gingivostomatitis.

Management of viral infections is nonspecific and symptomatic. Antibiotics are helpful in cases of secondary bacterial infection.[30]

Epstein-Barr Virus

One particular type of viral infection that deserves special attention is the Epstein-Barr virus (EBV). EBV induces the mononucleosis syndrome, which consists of high fever; general malaise; large, swollen, dirty-gray tonsils (Fig. 196-3); sore throat; dysphagia; and odynophagia. Petechiae located at the junction of the hard and soft palate are highly

Figure 196-2. Viral ulcer on the right tonsil consistent with coxsackievirus infection.

Figure 196-3. Tonsillar hypertrophy and mononucleosis with significant airway obstruction.

suggestive of EBV infection, although not pathognomonic. Often patients with EBV infection have hepatosplenomegaly with resultant liver damage. The most common method of transmission is oral contact.

Diagnosis of EBV is confirmed by laboratory studies. A differential blood count showing 50% lymphocytosis with 10% atypical lymphocytes is characteristic of EBV infection. Serologic studies include monospot and other serum heterophil antibody titer measurements. Results of these tests may be negative initially, and repeat testing in 1 to 2 weeks is warranted if clinical suspicion of EBV infection is strong. The heterophil antibody titers are detected by the Paul-Bunnell-Davidsohn or ox-cell hemolysis test. If the heterophil antibody agglutination test result is negative, the disease may still be present. Only 60% of patients with infectious mononucleosis have a positive result within the first 2 weeks after onset of the illness; 90% have a positive result 1 month after onset.[31] EBV-specific serologic assays have become the method of choice for confirmation of acute or convalescent EBV infection. Figure 196-4 shows the serologic response time. Management of this condition is symptomatic. Recovery may take weeks, and antibiotics are used to treat secondary bacterial infections. Ampicillin should be avoided because a rash may occur despite previous intake without similar reactions. Upper airway obstruction from severely enlarged tonsils can be life-threatening and should be managed promptly with the insertion of a nasopharyngeal airway and short-term high-dose steroid therapy. If the obstruction is severe and unrelieved by these measures, a tonsillectomy or tracheotomy may be necessary.

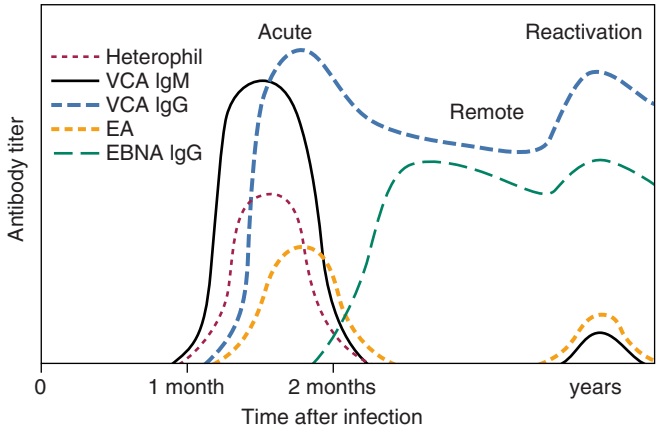

Figure 196-4. Serologic response time in diagnosis of EBV infection. EA, early antigen; EBNA, EBV nuclear antigen; Ig, immunoglobulin; VCA, viral capsid antigen. *(From Gulley ML. Molecular diagnosis of Epstein-Barr virus-related diseases.* J Mol Diagn. *2001;3:1-10.)*

Candida

Candidiasis can result in severe pharyngitis, particularly in patients who are immunocompromised or who have been undergoing treatment with antimicrobial agents. It is a fairly unmistakable syndrome consisting of coherent white plaques on the oral pharyngeal mucosa. Removal of these plaques may reveal a raw, bleeding surface. Management is with nystatin or, in refractory cases, fluconazole.

Neisseria

Pharyngitis as a result of *Neisseria gonorrhoeae* is common in homosexual men. It has been detected in 6% of adolescents with acute pharyngitis.[32] Although the infection is often asymptomatic, it can result and persist after treatment. Acute exudative tonsillitis is a manifestation of gonococcal pharyngitis. The clinical syndrome may range from an asymptomatic to an exudative pharyngitis, but most cases tend to fall toward the exudative pharyngitis end of the spectrum. Nonetheless, disseminated gonococcemia can result even from mild or asymptomatic infection. Penicillin and tetracycline are the most effective therapeutic agents.

Vincent's Angina

Vincent's angina is secondary to *Spirochaeta denticulata* and Vincent's fusiform bacillus *Borrelia vincentii* (*Treponema vincentii*). This condition arises slowly, manifesting both mild local and systemic symptoms. The infection arises most commonly in overcrowded conditions. Patients present with complaints of high fever, headache, sore throat, and physical findings of cervical lymphadenopathy and a membrane on the tonsil that, when removed, reveals an ulcer that remains confined to the surrounding tissue and usually heals in 7 to 10 days.[33] Management consists of penicillin therapy. Local treatment in the form of oral hygiene is helpful. This condition may be confused with trench mouth, which is caused by the same organisms but in which oral cavity ulcers include the gums and oral mucous membranes.[34]

Syphilis

Treponema pallidum infections in both the primary and secondary stages of syphilis can be associated with oral pharyngeal lesions. In primary syphilis, oral chancres appear about 3 weeks after exposure. Grayish superficial mucous membrane patches surrounded by an erythematous border are generally found in patients with secondary syphilis.

Corynebacterium diphtheriae

The incidence of *Corynebacterium diphtheriae* infection has declined markedly since the introduction of diphtheria vaccination. This organism causes an early exudative pharyngotonsillitis with a thick pharyngeal membrane. Infection can then spread to the throat, tonsils, palate, and larynx.[35] *C. diphtheriae* organisms also produce a lethal exotoxin

that can damage cells in distant organs. Today only 200 to 300 cases of diphtheria occur in the United States each year, usually—but not exclusively—in people who have not been immunized.[36] The organism is a gram-positive pleomorphic aerobic bacillus that can be identified in a routine throat culture, particularly when the microbiologist is made aware of a clinical suspicion of this diagnosis. Only toxigenic strains infected with a bacteriophage can cause diphtheria.[30] Laryngeal inflammation combined with an exudative, necrotic, gray pharyngeal membrane may result in airway obstruction. Removal of this membrane causes bleeding. Early diagnosis is critical, and the goal of therapy is neutralization of unbound toxin with antitoxin. Myocarditis and neurologic sequelae resembling features of Guillain-Barré syndrome or poliomyelitis may result.[35,36] The organism is identified by fluorescent antibody studies. The presence of Klebs-Löffler bacillus in the membrane can be diagnosed with Gram staining.[34] Because diphtheria is an emergency condition, antitoxin must be given in the first 48 hours of onset to be effective. Airway obstruction should be managed with tracheotomy. Penicillin in high doses should be administered.

Streptococcal Tonsillitis-Pharyngitis

Group A *Streptococcus* is the most common bacterial cause of acute pharyngitis.[37] The public health importance of this infection lies not only in its frequency but also on the fact that it is a precursor of two serious sequelae, acute rheumatic fever and poststreptococcal glomerulonephritis. Although the incidence of rheumatic fever has decreased, all groups of β-hemolytic streptococci have been associated with rheumatic fever.[23]

Acute streptococcal tonsillitis is a disease of childhood, with a peak incidence at about 5 to 6 years of age, but can occur in children younger than 3 years and in adults older than 50 years.[34] Outbreaks may arise in epidemic forms in institutional settings such as recruit camps and daycare facilities. Acute tonsillitis manifests as a dry throat, malaise, fever, fullness of the throat, odynophagia, dysphagia, otalgia, headache, limb and back pain, cervical adenopathy, and shivering. Examination reveals a dry tongue, erythematous, enlarged tonsils, and yellowish white spots on the tonsils. In severe cases, a tonsillar or pharyngeal membrane or purulent exudate may exist along with jugulodigastric lymph node enlargement.[34]

The diagnosis of acute tonsillitis is made mainly on clinical grounds. The clinical manifestations of streptococcal and nonstreptococcal pharyngitis overlap so broadly that it is often impossible to make the diagnosis with certainty. For this reason, most authorities recommend that the diagnosis of group A β-hemolytic streptococcal (GABHS) pharyngitis be verified or ruled out by microbiologic tests in patients who appear likely, on the basis of clinical and epidemiologic considerations, to have this illness.[37,38] The time-honored method of diagnostic confirmation is the throat culture. This is a simple and extremely useful test but sampling must be skillfully performed by swabbing the posterior pharynx and tonsillar areas.[37] The specimen must also be appropriately processed and read. Such selective use of throat cultures represents good medical practice.

One of the major problems in the use of throat cultures in everyday medical practice has been the delay in obtaining results. The delay can range from 18 to 48 hours, which holds up the start of appropriate management but does not increase the likelihood of development of rheumatic fever. Nevertheless, it can be difficult for physicians to persuade parents of the wisdom of withholding antibiotics until results are known, especially if their children are cranky and febrile. If group A streptococcal pharyngitis is treated early in the clinical course, the period of communicability is reduced.[39] Management is thus initiated before culture results are available and unfortunately may not be terminated even when negative results are obtained. Development of rapid strep detection tests for the detection of the group A streptococcal antigen has therefore represented a useful advance.

Several rapid tests to detect group A streptococcal antigen in the pharynx have been developed. They employ either latex agglutination or enzyme-linked immunosorbent assay (ELISA) methods to extract the antigen from a swab. The streptococcal group A carbohydrate may be detected within a matter of minutes. The test kits are suitable for use in a physician's office. Although the rapid detection tests are highly specific, they are unfortunately not as sensitive as routine throat culture.[37,40,41] A negative rapid detection test result may prompt the practitioner to withhold antibiotic therapy while awaiting culture results. Most guidelines suggest that throat cultures should be performed when the body temperature is greater than 38.3° C or when the illness is characterized exclusively by a sore throat.[42] The most accurate and cost-effective method to diagnose acute GABHS infection is the use of the rapid strep test. This is followed by standard throat culture in patients with a negative rapid strep test result and a strong suspicion of streptococcal tonsillitis.

Even optimally obtained and processed, throat cultures are not without flaws. Throat culture cannot reliably differentiate acute from chronic infection. The treatment of all patients who have positive culture results leads to over-management. There are occasional false-negative results (approximately 10% of cases), although one report has found that patients with false-negative results are most likely carriers who do not require treatment.[37] Studies have reported that a single throat culture is 90% to 97% sensitive and 90% specific for GABHS growth.[43] The carrier state can be elucidated by serologic testing. A true infection is demonstrated by a positive throat culture result and at least a two-dilutional rise in the antistreptolysin-O titer.[44] A GABHS carrier without acute infection has a positive culture result with no change in dilution titer.[45] Excluding the diagnosis of group A streptococcal pharyngitis is quite important because the majority of patients with acute pharyngitis do not have "strep" throat.

Therapy has usually been directed at the aerobic pathogens traditionally associated with tonsillitis (e.g., GABHS). Penicillin is still the agent of choice in most cases. However, anaerobic bacteria play a major role in the complications associated with tonsillitis, so they are probably also involved in recurrent tonsillitis. One study has documented the prevalence of *Bacteroides* cultured from chronically inflamed tonsils.[46] Anaerobes also have been implicated in acute tonsillitis.[23] Clinical failure of penicillin should lead to the suspicion of β-lactamase–producing organisms. The reason for the treatment failure could be that these organisms either act as pathogens themselves, so-called direct pathogens, or protect susceptible pathogens from the effects of β-lactamase antibiotics, making them so-called indirect pathogens. In such cases, the patient complains of sore throat that never resolves completely despite penicillin management. An alternative to the use of penicillin is to use a penicillin plus a β-lactamase inhibitor such as clavulanic acid (e.g., amoxicillin/clavulanic acid). Other alternatives are clindamycin and a combination of erythromycin and metronidazole. Institution of antibiotic therapy within 24 to 48 hours of symptom onset will result in decreased symptoms associated with sore throat, fever, and adenopathy 12 to 24 hours sooner than without antibiotic administration. The use of antibiotics also minimizes the chance of suppurative complications and diminishes the likelihood of acute rheumatic fever.[47,48] Ten full days of therapy is necessary, as eloquently demonstrated by Schwartz and colleagues,[49] who showed that children receiving 10 days of therapy have lower clinical and bacteriologic recurrence rates than children receiving only 7 days of therapy.

There appears to be no need for further management for asymptomatic carriers because the carrier state does not lead to suppurative or nonsuppurative complications nor is the patient likely to spread the disease to others.[50] Although asymptomatic patients need neither culture nor management if results of follow-up culture are positive, certain high-risk situations should be approached differently. For example, if a family member had rheumatic fever or if a family has been experiencing recurrent streptococcal illness, another course of antibiotics would be recommended for the carrier. Patients who become symptomatic after an appropriate course of therapy may indeed represent true management failures for which a second course of therapy would also be justified.[50]

Tonsillar Concretions/Tonsilloliths

Tonsillar concretions or tonsilloliths (Fig. 196-5) arise from retained material and bacterial growth in the tonsillar or adenoid crypts and may exist in patients with or without a history of inflammatory disorders in either the tonsils or adenoids.[51] The clinical presentation of fetor oris (halitosis) and sore throat as well as the presence of whitish, expressible,

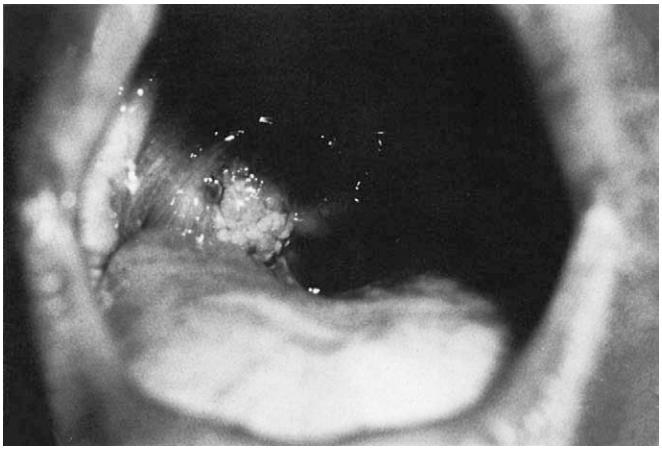

Figure 196-5. Tonsillolith of the right tonsil.

foul-tasting, and foul-smelling cheesy lumps from the tonsils characterizes the tonsillar concretions in many patients. Local management involves simple expression of the concretions by the patient, the use of pulsating jets of water to clean the pockets of debris mechanically, or application of topical silver nitrate to the tonsillar crypts in an effort to chemically cauterize and obliterate them. Persistent problems with pain, halitosis, foreign body sensation, or otalgia may require surgical removal of the tonsils as definitive therapy.

Complications of Tonsillitis

The complications of tonsillitis can be broken down into nonsuppurative and suppurative complications. Nonsuppurative complications include scarlet fever, acute rheumatic fever, and poststreptococcal glomerulonephritis. Suppurative complications are the result of abscess formation and include peritonsillar and parapharyngeal abscess development.

Nonsuppurative Complications

Scarlet fever is secondary to acute streptococcal tonsillitis or pharyngitis with production of endotoxins by the bacteria.[33] Manifestations include an erythematous rash; severe lymphadenopathy with a sore throat; vomiting; headache; fever; erythematous tonsils and pharynx; tachycardia; and a yellow exudate over the tonsils, pharynx, and nasopharynx. The membrane that is present over the tonsils is usually more friable than that seen with diphtheria. A strawberry tongue with a rash and large glossal papillae is a good diagnostic sign. Diagnosis of scarlet fever is made by culture and positive result of the Dick test, which is an intradermal injection of dilute streptococcal toxin.[34] Management of this condition involves intravenous administration of penicillin G. Otologic complications may include necrotizing otitis media with complete loss of the tympanic membrane and ossicles.

Fortunately, acute rheumatic fever is an uncommon illness in the United States today. The incidence of rheumatic fever following sporadic streptococcal infection is approximately 0.3%.[50] A patient with rheumatic fever who does not comply with penicillin prophylaxis should have a tonsillectomy and adenoidectomy because patients who have undergone surgery have a lower infection rate with β-hemolytic streptococcus.[52]

Poststreptococcal glomerulonephritis may be seen after both pharyngeal and skin infections. The incidence is approximately 24% after exposure to nephrogenic strains, but these strains account for less than 1% of the total pharyngeal strains.[50] Typically, an acute nephritic syndrome develops 1 to 2 weeks after a streptococcal infection. The infection is secondary to the presence of a common antigen of the glomerulus with the streptococcus. Penicillin management may not decrease the attack rate, and there is no evidence that antibiotic therapy affects the natural history of glomerulonephritis. A tonsillectomy may be necessary to eliminate the source of infection.

Suppurative Complications

Peritonsillar Infections

Peritonsillar abscess most commonly occurs in patients with recurrent tonsillitis or in those with chronic tonsillitis that has been inadequately treated. The spread of infection is from the superior pole of the tonsil with pus formation between the tonsil bed and the tonsillar capsule.[33] This infection usually occurs unilaterally and the pain is quite severe, with referred otalgia to the ipsilateral ear a few days after the onset of tonsillitis. Drooling is caused by odynophagia and dysphagia. Trismus is frequently present as a result of irritation of the pterygoid musculature by the pus and inflammation. There is gross unilateral swelling of the palate and anterior pillar with displacement of the tonsil downward and medially with reflection of the uvula toward the opposite side. Cultures of the peritonsillar abscess usually show a polymicrobial infection, both aerobic and anaerobic.[53]

Needle aspiration may be used to obtain a test aspirate and identify the site of the abscess. If pus is found on needle aspiration, the abscess may be opened with a long-handled scalpel to incise the mucosa over the abscess and a blunt-tip hemostat to spread and break up the loculi, draining as much pus as possible. If there has been a previous history of tonsillitis, a Quinsy tonsillectomy may be quite effective. This removes the possibility of recurrent infections and allows swift improvement of the patient's condition. This procedure is particularly favored in younger patients in whom further tonsillar infections are more likely and because of the difficulty of needle aspiration or surgical drainage in children under local anesthesia. Care must be taken to avoid abscess rupture and pus inhalation during the induction of anesthesia and endotracheal intubation.

Cellulitis should be differentiated from abscess in the management of peritonsillar infections. Some abscesses may be clinically obvious, whereas others are less obvious. When there is extension of infection of the peritonsillar abscess, computed tomography (CT) with contrast enhancement may be indicated (Fig. 196-6).

The choice between needle aspiration and incision and drainage in the management of peritonsillar abscesses is controversial. Traditional management has consisted of incision and drainage, with tonsillectomy 4 to 12 weeks later. Some surgeons advocate immediate tonsillectomy or Quinsy tonsillectomy as definitive management to ensure complete drainage of the abscess and to alleviate the need for a second hospitalization for an interval tonsillectomy.[54] Each therapeutic modality has advantages in certain situations. If incision and drainage or needle aspiration fails to drain an abscess adequately, a Quinsy tonsillectomy is indicated. In patients with a prior history of recurrent peritonsillar abscess or recurrent tonsillitis severe enough to warrant tonsillectomy, a Quinsy tonsillectomy should be considered. Quinsy tonsillectomy is particularly favored in children because they are likely to experience further episodes of tonsillitis, and needle aspiration or incision and drainage with a child under local anesthesia is often difficult or impossible.

Parapharyngeal Space Abscess

An abscess can develop in the parapharyngeal space if infection or pus drains from either the tonsils or from a peritonsillar abscess through the superior constrictor muscle.[33] The abscess is located between the superior constrictor muscle and the deep cervical fascia and causes displacement of the tonsil on the lateral pharyngeal wall toward the midline. Involvement of the adjacent pterygoid and paraspinal muscle with the inflammatory process results in trismus and a stiff neck. The thickness of the overlying sternocleidomastoid muscle often prevents the detection of fluctuance by palpation.

Patients with parapharyngeal space infections characteristically exhibit fever, leukocytosis, and pain. Progression of the infectious process of the abscess may spread down the carotid sheath into the mediastinum. As with most soft-tissue infections of the neck, lateral pharyngeal space infections are polymicrobial and usually reflect oropharyngeal flora. Intraoral examination reveals swelling of the lateral pharyngeal wall, especially behind the posterior tonsillar pillar. Anteromedial tonsil displacement is present. Clinically this may be confused with a peritonsillar abscess, so if indicated, a CT scan with contrast

Figure 196-8. Tonsillar hypertrophy with significant pharyngeal obstruction.

enhancement should be obtained. Neurologic deficits involving cranial nerves IX, X, and XII may occur.

Initially, lateral pharyngeal space infections should be managed with aggressive antibiotic therapy, fluid replacement, and close observation. Surgical intervention is often required to bring about resolution of these infections. Intraoral approaches should be confined to management of peritonsillar abscesses and should not be used in true lateral pharyngeal space abscesses because of inadequate exposure if severe bleeding arises. An external approach to the parapharyngeal space usually consists of a transverse submandibular excision approximately 2 cm inferior to the mandibular margin, which extends from the anterior limits of the submandibular gland just past the angle of the mandible. The submandibular gland is freed inferiorly and posteriorly by sharp, blunt dissection, and access to the space is achieved by dissection between the tail of the submandibular gland and the anterior aspect of the sternocleidomastoid muscle. With this approach, the skull base can easily be explored.

Retropharyngeal Space Infections

The superior limit of the retropharyngeal space is the cranial base. Inferiorly, the retrovisceral space extends into the mediastinum to approximately the level of the tracheal bifurcation. The buccal pharyngeal fascia is adherent to the prevertebral fascia in the midline, so that infection in the retropharyngeal space is unilateral. Lateral neck radiography, CT, or ultrasonography may help ascertain whether there is cellulitis or a true abscess (Fig. 196-7). The source of the retropharyngeal abscess is a chain of lymph nodes present on either side of the midline in the retropharyngeal space. These lymph nodes

receive drainage from the nose, paranasal sinuses, pharynx, and eustachian tube.

Retropharyngeal space infections occur most commonly in children younger than 2 years. Children with infection in the retropharyngeal space usually present with irritability, fever, dysphagia, muffled speech, noisy breathing, stiff neck, and cervical lymphadenopathy. Physical examination usually shows unilateral posterior pharyngeal swelling, which is visualized on inspection of the child's pharynx.

A transoral approach is recommended for incision and drainage of retropharyngeal space abscesses. If the abscess extends inferiorly below the hyoid bone (shown on the CT scan), an external approach should be used. The patient must undergo oral intubation, which can be done safely by introduction of the tube on the side opposite the abscess to avoid aspiration of purulent material. The patient must be positioned in the head-down Trendelenburg position, and packing should be placed around the endotracheal tube inferiorly. Gram staining, culture, and antimicrobial sensitivity staining should be performed on the purulent material. A small vertical incision is made in the lateral aspect of the posterior pharyngeal wall at a point between the junction of the lateral one third and medial two thirds of the distance between the midline of the pharynx and the medial aspect of the retromolar trigone.[55] The space is gently probed with a hemostat to break up the loculations and drain the abscess. A drain is not used because of the possibility of aspiration if swallowed postoperatively. If the abscess extends laterally to involve the parapharyngeal space, it should be drained through an external approach.

Chronic Adenotonsillar Hypertrophy

Etiology

Chronic adenotonsillar hypertrophy—manifesting as various degrees of airway obstruction in children—has become the most common indication for adenotonsillectomy in the United States.[56] Typically, the tonsils and adenoids are very small at birth and progressively enlarge over the first four years of life as a result of increased immunologic activity (Figs. 196-8 and 196-9). Brodsky and colleagues[27,57] reported that hypertrophied and chronically infected tonsils and adenoids had greater loads of pathogenic bacteria, especially β-lactamase producers, than nondiseased tonsils and adenoids.[57,58] These studies were based on core samples that were believed to be more accurate than surface cultures of the tonsils and adenoids. It is possible that equilibrium exists between the normal flora of the adenotonsillar tissue and their local immunologic response and that this equilibrium can become disrupted with recurrent acute viral or bacterial infections or colonization with pathogenic bacteria, resulting in hypertrophied lymphoid tissue.[27]

In addition to chronic bacterial infection, exposure to secondhand smoke has been implicated as a cause of adenotonsillar hypertrophy in children.[8]

Airway Obstruction

Obstructive sleep apnea is the most common indication for tonsillectomy in the pediatric population. Pediatric obstructive sleep apnea, confirmed by polysomnography, is reported to have an incidence of 1% to 3%.[59-61] The obstructive apnea is almost always associated with hypertrophy of the tonsils and adenoids. The tonsil and adenoid tissue, when large, fills the area of the oropharynx and nasopharynx, obstructing airflow. This obstruction is worse when the patient is supine and asleep owing to the effects of gravity and the relaxation of surrounding nasopharyngeal and oropharyngeal soft tissue. The obstruction can result in a mildly compromised airway, which leads to snoring, and most children with airway obstruction related to adenotonsillar hypertrophy have a history of significant snoring at night.[28,31,59,62,63] The obstruction may lead to intermittent complete airway obstruction with subsequent apnea and oxygen desaturation. The apnea typically is short and usually associated with a brief arousal wherein the patient repositions himself or herself and opens the airway. However, if the apnea is prolonged, oxygen desaturation can occur. Such desaturation episodes put stress on the cardiovascular system.

Before the syndrome of obstructive sleep apnea was widely recognized, children sometimes presented with pulmonary hypertension and cor pulmonale, failure to thrive, and developmental delay.[64] Such severe consequences rarely occur now, but the sleep disturbance manifests as multiple clinical symptoms that are commonly seen. Some of the more common symptoms that occur during the sleep of affected children are loud "heroic" breathing, diaphoresis, apnea, gasping, mouth-breathing, restless sleep, enuresis, drooling, night terrors, and sleepwalking. During the day affected children may suffer from daytime sleepiness, morning headache, dry mouth, halitosis, swallowing difficulty, behavioral difficulties and hyponasal speech, or, rarely, hypernasal speech (rhinolalia aperta) caused by enlarged tonsils impinging on normal palatal movement.[63] Behavioral difficulties include hyperactivity, inattentiveness in the classroom, problems with academic performance, and rebellious or aggressive behavior. The aforementioned behavioral difficulties are also clinical manifestations of the most commonly diagnosed psychiatric diagnosis in children—attention deficit–hyperactivity disorder (ADHD).

Today obstructive sleep apnea and its consequences are widely recognized, and for that reason it is the primary indication for tonsillectomy in this country.[65] There is no debate about the existence of the obstructive sleep apnea syndrome or that adenotonsillectomy is the treatment of choice. However, there is considerable debate about the methods of diagnosis and therefore considerable discussion about exactly how large a group of children is affected by the syndrome (see Chapter 183 for a full discussion).

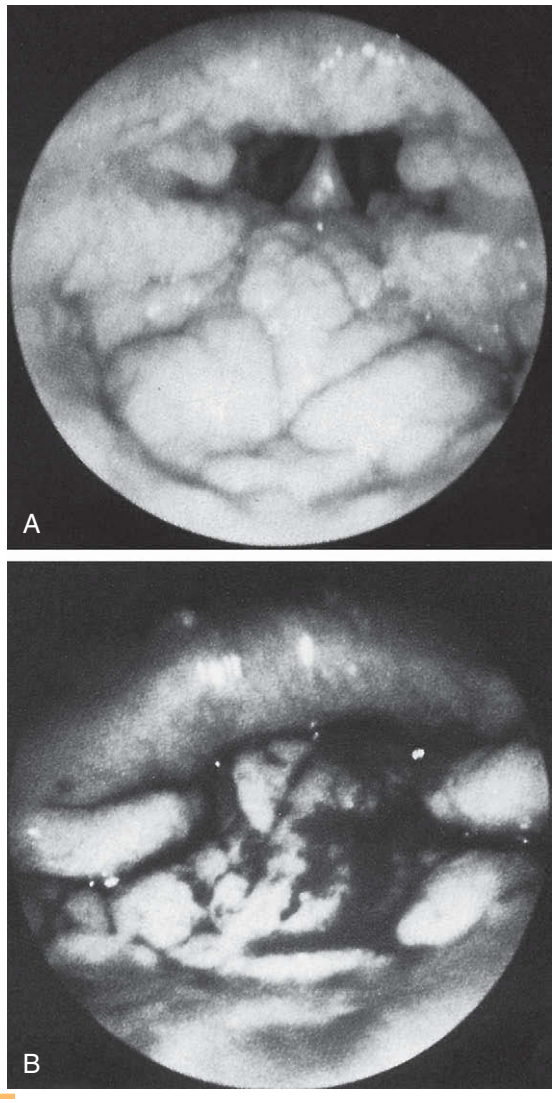

Figure 196-9. A, Endoscopic view of mild adenoid hypertrophy. **B,** Severe adenoid hypertrophy with total choanal obstruction.

Attention Deficit–Hyperactivity Disorder

As previously noted, inattention and hyperactivity are some of the daytime symptoms shown to have a relationship to pediatric sleep-disordered breathing (SDB). This relationship has been demonstrated in studies of children in whom obstructive sleep apnea syndrome has been documented by formal sleep study. However, an increased incidence of inattention and hyperactivity has also been found in children with significant snoring but with negative sleep study results, as well as in groups of snoring children without any formal sleep testing.

Numerous articles in the literature have shown a significant relationship between sleep-disordered breathing and the symptoms of ADHD. One study investigated 996 children aged 4 to 5 years seen consecutively in a community health clinic. Of the 782 for whom the questionnaires were completed, 95 or 12% of the children were found to snore on most nights. A group of 66 children considered at high risk for sleep disturbance was selected from these 95 children and compared with a control group who had no symptoms of sleep disturbance. The study used a modified version of the Conner's behavioral scale to assess symptoms of hyperactivity. These 66 children were studied with overnight oximetry and video monitoring. According to results of the overnight study, only 7 of the 66 children in the high-risk group had documented obstructive sleep apnea syndrome, but all the children in this high-risk group had significantly higher scores on parental and teacher reports of hyperactive behavior.[60]

Another study looked at the relationship between the symptoms of sleep-disordered breathing and problem behavior including hyperactivity and inattention. The study enrolled 3019 5-year-old children. The researchers used a questionnaire to evaluate for symptoms of sleep-disordered breathing as well as problems with behavior, and had a subset of 219 children's families complete the Revised Conners' Parent Rating Scale as a means of validating the results obtained with limited initial questioning. Symptoms of sleep-disordered breathing were present in 25% of the children. A strong association was found between parent-reported sleep problems and the parent-reported incidence of inattention, hyperactivity, and aggressiveness. Interestingly, a dose-response effect on problem behaviors was seen for both snoring frequency and snoring loudness. These results remained significant even when data were adjusted for sex, race, maternal education level, maternal marital status, household income, and respiratory history. Such adjustments had not been made in previous reports on the link between SDB and ADHD.[66]

A different study evaluated 2076 children and found 71 with behavioral or academic problems. These children had significantly more problems with snoring and difficulty breathing. This association was found to be strongest with children who had academic problems or in children whose specific behavioral problem was consistent with ADHD.[67]

Other studies have examined this issue from the opposite direction, evaluating a group of children diagnosed with neuropsychological problems and searching for signs and symptoms of SDB. These studies show that children with neuropsychological problems have a higher percentage of sleep problems than normal controls. Marcotte and associates looked at 200 children referred for psychiatric evaluation for possible ADHD; 79 children were diagnosed with ADHD, learning disability, or combined ADHD–learning disability. Through parent questionnaires, the investigators found a high incidence of reported sleep problems at night in comparison with the incidence in a control group of children. They did not find any difference in the reported length of sleep. Thus, the effect seems to depend on quality, not quantity, of sleep.[68]

Another study surveyed a group of parents at a child psychiatry unit and a group of patients at a general pediatric clinic. Children at the psychiatry clinic with the diagnosis of ADHD had a 33% incidence of habitual snoring, compared with 11% of the other children at the psychiatry clinic and 9% in those at the general pediatric clinic. Higher snoring scores derived from the validated pediatric sleep questionnaires were associated with higher levels of inattention and hyperactivity, again pointing to an apparent dose-response relationship.[69]

The pathophysiology of ADHD is unknown, but there are suggestions that an abnormal sleep pattern may be one causal factor. It has long been known that stimulants improve behavior in patients with ADHD. Stimulants are believed to work because ADHD is a disorder caused by hypovigilance rather than hypervigilance.[70] If hypovigilance is indeed the mechanism, it makes sense that a child with decreased or poor sleep secondary to obstructive sleep apnea syndrome would be much more likely to suffer from symptoms of ADHD. Consequently, if the sleep obstruction was removed, it should follow that the quality of sleep would improve and therefore symptoms of ADHD would diminish.

One small article in the European literature did show that symptoms of ADHD diminished after adenotonsillectomy.[71] At this point, however, no large prospective studies have looked carefully at this issue. This is an area of active research in the literature and one that receives a lot of attention, but still more work must be done to better clarify the cause-and-effect relationships.

Neurocognitive Development

Sleep is an important part of a child's growth and development, particularly during periods of brain maturation. Among different species, greater sleep requirements have been seen in maturing as opposed to fully mature individuals. Sleep, particularly in children, can be a very active process and may play a key role in proper brain maturation.

Multiple studies have indicated that children with a childhood history of snoring and SDB may have alteration in normal neurocognitive development. One study evaluated 297 first-grade children whose school performance was in the lowest 10th percentile in their class ranking. With both a parental questionnaire and overnight pulse oximetry monitoring and transcutaneous monitoring of partial pressure of carbon dioxide, the group was screened for signs and symptoms of a sleep disorder. The researchers found that 54 (18.1%) of these children had sleep-associated gas exchange abnormalities. Parents of these children were all offered surgical treatment, and 24 underwent tonsillectomy and adenoidectomy; parents of the remaining 30 refused surgical treatment. The group undergoing surgical treatment had a significant improvement in school scores the following year, whereas, the group refused treatment and a control group had no change in year-to year scores.[72]

In another study, the author sent questionnaires to the parents of seventh and eighth graders whose test scores placed them in either the top 25% or bottom 25% of the class. These students were matched for age, gender, race, address, and schools. The parents were sent questions related to their child's sleeping habits from age 2 to 6 years, in which the primary indicators of sleep disturbance were snoring frequency and loudness. Only those with reported loud frequent snoring during childhood years were included in the group with suspected sleep disorder. The few children with current snoring were excluded. The investigators ultimately had 800 students in each group and found that frequent and loud snoring was reported in 12.9% of the low-performing students, but in 5.1% of the high-performing children.[73] To the investigators, these results indicated that a significant sleep disturbance during the early important years of neurocognitive development may create deficits that cannot be overcome later in life, after the sleep disturbance has resolved.

One study compared the results of neurocognitive testing between 16 snoring children and 13 normal controls aged 5 to 10 years. Of the snoring children, 13 completed polysomnograms and none had clinically defined obstructive sleep apnea. The researchers found that the snoring children had lower attention, memory, and intelligence scores. They concluded that the impact of clinically mild SDB may be greater than suspected and may significantly affect future development of the child.[74]

Another study looked at a large community sample of 5-year-old children. The investigators screened the children for SDB and found that those with symptoms of SDB had significantly lower scores on a wide range of neurocognitive studies. These studies included assessments of executive function, memory, and general intellectual ability. All the test results were adjusted for any potentially confounding sociodemographic or health issues.[66] This study found that the differences in cognitive function were present even if the children with polysomnography-confirmed obstructive sleep apnea were excluded. Thus, even in children with what has been referred to as "primary snoring" were shown in this study to have measurable neurocognitive deficits.

The mechanism underlying possible cognitive deficits remains unclear. Three major processes occur during the sleep of children with upper airway obstruction—episodic hypoxia, repeated arousal leading to sleep deprivation or sleep fragmentation, and periodic or continuous alveolar hypoventilation combined with intermittent hypercapnia. Which of these sequelae or in what proportion they may be responsible for cognitive impairment is not known.[73] Central nervous system development is an ongoing process from infancy to adolescence, and developing neural elements are most likely more susceptible to injury. Neurocognitive deficits in children affected with SDB may be more prominent in the area of the prefrontal cortex because these areas do not finish development until adolescence.[75]

The National Institutes of Health–sponsored 2003 National Sleep Disorders Research Plan states, "In recent years it has become apparent that SDB and snoring are not as innocuous as previously thought." The report continues that failure to diagnose and treat such disorders in a timely manner may lead to long-lasting residual consequences. "However, the point of transition between what constitutes pathology and what is normal has yet to be defined."[76] In an editorial, one researcher active in this area discussed the accumulating evidence of a causal relationship between pediatric SDB and neurocognitive deficits. He concluded his thoughts, "The remaining but complex challenge will be to define at what age, and by what means, intervention will be required to prevent long-term neurocognitive dysfunction."[77]

An article by Garetz[78] offers a good review of the literature surrounding the issues of behavior and cognition associated with SDB. She discusses the need for further research while pointing out that none of the studies in this area has been randomized, and few studies have addressed well how ethnicity and obesity may play a role in these areas. Clearly, many questions are left unanswered at this point. First, we do not know what the dose-response relationship is between SDB and neurocognitive impairment. How long should a child be allowed to snore before treatment is recommended? We know snoring resolves spontaneously in many children, so how long do we allow a child's snoring to persist before we have concern that cognitive function will be affected? Is the tolerable length of time related to the age of the child—is a child more sensitive to the effects of sleep disturbance at 3 years or 7 years, and thus should we wait less time in a 3- year-old with significant SDB? These are all questions that further research must address.

Enuresis

Enuresis is another indicator of severe underlying airway obstruction in children. Weider and associates[79] described enuresis related to chronic adenotonsillar hypertrophy and significant airway obstruction that was relieved by adenotonsillectomy. In this study, all patients with secondary enuresis (developed later during childhood) showed response to adenotonsillectomy, whereas 24 patients with primary enuresis (congenitally present) showed no response to surgery, possibly as a result of other neurologic factors. A proposed cause of enuresis is poor nocturnal regulation of antidiuretic hormone release that is related to disorders of rapid eye movement (REM) sleep.

Growth Problems

Children with chronic adenotonsillar hypertrophy and airway obstruction may also present with failure to thrive.[64,80] A review of the literature further confirmed this apparent relationship between SDB secondary to adenotonsillar hypertrophy and the risk of growth failure in children.[81] This relationship may be related to abnormal regulation of growth hormone. During rapid eye movement sleep, growth hormone may be severely disrupted in children with obstructive sleep apnea.[80] Several studies have confirmed a postoperative increase in circulating insulin-like growth factor and its binding proteins in children with obstructive sleep apnea secondary to adenotonsillar hypertrophy.[82,83]

Cardiopulmonary Complication

Severe cases of sleep obstruction may result in cor pulmonale, pulmonary vascular hypertension, and alveolar hypoventilation, all of which may be reversed by adenotonsillectomy (Fig. 196-10).[19,84,85] The etiology of cor pulmonale is related to chronic upper airway obstruction, which leads to pulmonary ventilation-perfusion abnormalities and chronic alveolar hypoventilation. The result is chronic hypercapnia and hypoxia with respiratory acidemia, pulmonary artery vasoconstriction, and right ventricular dilation. Eventual cardiac failure may occur.[31,86,87] Relief of upper airway obstruction by adenotonsillectomy will eventually reverse this condition. However, increased partial pressure of carbon dioxide (P_{CO_2}) values may persist after relief of the obstruction, occasionally requiring prolonged endotracheal intubation and mechanical ventilation until P_{CO_2} values return to normal.

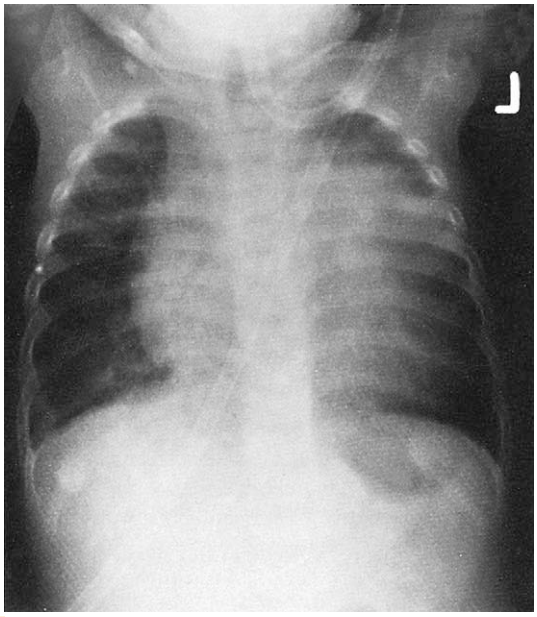

Figure 196-10. Posteroanterior chest radiograph of a patient with adenotonsillar hypertrophy, severe airway obstruction, pulmonary vascular hypertension, and cor pulmonale.

Craniofacial Growth and Adenotonsillar Hypertrophy

Chronic mouth-breathing secondary to adenotonsillar hypertrophy and upper airway obstruction has been shown to affect craniofacial growth patterns in children. As early as 1872, Tomes[88] reported that children who were chronic mouth-breathers secondary to adenoid hypertrophy displayed evidence of malocclusion and maxillofacial growth abnormalities. Mouth-breathing leads to downward and backward displacement of the mandible and tongue and potential postural changes of the head and neck that may secondarily affect dental occlusion and jaw growth.[89] Numerous animal and human studies have demonstrated the effect of chronic nasal obstruction on maxillofacial growth patterns. Harvold[90] showed that chronic nasal obstruction may lead to narrow maxillary dental arches in rhesus monkeys. Linder-Aronson and colleagues[91] demonstrated the classic stigmata of adenoid facies in children with chronic nasopharyngeal obstruction from adenoid hypertrophy. These consisted of longer total anterior face height with a tendency toward a retrognathic mandible in comparison with controls.

Adenotonsillectomy has been shown to reverse some of these findings.[91,92] Other investigators have confirmed the relationship between chronic nasal obstruction, adenotonsillar hypertrophy, and increased facial height.[93,94] A later study showed a significant correlation between adverse cephalometric data and adenotonsillar hypertrophy in a group of children 4 to 12 years old.[95] Although there is significant support in the literature for the effect of upper airway obstruction and adenotonsillar hypertrophy on craniofacial growth, other studies have been less conclusive about this relationship.[94,96,97] Maxillofacial growth disturbances in children who are mouth-breathers may also be multifactorial in etiology.[98] As a result of this apparent relationship among upper airway obstruction, adenotonsillar hypertrophy, and craniofacial

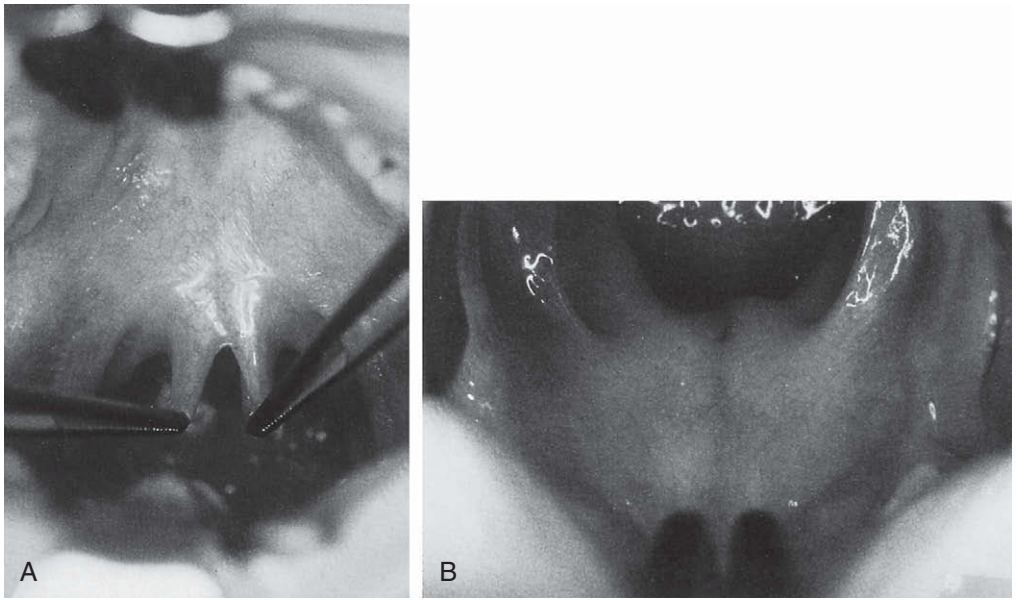

Figure 196-11. **A,** Bifid uvula in a patient with a submucous cleft palate. **B,** Submucous cleft palate.

growth disturbance, an otolaryngologic evaluation may be warranted in children undergoing orthodontic procedures for malocclusion who show evidence of adenotonsillar hypertrophy and mouth-breathing.

