- CT and MRI have become the procedures of choice for defining mass lesions and traumatic abnormalities and supplement the findings at laryngoscopy when additional diagnostic information is required to plan treatment.
- Appreciation of normal anatomy is essential when analyzing cross-sectional images.
- Diagnosis and extent of involvement of inflammatory lesions such as croup, epiglottitis, and retropharyngeal abscess can be confirmed with imaging.
- Cross-sectional imaging is extremely useful in evaluating the patient with vocal cord paralysis.
- In the laryngeal carcinoma patient, cross-sectional imaging provides crucial information about involvement of deep structures such as the paraglottic space, cartilage, and lymph nodes.
- MR scanning is now preferred for post-therapy evaluation. Additionally, combined PET/CT can be used for more confident diagnosis of recurrent tumor and for biopsy.
- In laryngeal trauma, cross-sectional imaging permits easy and rapid evaluation of the extent of cartilaginous injury, adjacent soft tissue changes, and the degree of airway compromise.
- Plain film and CT are useful in localizing foreign bodies within the larynx, trachea, and esophagus.

The radiologist plays an important role in the evaluation of upper airway disorders in children and adults by providing unique and useful diagnostic information directly affecting the treatment of the patient.[1,2] In the past, evaluation of the airway included plain-film radiography, barium studies, and fluoroscopy. Now computed tomography (CT) and magnetic resonance imaging (MRI) have become the procedures of choice for defining mass lesions and traumatic abnormalities. These procedures can supplement the findings at laryngoscopy when additional diagnostic information is required to plan treatment.

Normal Airway

Technique

Plain films remain an effective and inexpensive screening examination for acute airway obstruction. Except in rare circumstances, plain-film examination of the airway should include anteroposterior and lateral radiography of the pharynx and laryngotracheal air column. In cooperative patients, these films should be exposed during inspiration with the patient upright because acute respiratory obstruction may be exacerbated in the recumbent position. Although conventional soft tissue techniques are often adequate, high kilovoltage magnification technique with selective filtration better visualizes the airway with improved air/soft tissue interfaces.[3-5] Xeroradiography has been abandoned in clinical practice.[6,7] When plain films are inconclusive, fluoroscopy and barium studies of the esophagus may be required for diagnosis. Abnormal vocal cord motion or swallowing mechanisms, vascular impressions, mass lesions, or nonopaque foreign bodies are best evaluated by these methods. Cross-sectional imaging may also be helpful in chronic airway disease.

Anatomy

Lateral radiography is excellent for identifying the tongue, adenoids, tonsils, epiglottis, aryepiglottic folds, pyriform sinuses, laryngeal ventricle, and subglottic trachea (Fig. 106-1A). The anteroposterior airway is superb for examining the glottic and subglottic areas (see Fig. 106-1B). During quiet inspiration, the vocal cords are abducted and the width of the upper airway almost equals that of the trachea. During phonation of the vowel "e," the vocal cords adduct, resulting in narrowing of the glottic area. However, narrowing of the subglottic area should be considered abnormal.

The airway may show considerable variability in children, unlike in adults. Therefore knowledge of the normal airway anatomy is essential before attempting to recognize pathology. This requires that the patient be properly positioned for the study. Lateral airway radiography should be obtained as much as possible in full inspiration with the neck extended. If the study is performed during expiration or with forward flexion of the neck, the retropharyngeal soft tissue in children bulges anteriorly and may simulate a retropharyngeal mass (Fig. 106-2).[8]

The size of the adenoids and tonsils in children and irregular cartilage ossification in adults can present significant problems in evaluation of the airway. In newborns and infants, the tonsils and adenoids are normally sparse; lymphoid tissue can be identified radiographically in all children at 6 months of age.[9] After age 6 months, the tonsils and adenoids vary considerably in size and may encroach on the nasopharynx or oropharynx, suggesting a pathologic soft tissue mass. In most cases these structures, even when large, are normal and are frequently noted as incidental findings on plain-film radiography or cross-sectional imaging scout views or sagittal views. Occasionally, however, they can

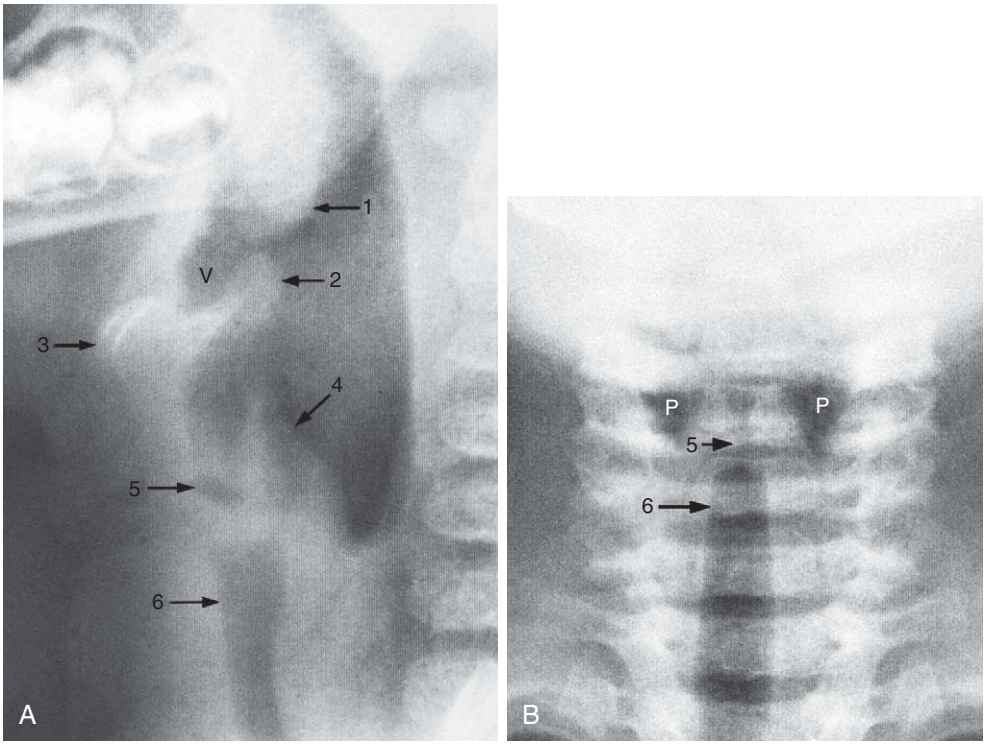

Figure 106-1. **A** and **B,** A healthy upper airway in a 20-month-old child. The following structures are well visualized: palatine tonsils *(1)*, epiglottis *(2)*, body of the hyoid bone *(3)*, aryepiglottic folds *(4)*, laryngeal ventricle *(5)*, subglottic airway *(6)*, vallecula *(V)*, and pyriform sinus *(P)*.

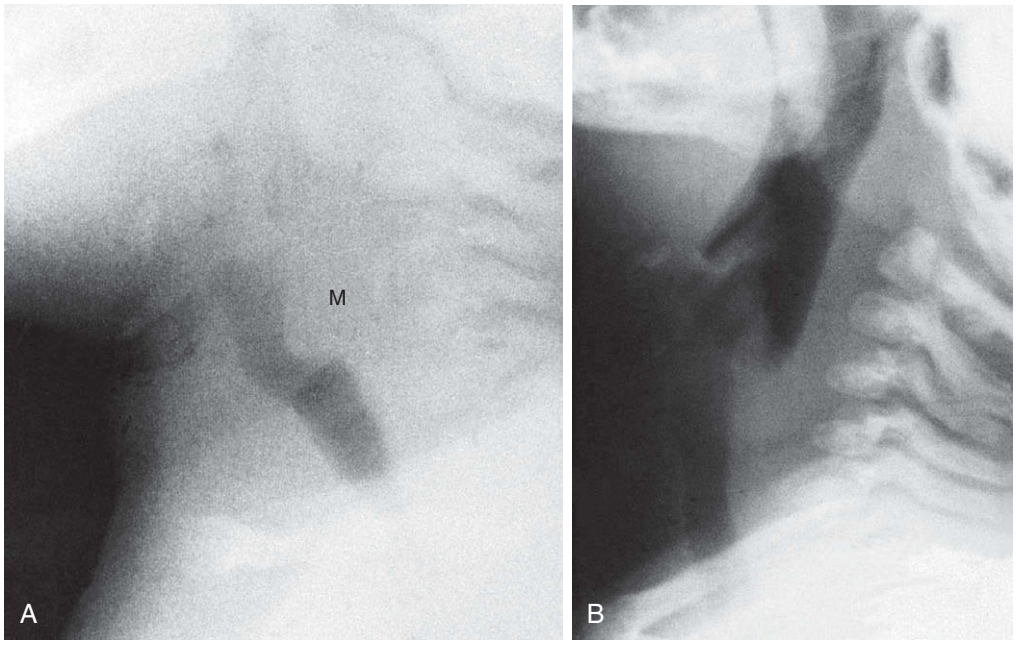

Figure 106-2. Pseudoretropharyngeal mass. **A,** A retropharyngeal mass *(M)* is suggested in this child, who was examined with the neck flexed and the airway only partially distended. **B,** Healthy retropharyngeal soft tissue is seen when the examination is repeated during inspiration with the neck extended.

be associated with airway obstruction (Fig. 106-3).[10,11] The adenoids are largest at 7 years to 10 years of age and then decline by the seventh decade.[12] In most instances, adenoidal size can be evaluated subjectively, but objective methods of assessing adenoidal size using an adenoidal-to-nasopharyngeal ratio have been described.[12,13] The final decision as to whether adenoid or tonsillar tissue is of symptomatic importance is clinical, not radiographic.

Cartilage of the neck may pose another problem because in certain adults, normal thyroid and cricoid calcifications can be irregular and incomplete, thereby simulating a foreign body or neoplastic destruction.[14] These normal calcifications can be seen occasionally in older children, but as a rule the only cartilage calcified routinely in the younger child is the hyoid bone. Any other radiopaque structure is usually abnormal.

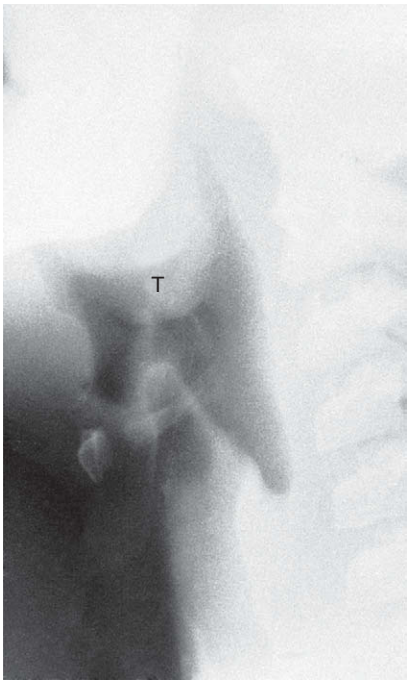

Figure 106-3. Tonsillitis. Lateral view shows enlarged palatine tonsils *(T)*.

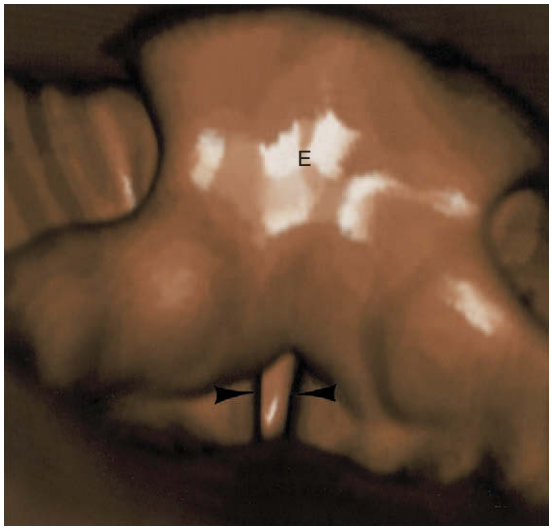

Figure 106-4. Volume-rendered three-dimensional image of the normal epiglottis (*E*) and normal vocal cords *(arrowheads)* derived from multirow detector spiral CT data. *(Case courtesy of Dr. Elizabeth McFarland.)*

Cross-sectional imaging also adequately shows the airway. Configuration of the airway on axial or transverse images varies depending on the level of the image. At the level of the epiglottis and aryepiglottic folds, the airway is elliptic. Approaching the false cords, the airway narrows and assumes a tear-drop shape. The airway becomes elliptic at the true cords. The term *rima glottidis* refers to the airway at the level of the true vocal cords. The intermembranous portion of the rima glottidis (glottis vocalis) consists of the ventral 60% of the cords, and the dorsal intercartilaginous portion (glottis respiratoria) consists of the portion between the arytenoid cartilages.[15] Below the cricoid cartilage, the airway appears circular. The posterior membrane of the trachea may posteriorly flatten, and the normal esophagus occasionally indents the airway silhouette.[16] Nodular projections into the airway or asymmetric tracheal wall thickening should be viewed suspiciously as subglottic tumor involvement. Multirow detector CT imaging has recently allowed computer-generated, three-dimensional visualization of the airway lumen and contiguous structures by reconstructing two-dimensional data. Named "virtual laryngoscopy," this technique offers noninvasive interactive evaluation of the tracheal lumen that correlates well with conventional rigid endoscopy (Fig. 106-4).[17,18]

Inflammatory Disease of the Larynx

Epiglottitis

Epiglottitis is an inflammation of the epiglottis caused by the bacteria *Haemophilus influenzae.* The entire supraglottic airway may be involved, but the epiglottis and aryepiglottic folds are most extensively involved. These normally well-defined thin structures become edematous, enlarged, and unsharp, resulting in a rounded, thumblike density in place of the epiglottis. The edema often encroaches on the vallecula and rarely may extend to the posterior pharyngeal wall. In addition, the hypopharynx and pyriform sinuses are usually mildly to moderately overdistended.[19-22] The remainder of the airway is fairly normal, although at least 25% of children with epiglottitis have subglottic narrowing.[23]

The changes of epiglottitis are shown best on lateral radiography (Fig. 106-5). Extensive manipulation of the patient should be avoided because of the possibility of inducing glottic spasm. Cross-sectional imaging is unnecessary.

Figure 106-5. Epiglottitis. Marked thickening of the epiglottis *(arrow)* and aryepiglottic folds *(arrowheads)* is seen. Mild hypopharyngeal overdistention is also present.

Enlargement of the epiglottis may result from various other disorders including irritation from a foreign body or burn, tumors such as epiglottic cysts or neoplasms (e.g., lymphoma), granulomatous disease (e.g., sarcoidosis, tuberculosis, Wegener's granulomatosis), and angioneurotic edema.[24,25] The radiographic findings should therefore be correlated with the patient's clinical history (Fig. 106-6). On occasion, an omega epiglottis—a normal anatomic variant in children in which the epiglottis is floppy, vertically positioned, and resembles the capital Greek letter "omega"—may be misdiagnosed as epiglottitis.[26] An important distinguishing feature is the absence of thickened aryepiglottic folds or other edematous changes.

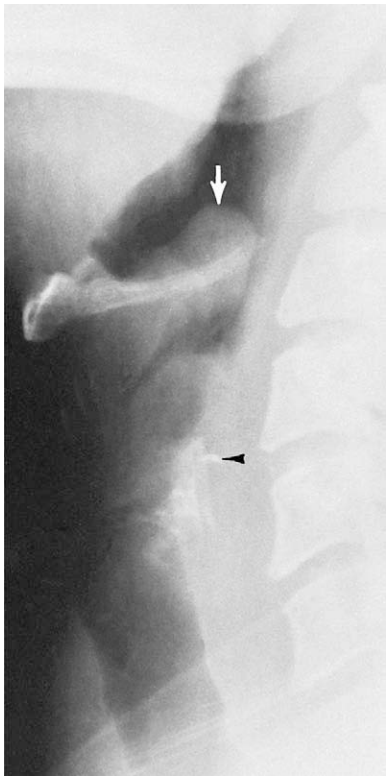

Figure 106-6. Sarcoidosis. Marked enlargement of the epiglottis *(arrow)* is present. *Arrowhead* points to normal calcification in the posterosuperior aspect of the cricoid cartilage.

Croup

Croup is an inflammation of the subglottic larynx usually caused by parainfluenza virus type 1. It typically occurs in young children. Radiographic studies are not indicated or obtained routinely in patients with croup but are useful in confusing cases, primarily to exclude other causes of stridor. The radiographic changes are the result of inflammatory edema affecting the larynx and subglottic tissue. Radiographically, the frontal view is most helpful in the diagnosis (Fig. 106-7). Symmetric subglottic airway narrowing or "penciling" of the airway is the major radiographic finding.[19-22] In contrast to congenital subglottic stenosis, narrowing of the subglottic portion of the trachea is not fixed and may improve on expiration.[27] The lateral view of the neck appears less helpful, although the narrowing may be noted. This projection shows hypopharyngeal airway distention, but more importantly it establishes that the epiglottis and aryepiglottic folds are normal.

Membranous or bacterial croup and viral croup may present with similar symptoms; however, membranous croup is characterized by diffuse inflammation of the larynx, trachea, and bronchi with adherent exudate and mucus on the surface of the upper tracheal mucosa.[28] Radiography shows subglottic narrowing and multiple tracheal soft tissue excrescences (Fig. 106-8). These intraluminal lesions can be mistaken for foreign bodies, so clinical correlation is required for diagnosis.

Retropharyngeal Abscess

The retropharyngeal space lies posterior to the larynx between the middle and deep layers of the deep cervical fascia. It extends from the base of the skull to the mediastinum and frequently serves as a conduit for spread of disease from the neck into the chest.[29,30] Retropharyngeal abscess results from suppuration of retropharyngeal lymph nodes in patients with upper respiratory tract infection or from perforation of the pharynx or upper esophagus by a foreign body. If the abscess compresses the larynx and upper trachea, symptoms of upper airway obstruction develop.

Lateral soft tissue radiography of the neck will show fixed thickening of the retropharyngeal soft tissues, anterior displacement of the

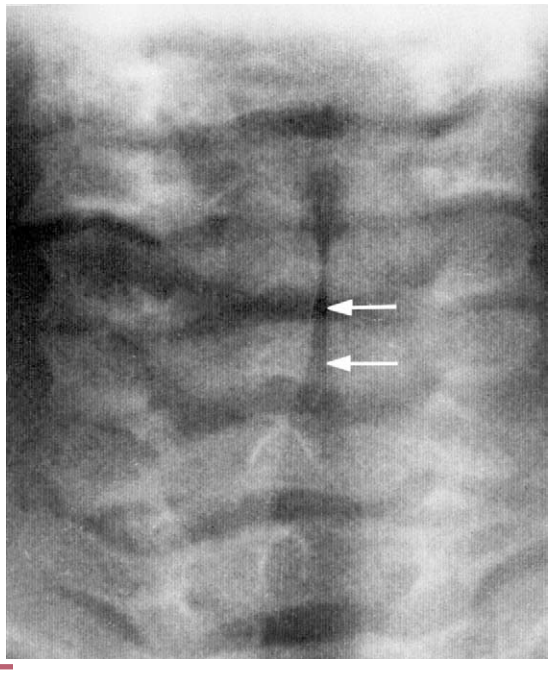

Figure 106-7. Croup. Frontal view shows typical funnel-shaped subglottic narrowing *(arrows)*.

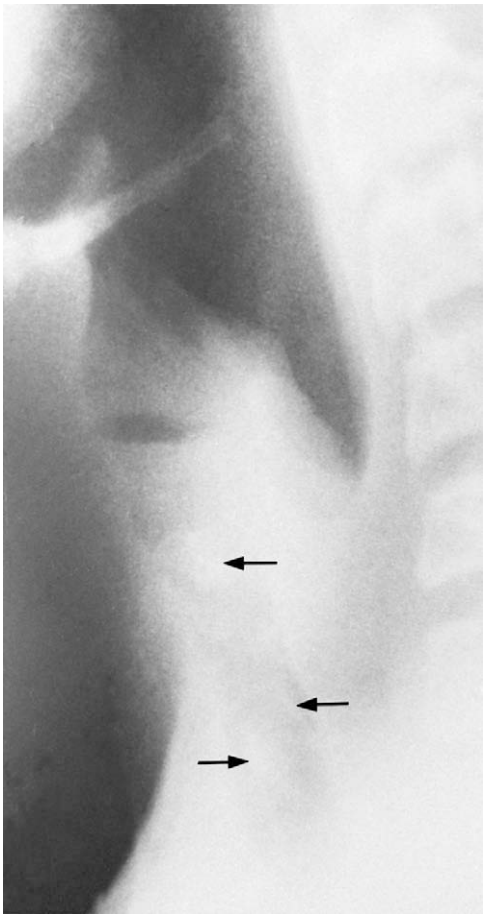

Figure 106-8. Membranous croup. Multiple irregular membranes *(arrows)* are present in the subglottic airway.

airway, reversal of normal cervical lordosis, and occasionally gas bubbles within the abscess (Fig. 106-9).[19,21,27] The retropharyngeal space should not exceed 7 mm as measured from the most anterior aspect of C2 to the posterior pharyngeal wall. At C6, the thickness of the retropharyngeal tissues should not be greater than 14 mm in children and 22 mm in adults.[31] Fluoroscopy or barium esophagography may be necessary to confirm that the radiographic changes did not occur with expiration or with the head in a flexed position.

Figure 106-9. Retropharyngeal abscess secondary to foreign body perforation of the esophagus. The prevertebral soft tissues are markedly swollen, and the trachea is displaced anteriorly *(small arrows)*. *Large arrow* points to a metallic foreign body.

CT and MRI superbly evaluate the retropharyngeal space. Suppurative adenopathy is usually limited to the suprahyoid region of this space and spares the midline. As infection becomes extranodal, the entire width of the retropharyngeal space frequently becomes thickened. Inflammation can then easily track into the infrahyoid region. The full extent of the process can be imaged by CT or MRI before therapy.[29] Abscess will appear hypodense on CT, hypointense on T1-weighted, and hyperintense on T2-weighted magnetic resonance (MR) images, reflecting the presence of liquefaction (Fig. 106-10). Ring enhancement may be seen following administration of intravenous contrast. Differentiation between retropharyngeal abscess and adenitis is difficult on CT because both processes cause hypodense regions within the inflammatory mass. Some authors advocate the use of ultrasound in this evaluation.[32] If air bubbles or a foreign body is present within the mass, the diagnosis of a retropharyngeal abscess is more likely.

Thickening of the retropharyngeal soft tissues also can occur secondary to bleeding and edema from cervical spine trauma, lymphadenopathy (e.g., lymphoma, tuberculosis), or retropharyngeal tumors (e.g., cystic hygroma, neuroblastoma, hemangioma, retropharyngeal goiter, cancer).[27,33-35] The imaging findings should therefore be correlated with the clinical history.

Laryngomalacia

Laryngomalacia or congenital flaccid larynx is one of the most common causes of inspiratory stridor in the neonate and infant.[21] Laryngoscopy shows flaccidity of the epiglottis, aryepiglottic folds, or the entire larynx, which collapses during inspiration. The corresponding radiographic findings are best shown with fluoroscopy. Hypopharyngeal overdistention with associated collapse of the aryepiglottic folds and epiglottis is observed on inspiration. Paradoxic narrowing of the subglottic portion of the airway may also be seen as the patient inspires. The primary reasons for laryngoscopy and radiography are to exclude other causes of congenital stridor (e.g., cysts, webs, tumors, stenoses). In most children, the symptoms disappear by 1 year of age.

Vocal Cord Paralysis

Paralysis of the vocal cord may be caused by any process involving the vagus nerve or its recurrent laryngeal branch between the jugular foramen and its entrance into the larynx. Almost 75% of patients have unilateral paralysis.[36] Almost 90% of paralyses are caused by lesions that

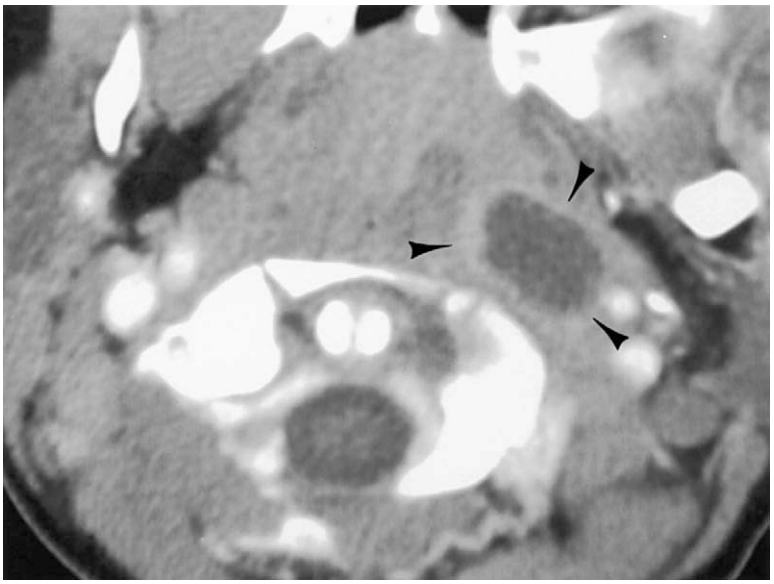

Figure 106-10. Retropharyngeal abscess. Enhanced CT image of the neck demonstrates a fluid collection in the left retropharyngeal space (*arrowheads*).

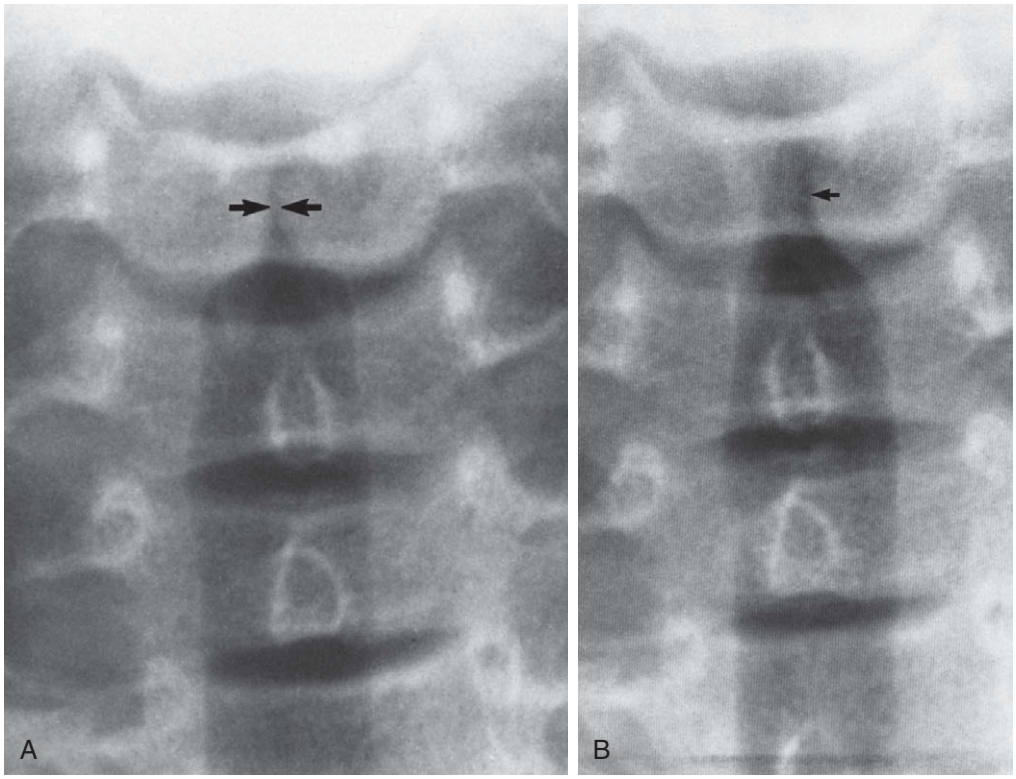

Figure 106-11. Left true vocal cord paralysis. **A,** During phonation, both vocal cords are in a paramedian location *(arrows)*. **B,** During inspiration, the left true vocal cord remains in a paramedian position *(arrow)*, whereas there is abduction of the normal right true vocal cord.

compress the nerve along peripherally located segments, and only 10% originate in the central nervous system or before the nerve exits the jugular foramen; central paralyses are accompanied by other cranial neuropathies.[37] The peripheral location of most lesions reflects the long and redundant routes of the recurrent laryngeal nerves. Specific causes include neoplasm (36%); postoperative complications, such as from parathyroid and thyroid surgery (25%); and inflammation (13%). Some cases are idiopathic.[36] Congenital central nervous system anomalies are often associated with childhood vocal cord paralysis.[38] Although laryngeal cancers can paralyze the cord by direct invasion of the thyroarytenoid muscle, infiltration of the recurrent or superior laryngeal nerves by local tumor is rare.[39]

Although plain-film radiography, fluoroscopy, and CT can evaluate vocal cord mobility, abnormal vocal cord motion is generally diagnosed by laryngoscopy (Fig. 106-11).[40,41] However, in patients with vocal cord paralysis secondary to neoplasm, imaging helps show the extent of neoplasm and its relationship to the adjacent cartilaginous structures.[42,43] Radiologic evaluation of the isolated paralyzed cord should entail imaging of the entire vagus nerve from the skull base to the pulmonary hila. CT is excellent for evaluating the neck and chest; MRI is superior for the skull base (Fig. 106-12).[36,44,45,] Imaging signs of cord paralysis include paramedian position of the cords, displaced arytenoid cartilage, ipsilateral dilation of the pyriform sinus, tilting of the thyroid cartilage, and prominent laryngeal ventricle.[37] Dynamic MRI using an open-bore configuration, with the patient seated, has recently been explored as a technique for evaluating swallowing and other laryngeal and pharyngeal functions.[46]

Figure 106-13. Subglottic hemangioma. Lateral view shows a soft tissue mass *(arrows)* in the posterior portion of the subglottic airway.

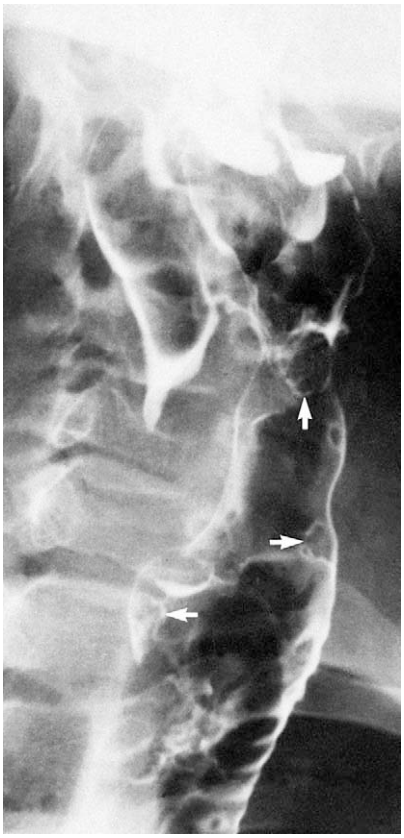

Figure 106-14. Laryngotracheal papillomatosis. Oblique view from a bronchogram shows multiple nodules *(arrows)* of varying sizes in the glottic and subglottic airway.

Benign Laryngeal Masses

Benign neoplasms can cause respiratory obstruction. Symptoms and imaging features depend on tumor distribution and extent. CT is the preferred screening method because of its widespread availability and superior information.

Although rare in adults, subglottic hemangioma is the most common laryngeal and upper tracheal neoplasm in the newborn and infant. The lesion typically appears as a well-defined mass in the posterior or lateral portion of the subglottic airway (Fig. 106-13).[25,47] The subglottic narrowing is usually eccentric; however, circumferential narrowing suggestive of croup may also be seen. Additional hemangiomas may occur on the skin or elsewhere in the body.

Squamous papillomas, the most frequent laryngeal tumors in children, have also been reported in adults.[48,49] The imaging appearance of papillomatosis is contingent on the size and location of the lesions. Generally single or multiple intraluminal soft tissue nodules are seen in the glottis or in the tracheal air column (Fig. 106-14). Because papillomas may extend to the bronchial tree or pulmonary parenchyma, chest CT is extremely important in defining the extent of disease. Localized areas of atelectasis, air trapping, or pneumonia have been reported. Papillomas also may appear as well-defined discrete pulmonary nodules that eventually cavitate, forming multiple thin-walled cystic lesions.[50,51]

A laryngocele is an abnormal elongation and expansion of the saccule of the laryngeal ventricle and represents more than 20% of submucosal lesions of the larynx.[52,53] Almost 25% are bilateral.[54] Although laryngoceles are usually asymptomatic, large lesions may be associated with airway obstruction and vocal cord paralysis.[55] Laryngoceles within the paraglottic space and confined by the thyroid lamina are termed *internal*. These lesions may present on laryngoscopy as soft, localized bulges of the aryepiglottic fold and may be mistaken clinically for submucosal neoplasms.[56-58] Lesions that pierce the thyrohyoid membrane to present in the lateral neck are termed *external*. Most cases are a combination of external and internal lesions and are referred to as *mixed*. Regardless of position, laryngoceles are usually visualized as sharply defined air-containing structures on imaging (Fig. 106-15).[59] A modified Valsalva's maneuver occasionally improves visualization of these lesions. Laryngeal mucocele is a fluid-filled laryngocele caused by obstruction of the ostium of laryngeal saccule and may appear as a soft tissue mass. These lesions are overwhelmingly benign; however, up to 15% may be associated with a small ventricular cancer.[57,60,61] Rarely, cystic lesions such as cystadenomas can mimic a laryngeal mucocele.[62]

CT can be helpful in showing fluid-containing and air-containing laryngoceles (Figs. 106-16 and 106-17).[56] If the mass is of soft tissue density because it contains either mucoid or purulent material, the distinction from neoplasm may be more difficult. However, its location and smooth surface in conjunction with a healthy mucosa on laryngoscopy should suggest a laryngocele. CT may also help show the external component of a laryngocele that is not apparent on physical examination. An enhancing wall usually indicates infection. The endolaryngeal origin of this lesion differentiates it from a lateral thyroglossal duct cyst.[57]

Congenital cysts of the larynx are rare causes of respiratory obstruction in infants. They most commonly arise in the region of the epiglottis or aryepiglottic fold. Plain-film examination of the airway will disclose a soft tissue mass of varying size, encroaching on and displacing the healthy airway.

Laryngeal Carcinoma

Nearly all mucosal tumors are diagnosed by direct inspection and biopsy; imaging provides crucial information about involvement of deep structures such as the paraglottic space, cartilage, and lymph nodes. CT is a proven imaging technique for evaluating patients with laryngeal carcinoma.[63-67] In most patients, CT shows more extensive disease than is initially appreciated by laryngoscopy. The cross-sectional

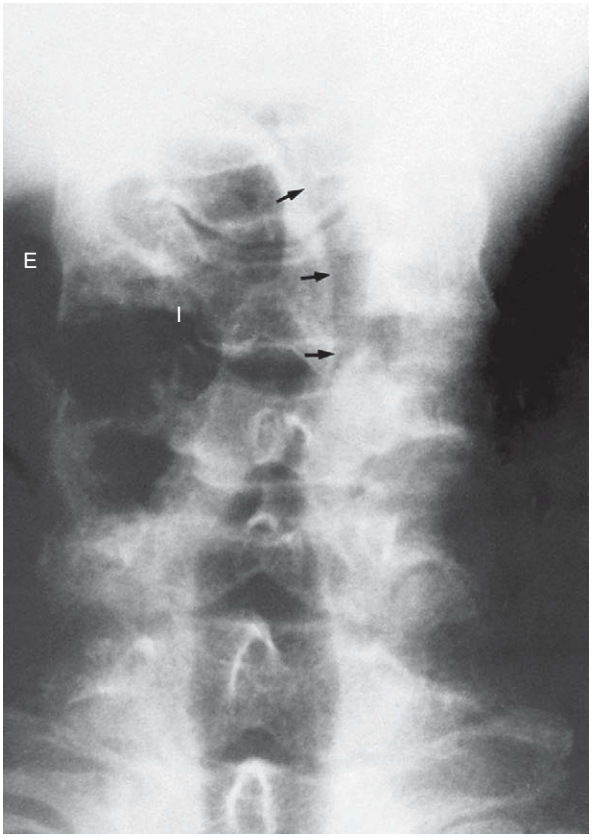

Figure 106-15. Mixed laryngocele. Frontal view shows the large internal *(I)* and external *(E)* components of the laryngocele with compression of the supraglottic airway *(arrows)*.

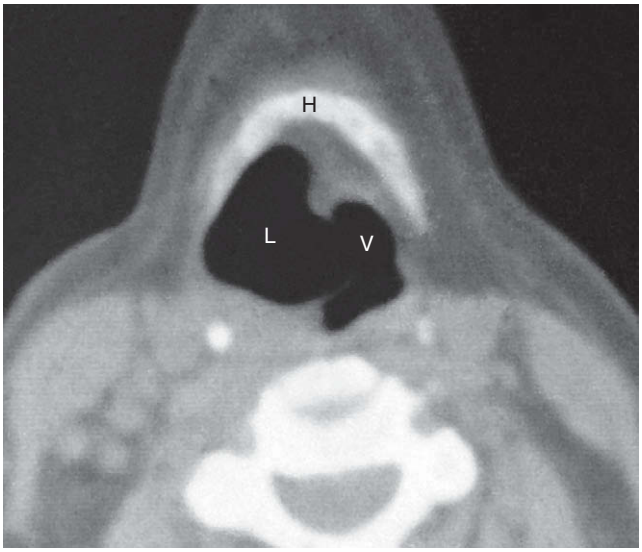

Figure 106-16. Internal laryngocele. Computed tomography shows the air-filled laryngocele *(L)* filling the right paraglottic space and compressing the laryngeal vestibule *(V)*. The hyoid bone *(H)* is also seen.

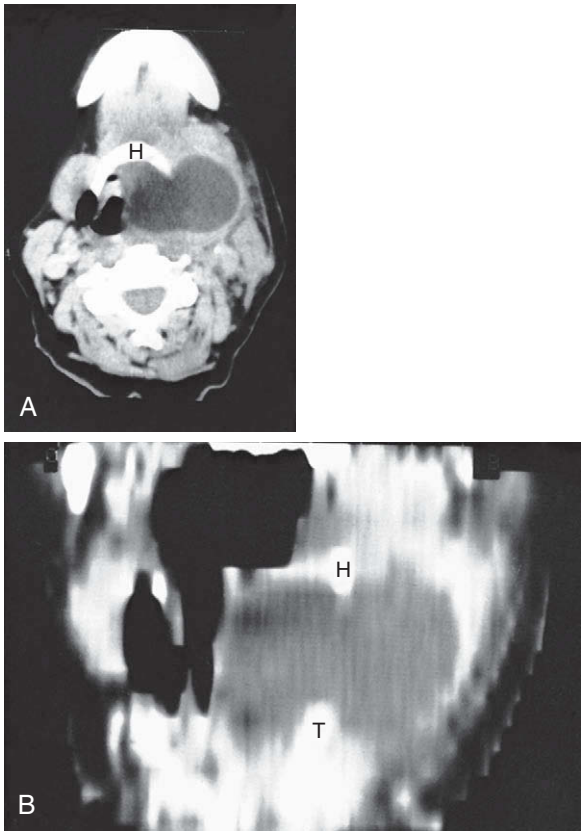

Figure 106-17. Bilateral mixed laryngoceles. **A,** Computed tomography (CT) shows a fluid-filled, dumbbell-shaped cyst with intralaryngeal and extralaryngeal components on the left. Smaller air-filled laryngocele is seen on the right. **B**, Reformatted coronal CT shows both laryngoceles herniating through the thyrohyoid membrane. The hyoid bone *(H)* and thyroid cartilage *(T)* are also seen.

imaging provided by CT allows evaluation of the intrinsic and deep soft tissues of the larynx and the cartilaginous skeleton.

MRI provides anatomic information on the neck that compares favorably with CT.[68-72] Advantages of MRI include its excellent soft tissue contrast, which is superior to CT. Multiplanar display enables coronal, transverse, and sagittal anatomic formatting, whereas CT is usually limited to the transverse plane. Newer multirow detector CT scanners allow for multiplanar reconstructions; however, these views are derived from data obtained in the transverse plane. MRI uses no ionizing radiation and is not plagued by artifacts caused by beam hardening, dental amalgam, or poor beam penetration of the shoulders. MRI does have limitations, however. It is slower than CT, and therefore motion artifacts from breathing, carotid artery pulsations, and swallowing may degrade images.[73-75] This should be considered when choosing a modality in laryngeal cancer patients, who are often elderly and may have other medical debilities (e.g., chronic obstructive pulmonary disease).[74] MRI does not image cortical bone or calcifications well. Furthermore, MRI is contraindicated in patients with cardiac pacemakers, metallic cochlear implants, and cerebral aneurysm clips.[76-79]

The decision for selecting radiotherapy, conservation surgery, or total laryngectomy depends on an accurate delineation of tumor extent.[80,81] CT and MRI are excellent noninvasive methods capable of three-dimensional (3D) anatomic display of portions of the larynx that are not well examined by laryngoscopy. Submucosal extension of tumor and cartilaginous destruction that are not suspected clinically can be assessed. Because imaging modalities have different strengths and weaknesses, the choice of CT or MRI should be tailored to the patient. Furthermore, imaging is not a substitute for but is complementary to laryngoscopy. Although imaging may show advanced mucosal abnormalities, minor mucosal abnormalities and abnormalities of intrinsic motion are best studied by laryngoscopy.[82]

Neoplasm is identifiable on CT as an area of increased soft tissue density that alters the normal symmetric laryngeal anatomy. Similarly, the hallmark of an abnormal larynx on MRI is asymmetry. The superb soft tissue contrast provides additional information. On T1-weighted images, fat signal is hyperintense and differs significantly from the mucosa and muscles in appearance. Signals from lymph nodes and

infiltrating tumor, which are less intense than fat, are well visualized on T1-weighted images. On T2-weighted images, muscle signal is less intense than mucosa, fat, and many tumors. Carcinomas within the mucosa and muscles can be well delineated.[83] Neither CT nor MRI findings are histologically specific, and similar appearances can be produced with hemorrhage, edema, inflammation, or fibrosis. Therefore, examination should be correlated with the clinical history and should be performed before laryngeal biopsy or at least 48 hours after biopsy to avoid confusion with postbiopsy edema and hemorrhage.

Technique

Spiral (helical) CT using multidetector technology and volumetric data sets has largely replaced conventional dynamic CT (slice-by-slice acquisition) in most medical centers.[69,84] Spiral CT permits rapid scanning of large volumes of tissues during quiet respiration.[85] Spiral images are less susceptible to patient motion than conventional CT, although image noise is slightly increased.[86,87] Thin sections can provide information about specific regions, such as the anterior commissure.[88] Moreover, volumetric spiral data permit multiplanar and 3D reconstructions.[87,89,90] The amount of intravenous contrast may be reduced compared with dynamic CT.[91] Iodinated contrast is administered intravenously to distinguish nonenhancing lymph nodes from enhancing vessels. Images are obtained during slow inspiration. If the images are performed during suspended inspiration, adduction of the true vocal cords may cause the airway to appear falsely narrowed. Scans are occasionally obtained during phonation or during modified Valsalva's maneuver to distend the pyriform sinuses and improve visualization of the aryepiglottic folds.

3D CT is currently being used for radiotherapy planning. Slices are obtained in the conventional axial orientation. Using special computer software, selected anatomic structures are then traced and reformatted into a 3D wire diagram depicting the tumor and key adjacent tissues that can then be manipulated to reveal the optimal radiation port. This technique limits extraneous collateral radiation to other organs such as the salivary glands.[92,93] CT is also useful for guiding percutaneous biopsies.[94-97]

MR techniques may vary depending on scanner type and available hardware and software. Surface coils are essential to adequately image the larynx.[42,98] Sagittal, transverse, and coronal T1-weighted images best display anatomic relationships. T1-weighted and T2-weighted transverse images further define the signal characteristics of the tissues. Sections are usually 3 to 5 mm thick. Gradient moment nulling, flow compensation, cardiac gating, and presaturation pulses minimize motion artifacts.[74] Fast spin-echo T2-weighted technique has replaced conventional spin-echo technique and offers relatively short acquisition times.[99-102]

Gadolinium-enhanced images improve delineation of margins in many lesions,[103-107] although lesions embedded in fat may be obscured.[108,109] Another potential pitfall is that healthy aerodigestive mucosa enhances, therefore possibly obscuring small mucosal tumor volumes.[54] Fat-suppression techniques improve conspicuity of soft tissue lesions embedded in fat by selectively diminishing the hyperintensity of fat on T1-weighted images.[108,110] Gadolinium-enhanced, fat-suppressed T1-weighted images are especially useful in staging nodal disease.[111] Agents are typically well-tolerated.[104,112] Newer agents such as gadobenate dimeglumine are improving lesion conspicuity compared with equivalent doses of older agents. A word of caution is necessary, however. Recently, several cases of nephrogenic systemic fibrosis/nephrogenic fibrosing dermopathy (NSF/NFD) have been reported in patients with renal failure receiving gadolinium compounds, especially in high doses. (It is worth noting that the use of double and triple doses of contrast, sometimes valuable in intracranial disease, has little value in neck imaging.[113]) NSF/NFD, a rare and somewhat mysterious complication, causes a progressive sclerosis of the skin and connective tissue and may lead to death. Currently, recommendations include calculating a glomerular filtration rate for patients with renal insufficiency or frank failure and avoiding the use of contrast agents in the impaired patient.

Fat suppression may produce several annoying artifacts, however, such as signal loss at bone-air interfaces, inhomogeneous suppression at the base of skull compared with the infrahyoid regions, and frank failure of suppression at fat-air interfaces producing aberrant hyperintense signal.[114] Moreover, some techniques may be misleading because nonfatty tissue with T1 values similar to fat (e.g., proteinaceous fluid, methemoglobin, intensely enhancing soft tissue) may also be suppressed.[115]

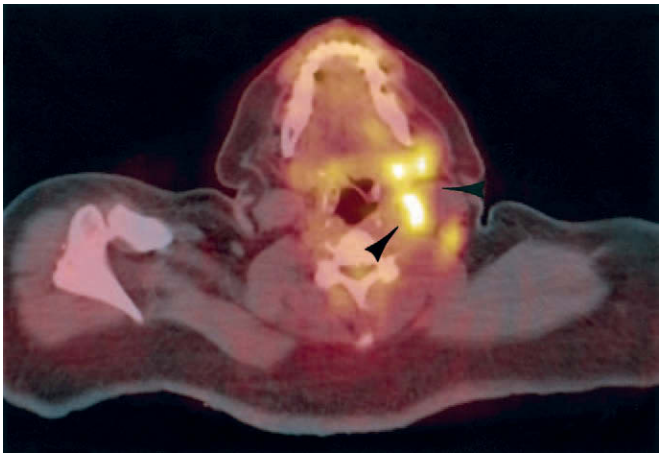

Figure 106-18. Combined positron emission tomography/computed tomography (PET/CT) image of the neck demonstrating increased PET activity *(arrowhead)* superimposed on the corresponding CT image. The increased PET activity indicates hypermetabolic tumor. The CT image allows accurate anatomic localization of this tumor.

MR techniques and applications such as magnetization transfer improves the contrast between lesions and background tissue.[116-120] Reconstruction algorithms permit simultaneous 3D depiction of the tumor volume embedded within the surrounding soft tissues. This display assists the transformation of two-dimensional information into a 3D format and allows the examiner to "dissect" the display to a desired tissue depth.[121,122] Diffusion-weighted MRI, nanoparticle-enhanced MRI, and perfusion MRI are also currently being explored.[123]

Open-bore units are being used to guide biopsies.[124,125] These units are useful for the claustrophobic patient, who would otherwise be unable to tolerate the confining space of conventional magnets. Unfortunately, many of these scanners lack sufficient magnet strength to optimally display difficult or complex anatomic relationships.

Special applications such as MR spectroscopy have been evaluated for certain head and neck tumors.[126] MR spectroscopy measures and graphically displays tissue metabolites.[127] Choline (Cho), a precursor to phosphatidylcholine, is involved in membrane turnover. An elevation of the Cho spectral peak within tissue implies cellular turnover and may serve as a potential tumor marker.[128,129] MR spectroscopy may prove useful by using metabolic data to map tumors and complement anatomic data from conventional imaging.[130] Although MR spectroscopy has advanced rapidly on the intracranial application front, initial enthusiasm for head and neck lesions has dampened. Formidable technical issues such as artifacts from paranasal sinuses, airway, neck fat, and blood vessels have made consistently reliable spectra difficult. Therefore widespread use in head and neck awaits significant refinement.

Combined positron emission tomography (PET) CT is a new technique in which near simultaneously acquired PET and CT information is superimposed. This image fusion has the advantage of comparing superior sensitive functional PET data with the superior anatomic data offered by CT (Fig. 106-18). Promising applications include evaluation of post-therapy patients for evidence of recurrent tumor, analysis of ambiguous lymph nodes and soft tissue masses, and verification of biopsy sites.[123,131,132]

Normal Anatomy

Accurate interpretation of scans of the larynx necessitates understanding of normal laryngeal anatomy as depicted on CT or MR images (Figs. 106-19 through 106-26).[133] Some degree of normally occurring

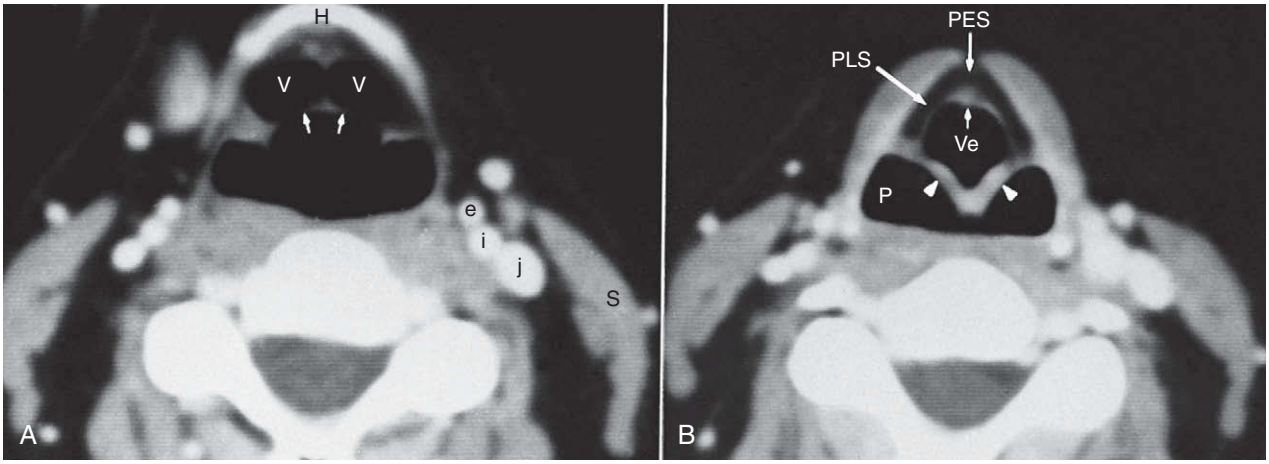

Figure 106-19. Normal anatomy on computed tomography showing supraglottic larynx after intravenous contrast injection. **A,** The two air-filled valleculae *(V)* separated by the median glossoepiglottic fold are seen anterior to the epiglottis *(arrows)*. The jugular vein *(j)*, internal carotid artery *(i)*, external carotid artery *(e)*, sternocleidomastoid muscle *(S)*, and hyoid bone *(H)* are also seen. **B,** Eight millimeters inferiorly, a fat-containing pre-epiglottic space *(PES)* anteriorly contrasts with the soft tissue density of the epiglottis *(arrow)*. The fat in the pre-epiglottic space extends posterolaterally into the paralaryngeal (paraglottic) space *(PLS)*. The aryepiglottic folds *(arrowheads)* separate the air-containing pyriform sinuses *(P)* and the laryngeal vestibule *(Ve)*.

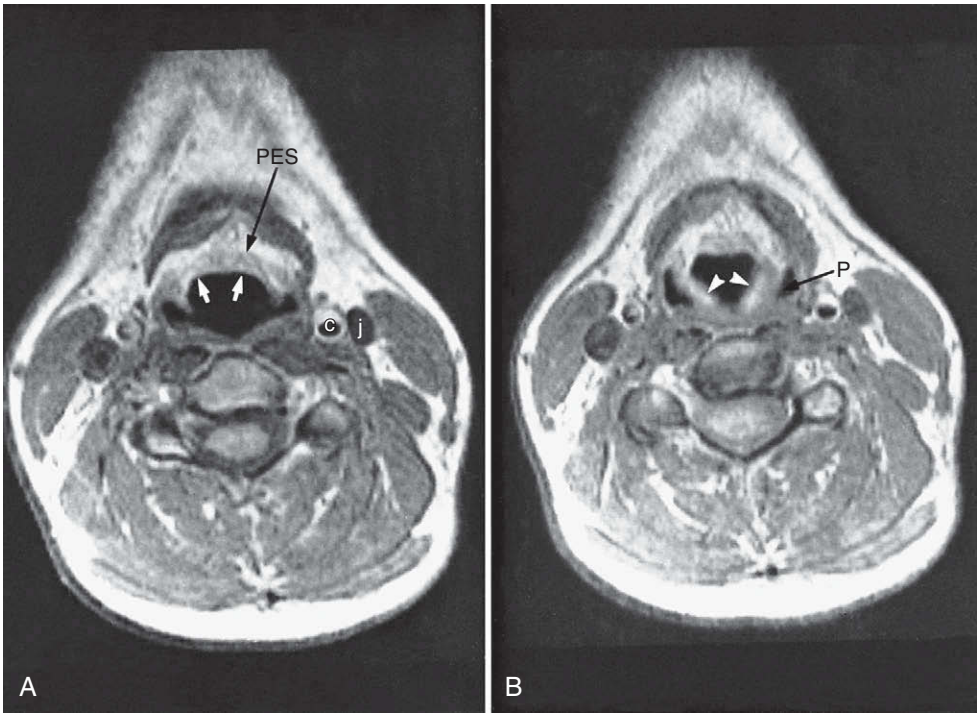

Figure 106-20. Normal anatomy of the supraglottic larynx on magnetic resonance imaging. **A**, A fat-filled pre-epiglottic space *(PES)* is anterior to the epiglottis *(arrows)*. The internal carotid artery *(c)* and internal jugular vein *(j)* are also seen. Fat on this sequence is higher in signal intensity than the epiglottis or muscle. **B,** Five millimeters inferiorly, the pyriform sinuses *(P)* are lateral to the aryepiglottic folds *(arrowheads)*.

asymmetry should be recognized in patients with suspected laryngeal abnormalities to avoid misinterpretation of scans.

The laryngeal skeleton consists of the epiglottic, thyroid, arytenoid, and cricoid cartilages. The hyoid bone is considered part of the lingual apparatus, but relationships with the larynx are important. The unique appearance of the hyoid bone and laryngeal cartilages allows for easy orientation on CT. The degree of cartilaginous mineralization varies considerably. In particular, calcification of the thyroid cartilage may be irregular and incomplete, simulating neoplastic invasion. The calcified or ossified portions of the laryngeal skeleton are hypointense on MR scans and may be more difficult to identify than on CT. Non-calcified cartilage such as the epiglottis is intermediate in signal intensity. Fat within medullary spaces is hyperintense on T1-weighted sequences.

The intrinsic soft tissue structures of the larynx include the aryepiglottic folds, true vocal cords, and false vocal cords. The aryepiglottic folds, which form the medial walls of the pyriform sinuses, extend obliquely from the top of the epiglottis toward the false cords inferiorly (see Figs. 106-19 and 106-20). Although the aryepiglottic folds may be asymmetric during inspiration, distention of the pyriform sinuses during modified Valsalva's maneuver or phonation results in a more symmetric appearance.

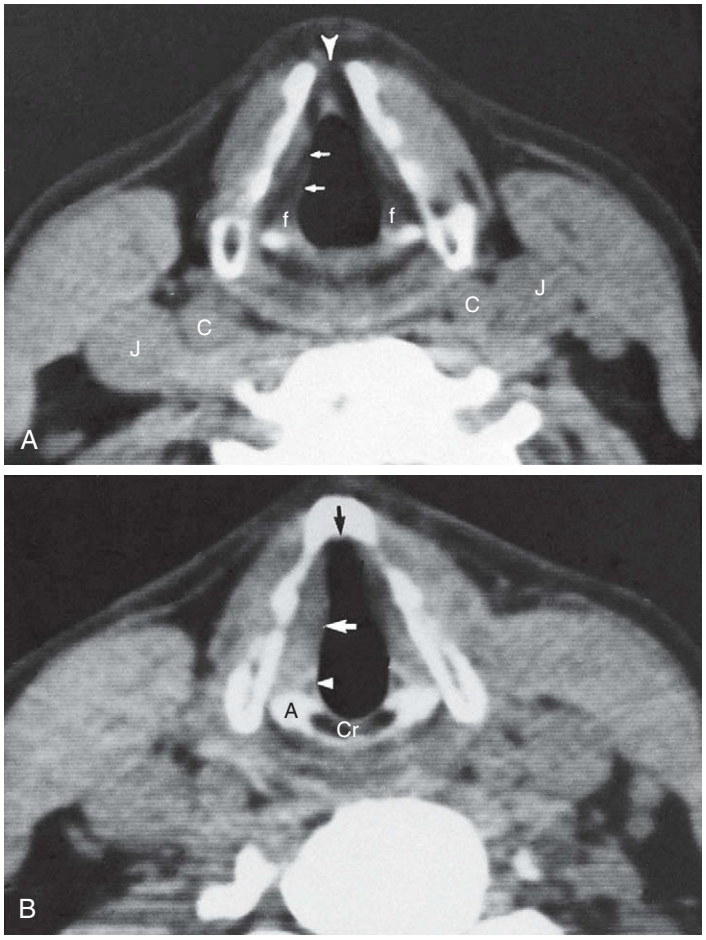

Figure 106-21. Normal anatomy of the false and true vocal cords on computed tomography. **A,** The false vocal cords *(arrows)*, medial to the fat-containing paraglottic space, lie at the level of the foot processes *(f)* of the arytenoid cartilages. The superior thyroid notch *(arrowhead)* is noted anteriorly between the thyroid laminae. The thyroid cartilage is incompletely calcified, which is a normal variation that should not be mistaken for cartilage destruction. The jugular vein *(J)* and carotid artery *(C)* are also seen. **B,** Four millimeters inferiorly, the true vocal cords *(white arrow)* are seen at the level of the vocal processes *(arrowhead)* of the arytenoid cartilages *(A)*, located superolateral to the upper posterior border of the cricoid cartilage *(Cr)*. Thyroid lamina join anteriorly to form the laryngeal prominence. The soft tissues at the anterior commissure *(black arrow)* are normally less than 2 mm in thickness.

Figure 106-22. Normal anatomy of the true vocal cords on magnetic resonance imaging. The true cords *(arrowheads)* are of soft tissue intensity. The arytenoids *(small arrows)* and thyroid lamina *(curved arrow)* are seen as high signal intensity on this sequence because of fatty marrow. The superior portion of the cricoid is also shown *(arrow)*.

The pyriform sinuses are bilateral air-containing structures bulging into the laterally positioned paraglottic spaces (see Figs. 106-19 and 106-20). They are partially collapsed during quiet breathing but distend during modified Valsalva's maneuver or phonation. The pyriform sinuses are frequently asymmetric on scans, both in their size and their caudal extent.

The true vocal cords are visualized in an abducted position during slow inspiration (see Figs. 106-21 and 106-22). They are triangular in shape and wider posteriorly, measuring about 9 mm in thickness. The posterior commissure is located in this area between the vocal processes of the arytenoids. At the anterior commissure, where the true vocal cords meet and attach to the thyroid cartilage, the thickness tapers to 1 mm. Only minimal soft tissue thickening (≤1 to 2 mm) should be seen in the anterior or posterior commissure. If the cords are adducted, the soft tissues in the anterior and posterior commissures may appear falsely thickened. The rapid scanning times with spiral CT permit study of vocal cord motion and verification of questionable abnormalities detected with dynamic CT.