Diagnostic Assessment of the Tonsils and Adenoids

The physical examination of patients with suspected adenotonsillar disease should include a thorough head and neck examination to rule out manifestations of chronic adenotonsillar hypertrophy (i.e., the craniofacial stigmata of chronic nasal obstruction, which includes open-mouth breathing, an elongated face, dark circles under the eyes, and evidence of dental malocclusion). Other possible causes of nasal obstruction and these findings (e.g., turbinate hypertrophy secondary to allergic rhinitis) should also be evaluated. It is important to listen to the patient's speech to assess the presence of hyponasality. Having the child repeat words such as "Mickey Mouse," which emphasize nasal emission, and "baseball," which does not, better illuminates the presence of hyponasality.[4]

Brodsky and coworkers[57] described an assessment scale for tonsillar hypertrophy. In this scale, 0 indicates that the tonsils do not impinge on the airway; 1+ indicates less than 25% airway obstruction; 2+ indicates 25% to 50% airway obstruction; 3+ indicates 50% to 75% airway obstruction; and 4+ indicates more than 75% airway obstruction. It is also important to assess the palate on oral examination. Patients with evidence of overt or submucous cleft palate are at increased risk for the development of velopharyngeal insufficiency (VPI) after adenoidectomy. Submucous cleft palate may manifest only as a bifid uvula. However, notching of the posterior hard palate may be palpable, and an obvious translucent line through the mid–soft palate may be evident (Fig. 196-11). Although diagnostic assessment of the tonsils is apparent with oral examination, evaluation of adenoid tissue is much more difficult because it is not easily accessible on physical examination.

Lateral neck radiography may be helpful in assessing adenoid hypertrophy (Fig. 196-12). Fujioka and associates[99] determined that the adenoid-nasopharyngeal ratio, measured by lateral neck radiography, closely correlated with clinical symptomatology related to adenoid hypertrophy. This conclusion has been confirmed by other reports.[100] However, physiologic variations during nasal and oral breathing may affect these nasopharyngeal dimensions as measured by lateral neck radiography.[101] Furthermore, during an upper respiratory or sinonasal infection, significant nasopharyngeal secretions and purulence can obscure the nasopharynx and give the false impression of adenoid obstruction.

Figure 196-12. Lateral neck radiograph demonstrating significant adenoid hypertrophy and nasopharyngeal obstruction.

Lateral neck radiography is not necessary for the evaluation of all patients with suspected adenoid hypertrophy. Patients with significant obstructive symptomatology and obvious tonsillar hypertrophy most likely require surgical intervention, and findings on lateral neck radiography would not alter the decision to proceed with surgery. Patients with significant nasal obstruction and insignificant tonsillar hypertrophy should undergo radiographic assessment of the nasopharynx. Patients with significant nasal obstruction and evidence of allergic rhinitis may have concurrent underlying adenoid hypertrophy and would benefit from lateral neck radiography.

Flexible endoscopic nasopharyngoscopy may also be valuable in the assessment of adenotonsillar disease. With appropriate topical anesthesia, pediatric endoscopes, and reassurance from the physician, children generally tolerate this procedure well. The presence of adenoid tissue obstructing the posterior nasal choana will be apparent with this technique. The degree of hypopharyngeal extension of tonsillar hyper-

trophy may also be apparent. Sometimes tonsils that do not appear significantly large on oral examination can be seen to impinge upon and actually push back the epiglottis when viewed from above with the flexible laryngoscope. VPI secondary to tonsillar hypertrophy limiting palatal movement will be apparent on nasopharyngoscopy. The presence of adenoiditis may also be diagnosed from the presence of purulent secretions covering the adenoid pad. Wormald and Prescott[102] and Wang and others[103] demonstrated the greater efficacy of flexible nasopharyngoscopy in comparison with lateral neck radiography and clinical symptomatology in the assessment of adenoid hypertrophy in children. Rhinomanometry has also been demonstrated to correlate with the presence of nasal obstruction secondary to adenoid hypertrophy; however, this test is not well tolerated by children, is difficult and time-consuming to administer, and is probably not of clinical benefit in its current form.[104]

The role of polysomnographic testing in children has been previously reported.[64,80,105] Because of the high cost of polysomnography, it is important for the otolaryngologist to be selective in referring patients for this diagnostic modality. Furthermore there are few dedicated pediatric sleep laboratories and the wait for a study can often be very long. Patients with obvious symptoms related to adenotonsillar hypertrophy confirmed by physical examination most likely do not require polysomnographic testing. Patients with significant symptomatology—suggesting sleep apnea or a significant sleep disturbance without evidence of significant adenotonsillar hypertrophy on examination—should undergo polysomnographic testing to determine the severity of the sleep disturbance. Children with significant comorbidities that may increase surgical risk are also candidates for a polysomnogram to help in the preoperative risk-benefit assessment of surgical intervention. A polysomnogram may also help in the evaluation of the neurologically compromised child, in order to differentiate between obstructive and central apnea, because surgery is not likely to improve the latter. Screening chest radiography and electrocardiography are also recommended in the preoperative assessment of severe cases.

Preoperative Assessment

Preoperative assessment in patients undergoing adenotonsillectomy is crucial and may reveal problems that could complicate either surgery or the patient's postoperative course. It is crucial to detect the existence of any coagulation abnormalities. A family history of coagulation disorders or easy bruising may be a warning sign of an underlying bleeding disorder that warrants further hematologic evaluation. Routine evaluation of coagulation parameters before surgery in patients undergoing adenotonsillectomy is controversial. Manning and colleagues,[106] examining the records of 994 of 1050 consecutive patients undergoing tonsillectomy, adenoidectomy, or adenotonsillectomy, determined that evidence of coagulation disorders in patients with no clinical history of or findings consistent with a hematologic disorder was extremely low, thereby not justifying routine preoperative coagulation studies. This conclusion was confirmed by Close and associates,[100] who suggested that excessive bleeding associated with tonsillectomy was usually not the result of an identifiable coagulation disorder.

Conversely, Kang and coworkers[107] studied the risk of postoperative hemorrhage in 1061 children undergoing adenotonsillectomy. In this study, 2.5% of the children had at least one abnormality on preoperative coagulation screening, which consisted of determinations of prothrombin time, partial thromboplastin time, bleeding time, and platelet count. These researchers suggested that, although hematologic disorders were diagnosed infrequently by preoperative coagulation screening, the coagulation profile may detect patients who are more likely to bleed postoperatively.[107] This suggestion is consistent with the findings of Bolger and colleagues,[108] who demonstrated abnormal initial coagulation screening results in 11.5% of patients undergoing adenotonsillectomy. It is apparent that patients who have an obvious family or clinical history of excessive bleeding or an underlying hematologic disorder require close monitoring of coagulation profiles and consultation with a hematologist. Use of preoperative coagulation screening should be left to the discretion of the surgeon until its role is better clarified by further study.

Box 196-1

Surgical Indications for Tonsillectomy

Infection

- Recurrent, acute tonsillitis (more than 6 episodes per year or 3 episodes per year for 2 years or longer)
- Recurrent acute tonsillitis associated with other conditions:
  - Cardiac valvular disease associated with recurrent streptococcal tonsillitis
  - Recurrent febrile seizures
- Chronic tonsillitis that is unresponsive to medical therapy and is associated with:
  - Halitosis
  - Persistent sore throat
  - Tender cervical adenitis
- Streptococcal carrier state unresponsive to medical therapy
- Peritonsillar abscess
- Tonsillitis associated with abscessed cervical nodes
- Mononucleosis with severely obstructing tonsils that is unresponsive to medical therapy

Obstruction

- Excessive snoring and chronic mouth-breathing
- Obstructive sleep apnea or sleep disturbances
- Adenotonsillar hypertrophy associated with:
  - Cor pulmonale
  - Failure to thrive
  - Dysphagia
  - Speech abnormalities
  - Craniofacial growth abnormalities
  - Occlusion abnormalities

Other

- Suspected neoplasia–asymmetric tonsillar hypertrophy

Patients with obvious severe airway obstruction secondary to adenotonsillar hypertrophy may require polysomnography, chest radiography, electrocardiography, and, possibly, cardiology consultation. Patients with cor pulmonale and hypercapnia may need postoperative intensive care monitoring with mechanical ventilation to avoid postobstructive pulmonary edema. If the severity of airway obstruction is not clear from history supplied by the parents, polysomnography may be warranted.

Patients with other medical conditions may require further testing or preoperative consultation. Patients with a history of significant bronchospasm may require pulmonary medicine evaluation and management in the perioperative period. Black patients should be screened for sickle cell disease preoperatively, and girls of reproductive age should undergo a preoperative serum β-human chorionic gonadotropin test to rule out pregnancy. Velocardiofacial syndrome may require preoperative angiography to determine the presence of abnormally medially displaced carotid arteries, which may be at risk during tonsillectomy.[109]

Adenotonsillectomy

The technique of adenotonsillectomy has evolved significantly over the past 2000 years, and various techniques are used today for extirpation of the tonsils and adenoids. Multiple tonsillectomy techniques exist, including the sharp dissection initially described by Crowe and associates[7]; various electrocauterization techniques; lasers (including potassium-titanyl–phosphate [KTP][110] and CO_2[52]); the tonsil guillotine; as well as newer technologies and techniques such as Coblation (ArthroCare Corporation, Austin, TX), the Harmonic Scalpel (Ethicon Endo-Surgery, Inc., Cincinnati, OH), and the Microdebrider (Medtronic Xomed, Inc., Jacksonville, FL). The number of adenotonsillectomies

Surgical Indications for Adenoidectomy

Infection

Purulent adenoiditis

Adenoid hypertrophy associated with:

- Chronic otitis media with effusion
- Chronic recurrent acute otitis media
- Chronic otitis media with perforation
- Otorrhea or chronic tube otorrhea

Obstruction

Adenoid hypertrophy associated with excessive snoring and chronic mouth-breathing

Sleep apnea or sleep disturbances

Adenoid hypertrophy associated with:

- Cor pulmonale
- Failure to thrive
- Dysphagia
- Speech abnormalities
- Craniofacial growth abnormalities
- Occlusion abnormalities
- Speech abnormalities

Other

Suspected neoplasia

Adenoid hypertrophy associated with chronic sinusitis

performed in the United States appears to have peaked in the 1940s and 1950s.[56] In 1959, 1.4 million tonsillectomies were performed. This number decreased to 500,000 in 1979 and fell even further to 340,000 in 1985.[50,56] In the past 30 years there has been a significant decrease in the number of adenotonsillectomies performed in the United States, as well as a change in the preoperative indications for surgery. Whereas chronic infection was the primary surgical indication for adenotonsillectomy in the 1950s and 1960s, airway obstruction and obstructive sleep apnea have now become the most common preoperative indications for surgery.[56] Apparent drops in the number of adenotonsillectomies performed in the United States reflect a higher degree of selectivity by otolaryngologists and referring primary care physicians.

Indications

The current indications for tonsillectomy and adenoidectomy are shown in Boxes 196-1 and 196-2. Generally, the indications for adenotonsillectomy can be related primarily to chronic upper airway obstruction in conjunction with adenotonsillar hypertrophy, which manifests as snoring, obstructive sleep apnea, or chronic infectious conditions such as chronic recurrent tonsillitis.

Upper Airway Obstruction

Patients with airway obstruction related to adenotonsillar hypertrophy typically present with excessive snoring and sometimes with witnessed brief apneic events. The severity of the condition can often be elicited with a history supplied by the parents. However, there may often be no indications of airway obstruction other than loud snoring. It has been demonstrated that patients who snore loudly at night may manifest significant sleep apnea on polysomnographic testing when no significant parental history of witnessed apnea has been noted.[111] Patients who have obvious adenotonsillar hypertrophy on physical examination, a significant history of loud snoring with the associated symptoms of restless, disturbed sleep, or daytime somnolence do not necessarily need preoperative polysomnographic testing. If the parent is unclear about the severity of airway obstruction or if the physical findings and history are not consistent, preoperative polysomnographic testing is warranted to demonstrate the severity of airway obstruction.

Chronic Infections

Patients with chronic recurrent tonsillitis or chronic tonsillitis may benefit from tonsillectomy and possibly adenoidectomy. In 1995, the American Academy of Otolaryngology–Head and Neck Surgery Clinical Indicators Compendium stated that patients who have three or more infections of the tonsils and/or adenoids per year despite adequate medical therapy are candidates for tonsillectomy and adenoidectomy.[112] Other indications are chronic tonsillitis unresponsive to medical therapy that results in a persistent foul taste or halitosis and recurrent tonsillitis associated with the streptococcal state that has not responded to β-lactamase–resistant antimicrobial therapy.[112] The efficacy of elective tonsillectomy for recurrent sore throats has been demonstrated by numerous investigators.[113,114] The efficacy of elective tonsillectomy has also been shown in children with recurrent throat infections, including GABHS.[114]

In a study by Paradise and associates,[114] 187 children participated in a randomized clinical trial. Inclusion criteria for the study were seven or more sore throat episodes in the preceding year that were treated with antibiotics; five or more sore throat episodes in the 2 preceding years; or three or more episodes in each of the 3 preceding years. Elective tonsillectomy or adenoidectomy resulted in better status than that in a control group of children who were managed nonsurgically. Factors that should be taken into account in the consideration of surgery for recurrent throat infections in children are (1) the severity of each episode, (2) how well infections have responded to medical therapy, and (3) quality of life issues (e.g., number of school days missed).

Tonsillectomy and adenoidectomy should be considered in patients with recurrent tonsillitis, as well as other medical conditions such as cardiac valvular disease with recurrent streptococcal tonsillitis, a history of febrile seizures, poorly controlled diabetes, and, possibly, ventricular peritoneal shunts. Systemic infections in these situations could become life-threatening.

Tonsillectomy is the management of choice for peritonsillar abscess in children who do not tolerate needle aspiration. Peritonsillar abscesses that have been successfully drained by needle aspiration are not necessarily absolute indications for tonsillectomy. However, tonsillectomy is definitely indicated in cases of recurrent peritonsillar abscess.[54,115-117]

Although diphtheria is currently unusual, tonsillectomy may be warranted in patients who are diphtheria carriers and have not shown response to antibiotic therapy. Finally, patients with chronic halitosis related to debris in the tonsillar crypts or secondary to chronic tonsillitis are candidates for tonsillectomy.

Adenoidectomy

Indications

Adenoid hypertrophy or chronic adenoiditis may cause significant problems requiring adenoidectomy in situations in which the tonsils themselves are not diseased and are not contributing to symptomatology. Patients with chronic adenoid hypertrophy causing craniofacial morphology problems, excessive snoring, or, possibly, quality of life issues (e.g., poor olfaction) are candidates for adenoidectomy.[118] Adenoid hypertrophy may be confirmed by flexible nasopharyngoscopy or lateral cervical radiography.

Patients with a history of chronic recurrent sinusitis may also benefit from adenoidectomy. Patients with chronic sinusitis and significant adenoid hypertrophy may initially benefit from adenoidectomy rather than undergoing more extensive sinus surgery.[119] In addition, patients with chronic purulent rhinitis secondary to chronic adenoiditis may also have response to adenoidectomy if their rhinitis has not responded well to appropriate medical therapy. Evidence now points to a possible reason for the efficacy of adenoidectomy in these situations. Coticchia and colleagues[120] showed that biofilms were prominent in the adenoids of children with chronic sinusitis. The group compared pediatric adenoids removed for chronic sinusitis with those removed for obstructive sleep apnea. In the sinusitis-related adenoids, 94.9% of the mucosal surface was covered with dense mature biofilms, compared with just 1.9% of the surface in the hypertrophy-only adenoids. This

study suggests that the biofilms may be a natural reservoir for resistant bacteria and that their removal during adenoidectomy may be the reason for the observed benefit of the procedure.

Patients with hyponasal speech (rhinolalia clausa) are also candidates for adenoidectomy. Hypernasal speech (rhinolalia aperta) is a contraindication to adenoidectomy. However, in unusual cases, excessive tonsillar hypertrophy may impede palatal movement, which may improve after tonsillectomy.[121]

Although surgical intervention should be considered in cases of severe nasal obstruction related to adenoid hypertrophy, there is evidence that alternative medical therapy exists to manage adenoid hypertrophy. Demain and Goetz[122] demonstrated that aqueous nasal beclomethasone therapy led to significant improvement of nasal obstruction secondary to adenoid hypertrophy, which was confirmed by pre- and post-management flexible nasopharyngoscopy. In addition, patients with underlying inhalant allergies may benefit from antihistamine therapy and, possibly, from allergic immunologic desensitization therapy.

Conservative adenoidectomy should be performed in patients with a cleft palate or submucous cleft palate, leaving the lower portion of the adenoid pad intact to decrease the risk of postoperative VPI.

Adenoidectomy and Otitis Media

The role of the adenoids in the etiology of otitis media has been controversial. However, several investigations have demonstrated that appropriate management of the adenoids plays an important role in the diagnosis and management of chronic otitis media in children. Numerous reports have demonstrated that adenoidectomy alone or in conjunction with myringotomy tube placement may reduce the incidence of future episodes of otitis media and possibly reduce the necessity for future ventilation tubes.[123,124] Gates and colleagues[123] randomly assigned 578 children between the ages of 4 and 8 years to four management groups; group 1 underwent bilateral myringotomy and no ventilation tube placement; group 2 underwent placement of ventilation tubes; group 3 underwent adenoidectomy alone; and group 4 underwent adenoidectomy and placement of ventilation tubes. They demonstrated with statistical significance that patients who underwent adenoidectomy in conjunction with bilateral myringotomy had significantly lower postmanagement morbidity, as measured by hearing loss secondary to middle-ear effusion and the number of subsequent placements of ventilation tubes. Paradise and associates[124] randomly studied 213 children who had previously received ventilation tubes that had since extruded. These patients were randomized into two groups, those undergoing adenoidectomy and those who did not (control group). The adenoidectomy group had statistically significant less otitis media than control subjects. Another, large study further demonstrated the effectiveness of adenoidectomy in this regard. Kadhim and associates,[125] evaluating data on 50,000 children younger than 10 years who had undergone myringotomy tube placement, found that adenoidectomy at the time of tube placement decreased the odds of needing subsequent tube placement regardless of whether or not the child was having adenotonsillar disease. The actual mechanism by which adenoidectomy affects the course of otitis media in children is unclear. Surgical extirpation of the adenoids may remove a nasopharyngeal nidus of contaminated tissue that secondarily acts as a source of infection in the middle ear, or adenoidectomy may simply remove an anatomic obstruction of the eustachian tube. The actual size of the adenoid pad has not necessarily been implicated in the etiology of chronic otitis media with effusion. Many studies have been unable to determine the relationship between adenoid size and chronic otitis media with effusion.[126-129]

On the basis of current evidence, adenoidectomy should be considered in children undergoing primary ventilation tube placement who have symptomatology suggestive of chronic nasal obstruction or adenoid hypertrophy that is confirmed by nasopharyngoscopy or nasopharyngeal radiography. Patients who require subsequent sets of ventilation tubes also may be candidates for adenoidectomy, regardless of adenoid size or symptomatology. If surgery is elected, proper technique is important, as Bluestone[115] and McKee[130] reported that surgical manipulation of the eustachian tube during adenoidectomy may predispose children to eustachian tube malfunction and the subsequent development of otitis media with effusion.

Adenotonsillectomy: Surgical Technique

Many surgical techniques have been described for extirpation of the tonsils and adenoids. Crowe and associates[7] described the first meticulous surgical dissection technique with use of sharp instrumentation. More recently, however, dissection with electrocautery has become the most popular and common technique. Other current techniques are the Coblator (ArthroCare Corporation), the Microdebrider, the ultrasonic Harmonic Scalpel, bipolar electrocautery, and, less frequently, CO_2 or KTP laser tonsillectomy.[62,110,131-135] A 2007 survey of pediatric otolaryngologists showed monopolar cautery to be by far the most common method of tonsillectomy, favored by 53% of the respondents. Coblation at 16% was the second most common method, cold dissection combined with electrocautery was third at 10%, followed by bipolar electrocautery at 6%.[136] Evidence also suggests that sharp dissection may lead to slightly less postoperative pain. However, there may be less intraoperative blood loss with electrocautery techniques.[132,137,138] Guillotine tonsillectomy techniques are still used and have been shown to have a low complication rate.[140-141] In China, the technique of guillotine tonsillectomy in children without anesthesia has been described.[142]

Of the new technologies, Coblation tonsillectomy has received possibly the most attention and acceptance. Coblation technology utilizes a system of radiofrequency bipolar electrical current that passes through a medium of normal saline, which results in the production of a plasma field of sodium ions. These energized ions are able to break down intercellular bonds and effectively vaporize tissue at a temperature of only 60° C. This vaporization theoretically results in effective dissection with less postoperative pain from thermal injury.[143,144] The technique can be utilized for complete tonsillectomy or for intracapsular tonsillectomy, otherwise known as tonsillotomy, in which the tonsil is debulked, leaving a small amount of lymphoid tissue to cover the inferior constrictor muscle. Multiple newer studies suggest decreased pain and recovery time with Coblation than with electrocautery and the Harmonic Scalpel.[145-147] These studies report no higher incidence of postoperative hemorrhage with this technique. Some researchers, however, have found a higher bleeding rate with the Coblator, and this issue remains a concern for some writers.[148-150]

The Coblator consists of a hand piece with a suction irrigation tip that transmits the radiofrequency current and dissects tissue and also has a cautery capability for hemostasis. With the Coblation technique, a separate suction cautery device is theoretically not necessary, because adenoidectomy can be performed with the Coblator. The blade can be bent to allow placement into the nasopharynx to allow Coblation of adenoid tissue with use of mirror visualization. This technique may work adequately for small adenoid pads; however, it may not be as efficacious for large obstructive adenoid pads. Research is ongoing to improve the Coblator to enhance its capabilities to perform adenoidectomy.

The Harmonic Scalpel utilizes ultrasonic technology to cut and coagulate tissues, resulting in minimal tissue damage from thermal trauma. The device converts electrical energy from a generator into mechanical vibration through a transducer that consists of piezoelectric ceramics, generating a back-and-forth vibration of the blade at a frequency of approximately 55.5 kHz. The device can cut tissue on low- and high-power settings and can also coagulate bleeding tissue. Initially, the Harmonic Scalpel found its use in laparoscopic surgery in the field of pediatric and general surgery. However, its use in tonsillectomy has been reported to have encouraging results.[103,151] Wiatrak and Willging[151] reported on a prospective study consisting of 117 patients undergoing either traditional electrocautery technique or Harmonic Scalpel surgery. They found a trend toward decreased postoperative pain over the first 3 postoperative days and a significant increase in the ability to sleep comfortably through the first three postoperative nights in children undergoing Harmonic Scalpel surgery. The duration of the procedure was longer for the Harmonic Scalpel than for electrocautery. The complication rates were equivalent in the two groups. At this time the Harmonic Scalpel cannot be utilized for adenoidectomy, so other techniques must be used for that operation. A concern about its use is higher costs incurred for each blade utilized for tonsillectomy. Other studies

have shown the Harmonic Scalpel to be an effective instrument for tonsillectomy but have not found it to have a significant advantage over electrocautery.[152]

Subtotal tonsillectomy has become a more popular technique over the last several years. The concept of partial intracapsular tonsillectomy or tonsillotomy is not new to otolaryngology.[153] This procedure can be performed using any of the described instruments but is now most commonly performed with powered instrumentation.[154,155] Ideally in this technique, the only tissue manipulated and dissected is the tonsil itself. No mucosal cuts are made, the peritonsillar capsule is not dissected, and there should not be any direct cauterization of the peritonsillar fascia and underlying pharyngeal musculature. All of the preceding features are thought to make the postoperative pain and discomfort much less with this technique. With use of a microsurgical debrider, the hypertrophied tonsils are sequentially shaved behind the levels of the anterior and posterior tonsillar pillars. Exposure is obtained by retraction of the anterior tonsillar pillar with a Herd retractor. Hemostasis is obtained with suction cautery. Multiple studies point to a reduced need for pain medicine and more rapid return to normal activity and normal diet with subtotal microsurgical debrider tonsillectomy.[156-158] The incidence of postoperative bleeding is not increased with this technique and may actually be slightly less than with traditional electrocautery.[159] However, at least one study did not show a significant difference in return to normal activity and pain resolution between these two methods.[160] The indications for this technique are controversial, with some advocating this technique as appropriate for all indications in all ages and others stating that it should be performed only in children without a history of tonsillitis, owing to the concern about persistent tonsillitis in the residual tonsil tissue. Cost is a factor in the use of disposable microsurgical debrider blades for partial intracapsular tonsillectomy. At this point there is little evidence that the residual tissue is associated with recurrent tonsillitis as the child ages, but more long-term data are needed for confirmation. The most significant concern with this technique is the possibility of regrowth and the subsequent recurrence of obstructive symptoms. In one series of 278 patients, the incidence of regrowth was 3.2%.[161] This event is rare but does occur, and the patient's parents must be made aware of this possibility during the informed consent discussion for this procedure.

The microsurgical debrider can be effective for performing adenoidectomy. Koltai and others have reported on and shown the safety and efficacy of this technique.[155,162-165] Koltai, Chan, and Younes[166] report that the utilization of power-assisted adenoidectomy allows more precise, rapid, and safe removal of adenoid tissue. This technique is especially useful in removing adenoid tissue that extends through the choanae and into the nasal cavity. However, the cost of microsurgical debrider blades continues to be an issue related to its use. Stanislaw and coworkers,[167] in a prospective evaluation of power-assisted adenoidectomy or curette adenoidectomy in 90 children, found that power-assisted adenoidectomy was 20% faster, involved 27% less blood loss, and provided a more complete resection and better control of depth of reception. It also had higher surgeon satisfaction.

Technique Description

Electrocautery tonsillectomy using a meticulous dissection technique and low electrocautery wattage results in very minimal intraoperative blood loss and acceptable postoperative discomfort. This technique is described in detail. Instrumentation is shown in Figure 196-13.

Patients should not eat solid foods for 8 hours before surgery. If the patient is closely supervised, he or she may drink clear liquids until 3 hours before surgery. Preoperative sedation with midazolam hydrochloride (0.5 to 1 mg/kg) approximately 30 minutes before surgery may be necessary for patients with excessive preoperative anxiety. Anesthesia is typically induced by mask ventilation, with subsequent intravenous access after the anesthetic has taken effect. Patients usually receive intravenous antibiotics such as ampicillin (20 mg/kg; maximum dose, 1 g). Telian and colleagues[168] demonstrated that intravenous antibiotics followed by a 1-week course of postoperative oral antibiotics significantly decreased morbidity after tonsillectomy.

Patients who have a significant history of obstructive sleep apnea or are younger than 3 years receive intraoperative corticosteroids, most commonly dexamethasone (0.5 mg/kg). Catlin and Grimes[169] reported that one dose of intraoperative intravenous corticosteroids improved

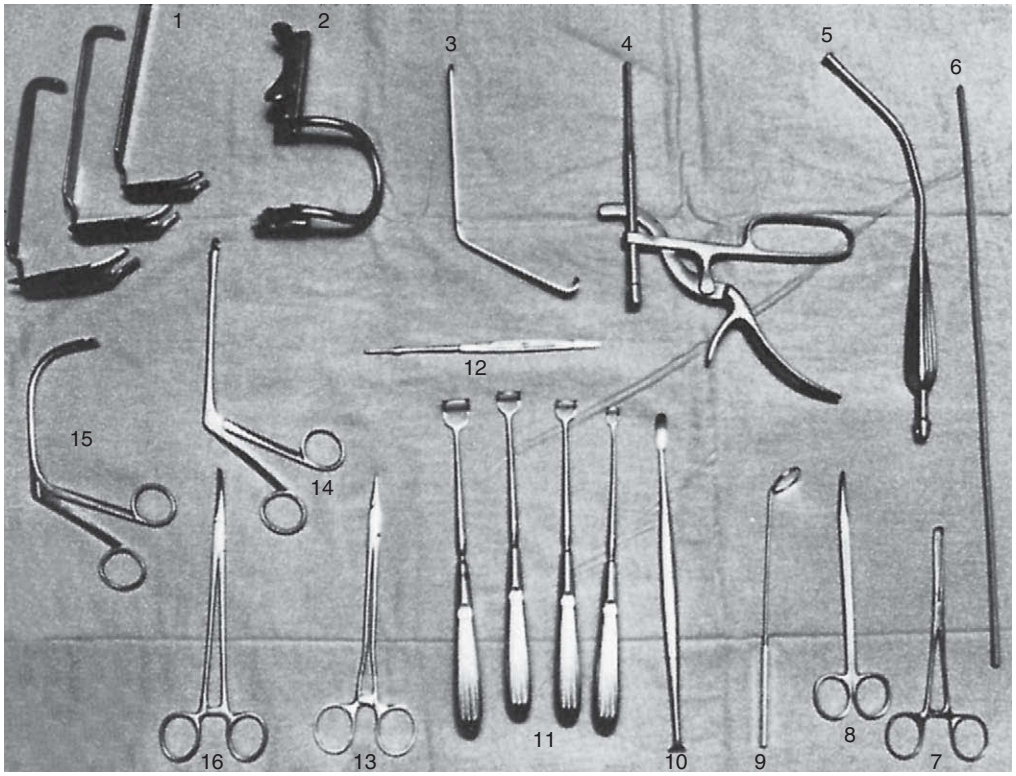

Figure 196-13. Instrumentation used in tonsillectomy and adenoidectomy procedures.

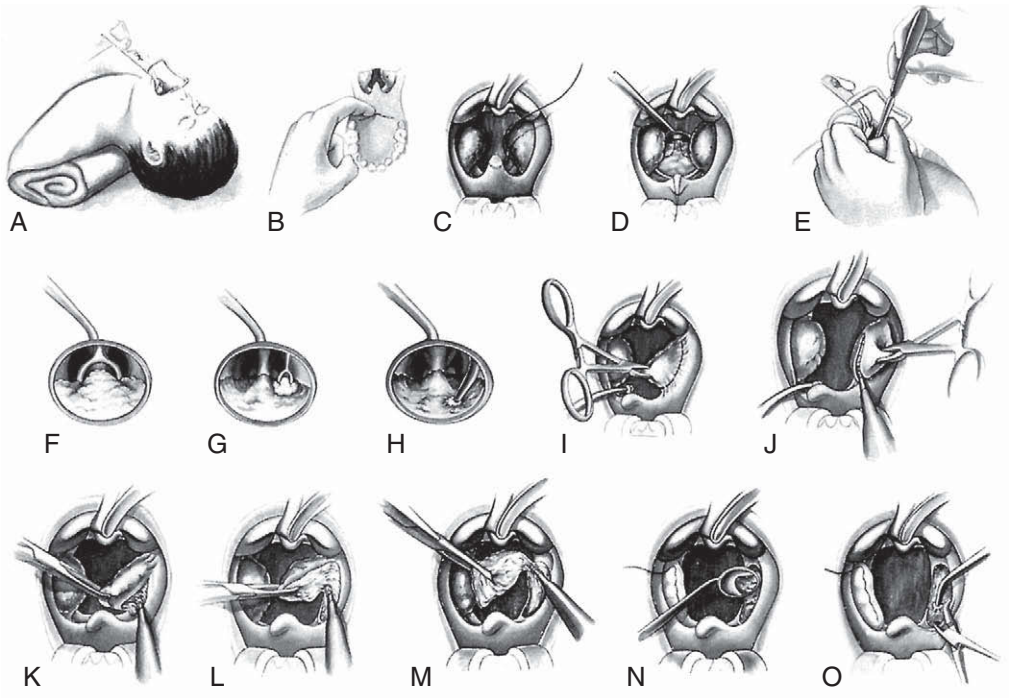

Figure 196-14. Adenotonsillectomy technique. **A,** Patient placed in Rose's position. **B,** Palate inspected for presence of submucous cleft. **C,** Nylon suture placed through uvula for retraction. **D,** Nasopharynx inspected with mirror. **E** and **F,** Positioning of curette for adenoid removal. **G,** Removal of adenoid remnants with small curette. **H,** Removal of adenoid remnants and control of bleeding with suction cautery. **I** and **J,** Grasping of right tonsil and incision of mucosa using cautery. **K** to **M,** Dissection of tonsil with cautery. **N,** Inspection of superior pole with mirror. **O,** Control of bleeding with suction cautery.

recovery time in children following tonsillectomy. However, Ohlms and associates[170] and Volk and coworkers[171] demonstrated no significant effects on recovery time of a single dose of intravenous steroids. We use corticosteroids to potentially reduce airway edema in patients who are more susceptible to airway complications after tonsillectomy. Although we do not routinely use peritonsillar infiltration with local anesthetic agents, numerous reports have described short-term benefit of this procedure with regard to postoperative pain in the immediate recovery period after tonsillectomy.[172-174] Peritonsillar infiltration with local anesthesia may also decrease intraoperative blood loss in patients undergoing sharp-dissection tonsillectomy.[172]

After induction of general anesthesia and placement of an endotracheal tube, the patient is placed in Rose's position (Fig. 196-14A) and a Crowe-Davis mouth gag is placed for exposure of the oropharynx. A red rubber catheter is placed through the right nares, brought back out through the oral cavity, and clamped with a Kelly clamp to retract the soft palate for better visualization of the nasopharynx. At this point the hard and soft palate are examined by visual inspection and palpation for evidence of a submucous cleft palate. Adenoidectomy should not be performed in the presence of an occult submucous cleft palate unless absolutely necessary. Conservative adenoidectomy should be considered in these situations. The Microdebrider is especially useful in this rare situation.

Adenoidectomy in the United States is still most commonly performed with adenoid curettes, which have either straight or curved handles.[175] The LaForce adenotome also has been described as an instrument for adenoid extirpation.[176] The nasopharynx is inspected with a nasopharyngeal mirror to assess the size of the adenoid pad and guide placement of the curette. The curette is placed high in the nasopharynx so it abuts the posterior aspect of the nasal septum. The adenoid pad is then carefully curetted, with care taken not to penetrate deeply into the prevertebral region. Care must also be taken during use of the curette not to extend too far laterally and thus potentially risking damage to the torus tubarius and eustachian tube orifice. Small curettes may be used to remove residual adenoid tissue in the posterior choanal region. This step entails removal of the superior portion of the adenoid pad and preservation of the inferior aspect with cautery or curettes. Packs are placed into the nasopharynx to obtain hemostasis.

With use of the Microdebrider, the exposure is the same. The instrument is set to oscillate at a maximum of 1500 rpm. With the nasopharyngeal mirror, the adenoids are débrided, with protection of the eustachian tube opening and care taken to not débride too deeply. When all the desired adenoid tissue has been removed, the nasopharynx is packed.

After tonsillectomy has been performed, the nasopharynx is reexamined, and hemostasis is obtained with suction electrocautery. It is important to remember that the mouth-gag tongue blade places pressure on the base of tongue and should be released intermittently to allow blood circulation in the tongue and possibly aid in reducing postoperative pain. A throat pack may be used to prevent blood and secretions from entering the esophagus. Swallowing of blood and secretions may lead to postoperative nausea and vomiting. In addition, blood oozing around the endotracheal tube may form a laryngeal clot, which may lead to postextubation airway obstruction. Children undergoing adenotonsillectomy typically have an uncuffed endotracheal tube, which may allow leakage of air around the tube with positive-pressure ventilation. Fires and endotracheal tube explosions have been reported during tonsillectomy, presumably related to oxygen leaking around uncuffed endotracheal tubes.[177]

At this point, the tonsillectomy is performed with electrocautery. The tonsil is grasped with an Allis clamp or tenaculum. It is then retracted medially, and the superior pole is incised with the electrocautery; the surgeon identifies the tonsillar capsule and carefully dissects the avascular plane between the capsule and the tonsillar bed. When sharp dissection is used, the superior mucosal incision may be made with a knife, and blunt dissection may be used to separate the tonsil from the tonsillar bed with a Thompson dissector or a Fischer knife. With the electrocautery, the tonsil is carefully dissected down to its inferior extent, where it is amputated. With sharp dissection, a tonsil snare can be used to amputate the tonsil at the inferior pole. If bleeding is noted at this point, a pack may be placed in the tonsillar fossa, and the other tonsil is then excised in the same manner. Care must be taken

to preserve the mucosa and muscle in the posterior pillar, especially superiorly. Extensive cauterization and tissue loss of the posterior pillar may predispose the patient to postoperative nasopharyngeal stenosis. If electrocautery is being used, great care must be taken that other metal instrumentation in the oropharynx (e.g., the mouth gag or Yankauer suction) not touch the electrocautery blade, so as to avoid burning the oropharynx and lips. In addition, the electrocautery blade should be guarded with a nonconducting material.

After removal of the tonsillar fossa packs, residual bleeding may be controlled with electrocautery on a low-wattage setting. Significant bleeding vessels may have to be clamped and ligated. Great care should be taken in the use of suture ligatures in the tonsillar fossa. The external maxillary and lingual arteries may inadvertently be ligated in the region of the inferior tonsillar pole, thus leading to sloughing and severe hemorrhage. In addition, the internal carotid artery, which is in close proximity to the tonsillar fossa, may be damaged inadvertently, resulting in complications such as pseudoaneurysm formation and excessive hemorrhage.[52] After hemostasis has been obtained in the oropharynx and nasopharynx, the oral and nasal cavities are thoroughly irrigated. The hypopharynx is suctioned to evacuate all secretions and potential blood clots, and the stomach is also suctioned at this point. The patient is then awakened and extubated.

In general, accepted practice is to admit for overnight admission patients who have a significant history of obstructive sleep apnea, those younger than 3 years, and those with other medical problems or extenuating circumstances. If they are taking oral fluids adequately, all patients undergoing outpatient surgery are discharged after an observation period of approximately 2 to 4 hours. Intravenous fluids are administered according to deficit replacement and maintenance until oral intake resumes satisfactorily; lactated Ringer's solution or 0.5 normal saline is used. Acetaminophen with or without codeine is given for analgesia. A 1-week course of oral antibiotics is also prescribed. The patient's diet advances from clear liquids on the day of surgery to a soft diet the following day and then solid foods subsequently as tolerated. Soft foods are generally well tolerated. However, patients with unrestricted diets have not been shown to have significant complication rates postoperatively.[6,58,178] Patients or their parents are instructed to return immediately to the emergency room if there is any evidence of bright red bleeding from the nose or oral cavity.

Inpatient versus Outpatient Procedures

It has been clearly demonstrated in the literature that adenotonsillectomy in appropriately selected children may be performed on an outpatient basis.[14,25,105,179,180] It is important that patients are observed postoperatively and that they obtain significant postoperative intravenous rehydration. Postoperative observation times discussed in the literature vary from 136 minutes to 6 to 8 hours.[133,181] Although short-stay outpatient tonsillectomy has been demonstrated as a safe and cost-effective procedure, it is important preoperatively to identify outpatients who are at risk for postoperative complications and who may benefit from longer observation periods following surgery.

Numerous writers believe that children younger than 3 years should be admitted for observation after surgery because they are at increased risk for postoperative complications, most of which are airway-related.[94,180,182-185] The ultimate decision for postoperative admission lies with the surgeon. Other patients who may warrant admission after adenotonsillectomy include those with (1) a history of an abnormal bleeding disorder or abnormal preoperative coagulation profile, (2) evidence of severe obstructive sleep apnea, (3) underlying craniofacial abnormalities such as Down syndrome, and (4) systemic disorders such as cardiopulmonary disease or asthma. Postoperative admission also should be considered for patients undergoing tonsillectomy for peritonsillar abscess, for patients who live a long distance from the hospital (>60 miles or 1 hour driving time), or for patients whose home situation is not consistent with close postoperative observation.[116,117,186]

Complications

Serious postoperative complications secondary to surgery of the tonsils and adenoids are primarily related to pain, hemorrhage, airway obstruction, postoperative pulmonary edema, VPI, nasopharyngeal stenosis, and death.[187] Meticulous attention to surgical technique and technical advances in modern anesthesiology have significantly reduced the number of complications related to adenotonsillectomy. Paradise reported an overall complication rate of 14%; all of these complications were self-limiting.[124] Richmond described a series of 794 patients undergoing adenotonsillectomy, of whom 4.2% had variable degrees of postoperative bleeding and 1.3% had self-limiting postoperative airway obstruction. In 9409 pediatric patients undergoing adenotonsillectomy, Crysdale and Russel[188] reported an overall hemorrhage rate of 2.15%, with only 0.06% of patients requiring a second general anesthetic for hemostasis. For reasons other than the hemorrhage (including fever, airway distress, pneumonia, inadequate oral intake, vomiting, and pain), 0.6% of the patients required delayed hospitalization. The incidence of serious surgical complications has been reported to be approximately 15 cases per 1000.[189] Pulmonary abscess, although dreaded in the past, is now extremely rare. However, this complication may still be encountered, as may other rare complications, including Horner's syndrome, optic neuritis, meningitis, brain abscess, paralysis of the glossopharyngeal and recurrent laryngeal nerves, salivary fistulas from the submandibular gland to the tonsillar fossa, and mediastinal emphysema.[187,190,191]

Chronic postoperative pain related to fibrosis and calcification of the stylohyoid ligament (Eagle's syndrome) may be encountered occasionally. Pain referred to the ipsilateral ear may be diagnosed by palpation of the tonsillar fossa and from demonstration by radiographic studies of an elongated styloid process. Aspiration of foreign bodies (e.g., dislodged teeth, sponges, and lymphoid tissue) may also be encountered. If a tooth aspiration is suspected, a radiographic study should be obtained immediately. If a permanent tooth has been dislodged, a dental consultation should be obtained. A thorough investigation, including endoscopy, must be performed when a suspected foreign body has been aspirated.

Postoperative Hemorrhage

Postoperative hemorrhage is the most common serious complication of adenotonsillectomy. Reported postoperative hemorrhage rates range from 0.5% to 10%, although variable rates have been reported with different surgical techniques.[188,192-195] Meticulous attention to surgical technique and intraoperative hemostasis, regardless of the technique used, will lead to acceptable postoperative hemorrhage rates. Detection of underlying coagulation disorders by history and physical findings or through preoperative screening in appropriately selected patients will help avert significant intraoperative blood loss. Appropriate preoperative and intraoperative measures are taken in conjunction with a hematology consult. Certain analgesics (e.g., ketorolac tromethamine) have been associated with increased hemorrhage rates when given in the perioperative period and should be avoided in patients undergoing adenotonsillectomy.[63,196]

The extensive blood supply of the tonsillar fossa is composed of a complex network of anastomosing arteries primarily arising from the ipsilateral external carotid artery system. However, there are contributions from the internal carotid and vertebral arteries, and contralateral vessels circulate through the circle of Willis.[197] Therefore, extensive intraoperative or postoperative hemorrhage may not always cease after ligation of the external carotid artery. In rare, severe cases, ligation of other branches (e.g., the maxillary, facial, lingual, or superior thyroid artery) may be necessary.[192]

The arterial blood supply of the nasopharynx and adenoids arises from both the internal and external carotid arterial system. However, bleeding in this region can be controlled most commonly with compression and electrocautery. In severe cases, application of caustic agents (e.g., tannic acid, bismuth subgallate) or hemostatic agents (e.g., Avitene) may be beneficial. Aberrant arterial vessels in the oropharynx and nasopharynx may be damaged intraoperatively (Fig. 196-15). McKenzie and Wolfe[97] reported an aberrant carotid artery arising in Rosenmüller's fossa that was injured during adenoidectomy, necessitating subsequent ligation of the common carotid artery with resultant transient hemiplegia.