The false vocal cords appear as a thicker band of soft tissue at the level where the foot processes of the arytenoids are present (see Fig. 106-21). In contrast to the region of the anterior commissure and true vocal cords, normally appreciable soft tissue thickening occurs anteriorly behind the thyroid lamina, in part because of insertion of the

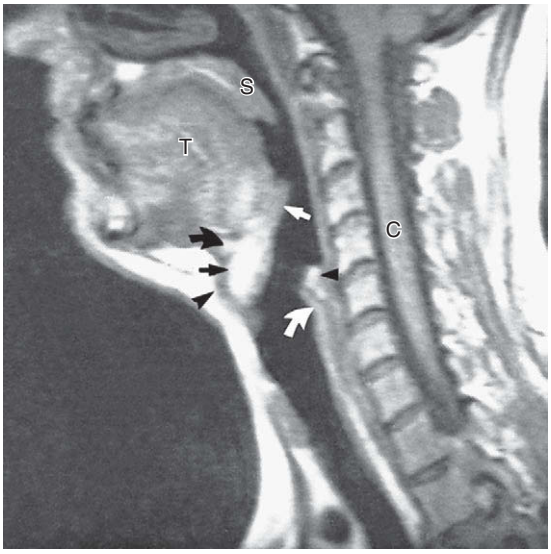

Figure 106-23. Normal anatomy of the midsagittal plane on magnetic resonance imaging. Epiglottis *(white arrow)*, fat-containing pre-epiglottic space *(black arrow)*, extrinsic strap muscles *(black arrowhead)*, arytenoid cartilages and muscles *(small black arrowhead)*, hyoid bone *(curved black arrow)*, and cricoid cartilage *(curved white arrow)* are shown. The soft palate *(S)*, tongue *(T)*, and spinal cord *(C)* are also seen.

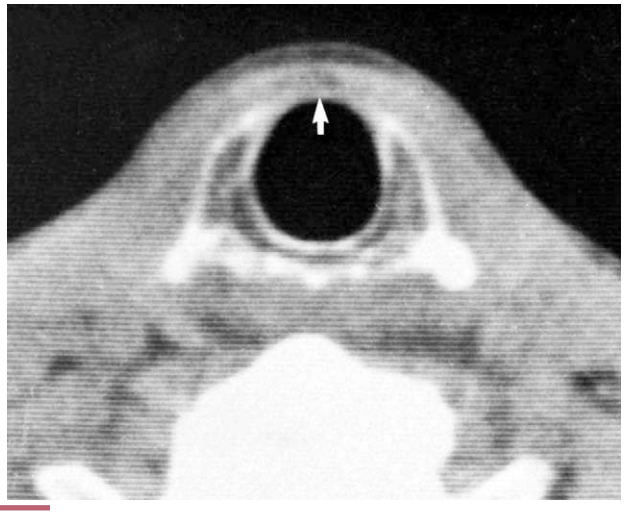

Figure 106-24. Normal anatomy of the subglottic level on computed tomography. The cricoid ring is almost complete, except in the area of the cricothyroid membrane anteriorly *(arrow)*. Note that the circular subglottic airway is in close apposition to the cricoid cartilage.

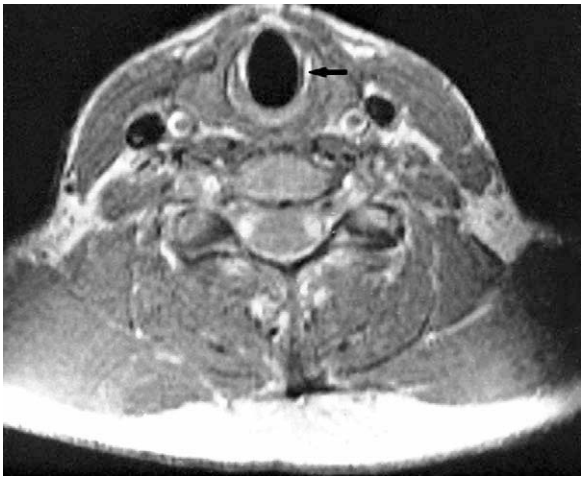

Figure 106-25. Normal anatomy of the subglottic level on magnetic resonance imaging. Fat-containing cricoid surrounds the airway *(arrow)*.

Figure 106-26. Normal anatomy of the coronal plane on magnetic resonance imaging. Cricoid cartilage *(large black arrowhead)*, thyroid cartilage *(small black arrowhead)*, true cords *(white arrowhead)*, and aryepiglottic folds *(white arrow)* are shown.

thyroepiglottic ligament. The laryngeal ventricle separating the true and false vocal cords is visualized only in 10% of patients scanned in the axial plane because of partial volume averaging. On MR imaging, the ventricle is best identified in the coronal plane. The use of a reverse "e" maneuver may improve visualization of the laryngeal ventricle.

The soft tissue (pre-epiglottic and paraglottic spaces) deep to the endolarynx is well visualized on CT because it is composed primarily of fat. Consequently it is more hypodense than the true vocal cords or neoplasm (see Fig. 106-19). On MR imaging, these spaces display relative hyperintensity on T1-weighted images, reflecting the fat composition. Sagittal MR images are especially useful in evaluating the preepiglottic space (see Figs. 106-20 and 106-23).[134,135]

The laryngeal airway has different shapes at different levels. The laryngeal vestibule or supraglottic portion of the airway is elliptic with a long lateral axis. The anterior-posterior dimension of the airway increases at the level of the true vocal cords. The subglottic region has a circular configuration with a flat posterior border at the level of the trachea. The cricoid ring indicates the level of the subglottic space. In this area, soft tissue should not be detectable on CT or MR scans between the inner surface of the cricoid cartilage and the airway (see Figs. 106-24 through 106-26).

The jugular veins and carotid arteries can be clearly visualized posterolateral to the thyroid laminae. The right jugular vein, which is usually larger than the left, may be confused with lymphadenopathy on imaging and physical examination. In such cases, CT performed after administration of intravenous contrast improves identification of the normal vascular structures. Rapidly flowing blood within the jugular vein and carotid arteries is devoid of signal on MR imaging and

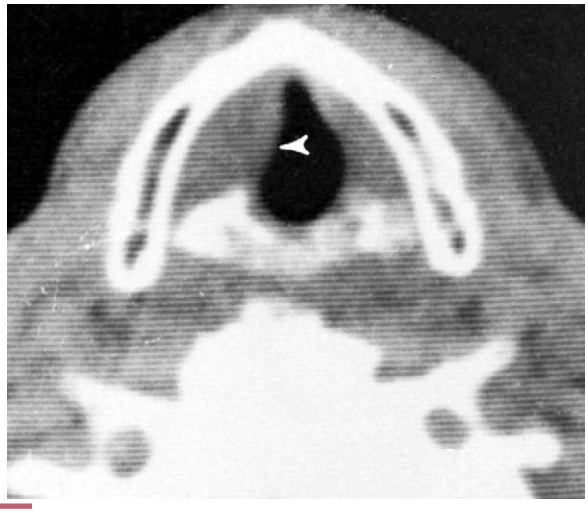

Figure 106-27. Localized true vocal cord carcinoma on computed tomography. A neoplasm diffusely thickens the right true vocal cord *(arrowhead)*. CT more inferiorly showed no subglottic extension.

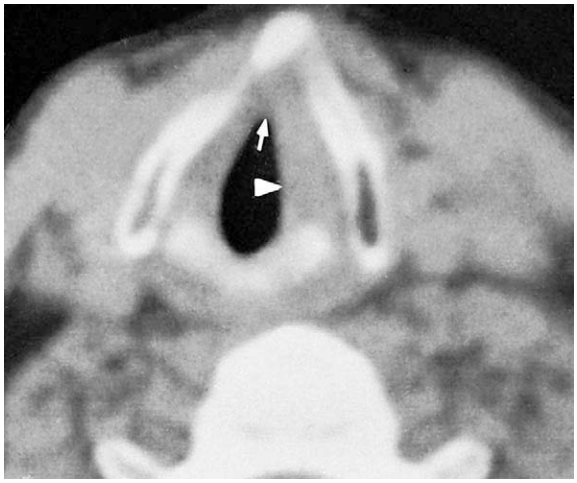

Figure 106-28. True vocal cord carcinoma with involvement of anterior commissure on computed tomography. Tumor of the left true vocal cord *(arrowhead)* extends anteriorly to involve the anterior commissure *(arrow)*.

therefore can be easily separated from soft tissue structures; however, turbulence of flow may require careful image analysis.[136]

Glottic Tumors

Carcinomas confined to a normally mobile true vocal cord may be treated with radiotherapy, laser, cordectomy, or partial laryngectomy.[81,82] In these cases, imaging may be normal or show nonspecific focal or diffuse vocal cord thickening (Fig. 106-27). If the true cord is fixed in the midline, imaging shows deep infiltration of tumor before surgery.[43] CT cannot distinguish whether the cord is paramedian in position because of paralysis or direct involvement with tumor. MR imaging is helpful in this determination because of its superior soft tissue contrast. Nevertheless, signal characteristics are often nonspecific. CT occasionally shows that vocal cord fixation or a laryngeal mass is secondary to prior occult trauma and that the laryngeal neoplasm is less extensive than suspected clinically.

Glottic tumors spread anteriorly, posteriorly, inferiorly, or laterally into the paraglottic space. The primary role of imaging true vocal cord neoplasms is evaluation of the anterior and posterior commissures, the paraglottic and subglottic spaces, and the thyroid and cricoid cartilages. CT and MR imaging reliably show tumor involvement at these sites. If involvement is greater than 30% of the contralateral true vocal cord, thyroid cartilage invasion is evident, or subglottic extension of tumor is demonstrated, partial laryngectomy is generally contraindicated.[81,82]

Tumors can extend anteriorly to the anterior commissure and posteriorly to the arytenoid cartilage, posterior commissure, and cricoarytenoid joint (Fig. 106-28). Identification of air abutting the thyroid cartilage at the anterior commissure on transverse images indicates tumor absence in this area. If soft tissue thickening of the anterior commissure is greater than 1 mm on imaging, tumor invasion is implied.[71,89,137] Tumor that has reached the anterior commissure can grow into the thyroid cartilage, pre-epiglottic space, opposite vocal cord, or subglottic space.[138] Care should be taken to avoid misdiagnosis of anterior tumor spread caused by various cord configurations that occur in different phases of respiration. Tumor that has reached the posterior commissure results in soft tissue thickening over the arytenoid cartilages; rotation or displacement of the arytenoid cartilages may also occur.

Subglottic tumor is diagnosed on imaging by determining the relationship of the tumor mass to the level of the true cords (Fig. 106-29). Exophytic tumor will distort the tracheal air column (Fig. 106-30). If the extent of tumor caudad from the inferior margin of true vocal cords is greater than 1 cm anteriorly and 6 mm posteriorly, total laryngectomy may be indicated.[81,138] However, the relationship between the subglottic tumor and the cricoid cartilage is more important than a standard measurement because the cricoid cartilage supports the larynx. On CT and MR scans, no measurable soft tissue thickness should be observed between the cricoid cartilage and the airway. MR imaging also can image the coronal plane, which allows tracing of tumor extension below the level of the conus elasticus.[68]

Imaging also shows spread of laryngeal carcinoma into the paraglottic space. Although a thin line of fat density may be seen medial to the thyroid cartilage at the level of the true vocal cords, the paraglottic space is wider in the area of the false vocal cord.[139] Therefore extension into the paraglottic area is easier to show at this level. CT, however, may not be able to determine extension into the false vocal cord itself; this is better evaluated by laryngoscopy. Coronal MR images help document paraglottic extension.

CT and MR imaging are excellent methods for showing cartilaginous invasion by laryngeal carcinoma, although limitations exist.[15,73,140-143] Because the thyroid cartilage normally may have an irregular pattern of calcification and ossification, neoplastic involvement can be confidently diagnosed only when advanced. Frank destruction of the cartilage by an adjacent mass or demonstration of intramedullary cancer are the most reliable imaging signs of cartilage invasion. On CT, marked destruction of the cartilage appears as fragmentation of the cartilage with lateral extension of soft tissue tumor (Fig. 106-31). Cartilage involvement may also be suggested by abnormal bowing of the thyroid cartilage. Because of its symmetry, sclerosis or destruction of the cricoid is easier to appreciate on CT than on MR scans.[137]

Ossified portions of cartilage are at higher risk for invasion possibly because of vascular channel penetration, whereas intact perichondrium surrounding avascular unossified cartilage resists tumor encroachment.[144-148] Almost 50% of pathologically sclerotic cartilages associated with a mass show invasion at surgery.[145,149] Nonmalignant causes of thyroid cartilage sclerosis include rheumatoid arthritis and polychondritis; however, these conditions can usually be differentiated from cancer by the presence of sore throat, difficult inspiration, subluxation of the arytenoid cartilages, and the absence of a mass.[145]

Many investigators contend that MR images detect cartilage invasion better than CT.[72,73,126,150-153] On MR scans, cortical bone and dense calcification have no signal on T1- or T2-weighted sequences. However, medullary fat is hyperintense on T1-weighted images. Invasion of fat lowers this signal and can be further differentiated from nonossified cartilage on T1-weighted and T2-weighted images because of the hyperintensity displayed by tumor (Fig. 106-32).[42,72,109,142,146,154,155] Almost 10% of healthy thyroid cartilage may have focal areas of signal intensity; however, an associated mass increases confidence in the diagnosis, especially if the mass exceeds 5 cm^3 in volume.[42,156] If the imaging

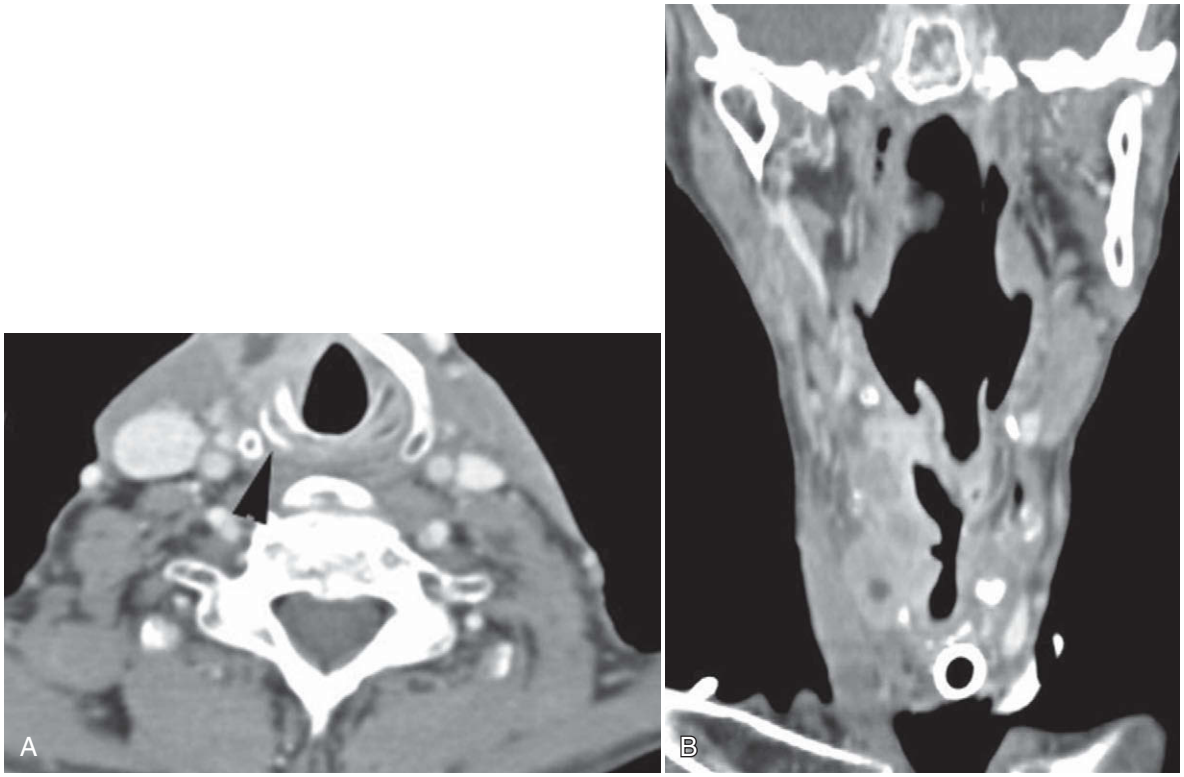

Figure 106-29. Massive transglottic carcinoma on computed tomography. **A,** Necrotic tumor has destroyed the right thyroid cartilage lamina. The right portion of the cricoid cartilage is sclerotic *(arrowhead),* indicating involvement with tumor. The mucosal thickening adjacent to the cricoid and extending inferiorly (slices not shown) suggests subglottic extension. **B,** Reformatted coronal scan nicely demonstrates the cranio-caudal extent of the tumor. Spiral scanning technology permits superb multiplanar reformations.

Figure 106-30. Magnetic resonance imaging of subglottic extension of carcinoma shows high signal in an extensive neck mass *(arrow).* Subglottic extension *(arrowheads)* compresses the tracheal air column.

findings are equivocal, biopsy of the cartilage confirms the need for radical surgery.

Supraglottic Tumors

Imaging is extremely useful in staging supraglottic carcinoma and may discover more advanced disease than clinically suspected in up to 20% of patients.[157] Carcinoma of the epiglottis is seen on imaging as thickening of one of the margins of the epiglottis or as a large soft tissue mass (Figs. 106-33 and 106-34). Localized carcinoma of the epiglottis may be managed with radiotherapy or a supraglottic laryngectomy.[158] However, if there is invasion of the pre-epiglottic space, radiotherapy alone is considered inadequate.[159] Extension of epiglottic carcinoma to the pre-epiglottic space is frequently difficult to show clinically. CT and MR imaging help evaluate the pre-epiglottic and paraglottic spaces because infiltrating tumors usually obliterate the normal appearance of fat in these areas (Figs. 106-35 and 106-36).[68,109,160] T1-weighted sagittal MR imaging is especially useful for examining pre-epiglottic tumor invasion.[146,161] Transversely oriented CT or MR images are helpful when the vocal cords and the space immediately superior to the cords are normal. Similarly, transverse slices are useful when the cords are unequivocally involved. In patients with supraglottic disease that approaches the ventricles but in whom transverse imaging does not clearly depict the ventricle, a coronal MR scan is the best study.[68] CT and MR scans can also show deep spread of tumor into the region of the anterior commissure. Spread of tumor into the base of the tongue is best evaluated by sagittal MR images.

Carcinoma of the aryepiglottic fold is recognizable by thickening of the aryepiglottic fold and is often better seen on scans obtained during phonation or a modified Valsalva's maneuver (Fig. 106-37). The rapid scanning speed of spiral CT is ideally suited for such functional imaging. CT obtained during phonation shows distention of the pyriform sinuses and thinning of the healthy aryepiglottic fold, allowing for easier CT demonstration of tumor. If the tumor extends anteriorly across the midline, imaging studies may not determine whether the tumor originates in the aryepiglottic fold or in the epiglottis.

Neoplasms of the pyriform sinus generally are more aggressive than lesions of the endolarynx and have a high incidence of thyroid cartilage invasion. They may also spread to the true and false vocal cords, aryepiglottic folds, and pre-epiglottic space. CT or MR images can show tumor spread outside of the larynx between the thyroid and

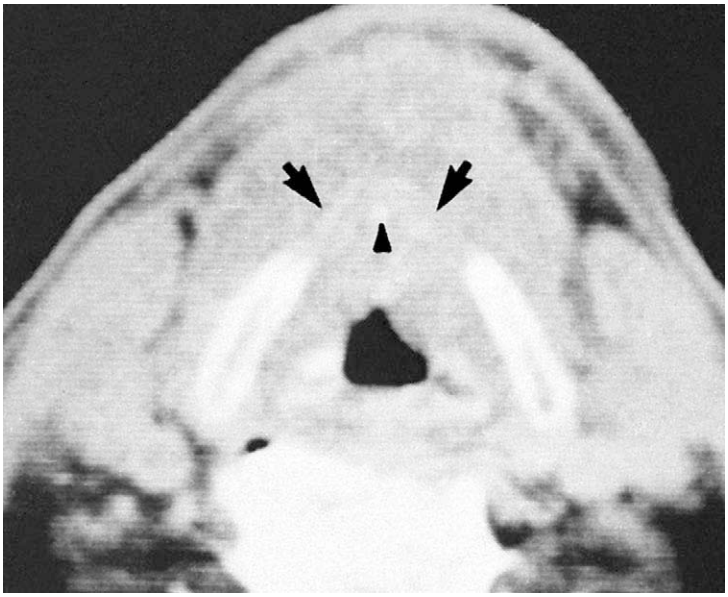

Figure 106-31. Thyroid cartilage destruction on computed tomography. A large neoplasm involving the anterior commissure destroys both thyroid alae anteriorly *(arrows)* and extends into the adjacent soft tissues. A small bony fragment can be seen within the tumor *(arrowhead)*.

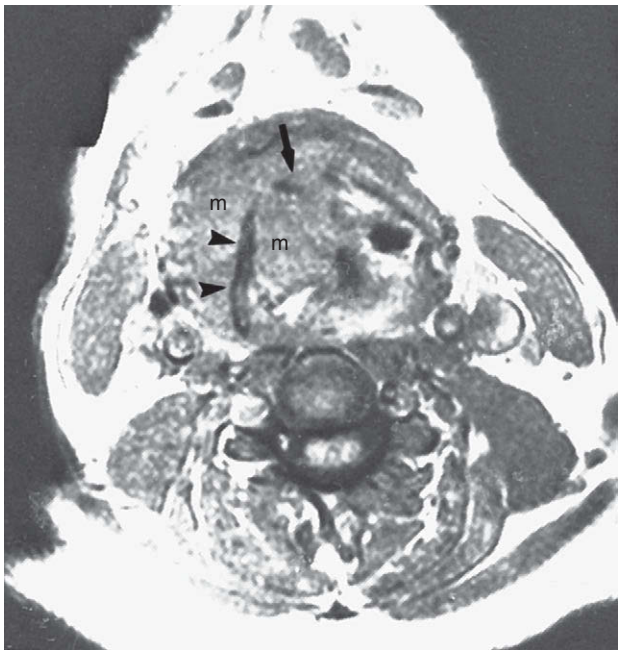

Figure 106-32. T1-weighted magnetic resonance imaging shows thyroid cartilage destruction. An extensive carcinoma *(m)* envelopes the thyroid cartilage destroying anterior portions *(arrow)*. The invaded lateral cartilage has lost its hyperintensity because of tumor replacement *(arrowheads)*.

cricoid cartilages. This appearance usually is seen only with pyriform sinus tumors (Fig. 106-38).[162]

In addition to using imaging appearances to evaluate stage of disease, quantitative methods may prove valuable. Calculated pretreatment tumor volumes using CT may predict local control following radiation or surgery.[163,164]

Transglottic Tumors

Transglottic tumors extend across the laryngeal ventricle to involve the supraglottic, glottic, and often the subglottic portions of the larynx (see Fig. 106-38).[137,165] This extension of tumor may be mucosal or submucosal. Transglottic tumors have a high incidence of thyroid cartilage destruction and extralaryngeal spread that may not be apparent clinically. Coronal MR scans may better show spread of tumor than axial images. MR imaging is also effective, demonstrating tumor involvement of the prevertebral space.[166]

Lymph Nodes

Most enlarged lymph nodes identified on CT are clinically palpable, but occasionally CT may show enlarged lymph nodes that cannot be felt on physical examination.[167] MR imaging and ultrasonography are also effective methods for evaluating lymph nodes.[123,168,169] Imaging also helps show the relationship of enlarged lymph nodes or tumor extension to adjacent vessels (Fig. 106-39). Surgical salvage is less likely if the neoplasm totally encases or invades vascular structures. Knowledge of the vessels of the neck is crucial in order to avoid mistakenly identifying a vein as a lymph node.[136]

Post-Therapy Larynx

Physical examination of patients who have undergone prior irradiation or surgery may be difficult because of altered normal laryngeal anatomy and swelling of the adjacent soft tissues. Although CT can define the anatomy of the postoperative larynx and assist laryngoscopy in the detection of recurrent neoplasm (Fig. 106-40),[170-173] MR scanning is now preferred for post-therapy evaluation.[174]

In patients with previous vertical hemilaryngectomy, recurrent intralaryngeal cancer is suggested by increased width of the contralateral true vocal cord, convexity of the postsurgical pseudocord at the glottic level, mass in the subglottic region, or masses in the extralaryngeal neck.[171] In patients with supraglottic subtotal laryngectomy, recurrence is usually heralded by mass effect on the pharyngeal or laryngeal air column, obliteration of the adjacent soft tissue planes, destruction of cartilage, or development of lymphadenopathy.[172] Imaging signs of recurrence in patients who have undergone total laryngectomy include masses involving the internal jugular lymph node chain adjacent to the neopharynx or neurovascular bundle, masses within the mediastinum, thickening of the tracheal wall, or thickening of the soft tissues surrounding the tracheostomy.[170] Nodular masses at the site of radical neck dissection are unusual and should prompt evaluation for tumor.[173] Care should be taken in radiographically evaluating the postoperative patient because abscess or granulation tissue can mimic recurrent tumor.[171]

Regardless of the surgical procedure, hemorrhage and edema are usually evident on imaging during the early postoperative period and persist for 4 to 6 weeks. A baseline scan is therefore best postponed for

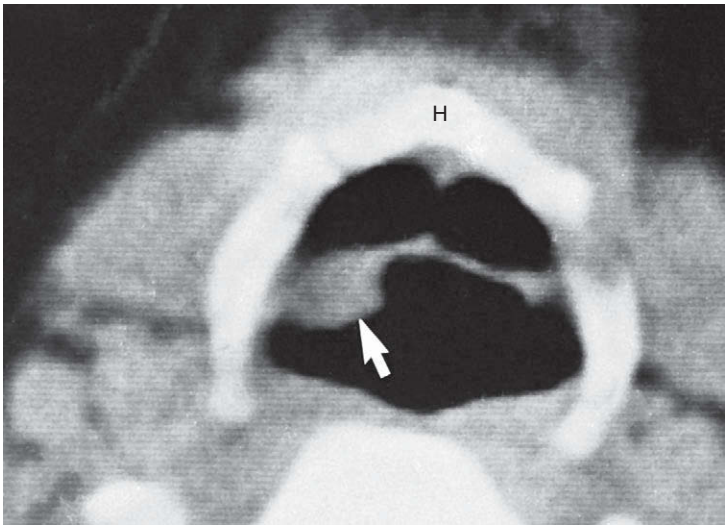

Figure 106-33. Epiglottic carcinoma on computed tomography. A tumor produces thickening of the right side of the epiglottis *(arrow)* at the level of the hyoid bone *(H)*.

The right pyriform sinus is shown *(P)*. **B,** CT performed during a modified Valsalva's maneuver more clearly shows a tumor involving the left aryepiglottic fold *(arrow)* and compressing the left pyriform sinus *(P)*.

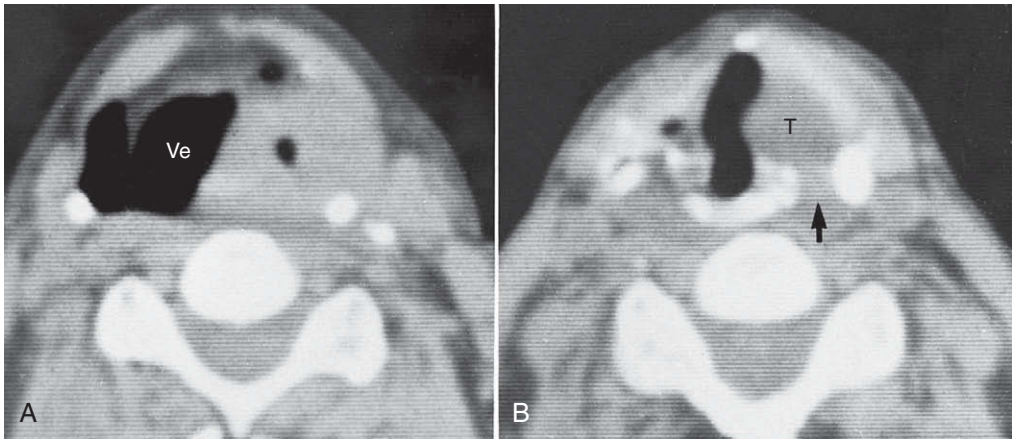

Figure 106-38. Transglottic pyriform sinus carcinoma on computed tomography. **A,** A large tumor is seen arising in the left pyriform sinus and displacing the laryngeal vestibule *(Ve)* to the right. **B,** Tumor extends inferiorly to involve the left true vocal cord *(T)* and widen the distance *(arrow)* between the left thyroid lamina and the arytenoid cartilage.

at least 1 month and preferably for 6 to 8 weeks to avoid potentially confusing soft tissue masses.[82] Scanning every 4 to 6 months for the first 3 years is recommended.[175,176] Examinations are then performed yearly unless an ominous change in clinical status prompts a more timely scan.[176]

Typically, cancer recurrence within the first 2 months after surgery is unusual if the specimen margins were free of tumor.[176] With time, tissue planes become more defined but remain somewhat obscured compared with the preoperative images. Scar tends to be less dense on CT but may be difficult to differentiate from fibrous tissue without biopsy. MR images usually cannot reliably distinguish recurrent tumor from edema, radiation necrosis, or inflammatory lesions.[146] Fibrosis tends to be hypointense on T2-weighted images, whereas recurrent tumor is hyperintense.[175] Growth of any soft tissue density on imaging is another sign of recurrence, whereas scar remains stable or diminishes with time.[176]

Radiotherapy can also change the appearance of the neck on imaging.[177] The major and minor salivary glands are especially sensitive to radiation, and 1000 to 2000 cGy causes mucositis.[178] On CT, the major salivary glands enhance and eventually atrophy.[179] 3D Radiation port planning shields the parotid glands and ameliorates post-therapy xerostomia.[92] The subcutaneous fat becomes thickened and streaked with linear soft tissue densities at 6500 to 7000 cGy.[137,179] The skin also may become thickened. With doses approaching 7000 cGy, skin ulceration becomes increasingly likely.[178] At doses greater than 7000 cGy, the pharyngeal walls and aryepiglottic folds become thickened as the paraglottic and pre-epiglottic spaces increase in CT density.[161,178] Higher doses of radiation weaken membranes and cartilage and may contribute to chondronecrosis and cartilage collapse.[137] Chondronecrosis is difficult to differentiate from recurrent tumor on CT. The soft tissues are thickened, and cartilages may be distorted or fragmented.[82] Radiated cartilage is also more prone to infection and may develop perichondritis if biopsied.[180]

Other organs may be affected by neck radiation. The adjacent skeleton may show hyperintense marrow signal on T1-weighted images because of post-therapy marrow fat infiltration, the mandible may succumb to osteoradionecrosis, and rarely, the radiated bone may give rise to sarcomas.[178] Osteoradionecrosis involves the devitalization of radiated bone and is caused by vascular damage and direct injury to osteoblasts augmented by xerostomia and resultant dental caries. The involved bone has focal demineralization, disorganized trabeculae, cortical thickening, patchy sclerosis, and occasionally pathologic

fractures.[178] Periosteal reaction is unusual and should prompt consideration of infection.

Carotid rupture or "blow out" is a life-threatening complication with a high morbidity and mortality. Catheter angiography with endovascular therapy effectively diagnoses and treats many of these lesions.[181]

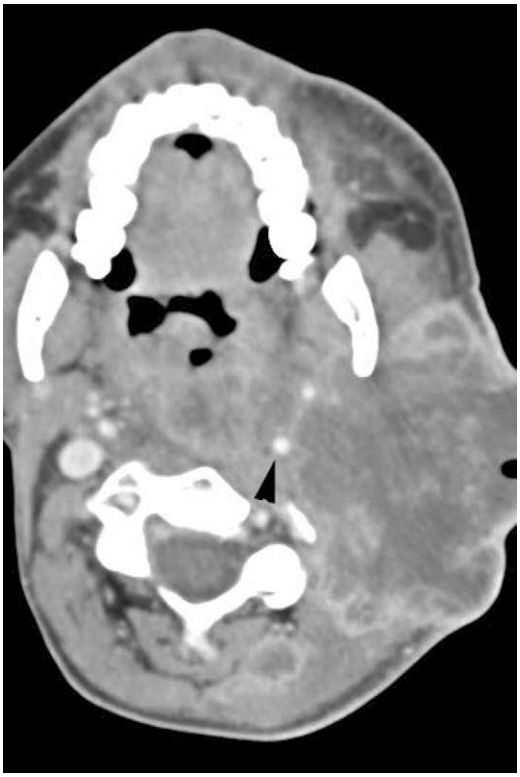

Figure 106-39. Laryngeal carcinoma with lymph node metastases on computed tomography. Massive necrotic cervical and retropharyngeal lymph node metastases are seen encasing the left internal carotid arteries *(arrowhead)*.

Differentiating postradiation changes from recurrent tumor is difficult on imaging studies.[182] Intralaryngeal edema may be symmetric or asymmetric and therefore offers no definitive criteria for tumor recurrence.[82,161,178] Residual tumor usually maintains a high signal intensity on MR scans, and the signal intensity of successfully managed tumor tends to diminish with development of fibrosis.[183] However, similar nonspecific and occasionally confusing signal intensities can also be produced by edema, hyperplastic lymphadenopathy, infection, and hemorrhage.[174,178,183,184] Differentiation between fibrosis and early recurrent tumor often requires laryngoscopic biopsy. Complete or near complete resolution of the primary lesion on imaging is one of the best criteria for a successful radiation response. Residual mass greater than 50% of the original tumor volume usually indicates therapy failure.[185] Finally, growth of associated soft tissue mass suggests tumor recurrence. The appearance of new focal masses and ulcerations on barium pharyngography supports the clinical diagnosis of recurrence.[186] Other modalities such as PET or single photon emission CT (SPECT) with fluorodeoxyglucose may be more useful than conventional cross-sectional imaging.[73,161] Combined PET/CT merges PET and CT data into a single scan that couples functional metabolic information with precise anatomic localization. This information can be used for more confident diagnosis of recurrent tumor and for biopsy.[131]

Postradiation sarcomas are rare and usually appear after a latent period lasting decades. Because of the age of the typical neck cancer patient, the associated multisystem debilities from chronic smoking, and the unfortunately high rate of recurrent tumor, sarcomas are usually not seen.

Laryngeal Trauma

Laryngeal trauma usually results from direct blunt injury to the anterior neck. The usual mechanism for the observed damage is the forceful impact of larynx against the cervical spine. The thyroid cartilage may be fractured in almost 50% of cases. The cricoarytenoid joint may also be dislocated. The ring-shaped cricoid cartilage may also fracture. Because of its configuration, usually two or more sites are involved. Rarely, the epiglottis may be disrupted.[187] Hemorrhage and edema may spread into the paraglottic and pre-epiglottic spaces.[188] Nondisplaced fractures may be managed conservatively; however, displaced and comminuted fractures require surgery.[189-191]

Cross-sectional imaging permits easy and rapid evaluation of the extent of cartilaginous injury, adjacent soft tissue changes (e.g., edema, hemorrhage), and the degree of airway compromise (Figs. 106-41 and

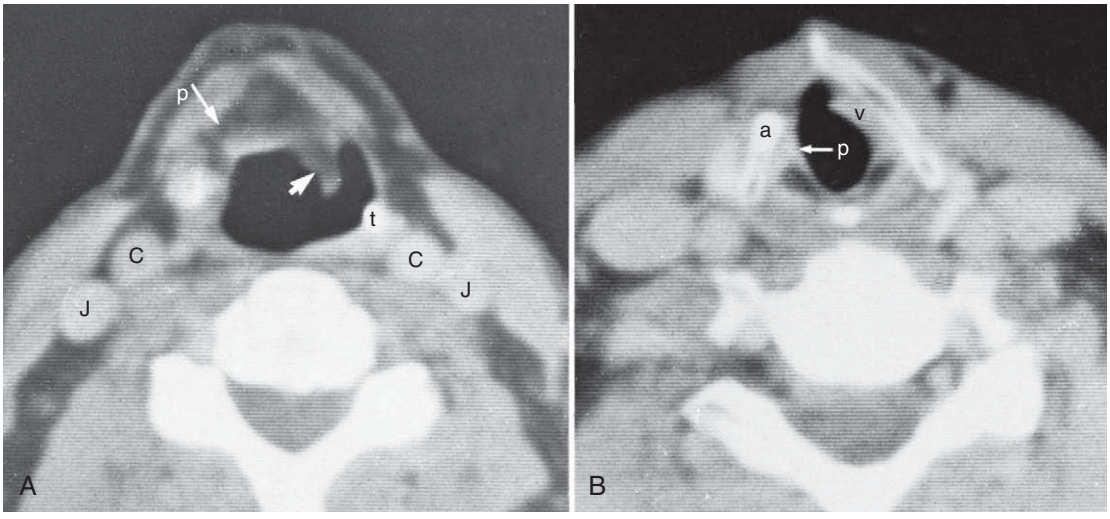

Figure 106-40. Computed tomography of normal anatomy after right vertical hemilaryngectomy. **A,** Level of superior cornua of the thyroid cartilage. *Arrow* points to residual aryepiglottic fold on the nonoperated side. The superior cornu of thyroid cartilage *(t)*, pre-epiglottic space with diminution of fat content *(p)*, carotid artery *(C)*, and internal jugular vein *(J)* are also seen. **B,** Level of glottis. Note the normal tilt of the airway to the right. The residual right thyroid ala *(a)*, surgically created pseudocord *(p)*, and residual left true vocal cord *(v)* are also seen.

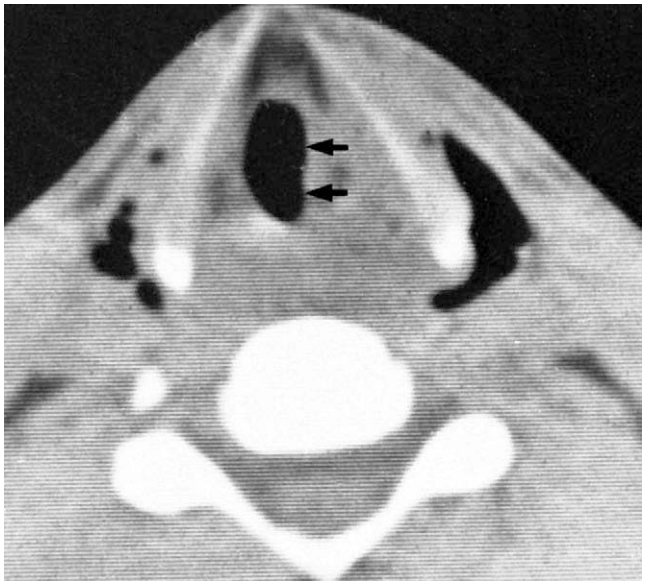

Figure 106-41. Soft tissue swelling with intact cartilage on computed tomography. Marked soft tissue thickening of the right paraglottic space is seen with compression of the airway *(arrows)*. Both thyroid alae are intact. Subcutaneous emphysema is secondary to a mucosal tear from an emergency tracheotomy.

Figure 106-42. Computed tomography shows multiple fractures of the thyroid cartilage. Extensive hemorrhage and edema almost totally obliterate the airway *(arrow)*.

106-42). Although conventional frontal and lateral radiography can provide useful information about the injured larynx, CT is preferred in the acutely injured patient because of its speed and ability to define calcified cartilages and soft tissue damage.[191-193] Spiral techniques are well suited for this situation. A complete examination of the neck can be acquired within seconds. With the addition of intravenous contrast, the raw CT data can be used to reconstruct 3D images of the carotid and vertebral arteries in a technique known as *CT angiography* (CTA). CT also is useful in patients with marked supraglottic swelling that prevents adequate laryngoscopic evaluation. CT can accurately identify

Figure 106-43. Foreign body. A straight pin *(arrow)* is lodged in the vallecula.

transverse or vertical fractures of the thyroid or cricoid cartilage, dislocation of the arytenoid cartilages at the cricoarytenoid joint, disruption of the cricothyroid joint, and extensive hemorrhage obliterating the airway. On occasion, the thyroid notch may be mistaken for a fracture, although contiguous sections usually provide the correct diagnosis. MR scans do not image calcified cartilage well and are therefore of no use in the initial evaluation of acute laryngeal trauma. Following patient stabilization, MR imaging may be useful in evaluating adjacent soft tissue damage or spinal injury.

Pharyngeal perforation is a rare but known complication of endotracheal intubation.[194,195] Traumatic intubation may also cause severe soft tissue damage, soft tissue emphysema, and arytenoid cartilage dislocation. Radiography of the area often shows air within the retropharyngeal soft tissues or in the anterior mediastinum. Oral contrast studies of the esophagus may define the problems related to perforation including subsequent development of a pseudodiverticulum.

Foreign Bodies

Foreign bodies in the larynx, trachea, or esophagus should be considered in patients, particularly children, with symptoms of acute or recurrent airway disease.[196,197] The radiopaque objects are readily diagnosed (Fig. 106-43). With plain-film techniques including high kilovoltage radiography, nonopaque foreign bodies also may be identified at times. The radiographic findings of aspirated foreign bodies vary directly with the location and extent of obstruction. On occasion, calcification of a laryngeal cartilage or of the stylohyoid ligaments may be confused with aspirated foreign bodies, although oblique projections usually permit separation (Fig. 106-44).[14]

In patients with suspected aspiration of a foreign body and a normal examination of the upper airway, inspiratory-expiratory plain chest radiography or decubitus chest radiography should be performed. These may show regional obstructive emphysema resulting from aspirated foreign bodies in the bronchi.[19,198] In uncooperative patients, fluoroscopic examination of diaphragmatic and mediastinal excursions may help determine if air trapping is present.

Figure 106-44. Stylohyoid ligament. Ossification of the stylohyoid ligament *(arrows)* can simulate a foreign body.

Figure 106-45. Esophageal foreign body in a child with stridor. Lateral view from a barium esophagram discloses a piece of meat *(large arrows)* in the upper esophagus compressing the posterior wall of the trachea *(small arrows).*

Swallowed foreign bodies in the upper esophagus may produce airway obstruction by compressing the posterior wall of the larynx and trachea. Tracheal compression, appreciated best on lateral radiography, is the expected radiographic finding. A barium esophagram is the definitive procedure in disclosing the occult esophageal foreign body, although CT may prove a useful adjunct method (Fig. 106-45).[197] If the object erodes through the esophageal wall, a retropharyngeal abscess may form with resulting compression of the adjacent airway.

Various synthetic materials may be inserted into the larynx and neck. Teflon injected into the paraglottic space adds bulk to a paralyzed or reconstructed vocal cord. Stents ensure patent airway in patients with laryngeal stenosis. Speaking tubes and valves help the laryngectomy patient use the esophagus when speaking. Tracheostomy tubes are inserted into the midcervical region in the patient with laryngeal stenosis, acutely compromised airway, or laryngectomy.[180] Some of these materials may be incidentally noted on scans in patients who have failed to mention past surgical procedures; these materials should not be misinterpreted as masses or traumatic foreign bodies.

CHAPTER ONE HUNDRED AND SEVEN

Malignant Tumors of the Larynx

William B. Armstrong

David E. Vokes

Robert H. Maisel

Key Points

- Squamous cell carcinoma (SCC) accounts for 85% to 95% of malignant laryngeal tumors.
- Tobacco and alcohol are the two most important risk factors for the development of laryngeal SCC.
- In the United States, laryngeal SCC occurs in the glottis more frequently than in the supraglottis. Subglottic SCC is rare.
- Laryngeal preservation may be achieved in properly selected cases by the use of conservation laryngeal surgery (partial laryngectomy), radiotherapy, or chemoradiotherapy.
- Early laryngeal SCC (stage I, II) is generally treated with single-modality therapy: either surgery or radiotherapy.
- Advanced laryngeal SCC (stage III, IV) is generally treated with combined-modality therapy.
- Endoscopic partial laryngectomy (transoral laser microsurgery) has similar oncologic outcomes to open partial laryngectomy with less functional morbidity.
- Total laryngectomy is the gold standard surgical procedure for the treatment of advanced laryngeal SCC.
- Concurrent chemoradiotherapy in a properly executed organ preservation protocol is the most effective nonsurgical treatment for advanced laryngeal SCC.
- The stage of disease is the most important factor predictive of prognosis, with N (nodal) stage more significant than T (tumor) stage.

Cancer of the larynx is the second most common malignancy of the upper aerodigestive tract (UADT), with over 11,000 cases annually in the United States alone.[1] Although a large variety of malignancies may occur in the larynx, 85% to 95% of laryngeal malignancies are squamous cell carcinoma (SCC), arising from the epithelial lining of the larynx.[2] The successful management of laryngeal malignancy requires accurate diagnosis, staging, assessment of patient wishes, and the selection of the most appropriate treatment for the individual patient, with close post-treatment surveillance. Treatment options have expanded and become more complex as new surgical procedures have been developed, advanced radiation therapy (RT) modalities have evolved, and new chemotherapeutic drugs have become available. These treatments still have significant morbidity and pose risks of adverse impact on voice quality, airway integrity, and swallowing. In recent decades, major efforts have been made to develop therapeutic strategies to preserve the larynx anatomically and functionally using RT, conservation laryngeal surgery, and chemoradiotherapy (CRT). These techniques are now important tools in the armamentarium of the head and neck oncologist. This chapter focuses on the principles of the diagnosis, evaluation, and treatment of SCC of the larynx. Non–squamous cell malignancies form a small but important subset of laryngeal malignancies and are also covered in detail. More specific details of surgical techniques are discussed in subsequent chapters.

Anatomy and Embryology

A detailed understanding of laryngeal embryology and anatomy is necessary to understand patterns of spread of laryngeal cancer and help understand its clinical behavior. The pattern of spread of tumors within the larynx is guided by the ligaments, connective tissue membranes, and major cartilages of the larynx that contain the spread of tumors, as well as by the soft tissue spaces within the larynx that act as pathways for the spread of tumors within and outside of the larynx. The lymphatic drainage of the three regions of the larynx differs, and therefore the risk of metastasis to regional lymph nodes, the likelihood for contralateral metastasis, and the first echelon nodes vary according to the site of the primary tumor. This characteristic of tumor behavior can be explained by the embryologic development of the larynx.

Embryology

The embryologic development of the larynx determines the pattern of metastatic spread of laryngeal cancer. The supraglottic larynx is derived from the buccopharyngeal primordium, which develops from the third and fourth branchial arches. The glottis and subglottis are derived from the tracheobronchial primordium from the sixth branchial arch and are formed by the union of lateral furrows that develop on each side of the tracheobronchial primordium. Therefore the larynx has a dual blood supply and lymphatic drainage. The supraglottis is supplied by the superior laryngeal arteries, and its lymphatic drainage follows these vessels to the carotid sheath to drain into deep cervical chain nodes in levels II and III. The glottis and subglottis are supplied by the inferior laryngeal arteries, and similarly, lymphatic drainage from these two regions follows these arteries to drain into prelaryngeal and pretracheal nodes (Level VI), before reaching the deep cervical chain nodes in level IV.[3]

The glottic region is formed by paired structures that fuse in the midline. The lymphatics drain unilaterally. The vocal folds have sparse

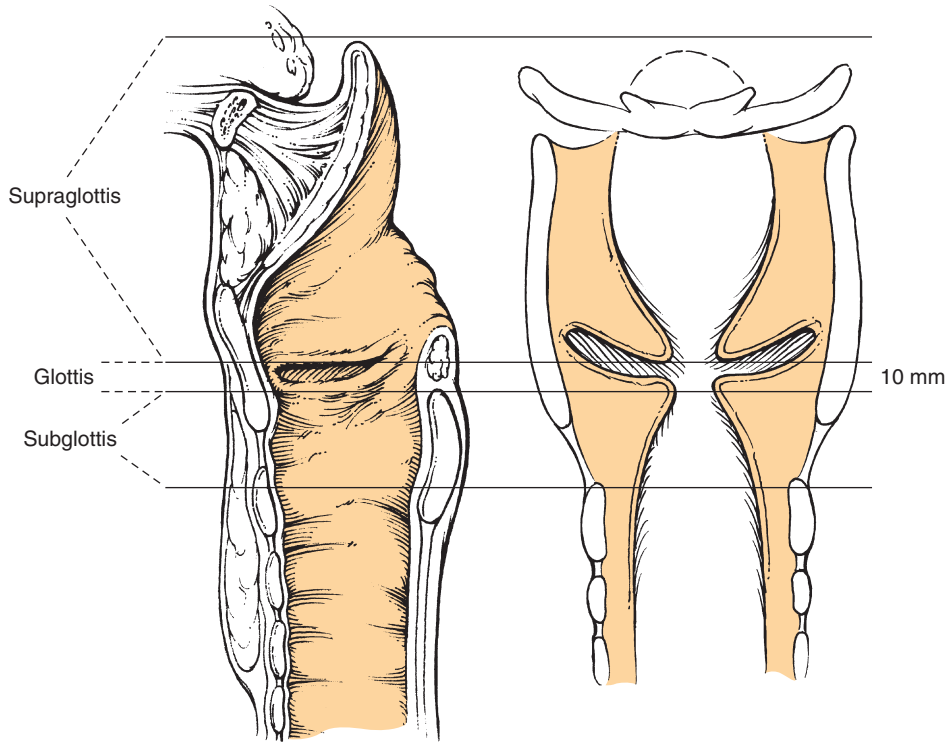

Figure 107-1. Classification of laryngeal lesions by the anatomic site involved. *(Adapted from Ogura JH, Biller HF. Partial and total laryngectomy and radical neck dissection. In: Maloney WH, ed.* Otolaryngology. *Vol 4. New York: Harper & Row; 1971.)*

lymphatics. Therefore, glottic cancers must invade deeply before getting access to lymphatic channels. These factors explain the lower incidence of lymphatic metastasis in glottic SCC, as well as the propensity for unilateral metastases. Because the supraglottis is formed without a midline union, its lymphatics drain bilaterally and the increased likelihood of bilateral lymphatic metastases from supraglottic carcinoma is ascribed to this embryologic factor, as described by Frazer in 1909.[4] Pressman and colleagues[5] noted that the inferior extent of supraglottic injection was the inferior false vocal cord, with the ventricle defining an anatomic barrier and halting further inferior flow of the dye.

Anatomy

A complete description of the anatomy of the larynx is beyond the scope of this chapter, so the following discussion is limited to a description of the boundaries of the larynx, its compartments, and its lymphatic drainage. The laryngeal framework is formed by three unpaired cartilages (epiglottis, thyroid, cricoid) and the paired arytenoid cartilages. The superior boundary of the larynx consists of the superior surface of the epiglottis and the superior edge of the aryepiglottic folds. The anterosuperior limit is formed by the lingual surface of the suprahyoid epiglottis and the hyoepiglottic ligament, which forms the superior boundary of the pre-epiglottic space. The anterior boundary of the larynx is formed by the thyrohyoid membrane and thyroid cartilage in the supraglottis, thyroid cartilage in the glottis, and cricothyroid membrane and anterior arch of the cricoid cartilage in the subglottis. The inferior limit of the larynx is defined by the horizontal plane, which passes through the inferior edge of the cricoid cartilage.[6] The posterior and lateral borders of the larynx are composed of the laryngeal surface of the aryepiglottic folds, arytenoid cartilages, interarytenoid space, and posterior surface of the subglottic space (which is defined as the mucosa covering the surface of the cricoid cartilage).

The larynx is divided into three regions or sites: the supraglottis, the glottis, and the subglottis (Fig. 107-1). This division reflects the embryologic structure of the larynx and the anatomic barriers to spread of laryngeal cancer outlined earlier. The TNM staging system further subdivides the supraglottis and glottis of the larynx into multiple subsites, used to define the T stage (Table 107-1).[6]

Table 107-1

Anatomic Sites and Subsites of the Larynx

Site	Subsite
Supraglottis	Suprahyoid epiglottis Infrahyoid epiglottis Aryepiglottic folds, right and left (laryngeal surfaces) Arytenoids, right and left Ventricular bands, right and left
Glottis	True vocal cords, right and left (including the anterior and posterior commissures)
Subglottis	No separate subsites defined

From Greene F, Page D, Fleming I, et al. *AJCC Cancer Staging Manual.* 6th ed. New York: Springer; 2002.

The supraglottis is composed of the suprahyoid and infrahyoid epiglottis (both the lingual and the laryngeal surfaces), aryepiglottic folds (laryngeal surfaces only), arytenoids, and ventricular bands (false vocal cords). The boundary between the suprahyoid and infrahyoid epiglottis is a horizontal plane passing through the hyoid bone. The inferior limit of the supraglottis is a horizontal plane through the lateral margin of the ventricle at its junction with the superior surface of the true vocal cord. The glottis is composed of the true vocal cords (both the superior and inferior surfaces) and includes the anterior and posterior commissures. The inferior boundary of the glottis is a horizontal plane 1 cm inferior to the inferior limit of the supraglottis (defined as the lateral margin of the ventricle at its junction with the superior surface of the vocal cord). The subglottis extends from the inferior limit

of the glottis to the inferior edge of the cricoid cartilage. It is not divided further into any subsites.[6]

The mucosal lining of the larynx differs in the three regions. The epithelium of the supraglottis is predominantly of the pseudostratified columnar type, except at the edges of the aryepiglottic folds and the lateral borders of the epiglottis, which are stratified squamous epithelium. The supraglottic mucosa has an abundance of mucus glands and lymphatic vessels. The true vocal cords have a unique structure: stratified squamous epithelium covers a three-layered lamina propria (composed of superficial, intermediate, and deep layers). The intermediate and deep layers of the lamina propria make up the vocal ligament, which forms the superior border of the conus elasticus and interdigitates with the vocalis muscle. The true vocal cords (and thus the glottis) have few lymphatic vessels. The subglottis is lined by pseudostratified columnar epithelium, which is in close approximation to the cricoid cartilage and cricothyroid membrane.[7]

The laryngeal cartilages, hyoepiglottic ligament, thyrohyoid membrane, quadrangular membrane, conus elasticus, anterior commissure, and cricothyroid membrane form natural barriers to the spread of tumor. Within the larynx, the pre-epiglottic space (PES) and the paraglottic space (PGS) provide pathways for spread of laryngeal tumors (Fig. 107-2). The boundaries of the PES are: *anteriorly,* the thyroid cartilage and thyrohyoid membrane; *superiorly,* the hyoid bone, hyoepiglottic ligament, and valleculae; *posteriorly,* the anterior surface of the epiglottic cartilage and the thyroepiglottic ligament; and *laterally,* the PES is open and continuous with each of the two PGSs. The PES contains fat and areolar tissue[7] and is frequently invaded by tumors because the cartilage of the epiglottis has multiple small fenestrations through which cancers arising from the infrahyoid epiglottis may pass. Superiorly, the hyoepiglottic ligament provides a barrier to spread of tumor to the tongue base (Fig. 107-3). The lymphatics of the PES drain through the thyrohyoid membrane, spreading to lymph nodes on both sides of the neck, primarily in zones II and III (Fig. 107-4).[5] Supraglottic tumors with PES involvement are staged as T3 lesions.

The PGS lies lateral to the true and false vocal folds and extends laterally to the thyroid cartilage (Fig. 107-5). The boundaries of each PGS are: *medially* (from superior to inferior), the quadrangular membrane, laryngeal ventricle, and conus elasticus; *laterally,* the thyroid cartilage (anteriorly) and the mucosa of the medial wall of the pyriform sinus (posteriorly); and *inferolaterally,* the cricothyroid membrane.[8] Anteriorly, each PGS is continuous with the PES, and tumors may spread along this pathway (see Fig. 107-2). Paraglottic space involvement in either a glottic or supraglottic tumor is staged as T3 and is significant because the extent of the PGS means that tumors in this

space may spread to involve any or all of the three regions of the larynx (Fig. 107-6).

Conservation laryngeal surgery is undertaken on the basis of the theory of compartmentalization of the larynx, which evolved from the work of Frazer,[4] Pressman and colleagues,[5] and Tucker and Smith.[9] Pressman and colleagues found that this separate embryologic derivation explains why supraglottic tumors of substantial bulk do not spread across the laryngeal ventricle to the vocal cord. In experiments using submucosal vital dyes and radioisotopes, Pressman also noted that the inferior extent of supraglottic injection was the inferior false vocal cord. The ventricle was an anatomic barrier to the inferior flow of the dye and thus was confirmed as a barrier to tumor spread. Using animals, cadavers, and whole organ serial sections of human tumor specimens, Tucker and Smith confirmed that elastic tissue barriers within the larynx explained the findings of the dye studies. Although these studies confirm compartmentalization of the larynx and clinically supraglottic tumors are observed to invade the glottis (and vice versa) uncommonly, there is no true anatomic barrier separating the supraglottis from the glottis.

Transglottic Cancer

Transglottic tumors are an important subset of laryngeal tumors with aggressive behavior and high risk of lymphatic metastasis. The term *transglottic* was first used by McGavran and associates in 1961.[10] It is not used in the American Joint Commission and associates for Cancer (AJCC) staging system and is defined by Kirchner and colleagues and colleagues as a tumor that crosses the ventricle in a vertical direction.[11] LeRoux-Robert probably first described this type of cancer, proposing that the site of origin was the ventricle and was the only tumor that invaded supraglottic and subglottic areas.[12] Kirchner and colleagues[11] have shown that transglottic tumors do not necessarily arise from the ventricle. Tumors can become transglottic in four ways: by crossing the ventricle directly; by crossing at the anterior commissure; by spreading through the paraglottic space; and by spreading along the arytenoid cartilage posterior to the ventricle.[11,13] The latter form of spread does not predict deep invasion: in Kirchner's series of 50 transgottic tumors studied in whole organ preparations, none of the 8 tumors with transglottic spread along the arytenoid demonstrated laryngeal cartilage invasion. In the same series, invasion of the laryngeal framework was seen in over half of transglottic tumors over 2 cm. Cervical metastases were seen in 30% of cases; and in primary tumors greater than 4 cm in dimension, 55% of tumors had nodal metastases.[11]

Anterior Commissure

The anterior commissure is the part of the glottis in which the true vocal cords meet anteriorly. The anterior commissure tendon is a band of fibrous tissue 1 mm wide and 10 mm in length extending from the vocal ligaments to the midline of the inner surface of the thyroid cartilage. At this insertion, the thyroid cartilage is devoid of perichondrium.[14] In this area the true vocal cords are therefore in close approximation to the thyroid cartilage. Kirchner has studied factors associated with spread of tumors along the anterior commissure.[15] The anterior commissure tendon forms a strong barrier to spread of cancer. Tumors crossing from one true vocal cord to the opposite cord do not necessarily have deep invasion. Thyroid cartilage invasion or extralaryngeal spread of cancer at the anterior commissure requires significant supraglottic or infraglottic extension. Superiorly, tumors have access to the petiole of the epiglottis and pre-epiglottic space, while inferiorly they have access to subglottic lymphatics, the thyroid cartilage, and the cricothyroid membrane. Inferiorly, the thyroid cartilage is more likely to be ossified, and ossified cartilage is not as strong a barrier to invasion as cartilage.[16]

Classification of Malignant Tumors of the Larynx

Although the vast majority of malignant tumors of the larynx originate from squamous epithelium, a small number arise from other tissues within the larynx. Because of the differing clinical behavior of these tumors, an accurate histologic diagnosis is crucial. Recognizing the importance of this issue and the need for standardization in the histologic nomenclature of laryngeal tumors, the World Health Organization (WHO) has published a histologic classification of laryngeal tumors.[17] This classification system is outlined in Table 107-2. Non–squamous cell laryngeal malignancies are described individually later in the chapter.

Staging

For the staging of malignant tumors, the AJCC and the International Union against Cancer (UICC) use the TNM classification system, which was developed by Pierre Denoix in 1943.[6,18] The TNM system takes into account the extent of the primary tumor (T), the absence or presence and extent of regional lymph node metastasis (N), and the absence or presence of distant metastases (M). The 2002 AJCC/UICC TNM definitions for epithelial laryngeal malignancies are given in Table 107-3. Using this system, tumors with varying combinations of T, N, and M are grouped into stages, which are described in Table 107-4. A tumor may be classified clinically, designated cTNM or simply TNM, or pathologically, designated pTNM. The clinical classification is based on evaluation of the patient before treatment is commenced and includes information obtained from physical examination, radiologic imaging, endoscopy, and biopsy.