Bleeding can be intraoperative, immediately postoperative (within 24 hours), or delayed (after 24 hours). Intraoperative hemorrhage may

Figure 196-15. Computed tomography scan with contrast enhancement demonstrating an aberrant artery in the left retropharyngeal region.

be related to an underlying coagulopathy or possibly to major arterial damage in severe cases. Steps to control major intraoperative hemorrhage include use of suction cautery or ligation or, possibly, placement of a pack in the tonsillar fossa and over-suturing of the tonsillar pillars to provide constant compression of the fossa. Suture ligatures may damage underlying arterial vessels, thereby worsening the bleeding or possibly leading to delayed postoperative hemorrhage and should be placed with extreme care if they are used.[87,198] In severe cases, ligation of larger arteries through an open-neck exploration may be necessary. However, this should be an extremely uncommon step. Persistent hemorrhage from the nasopharynx after adenoidectomy is often related to residual remnants of adenoid tissue that should be completely removed to best obtain hemostasis.

Immediately postoperative bleeding after adenoidectomy may be controlled initially with topical decongestant nose drops. However, patients with severe bleeding should be taken back to the operating room for examination of the nasopharynx and definitive hemostasis, in which the clots are suctioned, adenoid remnants are removed, and the nasopharyngeal pad is definitively cauterized.

Delayed postoperative bleeding, although typically not as dangerous as intraoperative or immediately postoperative bleeding, may be fatal if not managed appropriately. Patients or parents should be well informed before discharge about the possibility of delayed postoperative hemorrhage and should be told to return for immediate evaluation if there is any evidence of bright red bleeding from the nose or mouth. The most common time for delayed postoperative bleeding is between the fifth and seventh postoperative days. When hemorrhage occurs, patients should be returned to the operating room for immediate hemostasis if active bleeding is confirmed on physical examination. If no active bleeding is apparent and a blood clot is evident in the tonsillar fossa, it should not be disturbed. However, if the surgeon cannot determine whether active bleeding is taking place, the clot should be suctioned to allow better examination. Blood clots often hide bleeding vessels and may prevent appropriate coagulation as a result of fibrinolysis.[199] Patients with delayed hemorrhage who are not actively bleeding and have a blood clot present in the tonsillar fossa should at least be admitted for overnight observation. A coagulation profile and hematocrit measurement should be obtained.

Airway Obstruction and Pulmonary Edema

Postoperative airway obstruction may occur after adenotonsillectomy, especially in children younger than 3 years.[58,182] Edema of the tongue, nasopharynx, and palate may necessitate temporary replacement of a nasal trumpet and also may require intravenous corticosteroid therapy. Dislodging of pharyngeal clots may obstruct the larynx postoperatively, resulting in death.[200] Therefore, all clots should be evacuated from the pharynx before termination of the procedure.

Postoperative pulmonary edema may arise in patients with long-term upper airway obstruction related to adenotonsillar hypertrophy, often necessitating prolonged mechanical ventilation. Patients with a prolonged history of obstructive sleep apnea—as documented by polysomnography and evidence of cor pulmonale—should be observed closely after surgery with pulse oximetry in a monitored setting. Patients with persistent hypercapnia may require planned postoperative mechanical ventilation until P_{CO_2} values return to normal.

Velopharyngeal Insufficiency

Velopharyngeal insufficiency (VPI), or hypernasality, is a relatively unusual complication primarily related to adenoidectomy. In patients with excessively large tonsils and preoperative VPI, the velopharyngeal insufficiency may actually improve after the obstructive tonsils have been removed. Patients with a history of cleft palate or evidence of an occult submucous cleft palate on physical examination (see Figure 196-11) should not undergo adenoidectomy unless it is absolutely necessary. In these situations conservative or partial adenoidectomy should be performed. The actual incidence of VPI after adenoidectomy in otherwise healthy children has been estimated to be between 1 in 750 and 1 in 1459.[189,201] It is important to determine preoperatively whether there is a family history of VPI or whether the patient had a prior history of hypernasal speech or nasal regurgitation as an infant. These signs may herald the development of postoperative VPI. If an underlying speech abnormality exists preoperatively, speech therapy evaluation should be performed. It also is important to determine whether reported hyponasal speech is truly related to a nasal obstruction or is actually related to hypernasal speech, which can be misinterpreted by parents.

Patients in whom postoperative VPI develops should be evaluated and managed initially by a speech pathologist. Most cases are transient and will resolve with time. However, severe cases may require surgical intervention, such as formation of a pharyngeal flap, sphincteroplasty, or, possibly, posterior pharyngeal wall augmentation. Reconstructive surgery should be considered in patients with persistent VPI that has not responded to speech therapy for at least 1 year. *Habit palsy* is transient postoperative VPI that develops secondary to pain when the patient has altered pharyngeal muscle control during speech and swallowing. If it is not resolved shortly after surgery, speech therapy is usually successful.

Nasopharyngeal Stenosis

Nasopharyngeal stenosis is an extremely difficult management problem that requires surgical intervention for satisfactory resolution. This situation may arise from excessive cauterization with extensive mucosal destruction involving the nasopharynx, lateral nasopharyngeal wall, and superior tonsillar pillar along with excessive resection of posterior tonsillar pillar tissue. Other predisposing factors are performance of surgery during an acute episode of pharyngitis or purulent sinusitis, revision adenoid surgery with removal of lateral pharyngeal bands, and keloid formation.[202] Figi[203] described 37 cases of nasopharyngeal stenosis, 22 of which were secondary to adenotonsillectomy.[109] Guggenheim[204] reported 18 cases of nasopharyngeal stenosis secondary to adenoidectomy caused by stripping of the lymphoid tissue from the torus tubarius, Rosenmüller's fossa, and the lateral nasopharynx.[205]

Numerous techniques have been described for surgical repair using a combination of skin flaps, local mucosal flaps, stents, skin grafts, and scar incisions.[206] Cotton[207] described a technique using incision of the stenosis with rotation of a laterally and inferiorly based pharyngeal flap to reline the nasopharynx. Occasionally, second-stage repair is necessary. Physical findings in patients with nasopharyngeal stenosis

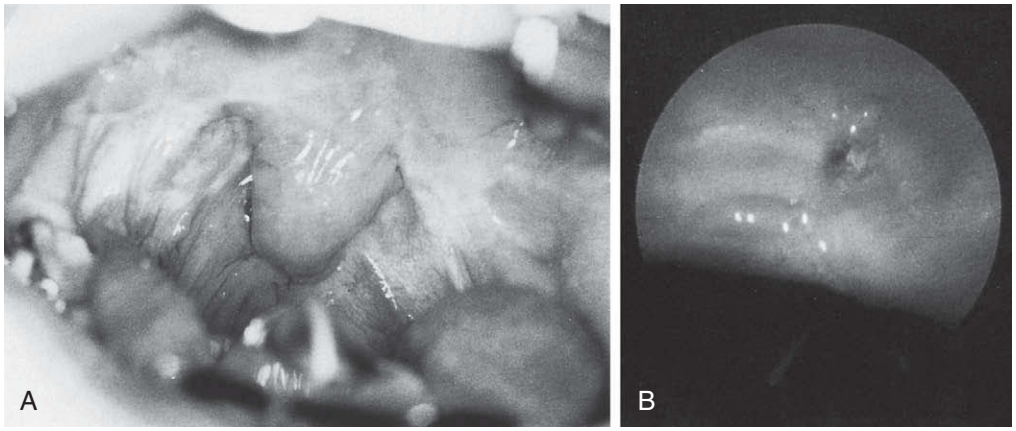

Figure 196-16. **A,** Oropharyngeal view of postadenotonsillectomy nasopharyngeal stenosis. **B,** Endoscopic view of nasopharyngeal stenosis by means of a 120-degree rod-lens telescope.

typically consist of scarring of the uvula down to the posterior pharyngeal wall with possibly a small opening visible on mirror examination or flexible nasopharyngoscopy (Fig. 196-16). The majority of the scarring is based laterally in the region of the posterior tonsillar pillars. This results in partial or complete obstruction of the nasopharyngeal airway and can be extremely debilitating.

Cervical Spine Complications

A rare complication of adenoidectomy or tonsillectomy is atlantoaxial subluxation (Grisel's syndrome). Although up to 10% of patients may report neck pain after adenoidectomy, patients with Grisel's syndrome have decalcification of the anterior arch of the atlas and laxity of the anterior transverse ligament between the atlas and axis.[63,208] This leads to complaints of stiff neck with spasm of the sternocleidomastoid or deep cervical muscle. The patient holds the head to one side with slight rotation toward the opposite side. Radiographic evaluation in suspected cases should include anteroposterior and lateral cervical spine radiography in addition to flexion-extension radiographs, which may detect mild subluxation. In severe cases, CT and possibly magnetic resonance imaging may demonstrate evidence of decalcification, which may be associated with cervical spine osteomyelitis. Most cases of atlantoaxial subluxation are related to infection or trauma and only rarely are secondary to adenotonsillectomy.[209] Patients with Down syndrome are more prone to traumatic atlantoaxial subluxation following adenotonsillectomy. Great care should be taken in cervical spine manipulation during surgery in patients with Down syndrome.[104]

Management of atlantoaxial subluxation after adenoidectomy or adenotonsillectomy should be individualized according to the duration and the symptoms present. Intravenous antimicrobial therapy and possibly cervical traction may be necessary. In the presence of cervical osteomyelitis, long-term (4-8 weeks) intravenous antimicrobial therapy, coupled with cervical stabilization, will be necessary.[209] Retropharyngeal abscess after adenoidectomy has also been reported.[190]

CHAPTER ONE HUNDRED AND NINETY-SEVEN

Infections of the Airway in Children

Newton O. Duncan

Key Points

- The diagnosis of pediatric airway infections requires astute clinical acumen and judicious use of laboratory testing and imaging techniques.
- Prompt and evidence-based management of these potentially life-threatening infections provides reliable, successful outcomes.
- Viral croup, or laryngotracheitis, is the most common airway obstructive infection in children with well-defined diagnostic criteria and clinically documented management schemes.
- Supraglottitis or epiglottitis has become a rare clinical entity, but its diagnosis and management should not be forgotten.
- Bacterial tracheitis, or exudative tracheitis, is also uncommon, but prompt diagnosis and management may be lifesaving.
- Retropharyngeal cellulitis and abscesses are common airway infections in children and a high index of suspicion may be needed for diagnosis. Well-defined CT imaging results can help determine where surgical management is appropriate.

Children may experience a variety of infections involving the upper respiratory tract and surrounding structures. Some infections occur commonly, some may be self-limited, and some may be relatively inconsequential. However, other infections, some of which are more rare, may be life threatening. The astute clinician can often identify the various airway infections by an accurate clinical history and targeted physical examination. Radiologic imaging, laboratory studies, or airway endoscopy may also be helpful for accurate diagnosis. Nevertheless, a keen understanding of the various signs and symptoms of airway infections is important. The signs and symptoms of the various airway infections may have many similarities because the anatomic structures and tissues involved are close in proximity. These similar airway findings also can be present in children with acute tonsillitis, infectious mononucleosis, diphtheria, peritonsillar abscess, congenital airway anomalies, subglottic stenosis of any etiology, and in those with airway foreign bodies. Therefore great familiarity with the spectrum of childhood airway disease entities can be extremely important in their prompt diagnosis and management. This chapter emphasizes the current recognition and management of croup (laryngotracheitis), supraglottitis (epiglottitis), bacterial tracheitis, and retropharyngeal abscesses.

Croup (Laryngotracheitis)

The term *croup* is from the ancient Scottish language that refers to the harsh, barking cough that may be present in those with a number of different acquired or congenital disorders.[1,2] Several terms have been used synonymously with croup, leading to confusion about the exact nature of the disease. These terms include *croup, viral croup, laryngotracheitis, laryngotracheobronchitis, pseudomembranous croup, spasmodic croup,* and *postintubation croup.* This infectious disease primarily involves the vocal folds or glottis and the subglottis. Because viruses predominantly cause this entity, the most descriptive and widely used terms are either viral croup or, more properly, viral laryngotracheitis. Viral laryngotracheitis, or croup, is the most common form of infectious upper airway tract obstruction in children. It is estimated that this condition accounts for 90% of infectious airway obstructions and that 3% to 5% of children have at least one episode of croup. This condition can be recurrent in approximately 5% of children.[3] Most children with croup have mild-spectrum symptoms but some children (1.5% to 15%) with more severe spectrum croup require hospital admission for airway obstructive symptoms, and during hospitalization 1% to 5% may require intubation.[4] Parainfluenza viruses 1 and 2 primarily are implicated in this disease (up to 75%), but influenza A and B, respiratory syncytial virus, measles, adenovirus, varicella, and herpes simplex virus type 1 all have been isolated.[5] Measles involvement in those with croup historically leads to an aggressive form of the disease.[6] More recently, influenza viruses and herpes simplex viruses have both been implicated in more severe or prolonged courses of croup.[7,8]

Children are most commonly affected when they are between 6 months and 3 years of age, with a peak incidence at 18 to 24 months of age. Boys are more likely affected, by more than a 2 : 1 ratio. Although croup can occur at any time of the year, there is a strong seasonal occurrence in late autumn and winter. Croup may be called atypical if it occurs in infants younger than 6 months of age, lasts more than 7 days, or does not respond to appropriate treatment. Other etiologies besides acute viral laryngotracheitis should be considered in these atypical cases.

Viral croup transmission occurs by direct contact and exposure to nasopharyngeal secretions.[9] The incubation period before onset of clinical symptoms is 2 to 6 days for parainfluenza virus type 1, and children may continue to shed the virus for up to 2 weeks.[10] After acquisition, the viral infection involves the nasopharynx, producing nasal symptoms. Local spread to the larynx and trachea ensues. The mucosa of the vocal folds and subglottis become erythematous and swollen. Lymphocytes, histiocytes, and polymorphonuclear leukocytes infiltrate the lamina propria, submucosa, and adventitia. In addition, generalized mucosal edema is present. The duration of illness usually is from 3 to 5 days. The crucial factor in those with viral croup is the amount of swelling in the subglottic area. The subglottis is the narrowest portion of the upper respiratory tract and, because of the complete cartilaginous cricoid ring, any edema that occurs in the subglottis does so at the expense of the airway lumen. Because stridor does not occur until there is already significant airway obstruction and because any decrease in cross-sectional area is proportional to the square of the radius of the airway lumen, any further decrease in airway size caused

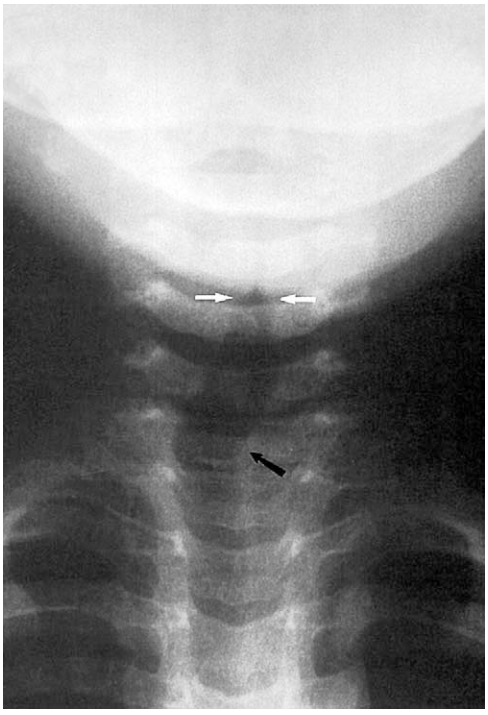

Figure 197-1. Normal anteroposterior radiographic view of the soft tissues of the neck demonstrating the normal shouldering contours of the proximal trachea *(white arrows).* Many children will show slight angulation of the trachea, which is a normal variant *(black arrow).*

by mucous plugging or crusting may lead to rapid and complete airway obstruction.

Clinical Features

Characteristically, children with viral croup have a history of prodromal upper airway infection. Low-grade fever may be present. There also may be leukocytosis, although the leukocyte count in most patients is normal. Inspiratory stridor, hoarseness, and a barking cough are cardinal symptoms of viral croup. This cough is invariably present and may help distinguish croup from other illnesses. The presence of biphasic stridor, retractions, high respiratory rate, or oxygen desaturations indicates severe airway obstruction.

Viral croup may present with only mild symptoms of airway obstruction, but it also can be severe with life-threatening airway obstruction. Many different schemes have been developed to assess the spectrum and severity of croup in an effort to assist in determining how to best manage the different presentations of croup.[1,5,10] Regardless of the scheme used, it is important to consider the following parameters when evaluating children with croup or airway obstruction in general: (1) stridor—inspiratory versus expiratory; (2) respiratory rate; (3) chest retractions; (4) air entry into the chest by auscultation (decreased with severe obstruction); (5) anxiety or restlessness; (6) color or cyanosis; (7) oxygen desaturation by pulse oximetry; and (8) level of consciousness.

Diagnosis

The diagnosis of croup is highly suggested by history and physical examination alone. Detailed questioning about possible foreign body ingestion should be made, along with any previous intubation history. Radiographic imaging of the airway traditionally has been helpful in evaluating those with airway disorders (Figs. 197-1 and 197-2). The diagnosis can be confirmed radiographically by anteroposterior (AP) and lateral (high kilovoltage) films of the upper airway. The frontal AP view classically shows a "steeple sign" in the subglottic area, whereas the lateral view is characterized by haziness of the same area (Figs. 197-3 and 197-4). Flexible fiberoptic laryngoscopy occasionally may be helpful in establishing the correct diagnosis of viral croup. This procedure should be performed with utmost care if there are moderate-to-

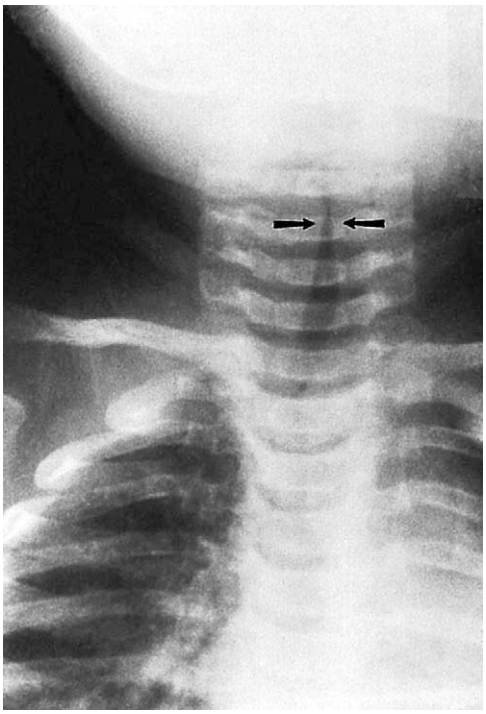

Figure 197-3. Narrowed subglottis in viral croup *(arrows)* in the anteroposterior radiographic view.

severe airway obstructive symptoms. In patients with severe airway obstruction, the diagnosis may be confirmed by direct laryngoscopy at the time of intubation (Figs. 197-5 and 197-6).

Differential Diagnosis

The most important differential diagnosis to consider in children with suspected croup is supraglottitis (Table 197-1). Thereafter, the possible

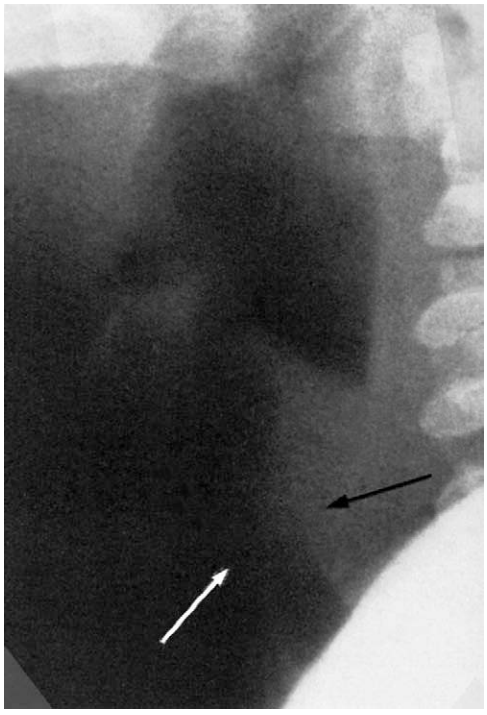

Figure 197-4. Hazy subglottis in the lateral radiographic view *(arrows)* seen in viral croup.

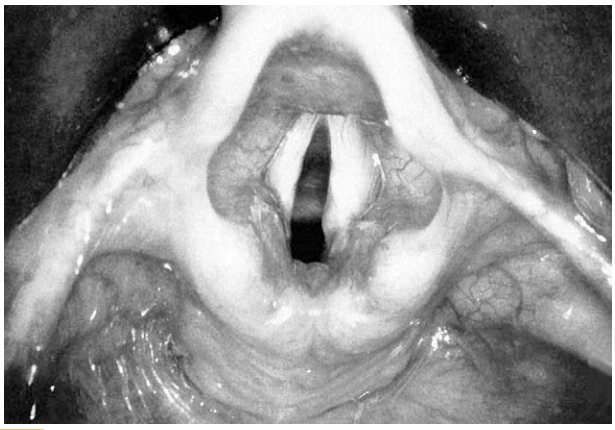

Figure 197-5. Normal child larynx with crisp vocal folds and widely patent subglottis visualized by a rigid rod telescope.

presence of any airway foreign body, particularly in the larynx or subglottis, must be considered. Subglottic hemangiomas may have similar symptoms in infants younger than 6 months of age. Recurrent episodes of a crouplike illness may occur not only in those with congenital subglottic narrowing, but also in children with acquired subglottic stenosis. Therefore a history of intubation may be important. Viral croup in the presence of any preexisting laryngeal or subglottic narrowing may lead to early or recurrent stridor and symptoms of croup. Atypical or recurrent symptoms of croup always demand close attention for other etiologies of airway compromise in addition to viral croup. Gastroesophageal reflux also may be a contributing cause of recurrent croup.[11] When viral croup is not responding to appropriate therapy and when children exhibit an increasingly febrile or toxic appearance, bacterial superinfection in the subglottis or trachea should be suspected. This may occur in 10% to 15% of patients hospitalized with more severe croup. Bacterial tracheitis actually may originate as a complication of viral croup.[12]

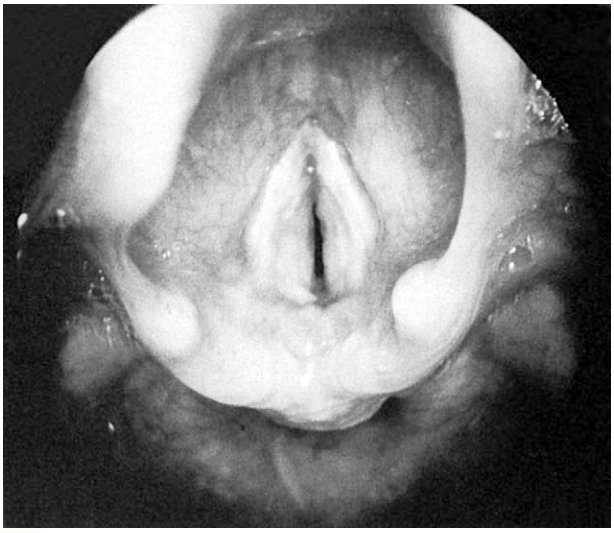

Figure 197-6. Viral croup with severe vocal fold and subglottic edema as seen with a rigid rod telescope.

Spasmodic Croup

Spasmodic croup is a poorly understood entity that is manifested by the sudden onset of stridor, usually at night, in a healthy child between 1 and 3 years of age with no concomitant upper respiratory tract infection. A barking cough and dyspnea accompany the stridor. These episodes may be recurrent in nature and usually resolve spontaneously or with cool humid air within several hours. The vocal folds may be involved with spasm, and mild, pale transient vocal fold and subglottic edema may be present. Some of the same viruses that cause viral croup may be involved with causing spasmodic croup. An increasing body of evidence suggests an association between spasmodic croup and recurrent croup with nonspecific bronchial hyperactivity, asthma, and allergic disease.[13-16] Spasmodic croup and viral croup also may well represent two ends of a broad spectrum in the clinical presentation of a single disease.[17]

Management

Most children with viral croup have symptoms within the mild spectrum of the illness and do not require a physician visit. The illness usually is self-limited, peaking in severity through 3 to 5 days with no specific treatment required at home. A quiet environment and parental comforting or support is universally important in the treatment of children with croup. Any stimulus or disturbance promotes crying and an increased respiratory rate. The airway is stabilized with less mucosal dryness when the child is quiet and when anxiety or crying is diminished.

Management strategies for viral croup have included glucocorticoids, racemic epinephrine, heliox, and mist. Although viral croup is the most common form of airway obstruction in young children, many controversies remain and there is no consensus regarding optimal treatment. Recently, croup clinical pathways have been devised to promote consistent, safe, and effective management that might result in reduced hospital admissions and earlier hospital discharge.[18]

Overwhelming evidence is present to support the use of glucocorticoids in both outpatient and inpatient settings in the management of moderate to severe decrease in croup.[19-22] Segal and others[23] have documented an 86% decrease in hospital admissions for treatment of croup when steroids were used. The exact mechanism of action of glucocorticoids in croup is unknown, but they probably decrease endothelial permeability, thus leading to decreased mucosal edema. This effect commonly takes at least 3 hours. In mild to moderate cases, oral prednisolone 2 mg/kg/day in two divided doses may be used in the outpatient setting or home for approximately 3 days. This regimen is particularly useful in milder, recurrent cases of croup, with parents keeping prednisolone at home to use when symptoms occur.

Table 197-1

Differential Diagnosis of Upper Airway Infections in Children

	Laryngotracheitis (Viral Croup)	Supraglottitis (Epiglottitis)	Bacterial Tracheitis	Retropharyngeal Abscess
Age	6 mo to 3 yr	1-8 yr	6 mo to 8 yr	1-5 yr
Onset	Slow	Rapid	Rapid	Slow
Prodrome	URI symptoms	None or mild URI	URI symptoms	URI symptoms
Fever	Variable or none	High	Usually high	Usually high
Hoarseness/barky cough	Yes	No	Yes	No
Dysphagia	No	Yes	Yes	Yes
Toxic appearance	No	Yes	Yes	Variable

URI, upper respiratory infection.

In the emergency center, dexamethasone has been extensively used in doses from 0.15 mg/kg to 0.60 mg/kg, with maximum doses of 1 mg/kg for moderate to severe croup.[22,24] Oral administration is as effective or better than intramuscular injection or nebulized therapy.[15,22] Nebulized budesonide has also been compared with dexamethasone but has had no clear clinical advantage.[24] If the symptoms of croup are severe enough to warrant the use of racemic epinephrine, then glucocorticoids are helpful in preventing any associated mucosal rebound edema 2 to 3 hours later. Glucocorticoids have had a significant impact in the outpatient setting but have also greatly decreased the severity of symptoms and the duration of hospitalization.[22,25,26] At this point it appears that an initial dexamethasone dose of 0.60 mg/kg orally is preferred because of its low dose and ease of administration.[27] Further doses of prednisolone (2 mg/kg/day) or dexamethasone (1 mg/kg/day) in divided doses may be used to sustain the glucocorticoid effect in either inpatients or outpatients. Intravenous administration is preferable in serious inpatient disease. Prolonged use of glucocorticoids should be monitored carefully, particularly when antibiotics may be used, to prevent candida overgrowth in the subglottis or trachea.[28] In the absence of clinical evidence of an emerging bacterial process, there is no support for the use of antibiotics in the management of viral croup.

Racemic epinephrine in an equal mixture of the d- and l-isomers of epinephrine has been used in the United States and Canada since 1971[29] but has become available and accepted in other countries as well. It has been shown that l-epinephrine is at least as effective as racemic epinephrine, is readily available worldwide, has no increased side effects, and is less expensive than d-epinephrine.[30] The α-adrenergic effects of epinephrine cause mucosal vasoconstriction, leading to decreased edema in the subglottic region. Using 0.5 mL of a 2.25% solution of racemic epinephrine diluted in 3 mL of saline delivered by a nebulizer results in rapid clinical improvement of moderate to severe respiratory distress within 10 to 30 minutes.[17,31] Alternatively, 5 mL of a 1:1000 solution of l-epinephrine produces equivalent results. This effect wanes and disappears by 2 hours after administration, with rebound mucosal edema in some patients. Because of this temporary effect and possible rebound, children should be observed closely after administering racemic epinephrine for 2 to 3 hours. Recent reports document the safe use of racemic epinephrine in an outpatient setting. These children were observed for at least 2 to 3 hours, were significantly improved, could easily return to the hospital if needed, and were closely followed as outpatients.[32-35] Racemic epinephrine has become widely used in outpatient settings for moderate to severe croup within similar observation criteria described in the studies. In an intensive care setting it can be used every 30 minutes, but it is usually spaced every 3 to 4 hours in a regular hospital unit. Glucocorticoid administration is important in any setting to prevent or diminish the mucosal rebound potential of racemic epinephrine. Racemic epinephrine should be used with great caution in patients with tachycardia or cardiac anomalies such as tetralogy of Fallot or idiopathic subaortic stenosis.

Heliox, a helium-oxygen mixture, may be helpful in severe croup. It decreases the work of breathing by promoting laminar flow through the partially obstructed airway. One study has shown similar improvement in croup scores with heliox administration when compared with patients given epinephrine.[36] Heliox may be used as an adjunct to all other medical therapy for croup.

Humidified air or mist has historically been used to treat croup before other medical therapy was available. Humidifiers or steam showers at home and mist tents or blow-by mist in hospital settings presumably moisten secretions, make for easier expectoration, and prevent drying or crusting that may further compromise a narrow airway. There may also be soothing of the involved mucosa, making children more comfortable and less likely to increase submucosal inflammation by vigorous coughing. However, only several studies have investigated the effectiveness of moist air in the management of croup and have demonstrated no benefit over control patients.[22,26,37,38] Furthermore, the issue of warm versus cool mist has not been settled. Despite the lack of objective benefit, strong anecdotal experience may support the continued use of mist, particularly in severe hospitalized cases of viral croup or in low-humidity environments. Mist tents should be avoided or used with caution because they may provoke more anxiety in children and therefore blow-by mist may be a better alternative. Well-designed studies are necessary to define the role of mist in the management of viral croup.

When medical therapy fails to alleviate respiratory distress, endotracheal intubation (nasotracheal or orotracheal) may be necessary. A tube at least a half size smaller than estimated for the child's size or age should be used. When possible, intubation should be done in a controlled situation in the operating room with an inhalation agent, while the child is spontaneously breathing. This also may allow for airway endoscopy at the same time. Optical rigid rod telescopes should be used to assess the airway, and rigid bronchoscopes should be avoided if possible to prevent further airway mucosal injury. Extubation can be performed when an air leak is detected. If no air leak is detected after 5 to 7 days, thorough airway endoscopy is indicated. Airway endoscopy also is important in recurrent, prolonged, or atypical cases of croup. Ideally, endoscopy should be performed 3 to 4 weeks after the acute episode has resolved so that acute inflammatory changes can be differentiated from previous existing anatomic abnormalities. A thorough evaluation of the larynx, subglottis, and trachea with rigid rod telescopes then should be performed.

Supraglottitis (Epiglottitis)

Since Michel's original description of "angina epiglottidea anterior" in 1878,[39] acute epiglottitis, or *supraglottitis* as it is more correctly called, has become recognized as a rapidly progressive, life-threatening airway

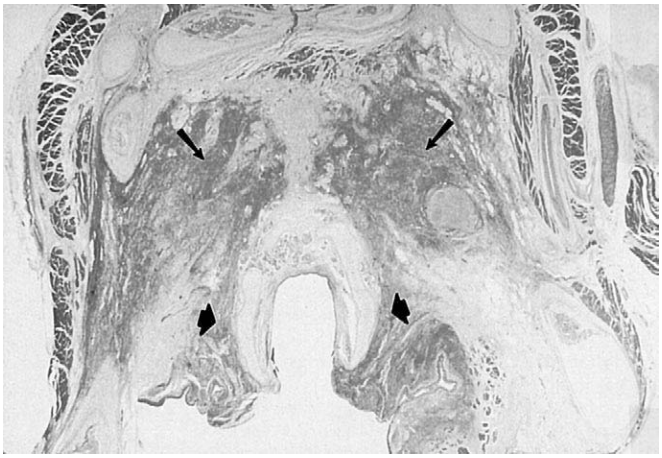

Figure 197-7. Histologic section of a larynx (postmortem) in supraglottitis showing posterior curling of the epiglottic cartilage *(arrowheads)* and severe inflammatory edema of the lingual surface of the epiglottis *(arrows)*.

emergency. Supraglottitis predominantly affected children in what may be termed the prevaccine era. A precipitous decline in supraglottitis in children has occurred since the introduction of the Haemophilus influenzae type b (HIB) vaccine.[40-42] Before widespread use of the HIB vaccination, the incidence of HIB among children ranged from 6 per 100,000 in Canada[43] to 34 per 100,000 in Switzerland.[44] In 1988 conjugated HIB vaccine was introduced with recommendations for universal use in children by 2 years of age in 1990 and immunized levels of at least 90% by 1995. Invasive HIB disease, primarily supraglottitis and meningitis, has declined nationally in the United States by 95%.[45] Immunization works by producing antibodies to the polysaccharide capsule of HIB. Supraglottitis may infrequently occur even when immunization has occurred because of failure of antibody production.[45] Acute supraglottitis remains a rare infection. Its importance lies in its high mortality if the diagnosis is not made promptly.

Supraglottitis is a cellulitis of all the supraglottic structures (not just the epiglottis) that may completely obstruct the airway. As the supraglottic edema increases, the epiglottis curls posteriorly and inferiorly as a result of diffuse inflammatory infiltration of the lingual surface of the epiglottis (Fig. 197-7). The aryepiglottic folds are also affected. With the airway partially occluded, mucus can easily complete obstruction of the airway. Diffuse infiltration of polymorphonuclear lymphocytes and inflammatory edema are seen histologically. Progress is rapid, in terms of hours rather than days. The disease classically occurred in children 2 to 6 years of age; however, it may occur at any age including in newborns.[28,46] A higher incidence may be seen in the winter or spring, although the disease may occur at any time of the year. Supraglottitis may be more commonly seen in older children and adults in today's HIB vaccine era.[23]

The causative organism most commonly identified in more than 90% of supraglottitis in the prevaccine era was *H. influenzae* type b (HIB).[40,47] This bacterial species may be part of the normal nasopharyngeal flora, or it may be acquired by respiratory transmission from other intimate contact. These bacteria may become blood borne and subsequently seed the epiglottis, meninges, facial skin, lungs, or joints. As the frequency of HIB disease has decreased in the HIB vaccine era, the epidemiology of supraglottitis has shifted.[48] Group A β-hemolytic streptococci comprise the majority of cases.[21,49] Other pathogens such as staphylococcus,[50] pneumococcus,[51] klebsiella,[52] Haemophilus parainfluenzae,[53] pseudomonas,[54] viruses,[53,55-57] and candida[58] have been isolated. Other rare causes including crack cocaine,[59] Kawasaki disease,[60] thermal epiglottitis caused by hot food or drink,[61,62] and post transplant lymphoproliferative disorder[63] have been reported. With the appearance of the human immunodeficiency virus (HIV), chronic epiglottitis associated with lymphoid hyperplasia within the epiglottis of an HIV-infected child has been reported.[64]

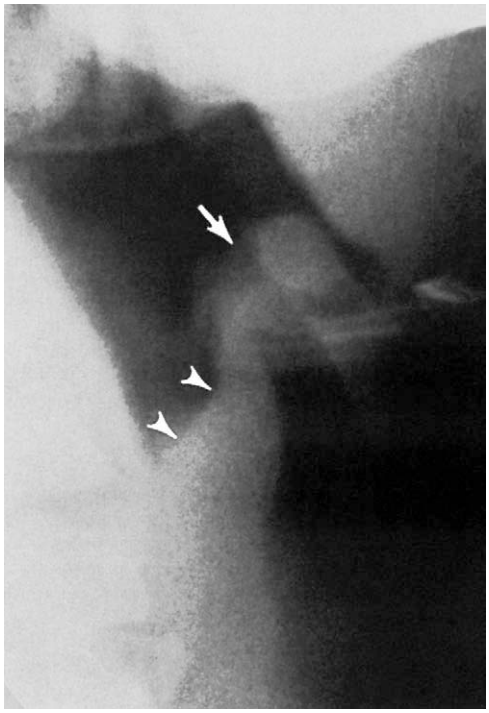

Figure 197-8. Supraglottitis seen on lateral soft tissue radiograph with a rounded epiglottis *(arrow)*, thickened aryepiglottic folds *(arrowheads)*, and distention of the hypopharynx.

Clinical Features

Due to the rarity of supraglottitis in the HIB vaccine era, the diagnosis may be more challenging. Regardless of the age at presentation, the three most common signs of supraglottitis are fever, difficulty breathing, and irritability. Children are toxic in appearance and have clinical evidence of major upper airway obstruction. The child exhibits shallow respiration, inspiratory stridor, retractions, and drooling. There is severe throat pain and dysphagia. Speech is limited because of pain. A cough or hoarseness is usually not present, but the voice may be muffled. Stridor occurs late when airway obstruction is almost complete. Activity is minimal, and the patient usually prefers sitting or leaning forward. The child may assume a "tripod" position (i.e., seated, with the hands braced against the bed and the head held in the sniffing position to maximize airflow through a narrowed laryngeal inlet). Sudden laryngospasm may occur with aspiration of secretions into an already compromised airway and produce respiratory arrest. Some of the atypical causes of supraglottitis may have a more protracted presentation.

Diagnosis

Prompt recognition of this acute airway emergency is essential to prevent airway obstruction. The diagnosis of acute epiglottitis is made by direct inspection of the supraglottic structures in a controlled environment, usually in the operating room. In a cooperative patient with no imminent complete airway obstruction, the pharynx may be visualized without a tongue blade to rule out acute tonsil or peritonsillar infection. Attempts to visualize the epiglottis in the office or emergency department without the ability or equipment to manage an obstructed airway are strongly discouraged.

The need for radiologic studies is controversial. Although there is no question that supraglottitis can be diagnosed on a lateral neck radiograph, the question arises whether this is a safe and necessary procedure. Most radiology suites lack the facilities to handle an obstructed pediatric airway. A child presenting with the previous signs and symptoms probably should forego radiologic testing and proceed directly to the operating room. If there is any question as to the correct diagnosis and if the child is not in respiratory distress, radiologic examination can confirm

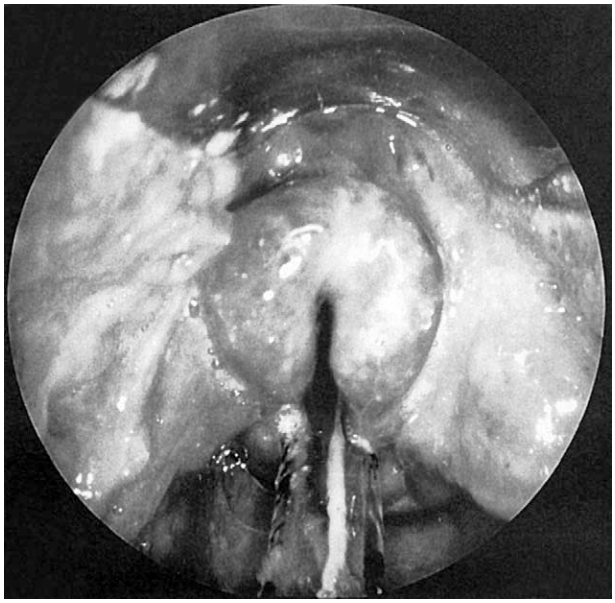

Figure 197-9. Supraglottitis just after intubation, visualized by a rigid rod telescope.

the diagnosis and exclude other causes of acute airway obstruction. Among the different diagnoses to be excluded are foreign bodies, retropharyngeal abscesses, and viral croup or laryngotracheitis.

Lateral neck radiographs in those with epiglottitis reveal swelling and rounding of the epiglottis with thickening and bulging of the aryepiglottic folds and distention of the hypopharynx (Fig. 197-8). In addition, the subglottic airway will appear normal on AP radiographs. In the operating room, examination of the supraglottis reveals an edematous, erythematous epiglottis with variable degrees of obstruction of the airway (Fig. 197-9). The cartilaginous landmarks are often obscured. Mucosal changes range from erythema to frank ulceration or sloughing. Rarely, an abscess can be found in the lingual surface of the epiglottis. The differential diagnosis of inpatients with possible supraglottitis includes viral croup or laryngotracheitis, bacterial tracheitis, uvulitis, acute tonsillitis, retropharyngeal or peritonsillar abscess, and diphtheria. Diphtheria is a rare infection seen only in certain areas with nonimmunized patients. A history of diphtheria immunization and the absence of pharyngeal membranes make the diagnosis unlikely. Foreign body aspiration in a child with an acute upper respiratory infection also may mimic supraglottitis.

Management

Close cooperation among the otolaryngologist, pediatrician, and anesthesiologist is paramount in the management of supraglottitis. If the diagnosis of acute supraglottitis is suspected, care should be taken to avoid stimulating the child. The child will naturally assume a posture and breathing pattern that maximizes ventilation. Any intervention may convert a functional—albeit unstable—airway into a nonfunctional, acutely obstructed airway. Anything that causes the child to cry may precipitate obstruction. Therefore drawing blood, throat examination, establishing an intravenous line, restraining for a radiograph, undressing the child, or even separating from a parent may cause distress and lead to airway obstruction. Any of these procedures should wait until a stable airway has been established.

Once the diagnosis of acute supraglottitis is made, survival is closely related to the establishment of an artificial airway. For many years, this meant a tracheotomy was performed when the diagnosis was made. Since the 1970s, the safety of intubation has been established, and now endotracheal intubation by nasal or oral routes has become the standard method of managing acute supraglottitis. The rationale for this change is based on the rapid response of the infectious process to appropriate antibiotic therapy. The edema of the supraglottic larynx usually subsides within 48 to 72 hours, allowing safe removal of the endotracheal tube.[65] Despite this observation, if personnel skilled in endotracheal intubation will not be available postoperatively or if the airway can only initially be secured with a rigid bronchoscope, then a tracheotomy still may be the most appropriate choice.

If supraglottitis is suspected, the patient should be taken to the operating room, accompanied by personnel experienced in the establishment of an emergency airway including tracheotomy. Once in the operating room, the patient undergoes gentle, slow, inhalational induction of general anesthesia with a nonirritating inhalation agent. Muscle relaxants should be avoided until an airway is established. Only after adequate anesthesia is obtained should blood samples be taken or intravenous lines be established. A small rigid rod telescope with an endotracheal tube threaded over it may also be useful in patients in whom the glottic airway cannot be visualized. The telescope is advanced through the larynx, and then the endotracheal tube is advanced over the telescope into the trachea. A rigid bronchoscope of the appropriate size and one size smaller should be available. In addition, equipment for a tracheotomy should be at hand. The larynx is examined by the otolaryngologist, and the diagnosis is confirmed. Temporary orotracheal intubation is performed. Cultures are taken from the surface of the epiglottis, and simultaneous blood cultures are drawn. Blood cultures are almost always positive for HIB when this is the causative organism. Orderly nasotracheal intubation can be performed in most patients with removal of the orotracheal tube. Nasotracheal intubation is preferred because there is less motion and resultant irritation of the subglottis. Adequate sedation or restraint is essential to prevent accidental self-extubation.

Appropriate antibiotic therapy is begun with the first dose given in the operating room. Ceftriaxone, cefotaxime, or ampicillin-sulbactam are all appropriate choices even in the HIB-vaccine era. Vancomycin may be used if the child is sensitive to cephalosporins. Adjustments in antibiotics can be made on the basis of culture results. The duration of antibiotic therapy depends on the clinical response of the child. Oral antibiotics indicated by culture results can be used to complete a 7- to 10-day course of therapy as soon as extubation has been accomplished and adequate oral intake is present. Adjunctive treatment with corticosteroids is controversial. Antibody levels to HIB should be measured if there is a history of HIB vaccine administration.

Extubation generally can be accomplished within 48 hours.[65] Criteria for extubation include decreased erythema and swelling of the epiglottis on laryngoscopy and the development of an air leak around the endotracheal tube or after an empirical 48 hours of intubation. Visualization of the supraglottis offers the best guide to extubation. When there is no air leak at 48 hours, flexible fiberoptic laryngoscopy or even direct laryngoscopy can be performed safely and quickly in the intensive care unit in an effort to determine when extubation is safe and to shorten the duration of intubation.

Complications

Although the airway compromise in supraglottitis itself is a life-threatening illness, other infections may occur simultaneously, which may have an equally deleterious effect. In the era of HIB supraglottitis, there was a 90% to 95% rate of positive blood culture for HIB.[66] Therefore it was not surprising that hematogenous dissemination of the disease occurred. The most common infectious complication was pneumonia. Other concomitant HIB infections included meningitis, cervical adenitis, pericarditis, septic arthritis, and otitis media.[66-68] Meningitis may be difficult to diagnose in a sedated patient, and therefore one must be cognizant of this manifestation of HIB disease. The dose of antimicrobial agent ordinarily given may be below that which is recommended for managing meningitis.

Noninfectious complications may also occur in patients with supraglottitis. Any patient with complete airway obstruction and respiratory arrest can suffer hypoxic damage of the central nervous system and other organ systems. Even patients who have had appropriate management of their airway obstruction can become hypoxic. The sudden relief of upper airway obstruction can result in postobstructive pulmonary edema with subsequent hypoxia.[69] This potential complication should be anticipated before the placement of an artificial airway, especially in those patients exhibiting a high degree of airway obstruc-

tion. Appropriate levels of positive end-expiratory pressure after endotracheal intubation can provide a protective mechanism against the development of pulmonary edema.

Bacterial Tracheitis (Exudative Tracheitis)

Bacterial tracheitis, perhaps better known as *exudative tracheitis,* has also been termed bacterial laryngotracheobronchitis, membranous laryngotracheobronchitis, and pseudo-membranous croup. It is a rare but potentially life-threatening disease. The disease was certainly described by C. L. Jackson in 1945, but it was not until 1979 that it was redescribed in detail.[70-72] Since then, there has been a growing consensus of opinion that bacterial tracheitis represents a secondary or complicating bacterial infection of viral croup or laryngotracheitis.[12,73] The secondary bacterial pathogen most often described is *Staphylococcus aureus,* but a more recent report found *Moraxella catarrhalis* to be the most frequently implicated pathogen followed by *S. aureus.* This series and others also suggested an epidemiologic change to a slightly less morbid condition.[74,75] Other pathogens include *Streptococcus pyogenes, H. influenzae,* and more rarely gram-negative enteric bacteria.[3]

Bacterial tracheitis primarily occurs during the respiratory virus seasons of autumn and winter, similar to viral croup. It may be seen in a wider range of ages than typical croup, with a mean age of 7.9 years.[72] The infectious inflammatory process involves the subglottis and trachea with marked edema in the subglottis as in those with viral croup. Diffuse mucosal ulceration and pseudo-membrane formation follow, with sloughing of these membranes into the tracheal lumen further contributing to airway obstruction. A purulent exudate is commonly present in copious amounts throughout the trachea and main bronchi as well. Blood cultures are usually negative, but tracheal cultures reliably reveal the bacterial pathogen.[3]

Clinical Features

The onset of bacterial tracheitis is variable. Some children become acutely ill and have severe respiratory distress within hours of the onset of illness. In other children there is a several-day prodromal period of stridor, barky cough, and hoarseness typical of viral croup that precedes the rapid, dramatic onset of higher fever, increasing respiratory distress, and toxic appearance. These patients often do not respond to racemic epinephrine because the disease rapidly progresses. High fever, cough, and stridor occur almost simultaneously over several hours. The rapid onset of the illness is similar to supraglottitis, but there usually is no dysphagia or drooling. Leukocytosis often is prominent in those with bacterial tracheitis.

Diagnosis

The diagnosis may be suspected on the basis of signs and symptoms, but it is confirmed by endoscopic examination of the airway. Plain radiographic imaging of the upper airway will show a "steeple" sign of the upper trachea or subglottis in anterior views, similar to viral croup, but it is the lateral view that can be most helpful. Diffuse haziness is present in the tracheal air column, along with soft tissue irregularities within the lumen, indicating pseudo-membrane detachment (Fig. 197-10).

No clinical, radiologic, or laboratory feature alone or in combination is a reliable predictor of bacterial tracheitis. The only diagnostic procedure that distinguishes bacterial tracheitis promptly and accurately from other acute upper airway disease is airway endoscopy.[76]

Management

Airway endoscopy is not only diagnostic of bacterial tracheitis but also is therapeutic at the same time. Children should be taken to the operating room, where induction of anesthesia with spontaneous ventilation is similar to that in children with supraglottitis. Direct laryngoscopy then is performed with careful examination of the larynx, subglottis, trachea, and main bronchi with a rigid rod telescope (Fig. 197-11). A rigid bronchoscope may be necessary along with the rigid rod telescope to adequately suction and remove the copious secretions and pseudomembranes. Cultures and a Gram stain should be obtained from the tracheal secretions. Orotracheal or nasotracheal intubation then can be performed to secure the airway, if necessary. When rigid bronchoscopy is performed, this may induce further mucosal injury and edema in the subglottis, requiring a longer period of intubation. Tracheotomy is rarely necessary.

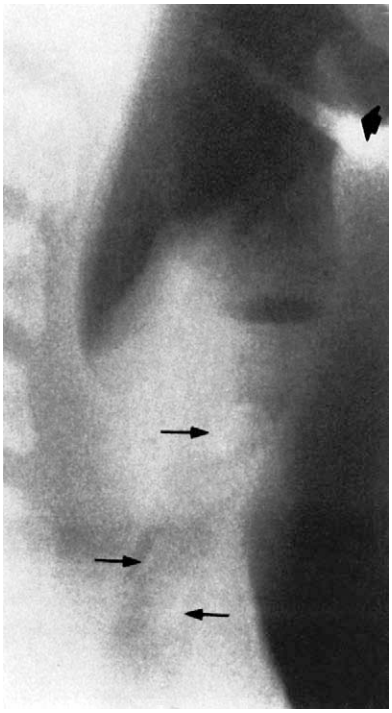

Figure 197-10. Bacterial tracheitis in a lateral soft tissue radiograph with obscured tracheal airway caused by sloughed mucosa *(arrows).* The epiglottis *(arrowhead)* is normal.

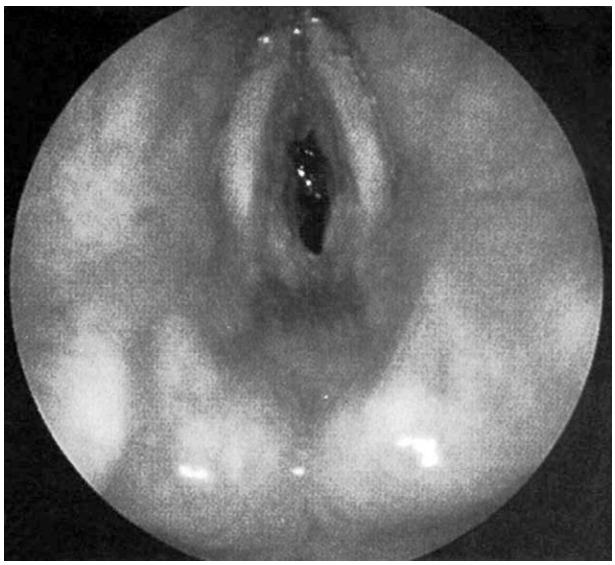

Figure 197-11. Bacterial tracheitis with severe glottic and subglottic edema with sloughed mucosa in the lumen.

Historically, the majority of patients (up to 80%) with bacterial tracheitis required intubation and ventilatory support.[44,72] More recent reports again suggest a milder illness with only 53% needing intubation.[75] While intubated, meticulous airway care with frequent saline administration and suctioning of the trachea should be performed to evacuate the thick and copious secretions. Occasionally, repeat rigid bronchoscopy may be necessary to handle unusually tenacious secretions. Initial parenteral antibiotic therapy should include vancomycin—because of the rise in resistant *S. aureus* organisms—along with cefotaxime or ceftriaxone for gram-negative organisms or mixed flora.

Gram's stain, culture results, and sensitivity results will direct ultimate antibiotic choices. Nafcillin, ampicillin-sulbactam, and cefuroxime may be good secondary antibiotic choices when culture and sensitivity results are known. Parenteral antibiotics should be continued beyond extubation when the child has undergone major clinical improvement. Extubation can be safely performed when the child's temperature has returned to normal, when a leak is present around the endotracheal tube, and when the secretions have markedly decreased. Oral antibiotics then can be used to complete a 10- to 14-day course of therapy. Intubation may be necessary for 6 to 7 days in more severe cases with a mean hospitalization of 10 days, which usually is longer than that of those with viral croup.[3]

The most common complication of bacterial tracheitis is pneumonia, occurring in about 50% of children. Severe hypoxia with death has occurred after respiratory arrest in severe cases of airway obstruction.[77]

Retropharyngeal Abscess

Retropharyngeal abscesses occur primarily in children, but they can be seen in adults where it is an entirely different disease associated with direct extension from adjacent structures, penetrating trauma, granulomatous disease, and cervical spine osteomyelitis. In children, retropharyngeal abscesses have been described since antiquity, but they have become less common as a result of antibiotic use since the 1950s.[78] However, Kirse and Roberson,[79] in a large review, reported a dramatic increase in the incidence of retropharyngeal abscess in 2001. Because of its anatomic location, a retropharyngeal abscess can still be a life-threatening illness that requires prompt diagnosis and treatment.

The retropharyngeal space extends from the skull base into the mediastinum as far as T6. It is limited posteriorly by the prevertebral fascia; anteriorly by the buccopharyngeal fascia, pharyngobasilar fascia over the three pharyngeal constrictor muscles, and the esophagus; and laterally by the carotid sheath. The space communicates directly with the parapharyngeal space anterolaterally. Within the retropharyngeal space are two vertical paramedian chains of lymph nodes that drain potential infections in the nasopharynx, oropharynx, paranasal sinuses, and possibly middle ear.[3] These lymph nodes are common in childhood, but they undergo atrophy by puberty. Suppuration of these nodes leads to abscess formation within the retropharyngeal space. Other sources of infection in this space include penetrating foreign bodies, endoscopy or intubation trauma, pharyngitis, pyogenic or mycobacterial vertebral body osteomyelitis, petrositis, and dental procedures.[80]

Retropharyngeal abscesses are most common in early childhood, with 70% of patients younger than 6 years of age and 50% younger than 3 years of age.[79,81] Coulthard and Isaacs[82] reported that 55% of their cases were younger than 1 year of age, and 10% presented in the neonatal period. Boys are more likely to be affected than girls by a 2 : 1 margin.[79]

Clinical Features

The symptoms of retropharyngeal abscess often, but not always, begin insidiously after an antecedent mild upper respiratory infection. Children usually present with fever, sore throat, progressive dysphagia, and drooling. Neck stiffness and mild torticollis may be present and may be suggestive of the diagnosis, distinguishing it from supraglottitis. Stridor is more prominent in younger children and increases as the abscess increases in size. Examination of the pharynx may reveal asymmetric swelling of the posterolateral oropharyngeal wall, but this may be difficult to assess in an uncooperative child with pooling of pharyngeal secretions. Cervical adenopathy also is common. Because of the presence of nonspecific signs and symptoms, a high degree of suspicion is required to ultimately make the diagnosis of retropharyngeal abscess.

Diagnosis

When there is clinical suspicion of retropharyngeal abscess, a complete blood count with differential and a lateral soft tissue radiograph of the neck should be obtained. The neck should be extended, and the radiograph should be taken on inspiration. The diagnosis of retropharyngeal cellulitis or abscess is suggested when the retropharyngeal space at the level of C2 is twice the diameter of the vertebral body (Fig. 197-12).[10]

Figure 197-12. Retropharyngeal cellulitis and abscess seen on a lateral radiographic view with widened soft tissue in the retropharynx compared with the adjacent vertebral bodies.

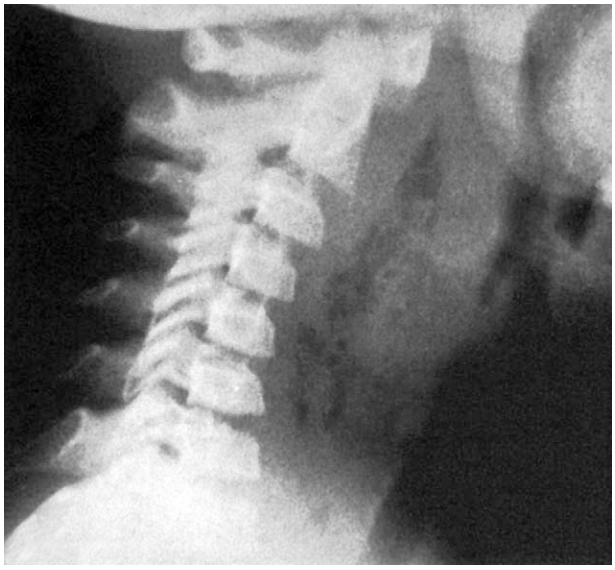

Figure 197-13. Retropharyngeal abscess in a lateral view with gas production within the soft tissues of the retropharynx.

This criterion has a sensitivity of nearly 90%.[82] The lateral radiograph also may reveal gas caused by gas-producing bacteria within the widened retropharyngeal tissues (Fig. 197-13). The normal cervical spine lordosis may be lost or even reversed, and the radiograph should be examined carefully for vertebral or intervertebral disease. The radiographic technique is extremely important because retropharyngeal thickening may be seen when the neck is flexed or when the view is taken on expiration. A chest radiograph should also be performed to exclude mediastinitis or aspiration pneumonia.

When the lateral neck radiograph reveals widened retropharyngeal soft tissues or there are equivocal findings with a strong clinical suspicion of retropharyngeal abscess, computed tomography (CT) of the neck with contrast is extremely helpful in differentiating an abscess from retropharyngeal cellulitis or phlegmon (Fig. 197-14). If there is no airway compromise, the child may be sedated for the CT scan, but, when significant obstruction is present, intubation may be necessary

Figure 197-14. Axial computed tomography showing a hypodense area in the left retropharynx with early ring enhancement, indicating a retropharyngeal abscess *(arrow)*.

with the involvement of anesthesia and otolaryngology specialists. Scans should be obtained from the skull base to the thoracic inlet with delayed imaging at least midway through the intravenous contrast injection. Round, central hypodense nodes without clear ring enhancement suggest edematous nodes or phlegmon. When central hypodensity is associated with clear ring enhancement and irregular or scalloped walls, this is most suggestive of an abscess.[79] Using these criteria, CT imaging should accurately delineate abscess from cellulitis in more than 75% of cases. Roberson and colleagues[83] described a comprehensive practice guideline for diagnosis and management of retropharyngeal abscesses with standardized care and good outcomes. The CT scan also defines the exact abscess location and any possible extension into other anatomic areas such as the parapharyngeal space. This is most valuable information when incision and drainage of the abscess is performed.

Management

As in other airway infections, the airway should be secured in severe cases of respiratory distress before ever performing diagnostic procedures. Once the diagnosis is confirmed, initial antibiotic therapy is directed empirically toward aerobic and anaerobic flora of the nasopharynx. Aerobic species include Streptococcus, S. aureus, and Haemophilus. Group A β-hemolytic streptococci have emerged as important organisms either alone or in polymicrobial infections. Bacteroides, Peptostreptococcus, and fusobacteria are the most commonly encountered anaerobes.[79,80] Initial antimicrobial therapy should include clindamycin or ampicillin-sulbactam. An aminoglycoside or third-generation cephalosporin may also be necessary in neonates to provide management for gram-negative enterics.

When CT suggests only a phlegmon or cellulitis, a trial of intravenous antibiotics is warranted. If after 48 hours the child is clinically well, then outpatient antibiotic therapy is appropriate. If the clinical course is worrisome, however, a repeat CT scan or surgical intervention should be considered.

With the availability of CT imaging to distinguish retropharyngeal cellulitis from abscess formation, the surgeon can best determine those children who will require abscess incision and drainage. When an abscess is found or suspected, incision and drainage should be performed in most cases because this may greatly expedite resolution of this disease. Very small abscesses in children who are clinically improving may be treated medically. The transoral approach is indicated in almost all children, except in those rare cases when there is extension or involvement lateral to the great vessels. The vessels should be well examined on the imaging study to rule out the rare possibility of vascular wall compromise. Careful oral intubation should be performed to avoid abscess rupture and possible aspiration of purulent material. The pharyngeal incision is made over the most prominent bulging area, which is almost always located on one side of the posterior pharynx near the lateral pharyngeal wall. Blunt dissection may reveal thin secretions in early abscess formation but thicker mucopurulent secretions in a more defined abscess. Needle aspiration may be helpful in localizing a purulent collection. A drain is not required. When a child presents with a major inflammatory lateral neck mass and a large parapharyngeal space abscess, in addition to retropharyngeal involvement, a lateral cervical incision and drainage procedure is indicated with drain placement. Cultures of the purulent drainage from either approach will help direct antibiotic therapy. When the child is afebrile, asymptomatic, and swallowing well, appropriate oral antibiotics (e.g., amoxicillin–clavulanic acid or clindamycin) can be used to complete a 10- to 14-day course of therapy.

Complications

Complications that should be considered in children with retropharyngeal abscesses include airway obstruction, spontaneous abscess perforation, aspiration pneumonia, mediastinitis, and sepsis. More rarely, retropharyngeal abscess can result in chest empyema, thrombosis of the internal jugular vein, erosion of the carotid artery, and atlantoaxial dislocation.[10,80] With early suspicion of the clinical possibility of a retropharyngeal abscess, along with CT imaging, good anesthesia, and prompt surgical drainage, complications should be extremely low with near zero mortality.

Acknowledgments

I want to gratefully acknowledge the support of my mentor Dr. Bruce N. P. Benjamin, Sydney, Australia, in collecting the endoscopic airway photographs in this chapter; Dr. Lynn Trautwein, Texas Children's Hospital, Houston, for helping assemble the radiographs and imaging views; and Ms. Nancy Turner for manuscript editorial assistance.

CHAPTER ONE HUNDRED AND NINETY-EIGHT

Differential Diagnosis of Neck Masses

Ralph F. Wetmore

William P. Potsic

Key Points

- The two major categories of neck masses in children are congenital and acquired lesions. Congenital cysts make up the majority of the congenital lesions, whereas infectious masses comprise a majority of the acquired ones.
- A good history and physical are essential to narrow the differential diagnosis of a pediatric neck mass. Computed tomography (CT), magnetic resonance imaging (MRI), and neck ultrasound are the major radiologic studies that help in the evaluation of a neck mass.
- Most branchial cleft cysts are either second or third branchial derivatives. Thyroglossal duct cysts develop within the embryonic thyroid descent tract.
- Hemangiomas are proliferative lesions, rather than neoplastic, and typically begin to involute at 18 to 24 months of age. Vascular and lymphatic malformations are also congenital lesions but do not involute.
- Most infectious lymphadenopathy is viral, but streptococcal or staphylococcal organisms may cause suppurative lymphadenopathy.
- Lymphoma is the most common neck malignancy in children and presents as an enlarging neck mass with or without systemic symptoms of fever, weight loss, night sweats, or fatigue. Malignant neck lesions tend to occur most commonly in either the posterior cervical or supraclavicular regions.

The presentation of a neck mass in a pediatric patient has many diagnostic possibilities not normally encountered in an adult (Fig. 198-1). Neoplastic disease, especially malignant, is the primary consideration in the evaluation of a neck mass in an adult. In contrast, diagnosis of a pediatric neck mass can be categorized, depending on the location, growth factors, and the child's age. The possibility of malignancy should always be considered in the differential diagnosis in pediatric patients; however, it is not as overriding a concern as in adults.

The two major categories of pediatric neck masses include congenital and acquired lesions. Congenital masses have a high incidence (>50% in some series),[1] which initially differentiates them from acquired masses. The primary type of acquired masses is inflammatory (acute and chronic), which further narrows the differential diagnosis. Benign and malignant lesions are rare in the pediatric patient.

The approach to the child with a neck mass depends on the history and physical examination. Radiographic and laboratory studies may prove helpful, but some masses require surgical biopsy to establish the diagnosis. Thus the pediatric neck mass often poses a challenge to the surgeon.

History

In the evaluation of a pediatric patient with a neck mass, a detailed history alone can often exclude many lesions in the differential diagnosis. Consideration of temporal relationships can often prove helpful. A history of infection elsewhere in the patient or recent travel or exposure to farm animals may suggest an infectious origin. Preceding trauma may signal a hematoma, whereas an increase in the size of the mass or pain with eating may point to a salivary gland problem. Exposure to drugs such as phenytoin may also be contributory.

The growth characteristics of the neck mass are important. Slow growth suggests a benign process, whereas rapid enlargement occurs with infectious or malignant lesions. Some masses fluctuate in size (e.g., hemangiomas increase in size with straining and crying). Fever, weight loss, night sweats, or fatigue suggest a malignant process.

Physical Examination

In the evaluation of a child with a neck mass, comprehensive head and neck examination is essential. Clues to the pathogenesis of the neck mass may be found anywhere in the head. Likewise, a total physical examination should be performed with special attention to other lymph node groups such as the axillae and groin. Palpation for an enlarged spleen should always be attempted.

Infants frequently have small palpable lymph nodes in the posterior cervical region, whereas older children have palpable nodes in the anterior cervical, posterior cervical, and submandibular regions. Any node greater than 2 cm in diameter falls outside the range of these normal hyperplastic nodes and should be evaluated further.

In examination of abnormal lymph nodes or a neck mass, the location is important for determining the site of the precipitating infection or the primary source of a malignant neoplasm. For example, infection in the nasopharynx tends to drain into the posterior cervical

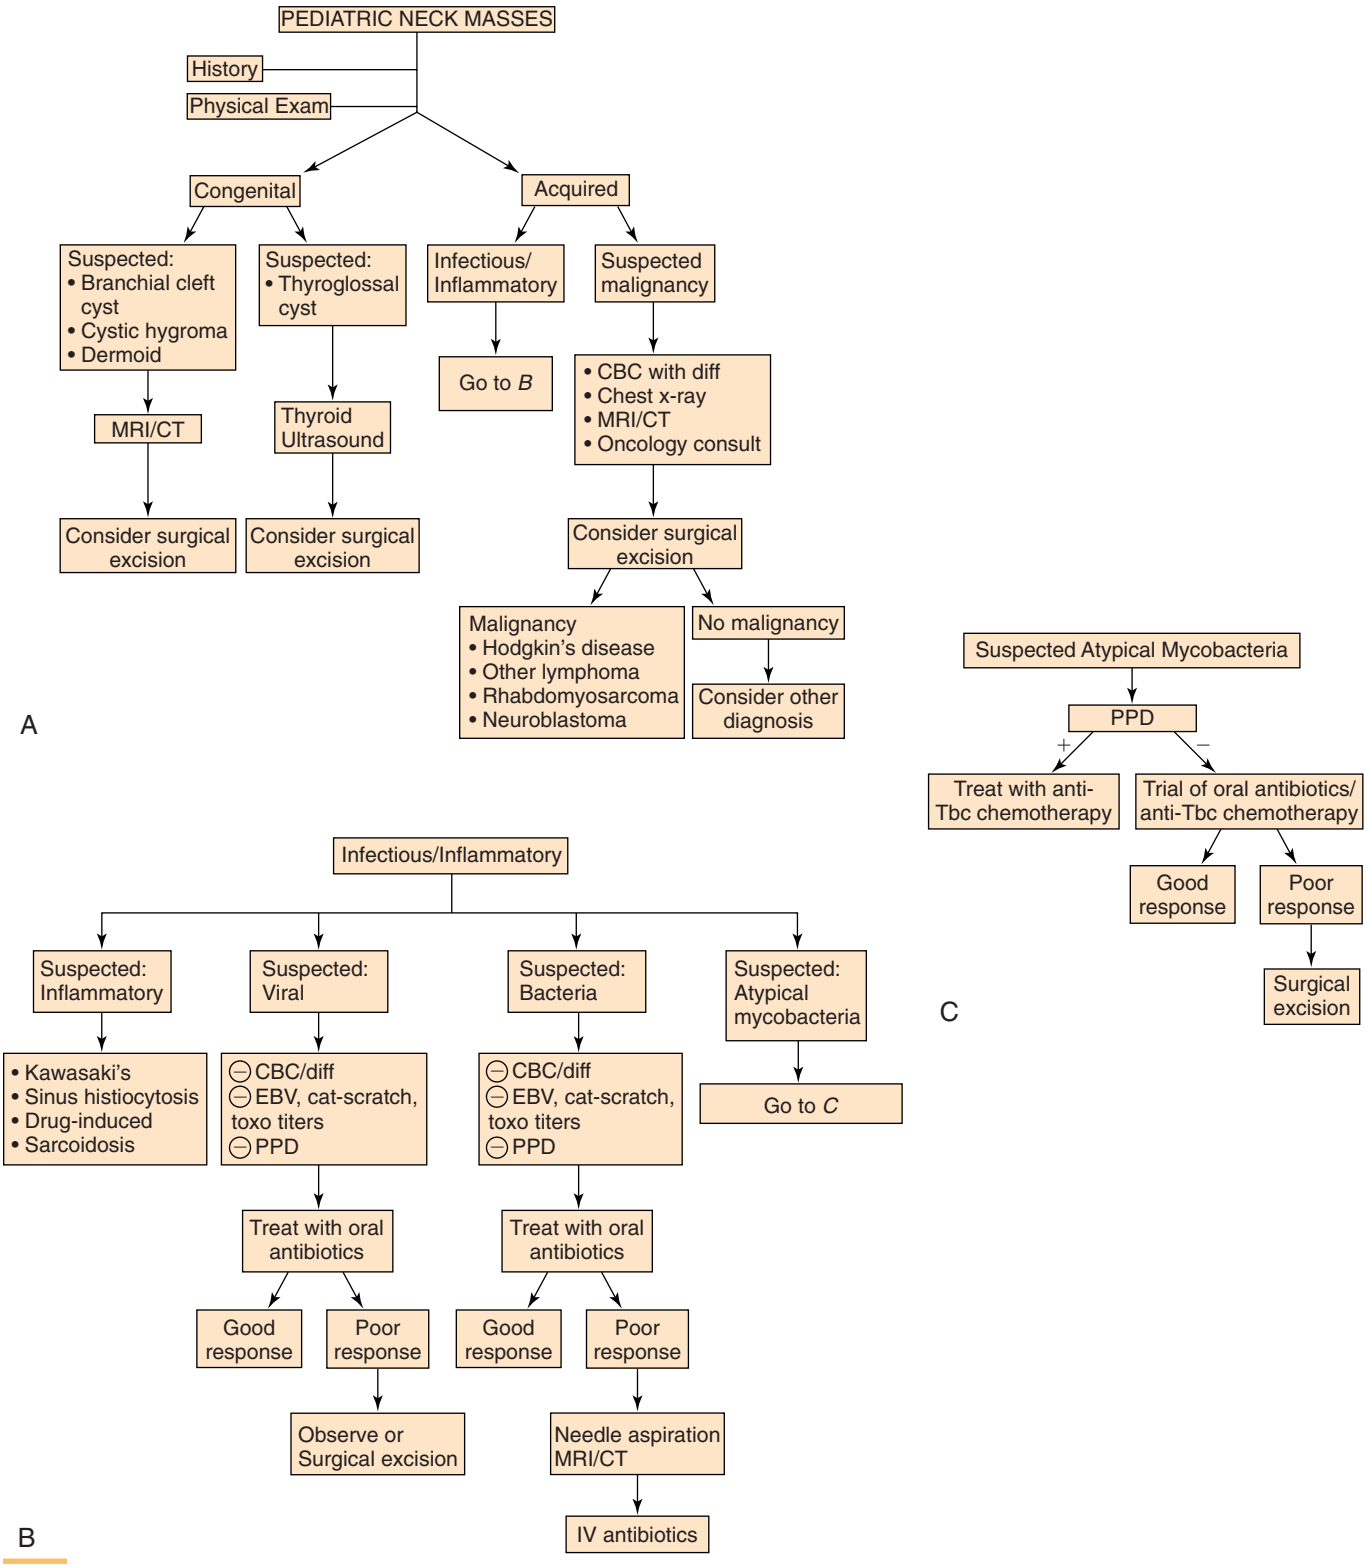

Figure 198-1. **A** to **C**, Algorithms for the differential diagnosis of neck masses.

region, whereas tonsillitis may cause enlargement in the anterior cervical region. Moussatos[2] and Putney[3] noted an increased incidence of malignancy in the posterior cervical triangle; in contrast, Torsiglieri and colleagues[1] reported an increased incidence in the supraclavicular region.

The consistency of a neck mass is frequently helpful in categorizing the mass. For example, hard masses tend to occur with infection or a malignant process. Fixation of a mass to the skin or deeper structures of the neck suggests a malignancy. A fluctuant mass tends to occur with abscess formation or a cyst.

Radiologic Studies

Depending on the clinical impression of a neck mass from the history and physical examination, selected radiographic studies may help narrow the differential diagnosis. Chest radiography is helpful if a malignancy, sarcoidosis, or pulmonary tuberculosis is suspected. In the

evaluation of the nasopharynx, cervical spine, or retropharyngeal region, lateral neck radiography may show an abnormality. Likewise, a sinus series may show evidence of an infection or neoplasm in the paranasal sinuses.

In cases of infection in the neck, computed tomography (CT) with contrast may differentiate cellulitis that may respond solely to antibiotic therapy from an abscess with rim enhancement that may necessitate surgery. CT with contrast also helps identify vascular masses such as hemangiomas. Magnetic resonance imaging (MRI) provides even better detail of soft tissue. When combined with contrast, MRI is also useful in the evaluation of vascular lesions.

Ultrasound of the neck is most helpful in differentiating a cystic structure from a solid mass. It should be included as part of the evaluation of any thyroid mass. Before excision of a thyroglossal duct cyst, ultrasound can confirm the presence of a thyroid gland in its normal position, ruling out the possibility of ectopic thyroid. Use of ultrasound in these cases is easier and more economical. Thyroid scanning remains essential in the evaluation of any thyroid mass.

Laboratory Studies

As with radiography, selected laboratory studies may be useful in the evaluation of the pediatric neck mass. A complete blood count with differential is indicated if a malignancy or systemic infection is suspected. Serologic testing for Epstein-Barr virus (EBV), cytomegalovirus, toxoplasmosis, syphilis, or cat-scratch disease may be diagnostic. An elevated serum calcium level is highly suggestive of sarcoidosis, whereas thyroid function studies are necessary in the evaluation of most thyroid masses. Urinary collection for vanillylmandelic acid (VMA) is helpful when neuroblastoma is suspected. Although not as accurate as a culture of infected tissue, skin tests, if available, remain a reliable indicator of mycobacterial disease.

Surgical Diagnosis

Although fine-needle aspiration of a suspected malignancy is not as reliable in children as in adults, fine-needle aspiration of a neck infection decompresses the mass and provides material for culture. In some cases, especially when the diagnosis of malignancy is considered, an incisional or excisional biopsy is indicated. Advantages of a biopsy include inspection of the lesion, providing a cuff of healthy surrounding tissue and tissue for frozen and permanent section, electron microscopy, and tumor markers.

Congenital Masses

Branchial Cleft Cysts

Although the definitive mechanism for the development of branchial cleft cysts is unclear, it is suspected that these congenital masses result from the cervical sinus of His becoming entrapped without an external or internal opening. An epithelium-lined cyst results. Others suggest that these cysts develop from epithelial rests of tissue from Waldeyer's ring.[4] Branchial cleft cysts are relatively common; in one series, they comprise one third of congenital neck masses.[1]

Branchial cleft cysts typically are seen as nontender, fluctuant masses that may become inflamed and abscess during an upper respiratory infection (Fig. 198-2). First branchial cleft cysts, although rare, typically present near the angle of the mandible (Fig. 198-3). Second branchial cysts are found high in the neck and deep to the anterior border of the sternocleidomastoid muscle. Third branchial cleft cysts, also rare, are seen near the upper pole of the thyroid gland. Other symptoms, depending on the size of the cyst, include dysphagia, dyspnea, and stridor.

Radiologic evaluation of a branchial cleft cyst may include ultrasound, CT, and MRI. Ultrasound shows a fluid-filled cyst and can differentiate cystic lesions from solid masses. CT and MRI also confirm the cystic characteristics of the mass and, more importantly, delineate the relationship of the cyst to surrounding structures (Fig. 198-4).

Management of branchial cleft cysts is surgical excision. It is advisable, if possible, to manage an infected cyst with antibiotics, allowing the inflammation to resolve before excision is attempted.

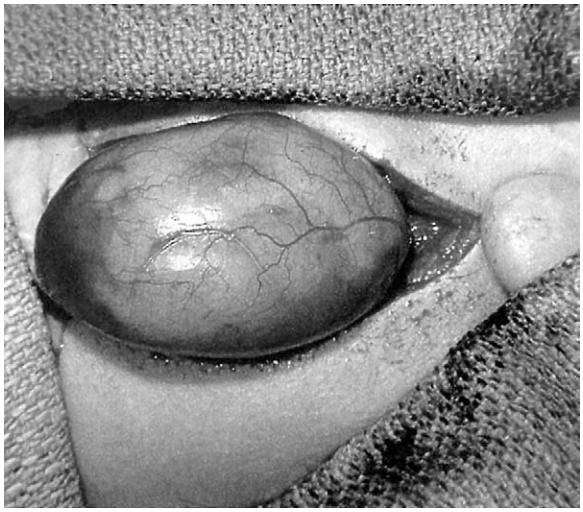

Figure 198-2. A typical branchial cleft cyst is an epithelium-lined cyst filled with mucoid material. This cyst presents along the anterior border of the sternocleidomastoid muscle.

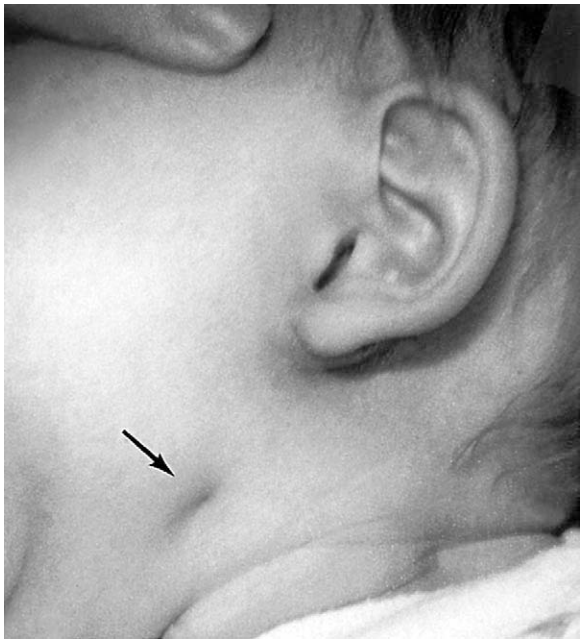

Figure 198-3. First branchial derivatives present as a pit or a mass near the angle of the mandible *(arrow)*. They frequently originate in or near the external canal and, during their course, involve the facial nerve.

Thyroglossal Duct Cysts

Thyroglossal duct cysts form in a persistent thyroid descent tract that begins as an elongation of the thyroid diverticulum. Beginning at the foramen caecum of the tongue, this tract may extend to the thyroid gland itself, where some tissue may persist in the region of a pyramidal lobe. These remnants are cysts and are not associated with a cutaneous sinus or fistula tract unless surgically drained and inadequately excised. They comprise approximately one third of congenital neck masses in children.[1]

Most thyroglossal duct cysts are seen in the midline near the level of the hyoid bone because the tract passes just anterior to the hyoid bone (Fig. 198-5). Some cysts may present laterally and are not infrequently found superior to the hyoid or as low as the level of the thyroid gland. Thyroglossal duct cysts that occur off the midline may be

Figure 198-4. Axial computed tomography of the neck shows a branchial cleft cyst in the hypolucent area *(arrow)*.

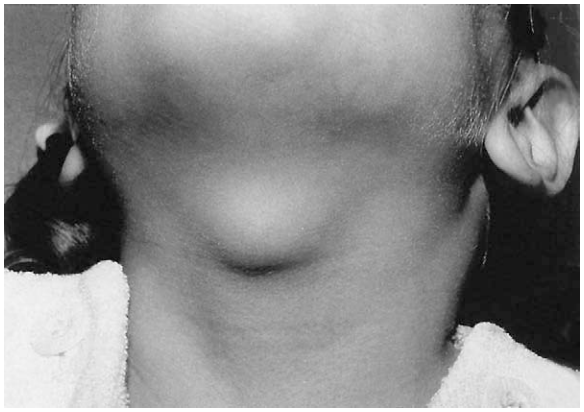

Figure 198-5. Thyroglossal duct cysts are often found in the midline of the neck at or near the hyoid bone.

difficult to differentiate from branchial cleft cysts, an important factor in their surgical excision. Other unusual presentations of thyroglossal duct cysts include formation on either side of the hyoid bone as dumbbell-shaped lesions and, rarely, as cystic lesions in the larynx. Thyroid tissue is found in surgical specimens in up to 45% of cases.[5]

A thyroglossal duct cyst usually presents as an asymptomatic mass but may be associated with mild dysphagia. Not infrequently, presentation of these cysts may be accompanied by infection, causing rapid enlargement that may produce significant dysphagia and choking.

In cases in which a thyroglossal duct cyst is suspected, it is important to differentiate ectopic thyroid from a cyst. Although only 10% of ectopic thyroid is found in the neck, it may represent the only thyroid tissue in 75% of patients.[6] Children with ectopic thyroid may be mildly hypothyroid; however, excision of this tissue necessitates hormone replacement for the remainder of the patient's life. Thyroid ultrasound and radionucleotide scanning can differentiate ectopic thyroid from a thyroglossal duct cyst; ultrasound is easier to perform, less expensive, and does not use radioisotopes.

The Sistrunk operation is the standard method of thyroglossal duct cyst excision. The cyst is excised along with a cuff of tissue including the center portion of the hyoid bone. Incision and drainage of an infected cyst should be avoided because violation of the cyst capsule may invite recurrence. Recurrence rates of nearly 10% have been reported in children who have undergone uncomplicated Sistrunk operations.[1]

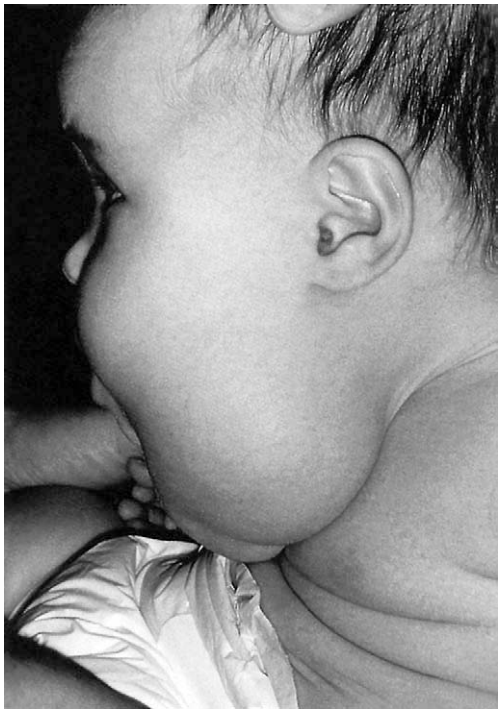

Figure 198-6. Lymphangiomas of the neck may cause significant cosmetic deformity and may impair respiration or alimentation.

Lymphatic Malformations (Lymphangiomas)

The term *lymphatic malformation* is a better definition of the lesion that was previously termed *lymphangioma.* Lymphatic malformations are congenital malformations of lymph tissue that result from the failure of lymph spaces to connect to the rest of the lymphatic system. Lesions containing both lymphatic and venous components may be labeled combined venolymphatic malformations. Macrocystic lymphatic malformations (previously termed *cystic hygroma*) contain large thick-walled cysts that have less infiltration of surrounding tissue. Microcystic lymphatic malformations have more extensive infiltration of the soft tissue structures of the head and neck, especially in the tongue and floor of mouth, making their excision difficult.

A lymphatic malformation presents as a soft, smooth, nontender mass that is compressible and can be transilluminated (Fig. 198-6). Typically, lymphatic malformations fluctuate in size as a result of infection or hemorrhage. They mostly impact the cosmetic appearance of the child. Depending on the size and location of the mass, there may be respiratory compromise and difficulty in feeding.

Radiographic evaluation with MRI or CT is invaluable for diagnosis and determination of the extent of the lesion. Radiography shows fluid-filled spaces with surrounding connective tissue. Because these malformations lack a capsule and extend along the lymphatic channels, MRI or CT is essential in defining normal anatomic structures that should be preserved when surgical excision is performed.

The goals of surgery are to improve cosmetic appearance and to counter impaired breathing or eating. Because of the infiltrative nature of these malformations, complete surgical excision is often difficult; debulking of the mass often accomplishes these goals.

Some experts recommend staging of surgical excision in extensive cases.[7] Management with radiotherapy has not been effective.[8] Macrocystic lesions can be treated with sclerotherapy using alcohol. An experimental lyophilized streptococcal compound, OK-432, has been used successfully to sclerose macrocystic lesions.[9]

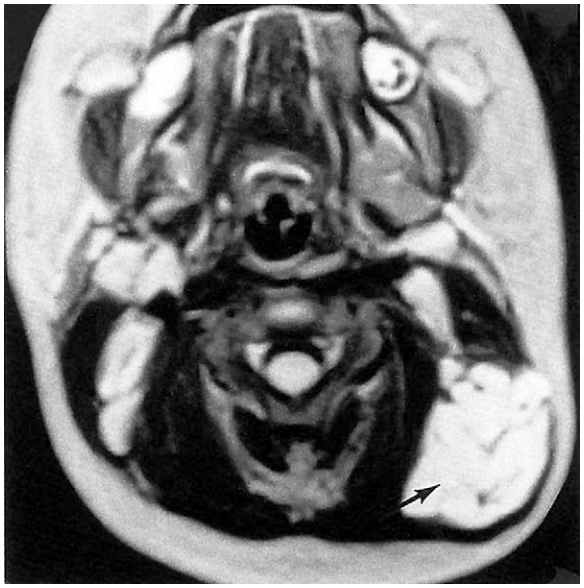

Figure 198-7. Magnetic resonance imaging with contrast shows an enhancing vascular lesion in the posterior neck consistent with a hemangioma *(arrow)*.