The TNM classification system for the larynx is used for epithelial malignancies of the larynx only—nonepithelial tumors such as those of lymphoid tissue, soft tissue, cartilage, or bone are not included, although such lesions may be staged according to the system relevant to their histopathology (e.g., lymphomas of the larynx are staged according to the TNM system for lymphoid neoplasms).

An additional comment regarding the T staging of glottic tumors should be made. The T2 classification for glottic tumors encompasses a wide variety of lesions including those with normal and impaired vocal cord mobility (vocal cord fixation denotes a T3 tumor). Because the local control rate of RT for T2 glottic tumors with impaired vocal cord mobility has been observed to be lower than that of T2 tumors with normal vocal cord mobility, many authors distinguish between these two subsets of the T2 group by using T2a to denote those tumors with normal vocal cord mobility and T2b for those with impaired mobility.[19] This division of the T2 stage has not been incorporated into the AJCC/UICC TNM system.

Premalignant Laryngeal Lesions and Carcinoma in Situ

The World Health Organization (WHO) classifies premalignant laryngeal lesions as hyperplasia; keratosis; mild, moderate, or severe dysplasia; and carcinoma in situ (CIS).[17] Very early lesions may demonstrate hyperkeratosis or parakeratosis without cellular atypia or dysplasia. Squamous cell dysplasia is a premalignant lesion of squamous epithelium characterized by cellular atypia and loss of normal maturation and stratification short of CIS. The cellular abnormalities of mild dysplasia are minor and are limited to the basal one third of the epithelium; moderate dysplasia displays more marked cellular abnormalities involving up to two thirds of the epithelial thickness; and severe dysplasia has cellular abnormalities involving more than two thirds of the epithelial thickness. Carcinoma in situ is an intraepithelial neoplasm in which the full thickness of the squamous epithelium shows the cellular features of carcinoma without violation of the basement membrane and stromal invasion (Fig. 107-7).[17] Severe dysplasia and CIS are classified as different lesions, but clinically they behave in a similar fashion and may be considered as one.[20] There is widespread variability in pathologic interpretation and diagnosis, which is inherently subjective.[21,22]

Malignant transformation of mild dysplasia has been reported to be as high as 11%.[23] The malignant transformation rates for severe dysplasia and CIS show significant variability (up to 45%), but 30% is the generally accepted figure. A recent review noted that 30% of patients with dysplastic lesions that progressed to invasive cancer eventually underwent total laryngectomy.[23] The likelihood of progression is related to the extent of disease, and at least one series observed that almost all diffuse lesions showing CIS developed invasive cancer.[24] Because some lesions showing mild dysplasia and even those without dysplasia may progress to invasive cancer, long-term follow-up of all premalignant laryngeal lesions is warranted. Malignant transformation is a multistep process that takes many years. Blackwell and colleagues[25] observed a 3.9-year interval between initial biopsy to progression to invasive cancer. In a large series of over 1000 keratotic larynx lesions, the mean time interval to malignant transformation was 3.1 years.[26] The latency was longer for earlier lesions, and 7% of lesions transformed to invasive carcinoma more than 10 years after the initial biopsy.

The visual appearance of a premalignant laryngeal lesion does not predict its histologic nature. Nor does laryngeal videostroboscopy reliably differentiate premalignant from malignant lesions.[27] Biopsy is the gold standard for diagnosis, and adequate sampling is important because an insufficient biopsy will result in sampling error.

Adjunctive techniques have been developed to improve the clinician's ability to characterize these lesions and to guide biopsies. The use of vital dyes including toluidine blue and methylene blue as a diagnostic aid have been explored.[28,29] Lundgren and coworkers used toluidine blue to detect dysplasia or malignant changes and noted 91%

Table 107-2

Differential Diagnosis of a Laryngeal Mass/Lesion

Non-Neoplastic Lesions
- Mucus retention cyst
- Laryngocele/saccular cyst
- Heterotopic thyroid tissue
- Vocal fold polyp
- Vocal process granuloma
- Infections
  - Tuberculosis
  - Candidiasis
  - Histoplasmosis
- Inflammatory
  - Wegener's granulomatosis
  - Foreign body granuloma (e.g., Teflon)
  - Relapsing polychondritis
- Pseudoepitheliomatous hyperplasia
- Squamous cell hyperplasia
- Keratosis
- Necrotizing sialometaplasia
- Chondrometaplasia
- Amyloidosis
- Langerhans' cell histiocytosis
- Rosai-Dorfman disease

Benign Neoplasms
- Epithelial
  - Papilloma
  - Pleomorphic adenoma
- Oncocytic papillary cystadenoma
  - Nonepithelial
  - Soft tissue
    - Lipoma
    - Schwannoma
    - Neurofibroma
    - Leiomyoma
    - Rhabdomyoma
    - Hemangioma
    - Lymphangioma
    - Granular cell tumor
    - Paraganglioma
- Inflammatory myofibroblastic tumor
  - Bone and cartilage
    - Chondroma
    - Giant cell tumor

Premalignant Lesions
- Squamous cell dysplasia
- Carcinoma in situ

Primary Laryngeal Malignancies

Epithelial
- Squamous cell carcinoma (SCC)
  - Verrucous SCC
  - Spindle cell carcinoma
  - Adenoid SCC
  - Basaloid SCC
  - Clear cell carcinoma
  - Adenosquamous carcinoma
  - Giant cell carcinoma
  - Lymphoepithelial carcinoma

Malignant salivary gland tumors
- Adenocarcinoma
- Acinic cell carcinoma
- Mucoepidermoid carcinoma
- Adenoid cystic carcinoma
- Carcinoma ex pleomorphic adenoma
- Epithelial-myoepithelial cell carcinoma
- Salivary duct carcinoma

Neuroendocrine tumors
- Carcinoid tumor
- Atypical carcinoid tumor
- Small cell carcinoma
- Malignant paraganglioma

Malignant soft tissue tumors
- Fibrosarcoma
- Malignant fibrous histiocytoma
- Liposarcoma
- Leiomyosarcoma
- Rhabdomyosarcoma
- Angiosarcoma
- Kaposi's sarcoma
- Malignant hemangiopericytoma
- Malignant nerve sheath tumor
- Alveolar soft part sarcoma
- Synovial sarcoma
- Ewing's sarcoma

Malignant tumors of bone and cartilage
- Chondrosarcoma
- Osteosarcoma

Hematolymphoid tumors
- Lymphoma
- Extamedullary plasmacytoma

Secondary Laryngeal Malignancies

Contiguous primary site
- Hypopharynx
- Oropharynx
- Thyroid

Distant primary site
- Kidney
- Skin (melanoma)
- Breast
- Lung
- Prostate
- Gastrointestinal tract

Table 107-3

Tumor Node Metastasis System for the Larynx (Epithelial Malignancies)[6]

Primary Tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Supraglottis	
T1	Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2	Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx
T3	Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, pre-epiglottic tissues, paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
T4a	Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Glottis	
T1	Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) with normal mobility
T1a	Tumor limited to one vocal cord
T1b	Tumor involves both vocal cords
T2	Tumor extends to supraglottis and/or subglottis, or with impaired vocal cord mobility
T3	Tumor limited to the larynx with vocal cord fixation, and/or invades paraglottic space, and/or minor thyroid cartilage erosion (e.g., inner cortex)
T4a	Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx, (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Subglottis	
T1	Tumor limited to the subglottis
T2	Tumor extends to vocal cord(s) with normal or impaired mobility
T3	Tumor limited to larynx with vocal cord fixation
T4a	Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
N2	Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension
N3	Metastasis in a lymph node, >6 cm in greatest dimension
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

sensitivity, but only 52% specificity.[29] Contact endoscopy provides magnification of 60 to 50× and, with methylene blue staining, provides histologic information and an assessment of vascular patterns.[30] However, subsurface visualization is limited to 150 to 200 microns and is inadequate for characterizing thicker lesions. Widespread adoption of this technique has been hindered by the need for extensive experience to interpret the findings and for special equipment.

Human tissue has many compounds that fluoresce when exposed to blue light. The differing fluorescence of abnormal tissues has been exploited as a diagnostic aid for laryngeal malignancy. With experience, this technique can be useful. Limitations include false-positive and false-negative examinations in scarring, hyperkeratotic lesions, and inflammation.[31] Induced autofluorescence using 5-aminolevulinic acid (5-ALA) also shows potential diagnostic utility. 5-ALA selectively induces accumulation of protoporphyrin IX fluorescence in tumors. Using a nebulizer, it is topically applied 1 to 2 hours before the examination and a light source emitting short wavelength visible light (375 to 440 nm) is used to induce fluorescence. Protoporphyrin IX fluorescence appears red during imaging. A series of 16 patients with suspected or proven laryngeal malignancy subjected to 5-ALA–induced

fluorescence endoscopy demonstrated a sensitivity of 95% and a specificity of 80%.[28]

A prospective evaluation of autofluorescence and 5-ALA–induced fluorescence in 56 patients demonstrated that the two techniques have similar sensitivities (94% and 97%) and specificities (82% and 64%) to distinguish hyperplasia or mild dysplasia from moderate dysplasia, severe dysplasia, CIS, and invasive SCC.[32] Autofluorescence was unreliable when scarring was present, whereas 5-ALA–induced fluorescence resulted in false-positive findings in inflamed lesions.

The combined use of autofluorescence and contact endoscopy ("compact endoscopy") has also been explored. A pilot study by Arens and colleagues of 83 patients with hyperkeratotic, dysplastic, and invasive laryngeal lesions found correlation with histology in 88% of cases.[33] Inflammation and scarring resulted in overestimation of disease, whereas underestimation of disease was seen in hyperkeratotic lesions.

Current noninvasive diagnostic modalities do not reliably distinguish premalignant lesions from invasive SCC. Optical and microscopic imaging is limited by the inability to see below the first few layers of epithelial cells to evaluate the submucosal architecture. Infrared light has increased tissue penetrance and can provide diagnostic information about subsurface tissues. Optical coherence tomography (OCT) is a new diagnostic modality under investigation to examine the epithelial and subepithelial architecture that uses near-infrared light waves to produce cross-sectional images of tissue in vivo, with a resolution approaching that of histology.[34,35] In the larynx, OCT clearly identifies basement membrane violation from laryngeal cancer and is able to identify transition zones at the margins of the cancer (Fig. 107-8).[36] OCT has been used to assess the larynx intraoperatively to guide the extent of transoral laser resections for laryngeal cancer to ensure that excision is complete.[37] The primary disadvantage of OCT is the limited depth of penetration (<2 mm), which limits its utility in bulky lesions. However, OCT has potential as a useful tool in the management of laryngeal cancer: for the diagnosis of smaller epithelial lesions, for guiding surgical biopsies and resections, and for monitoring larynges post treatment.[36,37]

Table 107-4

Tumor Node Metastasis Stage Groupings

Stage	Primary Tumor	Regional Lymph Nodes	Distant Metastasis
0	Tis	N0	M0
I	T1	N0	M0

Treatment of Premalignant Lesions

The treatment of a premalignant lesion should aim to eradicate the lesion while preserving voice quality and laryngeal function. Accurate diagnosis is critical for proper decision making, and a number of factors related to the characteristics of the lesion, as well as patient factors, affect the treatment decision-making process (Table 107-5).

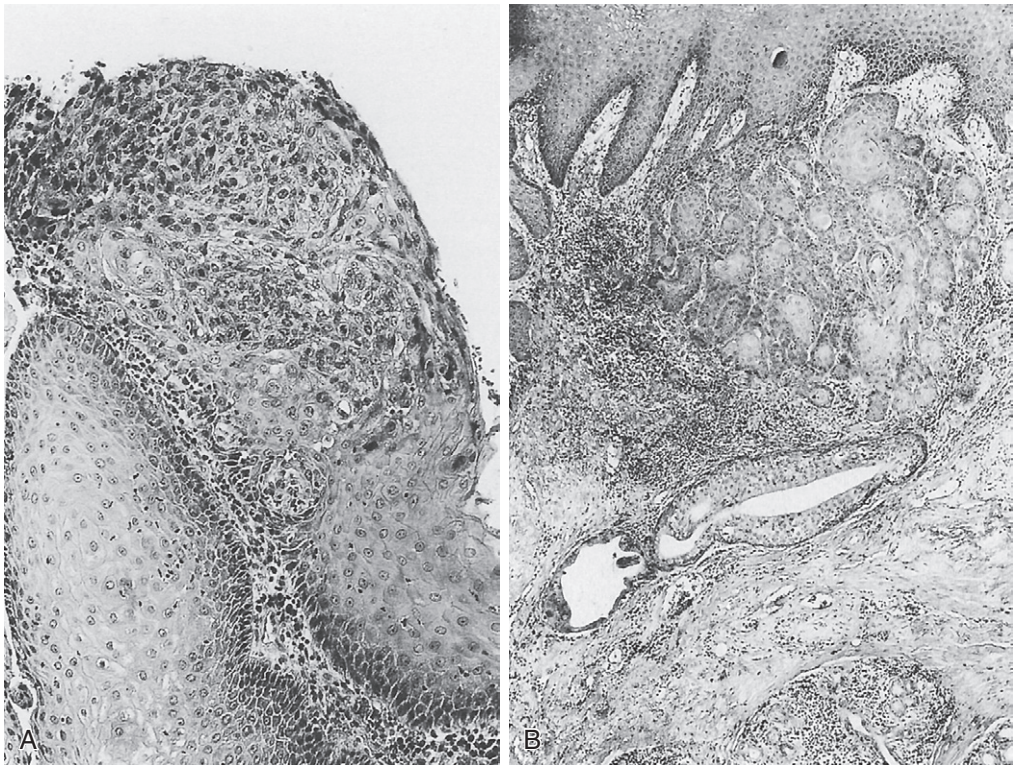

Figure 107-7. A, Carcinoma in situ. **B,** Microinvasive carcinoma. In the early phase of invasion, irregular nests of well-differentiated squamous cells infiltrate the lamina propria and evoke an inflammatory response. A gland with squamous metaplasia is present near deeper carcinomatous cells. *(From Ferlito A, Carbone A, Rinaldo A, et al.* Ann Otolaryngol. *1996;105:245.)*

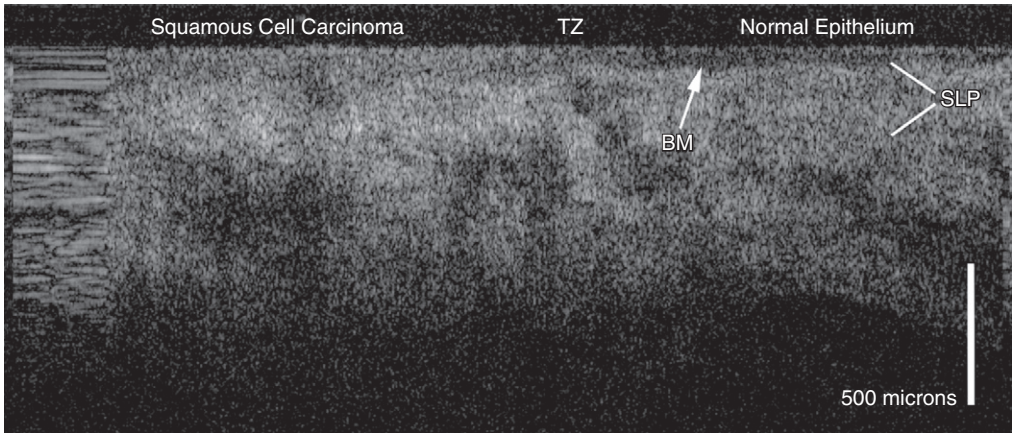

Figure 107-8. Optical coherence tomography image of a recurrent T2 glottic squamous cell carcinoma (SCC) following radiation therapy. Normal epithelium is present on the right, and a transition zone (TZ) between normal epithelium and squamous cell carcinoma is seen in the middle of the image. The basement membrane (BM) is not visualized on the left side, corresponding to the region of invasive SCC. SLP, superficial lamina propria.

Table 107-5

Factors to Consider in Treatment of Premalignant Laryngeal Lesions

Patient Factors	Tumor Factors
General health/comorbidities	Extent of lesion Unilateral vs. bilateral Anterior commissure involvement Extension beyond the glottis Focal vs. diffuse lesion
Vocal demands (e.g., professional singer)	Previous treatment Prior surgical excision Prior radiation therapy
Compliance with Tobacco cessation Alcohol cessation Reflux treatment	
Patient choice	

Hyperplastic and dysplastic lesions are excised with microlaryngoscopic techniques to remove the visible lesion. Close follow-up is required due to the risk of recurrence of the lesion and possible malignant transformation. Carcinoma in situ may be treated with either surgery or RT. Surgical management is microlaryngoscopic excision. Critical to this is high-power magnification, fine microsurgical instruments, and meticulous surgical technique to remove the entire lesion and preserve underlying lamina propria. The carbon dioxide (CO_2) laser is useful for precise excision, although thermal injury to the underlying lamina propria may result. Vocal cord stripping is the removal of the mucosa of the vocal fold including the lesion from the vocal process up to, but not across, the anterior commissure. It has significant risk of producing scarring and has been superseded by the more controlled microsurgical excision. Surgery provides tissue for pathologic analysis and can be repeated as often as needed. Voice quality is preserved in most cases. The recurrence rate for CIS treated with surgery is greater than those treated with RT and is reported to be approximately 20% after initial excision.[23] With repeated surgical excision the ultimate local control rate is excellent and is at least equivalent to that of RT.[38,39] Surgical treatment is preferred for focal lesions in patients who are reliable and will attend routine follow-up.

Radiation therapy is also an effective treatment for CIS: a recent review of 16 studies of CIS treated with RT determined that the local control rate was 93.5%.[23] Radiation therapy is particularly useful for multiple recurrences following surgical excision; for diffuse lesions extending beyond the vocal cords that cannot be excised without inducing significant morbidity; for patients who are unlikely or unable to attend follow-up; and for medically infirm patients unfit for general anesthesia. Voice quality is well preserved following RT.[40,41] The primary disadvantage of RT is that it cannot be repeated if there is a recurrence or second tumor in the irradiated field. The successful management of premalignant laryngeal lesions also requires implementation of tobacco and alcohol cessation strategies and treatment of laryngopharyngeal reflux when present.

In-Office Treatment of Premalignant Lesions

In recent years, in-office management of laryngeal pathology has become more common. This includes the treatment of premalignant lesions using photodynamic therapy (PDT) and fiber-based laser systems such as the pulsed dye laser (PDL) and the pulsed KTP laser.

The 585nm PDL and 532nm pulsed KTP lasers are the two most widely used lasers for the in-office treatment of laryngeal epithelial lesions including leukoplakia, keratosis, and dysplasia. In a pilot study, Franco and colleagues[42] used PDL for the treatment of dysplasia in the operating room under general anesthesia. In most cases the treated lesions were then excised and sent for histologic examination. This treatment was effective: 81% of patients had greater than 70% regression of their lesions. The authors also noted that regression occurred in treated lesions that were not excised. A subsequent report from the same group demonstrated the efficacy of PDL delivered via a flexible endoscope in the office for the treatment of dysplasia.[43] Koufman and colleagues found that 64% (16/25) of their patients with dysplasia required no further treatment during the follow-up period of their study.[44] Franco[45] has also described favorable experience with the use of PDL for dysplasia. Zeitels and colleagues[46] have subsequently adopted the pulsed KTP laser for in-office use, citing smaller fiber diameter, greater reliability, improved intralesional energy absorption, and improved hemostasis as advantages of the pulsed KTP system over PDL.

The energy from these lasers is preferentially absorbed by oxyhemoglobin, with the absorption of energy from the pulsed KTP being superior to that of PDL, causing photoangiolysis of the sublesional blood vessels.[46] Preferential destruction of intraepithelial desmosome junctions and separation of the treated epithelial cells from the basement membrane have also been observed microscopically.[47] Apart from the obvious advantages of in-office procedures (avoidance of general anesthesia, lower cost, improved efficiency, and patient preference), these lasers have minimal effect on the surrounding tissue and the scarring is uncommon. The bilateral simultaneous treatment of lesions in

and around the anterior commissure is possible, with minimal risk of web formation.[44]

One of the major criticisms of in-office procedures for the treatment of laryngeal lesions, especially dysplasia, is that there is no specimen obtained for pathologic examination, and therefore a definitive assessment of the tumor extent and margin status is not possible. In the reports published to date, all patients have been biopsied before the commencement of treatment.[44,46] A biopsy may be obtained in the operating room and initial treatment with the laser given at this time, or it may be taken in the office via the endoscope. Potential complications of in-office treatment include poor exposure of the lesion or poor patient tolerance of the procedure; however, these issues only arise in a small minority of cases.[44] Further studies with long-term follow-up are awaited to ensure that this novel technology has similar outcomes for patients with dysplastic laryngeal lesions.

Photodynamic therapy uses nontoxic chemicals that are taken up preferentially by dysplastic or malignant cells. These photoreactive chemicals are activated by light of a specific frequency range unique to the compound used. The light activation of tissues at the target site in the presence of oxygen results in cell death that is confined to the cells that have selectively accumulated the chemical.[48] Several agents have been used in the head and neck including 5-ALA, Photofrin, hematoporphyrin derivative, and Foscan. In the United States several photosenstitizers have been approved for use by the Food and Drug Administration, but treatment of head and neck malignancies is an off-label use at the present time. In the European Union, Foscan has been approved for treatment of early head and neck cancer. At present, data are available for approximately 1500 subjects treated with PDT for head and neck SCC. Biel[48] reported on 115 patients with Tis to T2 larynx SCC treated with Photofrin PDT. With a mean follow-up of 91 months, the 5-year cure was 91%. All recurrences were salvaged successfully.

Photodynamic therapy has several useful characteristics: it is performed in an outpatient setting and is repeatable. The effects on voice quality are minimal, and scarring of the vocal folds has not been observed.[48] Careful light-avoiding precautions are required because light sensitivity lasts up to 4 weeks. There is no pathologic specimen, and care must be taken to accurately assess tumor depth. PDT may have a particularly useful role for diffuse dysplasia or CIS. Schweitzer[49] reported 80% local control with PDT in 10 cases of diffuse laryngeal CIS previously treated with RT. Published reports show promise for this modality, but currently it is used by a small number of practitioners and is not widely available.

Chemoprevention of Laryngeal Cancer

Carcinogenesis is a multistep accumulation of genetic damage, the end result of which is the development of cancer.[50,51] The early arrest or reversal of carcinogenesis offers the opportunity to make a meaningful impact on cancer in the premalignant disease state, or before development of a second tumor.[52,53] Chemoprevention is the use of specific chemical agents to reverse, suppress, or prevent carcinogenesis before invasive cancer develops.[54] In numerous studies a low -fat diet and an increase in the consumption of fruits, vegetables, and fiber were associated with a protective effect against a number of cancers.[55,56]

13-cis-retinoic acid (13-cRA) has been studied extensively in oral leukoplakia.[57,58] In randomized placebo-controlled trials, 13-cRA showed encouraging results against oral premalignant lesions. In the first major human trial of 13-cRA completed in 1986, Hong and colleagues[58] observed a 67% response rate of oral leukoplakia in the treatment arm versus a 10% response rate for the placebo group. Significant side effects were seen and, unfortunately, mucosal lesions recurred in half of the patients receiving 13-cRA within 3 months following discontinuation of 13-cRA. In an effort to improve effectiveness and decrease toxicity, a multiagent trial using 13-cRA, alpha tocopherol, and interferon-α was conducted at the same institution. A complete remission was observed in 50% (7/14) of laryngeal lesions at 12 months. Subsequent analysis of biomarkers found the laryngeal lesions tended to have a lower level of chromosomal polysomy, and the level of chromosomal polysomy correlated with higher response rates to the three agents. There was also a trend toward a better response rate in cases without abnormal p53 accumulation, presumably reflecting less advanced disease.

A number of other agents show potential as chemopreventive agents for head and neck cancers including green tea polyphenols, sulindac, COX II inhibitors, curcumin, and protease inhibitors.[54] None have undergone the same level of study as the retinoids, and considerable effort will be required to determine the ultimate potential of promising agents.

Squamous Cell Carcinoma of the Larynx

Squamous cell carcinoma is the most common malignant tumor of the larynx, responsible for between 85% and 95% of all laryngeal malignancies.[2,59] This tumor arises from stratified squamous epithelium or from respiratory epithelium that has undergone squamous metaplasia. The incidence of SCC in each of the three regions of the larynx—the supraglottis, glottis, and subglottis—varies according to the patient population. In the United States, Canada, England, and Sweden, glottic SCC is more common than supraglottic SCC, whereas the reverse is true in France, Italy, Spain, Finland, and the Netherlands. In Japan, glottic and supraglottic SCC have a similar incidence. Primary subglottic SCC is rare in all populations.[2] In a large review of nearly 160,000 cases of laryngeal SCC in the United States, the glottis was the site of origin in 51%, the supraglottis in 33%, and the subglottis in 2% (with 14% of lesions unable to be categorized accurately).[60]

Epidemiology

In the United States, approximately 11,300 cases of laryngeal cancer were diagnosed in 2007 and there will be approximately 3660 deaths. The male-to-female incidence ratio is 3.8:1.[1] The epidemiology and risk factors for laryngeal cancer largely parallel those for head and neck cancer overall. Over 90% of cancers occur in those older than 40 years of age, and 85% to 95% of these are SCC. The higher incidence in males is due to an increased exposure to risk factors rather than an inherent gender predilection, and therefore as the number of females smoking has increased over the past 60 years, the gap has narrowed from over 15:1 to approximately 4:1. There does not appear to be a racial predilection to laryngeal cancer.[61]

Risk Factors

Tobacco and Alcohol

Tobacco and alcohol use are the two primary risk factors for cancer of the larynx. The International Agency for Research on Cancer (IARC) has concluded that there is enough evidence to state that there is a causal link between tobacco use and alcohol use with development of head and neck cancer. The risk is proportional to the intensity and duration of tobacco or alcohol consumption, and the risk decreases slowly after cessation but does not return to the baseline rate for at least 20 years. There are variations in risk with the type of tobacco exposure (e.g., cigar vs. cigarette, filtered vs. nonfiltered cigarettes), but the most important factors are the amount of tobacco consumed and the duration of exposure. Tobacco and alcohol act synergistically to increase the risk of cancer.[62-64] The relative contribution of alcohol and tobacco varies by site. Alcohol consumption is a more important risk factor for supraglottic carcinoma, whereas tobacco use is strongly associated with glottic carcinoma.

Laryngopharyngeal Reflux

Chronic irritation of the larynx has been proposed as a risk factor for laryngeal cancer and may be a contributing factor for those who do not smoke or drink. Concern that laryngopharyngeal reflux (LPR) of acid could cause cancer was raised in the 1980s.[65,66] It is difficult to determine if the relationship is causal or merely an association. A large case-control study of U.S. veterans concluded that there is a moderately increased risk for laryngeal or pharyngeal cancer associated with LPR independent of tobacco and alcohol use.[67] A critical review of the literature indicates that the relationship between LPR and larynx cancer is unknown. LPR could be an associated factor, a cocarcinogen, or possibly an independent risk factor.[68] Alkaline bile reflux may also be a causative factor. One study identified a significantly higher incidence

of laryngeal carcinoma in patients who underwent gastrectomy compared with controls.[69] The significance of asbestos exposure is controversial. A meta-analysis published in 1999 concluded there was a weak association between asbestos exposure and laryngeal cancer.[70]

Other Toxins

Occupational exposure to toxins is another risk factor for laryngeal cancer. The incidence of laryngeal cancer is higher in unskilled manual workers who have both a high alcohol and tobacco intake and are exposed to disproportionate levels of potential toxins.[71-73] Numerous agents including diesel exhaust, asbestos, organic solvents, sulfuric acid, mustard gas, certain mineral oils, metal dust, asphalt, wood dust, stone dust, mineral wool, and cement dust have been implicated as risk factors for laryngeal cancer. Establishing a link between any one toxin and larynx cancer has been difficult because the studies have been underpowered and plagued with confounding variables.[74]

Human Papillomavirus

Human papillomavirus (HPV) has been recognized as a causative factor for cervical cancer. The role of HPV in cervical cancer is well studied, and several HPV vaccines are undergoing evaluation for prevention of cervical cancer. The link between HPV and head and neck SCC was first suggested in the early 1980s.[75] Further studies have brought to light that HPV is a significant and increasing risk factor for head and neck cancer, particularly in the oropharynx. HPV is an independent risk factor for head and neck SCC.[76] The association of sexual practices and risk of head and neck cancer has become clear over the past decade, and a recent study has emphasized the role of HPV on a subset of head and neck cancer patients.[77] Vaccination against HPV has been shown to be highly effective at preventing cervical HPV infection.[78] If the vaccine can also prevent oropharyngeal infection, then the vaccination of children has the potential for significantly reducing the risk of oropharyngeal cancer and possibly cancer at other sites in the head and neck. The mechanism for carcinogenesis is believed to be the E6 and E7 viral protein-mediated degradation of p53, which is involved in maintaining genomic integrity, controlling cellular proliferation, and apoptosis. A recent review shows a site-specific link between HPV and head and neck cancer: the magnitude of the association is strongest for the tonsil (Odds Ratio [OR] 15.1), intermediate for other subsites in the oropharynx (OR 4.3), and weakest for the oral cavity (OR 2.0) and the larynx (OR 3.0, 95%, confidence interval [CI] 1 to 4.2).[79] The influence of HPV as a risk factor for larynx cancer is lower than for the oropharynx. Nevertheless, in one series, HPV was isolated in 36% of laryngeal cancers.[80] Evidence suggests that the presence of HPV in a head and neck SCC is associated with a better prognosis.[81] This observation is supported by a recent meta-analysis of the effect of HPV on head and neck cancer survival, but the effect is limited to oropharyngeal SCC.[82]

Genetic Susceptibility

Most smokers will die prematurely as a result of tobacco use, but only a minority will develop cancer. Genetic susceptibility to cancer clearly plays a role in risk for development of head and neck, as well as other cancers, but the risks are not clearly delineated. Epidemiologic studies can stratify risk for developing head and neck cancer and other cancers, and biomarkers are under development to identify molecular changes associated with cancer development. These assays provide markers for genetic susceptibility to cancer (e.g., mutagen sensitivity) and have the potential to provide prognostic information about response to treatment.[83] Polymorphisms of phase I and phase II detoxifying enzymes are also associated with risk of developing head and neck cancer, as well as polymorphisms of DNA repair enzymes. These studies are useful for understanding the pathogenesis of cancer but currently do not provide assistance to guide the clinician managing individual patients.