Hemangiomas

Hemangiomas are proliferative endothelial lesions rather than true neoplasms. Hemangiomas present at birth, grow rapidly during the first year of life, and begin to slowly involute at 18 to 24 months of age. Hemangiomas occur in up to 10% of children with a female-to-male ratio of 2:1.[10]

Hemangiomas are seen as red or bluish soft masses that frequently have a skin component. Typically, these masses are compressible and increase with straining or crying. With large hemangiomas, a bruit may be heard over the lesion. CT or MRI with contrast often confirms the diagnosis of a vascular lesion (Fig. 198-7).

Because hemangiomas typically involute after several years, the usual management is observation, unless there is functional impairment, bleeding, skin necrosis, or a coagulopathy caused by thrombocytopenia. Use of systemic corticosteroids may be helpful in the management of complications such as skin ulceration, dysphagia, dyspnea, thrombocytopenia, or cardiac failure.[11-14] Surgical excision or laser therapy may be helpful in cases of incomplete involution or when mild functional or cosmetic abnormalities remain. Management with radiotherapy may lead to malignant transformation, and the use of sclerosing agents and cryotherapy has produced poor results.[8,15]

Teratomas

Teratomas in the head and neck are rare, comprising only 3.5% of all teratomas in one series.[16] Although there is a female-to-male preponderance of 6:1 in other body regions, the female-to-male ratio is equal in the head and neck.[17] Teratomas arise from pluripotential cells and consist of tissues foreign to the site from which they arise. A history of maternal polyhydramnios has been noted in up to 18% of neonates who have a cervical teratoma (Fig. 198-8).

Most teratomas present as firm neck masses. With large teratomas, there may be symptoms of respiratory compromise caused by tracheal compression. Intrinsic calcifications may be seen on CT or MRI, a finding that may assist diagnosis. Management is by surgical excision; failure of complete excision may result in recurrence.

Dermoid Cysts

Similar to teratomas, to which they are pathologically related, dermoid cysts arise from epithelium that has been entrapped in tissue during embryogenesis or by traumatic implantation. Dermoid cysts consist of epithelium-lined cavities filled with skin appendages (e.g., hair, hair follicles, sebaceous glands). They are found at other sites in the head and neck including the orbit, nose, nasopharynx, and oral cavity.

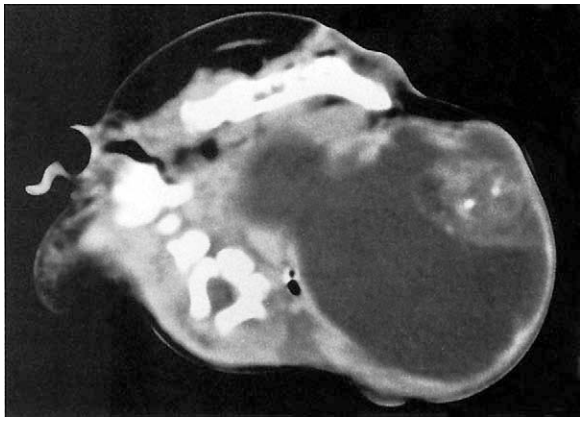

Figure 198-8. Computed tomography shows a large teratoma cyst in a newborn that severely compromised the respiratory tract and required a tracheostomy.

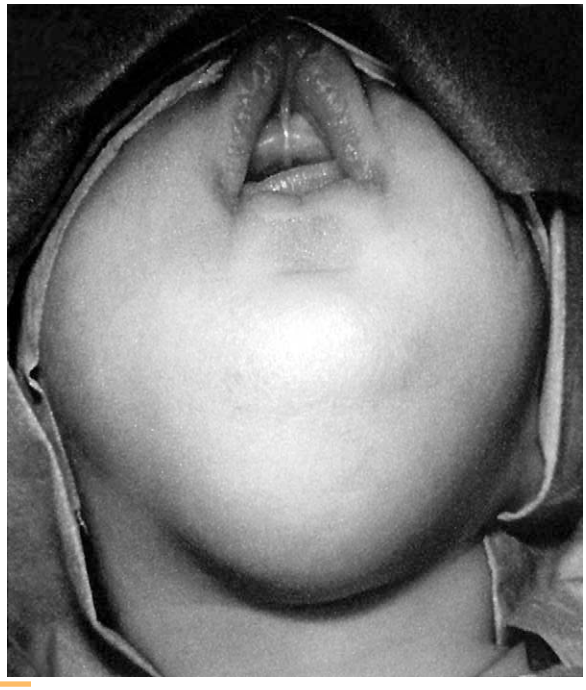

Figure 198-9. A large dermoid cyst presents in the midline of the submental region.

Typically, dermoid cysts are seen in the midline of the neck, usually in the submental region (Figs. 198-9 and 198-10). They are attached to and move with the overlying skin and are painless unless infected. Management is by complete surgical excision.

Laryngoceles

A laryngocele is an abnormal dilation or herniation of the saccule of the larynx. If this dilation lies within the limits of the thyroid cartilage, the laryngocele is internal. If it extends beyond the thyroid cartilage in a cephalad direction to protrude through the thyrohyoid membrane, the laryngocele is external. Some laryngoceles present with internal and external components. Laryngoceles are rare in infants and children but may present congenitally in newborns. Clinical differentiation of air-filled laryngoceles from fluid-filled saccular cysts may be impossible.[18]

Hoarseness, cough, dyspnea, and dysphagia suggest a laryngocele. CT may be helpful in diagnosis, especially in delineating the extent of the lesion and differentiating the laryngocele's air-filled space from the

Figure 198-10. Magnetic resonance imaging (sagittal view) shows a large dermoid cyst in the submental region just deep to the tongue *(arrow)*.

fluid of a saccular cyst. Surgical excision through an external approach is the management of choice.

Thymic Cysts

The thymus develops from the third pharyngeal pouch and descends into the chest. An implant of thymic tissue along this descent tract anywhere in the neck may result in a thymic cyst. Thymic cysts may be more common than suggested by several reports in the literature.[19] Almost all are unilateral (most commonly on the left side of the neck), and 90% are cystic.[20]

Typically, a thymic cyst presents as an asymptomatic mass, but it may be painful if infected or if there is a rapid increase in its size. CT or MRI may help differentiate a thymic cyst comprising a single cystic lesion from a cystic hygroma that has multiple large cysts within the mass. The preferred management is surgical excision. Diagnosis is confirmed by histologic identification of Hassall's corpuscles.

Vascular Malformations

Vascular malformations can be divided into two groups depending on blood flow. Slow-flow lesions include capillary malformations and venous malformations, whereas arterial and arteriovenous malformations are typically fast-flow lesions. Vascular malformations represent congenital structural anomalies, grow at the same rate as the child, and do not involute.

Venous anomalies of the external jugular vein may occasionally present as a neck mass.[21] Typically, the external jugular vein empties into the subclavian vein, but it may empty into the internal jugular vein outside the carotid sheath, forming a venous plexus. Jugular malformations present as soft, compressible masses along the anterior border of the sternocleidomastoid muscle. Management is by ligation or excision of the anomaly.

Sternocleidomastoid Tumors of Infancy

Neonates with sternocleidomastoid tumors present with neck masses that are usually not apparent at birth but appear at 1 to 8 weeks of age. Pathologically, the mass is characterized by dense fibrous tissue and the absence of normal striated muscle (Fig. 198-11). As the mass resolves, the remaining muscle continues to degenerate into fibrous tissue. The etiology of this disorder, also known as *congenital torticollis,* is unclear; however, birth trauma, ischemia of the muscle, and intrauterine positioning have been implicated.

Most patients are firstborn[22]; siblings are rarely affected.[1] Congenital torticollis presents as a firm, painless, discrete, fusiform mass within the sternocleidomastoid muscle that slowly increases in size for 2 to 3 months and then slowly regresses for 4 to 8 months (Fig. 198-12). Because the mass disappears in more than 80% of cases,[23] conservative management with physiotherapy (passive and active motion) prevents the development of restrictive torticollis. In resistant cases, surgical section of the sternocleidomastoid muscle may be required.

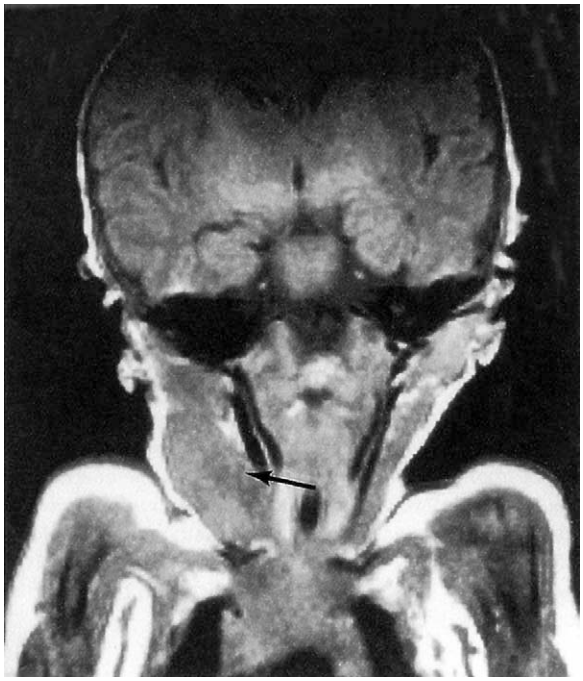

Figure 198-11. Magnetic resonance imaging of an infant with congenital torticollis shows enlargement of the sternocleidomastoid muscle *(arrow)*.

Figure 198-12. A firm mass in the midportion of the sternocleidomastoid muscle is seen in an infant with congenital torticollis.

Acquired Masses

Viral Lymphadenopathy

Reactive lymph nodes result from viral upper respiratory tract infections such as adenovirus, rhinovirus, or enterovirus (coxsackievirus A and B). EBV often presents with massive lymphadenopathy in addition

to enlargement of other lymphoid tissue (e.g., tonsils, spleen). On pathologic examination, there is a proliferation of normal cells; however, in contrast to neoplastic disease, the nodal architecture is intact.

Reactive lymphadenopathy is frequently bilateral and is associated with symptoms of the underlying respiratory infection. Management is observation, although not infrequently these nodes are biopsied because their consistency mimics lymphoma and their regression in size is often slow.

Unlike most cases of viral lymphadenopathy, human immunodeficiency virus (HIV) infection may result in acquired immunodeficiency syndrome (AIDS) whose associated findings, aside from generalized lymphadenopathy, include hepatosplenomegaly; weight loss; susceptibility to viral, bacterial, and fungal infections; and fevers. Pediatric AIDS should be suspected in cases in which multiple neck nodes are involved with bacterial infection and in cases that fail to respond to adequate antibiotic therapy.

Cervical lymphadenopathy is also a manifestation of posttransplantation lymphoproliferative disease (PTLD). PTLD is associated with an Epstein-Barr infection in patients who have undergone either solid organ or bone marrow transplantation. Histologic examination of a biopsied node and Epstein-Barr titers are essential in the diagnosis of this disorder.[7,24]

Bacterial Lymphadenopathy

Suppurative Lymphadenopathy

Staphylococcus aureus and group A β-*Streptococcus* are the most common causative organisms of suppuration in the neck, although other bacteria such as *Haemophilus* and *Moraxella* species have been implicated. Brodsky and colleagues[25] found a 19% incidence for anaerobic bacteria versus 67% for aerobic bacteria. Brook[26] reported a similar anaerobic incidence and β-lactamase-positive organisms in 34%. In neonates the offending organisms may be *Staphylococcus* or *Streptococcus,* but *Pseudomonas* and other gram-negative bacteria have also been reported.[27,28] Several studies have documented a rising incidence of methicillin-resistant *S. aureus* (MRSA) as the pathogen in community-acquired pediatric cervical neck infections.

No major differences between the *Staphylococcus* and *Streptococcus* groups are evident when demographic factors and occurrence of symptoms are compared. Frequently, the neck mass develops in the submandibular region, but it may occur in the anterior and posterior cervical triangles (Fig. 198-13).[29] Associated symptoms include a history of upper respiratory infection, sore throat, earache, and skin lesions.[29] Initial management is with antibiotic therapy, either orally or intravenously, depending on the severity of the infection. Failure to respond to medication may indicate the need for fine-needle aspiration or incision and drainage.

Cat-Scratch Disease

Most cases of cat-scratch disease occur in patients younger than 20 years,[30] and males are affected more frequently than females.[31] More than 90% of patients have a history of feline contact, and there is a fall and winter prevalence. Although the symptom complex of cat-scratch disease has been recognized for almost 50 years, only recently has the bacterium *Bartonella henselae* been implicated as the etiologic agent.[32] Serologic testing by indirect fluorescent antibodies for *Bartonella* DNA has a high sensitivity and specificity. Typically, affected children are seen with lymphadenopathy associated with mild fever and other symptoms of malaise. Antibiotic therapy with azithromycin, an aminoglycoside, or ciprofloxacin is usually curative.[32] Rarely is the infection severe enough to require surgery.

Toxoplasmosis

Infection with *Toxoplasma gondii* is usually contracted through the consumption of poorly cooked meat or ingestion of oocytes excreted in cat feces. Symptoms include fever, malaise, sore throat, and myalgias. Cervical adenitis occurs in greater than 90% of cases.[33] Complications of toxoplasmosis include myocarditis and pneumonitis. The diagnosis is confirmed by serologic testing, and management is with pyrimethamine or sulfonamides.

Figure 198-13. Computed tomography with contrast shows a neck abscess in the submandibular triangle *(arrow).* Abscess formation is characterized by hypolucency and rim enhancement.

Mycobacterial Infection

Most atypical mycobacterial infections are caused by a variety of mycobacteria including *Mycobacterium avium-intracellulare, Mycobacterium scrofulaceum, Mycobacterium kansasii, Mycobacterium fortuitum,* and *Mycobacterium haemophilum.* In the past few years, the reemergence *of Mycobacterium tuberculosis* has been noted; *M. tuberculosis* as a cause of cervical adenopathy is associated with pulmonary tuberculosis in endemic areas of the United States. In a series on the cause of mycobacterial neck infections, Hawkins and colleagues[35] showed a 59% incidence for atypical mycobacteria compared with 29% for *M. tuberculosis.*

Skin tests for *M. tuberculosis* and atypical mycobacteria are available[34] and were positive in 95% of cases in the series by Hawkins and colleagues.[35] Mycobacterial infection is definitively diagnosed by culture, which frequently takes weeks.

The most common site of mycobacterial infection in the neck is the anterior superior cervical region, followed by the posterior cervical, middle cervical, supraclavicular, and submental regions. Atypical mycobacterial infection is not infrequently found in the preauricular region (Fig. 198-14). It tends to occur unilaterally, whereas *M. tuberculosis* is more diffuse and frequently bilateral.[35] A painless, firm, enlarging mass in the face of antibiotic therapy suggests the diagnosis. The overlying skin is frequently discolored with atypical mycobacterial infection. In patients with *M. tuberculosis* infection, weight loss, fever, and anorexia may also be present.

The current management of *M. tuberculosis* infection is with antituberculous chemotherapy, usually including two drugs, although lymph nodes infected with atypical mycobacteria are best managed by surgical excision or incision and curettage. Hawkins and colleagues[35] showed resolution of neck masses in 4 of 18 cases of atypical mycobacterial infection with chemotherapy alone.

Fungal Infections

Fungal infections of the neck typically present in immunocompromised patients with symptoms and signs that suggest viral or bacterial infection. The usual pathogens include *Candida, Histoplasma,* and *Aspergillus.* The diagnosis is made by serology or fungal smear and culture.

Figure 198-14. Atypical mycobacterial infection frequently involves the submandibular triangle and preauricular regions.

Management of fungal lymphadenopathy requires intravenous amphotericin B.

Sialadenitis

The salivary glands are susceptible to viral and bacterial infection and, at times, may resemble infection of surrounding lymph nodes. Although rare since the development of a vaccine, mumps is a paramyxoviral infection that may cause orchitis, meningitis, or sensorineural hearing loss. One or both parotid or submandibular glands may be involved. Management includes supportive measures such as analgesics and hydration.

In addition to viral infection, dehydration and generalized disability of patients often predispose to bacterial infection of the salivary glands. The causative organisms include *S. aureus, Streptococcus* species, and *Haemophilus influenzae.*

Children with sialadenitis have a rapid onset of pain and swelling of the affected glands. Fever, chills, and malaise may also occur. Examination of the oral cavity may reveal purulent discharge from the ducts of the involved glands (Stensen's or Wharton's). Management of bacterial sialadenitis is hydration and oral or intravenous broad-spectrum antibiotic therapy.

Noninfectious Inflammatory Disorders

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease is an acute multisystem vasculitis of unknown etiology that tends to affect children younger than 5 years of age.[36] To confirm this diagnosis, the patient should have fever persisting for 5 days and four of the following features: (1) acute, nonpurulent cervical lymphadenopathy that is usually unilateral; (2) erythema, edema, and desquamation of the hands and feet; (3) polymorphous exanthem; (4) bilateral painless conjunctival infection; and (5) erythema and infection of the lips and oral cavity.

Associated findings in the acute stage include thrombocytosis and cardiac signs of pericardial effusion.[37] In the subacute stage, coronary artery aneurysms may develop in 15% to 20% of cases.[36] The goal of management is to reduce the inflammatory response with aspirin and γ-globulin therapy.

Sinus Histiocytosis (Rosai-Dorfman Disease)

Children with sinus histiocytosis have massive nontender cervical lymphadenopathy that is similar to infectious mononucleosis or lymphoma. The disease is thought to represent an abnormal histiocytic response to some precipitating cause, possibly either a herpesvirus or EBV.[38] Biopsy shows dilated sinuses, many plasma cells, and marked proliferation of histiocytes. In addition to massive adenopathy, fever and skin nodules may be present. Management of this disorder is expectant.

Drug-Induced Lymphadenopathy

Although phenytoin is the most well-known cause of drug-induced lymphadenopathy, pyrimethamine, allopurinol, and phenylbutazone have also been implicated.[39] Typically, the adenopathy resolves when drug therapy is discontinued; however, long-term use of phenytoin has been reported to progress to a premalignant pseudolymphomatous state.

Sarcoidosis

The etiology of sarcoidosis is unknown, but clusters of cases tend to suggest an infectious or toxic origin. It is found most commonly in the second decade of life, and men and women are affected equally. Patients typically have lymph node enlargement, fatigue, and weight loss. Depending on the sites of involvement, there may also be cough, dyspnea, hoarseness, bone and joint pain, visual symptoms, headaches, fever, and skin rash. Abnormalities on chest radiography help suggest the diagnosis, which is confirmed by finding noncaseating granulomas on biopsy of involved tissue. Management is expectant, although corticosteroids may be helpful in acute settings.

Benign Neoplasms

Lipomas

Lipomas are benign encapsulated fatty tumors found in subcutaneous tissue. In general, they rarely occur in the head and neck. The usual management is surgical excision.

Thyroid Adenomas

A thyroid adenoma presents as an isolated mass that is palpable within the thyroid gland. On ultrasound, an adenoma appears as a solid mass in contrast to a thyroid cyst. On thyroid scanning, an adenoma appears as a cold nodule; however, some adenomas take up radionucleotide and show function, although not as much as that seen with typical hyperfunctioning nodules. Thyroid adenomas usually require excision to differentiate them from thyroid carcinomas.

Neurofibromas

Neurofibromas are circumscribed tumors that arise from small cutaneous nerves and are composed of Schwann cells, nerve fibers, and fibroblasts. They may be solitary or more rarely occur as multiple neurofibromas (e.g., in von Recklinghausen's disease). Management is excision, taking care not to injure nearby anatomic structures.

Pleomorphic Adenomas

Pleomorphic adenomas are salivary gland tumors that typically arise in the lateral portion of the parotid gland. They present as slow-growing painless masses that show no evidence of nerve or skin involvement. A superficial parotidectomy is necessary for surgical excision.

Malignant Neoplasms

Lymphomas

Lymphomas are the most common neck malignancy in large pediatric series.[1,40] They may be divided into two histologic categories, Hodgkin's and non-Hodgkin's, which have different clinical courses and prognoses.

Rye classified Hodgkin's disease into four histologic types: nodular sclerosing, mixed cellularity, lymphocyte predominant, and lymphocyte depleted. Males of any age are more commonly afflicted with Hodgkin's disease than females, although the incidence is nearly equal during the teenage years.[41] Hodgkin's disease often presents as an asymptomatic cervical or supraclavicular mass (Fig. 198-15). Fever is commonly associated with cough, night sweats, and weight loss. After confirmation of cell type by biopsy, management consists of chemotherapy or radiotherapy, depending on the histologic findings and staging.

Non-Hodgkin's lymphoma is more likely to be disseminated and extranodal. Histologic types include lymphoblastic, large cell, and undifferentiated. The liver, lung, and bone marrow are the most common sites of extralymphatic involvement. In the neck, non-Hodgkin's lymphoma is less common than Hodgkin's disease.[42] Weight

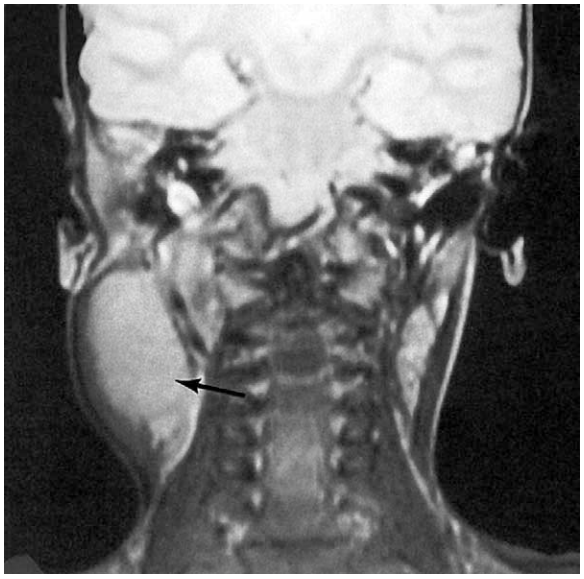

Figure 198-15. Magnetic resonance imaging of the neck shows Hodgkin's disease presenting in the posterior cervical region *(arrow)*.

loss, night sweats, and fever are common, especially when disease is more disseminated. Chemotherapy is the mainstay of management of non-Hodgkin's lymphoma.

Rhabdomyosarcomas

Soft tissue sarcomas comprise a small percentage of all childhood malignancies. Rhabdomyosarcoma is the most common soft tissue sarcoma; because it occurs most commonly in the head and neck, it comprises a significant percentage of malignant neck masses in series of pediatric patients.[43] The peak incidence of rhabdomyosarcoma occurs at 2 to 5 years, with another peak between 15 and 19 years of age.[44] White children are affected more often than children of other races, and there is a slight male predominance.[44] Embryonal rhabdomyosarcoma is the most common cell type, followed by alveolar and pleomorphic.[45]

Predominant sites of rhabdomyosarcoma in the head and neck include the orbit, nasopharynx, paranasal sinuses, ears, and oral cavity. Primary involvement of the neck occurred in 89% of cases in one series.[46] Metastatic disease from one area of the head to the neck is rare.[47]

Management of rhabdomyosarcoma includes a combination of surgery, radiotherapy, and chemotherapy. The role of surgery, biopsy, debulking, or radical excision depends on the site, extent, and presence of recurrence. Radiotherapy to the primary site is given at 5000 to 6000 cGy in children older than 3 years of age and lesser doses in younger children. Two thirds of patients experience long-term survival or cure.[43,9]

Thyroid Carcinoma

Thyroid carcinoma is uncommon in the pediatric age group but has been associated with exposure to low-dose ionizing radiation.[48] Female children are more commonly affected but less so than female adults. The usual histology is papillary or mixed papillary-follicular. Involved patients have a solitary mass in the anterior neck. More worrisome signs include rapid growth of the mass, hoarseness, dysphagia, and fixation of the mass to the surrounding structures. Metastases, when present, are found in regional lymph nodes and the lungs or bones. Ultrasound or thyroid scanning is helpful in diagnosis, although frozen section at the time of surgical excision is definitive. Because almost all thyroid carcinoma in children is papillary, management should be subtotal or total thyroidectomy with neck dissection if there is nodal involvement. Thyroid suppression is often used to prevent recurrence, and radioactive iodine helps eliminate unresectable tumor.

Salivary Gland Malignancies

Mucoepidermoid and acinic cell carcinomas of the salivary glands account for approximately 60% of malignant epithelial neoplasms in children.[49] With mucoepidermoid carcinoma, local invasiveness, regional metastasis, and prognosis depend on histologic differentiation; the behavior of acinic cell carcinoma does not correlate with histology. Mucoepidermoid and acinic cell carcinomas present as solitary firm masses that grow painlessly, usually in the parotid gland. Both tumors tend to be low grade and are seldom fatal.[49] Depending on which gland is involved, initial management is by superficial parotidectomy or submandibular gland excision. The use of adjuvant therapy including neck dissection or radiotherapy depends on cell type and tumor growth characteristics.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma may present with a mass in the neck associated with a nasopharyngeal mass, unilateral otitis media, rhinorrhea, and nasal obstruction. In advanced cases, there may be one or more cranial nerve palsies. There is an increased incidence of nasopharyngeal carcinoma in black and Asian teenagers.[50,51] Titers of EBV types 2 and 3 have been elevated in patients with nasopharyngeal carcinoma.[6] Although the diagnosis is confirmed by biopsy, CT and MRI may help determine the extent of tumor involvement. Bone or liver metastasis may be identified with a bone scan or CT of the abdomen. Management depends on clinical staging and includes radiotherapy with or without chemotherapy.

Neuroblastomas

Neuroblastomas are malignant neoplasms that originate from primitive neuroblasts and neural crest cells. Only 2% to 4% of neuroblastomas originate in the neck.[52] In the neck, these masses may be associated with an ipsilateral Horner's syndrome.[53] Because systemic involvement is common, evaluation of the patient should include MRI and CT of the neck, chest, and abdomen, looking for metastatic spread. Elevated urinary VMA found on 24-hour collection strongly suggests neuroblastoma. Management depends on the extent of involvement and may include surgical excision, radiotherapy, and chemotherapy.

Summary

A neck mass may provide a diagnostic challenge to the clinician and a source of anxiety to the parents. Systematic evaluation, paying particular attention to important details in the history and physical examination, can narrow the differential diagnosis and allow selection of appropriate radiologic and laboratory studies when indicated. In children, congenital and inflammatory masses are most common, but malignancy should be considered, especially if the mass continues to grow after appropriate therapy.

CHAPTER ONE HUNDRED AND NINETY-NINE

Vascular Anomalies of the Head and Neck

Jonathan A. Perkins

Eunice Y. Chen

Key Points

- The most common types of head and neck vascular tumors are hemangioma of infancy (HOI), whereas the most common head and neck vascular malformations are lymphatic malformations.
- HOIs are absent at birth, occur in infancy, proliferate up to the age of 9 to 10 months, and variably involute or shrink over years.
- HOIs and lymphatic malformations each have unique endothelium that distinguishes them from other types of vascular tumors and malformations.
- Periocular hemangiomas of infancy can cause deprivation amblyopia and astigmatic amblyopia.
- Superficial HOIs and other red, cutaneous vascular lesions can be treated with a pulsed dye laser.
- Surgical excision of focal hemangiomas can be done to both prevent complications and improve treatment outcomes.
- Lymphatic malformations are classified by stage and radiographic appearance as macrocystic or microcystic or a combination of both.
- Lymphatic malformations occur in utero and manifest at birth or in association with an infection or trauma later in life. Most malformations manifesting at birth or later in life are associated with a normal karyotype.
- Macrocystic lymphatic malformations can resolve spontaneously or be treated with either surgery or sclerotherapy. Microcystic suprahyoid lymphatic malformations are difficult to treat with any modality and frequently cause macroglossia.
- Venous malformations are associated with tyrosine-kinase type 2 receptor dysfunction, which causes abnormal venous structure. Histologically, venous malformations are a combination of both blood vasculature as well as lymphatic vasculature.
- Kasabach-Merritt phenomenon is most commonly associated with the vascular tumors kaposiform hemangioendothelioma and tufted angioma.
- Arteriovenous malformations are high-flow venous malformations that occur in any area of the head and neck and frequently require a combination of embolization and surgical therapy for treatment. Medical therapy is ineffective.

Vascular anomalies encompass vascular tumors and malformations and involve the head and neck 70% to 80% of the time. Clinical and radiographic findings, and occasionally histologic evidence, are used to distinguish among various vascular anomaly subtypes. A vascular anomaly classification system has been developed based on these factors[1,2] (Table 199-1). Hemangiomas of infancy (HOIs) were the first vascular lesions to be distinguished from other vascular anomalies, based on their natural history.[3] HOIs, unlike other vascular anomalies, are absent at birth, appear during infancy, grow rapidly within the first year of life, and then undergo a variable period of involution. Numerous recent discoveries have further solidified the distinction between vascular tumors and vascular malformations.[4-6]

Vascular tumors usually are benign, have neoplastic characteristics, and represent disordered angiogenesis.[4] Radiographically these tumors can be characterized by describing lesion size, blood flow, and location.[7,8] Certain clinical conditions, such as Kasabach-Merritt phenomenon and PHACES syndrome (*p*osterior fossa abnormalities, *h*emangiomas, *a*rterial anomalies, *c*ardiac anomalies, *e*ye abnormalities, *s*ternal or abdominal clefting), are associated with vascular tumors and not vascular malformations.[9-11] Vascular malformations often contain all vessel types—arterial, venous, and lymphatic—and seem to represent disordered vasculogenesis. Most vascular malformations are present at birth and demonstrate growth parallel to the child's growth. These lesions have a distinct radiographic appearance in their location, size, and blood flow—in particular, that through the lesion. Additionally, certain types of vascular malformations are characterized on the basis of the radiologic architecture of the lesion. This characterization has been most useful in identifying lymphatic malformations. These malformations also are associated with either local tissue or bony overgrowth (Fig. 199-1). Since the original distinction of hemangiomas from other types of vascular tumors and malformations, molecular characteristics as well as radiographic features of individual vascular anomaly subtypes have allowed further distinction between various types of vascular anomalies. This chapter outlines these distinctions and

explains how these distinctions have led to treatment improvements, potentially leading to better clinical outcomes.

A genetic and molecular basis for some vascular anomalies is being investigated.[12-14] The most apparent link between genetic defect and disease is seen in inherited venous malformations, in which a mutation in the protein receptor for tyrosine kinase (Tie2), which normally allows endothelial–smooth muscle communication essential for venous morphogenesis.[15] Defects in the smooth muscle layer of vessels with venous malformations result from this mutation. Similarly, vascular malformations in hereditary hemorrhagic telangiectasia types 1 to 3 are associated with gene mutations that adversely affect endothelial function.[16] Familial HOIs are linked to defects in the fifth chromosome.[17] Sporadic HOI endothelium is clonal.[18,19] Glomangiomas have defective "glomulin" function, distinguishing them from other venous malformations.[20] Ateriovenous malformations occurring with atypical capillary malformations have been linked to a gene *RASA1*.[21] Hypertrophy of tissues near vascular malformations has been linked in certain syndromes to a mutation in the *PTEN* tumor suppressor gene.[22,23] This information creates a basis for understanding the mechanisms behind the pathogenesis of vascular anomalies.

Table 199-1

Vascular Anomaly Classification*

Vascular Malformation	Vascular Tumor
Single-Vessel Type	Hemangioma
Capillary	Hemangioma of infancy
Venous	Congenital hemangioma
Lymphatic	Rapidly involuting congenital hemangioma (RICH)
Combined/Complex	Noninvoluting congenital hemangioma (NICH)
Malformations	Lobular hemangioma (pyogenic granuloma)
Arteriovenous	Vascular Neoplasm
Lymphaticovenous	Kaposiform hemangioendothelioma
Capillary-venous	Angiosarcoma
Capillary-lymphaticovenous	Hemangiopericytoma
Capillary-arteriovenous	Miscellaneous
	Tufted angioma

*Binary classification system adopted by the International Society for the Study of Vascular Anomalies (ISSVA) in 1996.

Vascular Tumors

Hemangiomas of Infancy

HOIs are absent at birth and appear in infancy; they proliferate for 6 to 9 months and then involute partially or completely over several years[24-26] (Fig. 199-2). Vascular lesions not following this pattern should be considered for alternative diagnoses.[6] In addition to clinical diagnosis, HOI diagnosis can be further confirmed through molecular staining and imaging.[27,28] HOI endothelium has several unique surface markers detected by immunohistochemistry. The first marker for HOI described was glucose transporter-1 (GLUT-1); others have since been described. GLUT-1 detection separates HOIs from other vascular anomalies and congenital hemangioma.[28] Improvements in image acquisition with both computed tomography (CT) scanning and magnetic resonance imaging (MRI) allow differentiation between HOIs and other vascular anomalies[8,29,30] (Fig. 199-3).

Clinical Presentation

At birth, HOI can be completely absent or may be present as a slight redness or pallor in the area in which a HOI subsequently appears.[24] In the first several months of life, HOIs grow rapidly and can involve any area of the head and neck. Often multiple hemangiomas are present in areas outside the head and neck. Two thirds of HOIs occur in girls. HOIs are more prevalent in premature infants and infants born to mothers of advanced maternal age, with a history of chorionic villus sampling. Terminology to describe types of HOIs and their appearances and locations[31] are illustrated in Figure 199-4. Segmental HOIs usually are superficial, variably involve cutaneous dermatomes, and have more associated morbidity than focal HOIs. These lesions are thought to occur in embryologic prominences that are related to neural crest cells, which influence vascular patterning.[32] In the head and neck, focal HOIs occur in identifiable patterns that are thought to be associated with lines of embryonic tissue fusion.[31,32] Building on the concept of embryonic fusion planes, several groups of investigators have observed that midface HOIs do not predictably involute.

PHACES Syndrome

An association between some HOIs and ventral clefting, congenital cardiac malformations, intracranial malformations, and ocular abnormalities has been described; the specific manifestations collectively make up the PHACES syndrome[11] (Fig. 199-5). Central nervous system symptoms include developmental delays, seizures, and congenital stroke. Patients suspected to have PHACES syndrome should undergo head imaging, ophthalmologic examination, and cardiac evaluation. Some clinicians recommend antiplatelet therapy for patients with abnormal cerebral vasculature, to prevent congenital stroke.[33,34] Further analysis of HOI biology is necessary to elucidate these associations.

Other Types of Vascular Tumors

Congenital Hemangioma

High-flow vascular tumors manifesting at birth that are histologically identical to HOIs except for positive GLUT-1 staining are called *congenital hemangiomas*.[73,74] There are two types of congenital hemangiomas—those that rapidly resolve over the span of a year and those that persist. Accordingly, they are named *rapidly involuting congenital hemangioma* (RICH) and *non-involuting congenital hemangioma* (NICH), respectively. These lesions often are difficult to distinguish from HOIs unless a careful history is taken and histologic analysis is performed. Often the diagnosis remains uncertain until the clinical behavior of a given lesion is observed (Fig. 199-6). Medical therapy is ineffective for congenital hemangiomas. Treatment for RICH usually is limited to observation, whereas NICH may require laser or surgical therapy.

Kaposiform Hemangioendothelioma and Tufted Angioma

Most nonhemangioma vascular tumors are benign. These tumors occur rarely in the head and neck. The two most common tumors are kaposiform hemangioendothelioma (KHE) and tufted angioma (TA). KHEs occur anywhere in the head and neck and have a significant lymphatic component in addition to blood vascular endothelium.[75] Clinically,

Figure 199-4. Hemangioma of infancy, types. **A,** Superficial focal hemangioma; forehead. **B,** Mixed segmental hemangioma; midface, lip, forehead. **C,** Deep focal hemangioma; malar region. **D,** Mixed focal hemangioma; malar lower eyelid. **E,** Mixed segmental hemangioma; cheek, malar region.

Clinical appearance in PHACES syndrome. **A,** Segmental hemangioma involving the lips, nose, left upper and lower face. **B,** Segmental hemangioma involving the lips, nose, left upper and bilateral lower face. **C,** Segmental lower lip hemangioma with sternal cleft. **D,** Focal lower lip hemangioma with sternal cleft.

KHEs appear as violaceous cutaneous nodules extending into deep tissues locally (Fig. 199-7). Their radiographic appearance is one of diffuse infiltrative vascular process (see Fig. 199-7). Careful assessment through imaging and diagnostic biopsy should guide KHE therapy. TAs are more localized and may or may not involve the skin. Treatment for both KHE and TA is centered on proper diagnosis, prevention of complications, and tumor control. Diagnosis requires an incisional biopsy with possible immunohistochemical staining. Curative surgical resection is possible and advisable for some localized tumors, but for large lesions, surgery may not be curative. With extensive KHEs or TAs that are causing pain, loss of function, or significant disfigurement, antiangiogenic chemotherapy may be necessary. The natural history of these lesions in the head and neck often is unclear; therefore, treatment needs to be individualized.

Figure 199-6. Appearance of noninvoluting congenital hemangioma.

Common Complications of Vascular Tumors

Because most vascular tumors are HOIs, which proliferate rapidly, complications occur most frequently with these lesions. HOI complications occur primarily from lesion-induced functional compromise and cutaneous ulceration. Breathing can become compromised and obstructed from airway HOI. HOI can cause biphasic stridor by narrowing the infant's subglottic airway[35] (Fig. 199-8). Obstruction of the visual axis by a proliferating HOI occurs with eyelid lesions, inducing deprivation amblyopia[36] (Fig. 199-9). Deformation of the eye from lesion compression or periocular tissue distortion before the age of 6 months induces astigmatic amblyopia.[37] Proliferating HOI located in places of repetitive skin trauma such as the lips and neck skinfolds can ulcerate, resulting in scarring. The reasons for ulceration are unclear, but when present, ulcerations begin as brown crusts, become painful, bleed, and require local wound care for healing. Extensive ulcerations of the hemangioma can become infected and result in tissue loss, further complicating healing and treatment[38] (Fig. 199-10). Ulceration involving the lip often makes oral feeding challenging because of pain and hemangioma-induced lip distortion. Large, deep head and neck HOIs involving the parapharyngeal and scalp regions often are associated with high-output cardiac failure, due to the increased blood flow in these vascular lesions.[39] The psychosocial consequences of HOI for the family and patient are important to consider in treatment planning.[40]

Unusual Conditions Associated with Vascular Tumors

Kasabach-Merritt Phenomenon

Kasabach-Merritt phenomenon is the occurrence of profound thrombocytopenia in association with vascular tumors. For unknown reasons, KHE and TA, not HOI, are the vascular tumors most frequently associated with Kasabach-Merritt phenomenon.[9,10,76] This occurs in infancy and requires extensive chemotherapy to reduce the risk of bleeding associated with thrombocytopenia. The mechanisms leading to thrombocytopenia are unknown. Before the capability of histologic distinction between the endothelium of KHE, TA, and HOI, many vascular tumors were called simply "hemangiomas," and Kasabach-Merritt phenomenon was associated erroneously with HOI. Newly described vascular entities, not classified as vascular tumors, also are associated with thrombocytopenia. The spectrum of this phenomenon as it relates to vascular anomalies is still being defined.[77]

Figure 199-9. Deep focal hemangioma of infancy, upper eyelid, impinging visual axis.

Bone Resorption

Bone resorption can occur in association with KHE, resulting in localized osteopenia. The mechanisms for bone resorption are unknown. When bone loss occurs, chemotherapy has not been shown to change outcome.

Treatment Overview

Analysis and Treatment of Facial Hemangiomas

A complete discussion of all aspects of facial hemangioma treatment is beyond the scope of this chapter.[72] Some general concepts and principles useful in management decisions follow:

1. Societal attitudes and recognition of treatment possibilities for HOIs that involve the face are changing. Lesions that formerly were allowed to "involute," followed by delayed treatment of residual skin changes, are being managed more aggressively in early childhood (Fig. 199-11).

2. HOIs in certain areas of the face are prone to complications and noninvolution. This is especially true of midface lesions. Recognition of the varied natural history of facial HOI is essential to treatment planning and family counseling.

3. HOIs distort involved tissue by creating tissue excess and sometimes inducing adjacent bone and soft tissue hypertrophy (Fig. 199-12). This hypertrophy creates surgical and reconstructive challenges that differ from usual tissue deficits associated with facial tumor resection.

4. Large facial HOIs require more intensive monitoring and treatment planning than smaller lesions. Often the treatment of these lesions requires combined modalities and occurs in multiple stages over several years (Figs. 199-13 and 199-14).

5. An understanding of the medical, laser, and surgical treatment implications and options associated with HOI type and facial location is essential in planning treatment of these lesions.

Medical Therapy

Medical therapy for proliferating HOI is directed at stopping angiogenesis and decreasing peritumoral inflammation; in contrast, medical therapy for nonproliferating HOI is ineffective.[4,41,42] Although controversial, the mainstay of medical therapy has been systemic corticosteroid administration, which is antiangiogenic and anti-inflammatory.

The major indication for corticosteroid use depends on the presence of HOI complications or the attempt to prevent such complications, which occur more frequently with extensive segmental lesions.[26] For extensive proliferating HOI, prednisolone is given orally with doses ranging from 1 to 5 mg/kg/day in treatment courses that begin with an empirical burst at a high dose and then a slow 4- to 6-week taper off the medication. In theory, this minimizes the systemic side effects of steroid usage, but no long-term efficacy studies have been done.[43] Effectiveness of therapy is monitored throughout therapy; live vaccine administration is avoided, and blood pressure is monitored. Focal HOI of the head and neck can be injected with corticosteroids to localize drug delivery.[44,45] This practice is controversial and specialty specific, owing to the risk of blindness, training differences, and uncertain efficacy. Despite this, it is frequently done under general anesthesia for eyelid HOI while directly visualizing the retina.[36,46] In this location steroids are very effective in reducing HOI size, thereby decreasing the risk of HOI-induced visual impairment, but intralesional steroid injections can induce measurable adrenal suppression.[46] The role of topical medications to treat hemangiomas is being defined.[47] Other forms of antiangiogenic chemotherapy, such as interferon, have been used to treat HOIs.[48,49] The initial optimism for interferon as an effective agent for treatment of extensive HOI was subdued by the realization that before the age of 1 year, the central nervous system appears to be sensitive to this medication; neurologic complications such as spastic dysplegia were frequent.[50] For this reason, interferon is not used without serious consideration. However, it is still used in selected patients during times of rapid HOI proliferation. The proper dose of interferon is controversial, because previously reported complications were attributed to inappropriately high interferon dosing. More recently, vincristine has been investigated as a medication that can be used safely for treatment of extensive HOI.[51,52] Trials are under way to determine its efficacy in comparison with corticosteroids. Most recently, propranolol has been found to have an effect on reduction of HOI size. Further study is necessary to refine its use in the treatment of HOI.[78]

Laser Therapy

Superficial HOIs are red; the pulsed dye laser with a cooling device can reduce and even remove this skin redness, while the epidermis overlying the HOI is preserved.[53,54] The pulsed dye laser does not reduce HOI volume. This device is advantageous because it spares the superficial epidermis and allows for treatment of cutaneous redness without scarring (Fig. 199-15). However, when this device is used in patients younger than 6 months of age, when the HOI is actively proliferating, it can induce epithelial disruption, ulceration, and scarring.[55] For this reason, most clinicians recommend waiting to use the pulsed dye laser until after the age of 6 months. Often, reducing HOI redness is the only therapy necessary, because the deep portion of the lesion resolves with involution.