The discovery of familial cancer syndromes drew attention to the role of genetic susceptibility to developing cancer.[84] Only a small proportion of head and neck cancers arise from familial syndromes (e.g., xeroderma pigmentosum); however, studies of head and neck cancer demonstrate an elevated risk of head and neck cancer in family members. Copper and colleagues found a relative risk (RR) of 14.6 for respiratory tract cancers in the siblings of cancer patients and an overall RR of 3.5 for first-degree relatives.[85] The host ability to tolerate exposure to carcinogens is highly variable and is related to the ability to prevent activation of procarcinogens, inactivate active carcinogens, repair deoxyribonucleic acid (DNA) damage, and maintain immune surveillance. These factors are highly variable among individuals and are still poorly understood.

Diet

There is evidence linking dietary factors to the risk of head and neck cancer.[86,87] An increased intake of fruit and vegetables and a decreased intake of meat and fat have a protective effect and are associated with a reduced incidence of head and neck cancer, as well as colon cancer and cardiovascular disease. However, these benefits may take 20 years or longer to accrue, and at present these epidemiologic observations have not led to the successful development of a cancer reduction program.[88,89]

Second Primary Tumors

The single greatest risk factor for head and neck SCC is prior head and neck SCC. The annual risk of a second primary tumor (SPT) following an index head and neck SCC is 1% to 7%, with the risk persisting for at least 10 years.[57,90-92] The cumulative risk of developing an SPT is at least 20% and is greater for those who continue to use tobacco and alcohol. An individual with stage I or II head and neck SCC is more likely to die from an SPT than from the index tumor. The majority of SPTs develop in the head and neck, but a significant proportion occur in the esophagus or lung. Second primary tumors may be synchronous (identified within 6 months of the index tumor) or metachronous (diagnosed more than 6 months after the index tumor). In a study of 875 patients with SCC of the head and neck, 207 had SPTs develop within 5 years of their index tumor.[93] Of these patients, 31% had a third primary malignancy develop and 10% had a fourth primary malignancy develop. For laryngeal cancer, the lung is a significant site for synchronous and metachronous SPTs. An isolated lung malignancy in a patient with larynx cancer is more likely to be an SPT than a metastasis from the laryngeal cancer. Therefore an isolated pulmonary nodule should be considered an SPT until proven otherwise.[92] Prior RT is associated with SPTs in a small number of cases.[74] Slaughter and associates[94] examined clinically normal tissue adjacent to head and neck cancers and identified many histologic changes seen in the malignant cells in the adjacent normal appearing tissue, leading him to propose the concept of "field cancerization." Improved understanding of head and neck carcinogenesis has provided a molecular explanation for Slaughter's observations.[50,95] Bedi and colleagues examined X-chromosome inactivation and performed microsatellite analysis to evaluate allelic loss at chromosomes 3p and 9p in females with multiple primary head and neck cancers. Both the original cancer and the second malignancy arose from a single clone.[95] Califano and coworkers similarly observed that tissues adjacent to malignant and premalignant lesions shared common genetic changes.[50] Multiple tumors generally do not arise from multiple transforming events, but instead a single transforming event produces a cell with growth advantage that spreads throughout the mucosal surface. The tumor may accumulate further genetic damage, resulting ultimately in additional malignancies that are geographically distinct but genetically related to the original cancer.[95]

Molecular Biology

The molecular biology of laryngeal SCC is similar to that of SCC in other sites of the head and neck. Carcinogenesis is a long process occurring over many years preceding the development of cancer. Disruption of multiple genes is required to induce malignant transformation, with 6 to 12 distinct mutations generally necessary to produce malignancy. Understanding the molecular biology of head and neck cancer is useful to predict who is likely to develop cancer, to measure response to preventive agents, to identify novel targets for treatment, and to predict a patient's response to RT or chemotherapy. The molecular biology of head and neck cancer is discussed in Chapter 76.

Pathology

Squamous differentiation is the hallmark of SCC, which is characterized by the formation of keratin and/or the presence of intercellular

bridges.[17] SCC is graded by its histologic appearance into three categories: well, moderately, and poorly differentiated. Well-differentiated SCC resembles normal squamous epithelium and contains basal-type cells and squamous cells with keratinization and intercellular bridges. The nuclei are hyperchromatic and irregular in size and shape (pleomorphic), and the nuclear-cytoplasmic ratio is reduced. Atypical mitoses are rare. Moderately differentiated SCC has less keratinization, more atypical mitoses, and more nuclear pleomorphism. Intercellular bridges are present. Poorly differentiated SCC has minimal (if any) keratinization, minimal intercellular bridges, and numerous atypical mitoses.[17,59] The histologic grade has been reported as having prognostic value; however, grading is subjective, and sampling error may influence the grade assigned.

SCC breaches the basement membrane of the epithelium to invade the underlying tissue. The interface between the tumor and the adjacent normal tissue varies according to the pattern of invasion, which may be expansive, characterized by well-defined pushing margins, or infiltrative, characterized by poorly defined margins with occasional cells or tongues of tumor found in the tissue adjacent to the tumor. The latter pattern of invasion is associated with a worse prognosis.[96] A lesion in which the entire thickness of the epithelium shows the cellular features of carcinoma without invasion of the underlying stroma is termed *SCC in situ.* Microinvasive SCC refers to SCC in which limited tumor invasion is confined to the area just deep to the basement membrane.[17]

SCC expresses epithelial markers such as cytokeratin and epithelial membrane antigen.[59] These markers are detected by immunohistochemistry, which is used to differentiate between malignant tumors of similar histologic appearance.

The pathologic diagnosis of SCC is usually straightforward; however, two entities in particular can be difficult to distinguish from SCC. Pseudoepitheliomatous hyperplasia (PEH) is characterized by an overgrowth of squamous epithelium that histologically mimics carcinoma. It can be a primary process or a secondary histologic finding associated with chronic irritation, trauma, infection, or giant cell tumor. The epithelium does not demonstrate cytologic evidence of malignancy; however, elongation of the rete ridges may simulate invasion when specimens are cut tangentially. Properly oriented specimens and careful examination will usually distinguish PEH from SCC, but immunostaining may aid differentiation of the two entities.[17,97]

Necrotizing sialometaplasia is thought to be the result of infarction of salivary tissue. It is extremely uncommon in the larynx, but a few cases have been reported.[98] It may develop in the larynx after ischemia or trauma and is characterized by squamous metaplasia of the ducts and acini of seromucinous glands, which may be confused with SCC or mucoepidermoid carcinoma. This lesion resolves spontaneously. Immunohistochemistry may be required to differentiate necrotizing sialometaplasia from SCC and certain nonsquamous malignancies such as mucoepidermoid carcinoma, neuroendocrine carcinoma, malignant melanoma, or lymphoma, which may have a similar appearance when examined histologically.[17,99]

Clinical Presentation

The symptoms of laryngeal SCC depend on the site from which the primary tumor originates. The cardinal symptom of glottic SCC is dysphonia, which develops early in the natural history of the disease as the normal vibratory characteristics of the vocal cord are altered by even a small lesion. Therefore patients with glottic SCC usually present with earlier stages of disease, although if the early symptoms are ignored or attributed to other diagnoses, symptoms of advanced disease such as dyspnea and stridor may arise. Glottic tumors remain localized in the glottis for prolonged periods, owing to the natural barriers to tumor spread (ligaments, membranes, and cartilages) and to the relative paucity of glottic lymphatics. Supraglottic tumors may cause dysphonia (often an alteration in vocal resonance), dysphagia, odynophagia, otalgia, stridor, dyspnea, or hemoptysis. Patients with supraglottic SCC may also present with metastatic cervical adenopathy, without obvious laryngeal symptoms, because the supraglottic larynx has a rich lymphatic drainage network. SCC of the subglottis often presents with advanced-stage disease. Dyspnea and stridor are the most common symptoms of subglottic SCC. Because their onset is usually gradual and insidious, subglottic SCC may be misdiagnosed as asthma or other pulmonary diseases.[100,101]

On examination of the larynx, SCC may appear as an ulcerative, exophytic, sessile, or polypoid lesion. However, in cases of ventriculosaccular SCC (which is uncommon), an epithelial lesion may not be seen in the early stages because the carcinoma arises from the ventriculosaccular system, which lies within the paraglottic space.[102] Fullness of the vestibular fold may be the only obvious examination finding. In this scenario, deep biopsies of the vestibular fold are necessary to confirm or exclude the diagnosis of malignancy. A second clinical presentation, in which occult laryngeal SCC may be the underlying etiology, is that of the laryngocele. An association between laryngoceles and SCC has been recognized for some time.[103] In patients with laryngoceles, direct laryngoscopy with careful inspection of the ventricle using angled endoscopes is mandated to exclude an SCC of the ventricle.

Cervical Nodal Metastases

The incidence of cervical metastases from SCC of the larynx, as well as the nodal groups involved, vary according to the site of the primary tumor (Fig. 107-9). Due to its rich network of lymphatics, supraglottic SCC has the highest incidence of regional metastases—both clinically apparent and occult metastases. Cervical metastasis has been confirmed pathologically in 10% of T1 supraglottic lesions, 29% of T2, 38% of T3, and 57% of T4.[104] The incidence of occult metastases (cN0, pN+) in supraglottic SCC varies from 12% to 40% for all T stages.[105-108] The incidence of occult metastases is greater in tumors with a higher T stage: T1 0% to 14%, T2 20% to 21%, T3 28% to 35%, and T4 40% to

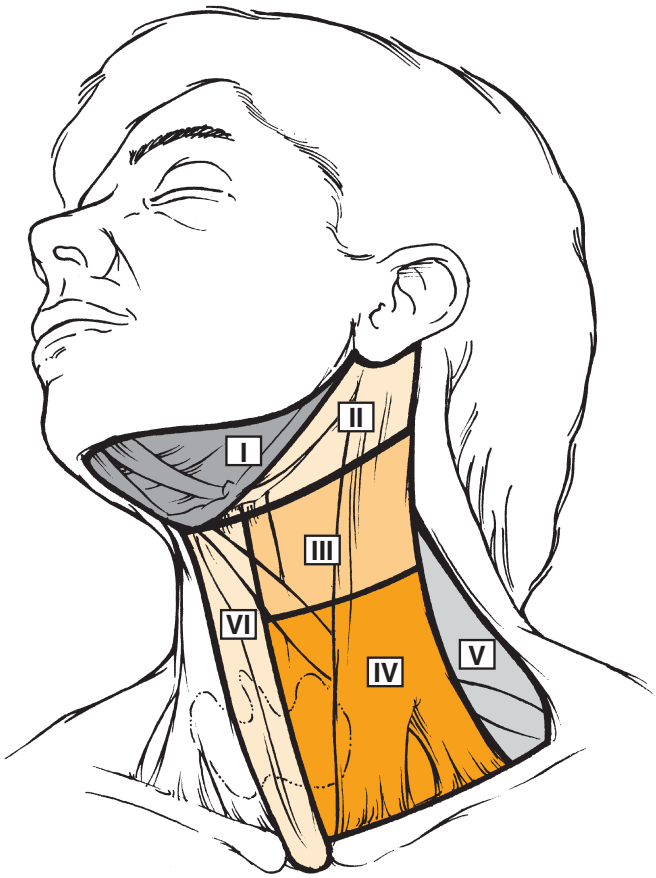

Figure 107-9. The six nodal levels of the neck. *(Redrawn from Robbins KT, Clayman G, Levine PA et al. Neck dissection classification update: revisions proposed by the American Head and Neck Society and the American Academy of Otolaryngology–Head and Neck Surgery.* Arch Otolaryngol-Head Neck Surg. *2002;128:751-758, Figure 1*).

75%.[106,109] Supraglottic SCC usually metastasizes to levels II, III, and IV. Levels I and V are involved by metastases rarely and only when other nodal levels are also involved.[110,111] Bilateral metastases (palpable and occult) occur frequently in supraglottic SCC and are more common in midline or bilateral tumors.[104,112] Therefore, in cases of supraglottic SCC, surgical treatment of the N0 and N1 neck is usually with a bilateral selective neck dissection (levels II-IV). For N2 or N3 disease, a comprehensive neck dissection (levels I-V) is indicated.

Glottic SCC has a low risk of cervical metastasis: in a series of 910 patients, the overall incidence of pathologically confirmed nodal metastasis was 5.9%, with an incidence of occult metastasis of 18%.[113] Similar to supraglottic SCC, the incidence of regional metastasis correlates with T stage. In the same series, nodal metastases were found in 0.1% of T1 tumors (one patient only), 5% of T2, 18% of T3, and 32% of T4.[113] The nodes at risk of metastasis from glottic SCC are those in levels II, II, and IV, as well as level VI (prelaryngeal, pretracheal, and paratracheal nodes). Bilateral or contralateral metastases are rare.

Primary subglottic carcinoma is rare, and descriptions of the clinical behavior of these tumors are based on a small number of patients. The paratracheal nodes (level VI) are most frequently involved with metastases, including contralateral or bilateral metastases. Metastases to levels III, IV and V are uncommon. Although these tumors are aggressive and have a poor prognosis, the incidence of cervical metastasis is generally reported to be low, with a range of 4% to 27%.[101,114] However, Harrison[115] detected metastatic tumor in approximately 50% of serially sectioned paratracheal nodes. Metastases to mediastinal lymph nodes are common (up to 46%), but they are classified as distant metastases.[116]

Distant Metastases

Distant metastases from laryngeal SCC include not only hematogenous metastases to distant organs, but also lymphatic metastases to nodal groups outside the neck.[59] The most common site for distant hematogenous metastases is the lung. The liver and skeletal system (ribs, vertebrae, and skull) are affected less often. The mediastinum is the most common site for distant lymphatic metastases.[117] Distant metastases are uncommon at initial presentation. Patients who develop distant metastases have almost always had regional metastases diagnosed at some stage in the course of their disease. The incidence of distant metastasis varies according to the site of the primary tumor: 3.1% to 8.8% in glottic SCC, and 3.7% to 15% in supraglottic SCC.[117-121] Supraglottic SCC usually has a higher incidence of distant metastases compared with glottic SCC. The frequency of distant metastases from subglottic SCC is less certain because primary tumors in this site are rare; however, Spector and colleagues[117] observed that 14.3% of subglottic SCCs developed distant metastases. Clinical and pathologic factors associated with an increased risk of distant metastases include advanced stage of primary tumor (especially T4 stage); presence of cervical metastases (especially N2 and N3 disease); duration, level, and extracapsular spread of cervical metastases; and locoregional recurrence.[117,121,122] Lymphatic metastasis to the skin is also a sign of advanced disease and, similar to distant metastases, has a grave prognosis.[123]

Diagnosis and Evaluation

A clinical diagnosis of SCC can usually be made on the basis of the appearance of the larynx on examination. Confirmation of the diagnosis and staging of the tumor are achieved with a thorough evaluation, which includes physical examination, flexible laryngosocopy, endoscopic examination under general anesthesia, biopsy, and imaging.

History and Physical Examination

A history of the presenting symptoms and any associated UADT symptoms should be elicited, with particular attention paid to symptoms suggesting impending airway obstruction such as stridor and dyspnea. Additional information that should be gathered includes exposure to risk factors for laryngeal cancer (primarily tobacco and alcohol), medications, and medical comorbidities such as cardiovascular, pulmonary, or renal disease that may affect the type of treatment that can be offered.

A complete head and neck examination is performed for suspected laryngeal cancer. Initial assessment should determine whether urgent intervention is required, for example, to secure an airway for a patient with a large obstructing lesion. Subsequent assessment is directed at assessing the location and extent of the primary tumor, palpating for neck nodes, and examining the rest of the upper aerodigestive tract for synchronous tumors.

Indirect laryngoscopy (IDL) using a mirror may provide an excellent three-dimensional view of the larynx and any lesions. However, images are not recorded, the hypopharynx is not adequately visualized, and in patients who do not tolerate IDL, the larynx cannot be evaluated completely. Flexible fiberoptic laryngoscopy permits photographic and video documentation, as well as examination during dynamic maneuvers (e.g., Valsalva's maneuver, coughing, swallowing). Laryngeal videostroboscopy is useful for the documentation of small lesions on the vocal fold and assessment of the mucosal wave before and after treatment. However, videostroboscopy cannot reliably distinguish intraepithelial neoplasia from invasive carcinoma, nor is it reliable for determining the depth of invasion of vocal cord carcinoma.[124]

In the patient with laryngeal cancer, specific examination findings that should be noted include the site of the primary tumor; the subsites involved; extension to adjacent structures; vocal cord mobility (normal vs. impaired vs. fixed); and patency of the airway. A biopsy may be taken in the office via a transoral approach or via the working channel of the flexible laryngoscope, although this is usually performed in the operating room under general anesthesia, unless there are concerns regarding a patient's fitness for anesthesia. The base of tongue and the laryngeal skeleton are palpated to assess for extralaryngeal spread, and the neck is palpated to assess the nodal status.

Imaging

Radiologic imaging is a critical part of the evaluation of a patient with a suspected laryngeal malignancy.[125] When feasible, imaging is performed before operative endoscopy and biopsy to obtain images before potential edema and distortion from biopsy and manipulation of the larynx. Information obtained with imaging can be integrated with endoscopic findings and, in some cases, can guide the surgeon to focus attention on deeper areas not normally visible on endoscopy requiring a biopsy. Cross-sectional imaging, using either computed tomography (CT) scanning or magnetic resonance imaging (MRI), yields the most useful information in the evaluation of tumors of the larynx.

Computed tomography is the most commonly used radiologic investigation in the evaluation of laryngeal cancer, although MRI is superior in some situations. CT is superior to MRI for imaging bony structures (such as ossified cartilages) and calcifications.[125] MRI is superior for detecting cartilage invasion and has enhanced ability to discriminate soft tissues. The disadvantages of MRI of the larynx compared with CT include increased imaging time (resulting in motion artifact), decreased spatial resolution, inferior ability to detect bone invasion, and increased cost.[126] MRI is also contraindicated for patients with pacemakers or other ferromagnetic foreign bodies, and false-positive findings are common because MRI is often unable to distinguish clearly between reactive inflammatory changes and tumor.[127]

Evaluation with CT includes a standard neck scan to evaluate extralaryngeal structures and lymph nodes, and finely cut images (≈1 mm) through the larynx to avoid partial volume averaging of the vocal folds, and allow multiplanar reconstruction.[128] The axial images should be aligned parallel to the true vocal cords to allow correct interpretation of tumor location and size.[125] Intravenous contrast is especially important because the primary tumor usually enhances with contrast, improving its visualization, and because the contrast will differentiate between nodal disease and blood vessels in the neck. Contrast (gadolinium)-enhanced, T1-weighted MRI images improve the definition of pathologic tissue, although some authors have found the use of contrast adds no information when assessing laryngeal tumors.[129,130] Special MRI series such as fat suppression are often helpful, especially when assessing the paraglottic and pre-epiglottic spaces.[125]

Positron emission tomography (PET), using radiolabeled glucose (18 F-fluorodeoxyglucose, FDG), is able to distinguish between malignancy and other pathologic processes such as inflammation.[131] PET is

particularly useful in the head and neck when performed in conjunction with CT (PET/CT), giving superior anatomic localization of suspicious areas.[132] PET has several potential uses: the staging of malignant tumors (especially for the detection of regional and distant metastases); the diagnosis of the unknown primary; the detection of synchronous lesions in addition to the index malignancy; and in the diagnosis of residual or recurrent cancer, which is particularly challenging in the irradiated larynx (see later).[133] PET is being used more commonly in the head and neck as our understanding of its abilities and applications improves.

Radiology plays an important role in the staging of laryngeal SCC because deep invasion by the primary tumor is assessed poorly by clinical and endoscopic examination. Several characteristics of the primary tumor used for staging cannot be determined without imaging including invasion of the PES, the PGS, the thyroid or cricoid cartilage, the extralaryngeal tissues, the prevertebral space, mediastinal structures, and encasement of the carotid.[6]

Invasion of the PES is diagnosed on CT by a loss of fat in the PES and replacement with a moderately enhancing mass.[128] On MRI, tumor has a low to intermediate signal on T1-weighted images, with a high signal on T2, and enhances with contrast on T1.[128] MRI is highly sensitive in the diagnosis of PES and base of tongue invasion and is superior to CT.[134] The radiologic appearance of the thyroid and cricoid cartilages depends on the degree of ossification. Although CT is superior to MRI for imaging bone and calcium, MRI is superior to CT in the detection of laryngeal cartilage invasion.[126,127,135] MRI is highly sensitive for cartilage invasion and has a high negative predictive value; however, it is not good at distinguishing between reactive inflammation and tumor, resulting in a lower specificity and a positive predictive value of approximately 70%.[126,127,135] CT is less sensitive than MRI in the diagnosis of cartilage invasion. Findings on CT such as extralaryngeal spread, sclerosis, erosion, and lysis suggest cartilage invasion.[136] MRI is also better than CT at detecting cricoid invasion in subglottic tumors.[137] The accurate diagnosis of cartilage invasion is important because it will upstage a carcinoma to T3 or T4a and is associated with a worse response to radiotherapy, poorer local control, and an increased risk of chondroradionecrosis.[126,138]

Imaging is also important to stage the neck accurately and detect distant metastases. In one series, CT and MRI were equivalent in the detection of cervical metastases in larynx cancer and superior to clinical examination and ultrasound. However, ultrasound-guided FNA and PET were the most accurate.[139] PET has not been used extensively in the pretreatment evaluation of laryngeal cancer because standard PET lacks anatomic detail. However, fused PET/CT scanning addresses this issue and in all likelihood will become more widely used for this indication.[140]

The lungs are the most common site of metastasis for lung cancer, and second primary tumors commonly occur in the lungs as well. A chest radiograph or a chest CT should be obtained to exclude pulmonary lesions. In patients with advanced primary tumors and low cervical metastases, PET/CT is useful for identifying distant metastases or SPTs that would alter patient management.[140]

Operative Endoscopic Examination

Unless there are medical contraindications, all patients with suspected laryngeal cancer should undergo an endoscopic examination under general anesthesia. Direct laryngoscopy allows the clinician to examine the larynx in greater detail, palpate the larynx, and obtain a biopsy for histologic analysis. Angled endoscopes are useful to evaluate the laryngeal surface of the epiglottis, anterior commissure, ventricles, and undersurface of the true vocal cords. If vocal cord mobility is noted to be abnormal on preoperative examination, palpation of the vocal cord and arytenoid cartilage will differentiate arytenoid fixation from vocalis muscle invasion causing cord immobility. Invasion of adjacent sites in the oropharynx or hypopharynx is assessed with direct pharyngoscopy and palpation of the tongue base. The neck may be palpated under general anesthetic to assess nodal status. The complete examination should be documented with photos, video, and a diagram of the extent of the primary tumor. Esophagoscopy is performed to exclude an SPT in the esophagus. Bronchoscopy is not required routinely if the preoperative chest imaging is normal.[141] Biopsies of the primary tumor and any suspicious areas are taken to confirm the histologic diagnosis and to determine the extent of tumor.

Caution should be exercised when performing direct laryngoscopy for patients presenting with laryngeal tumors obstructing the airway. Maintenance of a secure airway at all times is the paramount concern, and for severely compromised airways a tracheostomy under local anesthetic may be necessary. However, if possible, debulking of the obstructing tumor (using either cup forceps, a microdebrider, or the CO_2 laser) is the preferred technique to avoid a tracheostomy and to maintain the airway so that thorough evaluation and staging can be performed before selection of the definitive treatment.[142] If a tracheostomy is necessary, a high tracheostomy is performed so that any subsequent resection allows preservation of as much of the trachea as is oncologically possible. Surgical treatment is usually required for patients requiring tracheostomy because significant destruction of the larynx is usually present. The traditional treatment of an obstructing laryngeal SCC requiring a tracheostomy was an emergency laryngectomy (after a biopsy and frozen section biopsy had confirmed the diagnosis). However, emergency laryngectomy does not offer a survival advantage over tracheostomy with delayed laryngectomy and does not allow the patient to be counseled and prepared both psychologically and nutritionally before such radical laryngeal surgery.[142,143] Tracheostomy has not been found to increase the risk of peristomal recurrence, which is more strongly associated with advanced local disease, especially subglottic tumor extension.[143-146]

Differential Diagnosis

The differential diagnosis of laryngeal SCC includes non-neoplastic conditions, benign tumors, premalignant squamous cell lesions, and non–squamous cell malignant tumors (see Table 107-2).

Treatment of Squamous Cell Carcinoma

The goals in the treatment of laryngeal cancer are (1) to cure the patient; (2) to preserve the larynx or, more correctly, to preserve the function of the larynx; and (3) to minimize the morbidity of the treatment. A functional larynx should allow the patient to communicate with an intelligible voice; to swallow adequate nutrition without aspiration; and to breathe through the nose or mouth without the need for a stoma or a tracheostomy tube.

The most important information required for therapeutic decision making are (1) the histologic diagnosis of the tumor; (2) the site of origin of the tumor; and (3) the stage of disease (T, N, and M stage). The importance of accurate staging cannot be underestimated, and therefore a thorough evaluation of the patient is crucial.

A number of treatment options are available for patients with laryngeal cancer. Surgery and RT have long been the two most important treatment modalities. In the past 30 years, further therapeutic options have become available with the introduction of new surgical techniques for conservation laryngeal surgery (partial laryngectomy) and of chemotherapy combined with RT (CRT), which may be used in a neoadjuvant, concurrent, or adjuvant role. In general, early laryngeal cancer (stage I or II) is treated with single-modality therapy, either surgery or RT. Advanced laryngeal cancer (stage III or IV) is treated with combined-modality therapy, either primary surgery followed by RT or CRT, or primary CRT or RT with surgery for salvage. The selection of which modality to use, or (in advanced laryngeal cancer) which modality to use initially, should be made after careful consideration of a number of factors, which can be grouped into patient factors, disease factors, and institution factors (Table 107-6). For early-stage disease, voice quality, swallowing function, the duration of therapy, and patient preference are the major factors considered when selecting treatment.

The following general discussion of the therapeutic options available emphasizes decision making and treatment selection. Subsequent chapters will describe the specifics of the treatment of early glottic cancer (Chapter 108), transoral laser microsurgery (Chapter 109), conservation laryngeal surgery (Chapter 110), total laryngectomy (Chapter 111), radiation therapy (Chapter 112), and vocal rehabilitation following total laryngectomy (Chapter 113).

Table 107-6

Prognostic Factors in Treatment of Laryngeal Cancer

Patient Factors	Tumor Factors	Institution Factors
Age	Histologic diagnosis	Surgical expertise & experience
Comorbidities & general health	Site of primary tumor	Oncologic expertise & experience
Performance status	Stage (T,N,M)	
Occupation	Histologic features:	
Vocal demands	• Adequacy of resection margins	
Compliance & reliability (for treatment & follow-up)	• Extracapsular spread	
Smoking status	• Perineural invasion	
Nutritional status	• Lymphovascular invasion	
Distance from the treatment center		
Patient preference		

Treatment of Glottic Squamous Cell Carcinoma

Treatment of the Early Primary Tumor in Glottic Squamous Cell Carcinoma

Early glottic SCC (defined as stage I or II disease, i.e., T1-2N0) may be treated with either RT or surgery, without the need for elective treatment of the neck.[147] Primary RT for T1 glottic SCC provides 5-year local control rates of 81% to 90% and laryngeal preservation in 90% to 98% of patients.[148-150] For T2 tumors with normal vocal cord mobility, RT achieves local control in 64% to 87%, with laryngeal preservation rates of 75% to 87%.[148,151,152] The effectiveness of RT may be overestimated due to complete excision of the tumor at the time of the initial biopsy. In 12 of 60 patients undergoing partial laryngectomy for early glottic SCC, Stutsman and McGavran found that there was no tumor in the pathologic specimen.[153,154]

Surgical treatment of early glottic SCC also aims to preserve the larynx and is referred to as *conservation laryngeal surgery* or *partial laryngectomy.* Traditionally, these limited laryngeal resections were performed via an external approach: Cordectomy and vertical hemilaryngectomy (VHL) are the two classic open procedures for the treatment of early glottic carcinoma. Cordectomy is the removal of the diseased true vocal cord via a laryngofissure. Vertical hemilaryngectomy removes the ipsilateral true and false vocal cords, extending laterally to the perichondrium of the thyroid cartilage. The lamina of the thyroid may be removed to allow the soft tissues adjacent to the larynx to collapse medially to reconstitute the glottis for phonation, or it may be preserved, with transposition of soft tissue (such as a strap muscle) medial to the lamina to recreate the glottis. Variations of the VHL (extended VHL) have been described to include the resection of the anterior commissure, contralateral true vocal cord, arytenoid, and supraglottic or subglottic tumor extension. Open surgical treatment oncologic results are reported as having 90% to 98% local control rates and 93% to 98% larynx preservation rates.[155,156]

In the past 30 years, endoscopic approaches analogous to the open procedures have been developed to accomplish the same resection without disruption of the supporting structures of the larynx. The oncologic results for transoral laser microsurgery (TLM) have been reviewed by Ambrosch.[157] For Tis-T2 tumors, local control rates are 80% to 94% with a greater than 94% laryngeal preservation rate.[158] In the hands of experienced surgeons, local control and laryngeal preservation rates following TLM equal those following open surgical techniques.[158] In comparison with open surgical techniques, TLM avoids a tracheostomy, the hospital stay is shorter, the cost is reduced, and there is a lower incidence of dysphagia postoperatively.[157]

Lesions of the middle third of the true vocal cord have the best local control rates and may be treated by either TLM, open cordectomy or RT; local control approaches 100% after surgical excision, whereas RT achieves a 95% local control rate.[159] Radiation failures may be caused by unrecognized deep invasion. Following surgical excision, repeat surgery or RT may be used to treat residual or recurrent tumor. Although RT alone has excellent results, a second course of radiation for a recurrence or for a second tumor cannot be offered. Recurrent tumors may not be amenable to conservation surgery after previous RT.