Surgical Therapy

When HOIs cause functional compromise of vision or breathing and are unresponsive to medical therapy, surgical excision may be necessary to preserve function.[56-58] HOIs that partially involute may leave significantly abnormal fibrofatty skin changes, requiring surgical resection.[59] A variety of techniques for HOI removal and reconstruction have been described. In most cases, waiting until the HOI has stopped proliferating is advisable.[60,61] When the HOI is causing airway or visual compromise, surgery during proliferation may be necessary. HOI occurring on the face can be significantly disfiguring and may be best treated with surgical excision.[62] When this type of lesion is mixed, with a larger superficial component, staged treatment with pulsed dye laser induces skin and dermal thickening, allowing HOI excision with minimal skin loss and tension-free closure of the defect (see Fig. 199-13).[63]

Assessment and Treatment of Airway Hemangiomas

One of the conditions associated with HOI that warrant the direct involvement of the otolaryngologist is an airway hemangioma. HOIs can occur anywhere in the upper and lower airways.[35] Usually the lesion is asymptomatic, involving the superficial mucosa. When a parapharyngeal HOI is large and abuts the pharynx, extrinsic compression of the airway can occur, particularly during sleep. Symptoms of sleep-disturbed breathing may arise during HOI proliferation or inflammation. Laryngeal involvement with HOI frequently manifests during infancy in the proliferative phase in association with an upper respiratory infection, or later in life with recurrent croup.[64] This clinical

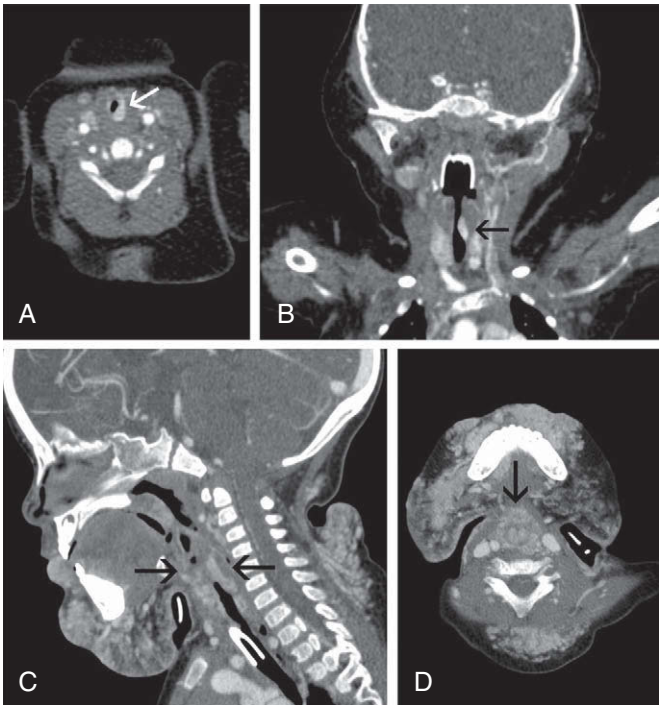

Figure 199-16. Computed tomography (CT) assessment of airway hemangioma of infancy. **A** and **B,** CT appearance of focal airway hemangioma of infancy. **A,** Axial scan; **B,** coronal scan. Compare endoscopic photograph of the same patient in Figure 199-8B. **C** and **D,** CT appearance of segmental airway hemangioma of infancy. **C,** Sagittal scan; **D,** axial scan. feature is different from those of other types of hemangiomas, such as a lobular hemangioma (also known as a pyogenic granuloma).[65] Because the subglottic airway is the narrowest portion of the pediatric airway, HOIs in this area induce the greatest degree of respiratory embarrassment. Assessment of a stridorous infant must include the possibility of an airway hemangioma, especially if a cutaneous HOI is present. Segmental HOIs in the lower face are associated with airway lesions in at least 50% of cases.[66] Stridor in association with this type of HOI should prompt hospital admission, fiberoptic laryngoscopy, and even operative endoscopy if the initial evaluation is nondiagnostic. Advances in CT imaging techniques enable accurate assessment of HOI extent, to include evaluation of airway lesions (Fig. 199-16). Along with careful endoscopy, such imaging will reveal a pattern of HOI in the airway that can be described as similar to cutaneous HOI. In other words, there can be focal HOIs located only in the subglottis or segmental HOIs that are transglottic and extend into the soft tissues surrounding the airway.

Treatment of airway HOI is aimed at preventing the need for a tracheotomy. Initial treatment with high-dose oral corticosteroids usually improves the respiratory status within 24 hours. Empirical use of steroids in any patient with cutaneous HOI and new-onset stridor can be used as a diagnostic assessment. If rapid improvement occurs, then presence of an airway HOI is likely. If no improvement is obtained, some other problem exists. Airway protection, when necessary, can be accomplished with endotracheal intubation using a small uncuffed endotracheal tube. This option allows safe transfer to a facility capable of comprehensive HOI care and avoids using a tracheotomy for immediate airway protection. Chemotherapy has been used to treat these lesions, but safety of this management method is controversial.[67] Numerous methods of operative interventiont have been used successfully for many airway hemangiomas.[56,57,68-70] Several themes have emerged from analysis of airway hemangiomas over several decades. "Focal" lesions that involve one side of the subglottis are successfully treated with steroid injection, laser ablation, or surgical excision. Larger circumferential "segmental" lesions are more difficult to treat and may necessitate tracheotomy management. Frequently, these lesions respond temporarily to steroid treatment. Laser use for circumferential lesions is done only on one side of the larynx at a time, necessitating multiple treatments that can result in airway scarring and stenosis.[71] Surgical excision as initial treatment for extensive airway HOI is being done more routinely and successfully, but careful case selection is imperative.[56] In all airway hemangiomas, use of oral corticosteroids, intermittently and long-term, usually is necessary until the HOI stops proliferating. Analysis of treatment outcomes for airway hemangiomas is in its infancy, owing to ongoing changes in the current understanding of HOI biology.[35]

Vascular Malformations

Lymphatic Malformations

In our experience, lymphatic malformations are the most common vascular malformation affecting the head and neck in children.[79,80] Seventy-five percent of all lymphatic malformations occur in the head and neck. The etiology of lymphatic malformations remains unknown. Histologically, they consist of abnormally dilated lymphatic channels. Most lymphatic malformations are present at birth, although some appear later in childhood when they enlarge in response to infection or trauma. Unlike the detection of nuchal thickening and lucency in utero, the postnatal presence of these malformations is not associated with chromosomal abnormalities.[81-83] Up to 60% of all lymphatic malformations are detected by ultrasound examination in utero.[84] It has been suggested that the sporadic occurrence of lymphatic malformations is due to de novo somatic mutations.

Diagnostic Evaluation

Diagnosis and characterization of lymphatic malformations can be accomplished with either MRI or CT scanning.[7] On MRI, T1-weighted images show nonenhancing muscle signal intensity, whereas T2-weighted images demonstrate nonenhanced high signal intensity without any feeding or draining vessels. CT scans show nonenhancing fluid density areas.[8] Either modality is useful for classifying the lesion as macrocystic (cystic spaces measuring 2 cm or larger), microcystic, or mixed.[85] Additionally, the prominent venous component of microcystic suprahyoid malformations is demonstrated with CT. Prenatal ultrasound examination can be used not only to detect the malformation but also to determine if there is a possibility of airway compromise at birth.[86] If further information regarding the lesion is required, a prenatal MRI study also can be used. With this information, delivery procedures that protect the infant airway while maintaining maternal-fetal circulation can be planned.[87]

Clinical Assessment and Behavior of Lesions

Clinical understanding of lymphatic malformation behavior and treatment outcome has improved through better diagnostic imaging and head and neck staging systems[88] (Fig. 199-17). Macrocystic malformations in the posterior neck, without septations, that are infrahyoid can resolve without treatment.[89] In general, macrocystic malformations in any location in the neck can be obliterated with sclerotherapy or surgery.[90-92] By contrast, bilateral suprahyoid lesions, which tend to be microcystic or mixed, respond poorly to any treatment and are more often associated with complications.[92-94] These lesions frequently involve the oral and pharyngeal mucosa, with consequent recurrent tongue swelling, persistent tongue hypertrophy, mucosal bleeding, speech difficulty, and airway compromise. In general, lymphatic malformations lateral to the lateral canthal line tend to be macrocystic, whereas medial midfacial lesions tend to be more mixed. Midface involvement is uncommon and usually is completely microcystic[95,96] (Fig. 199-18). The larger and more extensive suprahyoid malformations have the most unpredictable clinical behavior and cause the most problematic dysfunction of the upper aerodigestive tract.

Associated Conditions

Lymphatic malformations are associated with unique problems that complicate treatment. Repeated episodes of malformation swelling

Figure 199-17. Head and neck lymphatic malformation stages. **A,** Stage 1, unilateral infrahyoid. **B,** Stage 2, unilateral suprahyoid. **C,** Stage 3, unilateral supra- and infrahyoid. **D,** Stage 4, bilateral suprahyoid. **E,** Stage 5, bilateral supra- and infrahyoid.

Figure 199-18. Microcystic lymphatic malformation involving left upper lip.

in association with presumed infection or trauma frequently occur, especially in suprahyoid microcystic or mixed lymphatic-venous malformations with oral mucosal involvement.[97] Mucosal inflammation can trigger intermittent aggravation of airway and feeding issues. These inflammatory-infectious episodes are treated effectively with appropriate broad-spectrum antibiotics with or without systemic corticosteroids.[80] Patients with transmural tongue involvement by malformation benefit significantly from this treatment both acutely as well as prophylactically. What triggers inflammation of lymphatic malformations is unknown, but in some cases recurrent or persistent inflammation may be related to immune dysfunction. Patients with large bilateral or microcystic lymphatic malformations can have significant lymphocytopenia involving T, B, and natural killer (NK) cell subsets.[98] This lymphocytopenia is not related to lymphocyte sequestration within the malformation, as was previously thought. Large bilateral or microcystic lesions involving the oral mucosa require more intensive treatment in lymphopenic patients than in patients without lymphocytopenia.[99]

Lymphatic malformations frequently involve and can distort the facial skeleton. This distortion is most evident in the mandible in association with large bilateral suprahyoid lesions[93] (Fig. 199-19; see also Fig. 199-1). The reasons for skeletal overgrowth are unknown. Early surgical excision of the soft tissue lymphatic malformation does not appear to change the rate or incidence of bony involvement. When the mandible is enlarged by malformation, mandibular reduction surgery may be indicated. In rare cases, large lymphatic malformations near the skull and skull base may be associated with bone resorption and more widely disseminated lymphatic growth, which can be fatal.[78] Bone loss also occurs with some lymphatic malformations. Gorham syndrome (disappearing bone disease) is the most striking manifestation of lymphatic vessels overtaking bony structures.[99a]

Treatment Options: Sclerotherapy versus Surgery

Favorably staged lymphatic malformations, such as unilocular macrocystic posterior lateral malformations, can be observed over time. If problems such as infection do not occur during observation, the lesion may regress spontaneously[89] (Fig. 199-20). A decision for intervention usually is triggered by concerns for airway, feeding, speech, infection, and appearance.

Sclerotherapy

Sclerotherapy for macrocystic (cysts larger than 2 cm in diameter) malformations is no longer new, but popularity for this intervention appears to be on the rise, even though it is infrequenly used according to some reports.[100,101] Sclerotherapy with all reported agents is usually ineffective for microcystic lesions.[102] Sclerotherapy involves percutaneous needle aspiration of macrocystic spaces under fluoroscopic guidance

Figure 199-19. Facial asymmetry in parotid lymphatic malformation. **A,** Swollen lymphatic malformation before treatment. **B,** Persistent facial asymmetry after treatment; asymmetry involves both soft tissue and bone.

with subsequent injection of the sclerosing agent. Use of OK-432 (Picibanil, Chugai Pharmaceutical Company, Tokyo) as a sclerosant, because of its decreased toxicity and scarring risks, has led to increased interest in sclerotherapy. OK-432 is not commercially available in the United States, but published reports show promising results for macrocystic lesions after multiple treatments.[102,103] Similar efficacy for treatment of macrocystic lesions has been reported for doxycycline, bleomycin, ethanol, and sodium tetradecyl sulfate.[104,105] Major toxicity issues, including pulmonary fibrosis with bleomycin and permanent nerve injury with ethanol, are rare. Other rare complications include sepsis, shock, stroke, and seizures. Minor issues such as skin blistering and loss, fever, and erythema and pain at the injection site are more common.

Surgery

Surgical excision, the traditional treatment of choice for most types of lymphatic malformations, is still the most common treatment modality.[100] Excision of localized macrocystic lesions in the posteroinferior neck and parotid and submandibular regions generally has a high rate of complication-free surgical success.[80] However, in some reports, the complication rate, especially for large mixed suprahyoid lesions, is high.[93] Complications include cranial nerve or great vessel injury, tongue edema requiring tracheotomy, bleeding, and infection.

Surgical goals should be total excision with preservation of vital structures, when possible. Subtotal excision, not surprisingly, results in more postoperative persistent problems but may be necessary to preserve vital structures.[95] Lymphatic malformations are infiltrative and involve nerves, vessels, and muscles. It is common in large facial malformations to have facial nerve branches weave back and forth in the cyst walls and within the lesion, resulting in unusual nerve location and greater nerve length.[106] Intraoperative electromyographic nerve mapping can aid in these difficult dissections (Fig. 199-21). For bilateral suprahyoid lesions with mucosal involvement, waiting as long as possible before surgery and doing one side at a time (staged excision) may reduce the potential for permanent tongue enlargement. When the tongue becomes enlarged, surgical reduction may be indicated[107] (Fig. 199-22). Postoperative drainage of the surgical site is essential after resection, because significant lymphorrhea can occur.[108]

Figure 199-22. Microcystic lymphatic malformation, mucosa and deep tongue involvement.

Treatment Option Conclusions

New consensus views regarding treatment of lymphatic malformations appear to be emerging. The practice of waiting for the possibility of spontaneous resolution for unilocular or nearly unilocular lesions, especially if they are located in the posteroinferior neck, is becoming more common. Most vascular anomaly centers are treating macrocystic disease with either sclerotherapy or surgery. Systemic steroids, in addition to antibiotics, are used to treat severe acute inflammation and infection, although controlled studies are lacking and immune surveillance is necessary. Anecdotal evidence has led many clinicians to delay surgery, if necessary, as long as possible and to perform surgery for large suprahyoid lesions in stages to reduce complications (e.g., tongue edema). Little consensus exists regarding treatment to reduce mandibular and other facial overgrowth.

Venous Malformations

Venous malformations consist of tangled abnormal blood vessels filled with slow flow blood. Some of these lesions have been associated with a receptor tyrosine kinase (Tie2) dysfunction.[13] Other molecular mechanisms may be involved in the disordered vasculogenesis associated with these lesions.[109] These lesions frequently are present in muscle tissue, are compressible, enlarge with Valsalva maneuver or dependent positioning, and give a bluish hue under involved skin or mucosa[110] (Fig. 199-23). Occasionally, intracranial and skull base extension can occur, particularly with periorbital lesions.[111] Histologically, many of these lesions comprise blood and lymphatic vascular elements.[112] They usually are present at birth, slowly enlarge over time, and may become inflamed and painful during puberty and with trauma.[113] Diagnosis can be made clinically with radiographic confirmation. Duplex scanning shows slow blood flow, and lesions have a bright signal on T2-weighted sequences on MRI.[7] CT scans frequently demonstrate calcified phleboliths. Treatment consists of symptom management and malformation ablation or excision in selected lesions. Pain from enlargement is thought to be due to adjacent nerve irritation from the malformation and may be related to the intralesional consumptive coagulopathy present in some patients.[112,113] This coagulopathy can be detected through elevated D-dimers and low fibrinogen. Antiplatelet and anti-inflammatory agents can help control symptoms. In extreme situations, low-dose heparin may be necessary in conjunction with hematology consultation. Venous malformation ablation can be achieved with complete surgical excision if possible. Careful preoperative assessment is essential to detect any evidence of a subclinical coagulopathy. Combined therapy with sclerosis and surgery usually is necessary to minimize blood loss and morbidity.[110,114] When excessive intraoperative bleeding occurs, novel hemostatic measures have been used effectively.[115] For lesions that are amenable to sclerotherapy, intralesional sclerosants or laser can be utilized[116-118] (Fig. 199-24). Often, periodic treatments are necessary.

Arteriovenous Malformations

Arteriovenous malformations are high-flow vascular malformations that can manifest as enlarging masses throughout the head and neck, most frequently involving the cheek or auricle.[119] Some arteriovenous malformations are found with cutaneous capillary malformations and are associated with gene abnormalities.[21] Functionally, these congenital lesions arise from a nidus of blood vessels that have abnormal precapillary communication from arteries to veins. This creates the arteriographic diagnostic finding for arteriovenous malformations of "early venous filling." By contrast, arteriovenous fistulas are a solitary abnormal communication between arteries and veins that usually are acquired secondary to trauma. Diagnosis of arteriovenous malformations requires imaging with MR or CT angiography[29,120] (Fig. 199-25). Occasionally, interventional angiography also is necessary, but usually this can be done in conjunction with embolization, immediately before surgical treatment. The natural history of these malformations often is unclear, but four clinical stages—dormancy, expansion, destruction, and heart failure—have been described and correlated with treatment outcome.[119] In the dormancy stage, these malformations can be mistaken for other vascular anomalies. In some patients, enlargement and growth can occur during adolescence. Treatment of arteriovenous malformations includes nonintervention or intervention with a combination of preoperative embolization followed by surgical excision of the nidus.[121] Lesions contained within bone can be managed with embolization alone, but once the lesion involves adjacent soft tissue, surgery may be necessary.[122] These lesions recur commonly, so treatment decisions must be carefully planned.

Capillary Malformations

Skin capillaries that are persistently dilated form malformations commonly known as *port-wine stains*.[123] These capillary malformations frequently are seen in the mid- and upper face. In the upper face and eyelid region, they are associated with Sturge-Weber syndrome.[124] This condition is characterized by capillary malformations involving the eye, skin, and leptomeninges. Capillary malformations in the upper face warrant concomitant evaluation with brain MRI and ophthalmologic examination to rule out this syndrome. These lesions progressively darken and thicken throughout life and are associated with local tissue hypertrophy and hamartomatous nodule formation that may require

treatment[125] (Fig. 199-26). The superficial component of these lesions can be managed with serial pulsed-dye laser treatments.[126] Some malformations are resistant to this therapy, and other laser modalities can be used.[127] No therapy is curative.

Summary

Current understanding of vascular anomalies is evolving with new advances in molecular, genetic, diagnostic, disease staging, and therapeutic outcomes research. As a field of clinical medicine, the management of these anomalies crosses traditional boundaries between medical and surgical disciplines. This overlap necessitates a multidisciplinary approach, in order to optimize patient care and treatment outcomes. It is anticipated that future diagnostic and treatment modalities will be more effective in predicting the clinical course and preventing complications of these common and benign yet problematic lesions.

CHAPTER TWO HUNDRED

Pediatric Head and Neck Malignancies

Carol J. MacArthur

Richard J. H. Smith

Key Points

- Each year in the United States, cancer is diagnosed in 1 of every 7000 children 0 to 14 years of age.
- Although accidents are the leading cause of death in children, malignancies remain the most common cause of death from disease in the 1- to 14-year-old age group.
- Unlike adults, most childhood tumors are mesenchymal or neuroectodermal in origin.
- Nearly one third of pediatric malignancies are leukemias, and an additional 12% are lymphomas. Nonhematologic solid tumors account for the remaining 55%.
- Every child with suspected leukemia-lymphoma or neuroblastoma should have a workup to evaluate for gene translocations, antigen expression, and gene amplification. Critical to this histopathologic workup is the delivery of fresh tissue to the pathologist for proper handling.
- Pediatric head and neck cancer treatment is guided by the guidelines developed in accordance with collaborative, multimodality therapeutic protocols, such as the Intergroup Rhabdomyosarcoma Study Groups Committee (IRSC).
- Because of the high rate of metastatic disease in pediatric cancers, combined therapy usually is required (surgical biopsy or excision, chemotherapy, radiation therapy if needed for local control).
- With increasing numbers of long-term survivors of pediatric head and neck cancer, ongoing management of sequelae from treatment is essential, including attention to development of secondary malignancies 1 to 2 decades after treatment.

Each year in the United States, cancer is diagnosed in 1 of every 7000 children 0 to 14 years of age. In 1998, the diagnosis of cancer was given to 8700 children before their 15th birthday and to 3700 young adults between 15 and 20 years of age in the United States.[1] Data collected by the Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute (NCI) between 1972 and 1990 suggested that these numbers were on the rise. In 1972, 12 cancers were diagnosed per 100,000 children under the age of 15 years; by 1990, that number had increased to nearly 14 per 100,000.[2,3] However, the rates have been stable since 1990.[4] Among malignancies of the head and neck, the incidence rate increased from 1.1 to 1.49 per 100,000 person–years.[5] During this same period, cancer-related mortality rate decreased. Therefore, the changes in incidence probably coincided with earlier diagnosis because of advances in central nervous system (CNS) diagnostic imaging such as computed tomography (CT) scanning and magnetic resonance imaging (MRI), and not a true increase in rates of disease.[4] However, malignancies remain the most common cause of death from disease in the 1- to 14-year-old age group. Childhood cancers are exceeded only by accidents as the leading cause of death in children older than 1 year of age.

Certain populations of children are at a higher risk for developing childhood malignancies. Down syndrome (DS) patients have a 20-fold increased chance of developing leukemia over the normal population. Post-transplantation pediatric patients and children who have received chemotherapy or radiotherapy are at increased risk for development of a second malignancy, most commonly non-Hodgkin's lymphoma or leukemia. Beckwith-Wiedemann syndrome and hemihyperplasia (previously termed hemihypertrophy) is linked with an increased risk of Wilms' tumor and hepatoblastoma. Patients with Bloom's syndrome, ataxia-telangiectasia, X-linked hypogammaglobulinemia, Wiskott-Aldrich syndrome, common variable immunodeficiency syndrome, severe combined immunodeficiency syndrome, X-linked lymphoproliferative disorder, selective IgA deficiency syndrome, and autoimmune diseases are all at increased risk for development of lymphoma, leukemia, and solid tumors.

The types and relative frequencies of childhood cancers are vastly different from those of cancers in adults. Most childhood tumors are mesenchymal or neuroectodermal in origin, whereas adult tumors are usually epithelial in origin. Nearly one third of pediatric malignancies are leukemias, most commonly acute lymphocytic leukemia, and an additional 12% are either Hodgkin's lymphoma or non-Hodgkin's lymphoma. Nonhematologic solid tumors comprise the remaining 55%. Of all solid tumors in children younger than 15 years of age, brain tumors are most common, followed in frequency by neuroblastoma, Wilms' tumor, non-Hodgkin's lymphoma, Hodgkin's disease, and rhabdomyosarcoma.

Impressive gains have been made in survival rates for some childhood cancers. In children younger than 15 years of age who are

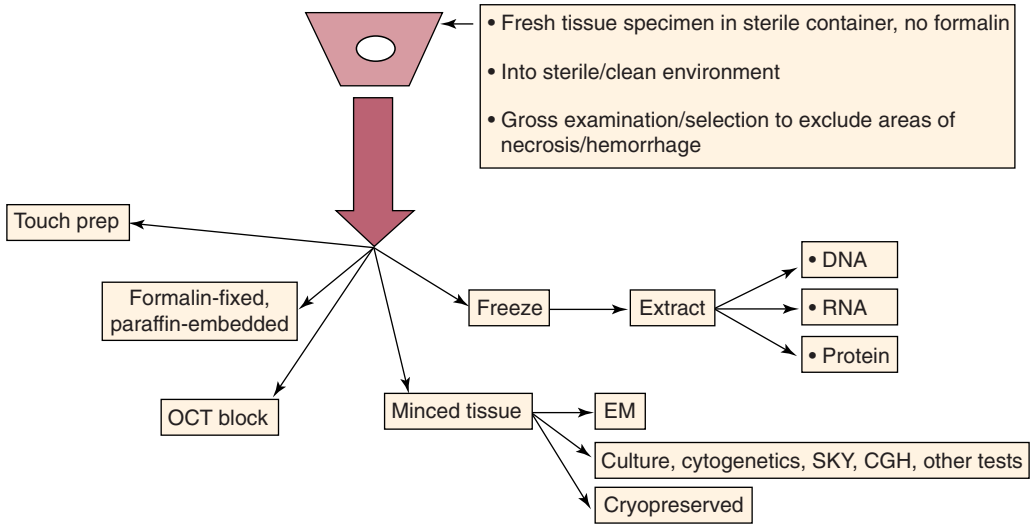

Figure 200-1. Tissue-handling algorithm for histopathologic workup. CGH, comparative genomic hybridization; EM, electron microscopy; FISH, fluorescence in situ hybridization; SKY, spectral karyotyping.

diagnosed with solid tumors, the survival rate has more than doubled—from 28% in 1960 to a more than 75% 5-year survival rate in 1993 and an 80% 3-year survival rate in 1995.[6] Particularly impressive survival gains have been achieved with Wilms' tumor and Hodgkin's lymphoma, both of which now have cure rates exceeding 90%.[2] Outcome data during this 30-year period show that the slopes of curves describing survival over time have remained fairly constant for all types of tumors. Advances in treatment and gains in survival have been achieved in a slow, incremental manner based on results of multicenter clinical trials. In spite of these advances, approximately 25% of children diagnosed with cancer will die of their disease.

The progress in survival rates for childhood cancer largely reflects the impact of clinical trials. Initiated first in 1948 to enable Farber and colleagues[7] to document the efficacy of methotrexate in inducing remission in some children with acute lymphocytic leukemia, most clinical trials today are conducted by the Children's Cancer Group or the Pediatric Oncology Group. In these trials, standard therapy is compared with a modification of that therapy, and if the modified protocol is superior, it then becomes the new standard. Progress is tedious, but from the perspective of time, it has been tremendously rewarding.

The possibility of more rapid advances in diagnosis and management is becoming increasingly real as studies of the molecular biology of childhood malignancies elucidate several requisite steps for tumorigenesis. Two important cytogenetic events, translocation and amplification, are important in tumor development and can act synergistically to generate potent oncogenic activity.[8] Nonrandom chromosomal translocations typically activate oncogenes by one of two mechanisms.[9] The first mechanism, frequently found in lymphoid malignancies, places the coding sequence of one gene under the regulatory control of a second gene. This juxtaposition results in increased or inappropriate expression of the first gene. The second mechanism generates a new gene, which is a chimera of two other genes that is formed by joining their coding regions. For amplification events, additional copies of a cellular gene are generated in the form of double-minute chromosomes or homogeneously staining regions.[10]

The pathologic evaluation of childhood tumors is very different from that of adult tumors. Because of the large numbers of mesenchymal tumors that can look very primitive and similar on light microscopy—small round blue cell (SRBC) tumors—use of newer techniques such as immunochemical, molecular, or ultrastructural analysis is necessary for accurate diagnosis. Proper diagnosis is crucial to developing a treatment plan and for prediction of clinical behavior. Every child with suspected leukemia-lymphoma or neuroblastoma should have a workup to evaluate gene translocations, antigen expression, and gene amplification. Critical to this pathologic workup is the delivery of fresh tissue to the pathologist for proper handling. Figure 200-1 shows proper tissue handling to ensure the availability of tissue for all types of analysis. Fresh tissue has the messenger ribonucleic acid (mRNA) necessary to carry out cell cultures for molecular genetic analysis and for growth of a permanent cell line. Because tissue often is not handled properly and is fixed in formalin before arriving at the pathologist's laboratory, techniques have been developed to obtain molecular genetic information from fixed or frozen tissue by such means as reverse transcriptase–polymerase chain reaction (RT-PCR) analysis, flow cytometry, fluorescence-activated cell sorting (FACS), and fluorescence in situ hybridization (FISH). However, RT-PCR analysis requires intact RNA, which can be obtained only by snap-frozen tissue stored at −70° C from viable tumor areas without tumor necrosis. Some success has been achieved with use of fixed, paraffin-embedded tissue for RT-PCR assays, but further work is needed in this effort.

Because resources are limited, a practical way to handle biopsy tissue must be adopted (see Fig. 200-1). After delivery of fresh tissue to the pathologist, the tissue is examined by routine hematoxylin and eosin (H&E) stains. If the diagnosis is not clear, additional methods are brought into play to establish a diagnosis such as immunohistochemistry, molecular genetic analysis, electron microscopy, cytogenetic studies, and deoxyribonucleic acid (DNA) sequencing (Table 200-1). These evolving techniques are used judiciously and are rarely all needed. The most common secondary procedure after examination of H&E stains is immunohistochemistry, followed by special stains, electron microscopy, and molecular studies. Immunohistochemistry is used to confirm the histogenesis of a tumor. Approximately 35 antibodies are commonly used in pediatric tumor workups in the categories of general (vimentin), hematopoietic, neural, myogenic, epithelial, and miscellaneous. Immunohistochemistry and electron microscopy have largely replaced the use of special stains, but a few are still useful, such as trichrome, pentachrome, reticulin, myeloperoxidase, and periodic acid–Schiff (PAS) stains. Electron microscopy is used primarily to clarify conflicting results from other studies such as immunohistochemistry. Molecular genetic techniques include five major methods: polymerase chain reaction (PCR) analysis, cytogenetic studies, FISH, spectral karyotyping (SKY), and comparative genomic hybridization (CGH). These techniques are used to detect genomic alterations (translocations, amplifications, or deletions) from chromosomal analysis. Many protocols require the use of special studies for ploidy and molecular genetics to enter a patient into a protocol treatment arm. The availability of molecular genetics has revolutionized childhood cancer diagnosis, providing accurate diagnoses that help guide therapy and predict clinical aggressiveness. Molecular genetic analysis of childhood tumors should not be taken with blind faith because two problems can

be encountered: certain tumor-specific translocations only occur in a percentage of tumors, and in some cases, the same translocation can occur in a phenotypically different tumor. Still, molecular genetics has enormous value in the diagnostic workup of the difficult, primitive pediatric tumors.

Head and neck tumors of childhood are reviewed in this chapter. This subset of malignancies accounts for approximately 12% of all childhood cancers and, in order of relative prevalence, includes lymphomas (27%: Hodgkin's lymphoma 17%, non-Hodgkin's lymphoma 10%), neural tumors (23%: retinoblastoma and neuroblastoma), thyroid malignancies (21%, with papillary carcinoma the most common pathologic diagnosis), and soft tissue sarcomas (12%: rhabdomyosarcoma; 8%, nonrhabdomyosarcoma soft tissue sarcomas [NRSTSs]).[5] Age has a marked effect on tumor type and modifies this order of prevalence considerably. The age factor is obviously pertinent to a directed evaluation and diagnostic workup (Table 200-2).

Discussion in this chapter is limited to lymphomas, rhabdomyosarcomas, neuroblastomas, NRSTSs, salivary gland malignancies, thyroglossal duct carcinomas, post-transplantation lymphoproliferative disorders, malignant teratomas, and the histiocytoses. Thyroid and nasopharyngeal carcinomas are adequately covered elsewhere in this book.

Table 200-1

Diagnostic Methods for Tumor Diagnosis

Method	Comment
Light microscopy	Used in all cases
Immunohistochemistry	Widely used ancillary diagnostic
Molecular genetic: reverse transcriptase–polymerase chain reaction (RT-PCR)	Common molecular diagnostic method
Molecular genetic: FISH	Replacing cytogenetics in many cases
Molecular genetic: in situ hybridization	Specialized use
Special stains	Still useful in some cases, inexpensive
Electron microscopy	Used to augment light microscopy
Cytogenetics	Used when no suitable FISH probes available
Molecular genetic: SKY, CGH	Newer diagnostic methods
Molecular genetic: DNA sequencing	For rare cases

CGH, comparative genomic hybridization; FISH, fluorescence in situ hybridization; SKY, spectral karyotyping.

Lymphomas

Non-Hodgkin's Lymphomas

Acute lymphoblastic leukemia, defined as leukemic involvement of greater than 25% of the bone marrow, is the most common pediatric malignancy. *Lymphomas*, defined as leukemic tumor cells extending beyond bone marrow sites and involving less than 25% of the bone marrow, are the third most common cancers in children in the United States,[11] and non-Hodgkin's lymphomas represent 60% of these diagnoses. The annual incidence in children younger than 15 years of age is 7 to 8 per 1 million, with peak ages between 7 and 11 years. Boys are preferentially affected in a 3:1 ratio,[12,13] and the disease is twice as common in whites as in blacks.[14] Although adult lymphomas are primarily nodal, childhood lymphomas are predominantly extranodal. Since 1973, the annual incidence of non-Hodgkin's lymphoma has risen by approximately 30%. Although the reasons for this increase remain unclear, specific populations of children who are at greater risk for non-Hodgkin's lymphoma have been identified. These groups include children with congenital immunodeficiency syndrome (Wiskott-Aldrich syndrome, ataxia-telangiectasia, and X-linked lymphoproliferative disease), children with acquired immunodeficiency syndrome (AIDS), and children who have received immunosuppressive therapy for organ or bone marrow transplantation. Patients treated for Hodgkin's lymphoma and solid tumors with chemotherapy are at an increased risk for non-Hodgkin's lymphoma as well. Common to all these patients is deficient or impaired T-cell function.

Geographic differences in the incidence rates and subtypes of non-Hodgkin's lymphoma are striking. For example, non-Hodgkin's lymphoma is rare in Japan, whereas in equatorial Africa and northeastern Brazil, Burkitt's lymphoma is endemic and accounts for approximately 50% of all cancers.[11] An association with Epstein-Barr virus (EBV) and BL has been demonstrated in these areas.[15] Even in cases of sporadic Burkitt's lymphoma in the United States for which standard screening yields a negative result,[16] EBV genomic DNA can be detected with molecular biology.

Presentation and Evaluation

Characterized by an acute onset with rapid progression, prompt diagnosis and initiation of therapy are important to reduce morbidity and ensure long-term survival.[17] In 23% to 46% of affected children, primary disease occurs within the abdominal cavity and involves, in decreasing order of frequency, the distal ileum, cecum, and appendix.[18,19] Mediastinal primary tumors are slightly less common and are

Table 200-2

Age-Incidence Ranking for Head and Neck Tumors in Children

Ranking of Tumors by Age (years)			
0-1	**1-5**	**6-10**	**11-20**
Neuroblastoma	Rhabdomyosarcoma	Lymphoma	Lymphoma
Rhabdomyosarcoma	Lymphoma	Rhabdomyosarcoma	Thyroid malignancies

NRSTS	NRSTS	Thyroid malignancies	Salivary gland neoplasms

Table 200-3

Diagnostic and Staging Evaluation for Non-Hodgkin's Lymphoma

Essential	Useful	Occasionally Indicated
History	Intravenous urography	Contrast studies of the gastrointestinal tract
Physical examination	Special radiologic views (airway)	CT, MRI of the brain
Specimens for histology, cytology, immunophenotyping, genotyping	CT, MRI of primary site	CT, MRI of spinal cord
Complete blood count		Creatinine clearance
Serum chemistries (electrolytes, liver, renal serum chemistries, LDH, uric acid)	Epstein-Barr virus studies	Urinary uric acid Serum lactic acid
Bone marrow aspiration and biopsy	Protein electrophoresis	
Cerebrospinal fluid analysis	Acid-base studies	Liver biopsy
Urinalysis		Bone scan
Chest radiography		
Gallium-67 scanning		
Abdominal imaging		

CT, computed tomography; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging.

diagnosed in 15% to 45% of cases.[20] Primary head and neck involvement occurs in 5% to 10% of children and originates in the salivary glands, larynx, paranasal sinuses, orbit, scalp, and Waldeyer's ring.[19] Proximity to the CNS makes direct extension possible.

The rapid progression of disease mandates prompt referral to a specialized management center before biopsy so that a pediatric oncologist can expedite the diagnostic and staging evaluation (Table 200-3) and determine the site and procedure to obtain tissue for histologic, cytologic, immunophenotyping, and genotyping analyses, with consultation from the surgeon and pathologist if necessary. Definitive diagnosis requires biopsy, sometimes by excision of a cervical node. Mediastinal involvement should be assessed by neck and chest CT before any procedure under general anesthesia. Disseminated disease is the rule, however, and often adequate numbers of malignant cells are found in the bone marrow, spinal fluid, or pleural or ascites fluid, obviating surgical intervention entirely. The presence of pancytopenia suggests bone marrow involvement, and when more than 25% of the marrow is replaced with tumor, children are assigned a diagnosis of acute lymphoblastic leukemia.

Management

Dramatic improvement in overall cure rates among children with non-Hodgkin's lymphoma reflects the incremental development of effective multimodal chemotherapeutic regimens through well-planned clinical trials. Systemic therapy is imperative because occult micrometastases affect more than 80% of children with non-Hodgkin's lymphoma and cure rates are less than 20% when only local therapy is used.[17] Management protocols are based on the extent of disease as determined by the staging workup and the histologic subtype.

The most widely used staging classification is the St. Jude Children's Research Hospital classification, based on the Ann Arbor staging system for Hodgkin's lymphoma, modified for non-Hodgkin's lymphoma (Table 200-4). Chemotherapy with combination drug therapy is the backbone of management, traditionally with agents used for acute lymphoblastic leukemia (i.e., cyclophosphamide, doxorubicin, vincristine, and prednisone, and for extensive or recurrent disease, methotrexate, Ara-C, etoposide, and ifosfamide). Overall cure rates are in the range of 70% to 90%, depending on tumor subtype. Radiotherapy has no routine role in the treatment of non-Hodgkin's lymphoma. Its use is reserved for massive disease, and surgery is used only occasionally in children with life-threatening tracheal compression. Response to therapy is assessed by monitoring tumor size and activity using a variety of imaging modalities or invasive techniques.

Histopathology and Molecular Biology

The histopathology of non-Hodgkin's lymphoma is extremely variable and has been categorized in various ways. The traditional and widely adopted Rappaport classification uses histologic pattern, cell type, and degree of differentiation to categorize tumors. In children, the categories seen with the most frequency are B-cell phenotype (Burkitt's lymphoma, Burkitt's-like lymphoma, large B-cell lymphoma), pre-T-cell origin (lymphoblastic lymphoma), and T-cell origin (anaplastic large-cell lymphomas and peripheral T-cell lymphomas). The diffuse histologic pattern is almost universal within these categories.[17]

The development of immunologic markers has added refinement to categorization and contributed to the identification of molecular mechanisms in pathogenesis. Best studied are the small, noncleaved-cell lymphomas, particularly Burkitt's lymphoma (Fig. 200-2). In Burkitt's lymphoma, EBV, a B-cell mitogen, probably fosters the establishment of a premalignant state by expanding the pool of lymphocytes in which chromosomal transformations can occur. Classic to Burkitt's lymphoma is the translocation of the *myc* gene from chromosome 8 to a position juxtaposed to an immunoglobulin receptor subunit gene on chromosomes 14 (80%), and less commonly to chromosomes 2 or 22 [t(8;14), t(8;2), t(8;22), respectively].[21,22] Unregulated expression of the *myc* gene disrupts regulation of the expression of target genes that are required for the normal progression of the cell cycle.[23-25]

Approximately 80% of large-cell lymphomas have a t(2;5) chromosomal rearrangement.[26] The precursor RNA can be detected by a RT-PCR assay, which has become an important diagnostic tool.[27] Although the impact of molecular biology has yet to revolutionize clinical practice, it will inevitably refine our diagnostic capabilities and permit the development of target tumor–specific therapy.

Hodgkin's Lymphoma

In 1832, Thomas Hodgkin described the disease that now bears his name. Although characterized by the presence of mononuclear cells (Hodgkin's cells) and binucleated or multinucleated tumor cells (Reed-

Table 200-4

Staging Systems for Non-Hodgkin's Lymphoma

	Staging System	
Stage	**Ann Arbor**	**St. Jude Children's Research Hospital**
I	Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (IE)	Single tumor (extranodal) or single anatomic area (nodal) excluding the mediastinum or abdomen
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of extralymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm (IIE)	Single extranodal site with regional lymph node involvement; two or more nodal areas on the same side of the diaphragm; two single extranodal tumors ± regional node disease on the same side of the diaphragm; primary gastrointestinal tract tumor, usually in the ileocecal area ± involvement of associated mesenteric nodes
III	Involvement of lymph node regions on both sides of the diaphragm (III) ± extranodal involvement (IIIE) ± splenic involvement (IIIS), or both (IIISE)	Two single extranodal tumors ± regional node disease on opposite sides of the diaphragm; two or more nodal areas on opposite sides of the diaphragm; all extensive primary intra-abdominal disease; unresectable; all primary intrathoracic tumors (mediastinal, pleural, thymic); all primary paraspinal or epidural tumors regardless of other sites
IV	Diffuse involvement of one or more extralymphatic organs; organs or tissues ± associated lymph node enlargement	Any of the above + initial CNS or bone marrow involvement (<25%)

CNS, central nervous system.

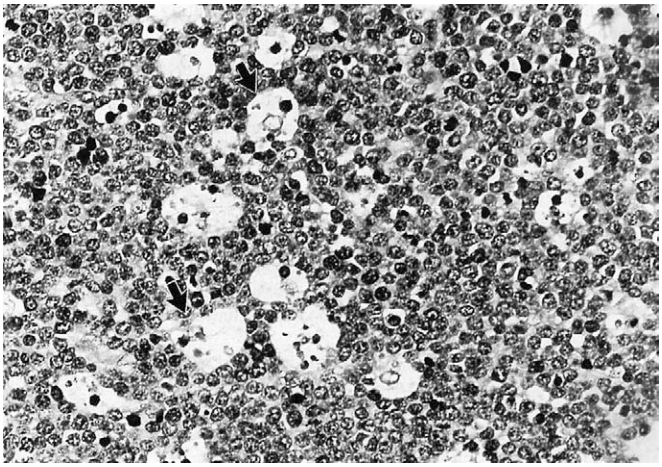

Figure 200-2. Non-Hodgkin's lymphoma categorized as malignant lymphoma with diffuse, small, noncleaved cells (Burkitt's lymphoma EBL7). Small non-cleaved lymphocytes diffusely replace this lymph node. The size is monotonous, differentiating it from non—Burkitt's lymphoma BL, which exhibits more variation in nuclei size and shape. Histiocytes *(arrows)* with their abundant pale cytoplasm and engulfed cellular material are scattered among the malignant lymphocytes, giving a "starry-sky" appearance. (Original magnification, 400×.)