T2 glottic lesions with impaired vocal cord mobility warrant special consideration. Although classified as T2 lesions by the TNM system, glottic tumors with impaired vocal cord mobility have a worse prognosis than tumors that are classified as T2 on the basis of supraglottic or infraglottic invasion. Impaired vocal cord mobility is usually secondary to either tumor bulk or deep invasion. Radiotherapy is less effective in controlling these lesions, and this is probably often due to tumor volume. Dickens and colleagues[148,160] noted that 4% of tumors less than 15 mm recurred after radiotherapy, whereas 26% of larger lesions of a similar stage recurred, even when only one true vocal cord was involved. T2 tumors managed by primary RT showed a 30% local failure rate, which, when surgically salvaged, improved to 94%.[19,161] Harwood and DeBoer[19] observed that impaired vocal cord mobility resulted in lower control rates in T2 lesions, and they suggested the classification be divided into T2a and T2b on the basis of mobility. In this analysis, a 70% local control rate was noted for the former category versus 51% in the latter. McLaughlin and colleagues[162] noted recurrence rates of 11% and 26% for T2a and T2b tumors, respectively.

Voice quality following either surgery or RT is influenced by the extent of tumor and depth of invasion. Small superficial tumors will have excellent voice quality with either surgery or RT. Deeper tumors with muscular invasion will have inferior voice outcomes with either treatment modality. Furthermore, the control rate with RT will be lower. Surgical treatment provides a better assessment of tumor extent and in some cases may result in upstaging of the tumor. For small superficial tumors, voice quality with surgery or RT is generally good with comparable voice results.[163]

Early Glottic Squamous Cell Carcinoma and the Anterior Commissure

Anterior commissure involvement has been associated with decreased local control rates with surgery and RT.[164,165] The topic has been controversial, and several explanations for the poorer control rates have been offered. One hypothesis for the decreased effectiveness of RT has been underdosage with supervoltage RT at the tumor-air interface. Increased dose fractions (to >2 Gy) are believed to have solved this problem. The anterior commissure is also a difficult region to assess, and deep invasion may not be recognized, resulting in understaging and thus undertreatment. The lack of perichondrium at the insertion of the anterior commissure tendon was thought to increase the risk of cartilage invasion. Kirchner and Carter[166] examined laryngeal carcinoma with anterior commissure invasion using whole organ sections of the larynx and discovered that the anterior commissure tendon is a strong barrier to cancer spread. Deep invasion was seen only in cases where the tumor had invaded the supraglottis superiorly or the subglottis inferiorly. Spread of tumor across the anterior commissure did not increase the risk of deep invasion. Kirchner concluded that supraglottic

spread provides access to the PES and that subglottic spread provides access to the thyroid cartilage and the cricothyroid membrane.

Frontolateral VHL obtains local control rates of 80% to 90% for T1 carcinomas involving the anterior commissure.[167,168] Supracricoid partial laryngectomy (SCPL) is a more extensive procedure that removes the anterior commissure and the anterior two thirds of the vocal folds. Laccourreye and colleagues have reported a 5-year local control rate of 98% for T1 and T2 glottic tumors with anterior commissure involvement.[169] Bron and colleagues[170] reported local control of 94.5% for 45 previously untreated laryngeal SCCs involving the anterior commissure treated with SCPL. Although oncologically effective, voice quality is significantly impaired following this technique.

Early reports of TLM for glottic carcinoma considered anterior commissure involvement to be a contraindication. Krespi and colleagues noted a high rate of failure at the anterior commissure.[171] This region may be difficult to visualize at the time of surgical resection. With improved understanding of the anatomy, instrumentation, and technique, excellent control rates have been obtained.[172,173] Pearson and Salassa[165] reported their initial experience of 39 patients with anterior commissure involvement. They had no local failures among 17 pT1 and pT2a tumors. The majority (19/22) of advanced tumors with anterior commissure involvement (pT2b, pT3-4) tumors were controlled with endoscopic surgery. Steiner and colleagues[158] reported results on 263 patients with early glottic tumors treated over a 10-year period and observed a modest decrease in local control and laryngeal preservation rates, with equivalent 5-year survival. For T1a tumors, local control was 90% when the anterior commissure was not involved and 84% with anterior commissure involvement. The corresponding laryngeal preservation rates were 99% versus 93%. Similar findings were seen with T1b and T2a tumors.

Treatment of the Advanced Primary Tumor in Glottic Squamous Cell Carcinoma

Advanced glottic SCC (stage III or IV disease) is associated with vocal cord fixation, cartilage invasion, transglottic spread of tumor, subglottic extension, laryngeal framework invasion, extralaryngeal spread, lymph node metastases, and distant metastases. These features portend worse prognosis. The treatment of choice for T3 and T4 glottic tumors remains controversial because of the heterogeneity of the tumors and lack of reliable studies comparing surgery and radiotherapy for T3 and T4 carcinoma of the larynx.[174] T3 and T4 glottic tumors are discussed separately in this chapter. T3 glottic carcinomas are unusual because despite their advanced T stage, in general they have a low risk of nodal metastasis. Furthermore, the spectrum of disease with T3 lesions is variable, ranging from low-volume tumors invading the vocalis muscle to cause fixation to very large transglottic tumors. Tumor volume and transglottic spread of T3 tumors predict increased aggressiveness, increased rate of lymph node metastasis, and poorer response to treatment. Tumors larger than 1.5 cm, subglottic extension, and lymph node metastasis laterally or to paratracheal or anterior pretracheal nodes predict failure above the clavicle.[175,176]

Traditionally, T3 tumors have been treated with total laryngectomy as single-modality therapy. Open VHL and more extensive partial laryngectomies are used in carefully selected cases. Kirchner and Som[177] reported a 2-year survival rate of 60% following open partial laryngectomy and noted that failures occurred when there was inferior tumor extension in the larynx. Biller and Lawson reported a 73% absolute 2-year, tumor-free control rate following partial laryngectomy (with resection extended to include a portion of the cricoid cartilage when there was >5 mm of subglottic extension).[178] Pearson and coworkers have published extensive experience of near-total laryngectomy (NTL) for patients with tumors not suitable for other conservation procedures.[179] This procedure preserves one arytenoid and a portion of the cricoid cartilage to create a diversionary voice shunt from the trachea. Patients remain tracheotomy dependent for breathing and use the shunt to produce speech.

Radiation therapy has a local control rate of approximately 50% for T3 tumors, which is lower than that of surgery.[180] For T3 tumors, the return of vocal cord mobility following RT predicts a good response. In a small series of 14 patients with T2b-3 laryngeal carcinomas, all five patients who did not have return of cord mobility and none of nine patients who had return of vocal cord mobility developed recurrent cancer.[181] Tumor volume may predict the response to irradiation, with poor results in larger tumors.[182] For small T3 tumors that would be amenable to partial laryngectomy, primary RT could be considered in those not wishing to pursue surgical option, although surgical resection generally has higher local control.[183,184] Intensified RT regimens including twice-daily treatments and the use of intensity-modulated radiotherapy (IMRT) may improve local control.[185] Further discussion on RT can be found in Chapter 112. Total laryngectomy or CRT is recommended for bulky T3 tumors or tumors not suitable for conservation laryngeal surgery.

In general, T4 glottic carcinoma is not considered amenable to conservative laryngeal resection. Options for T4 glottic carcinoma include total laryngectomy (usually with postoperative RT or CRT), near-total laryngectomy, or primary CRT in selected low-volume disease with limited cartilage destruction to preserve the larynx. Near-total laryngectomy may be considered in selected cases with limited subglottic extension and no interarytenoid involvement.[186] Recent encouraging results for TLM for T3-4 laryngeal cancer support its use in carefully selected cases by experienced surgeons for organ preservation.[187]

Primary RT for T4 glottic carcinoma has poor local control rates. A historical review of primary RT for laryngeal SCC found that only 2 of 25 T4N0 glottic carcinomas treated with primary RT survived 5 years.[188] In patients unable or unwilling to undergo concurrent CRT and unwilling to have a total laryngectomy, primary RT may provide a chance of local control. In some patients, the addition of newer agents such as cetuximab may increase the effectiveness of RT with acceptable risk of increased toxicity.[189]

Although attempts to avoid total laryngectomy are worthwhile, RT may result in significant local tissue destruction, scarring, and persistent edema. Thus the larynx may be preserved, but the patient may be left with a severely compromised organ with a restricted airway, a poor voice, dysphagia, and/or aspiration. If RT is selected for primary management, close follow-up is required as the success of this approach relies on the early detection of residual or recurrent disease, which may be challenging in a larynx scarred from irradiation. A total laryngectomy is usually required for salvage if recurrent disease is diagnosed. The successful salvage rate for recurrences after RT is approximately 60%. Persistent postradiation edema predicts persistent disease: 45% of patients with edema persisting for longer than 6 months after RT had a deep recurrence.[190] In these situations close follow-up with endoscopy and imaging is vital.[191] Distinguishing between recurrence and chondroradionecrosis of the larynx can be challenging. Deep biopsies required to obtain an accurate diagnosis can induce or exacerbate chondroradionecrosis. Positron emission tomography (PET) scanning has been helpful to resolve this dilemma and assists surveillance for tumor recurrence.[192]

Selected T4a tumors may be considered for nonsurgical organ preservation trials (see "Nonsurgical Organ Preservation" later). The success of organ-preservation protocols for bulky T4a tumors is lower than for T3 tumors because cartilage destruction predicts poor response to organ preservation protocols. These patients were excluded from the RTOG 91-11 trial comparing concurrent CRT, induction chemotherapy followed by RT, and RT alone.[193]

When total laryngectomy is undertaken for T4 disease, hemithyroidectomy or subtotal thyroidectomy is recommended for cases of palpable abnormality, subglottic tumors, or glottic tumors with greater than 1 cm of subglottic extension.[194] Thyroid gland invasion may be predicted if a positive Delphian node or cartilage destruction is present. Cancer is found in 3% to 8% of thyroid specimens.

Treatment of the Neck in Glottic Squamous Cell Carcinoma

The incidence of nodal metastasis for glottic SCC is lower than either supraglottic or subglottic SCC. Because the true vocal cords are nearly devoid of lymphatics, tumors limited to the glottis rarely metastasize to regional nodes. When metastasis does occur, the nodes at risk are the prelaryngeal, pretracheal, and paratracheal nodes, as well as the upper, mid, and lower deep cervical chain nodes (levels II, III, and IV).

Occult metastases from T1-2 glottic SCCs are uncommon, and elective treatment of the N0 neck is not required.[195] T3 glottic SCC is more controversial. In general, occult nodal metastases are uncommon from T3 glottic carcinomas unless there is transglottic spread of the tumor, which has a higher rate of occult metastasis.[196] A national survey of otolaryngologists published in 2003 reported that 87% of respondents treated the neck of patients with T3N0 glottic SCC, and 90% treated the neck of those with T4N0 glottic SCC.[197] T4 glottic carcinomas have a higher risk of occult metastases, approximately 20%, and treatment of the neck is recommended. If the primary tumor is being treated surgically, an ipsilateral selective neck dissection is recommended. For glottic carcinoma, the paratracheal nodes and levels II-IV are dissected. Adjuvant treatment with RT or CRT is used depending on pathologic findings in the neck dissection specimen.[198,199] If RT is used to treat the primary tumor, the central compartment and ipsilateral lateral neck are included in the field.

For all T stages, clinically evident nodal disease (N+) warrants aggressive treatment, the choice of which depends on the management of the primary tumor. If surgery is used for the primary tumor, an ipsilateral comprehensive neck dissection is indicated for N+ disease. Adjuvant treatment may be indicated depending on pathologic findings.

Postoperative RT is recommended when multiple nodes, extracapsular spread, extralaryngeal invasion, and perineural or lymphovascular invasion is present. Recently, two large studies have demonstrated improved locoregional control with use of platinum-based chemotherapy given concurrently with RT.[200,201] Cooper and colleagues[200] found a 10% increase in the 2-year locoregional control rate (82% vs. 72%), although there was an associated 43% increase in acute grade III or higher toxicity (34% vs. 77%). Similarly, Bernier and associates observed an 11% increase in 5-year progression-free survival, which was also associated with a higher rate of acute toxicity.[201] A comparative analysis of the combined results of these two studies found that extracapsular spread and microscopically positive surgical margins were the only risk factors for which adjuvant chemotherapy enhanced the efficacy of RT in both studies.[202] Other variables trended toward statistical significance, but patients who had two or more positive lymph nodes (without extracapsular spread) as their only risk factor did not seem to benefit from the addition of chemotherapy.

Improved locoregional control rate with primary concurrent CRT has led to the addition of chemotherapy to RT as an adjuvant treatment for patients with adverse pathologic findings in the surgical specimen. The decision to use chemotherapy in this setting requires careful consideration of the ability of the patient to tolerate the treatment. The success of this therapy is dependent on completion of the treatment regimen without significant breaks.[203-206] Encouragingly, a recent analysis of the tolerability of concurrent CRT in patients older than 70 years of age demonstrated high compliance with a regimen of concurrent carboplatin and RT.[207]

Treatment of Supraglottic Squamous Cell Carcinoma

SCC of the supraglottis metastasizes to the cervical lymph nodes more frequently than glottic SCC. Therefore management of the cervical lymphatics plays a prominent role in treatment planning of supraglottic SCC. Similar to head and neck SCC in other sites, the regional nodal status (N stage) of a patient with supraglottic SCC is the most important predictor of survival. A number of therapeutic options are available for supraglottic SCC, especially for early primary tumors (T1 and T2). Early-stage disease (stage I and II) is generally treated with single modality therapy, whereas advanced disease (stage III and IV) is generally treated with combined modality therapy.

Sessions and colleagues[208] reported the results of 653 patients with supraglottic SCC treated with a number of modalities (except chemotherapy). Overall 5-year, disease-specific survival for all stages was 66%, with rates of 77%, 74%, 64% and 50% for stages I, II, III, and IV, respectively. No treatment modality was found to result in superior survival. The larynx was preserved in 86% of patients treated with open partial laryngectomy, and in 73% of RT patients. In another large series of patients (n = 903) treated with conservation surgery, the 5-year uncorrected actuarial survival for stage I, II, III, and IV disease was 84%, 81%, 76%, and 55%, respectively.[209]

An important point to highlight is that survival from laryngeal SCC has diminished over the past 20 to 30 years in the United States. A review of the National Cancer Database by Hoffman and colleagues[60] found that 5-year relative survival from supraglottic SCC has decreased from 52.2% in 1985-1987 to 47.3% in 1994-1996. The greatest decline in survival for patients with supraglottic SCC occurred in those with T1N0 and T2N0 tumors, with a lesser but still significant decline in survival for T3N0 tumors. The authors noted that the frequency of use of the various treatment modalities has changed during this period, with an increase in RT and CRT, and hypothesized that the decreased survival observed in early supraglottic cancer could be explained by less aggressive surgical treatment of the primary and of the neck.

Treatment of the Early Primary Tumor in Supraglottic Squamous Cell Carcinoma

For early supraglottic cancer, the two most frequently used treatment options are supraglottic partial laryngectomy (SGL) or RT. SGL for early supraglottic SCC (as well as some T3 tumors) is achieved by an open supraglottic laryngectomy (OSGL) or by the more recently described TLM.

The traditional OSGL was first described by Alonso in 1947 and subsequently refined by Ogura and Som.[210-212] The oncologic validity of OSGL as a treatment for supraglottic SCC comes from the principle that the supraglottis is embryologically separate from the glottis and subglottis, and for this reason, supraglottic SCC remains localized to the supraglottis in most cases, despite the lack of an anatomic structure preventing invasion of the glottis.[213] OSGL removes all laryngeal structures superior to the floor of the ventricle, preserving both true vocal cords, both arytenoids, the base of tongue, and the hyoid bone (Fig. 107-10). Indications for OSGL are T1, T2, or selected T3 supraglottic tumors. T3 tumors with PES and no transglottic spread and/or vocal

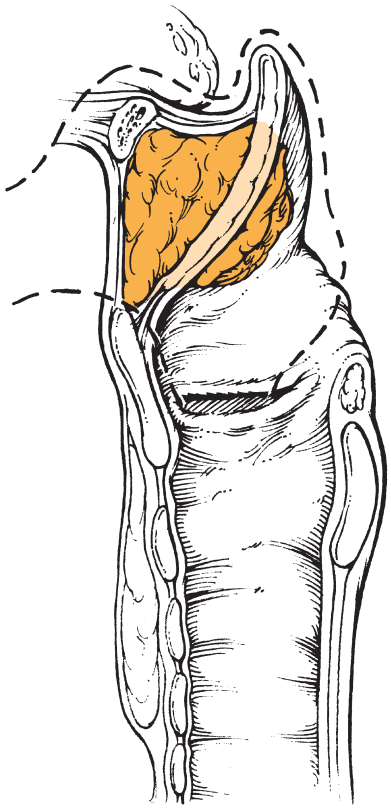

Figure 107-10. Outline of resection for open supraglottic laryngectomy. Note inclusion of entire pre-epiglottic space. *(Redrawn from Som ML. Conservation surgery for carcinoma of the supraglottis.* J Laryngol Otol. *1970;84:657.)*

cord impairment are amenable to OSGL. Contraindications to OSGL include poor general physical condition (e.g., advanced age, lung disease, neurologic disease, preexisting dysphagia or aspiration), glottic involvement, impaired mobility or fixation of the vocal cord, thyroid or cricoid cartilage invasion, involvement of the base of tongue to within 1 cm of the circumvallate papilla, or involvement of the deep muscles of the tongue.[214] The functional morbidity of OSGL is significant, and almost all patients will experience some aspiration postoperatively. Therefore careful patient selection is crucial to the overall success of this procedure: Candidates for OSGL must have good pulmonary function to tolerate the expected aspiration. An OSGL is referred to as an extended OSGL when a more extensive resection is carried out for the treatment of SCC involving the lingual surface of the epiglottis, the base of tongue, or one of the arytenoids.[214]

The functional and oncologic outcomes of OSGL are well documented. Because OSGL disrupts the pharyngeal muscles, the strap muscles, and the sensory innervation of the pharynx and larynx, swallowing is markedly impaired, especially in the early postoperative period. A tracheostomy is required in all patients to provide a safe airway and to protect the lower airway from aspiration. Suarez and colleagues[215] reported that 10% of patients in their series required a completion total laryngectomy for chronic aspiration. Advanced age (older than 65 years) was the major risk factor for intractable aspiration. A further 24% of subjects required permanent tracheostomy. Bron and colleagues[216] noted approximately one quarter of their patients aspirated in the early postoperative period. The median duration until normal oral feeding was established was 16 days, and the median duration until decannulation was 17 days.

OSGL yields excellent local control in the treatment of early supraglottic cancer in the range of 80% to 100%.[217-222] In patients treated with OSGL for T1-3 supraglottic SCC, Bron and colleagues[216] reported 5-year local control, locoregional control, and overall survival rates of 92.5%, 90%, and 92%, respectively. Adjuvant RT was given in 30% for positive surgical margins or adverse pathologic findings in the lymph nodes. Local control and survival were poor when cartilage invasion was present or when there was extralaryngeal extension of disease (i.e., pT4). Suarez and colleagues[222] treated 193 patients with supraglottic SCC with OSGL and ND. Nearly half of the subjects received adjuvant RT. Local control was 98% for T1 tumors and 91% for T2 tumors. No improvement in overall survival was noted with the addition of RT. In Bocca's series of 537 patients with supraglottic cancer (predominantly T2), local control was 94% for stage I and 82% for stage II. Overall 5-year survival was 78%.[218]

Robbins and colleagues[220] treated 139 T2 and T3 supraglottic SCCs with OSGL if technically possible, or with total laryngectomy or radiotherapy if not. Local control at 3 years was 100% for the OSGL group and 91% for the total laryngectomy group. Those subjects treated with primary RT had a 69% local control rate, which improved to 85% with salvage total laryngectomy. Five-year survival was 89% for those subjects treated with OSGL primarily, 78% with TL, and 70% with RT.

Transoral laser microsurgery for supraglottic carcinoma, first described by Vaughan in 1978, has become an accepted alternative to OSGL for supraglottic SCC.[223] The indications for TLM are similar to those for OSGL (i.e., T1-2 and selected T3 tumors), although some institutions will use TLM for more advanced lesions such as T4.[224,225] Few contraindications to TLM exist: incomplete exposure of the tumor; tumor involving the great vessels of the neck; and tumor location and/or bulk requiring an extensive resection that would place the patient at high risk of aspiration (e.g., extensive tongue base involvement).[225] The indications for neck dissection are not changed with TLM, and both sides of the neck may be dissected at the same time the primary is resected, or more commonly performed in a staged fashion several weeks after the initial TLM.[226] The local control rates of TLM are similar to those of OSGL; however, the functional morbidity is much less following TLM because the extrinsic muscles of the larynx, pharyngeal muscles, cartilaginous framework of the larynx, and superior laryngeal nerves are left intact.[227] The functional advantages of TLM include the possible avoidance of a temporary or permanent tracheostomy; less impairment of swallowing postoperatively including less aspiration; and a lower incidence of pharyngocutaneous fistulae.[224,228]

Steiner's group reported their experience with TLM for early supraglottic carcinoma in 1998.[224] Only 4% of subjects were treated with adjuvant RT—96% underwent TLM only. No tracheostomies were performed at the time of the resection, although one patient required a temporary tracheostomy to manage aspiration. The average duration of nasogastric tube feeding was 6 days, and overall swallowing was excellent postoperatively. The oncologic results were equivalent to OSGL: 5-year local control rates were 100% for pT1 and 89% for pT2 tumors, which were salvaged with either a second TLM or with OSGL to give an ultimate local control rate of 97%. Overall 5-year survival was 76%.

Iro and colleagues[229] reported the results of TLM in a series of 141 supraglottic cancers, which were predominantly T1-2. Half of the subjects also had neck dissections, and 45% received adjuvant RT. Tracheostomies were required in 13% of subjects during the course of treatment and were permanent in 9%. All but one of the subjects requiring a permanent tracheostomy were staged as pT4 and underwent extensive resection of the tongue base. Five-year local control rates were 86%, 75%, 75%, and 78% for stages I, II, III, and IV, respectively. Five-year, disease-free survival was reported as 66% (75% for stages I and II, 56% for stages III and IV).

Motta and colleagues[230] performed TLM on 124 subjects with T1-3N0 supraglottic carcinoma and observed local control rates of 82%, 63%, and 77% for T1, T2, and T3 lesions. Laryngeal preservation rates were 89%, 85%, and 95%. Overall survival rates were 91%, 88%, and 81%. Advanced supraglottic tumors were also included in a series of TLM reported by Rudert and associates.[231] The majority of patients (24 of 34) received RT and nearly 20% required tracheostomies. Local control was 100%, 75%, 78%, and 37% for T1, T2, T3, and T4 tumors; overall survival was 71% for stages I and II and 50% for stages III and IV tumors.

The functional outcomes of patients who underwent either TLM or OSGL for predominantly T1-2 supraglottic SCC were compared by Peretti and colleagues.[227] A temporary tracheostomy was required in 14% of TLM patients for an average of 4.5 days compared with 100% of OSGL patients who were decannulated after an average of 35 days. No permanent tracheostomies were required in either group. A feeding tube was used in 21% of the TLM patients for an average of 5 days, compared with 100% of OSGL patients, for an average of 19 days. No permanent feeding tubes were placed in either group. The average period of hospitalization was 11 days for the TLM group versus 26 days for the OSGL group. No significant difference in voice quality between the two groups occurred.

The role of adjuvant RT in TLM has been unclear, with up to 94% of subjects receiving adjuvant RT after TLM in some series.[232]

Zeitels and colleagues[233] concluded that small T1-2 supraglottic lesions in subsites amenable to endoscopic resection (suprahyoid epiglottis, aryepiglottic fold, vestibular fold) could be treated successfully with TLM without RT but recommended that RT should be given after endoscopic resections of larger lesions (T2-3) in less favorable sites (e.g., infrahyoid epiglottis). In this series there was a high rate of local failure after RT in those patients in whom negative margins were not achieved at TLM, suggesting that RT was unable to control residual disease at the primary site. Davis and coworkers described the concept of TLM as a neoadjuvant treatment to remove all carcinoma at the primary site (with negative margins), followed by RT to treat any residual microscopic disease and treat the neck.[234] Using this approach for T2 supraglottic SCC, TLM (and neck dissections for N+ subjects) was performed, with 83% of subjects receiving adjuvant RT. Over one third of subjects were staged as pT3 secondary to PES invasion. Local control was 100% in the surgery-only group and 97% in the combined-modality group. Regional control was 96% in the N0 subjects who received RT to the necks and 91% in the N+ subjects who received surgery and RT to the necks. Overall survival was low at 63% for the TLM/RT group and 50% for the TLM-only group due to a high rate of non–cancer-related deaths. A permanent feeding tube was required in 3%, but there were no permanent tracheostomies. The average time until normal swallowing was established was less than 14 days.

Because RT generally has an inferior local control rate compared with surgery, especially for bulky lesions, Agrawal and colleagues[232] proposed that a TLM procedure to debulk the primary tumor may improve the oncologic outcome. In a prospective trial of TLM with adjuvant RT for T1-2N0-1 supraglottic SCC, the 3-year local control rate was 97%, with one recurrence that was salvaged by TL. The overall survival rate was 88%. The functional results were not as good as in other TLM series, and this was probably due to the addition of the adjuvant RT: 21% of subjects experienced a prolonged period of dysphagia (3 to 10 months), and 9% required a permanent gastrostomy tube. Subject accrual for this trial became difficult as some coinvestigators were reluctant to use RT for all patients because they became increasingly comfortable in the use of surgery as single-modality treatment for these patients.

Radiation therapy plays an important role in the treatment of patients whose tumors are not amenable to partial laryngectomy, who are medically unfit for surgery, or who prefer to avoid surgery. In general, surgical excision has a higher local control rate for early supraglottic tumors than RT.[235] Radiation therapy alone is also less effective than surgery (with adjuvant RT) or CRT in patients with advanced laryngeal carcinoma; however, it may be used to treat patients who are not eligible for CRT protocols but wish to attempt to preserve their larynx. However, RT is not without complications including dysphagia, aspiration, laryngeal edema, and chondronecrosis, which may require tracheostomy or total laryngectomy.[235]

Harwood reported initial local control rates with RT of 70% for T1N0 tumors, 68% for T2N0, and 54% for T3-4N0.[236] Mendenhall and colleagues[235] treated 209 supraglottic carcinomas with primary RT and obtained initial local control rates of 100%, 85%, 64%, and 36% for T1, T2, T3, and T4 lesions. Patients with recurrent disease were salvaged with either a total laryngectomy or, if possible, an OSGL, to give an ultimate local control rate of 100%, 88%, 81%, and 57%. The cause-specific survival for the series was 100%, 92%, 75%, 47%, and 32% for stages I, II, III, Iva, and IVb. Tumor volume ($<6\,cm^3$) and vocal cord mobility were significant predictors of local control. Hinerman and coworkers[237] reported on 274 patients with supraglottic SCC treated with RT with or without neck dissection. The 5-year local control rate after RT was 100%, 86%, 62%, and 62% for T1, T2, T3, and T4 tumors. The 5-year cause-specific survival was 100%, 93%, 81%, 50%, and 49% for stages I, II, III, Iva, and IVb.

Primary RT was compared with partial laryngectomy (and neck dissection) by Spriano and colleagues[238] for the treatment of 166 stage I and II supraglottic SCC. The surgical group had a superior 5-year, disease-free survival rate of 88% versus 76% for the RT group. Salvage surgery was effective in 66% of the partial laryngectomy failures and in 50% of the RT failures. Altered fractionation regimens have also been used to treat supraglottic SCC, and several reports have suggested improved local control rates with twice-daily hyperfractionated RT compared with once-daily RT.[239-241]

Treatment of the Advanced Primary Tumor in Supraglottic Squamous Cell Carcinoma

Advanced primary supraglottic tumors (i.e., T3 or T4) have traditionally been treated with total laryngectomy, bilateral neck dissections, and postoperative RT. However, laryngeal preservation has become an important aim in the treatment of laryngeal cancer in an attempt to improve the quality of life of patients.[242] The therapeutic options for these advanced lesions currently include surgical excision (total laryngectomy or partial laryngectomy in selected cases) with bilateral neck dissections, followed by adjuvant RT (or concurrent CRT); primary RT with surgical salvage (usually total laryngectomy); or concurrent CRT with surgical salvage.[243]

The Department of Veterans Affairs (VA) Laryngeal Cancer Study, published in 1991, was a landmark trial in the development of nonsurgical organ preservation and chemotherapy for the treatment of advanced laryngeal cancer.[244] Nearly two thirds of the subjects (208 of 332) had supraglottic SCC, with the majority of tumors classified as T3. The section on nonsurgical organ preservation later in this chapter describes the design and results of the important studies of nonsurgical treatment of advanced laryngeal cancer.

A second important trial investigating the nonsurgical treatment of advanced laryngeal SCC, the Head and Neck Intergroup Study (RTOG 91-11), was reported in 2003.[193] Over two thirds of the subjects (356 of 518) had supraglottic tumors. Large-volume T4 tumors that extended into the tongue base by more than 1 cm or penetrated through cartilage were excluded. The concurrent CRT group had statistically significant higher rates of locoregional control (78%) and laryngeal preservation (88%) compared with the induction chemotherapy– and radiation therapy–alone arms. The findings of this study have led to concurrent CRT becoming the standard nonsurgical organ preservation protocol for advanced laryngeal cancers with T2, T3, and low-volume T4 tumors (without gross cartilage destruction). Further information on nonsurgical preservation is discussed later.