Sternberg cells) in a background of variable and often abundant reactive cells, a single unifying principle of the biologic nature of Hodgkin's lymphoma and of the origin of the Reed-Sternberg cell has remained elusive.[28] Current data suggest that Hodgkin's lymphoma represents a group of diseases with an uncertain relationship to each other.[29] Age at diagnosis follows a bimodal distribution, with the first peak occurring between 15 and 40 years of age and the second peak occurring after age 50. Approximately 4% of cases occur in children younger than 10 years of age, and 11% are found in children between 10 and 16 years of age.[30]

Presentation and Evaluation

In more than 90% of childhood and adult cases, Hodgkin's lymphoma arises in the lymph nodes, typically causing an asymmetrical adenopathy that is firm, rubbery, and nontender. Particularly common is the combination of mediastinal and right supraclavicular nodal disease. The spleen is the most common extranodal site of involvement. Constitutional symptoms (B symptoms) may be present and include fever of 38° C or higher, drenching night sweats, or unexplained loss of 10% or more of body weight. Diagnosis is made by lymph node biopsy, and the disease is then staged using the classification developed in 1971 by the Ann Arbor workshop[31] and modified 18 years later to incorporate newer procedures such as CT (see Table 200-4, Ann Arbor staging system).[32] Substage classifications include A for asymptomatic disease, B for B symptoms (as described earlier in the chapter), and E for extension to an adjacent extranodal site. The staging system is based on the premise that Hodgkin's lymphoma spreads through the lymphatics to contiguous nodal groups and through the circulation to extranodal sites, although these modes of spreading have not been clearly established and multifocal involvement may represent multicentric disease.[29]

Clinical staging procedures include history, physical examination with measurement of lymph nodes, chest radiograph, CT scan of neck and chest, CT or MRI of abdomen, and laboratory tests (complete blood count with differential, erythrocyte sedimentation rate determination, renal and hepatic function tests, alkaline phosphatase assay). CT has limited sensitivity for detection of abdominal adenopathy in children because of their lack of retroperitoneal fat.[33] Therefore, abdominal MRI may be a better study for determining extent of abdominal and pelvic disease. Pathologic staging includes excisional lymph node biopsy. Bone marrow aspiration and biopsy is reserved for patients with stage III or IV disease or B symptoms. Routine use of surgical staging with splenectomy and lymph node sampling is no longer in use because of improved imaging techniques, routine use of systemic therapy, and the knowledge that splenectomy is associated with increased infectious and neoplastic complications. Stage at presentation is similar among children and adults, with approximately 60% of patients presenting with stage I or II disease and 40% of those presenting with stage II or IV disease, regardless of age.[30] In children younger than 10 years of age, however, stage I disease is more common (18%) and stage IV disease is less common (3%) than in adolescents

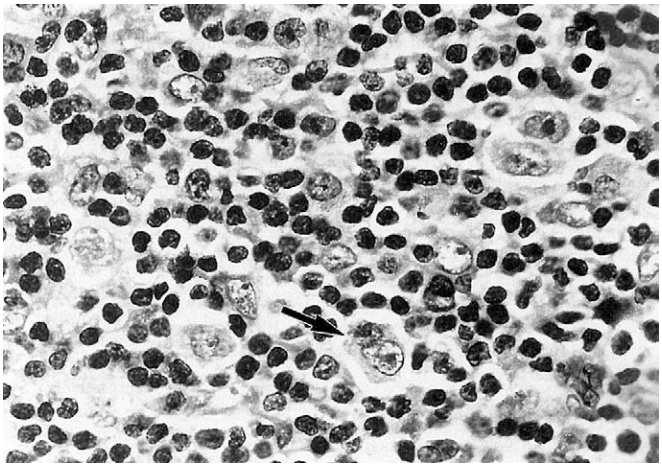

Figure 200-3. Hodgkin's lymphoma of the nodular sclerosing subtype. A mixed population of lymphocytes, histiocytes, and plasma cells along with binucleated Reed-Sternberg cells *(arrow)* are present. (Original magnification, 480×.)

(8% and 15%, respectively) and adults (11% and 11%, respectively). Systemic B symptoms also are less likely in younger patients (19%) than in adolescents (30%) and adults (32%).

Management

Management of Hodgkin's lymphoma varies according to stage. In most centers, radiation therapy is recommended for stage IA and stage IIA disease. Because of the high relapse rate among children with stage IIA disease of the mediastinum, chemotherapy also may be given.[34] For more advanced disease, chemotherapy either alone or as part of a combined regimen including radiotherapy is used.[35]

Long-term results for pediatric patients with early-stage Hodgkin's lymphoma suggest a prognosis similar to that in adults, with cure rates of approximately 90%.[36] With use of combined-modality therapy for stage IV disease, overall survival rates are slightly lower (approximately 80%).[35] When patients who have received only chemotherapy demonstrate relapse at nodal sites, salvage radiotherapy should be considered.[37]

Histopathology and Molecular Biology

The major histologic types of Hodgkin's lymphoma recognized by the Lukes, Butler, and Rye classifications include lymphocytic predominance, mixed cellularity, nodular sclerosis, and lymphocytic depletion (Fig. 200-3).[29] Further subclassification probably is unncessary, because current management protocols have eliminated differences in survival rates between the most common types (mixed cellularity and nodular sclerosis).

Micromanipulation of histologic sections to isolate and analyze individual Hodgkin's and Reed-Sternberg cells has verified an origin from B-lineage cells at various stages of development.[38] Ig heavy chain rearrangements have also been detected by PCR amplification in approximately 25% of cases.[39] These studies suggest that Hodgkin's lymphoma represents a clonal lymphocyte population and that different chromosomal rearrangements may be associated with different subclasses of disease.

Post-Transplantation Lymphoproliferative Disorder

As solid organ transplantation success rates have improved, diseases related to chronic immunosuppression have increased in prevalence. Post-transplantation lymphoproliferative disorder (PTLD) is the term for all abnormal proliferations of lymphoid tissue in the transplant recipient, ranging from lymphoid hyperplasia to malignant non-Hodgkin's lymphoma. Risk factors for the development of PTLD are the degree of immunosuppression, use of potent immunosuppressive agents such as tacrolimus, EBV seronegative status at time of transplantation, young age, donor-recipient mismatch, severe graft-versus-host disease (GVHD), T-cell depletion of donor marrow, use of anti–T-cell monoclonal antibodies, and high-dose antithymocyte globulin for GVHD prophylaxis. The rate of PTLD ranges from 8% to 28%,[40] depending on the immunosuppressive agents used. The rate of PTLD is higher in liver, heart, and heart-lung transplant recipients. The rate of PTLD is lower for renal transplant recipients, probably because of the higher level of immunosuppression needed in the former group.[41] Most PTLDs are of B-cell origin, but early PTLD can manifest as plasmacytic hyperplasia or as a polymorphic lymphoid process.[42] When PTLD affects the tonsils and adenoids, it often is of the plasmacytic hyperplasia type. When PTLD is seen in the lymph nodes, it is often a polymorphic lymphoid lesion. Treatment of PTLD includes decreasing the immunosuppression, to which most patients respond. When a transplant recipient presents with enlargement of the tonsils and adenoids, removal of the affected tissue (i.e., by tonsillectomy and adenoidectomy) is indicated to evaluate the tissue for PTLD. Removal of the affected tissue often is curative. Other therapies for PTLD include intravenous immunoglobulin, interferon alfa, antiviral therapy (with acyclovir or ganciclovir), and immunotherapy with donor T-lymphocyte infusion.

A correlation between EBV infection and PTLD is well documented.[43] In immunosuppressed patients, the T-lymphocyte response to the EBV infection is suppressed and the B-cell proliferation turned on by the virus infecting the B-lymphocytes is allowed to proceed unchecked. Thus, EBV seronegativity at the time of transplantation is a risk factor for the development of PTLD, because active EBV infection after transplantation can initiate this polyclonal response from the B lymphocytes infected with the Epstein-Barr virus.

Sarcomas

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood, representing 13% of all pediatric malignancies. Rhabdomyosarcoma is the third most common neoplasm in childhood after neuroblastoma and Wilms' tumor. The annual incidence of this tumor in children younger than 20 years of age is 4.3 cases per 1 million children, affecting approximately 350 children in the United States each year.[44] Approximately 35% of these children present with disease in the head and neck. Sites of involvement include the orbit, nose and paranasal sinuses, oropharynx, soft tissues, nasopharynx, and external ear or mastoid. Because of the high possibility of contiguous spread to the CNS, the paranasal sinuses, infratemporal fossa, middle ear, and nasopharynx are classified as parameningeal sites.

In the 1960s, fewer than one third of children with rhabdomyosarcoma survived, but cure rates now approximate 70%, largely reflecting advances made by the Intergroup Rhabdomyosarcoma Study Committee (IRSC).[45,46] Before the formation of the IRSC in 1972, the relatively small numbers of patients, short follow-up times, and the confounding effects of varied treatments limited univariate and multivariate analyses, especially for small subgroups of patients. However, when three pediatric centers agreed to pool patients and investigate resources, it became possible to identify prognostic variables of crucial importance for stratifying patients in clinical trials. Valid comparisons of alternative therapies were developed, and therapies were tailored according to the risk of relapse. The data obtained through the collaborative, multimodality therapeutic protocols developed and studied by the IRSC have allowed a steady improvement in the curability of rhabdomyosarcoma, especially the locally extensive tumors.

Presentation and Evaluation

A majority of affected children are younger than 6 years of age when the diagnosis of rhabdomyosarcoma is made.[47] The spectrum of presenting signs and symptoms varies greatly depending on the site of the primary tumor, the age of the child, and the presence or absence of metastatic disease. Presentation in the head and neck most frequently is heralded by a local swelling. Fewer than one half of these children have pain. Nasal discharge or obstruction, signs of cranial nerve

involvement, otorrhea, hearing loss, fetor, and proptosis are even less frequent.[48]

The orbit is involved in nearly one third of rhabdomyosarcomas of the head and neck,[48] with the typical presentation being that of a rapidly developing, unexplained proptosis. In decreasing order of frequency, rhabdomyosarcoma also affects the oral cavity and pharynx (29%), the face and neck region (24%), and the ears and sinuses (9%). Nasopharyngeal and paranasal sinus involvement can cause nasal obstruction or epistaxis, and otitis media, facial nerve palsy, or tumor filling the ear canal is often the presenting symptom of temporal bone disease.[49]

The diagnostic workup of children with suspected rhabdomyosarcoma must address two complementary issues: the nature and extent of the primary disease and the presence or absence of locoregional or metastatic disease. To assess the former, CT and MRI are essential. To assess the latter, common sites for metastases must be evaluated, including the lungs, bone, and bone marrow. A minimal test battery consists of complete blood count, serum electrolyte panel, liver and renal function tests, baseline coagulation studies, CT scan of the chest, a ^{99m}Tc-diphosphonate bone scan, and bilateral aspiration and biopsy of iliac bone marrow.

Surgery is a necessary part of the diagnostic and staging evaluation and is an essential component in the Intergroup Rhabdomyosarcoma Study Clinical Grouping Classification (IRSCGC) (Table 200-5). Although this staging system is widely used, it was revised in 1991 and the primary tumor, regional lymph nodes, and distant metastasis (TNM) classification is now used for Intergroup Rhabdomyosarcoma Study (IRS) patients in IRS groups IV and beyond. For instance, patients in IRSCGC group III represent a heterogeneous collection of patients who have resectable and unresectable tumors, depending on the experience of the institution. As surgery techniques have advanced, especially in the skull base, and reconstructive techniques such as microvascular reconstruction are more widely available, complete extirpation often is feasible for rhabdomyosarcoma in the head and neck.[48] In some centers, however, surgery may be limited to partial removal or excisional biopsy to establish the diagnosis. Additional important variables that were not considered in the IRSCGC were the degree of local extension and the status of the primary echelon nodes. To address these shortcomings, the IRSC now uses the TNM classification, similar to that used to characterize disease extent in adults with solid tumors (Table 200-6).

Table 200-5

Intergroup Rhabdomyosarcoma Study Clinical Grouping Classification*

Group	Definition
I	Localized disease, completely resected
II	Compromised or regional resections with microscopic residual disease
III	Incomplete resection or biopsy with gross residual disease
IV	Distant metastatic disease present at onset

*Used in Intergroup Rhabdomyosarcoma Studies I through III.

Management

Multimodal, multiagent therapy is the mainstay of management of rhabdomyosarcoma, along with surgical removal or biopsy and radiotherapy for local control. Several different chemotherapeutic agents are used, with appropriate selections based on the initial extent of disease and its site of origin. During the 1980s and 1990s, cisplatin, etoposide, and dacarbazine have been used in combination for rhabdomyosarcoma. Other agents used include ifosfamide and either etoposide or doxorubicin for new and recurrent rhabdomyosarcoma. IRS IV looked at combinations of these drugs; for metastatic rhabdomyosarcoma, it found that the combination of ifosfamide and doxorubicin improved outcome.[50] Some children, such as those with orbital rhabdomyosarcoma, require less intensive, two- or three-drug therapy and do well. By contrast, children with metastatic disease require extremely intensive therapy and still do poorly. Although they respond to initial chemotherapy, 75% relapse within 18 to 24 months.[51] To improve this outcome, efforts are ongoing to develop new active chemotherapeutic agents and to use dose-intensifying regimens with hematopoietic growth factors or autologous hematopoietic progenitor cells.

Radiotherapy is required to eradicate residual tumor cells at the primary site or to treat gross persistent disease. Guidelines for dosage and radiation fields evolved during the IRS I, II, and III. Local control is achieved in 80% to 90% of children using 4000 to 4500 cGy for microscopic residual disease and 4500 to 5000 cGy for tumors larger than 5 cm.[52] Prophylactic irradiation of clinically uninvolved regional nodes is unnecessary. With parameningeal tumors, 4500 to 5500 cGy is required. With overt parenchymal, meningeal, or cerebrospinal fluid involvement, whole-brain irradiation and intrathecal chemotherapy are indicated.[53,52] Hyperfractionation was evaluated in IRS IV as an approach to maintain local control rates and to reduce late side effects. Hyperfractionation did not result in significant improvement in local disease control over conventional radiation therapy.[54] Radiation therapy guidelines in IRS V have been simplified, with the basic emphasis placed on reducing the dose of radiation for most patients. This is being

Table 200-6

TNM Pretreatment Staging Classification for IRS Study IV

Stage	Sites	T*	Size	Nodes†	Metastases‡
1	Orbit, head and neck (excluding parameningeal), genitourinary (excluding bladder/prostate)	T1 or T2	A or B	N0, N1, or Nx	M0
2	Bladder/prostate, extremity, cranial parameningeal sites, other (includes trunk, retroperitoneum)	T1 or T2	A	N0 or Nx	M0
3	Bladder/prostate, extremity, cranial parameningeal	T1 or T2	B	N0, N1, or Nx	M0
4	All	T1 or T2	A or B	N0 or Nx	M1

*Tumor: T1, confined to anatomic site of origin; T2, extension or infiltration into surrounding tissue (A ≤5 cm in diameter; B >5 cm in diameter).
†Nodes: N0, no distant metastases; Nx, clinical status unknown; N1, clinically involved.
‡Metastases: M0, no distant metastases; M1, distant metastases present.
IRS, Intergroup Rhabdomyosarcoma Study; TNM, tumor-node-metastases.

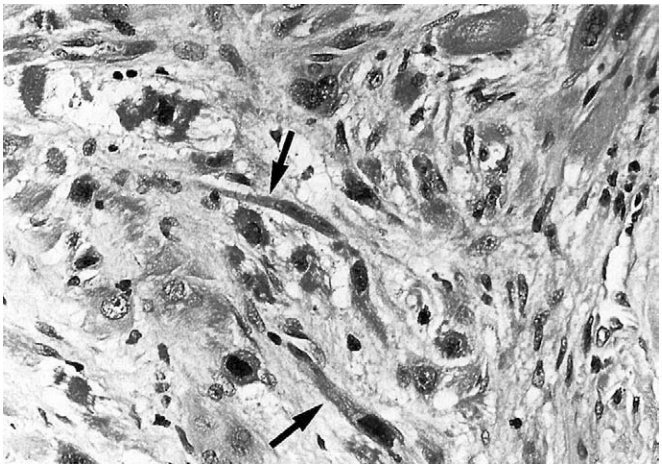

Figure 200-4. Embryonal rhabdomyosarcoma. The cells show a mixture of shapes but a spindled or elongated morphology is evident overall. Strap cells *(arrows)*, which resemble primitive muscle cells and are classically described in rhabdomyosarcomas, are easily seen in this example but may be difficult to identify in some cases. Immunohistochemical staining for muscle-specific markers can be useful in these instances. (Original magnification, 350×.)

accomplished in conjunction with delayed surgical resection of alveolar type tumors or initially unresectable tumors in anatomically unfavorable sites. With the refinement of aggressive craniofacial and intracranial surgical techniques that minimize postoperative morbidity, surgery is playing a more important role in selected patients with head and neck rhabdomyosarcoma. Specifically, if the tumor can be completely resected, the patient can avoid radiotherapy and its long-term complications, with no compromise in survival. Patients who are able to have complete removal of their tumors fare much better than those in whom gross residual tumor is left behind. Complete resection of skull base–parameningeal rhabdomyosarcoma is now more often a reality with advances of skull base surgery techniques and use of free-tissue transfer techniques for reconstruction.[55] In addition, salvage surgery after cytoreductive combination chemotherapy and radiotherapy can be offered to convert a partial response (PR) or stable disease (SD) to a complete response (CR).[56] For most children in group III, intensification of therapy using a risk-based study design has significantly improved management outcome. The largest gains have been realized in children with gross residual tumor after biopsy. In selected patient subsets, it also has been possible to decrease therapy.[57]

Histopathology and Molecular Biology

The histologic classification of rhabdomyosarcoma is based on the resemblance of these tumors to normal fetal skeletal muscle before innervation. The first formal classification was proposed by Horn and Enterline[58] in 1958 and subsequently was adopted by the IRSC and the World Health Organization. Subtypes include embryonal, botryoid (a subtype of embryonal), alveolar, and pleomorphic. Embryonal rhabdomyosarcoma of the botryoid subtype is the most common variant, accounting for 60% of tumors. It is characterized by variable amounts of spindle and primitive cells that are either tightly packed or loosely dispersed in a myxoid background. Rhabdomyoblasts are present in a variety of shapes, leading to unusual designations like tadpole, racquet, or strap cells (Fig. 200-4). The botryoid subtype accounts for 5% of cases and tends to arise in the mucosa-lined organs of the nasopharynx, external auditory canal, and genitourinary tracts. It is characterized grossly by the presence of polypoid masses and microscopically by the presence of subepithelial aggregates of tumor cells known as the cambium layer. Metastases are rare and the prognosis is excellent. Alveolar rhabdomyosarcomas are diagnosed in 20% of affected children and are characterized by the presence of fibrovascular septa that form alveolus-like spaces that contain freely floating monomorphous round malignant cells with abundant eosinophilic cytoplasm. Pleomorphic rhabdomyosarcomas show features of both embryonal and alveolar subtypes but are uncommon in children.[46] Cytogenetic studies of alveolar rhabdomyosarcoma have identified frequent chromosomal rearrangements and amplification. The most commonly recognized translocation events, t(2;13) and t(1;13), are found in 64% and 18% of cases, respectively.[59] The result is fusion of the *PAX3* gene on chromosome 2 or the *PAX7* gene on chromosome 1 with the *FKHR* gene on chromosome 13. In the case of *PAX3*, the new chimeric transcription factor excessively activates transcription from binding targets of wild-type *PAX3*. Molecular assays for *PAX3-PAX7* fusion genes have identified additional cases that do not have cytogenetically detectable rearrangements. On the basis of these more sensitive studies, the overall frequency of *PAX3-PAX7-FKHR* chimera appears to be higher than 90%.[8] Also, the presence of the *PAX3-FKHR* and *PAX7-FKHR* gene fusions correlate with poor clinical outcome. The prevalence and presumed importance of these fusion genes in tumorigenesis suggest that drugs designed to block their intracellular activity may be effective chemotherapeutic agents.

Nonrhabdomyosarcoma Soft Tissue Sarcomas

NRSTSs of childhood have a combined annual incidence of approximately 2 to 3 cases per 1 million and comprise a large number of uncommon tumors, including fibrosarcoma, dermatofibrosarcoma protuberans (DFSP), epithelioid sarcoma, synovial sarcoma, malignant fibrous histiocytoma, hemangiopericytoma, chondrosarcoma, osteosarcoma, leiomyosarcoma, liposarcoma, and soft tissue clear cell sarcoma.[47] Although rhabdomyosarcoma accounts for 60% of soft tissue sarcomas in children younger than 5 years of age, NRSTSs account for approximately 75% of all soft tissue sarcomas in teenaged patients (15 to 19 years of age).[44] The diagnostic evaluation for a child with a suspected NRSTS is identical to that for a child with rhabdomyosarcoma because tumor distinction is impossible on clinical grounds alone. This limitation makes it imperative to obtain enough tissue to establish a diagnosis without compromising the possibility of future surgical extirpation.

The rarity of these tumors has made the IRSCGC the most commonly used staging system (see Table 200-6), although the TNM system for soft tissue sarcomas in adults also has been applied by modifying the histologic grading classification.[60,61] The pathologic evaluation of these tumors typically takes into consideration factors such as necrosis, mitotic activity, cellularity, matrix formation, and pleomorphism. Because specific chromosome translocations define many of the soft tissue sarcomas, measures of ploidy and the demonstration of certain molecular genetic abnormalities will undoubtedly prove valuable in guiding prognostically based management protocols in the future.

Currently, the most important factors determining the likelihood of cure are histologic grade and tumor resectability.[62] The latter is particularly important for high-grade malignancies. Unfortunately, tumor size and invasiveness preclude complete resection in 30% to 50% of cases, and long-term locoregional control with adjuvant chemoradiotherapy usually is unsuccessful in the presence of either gross residual or metastatic disease (1 of 26 survivors with gross residual or metastatic disease versus 29 of 36 survivors with completely resected tumors or microscopic residual disease). Although the roles of radiotherapy and chemotherapy have not yet been standardized, data from the NCI Pediatric Branch indicate that a substantial number of children may benefit from appropriate intense multimodality therapy. Management of these children should be based on selected clinical protocols designed to assess responsiveness and long-term outcome.

Fibrosarcoma

Fibrosarcoma is a rare malignancy of the head and neck, with only 7 of 53 cases (13%) reported by the Armed Forces Institute of Pathology and 22 of 110 cases (20%) reported by Soule and Pritchard.[63] Neck disease occurs most commonly, followed in descending order of frequency by involvement of the oral cavity, scalp, auriculoparotid region, and face.[64] Hematogenous and lymphatic spread are extremely rare.[65]

Children of all ages are affected and typically present with an asymptomatic, slowly enlarging mass.[66] In infants, a unique form of

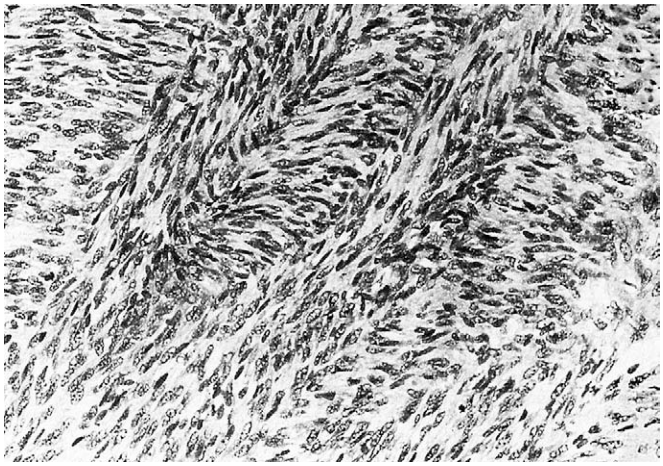

Figure 200-5. Fibrosarcoma. Discrete fascicles of spindle cells form intersecting patterns, sometimes producing a herringbone effect. (Original magnification, 200×.)

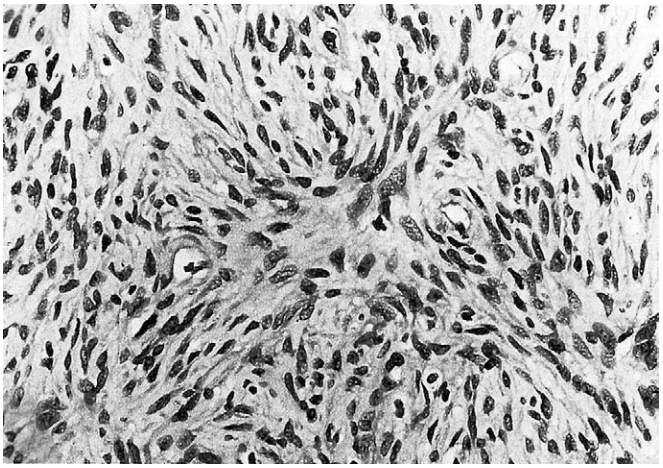

Figure 200-6. Dermatofibrosarcoma protuberans. This intermediate-grade malignancy is in the group of fibrohistiocytic tumors. Many of the tumors in this group have plump spindle cells arranged in patterns frequently described as cartwheel, whorling, or storiform (from the Latin *storea*—a rush mat) because of its woven appearance. (Original magnification, 275×.)

congenital fibrosarcoma occurs that is considered a histologically low-grade fibrosarcoma.[67] Although these tumors can be large, the long-term outlook is quite good, perhaps reflecting an enhanced sensitivity to chemotherapeutic agents. Some unresectable congenital fibrosarcomas respond to preoperative chemotherapy, permitting a later, less mutilating surgical procedure with clear margins.[68,69] By contrast, fibrosarcoma is more aggressive in older children, survival rate is lower, and the impact of multimodal therapy is not obvious. Management requires wide local excision to optimize the chances of survival. The absence of a true capsule makes intraoperative assessment of the degree of tumor spread difficult.

The excised mass typically is gray-tan with hemorrhagic and necrotic areas.[70] Composed mostly of spindle-shaped fibroblasts or myofibroblasts with scanty cytoplasm, histologic grading is possible and is based on degree of cellularity, cellular maturity, and amount of collagen production (Fig. 200-5). Cytogenetic studies have shown an association with trisomies of chromosomes 8, 11, 17, and 20.[71,72] Karyotyping studies show a recurring t(12;15) translocation.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans is a nodular cutaneous tumor with a high propensity for local recurrence after simple excision. It usually appears as a firm, solitary, flesh-colored nodule, although multiple masses or an area of induration can occur. The trunk is the favored site of involvement, followed by the extremities and the head and neck, especially the scalp and supraclavicular fossa.[73]

Approximately 12% of affected persons are older children,[73] but dermatofibrosarcoma protuberans has been diagnosed in patients younger than 10 years of age. Time to diagnosis may exceed 2 years, with size at diagnosis up to 2 cm. Management requires wide excision for a successful long-term outcome, reflecting the "pseudocapsule" and finger-like extensions of this tumor. With surgical margins less than 2 cm, recurrence rates approximate 40%; with margins wider than 2 cm, recurrence rates drop to 25%; and with margins wider than 3 cm, few recurrences are reported.[74,75] However, given the regional anatomy of the head and neck, achieving a 2.5- to 3-cm margin can be difficult. Even with Mohs' technique, extensive surgery may be required.[76] Although local recurrence rates of 50% to 70% are reported, with repeated procedures, 90% of affected patients can be rendered free of disease.[77] Consensus is lacking regarding the cell of origin of dermatofibrosarcoma protuberans. The primary mass usually is grossly encapsulated and well circumscribed, although it can send multiple pseudopod-like projections laterally and deeply (3 cm or more).[78] These extensions are easily missed on histologic sectioning. Histologic examination shows elongated cells with a storiform organization (Fig. 200-6).

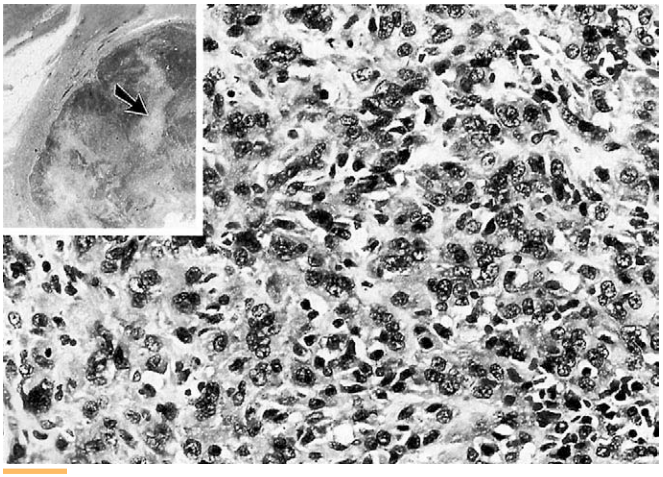

Figure 200-7. Epithelioid sarcoma. This unusual tumor is composed of epithelial-like cells that have polygonal-shaped cytoplasm. The lower-power view *(inset)* reveals a distinct nodular appearance. Necrosis *(arrow)* in the center of the nodules is characteristic. (Original magnification, 400×; low-power inset: original magnification, 5×.)

Epithelioid Sarcoma

Epithelioid sarcoma can easily be confused with a variety of benign and malignant conditions such as necrobiotic granuloma, rhabdoid tumor, rhabdomyosarcoma, and Ki-1 lymphoma.[79-82] It occurs throughout infancy and early childhood, although most individuals are not diagnosed until the second to fourth decades of life.[83] Approximately 10% of cases involve the head and neck, produce nontender, nonulcerated swelling, and follow a protracted course of repeated local recurrences with eventual distant metastases. More aggressive tumors that metastasize early are uncommon. Once the diagnosis has been made, complete surgical resection should always be attempted because the role and efficacy of chemotherapy and radiotherapy have not been clearly established.

The characteristic histologic pattern is one of nodules separated by fibrous septa (Fig. 200-7). The cells inside the nodules are polygonal, are variable in size, and may cluster, suggesting squamous differentiation. Areas of necrosis and an inflammatory infiltrate are common. The molecular biology of epithelioid sarcoma has shown multiple structural changes, most frequently the deletion of 1p21-22.[83]

Neuroectodermal Tumors

Neuroblastomas

Neuroblastomas are the most common extracerebral solid tumors of infancy and childhood.[84] Their annual incidences in white and nonwhite children under 15 years of age are 10.4 and 8.3 per 1 million, respectively.[85] Arising from primitive neuroectodermal cells of neural crest origin as embryonal tumors of the sympathetic nervous system, neuroblastomas can develop wherever sympathetic nervous tissue is found. Primary tumors occur paravertebrally along the sympathetic chain from the neck to the pelvis and from paraganglia from the adrenal medulla, the organ of Zuckerkändl, or the retroperitoneal, inguinal, paratesticular, testicular, oviductal, or ovarian paraganglia. The most unusual aspect of this tumor is the frequent occurrence of spontaneous regression, typically in infants with a small primary tumor, liver involvement, subcutaneous nodules, and patchy bone marrow infiltration without major replacement of hematopoietic cells.[86]

Presentation and Evaluation

Primarily a tumor of infancy and early childhood, as many as 50% of cases are diagnosed in infants younger than 1 year of age and 80% are detected in children younger than 5 years of age.[87] Presenting signs and symptoms depend on the site of the primary lesion, the presence and site of metastases, and the secretion of hormones and vasoactive substances. The most common site of origin is the adrenal medulla or adjacent retroperitoneum, but 2% to 5% of neuroblastomas develop in the head and neck region.

Primary cervical tumors generally are detected at an earlier age and at a lower stage than tumors detected elsewhere, reflecting the greater facility with which abnormalities in the neck are recognized. Laryngotracheal or pharyngeal compression can lead to airway obstruction, dysphagia, or aspiration. Ipsilateral ptosis occurs if the superior cervical ganglion is involved. Primary neuroblastoma of the orbit may cause proptosis, periorbital ecchymoses (panda eyes), and ocular muscle paresis. However, more subtle findings such as edema of the conjunctivae or eyelids, papilledema, and retinal hemorrhage may be noted. Because the sympathetic nervous system is intimately associated with the development and maintenance of eye color, heterochromia irides is possible.[88] Another finding peculiar to the head and neck is the cardiofacial syndrome, or "asymmetrical crying face." This type of congenital facial weakness becomes most apparent with crying and reflects disease involvement of the motor cortex, the nucleus or peripheral root of cranial nerve VII, or the muscles of facial expression.[89]

Paraspinal neuroblastoma may extend through adjacent intervertebral foramina into the spinal cord (*en sablier* tumors) to produce paraplegia. Although this finding is most commonly associated with mediastinal and retroperitoneal tumors, it can occur with cervical disease.[90,91] Neuroblastoma also is a noteworthy cause of congenital paraparesis; clinical features of neurologic dysfunction in neonates are difficult to recognize, however, and diagnosis may be delayed.

The diagnostic and metastatic evaluation of children with neuroblastoma of the head and neck requires multiple imaging studies, immunocytochemistry studies, routine histologic examination, and cytogenetic analysis. For suspected cervical disease, CT and MRI to evaluate the neck should be complemented by abdominal CT and MRI, chest radiograph, bone scans, and bone marrow aspirates and biopsies to appropriately stage the tumor. The International Neuroblastoma Staging System (INSS) was developed in 1991 to help stage patients uniformly for clinical trials and biologic studies. The staging system is based on clinical experience with neuroblastoma, reflecting the degree of tumor burden, surgical resectability, and the pattern of metastatic spread (Table 200-7).

Several genetic markers have been identified in neuroblastoma tumors correlating with clinical course, but determination of the best predictors awaits further study in large numbers of patients. These markers include tumor cell DNA index, *MYCN* gene copy number, allelic loss of 1p, and unbalanced gain of 17q. *MYCN* amplification occurs in approximately 25% of primary neuroblastomas and amplification is associated with advanced stage and poor prognosis. Tumor markers such as catecholamine metabolites, ferritin, neuron-specific enolase, lactate dehydrogenase, and the disialoganglioside G_{D2} are helpful in diagnosis and disease monitoring but have largely been replaced by genetic markers (e.g., *MYCN* amplification) for risk stratification.[86] The frequency of abnormal elevations depends on disease burden and therefore hampers detection of neuroblastoma at an early stage. Catecholamines and their metabolites (vanillylmandelic acid, homovanillic acid, and dopamine) are elevated in 90% to 95% of children with neuroblastoma and have been very successfully developed by the Japanese for use in urine screening programs despite high false-negative rates.[92] Tests on 115,000 infants suggest that a majority of neuroblastomas can be discovered before the age of 1 year, when prognosis is most favorable.[92]

Table 200-7

International Neuroblastoma Staging System

Stage	Description
1	Localized tumor with complete gross resection, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive)
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor (enlarged contralateral lymph nodes must be negative microscopically)
3	Unresectable unilateral tumor infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, or other organs (except as defined for stage 4S)
4S	Localized primary tumor (as defined for stages 1, 2A, or 2B), with dissemination limited to skin, liver, or bone marrow (limited to infants younger than 1 year of age)

Management

Management of neuroblastoma is determined by the stage of disease and sites of involvement. Patients are stratified into low-, intermediate-, and high-risk groups based on the various prognostic variables available (age at diagnosis, INSS stage, tumor histopathology, DNA content of the tumor, and *MYCN* amplification). Treatment of stage I neuroblastomas consists of surgical removal. Chemotherapy is the main modality of treatment in intermediate- and high-risk patients. Radiation therapy is also used, but by itself is not curative due to the high rate of metastatic disease. In the head and neck, surgical intervention most commonly implies excisional biopsy for stages II, III, and IV. A cervical sympathetic ganglion is usually involved and is resected. Adjacent, enlarged nodes should also be removed, although a formal radical neck dissection is not required.[93] In cases in which complete resection would cause unacceptable morbidity, a second surgical procedure can be planned

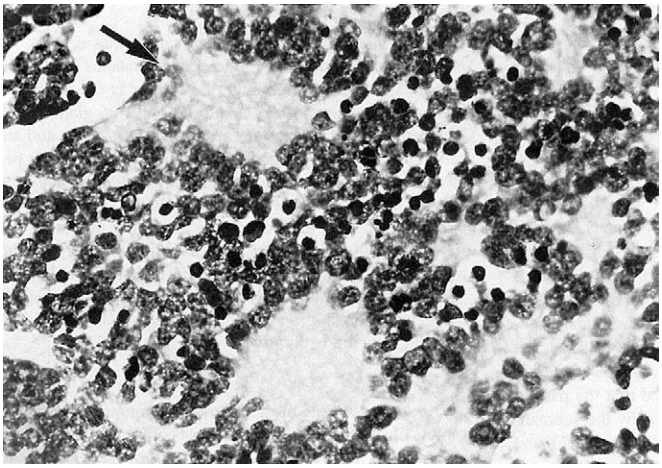

Figure 200-8. Neuroblastoma. Small blue cells characterize this neoplasm. The differential diagnosis of "small blue cell" tumors in children also includes lymphoma and peripheral neuroectodermal tumor/Ewing's sarcoma. Other tumors can also be considered in this group. Neuroblastoma can be differentiated by its relatively uniform cell appearance and neurofibrillary material between the cells. Pseudorosettes (Homer-Wright rosettes) are illustrated *(arrow)* but often are not seen. Immunohistochemical marking and electron microscopy can be useful to demonstrate neural-associated proteins or neural-associated structures (e.g., neurosecretory granules). (Original magnification, 425×.)

12 to 24 weeks after completion of chemotherapy.[94] Unfortunately, despite the large number of chemotherapeutic agents that are active in newly diagnosed patients, long-term remission remains elusive for children older than 1 year of age with INSS stage IV disease (approximately 45% of all children with neuroblastoma).

Histopathology and Molecular Biology

Grossly, neuroblastoma is a discrete solid mass with well-circumscribed contours. Coagulative necrosis may develop in nonviable areas, sometimes with dystrophic calcification. Microscopically, the tumor represents one of the "small blue cell" neoplasms of childhood that is exquisitely susceptible to smear or crush artifact. Iatrogenic damage may obscure cytologic details, making it difficult to make an unequivocal histologic diagnosis.[95] The prototype neuroblastoma is composed of small uniform cells that are 7 to 10 mm in diameter and have dense hyperchromatic nuclei with minimal perinuclear cytoplasm (Fig. 200-8). Immunohistochemistry has revolutionized diagnostic histopathology, and a battery of selected antibodies is used to evaluate specific cellular and subcellular aspects of these neoplasms.

Elucidation of molecular biology also has affected diagnosis and management protocols. Deletions in the short arm of chromosome 1 (1p36) are the most common structural aberration and identify children with a poor prognosis.[84] A less frequent abnormality is amplification of the N-*myc* oncogene.[96,97] This event is associated with advanced stages of disease and rapid tumor progression, perhaps because amplification usually accompanies 1p deletions.

The clinical implication of these studies is that infants with 1p deletions, N-*myc* amplification, and diploidy or tetraploidy are at high risk for recurrence and require aggressive therapy at diagnosis. Management failures appear to be a result of the development of multidrug resistance associated with overexpression of multidrug resistance–associated protein, even when a diverse range of structurally and functionally unrelated chemotherapeutic agents is used.[98]

Based on advances in the molecular biology of neuroblastoma, priorities for future trials will include defining subsets of children who do not require therapy, improving durability of remissions for disseminated disease by exploiting cytokines for dose intensification, defining the place of autologous bone marrow transplantation, exploring means for reversing drug resistance, evaluating tumor-targeted radiotherapy, and identifying new active chemotherapeutic agents.

Ewing's Sarcoma Family of Tumors

Ewing's Sarcoma and Peripheral Primitive Neuroectodermal Tumor

Ewing's sarcoma (ES) and peripheral primitive neuroectodermal tumor (PPNET) are now considered to be in the same spectrum of malignancy—the Ewing's sarcoma family of tumors (ESFTs). Based on molecular genetic and cytogenetic information, both of these tumors are now known to be of neural crest origin. The chromosomal translocation [t(11;22)(q24;q12)] is present in 85% of ESFTs.[99] This reciprocal translocation results in the formation of an *ews*-fli1 fusion gene. ES is a neuroectodermal tumor primarily affecting the long bones and pelvis. Extraosseous ES can occur in soft tissue. A more differentiated form of ES, PPNET (or neuroepithelioma) also can occur in bone or soft tissue. Both ES and PPNET appear similar on histochemical staining and share a unique nonrandom translocation. ESFTs occur primarily in the second decade of life and are seen in whites but rarely in blacks in the United States and in Africa. Although these tumors are primarily found in the extremities, pelvis, chest wall, and spine-paravertebral region, they can manifest in the head and neck as a primary or metastatic tumor. Cure can be expected in up to two thirds of patients with localized disease.

Evaluation of patients with ESFT should include plain films and MRI studies of the primary site, CT scan of the chest, bone scans, bone marrow aspiration and biopsy, complete blood count, baseline blood chemistry studies, and serum lactate dehydrogenase determination. Surgery, radiation therapy, and chemotherapy all are important modalities in treatment. Virtually all patients will have metastases or microscopic metastatic disease at presentation; therefore, chemotherapy is always needed.

Salivary Gland Malignancies

Childhood malignancies of the salivary glands are rare. In a review of 2135 children under 16 years of age who developed salivary gland tumors, only 17 (0.79%) malignancies were recorded (15 [0.7%] mucoepidermoid and 2 [0.09%] acinar cell carcinomas).[100] Most of these malignancies involved the parotid gland. Other authors have confirmed this bias, and from an overview of nine different studies, Rasp and Permanetter[101] concluded that the parotid gland is the favored site (88.5%), followed by the submandibular gland (7.7%), the minor salivary glands (3.3%), and the sublingual gland (0.5%). A unique feature of these tumors is that most appear to be induced by radiation.[102]

Presentation and Evaluation

Children with salivary gland malignancies usually are in their second decade of life at diagnosis. The majority also are survivors of another malignancy, most frequently acute lymphoblastic leukemia diagnosed 10 years earlier for which cranial radiotherapy was required.[103] Chemotherapy, age at the time of therapy, and genetic susceptibility are additional risk factors that may contribute to the development of secondary salivary gland malignancies.[102]

Regardless of location, the most common presentation is as an asymptomatic mass, although facial nerve involvement occasionally accompanies parotid gland disease.[103] The presence of cervical adenopathy does not imply metastatic disease. It more likely reflects common childhood reactive hyperplasia seen as a sequela of repeated upper respiratory infections. Evaluation by CT and MRI is helpful to delineate tumor boundaries and for planning surgical resection.

Management

Salivary gland malignancies in children should be excised. Although the primary principle of surgical excision is accepted, the extent of the procedure and the value of multimodal therapy are not as clearly defined. For parotid gland disease, superficial or total parotidectomy is required, and unless tumor invasion dictates otherwise, the facial nerve should be spared. Complete excision should also be the goal for tumors

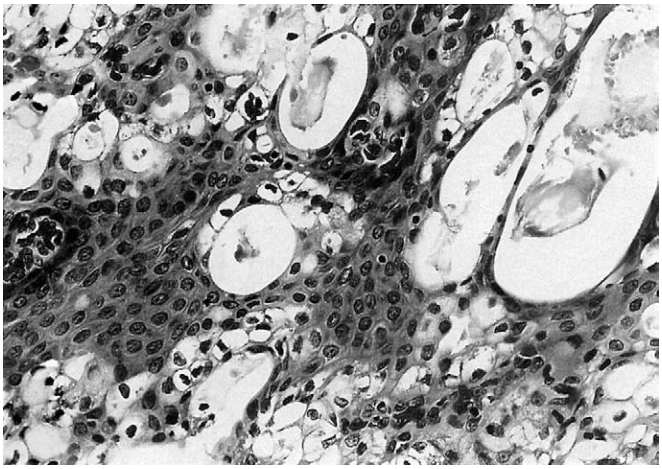

Figure 200-9. Mucoepidermoid carcinoma. Mucus-producing and squamous tumor cells are the prime histologic components of mucoepidermoid carcinomas. Mucous cells containing rounded intracytoplasmic mucous droplets are evident along with pavement-like squamous cells with distinct cellular boundaries. Larger cysts containing mucus also are present. (Original magnification, 320×.)

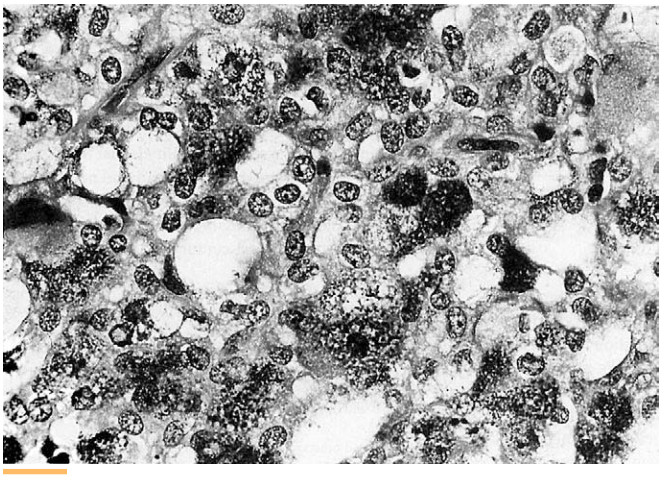

Figure 200-10. Acinic cell carcinoma. Tumor cells appear similar histologically to normal acinar unit cells, but their lack of arrangement of organization into functional units helps in differentiation. These cells have a granular appearance, and some show large basophilic granules. Microcystic changes are seen in this case. (Original magnification, 420×.)

of the submandibular, sublingual, and minor salivary glands. Radiotherapy is reserved for children with high- or intermediate-grade malignancies of the major salivary glands and high-grade malignancies of the minor salivary glands. The value of radiotherapy as adjuvant therapy in intermediate-grade tumors of the soft palate is debatable. Routine use of elective neck dissection for patients with clinically negative necks is not recommended or beneficial for children with malignant salivary gland disease. Chemotherapy with cisplatin-based drugs is reserved for palliation or metastatic disease.

Histopathology and Molecular Biology

Mucoepidermoid and acinic cell carcinomas account for 60% of childhood salivary gland malignancies (45% and 15%, respectively),[104] although the former is the only type that has been diagnosed in the intraoral salivary glands.[105,106] Mucoepidermoid carcinomas are usually low grade and are seldom fatal (Fig. 200-9), whereas acinic cell carcinomas behave like their adult counterparts (Fig. 200-10). Probably the only epithelial salivary gland tumor unique to children is the embryoma, or sialoblastoma.[107] Recognized only in newborns or during the first year of life, this malignancy is morphologically similar to stages in the development of the embryonic anlage of salivary gland tissue. Fewer than one quarter of such tumors show either biologic or histologic signs of malignancy, and complete surgical excision is curative.[107]

Table 200-8

Teratoma Types

Type*	Distribution of Cases (%)	Frquency of Hydramnios (%)	Mortality Rate (%)
I	12.4	56	100
II	45.6	23	43.4
III	17.1	8.1	2.7
IV	14.3		3.2
V	10.6		43.5

*I, moribund neonate or stillborn infant; II, neonate with respiratory distress; III, neonate without respiratory distress; IV, child 1 month to 18 years of age; V, adult.

Teratomas

Teratomas are the most common extragonadal germ cell tumors of childhood. They arise most commonly in a midline or paraxial location from the brain to the sacral area and involve the head and neck in 1 of every 40,000 births.[108] In this region, sites of involvement include the soft tissues of the neck (cervical teratomas), superficial facial structures in and about the temporal fossa and zygomatic area, oral cavity, oronasopharynx, and orbit.[109]

Presentation and Evaluation

More than 75% of cervical teratomas are diagnosed in neonates, two thirds of whom have respiratory distress significant enough to cause stridor.[62] Hydramnios, stillbirth, and premature labor are other frequent accompaniments.[109] This information, in addition to age at diagnosis and respiratory ability, was used by Jordan and Gauderer[110] to define five different disease types (Table 200-8). The high mortality rate in the adult group (type V) reflects the correspondingly high rate of malignant transformation. By contrast, death in neonates usually results from respiratory obstruction as a result of lesion bulk and location. Malignant degeneration is much less common, although it does occur.

Rothschild and associates[111] described seven neonates with teratomas that metastasized to the cervical nodes, lungs, and liver. The metastatic deposits were composed of either mature glial tissue or a mixture of mature and immature elements. Differentiation suggests that the presence of metastases does not necessarily portend a bleak prognosis.[112] This impression was supported by the findings of Rothschild's group,[111]: Death was secondary to metastatic disease in only one patient with metastases. Benign teratomas arising in the paranasal sinuses are extremely rare, and all of the malignant lesions of the sinonasal tract have occurred in adults.[109]

Management

The recommended treatment for head and neck teratomas is surgical excision. When a neonate is experiencing respiratory difficulty, the first priority should be stabilization of the airway. In utero diagnosis of a large cervicofacial teratoma will allow time for perinatal planning of the ex utero intrapartum treatment (EXIT procedure), to secure the infant's airway before the maternal-fetal circulation is divided.[113]

Histopathology and Molecular Biology

Teratomas in neonates and infants contain tridermic tissue elements: ectoderm, endoderm, and mesoderm. Although the preponderant tissue is most often neuroepithelium, other tissues that can be involved include fetal cartilage, myogenic tissue, and epithelium (squamous, ciliated, columnar, enteric, and endocrine). In type II and type III teratomas, malignancy is not equated with the degree of immaturity of the tissue elements and instead reflects immaturity of the host (Fig. 200-11).[109]

Thyroglossal Duct Carcinomas

Thyroglossal duct carcinoma may arise in a thyroglossal duct cyst, although this is a rare occurrence. It may be an incidental finding on removal of the benign-appearing cyst or may manifest as a midline enlarging mass with features suggestive of malignancy, especially if the cyst has a largely solid character. Treatment consists of complete removal along with the midline portion of the hyoid bone, as is done in the Sistrunk procedure. Close follow-up is necessary along with thyroid suppression.[114] Prophylactic total thyroidectomy is necessary if metastasis to the thyroid gland is detected. Incidence of papillary carcinoma in the remaining thyroid gland is 25%. Therefore, some workers recommend prophylactic total thyroid gland removal.[115]

Figure 200-11. Teratoma. Multiple cell types in a haphazard arrangement are evident in this low-power view showing squamous cells *(open arrow)*, mucus-containing goblet cells *(curved arrow)* lining a cyst, and smooth muscle cells *(solid straight arrow)*. (Original magnification, 50×.)

Histiocytoses

The histiocytoses are a family of disorders of histiocytes that can range in clinical importance from focal and easily controlled to fatal. The histiocytoses are diseases of histiocytes. Accordingly, infiltration or accumulation of cells of the monocyte-macrophage series is seen in the involved tissues. A majority of the histiocytoses are not malignant but proliferative lesions, possibly disorders of immunoregulation. It is thought that perhaps the initiating event for the histiocytoses is immunologic stimulation of a Langerhans cell, an antigen-presenting cell, which then continues proliferating in an uncontrolled manner. The International Histiocyte Society has proposed the classification system shown in Table 200-9.[116] Class I histiocytosis, formerly known as histiocytosis X, is now known as *Langerhans cell histiocytosis*, which includes the diseases formerly classified under the histiocytosis X label: eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease.

Pathology

Grossly, the lesions of Langerhans cell histiocytosis are granulomatous. By light microscopy, Langerhans cells are seen. By electron microscopy, Birbeck granules are seen. The lesions may be purely histiocytic or may be a mixture of histiocytes and eosinophils.

Clinical Presentation and Evaluation

The clinical presentation varies from an asymptomatic lytic bone lesion, found incidentally on radiographs, to generalized manifestations such as diabetes insipidus, fever, or weight loss. The first step in the evaluation and management of a patient with such a lesion must include a biopsy of the involved tissue. Care must be taken with the biopsy, because Langerhans cells with Birbeck granules can be found in normal skin. Pathologically, the diagnosis can be confirmed by Birbeck granules on electron microscopy, or by CD1a-positive staining in lesional cells. S100 immunostaining also is present in Langerhans cell histiocytosis cells and not on normal histiocytes. Once the lesion is identified

Table 200-9

Classification of Childhood Histiocytoses

Class I	Class II	Class III
Dieases included: Langerhans cell histiocytosis	IAHS; FEL; grouped together as the hemophagocytic lymphohistiocytoses (HLH)	Malignant histiocytosis; acute monocytic leukemia; true histiocytic lymphoma
Cellular characteristics of the lesions: Langerhans cells with cleaved nuclei and Birbeck granules seen on electron microscopy; cell surface antigens include S100 and CD1a; cells mixed with varying proportions of eosinophils; multinucleated giant cells sometimes seen	Morphologically normal, reactive macrophages with prominent erythrophagocytosis; process involves entire reticuloendothelial system	Neoplastic cellular proliferation of cells exhibiting characteristics of macrophages or dendritic cells or their precursors; localized or systemic
Proposed pathophysiologic mechanisms of the histiocytoses: Immunologic stimulation of a normal antigen-presenting cell—the Langerhans cell—in an uncontrolled manner	Histiocytic reaction secondary to an unknown antigenic stimulation (FEL) or to an infectious agent (IAHS), with erythrophagocytosis possibly reflecting foreign antigens adsorbed on erythrocytes or activation of macrophages by excess lymphokine production because of abnormal immunoregulation	Neoplasm; clonal autonomous uncontrolled proliferative process

FEL, familial erythrophagocytic lymphohistiocytosis; IAHS, infection-associated hemophagocytic syndrome.

as being in the histiocytosis family, the workup should include a complete blood count, skeletal survey, a CT scan of the head, liver function tests, coagulation studies, and determination of urine osmolality after water deprivation. Monostotic bone disease (formerly known as eosinophilic granuloma) clearly carries a better prognosis than polyostotic bone disease (formerly known as Hand-Schüller-Christian disease). The fulminant presentation, formerly known as Letterer-Siwe disease, is most commonly seen in infants younger than 2 years of age.

Treatment

Class I histiocytoses can be treated with curettage, excision, intralesional steroids, systemic steroids, or low-dose radiotherapy. Curiously, single monostotic lesions often regress spontaneously after biopsy, curettage, or steroid injection. If a single lesion is not resolving and is threatening a vital structure, low-dose radiotherapy, in the range of 500 to 800 cGy, can be curative,. The role of chemotherapy is reserved for multisystem involvement and widespread disease. The agents used are vinblastine and etoposide, with or without steroids. In general, the poor-prognosis groups are those comprising children younger than 2 years of age and children with organ dysfunction (liver, bone marrow, lungs). Unfortunately, little gain has been obtained in the treatment of the 15% of cases of Langerhans cell histiocytosis that are resistant to treatment or progress in a fulminant fashion. In an effort to optimize therapy for disseminated Langerhans cell histiocytosis, the Histiocyte Society opened a prospective, randomized treatment study in 1991, LCH-1. LCH-1 showed that vinblastine and etoposide are equivalent drugs in terms of response, toxicity, survival probability, probability of disease reactivation, and sequelae.[117] LCH-1 also identified lack of rapid response to treatment (less than 6 weeks) as another poor prognostic indicator. Other experimental treatment approaches include bone marrow transplantation, and 2-chlorodeoxyadenosine (an antimetabolite) for severe cases.

Class II histiocytoses, infection-associated hemophagocytic syndrome and familial erythrophagocytic lymphohistiocytosis (FEL), are diseases of the mononuclear phagocytic cell series, excluding Langerhans cells (see Table 200-9). The histiocytic reaction in these disorders is presumed to be from an underlying pathogenic process. FEL is usually rapidly fulminant and fatal, despite chemotherapy. Because the cells causing this disease are benign, it is not surprising that chemotherapy is usually not successful. Bone marrow transplantation is currently being studied in a controlled study and the initial results have been encouraging.

Class III histiocytoses are the only malignant histiocytoses (see Table 200-9). Three types are recognized: acute monocytic leukemia, malignant histiocytosis, and true histiocytic sarcoma. These diseases are treated with systemic chemotherapy.

Sequelae of Management

More than 12,000 children and adolescents under 20 years of age are diagnosed with cancer each year in the United States.[118] The overall survival rate is nearly 80%. A growing population of survivors requires long-term follow-up. The morbidity of managing head and neck cancers in children must be measured not during a 5- to 10-year interval but throughout a lifetime of more than 70 years. As cure rates improve, therapy must be refined to optimize growth potential and fertility and minimize the risk of second malignancies without sacrificing the primary goal of tumor eradication. The immediate sequelae of radiotherapy to the head and neck are similar in both children and adults. Acutely, mucositis, otitis externa, and alopecia are common. Subacutely, somnolence develops in approximately one third of children who receive whole-brain irradiation. Transient demyelination also can occur, leading to a sensation of electrical shocks at various levels below the neck elicited by flexion of the head or torso (Lhermitte's syndrome). Late effects include problems with transverse myelopathy, sensorineural hearing loss, endocrinopathies, and abnormal development of irradiated structures.[119]

Most disheartening of all is the possibility of a second malignancy. This risk is not insubstantial: Children who have survived one malignancy are three to six times more likely to develop another cancer than is the general population.[120] Thus, the risk of a second malignancy in long-term survivors (5 years) of all forms of childhood cancer appears to be 2% to 3%.[121] Contributing factors include radiotherapy, chemotherapy, age at treatment, and genetic susceptibility. Especially vulnerable are children previously treated for retinoblastoma and survivors of Hodgkin's lymphoma who receive mantle irradiation. Reported tumors include acute leukemias; bone and soft tissue sarcomas; and carcinomas of the skin, breast, thyroid, and salivary glands.[102]

Because children can tolerate greater doses or greater dose intensities of irradiation than adults, they also are at higher risk for delayed or chronic toxicities that become evident years after treatment. Growth retardation is found in approximately one third of pediatric brain tumor survivors, and in approximately 10% of pediatric leukemia survivors. Children treated at an age younger than 5 years with irradiation for brain tumors are especially susceptible to the linear growth retardation. Musculoskeletal problems such as scoliosis, avascular necrosis of bone, and osteoporosis are seen in approximately one third of pediatric cancer survivors, secondary to irradiation or steroid use, especially dexamethasone. Dental problems such as arrested tooth development or malocclusion and caries are common with radiotherapy to the facial or pharyngeal areas. Learning problems and neuropsychological problems are seen with cranial irradiation, especially in children younger than 36 months of age. Radiation to the neck also can cause thyroid dysfunction as a late effect.

Most radiation-induced second neoplasms occur more than 15 years after treatment of the first. Unfortunately, as duration of follow-up increases, so does risk.[122] Among chemotherapeutic agents, cyclophosphamide has been implicated in the development of solid tumors. Etoposide, an epipodophyllotoxin that acts by inhibiting the enzyme topoisomerase II, has been implicated in the development of second leukemias. The sobering reality is that the treatment of primary malignancies of the head and neck in children is extremely toxic, and the burden of a successful outcome can be immense. Addressing these issues remains a challenge for the 21st century.

CHAPTER TWO HUNDRED AND ONE

Salivary Gland Disease in Children

Gresham T. Richter

David L. Walner

Charles M. Myer, III

Key Points

- A good history and physical examination is the best tool in diagnosing salivary gland problems in children.
- Ultrasound with or without fine-needle aspiration is useful for diagnosis of most parotid and submandibular gland diseases in children who are tolerant of the procedure.
- For complete evaluation of the nature and extent of salivary gland masses, cross-sectional imaging with CT or MRI with contrast is necessary.
- Inflammatory conditions are the most frequently encountered salivary entities in young children.
- Salivary neoplasms are uncommon in children, mostly occur in the second decade, and are malignant in more than 50% of cases.
- The incidence of mumps virus parotitis is waning since the advent of the mumps vaccine. Beyond mumps, common viral etiologies of parotitis include Epstein-Barr virus, parainfluenza viruses, and adenovirus.
- A solid, firm, and fixed salivary mass that persists for greater than 6 weeks is an appropriate candidate for open surgical biopsy.
- Hemangiomas are the most frequently encountered benign tumors of the parotid gland. Pleomorphic adenomas are the most common benign epithelial tumors.
- Mucoepidermoid carcinoma is the most common malignancy of the parotid and most common tumor secondary to radiation exposure.
- Persistent sialorrhea beyond 4 years of age is considered abnormal and should be investigated for treatment including medical (glycopyrrolate) and surgical (submandibular gland excision and parotid duct ligation) options.

Salivary gland disease is an uncommon but manageable condition in the pediatric population. Inflammatory conditions of the salivary glands are more frequently encountered because salivary tumors account for only 1% of all childhood neoplasms. Infections can be either acute (bacterial and viral) or chronic (ductal obstruction, mycobacterial, and granulomatous disease) with the parotid being the most frequently affected gland. When a persistent salivary gland mass is present, possible neoplastic and congenital processes should be explored with an understanding that the risk of malignancy for salivary tumors is greater in young children. A complete differential diagnosis includes inflammatory, neoplastic, vascular, congenital, traumatic, and a myriad of less common diseases (Table 201-1). Clues gleaned from a thorough history and physical examination can help identify the disease in each pediatric patient. Ultrasound, computed tomography, magnetic resonance imaging, and fine-needle aspiration (FNA) have proven to be safe and valuable diagnostic tools for delineating inflammatory from benign and malignant salivary gland conditions (Figs. 201-1 to 201-3). Chronic sialorrhea (drooling) is a frequent and chronic problem, especially in neurologically impaired children, that can be addressed with both medical and surgical therapy.

Anatomy

The salivary system consists of the major paired parotid, submandibular, and sublingual glands and the minor salivary glands. All salivary glands are derivatives of ectoderm. During their development, they pierce the surrounding mesenchyme and arborize before terminating into multiple acini. The parotid gland lies between the external auditory canal, mandibular ramus, and mastoid tip. It is separated, by the stylomandibular ligament, from the submandibular gland, which rests between the anterior and posterior digastric tendons just below the body of the mandible. Both glands are covered by the superficial portion of the deep cervical fascia that either envelops (parotid) or separates (submandibular) the gland from adjacent lymph nodes. The largest salivary gland is the parotid, which is located in the parotid space harboring the facial nerve, external carotid artery, and retromandibular vein. It is artificially divided into two lobes, the deep and superficial, by the facial nerve. Accessory parotid glands with a connection to the parotid duct can be identified along the masseteric muscle in 20% of people. Although rare, agenesis of the parotid gland has also been reported.

An arborized draining system leads to a single and final secretory duct for both the parotid and submandibular glands known as Stensen's

Table 201-1

Differential Diagnosis of Pediatric Salivary Gland Disease

Inflammatory		Congenital	Neoplastic				
Acute	**Chronic**	**Cysts**	**Benign**	**Malignant**	**Traumatic**	**Autoimmune**	**Other**
Bacterial	*Obstructive*	Dermoid	*Vascular Anomaly*	*Epithelial*	Penetrating cheek	Benign lymphoepithelial	Allergy
Suppurative	Sialectasis	Branchial cleft	Hemangioma	Mucoepidermoid	Blunt gland trauma	disease	Medication induced
Lymphadenitis	Sialolithiasis	Branchial pouch	Lymphatic malformation	carcinoma	Radiation injury	Sjögren's syndrome	Chronic sialorrhea
Viral	Mucocele	Congenital ductal	Arteriovenous malformation	Acinic cell carcinoma			Systemic conditions
Mumps	cyst		Venous malformation	Adenocarcinoma			Obesity
EBV	*Granulomatous*		*Epithelial*	Adenocystic carcinoma			Prader-Willi
Parainfluenza	Mycobacterial		Pleomorphic adenoma	*Nonepithelial*			Cystic fibrosis
HIV	Actinomycosis		Cystadenoma	Rhabdomyosarcoma			
	Sarcoid		lymphomatosum	Lymphoma			
			Monomorphic adenomas

and Wharton's ducts, respectively. The sublingual glands are located in the floor of the mouth immediately below the mucosa and drain at its medial surface via 10 to 12 small ducts (ducts of Rivinus). They are the source of mucoid cysts, otherwise known as *ranulas,* which are frequently discovered in young children. The remaining upper aerodigestive tract is lined by literally hundreds of minor salivary glands that lie just deep to the mucosa. The highest concentration of minor glands are in the buccal, lingual, labial, and palatal regions. Each minor gland uses only one draining duct. Occlusion of these ducts can lead to small mucoceles. Frequently found along the lower lip of young children, treatment involves excision or marsupialization.

A few salient differences exist in the anatomy of the salivary system and its adjoining structures in children and adults. In infants the parotid gland is lighter and rounder. It lies wedged between the masseter muscle and the ear and gradually grows during childhood over the surface of the parotid duct. The facial nerve exits the skull base just deep to the subcutaneous tissue to enter the parotid gland in children younger than 2 years of age, making it particularly prone to traumatic injury. Thereafter, formation of the tympanic ring and mastoid tip allows the facial nerve to take a deeper and more protected position behind the mastoid bone and tragal cartilage. Similarly, after exiting the stylomastoid foramen, the nerve takes a more abrupt and lateral course in children than in adults, with the marginal mandibular nerve often riding in a superficial course over the mandible. These variations in facial nerve anatomy contribute to parotid and mastoid surgery as common iatrogenic causes of facial paralysis in children. Familiarity

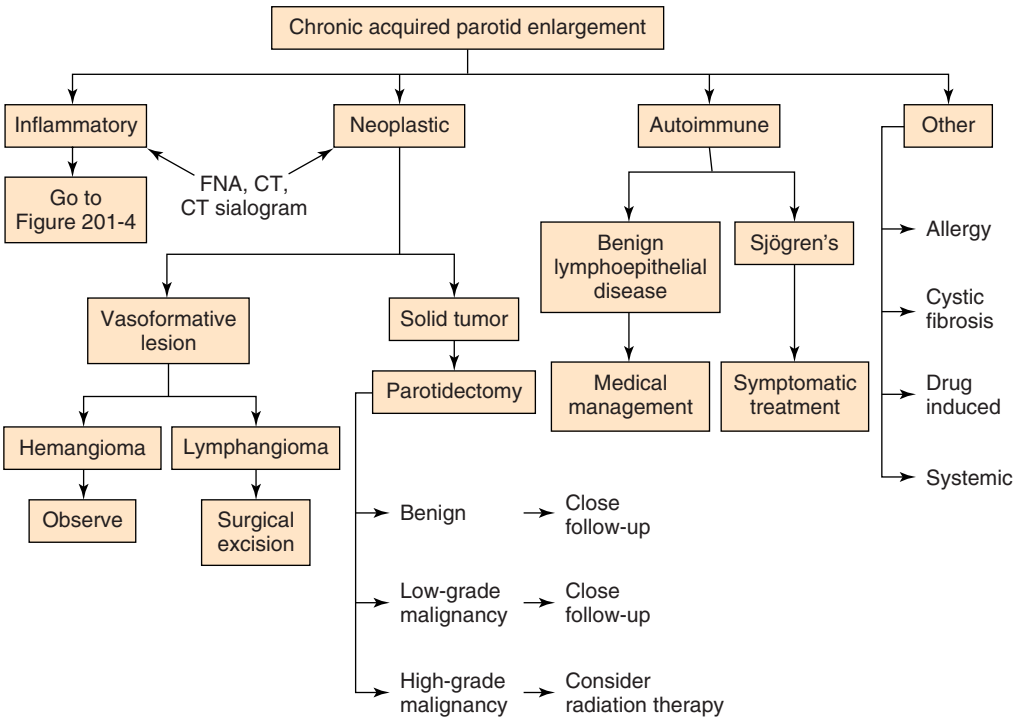

Figure 201-3. Chronic acquired parotid enlargement. CT, computed tomography; FNA, fine-needle aspiration.

with pediatric anatomy is thereby recommended before operating in a young patient.

In addition, the submandibular and sublingual glands are small in infants. Rapid growth of up to five times their initial size occurs during the first 2 years of life. Surgeons should be aware that, in very young children, the sublingual and submandibular glands are often anatomically contiguous.

Physiology of the salivary glands is thoroughly addressed in Chapter 84. Briefly, salivary flow is controlled by the superior salivatory nuclei (submandibular and sublingual glands) and inferior salivatory nuclei (parotid gland) via the autonomic nervous system. Only a small amount of saliva is secreted during the night because resting salivary flow increases during the day and peaks in the late afternoon. Resting salivary secretions are produced predominantly by the submandibular (60%) and sublingual (10%) glands with the submandibular glands creating the bulk of the fluid. The production of parotid secretions, which are serous in nature, is increased during eating. Saliva produced from all glands is critical for deglutition and acts as an infectious barrier for the mucosa and dentition by creating a surface coat of mucoid secretions, enzymes (e.g.. lysosyme), and immunoglobulins (IgA). In select children, excessive saliva and drooling (sialorrhea) can lead to aspiration, pulmonary compromise, mouth and skin maceration, and social isolation.[1] These patients often require medical or surgical therapy, or both, to reduce salivary flow from the major glands.

History and Physical Examination

A thorough history is the most important tool in diagnosing salivary gland problems in children. The onset, duration, and severity of symptoms provide valuable clues to the pathologic nature of the problem and allow the practitioner to quickly delineate among neoplastic, congenital, and inflammatory processes. Congenital disorders such as hemangiomas and cysts will often become evident shortly after birth. Neoplastic processes are more frequently seen in children older than 10 years.[2-4] In contrast, an inflammatory condition is the most common salivary pathology in toddlers and is marked by acute onset, brief duration, and painful swelling. Chronic conditions may be more difficult to differentiate by history alone, but gradual and painless growth at or near salivary tissue is suspicious for neoplasm until proven otherwise. Intermittent swelling associated with eating will signify salivary duct obstruction by stones or strictures, whereas recurrent and diffuse bilateral cheek swelling may indicate recurrent parotitis or chronic sialectasis.

The location and number of glands involved should be elicited in the history. Diffuse edema of the involved gland suggests inflammatory disease while focal and palpable lesions are the hallmark of neoplasm (Fig. 201-4). Bilateral involvement suggests systemic conditions. The character, quality, and quantity of the salivary secretions are also important. Serous secretions suggest a viral etiology, whereas malodorous purulent material indicates bacterial disease. The presence of fever, chills, or a recent upper respiratory infection should also be ascertained. An immunization history for mumps vaccine should be obtained. Questioning should elicit any history of trauma including injury from blunt or sharp objects, animal scratches, or recent dental procedures. The presence of congenital anomalies or cysts should be identified. Awareness of any underlying systemic diseases, which may include immune deficiency, allergy, or autoimmune disease, can be helpful.

The physical examination should include bimanual palpation of all major salivary glands. This consists of simultaneous palpation of the salivary gland structures in both intraoral and extraoral manners. This will also help distinguish salivary gland enlargement from cervical lymphadenopathy. It is important to identify whether the mass is cystic or solid, tender or nontender, and mobile or fixed. Facial movement (CN VII) should be assessed for subtle asymmetry or weakness. Symmetry and mobility of the tongue (CN XII) and sensation of the tongue (CN V) should be checked. Fixed nodules, cervical lymphadenopathy, and facial nerve involvement suggest malignant disease. Floor-of-mouth masses with enlarged perifacial lymph nodes need to be assessed for submandibular malignancy. Careful inspection of the salivary gland orifices should be performed with attention focused on the quantity (minimal, adequate, or excessive) and consistency (serous or suppurative) of the salivary content during palpation or "milking" the gland. Repeat examination may be helpful and necessary to follow the natural history of the disease.

Laboratory Studies

Laboratory studies are helpful in diagnosing and following salivary gland disease in children. If an infectious etiology is present, the leukocyte count will assist in determining whether adequate therapy is

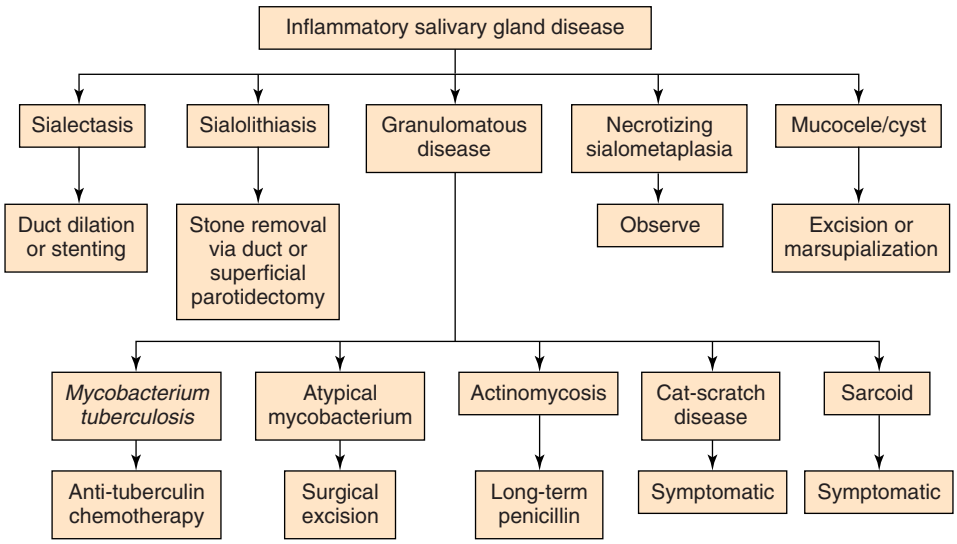

Figure 201-4. Inflammatory salivary gland disease.

being used. C-reactive protein is another nonspecific marker for bacterial infections and can be followed for treatment progress. Patients with risk factors or suspicion for human immunodeficiency virus (HIV) must be tested appropriately. A purified protein derivative (PPD) skin test and chest radiograph are employed in the pediatric population with salivary disease when mycobacterial infections (tuberculosis and atypical) are considered. Aerobic and anaerobic cultures of purulent material draining from duct orifices may help direct antibiotic coverage.

FNA is an easy and relatively safe technique for the diagnosis of palpable or deep-lying salivary masses. This can often be employed as an adjunct to diagnostic ultrasonography during the evaluation of pediatric salivary masses. With a well-trained cytopathologist, FNA can be an effective tool in diagnosing difficult lesions. In adults, up to 93% of benign and malignant lesions of the salivary glands can be differentiated.[5] Unfortunately, FNA is not commonly employed in the pediatric population because sedation or general anesthesia is often required. Moreover, pediatric pathologists are not universally versed in identification of salivary tumors due to the rarity of neoplasms in this population. Nonetheless, the unique architecture of pleomorphic adenoma and Warthin's tumor often makes it easy to diagnose them by FNA. Cytologic evaluation of sialadenitis shows polymorphonuclear leukocytes in a background of necrotic cellular debris. Cultures may also be obtained from aspirated contents at the time of FNA. Cystic lesions and poorly differentiated carcinomas are more difficult to assess by FNA and should undergo excisional biopsy for definitive answers.

In general, unusual and longstanding salivary masses should undergo FNA in tolerant pediatric patients before a surgical plan is developed. Surgical resection of discovered malignancies by FNA can be designed more appropriately. Misdiagnoses and nondiagnostic results are rare in FNA of pediatric head and neck masses. Regardless, most fine-needle aspirates lead to the diagnosis of a chronic inflammatory condition and can offset the use of open procedures in pediatric patients.[6,7]

Radiology

Radiographic imaging has played an increasing role in the diagnosis and perioperative decision making for salivary gland lesions. Improved radiographic instruments have allowed practitioners to delineate inflammatory and benign disease from malignant processes. Commonly employed techniques include plain film radiography, ultrasonography, sialography, radionucleotide scanning, computed tomography (CT), and magnetic resonance imaging (MRI). New MR technologies such as dynamic contrast-enhanced MRI, diffusion-weighted MRI, and MR spectrscopy have proven helpful in better differentiating benign from malignant salivary gland tumors.[8]

In children, ultrasonography is the most useful tool in evaluating salivary gland pathology and can be employed as a primary radiographic modality in nearly all cases. Ultrasound is an expedient, safe, and relatively painless technique that is ideal for examining pediatric patients. Ultrasonography can identify and assess adjacent vascular structures, distinguish focal from diffuse disease, clarify cystic from solid masses, and guide FNA. Lesions can be measured and easily followed with repeat examinations. The location of obstructing calculi within salivary ducts, despite their radiolucency, can be identified clearly with ultrasound. Nearly all sialoliths greater than 2 mm in size can be detected. Additional advantages to ultrasonography include low cost, avoidance of radiation, and avoidance of anesthesia.

Simple plain film radiography has become a less frequently used imaging tool for pediatric salivary masses as imaging speed and quality has improved in more informative radiographic tools such as CT and MRI. However, plain films remain easy to perform and detect the presence of radiopaque ductal stones within the major salivary glands. Unfortunately, up to 20% of submandibular calculi and 80% of parotid calculi are radiolucent and not well visualized with this technique.

Sialography involves the injection of contrast medium into the salivary duct during radiographic imaging in order to outline the salivary ductal system. Similar to plain film radiographs, this technique is gradually being replaced by CT sialography, MRI, and salivary duct endoscopy.[9,10] CT sialography can be valuable for detecting sialolithiasis, ductal dilatation, and strictures of the major salivary glands and has been used to evaluate obstructive disease, inflammatory lesions, penetrating trauma, and mass lesions. A filling defect and dilation of the main duct or intraglandular ducts will be seen when calculi are present. Chronic sialadenitis may show sialectasis or ductal ectasia. Salivary fistula or sialoceles can be picked up using this technique following trauma to a salivary gland.[11] Regardless, in the face of acute sialadenitis, sialography should not be performed because this can exacerbate disease and injure the involved gland.

For complete evaluation of the nature and extent of salivary gland masses, cross-sectional imaging with CT or MRI is necessary. Contrast-enhanced CT is best fitted for evaluating inflammatory conditions such as abscesses, obstructing sialoadenitis, cystic disease, sialolithiasis, and acute inflammation. Imaging should be performed both before and after administration of intravenous contrast. CT is an excellent tool to study both intrinsic and extrinsic masses of the parotid gland, and the relationship of the mass to critical anatomic structures such as the facial nerve are well illustrated with coronal and sagittal reconstructions.[8] The main benefits of CT scans in children are its speed and quietness relative to the slow, claustrophobic, and loud nature of MRI machines.

Bony architecture is better defined by CT and can provide information on the integrity of adjacent bone in malignant processes.

However, in patients with suspected neoplastic disease, MRI provides the best information on the exact location and degree of disease penetration.[11] In malignant processes, tumor infiltration of adjacent structures, soft tissue destruction, perineural spread, and meningeal penetration is best detected by MRI. This provides more information for operative planning. Standard axial T1- and T2-weighted MRI illustrate tumor margins and growth patterns. Coronal images, fat suppression, and gadolinium enhancement help identify perineural spread. Moreover, newer MR techniques have the ability to delineate benign from malignant processes with reported sensitivities and specificities above 90% using dynamic contrast or diffusion weighted methodology.[8] The drawback of MRI is that it can be difficult for children to tolerate and thereby be subject to the risks of sedation or general anesthesia required to perform the procedure.

Sialendoscopy

Sialendoscopy is a novel technique that has gained acceptance as a tool for diagnosing and treating a variety of salivary gland lesions in adults.[12] Since its development in the early 1990s, improvements in instruments and technique have allowed its application in the pediatric population. Semirigid sialendoscopes with external diameters between 1.1 mm and 1.6 mm are now available and can accommodate the pediatric salivary duct orifices. The endoscope includes two channels, one for irrigation and the other for instrumentation. Following routine dilation of the salivary duct, sialendoscopy is performed with continuous irrigation to maintain patency during exploration. This tool is best designed, and has proven applicable, to diagnose and treat obstructive pathology of pediatric unilateral salivary diseases. Diagnosis of salivary duct stenosis can be achieved with this technique, while wire baskets, lithotripsy, and YAG lasers can be simultaneously deployed to address small obstructing sialoliths.[13]

Biopsy

When diagnosis of a salivary mass has proven difficult with other modalities, open surgical biopsy is the next best approach. A solid, firm mass that persists for more than 6 weeks is a good candidate for open surgical biopsy. An incisional biopsy is inappropriate unless lymphoma is present; the cell type must be determined to direct management. An excisional biopsy should be performed following nondiagnostic FNA in a mass with a high index of suspicion for malignancy. Also, when confidence in cytopathology is low or an FNA cannot be performed, excisional biopsy is warranted. For masses within the superficial lobe of the parotid gland, an excisional biopsy will include the whole lobe with identification and preservation of the facial nerve. Occasionally, an isolated parotid tail lesion can be excised without the need for a superficial parotidectomy or facial nerve dissection. Tumors of the submandibular gland require complete excision of the gland and removal of adjacent lymph nodes (perifacial) for appropriate oncologic workup. Local excision with wide margins should be performed with minor salivary gland lesions. Examination of the draining lymphatic beds should be performed both prior and during excisional biopsies. Radiographic imaging with CT or MRI will help assess the extent of deep tissue penetration before elective biopsy.

Inflammatory Diseases of the Salivary Glands

Inflammatory conditions of the salivary glands are rare in children. Acute processes occur in the majority of cases that involve either viral or bacterial disease. The peak incidence is during puberty with most cases occurring between 12 and 18 years of age (>40%).[14] Submandibular disease is most commonly associated with proximal sialolithiasis and should be investigated appropriately. Granulomatous disease is a cause for a significant bulk of cases (primarily in toddlers) due to inflamed periglandular lymph nodes. Similar to adults, immunocompromised children are particularly prone to salivary gland infections and ductal stasis and obstruction and should be monitored closely. The most common clinical manifestation of salivary gland involvement is xerostomia and bilateral painless enlargement of the parotid glands.[15] Autoimmune disorders in children are rare but often manifest as inflammation of the major salivary glands.

Viral

Once the most common cause of viral sialadenitis, the mumps virus has virtually been eliminated as a cause of parotitis in the United States since the institution of the mumps vaccine in 1982. However, a few cases emerge annually in local and migrating patients who are without prior vaccination. The reader is directed to review the current guidelines and contraindications for mumps vaccination, which is beyond the scope of this chapter. However, other viruses can mimic mumps sialadenitis and should be included in the differential of vaccinated children with diffuse bilateral salivary gland disease. Beyond mumps, the most common viral sources of childhood sialadenitis are Epstein-Barr virus (EBV, incidence = 14%), parainfluenza viruses (4%, types 1, 2 and 3), adenovirus, (3%), HHV-6, human immunodeficiency virus, coxsackievirus, and influenza.[16] Most cases of viral sialadenitis are self-limited with conservative management of warm compresses, sialogogues, analgesics, anti-inflammatories, and hydration as the mainstay of therapy. The disease course of a few viral processes deserves special mention.

Mumps

Mumps parotitis is characterized by self-limiting bilateral diffuse parotid and submandibular gland enlargement. The gonads, meninges, and pancreas can also be involved and should be examined in these patients. The disease more frequently occurs during the winter and spring months, with 85% of cases occurring in the pediatric age group. The incubation period is 14 to 21 days, but the contagious period lasts from 2 to 3 days before the development of swelling and lasts until the swelling remits. During the incubation period, the patient develops a prodrome of symptoms including malaise, loss of appetite, chills, fever, and sore throat. The major salivary glands become tender and swollen, and the patient reports trismus and difficulty chewing. Although the duct orifice may be swollen, the saliva is clear. The temperature is elevated to 100° F to 103° F, and the leukocyte count is normal or slightly elevated with lymphocytosis. Although the diagnosis is clinical, amylase levels, complement fixation, and hemagglutination tests can be used for confirmation. Histologic examination reveals extensive cytoplasmic vacuolization of acinar cells. Management is symptomatic, and the swelling usually resolves over several weeks. Complications include sialectasis, exacerbation of diabetes, orchitis, meningoencephalitis, and sensorineural hearing loss (especially unilateral).

Epstein-Barr Virus

EBV is the cause of heterophil-positive infectious mononucleosis and has been implicated as a major cause of acute inflammation of the salivary glands in pubescent children.[16] Disease symptoms range from an asymptomatic infection to fulminant lymphoproliferative disease. EBV is emitted in the saliva and has been colloquially termed the "kissing" disease due to its oral transmission. In fact, 10% to 20% of healthy seropositive persons can shed EBV into their oropharynx.

The long incubation period of EBV ranges from 30 to 50 days. A triad of fever, sore throat, and posterior cervical adenopathy occurs in more than 80% of patients. Lethargy can persist for months in infected patients. The cervical adenopathy can involve the periparotid or perifacial (submandibular) lymph nodes with subsequent involvement of adjacent glands. Again, there is no specific therapy for EBV infection, but improvements in serologic detection have helped practitioners identify disease early and accurately. Children often need weeks of isolation and rest before returning to normal daily activity. Corticosteroids can be used for life-threatening complications but are unlikely necessary in isolated salivary gland cases. Recently, nearly 50% of salivary gland tumors and oral malignancies of nonodontogenic origin have been associated with EBV. Thus in children with rare oropharyngeal or salivary malignancies, isolation of EBV genome by polymerase chain reaction may help families come to terms with the source of such rare tumors.[17]

Human Immunodeficiency Virus

Salivary gland disease is a common manifestation of HIV in infected children. More than 50% of cases of pediatric HIV present with head and neck masses with the majority of patients having major salivary gland enlargement.[18] The enlargement can be lymphoproliferative, cystic, or both, with the parotid glands being the most frequently affected salivary entity. Parotid swelling of various degrees has been found in more than 10% of HIV-positive children.[19] The submandibular and sublingual glands can be involved as well. The incidence of ranula has been shown to be increased in HIV pediatric patients.[20] The high rate of salivary gland involvement is probably related to the presence of HIV within the saliva. Quantitative changes to the saliva can contribute to glandular hypertrophy, reduced salivary flow, stasis of secretions, and xerostomia.[21] Slow continuous enlargement is the hallmark disease in pediatric AIDS patients. The pathophysiology remains elusive. However, in children, bilateral lymphoepithelial cystic enlargement or intraglandular lymph node enlargement of the parotid glands is common. Cystic disease can often be seen in combination with lymphocytic interstitial pneumonitis.[22] Latent manifestation of EBV and cytomegalovirus in these patients may also contribute to salivary gland pathology.

Management of an HIV salivary lesion is generally conservative. Acute symptoms should be managed similarly to other salivary gland disease in healthy pediatric patients with techniques such as sialogogues and warm compresses. Imaging (CT or MRI) will help identify occult pathology. Antibiotic coverage for potential bacterial processes and fluoride treatment to prevent dental caries from xerostomia should also be employed. Consultation with an infectious diseases specialist is appropriate in these complex patients. Needle aspiration is indicated if a salivary lesion in an HIV-positive child grows to an uncomfortable or deforming size. Patients with HIV are particularly susceptible to lymphoma and Kaposi's sarcoma and can present with isolated salivary gland masses. Open biopsy is indicated only for lesions suspected of malignancy (lymphoma, Kaposi's sarcoma) that cannot be identified by FNA.

Bacterial

Primary bacterial salivary gland infections are rare in the pediatric population. Dental infections, periglandular lymphadenitis, and floor of mouth and submandibular triangle processes need to be considered in the differential of acute bacterial sialadenitis because these may be the source of inflamed salivary tissues. When suppurative sialadenitis does present, it most commonly occurs acutely and within the parotid gland. The normally serous saliva of these glands contains limited bacteriostatic activity (lysozymes) compared with the mucinous secretions of the submandibular and sublingual glands and likely contributes to the predominance of bacterial disease occurring in the parotid. Submandibular gland infections are associated with proximal sialolithiasis more than 40% of the time.[14] This is rare for the parotid gland.[23] The primary cause of submandibular infections appears to be salivary stasis of dependent and viscous mucous secretions of the submandibular duct. Predisposing factors include congential Wharton's duct stricture, ductal trauma, dehydration, autoimmune disorders, and congenital sialectasis. Similarly, recurrent sialadenitis has been associated with traumatic injury to the ductal orifices by repetitive biting of the buccal mucosa, dental appliances, and tooth eruption.[24] Retrograde oral bacteria transmission via the salivary ducts is thought be a culprit in disease.

Signs and symptoms of acute bacterial sialadenitis include rapid onset of focal pain, edema, and erythema of the soft tissues overlying the affected gland. Disease is predominantly unilateral. Spiking fevers are often present with symptoms worsening during deglutition. Purulent discharge found draining from the involved gland's duct is pathognomonic for disease. Most children remain nontoxic during acute episodes but, as the acute phase passes, residual induration and enlargement of the gland may persist for several months. Facial nerve paresis is extremely rare. The most common pathogens associated with bacterial sialadenitis are coagulase-positive *Staphylococcus aureus, Streptococcus viridans,* and *Haemophilus influenzae.* Less frequently identified bacteria include *Streptococcus pneumoniae, Escherichia coli, Bacteroides melaninogenicus,* and *Streptococcus micros* (Table 201-2).[25,26] Cultures of aspirated material or swabs of the purulent ductal secretions will help guide antibiotic coverage.

Table 201-2

Acute Suppurative Sialadenitis

Most common	*Staphylococcus aureus* (coagulase-positive) *Streptococcus viridans* *Haemophilus influenzae* *Peptostreptococcus* spp.
Less common	*Streptococcus pneumoniae* *Escherichia coli* *Bacteroides melaninogenicus*