The surgical excision of advanced primary tumors has traditionally been achieved by total laryngectomy, and although this remains the most commonly used procedure, conservative laryngeal resections such as OSGL, extended OSGL, supracricoid partial laryngectomy (SCPL), or TLM may be used for selected cases. Supracricoid partial laryngectomy, first described in 1959 by Majer and Rieder, is an organ-preserving surgical technique in which the aim is to preserve function without the need for a stoma of any kind.[245] It may be used as a primary treatment or as a salvage procedure after RT.[246] This procedure resects both true vocal cords, both false vocal cords, both paraglottic spaces, the entire thyroid cartilage, and the epiglottis. The hyoid bone and the cricoid cartilage are preserved. One of the arytenoids may also be included in the resection, but at least one intact cricoarytenoid unit must be preserved for postoperative function.[245] Following the resection of a supraglottic cancer, the surgical defect is closed by tightly apposing the hyoid bone and base of the tongue to the cricoid cartilage, termed *cricohyoidopexy* (CHP). A SCPL (with CHP) is used for selected T2, T3, and T4 supraglottic and transglottic tumors: T2 tumors not amenable to OSGL because of involvement of the true vocal cords or anterior commissure, extension to the floor of the ventricle, and/or impaired motion of the true vocal cord; T3 transglottic and supraglottic tumors with true vocal cord fixation and/or pre-epiglottic space invasion; and T4 transglottic and supraglottic tumors with limited invasion of the thyroid cartilage without extension to the outer thyroid perichondrium, or extralaryngeal spread.[245] Contraindications to SCPL include poor general health, poor pulmonary function, invasion of the cricoarytenoid joint, invasion of the cricoid cartilage, involvement of the posterior commissure, extension to the subglottis, invasion of the hyoid bone, extension of tumor to the outer perichondrium of the thyroid cartilage, or extralaryngeal spread.[214,247]

The oncologic results of SCPL with CHP are excellent, with 5-year survival rates of 67% to 95% and local control rates of 88% to 95%.[245,248] Total laryngectomy is the recommended salvage procedure for recurrent disease. In general, laryngeal function is good after SCPL. A tracheostomy and feeding tube are required for all patients initially but are temporary in most.[246,249] A completion total laryngectomy may be required on occasion for intractable aspiration.[170,246] The major disadvantage of SCPL is poor voice quality.[245]

In summary, for T3 or T4a supraglottic tumors without extensive base of tongue involvement or cartilage destruction, either nonsurgical organ preservation (using concurrent CRT) or, in selected cases, conservative laryngeal surgery (with adjuvant RT) may be used primarily in an effort to preserve a functional larynx. Adjuvant RT or concurrent CRT may be required after primary surgical treatment, and total laryngectomy may be required as a salvage procedure after either nonsurgical or surgical organ preservation treatment. For extensive T4 tumors with gross cartilage destruction and/or extralaryngeal spread, total laryngectomy is the preferred initial treatment.

Treatment of the Neck in Supraglottic Squamous Cell Carcinoma

Supraglottic SCC has a high incidence of clinically apparent and occult regional metastases. Supraglottic SCC usually metastasizes to levels II, III, and IV. Bilateral metastases occur frequently in supraglottic SCC. Elective treatment of the clinically negative neck is indicated in all supraglottic SCCs except T1 lesions. The choice of either surgery or RT for the neck will vary according to how the primary tumor is to be

treated. For early-stage tumors (T1-2), either surgery or RT may be used as a single modality to treat both the primary site and the neck. The indications for neck dissection do not alter when the primary tumor is treated with a partial laryngeal resection. For advanced primary lesions (T3-4), combined modality therapy is usually indicated. Often, nonsurgical organ preservation such as CRT or RT is used initially, with surgery to the primary and/or neck for salvage. Alpert and colleagues[250] investigated the use of RT for the treatment of clinically negative necks in SCC: for patients staged N0, both necks were treated with RT; and for patients with ipsilateral nodal metastases, the ipsilateral neck was treated with surgery and the contralateral neck was treated with RT. RT was effective in this role because failure was observed in only 3% of node-negative necks.

The standard surgical treatment of the neck in N0 supraglottic SCC is bilateral selective neck dissection of levels II to IV. Several studies have observed that levels I and V are rarely involved by metastases when clinically apparent metastases are present in levels II-IV and are never involved when occult metastases are present in the lateral neck.[104,251,252] A selective neck dissection (levels II to IV) is as effective as a comprehensive neck dissection (levels I to V) for N0 (and N1) disease.[253] Further studies of N0 supraglottic (and glottic) SCC have observed that metastases are not common in sublevel IIb and level IV, and therefore Ferlito and colleagues have suggested that a more targeted selective neck dissection of sublevel IIa and level III may be adequate for the elective surgical treatment of the neck in these cases.[111] An exception to these findings was a study that found occult metastases were present in level I in 82% of supraglottic SCC staged cN0.[108]

Treatment of the N+ neck is less controversial. If surgery is the primary treatment modality, a selective neck dissection (levels II to IV) is as effective as a comprehensive neck dissection for N1 disease, but for more extensive nodal disease (N2-3), a comprehensive neck dissection should be undertaken.[253,254] Bilateral neck dissection has been found to decrease the regional failure rate of the surgical treatment of supraglottic SCC from 20% of cases (in which the contralateral undissected neck was the most common site for recurrence) to 8%.[255] Adjuvant RT is indicated for neck dissections showing unfavorable pathologic findings including multiple involved nodes, extracapsular spread, or soft tissue extension of tumor.[209,218,256]

In summary, for supraglottic SCC, surgical treatment of the N0 and N1 neck is usually with a bilateral selective neck dissection (levels II to IV). For N2 or N3 disease, a comprehensive neck dissection (levels I to V) is indicated for the N+ neck, with a contralateral selective neck dissection (II to IV) if the contralateral neck is N0. Primary nonsurgical treatment should include RT to both necks.

Subglottic Squamous Cell Carcinoma

The treatment of subglottic SCC usually requires total laryngectomy and postoperative RT. Total laryngectomy is necessary because laryngeal framework invasion is frequent, and because of the difficulty of laryngeal reconstruction when a portion of the cricoid cartilage is resected in a partial laryngectomy. Ipsilateral thyroidectomy and paratracheal node dissection is also required (Fig. 107-11). Distal tracheal spread may occur, requiring a low tracheal resection and manubrial removal, and posterior extension into the cervical esophagus may be encountered. For patients with nodal metastases or extralaryngeal invasion, adjuvant RT (including the superior mediastinum) or concurrent CRT is used to decrease the likelihood of stomal recurrence.[101]

Despite such extensive treatment, survival is poor. Vermund reported 36% survival in pooled reports of subglottic SCC treated with primary RT compared with 42% for those treated surgically.[188] Stell and Tobin reported 44% cancer mortality in their series.[257] More recently, Garas and McGuirt reported a 25% three-year survival rate in 15 patients, the majority of whom presented with advanced disease.[101] Radiation therapy can be considered for early-stage lesions, but there are limited data to guide management.

Nonsurgical Organ Preservation Treatment

A number of studies in the 1980s found that the addition of chemotherapy before RT for surgery for advanced head and neck cancer resulted in high rates of complete tumor regression associated with prolonged survival.[258-260] Response to chemotherapy predicted tumor radiosensitivity. However, this improved response did not translate into increased survival.[261]

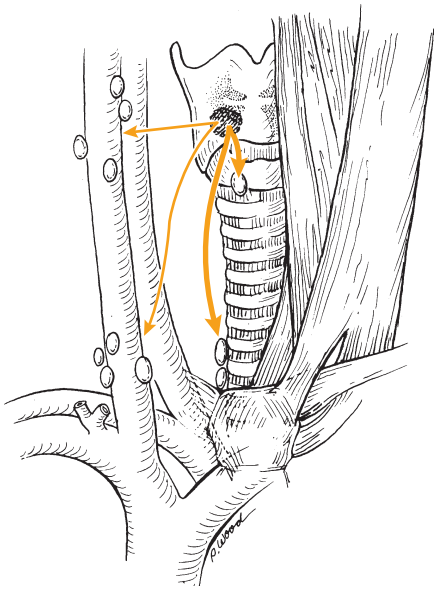

Figure 107-11. Pathways of nodal metastasis from primary subglottic tumors. Spread occurs along submucosal lymphatics to paratracheal nodes and along lower and midjugular chains.

These early studies provided the rationale for the VA laryngeal cancer study reported in 1991.[244] This was the first large prospective randomized study to demonstrate the effectiveness of the use of chemotherapy to define the more favorable patients and avoid laryngectomy in responders. This multi-institutional study reported on 332 patients with stage III or IV previously untreated laryngeal SCC. Subjects were randomized to receive either induction chemotherapy (IC) followed by RT, or surgery (total laryngectomy) and RT (Fig. 107-12). Two cycles of IC were given to the first group: nonresponders to the IC underwent immediate total laryngectomy, whereas responders received a third cycle of chemotherapy followed by RT (with salvage total laryngectomy for residual disease) (see Fig. 107-12). The laryngeal preservation rate was 64% for patients assigned to the IC/RT group, although only 39% had a fully functioning larynx. The 2-year survival for both groups was 68%. In a follow-up study, a further 10% decrease in the number of those with a functioning larynx was noted at 5 years, and there were no statistically significant differences in survival between the two groups.[262]

In an effort to determine the relative contributions of chemotherapy and RT to laryngeal preservation, as well as to determine whether concurrent chemotherapy as a radiosensitizer would improve the likelihood of organ preservation, the Head and Neck Intergroup conducted a prospective randomized study that included 518 patients randomly assigned to three arms (Fig. 107-13).[193] Subjects received either IC followed by RT, concurrent CRT, or RT alone. Previously untreated stage III and IV glottic or supraglottic carcinomas requiring total laryngectomy for surgical treatment were eligible. This study excluded subjects with T1 tumors and bulky T4 tumors with laryngeal cartilage destruction, invasion through the laryngeal cartilages, or extensive tongue base invasion. At 2 years, the larynx was preserved in 88% of patients in the concurrent CRT group, compared with 75% and 70% in the IC/RT- and RT-only groups. The overall survival rate for all three groups was similar (5-year survival 54% to 56%). The high rate of laryngeal preservation in the concurrent CRT group was associated with an 82% incidence of high-grade toxicity compared with an incidence of 81% and 62% in the IC/RT and RT groups, respectively. In those who failed nonsurgical organ preservation therapy, total laryngectomy salvaged approximately three quarters of the patients.

Adelstein and associates compared RT with concurrent CRT for stages III and IV laryngeal cancer and observed a significant difference in the recurrence-free interval (51% vs. 62%).[263] The 5-year overall survival was similar for the two groups (48% vs. 50%), which the authors believed was due to the efficacy of salvage surgery and non–cancer-related deaths. Most other studies of concurrent CRT in the head and neck do not address the larynx specifically and do not have large numbers of laryngeal cancer patients.[243] The utility of IC has been re-examined in a recent report by Urba and colleagues,[264] in which a single cycle of chemotherapy was used to select patients with advanced laryngeal cancer for treatment with concurrent CRT. The 3-year, cause-specific survival and overall survival rates were 87% and 85%, respectively, with a laryngeal preservation rate of 70%.

Despite the encouraging results, nonsurgical organ preservation is not without disadvantages, especially with regard to its toxicity, which must be taken into consideration when deciding on treatment. In the RTOG 91-11 study, acute toxicity was more common and severe with concurrent CRT when compared with the other two groups and included chemotherapy-related side effects (e.g., neutropenia, nausea, vomiting) and increased rates of severe radiation induced mucositis.[193] The total rate of severe toxic effects, acute and late, was 82% in the concurrent CRT group. There was no difference between the three groups with regard to speech, with 3% to 8% reporting moderate or worse speech impairment at 2 years. However, the incidence of dysphagia was high: 26% of patients treated with concurrent CRT had problems swallowing at 1-year post treatment. At 2 years, there was no significant difference between the groups, with 15% of the concurrent CRT group reporting ongoing dysphagia. Previous RT and CRT may also pose problems for both the patient and the surgeon if surgery (usually total laryngectomy) is required after nonsurgical organ preservation for residual or recurrent disease, chondronecrosis, or intractable aspiration. In a subsequent report on the RTOG 91-11 trial, Weber and colleagues[265] concluded that the morbidity of TL after organ preservation was acceptable but observed that up to 30% of patients developed a pharyngocutaneous fistula. The incidence was highest in the concurrent CRT group, but this difference was not statistically significant.

Therefore two important principles must be adhered to when nonsurgical larynx preservation treatment protocols are undertaken. First, if neoadjuvant chemotherapy or concurrent CRT is used, total laryngectomy must be performed for salvage in patients who fail to respond if survival is not to be compromised.[266] Second, the success of CRT is dependent on the completion of the treatment protocol. The efficacy of RT is significantly diminished if treatment breaks are taken due to toxicity.[267] Because nonsurgical larynx preservation therapy has significant toxicity (and mortality of 2% to 4%), patients with comorbidities and poor social support to help them through this challenging treatment regimen are less likely to complete the treatment and thus benefit from the addition of chemotherapy.

The success of nonsurgical larynx preservation treatment outside closely supervised clinical trials has also been questioned. Hoffman and colleagues[60] observed a concerning decrease in larynx cancer survival between 1985 and 2001, in patients with advanced glottic cancer, early supraglottic cancer, and T3N0M0 supraglottic cancer. During this same period there was a marked increase in use of nonsurgical larynx preservation treatment. Recently Chen and colleagues[268] analyzed 7019 larynx cancer cases from the National Cancer Database and observed that total laryngectomy was associated with a statistically significant increase in survival compared with CRT for stage IV laryngeal cancer.

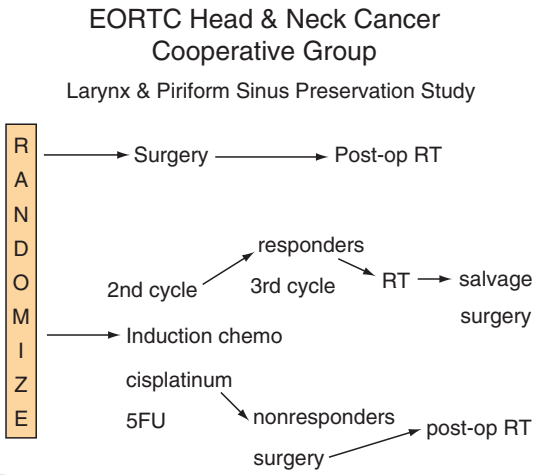

Figure 107-12. Schematic of the Department of Veterans Affairs Laryngeal Cancer Study.

Management of the Neck after Nonsurgical Organ Preservation Treatment

In all nonsurgical larynx preservation protocols, management of the neck and primary site must be considered both individually and together. Experts do not uniformly agree on the management of the neck in patients when there has been a complete response to treatment at both the primary site and in the neck. Traditionally, if any residual disease is detected in the neck after completion of RT or CRT, either by clinical examination or by radiographic evaluation, dissection of the neck is indicated.[244] In the initial VA study of the 106 patients who underwent IC and RT, 46 had N2 or N3 disease. A complete response to treatment was obtained in 18 of 46 patients (39%) with advanced neck disease and a partial response in 16 of 46 patients (35%). There

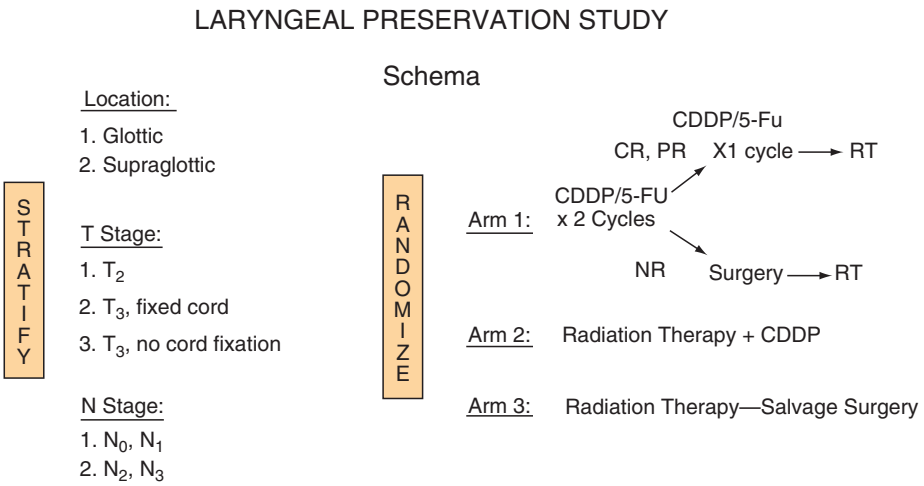

Figure 107-13. Schematic of the National Cancer Institute Intergroup Laryngeal Cancer Study.

was no response in 12 patients (26%). Fifty percent of the complete responders had N2 disease, and 33% had N3 disease. These data demonstrate that there is not a direct correlation between initial node size and response. Of the 18 patients who obtained a complete response in the neck, 5 eventually required a neck dissection. Of the 28 patients who had less than a complete response, 19 underwent neck dissection. When there was a delayed recurrence in the neck, survival was poor—less than 30%. When a poor response was obtained in the neck to the combined therapy, salvage by surgery still resulted in a poor outcome.

Further experience with CRT protocols for laryngeal preservation has focused attention on the cervical metastases, and a paradox has been identified. When routine neck dissection is performed after CRT, various series have reported a 14% to 39% incidence of positive findings in patients who had a complete clinical response to CRT.[269] In patients with less than a complete response, the majority of specimens did not demonstrate pathologic evidence of tumor.[270,271] Furthermore, in studies in which no neck dissection had been performed following CRT, the rate of recurrence in the neck was low at 0% to 6%.[272] It is hypothesized that in many patients with pathologic findings of tumor in the neck specimen, the cells are not viable but have not yet been cleared by the body. In a study of patients with persistent tumor after completion of treatment for nasopharyngeal cancer, serial biopsies every 2 weeks following treatment determined that positive biopsies showing tumor were seen for up to 12 weeks in patients who ultimately had complete response.[273] Increasingly, a PET scan 3 months after the completion of treatment is used to assess the effectiveness of treatment. A negative PET scan at 3 months reliably indicates the absence of persistent disease. For patients with N1-2 disease, the use of PET shows promise for predicting which patients can avoid a neck dissection post treatment.

Treatment of Recurrent Squamous Cell Carcinoma

Recurrent laryngeal SCC can be salvaged in approximately two thirds of cases, making close follow-up and the thorough investigation of any potential recurrence critical. Radiation therapy or CRT failures may be salvaged with surgery, whereas surgical failures may be salvaged with either further surgery or, in some cases, RT or CRT.

The detection of recurrent (or residual) disease is challenging and has become particularly important since the advent or nonsurgical organ preservation therapies. The status of the larynx may be difficult to assess following RT or CRT due to inflammation, edema, fibrosis and/or scarring, which develop as the result of the treatment. The symptoms of recurrence may vary according to the site of the original primary tumor and the nature of the recurrence. Signs of local recurrence include increasing edema, thickening of the true vocal cords, impairment of true vocal cord mobility, vocal cord fixation, leukoplakia, a mass lesion, and/or ulceration.[274] Recurrent cancer may be submucosal, and deep biopsies may be required because superficial biopsies of the epithelium may fail to diagnose recurrent tumor. A deep biopsy should be undertaken with caution in the irradiated larynx because it may cause infection, perichondritis, or chondroradionecrosis.[275] Recurrent disease must be differentiated from radiation-induced edema, perichondritis, or chondronecrosis because the clinical presentation of these entities may be similar, and a biopsy remains the gold standard for the diagnosis of recurrent disease.

PET scanning has been used successfully to distinguish between chondronecrosis and residual or recurrent tumor in the larynx following organ preservation therapy and helps to avoid unnecessary biopsies.[192,276] The sensitivity and specificity of PET for the diagnosis of residual or recurrent carcinoma in the larynx was found to be 80% and 81%, respectively, compared with 58% and 100% for CT.[277] In another report, the accuracy of PET for the diagnosis of recurrent cancer was superior to CT and clinical examination: 79% versus 61% versus 43%, respectively.[278] The utility of PET for the diagnosis of recurrent disease is still being evaluated, and a prospective trial comparing PET (followed by a direct laryngoscopy and biopsy if the PET scan is positive) and direct laryngoscopy (and biopsy) has been proposed.[279]

Almost half of the patients diagnosed with recurrent SCC have transglottic rT3 or rT4 tumors.[280] The standard treatment for recurrent laryngeal SCC is total laryngectomy. However, partial laryngectomy has been used to treat recurrent SCC for several decades and is particularly useful for early tumors that have failed RT. Som reported the use of an open approach (laryngofissure) for the salvage of radiation failures in the 1950s.[281] In 1970 Biller and colleagues[282] proposed criteria that would preclude the use of partial laryngectomy as surgical salvage, which included subglottic extension greater than 5 mm, cartilage invasion, contralateral vocal cord involvement, arytenoid involvement (except the vocal process), vocal cord fixation, and recurrence that did not correlate with the original primary lesion. In Ballantyne and Fletcher's series of 78 early glottic cancers that recurred following RT, 75% could be salvaged. Total laryngectomy was performed in 85% of cases and partial laryngectomy in the remainder.[274] A more recent report from the same institution observed that even though a greater variety of conservation laryngeal surgical procedures (such as TLM and SCPL) are available as treatment options, total laryngectomy is still required in approximately 70% of recurrences of early-stage (T1-2) glottic cancer.[283]

Therefore, in the minority of cases of early-stage recurrent disease, conservation laryngeal surgery may be possible. The results of open partial laryngectomy have been reported by several authors over the past 50 years.[281,282,284,285] The more recently described procedure of SCPL has good oncologic results in the small numbers of subjects reported to date.[246,286,287] Transoral laser microsurgery is effective for early-stage recurrences and, in the hands of experienced surgeons, for selected advanced stage recurrences.[283,288-290]

Nonsurgical organ-preservation therapies have become increasingly commonplace as a primary treatment modality for laryngeal SCC.[60] However, surgery still plays an important role and may be indicated for the salvage of residual or recurrent disease at the primary site, for residual or recurrent disease in the neck, for chondroradionecrosis, or for functional problems such as intractable aspiration, laryngeal stenosis, or pharyngoesophageal stenosis. These functional problems result from the adverse effects of RT on the soft tissue of the larynx, particularly decreased tissue vascularity and fibrosis.[291,292] Although it improves the oncologic efficacy of treatment, the addition of chemotherapy to RT also appears to increase the incidence and severity of these adverse soft tissue effects and there is a high risk of postoperative complications when surgery is required for these patients following RT or CRT.[193,265] Poor wound healing and high rates of pharyngocutaneous fistula formation were observed in patients in the RTOG 91-11 trial undergoing salvage surgery by Weber and colleagues.[265] Although a greater proportion of patients in the concurrent CRT group developed a fistula (30%), this was not statistically significant. There was no correlation between the timing of surgery and the incidence of complications.

Davidson and colleagues reported a series of 88 patients undergoing salvage surgery after RT without chemotherapy.[293] The 5-year survival rate was 35%, which did not correlate with the TNM stage of the original tumor or with the timing of the diagnosis of the recurrence. As expected, the highest rate of surgical complications occurred in patients undergoing pharyngectomy (48%), with pharyngocutaneous fistulae occurring in 27% of the subjects. Sassler and colleagues[294] studied patients undergoing surgery after nonsurgical organ preservation protocols and noted an overall complication rate of 61%. The rate of complications was 77% when surgery was performed within 1 year of treatment and only 20% when performed after 1 year. This was in contrast to the Davidson study. In this study (and in the literature in general), the risk of surgical complications was greatly increased when the pharynx was entered. Neck dissection alone (without entry into the UADT) has a much lower complication rate. Sassler observed a pharyngocutaneous fistula rate of 50%, with a mean time until closure of 7.7 months. The liberal use of free tissue transfer for reconstruction following total laryngectomy or laryngopharyngectomy for the treatment of RT or CRT failures decreases the incidence of pharyngocutaneous fistulae, decreases the duration of any fistulae that do occur, and decreases the rate of stricture formation and dependence on feeding tubes.[295,296]

In patients undergoing surgery following nonsurgical organ-preservation therapy, wound infection, delayed healing, and fistula formation cannot always be attributed to the RT or CRT alone and may be the result of malnutrition, metabolic abnormalities, or other comorbidities. Therefore, when surgery is indicated for this group of patients, their nutrition, thyroid status, and general health should be optimized beforehand.

Stomal Recurrence

After total laryngectomy, recurrence of SCC around the stoma is a grave sign. Stomal recurrence is often insidious and only discovered after the disease has become extensive. Recurrent disease may be secondary to paratracheal node involvement, invasion of the thyroid gland, intraoperative tumor spill with implantation of cells in the stoma, or incomplete excision of tracheal invasion by subglottic spread. Subglottic SCC is most frequently associated with stomal recurrence.[297,298]

The treatment of stomal recurrence is morbid and often unsuccessful, so prevention of stomal recurrence is paramount. When the risk of stomal recurrence is great (i.e., in primary subglottic SCC, glottic SCC with greater than 1 cm of subglottic extension, or T4 glottic tumors), the ipsilateral thyroid lobe is removed together with the larynx and bilateral paratracheal node dissections are performed. Adjuvant RT is also given, and the treatment field should include the upper mediastinum. In a large series reported by Rubin and colleagues,[146] the majority of stomal recurrences (12 of 15) were from primary subglottic tumors.

Dissection of the mediastinum and wide local resection for stomal recurrence was pioneered by Sisson, who proposed a four-category classification system (Fig. 107-14).[299] Significant morbidity and mortality are associated with the surgical treatment of stomal recurrence including injury to the great vessels, mediastinitis, hypocalcemia, and fistula formation. Aggressive treatment of stage III and IV stomal recurrence is usually not indicated because the prognosis for these patients is poor.[300] Sisson concluded that mediastinal failure was an important factor in advanced head and neck cancer and should be considered for T4 glottic and subglottic tumors in which mediastinoscopy was positive for nodes.[299]

Prognosis and Prognostic Predictors

The 5-year relative survival rate for laryngeal SCC is 64%.[60] The 5-year relative survival rates for the individual sites are 47% for supraglottic SCC, 79% for glottic SCC, and 30% to 50% for subglottic SCC.[60,114] The prognosis for patients with laryngeal SCC depends on many variables, which may be classified as either disease factors or patient factors.

Disease Factors

Clinical Features

The most important predictor of prognosis for patients with laryngeal cancer is the clinical stage: An increase in T stage or in N stage is associated with a decrease in survival.[301,302] However, the N stage is more important than the T stage in predicting survival.[303] Overall survival is significantly better for patients who are N0 compared with patients who are N+.[302] In patients with cervical metastases, the presence of extracapsular spread (ECS) on histologic examination is an unfavorable prognostic sign and is associated with a significant further reduction in survival.[304,305] The prognosis for patients with distant metastases is poor, with a 5-year survival of less than 10%.[117] The site of the primary tumor is the second most important predictor of prognosis. Glottic SCC has the best prognosis, and subglottic SCC has the worst.[60,114]

Local control of laryngeal SCC with RT is worse with tumors of larger volume.[306,307] Fixation of the vocal cord upstages an SCC to T3; however, impaired vocal cord mobility is also an important clinical sign. Having observed lower local control rates after RT for T2 tumors with impaired vocal cord mobility, Harwood and DeBoer[19] proposed that the classification for T2 tumors be divided into T2a (normal vocal cord mobility) and T2b (impaired vocal cord mobility). A recent study reported that the failure of return of vocal cord movement in a small series ($n = 14$) of T2b and T3 tumors treated with RT plus or minus chemotherapy was associated with locoregional recurrence in all cases, while none of the patients with return of vocal cord mobility had a recurrence.[181]

Radiologic Characteristics

Several reports have examined whether characteristics of the primary tumor observed on imaging can predict the outcome of treatment, particularly RT or CRT. Using CT or MRI, involvement of particular regions or structures of the larynx by tumor such as the anterior commissure, the PES, the laryngeal cartilages, or even having tumor adjacent to the thyroid cartilage has been found to be a predictor of local control.[308-312] Tumor volume measured by CT, MRI, or even PET is also a reliable predictor of local control, although this is not always an independent factor.[312-315] PET is the most accurate modality for determining tumor volume, which may be overestimated by CT or MRI.[316] Another potential prognostic indicator determined by PET has recently been described: A high pretreatment standard uptake value of FDG by the primary tumor was associated with poorer local control and disease-free survival.[317,318] At present there are no standardized criteria to predict local control or failure on the basis of CT, MRI, or PET.[125]

Histopathologic Characteristics

Several histologic features have been reported to be predictive of prognosis. The most important is the extracapsular spread of metastatic tumor in cervical nodes, which is associated with a significant decrease in survival in SCC of the head and neck including the larynx.[304,305] The histologic type of tumor is also important. There are several variants of SCC, some of which have a different biologic behavior to conventional SCC. Verrucous carcinoma is less aggressive and has a better prognosis than conventional SCC, whereas the opposite is observed in cases of adenosquamous carcinoma. These variants are discussed in more detail in a subsequent section of this chapter.

The histologic grade of the tumor (well vs. moderately vs. poorly differentiated),[319,320] the pattern of invasion (a pushing vs. infiltrative

interface between the tumor and the normal tissue),[96,321] and the presence of perineural and/or vascular invasion[322] may also influence local control and survival.

The risk of local recurrence in the larynx is increased if the excision margins of the primary tumor are positive after open partial laryngectomy.[323,324] Although complete excision of the primary tumor remains the most important principle of oncologic surgery, excision margins may be close without compromising local control, as reports of endoscopic laser resections have demonstrated.[325]

The prognostic usefulness of DNA ploidy is controversial. DNA ploidy status has been shown to be a marker for nodal metastases in laryngeal carcinoma and predictive of overall survival following RT.[326] Aneuploid tumors have an increased risk of local recurrence after RT.[327] However, some authors have not found DNA ploidy to be a significant prognostic factor.[328]

Patient Factors

Several factors independent of the stage or histologic characteristics of the tumor may affect the outcome of laryngeal SCC. Patient variables that have consistently been found to be important predictive factors include comorbidity (general health), age, and performance status. Comorbidity may be measured using one of several validated scales such as the Washington University Head and Neck Comorbidity Index (developed specifically for head and neck cancer patients)[319] and is an independent prognostic factor for patients with laryngeal cancer.[329,330] Advanced age (older than 65 years) is associated with a worse prognosis for SCC of the head and neck including laryngeal carcinoma.[302,319] Patients with a higher performance status, as measured by scales such as the Karnofsky Performance Status, have a more favorable outcome.[331,332] The significance of gender as a prognostic factor is controversial, with some reports finding no difference[319,331] and others reporting a worse prognosis for women with laryngeal cancer.[333,334] For patients undergoing RT for laryngeal SCC, a normal hemoglobin level is associated with increased overall survival.[335]

Molecular Markers of Prognosis

Clinicians and researchers alike are searching for molecular markers that will allow the identification of patients with laryngeal cancer who have adverse prognostic features so that more aggressive and successful treatment may be offered. The most commonly mutated gene in human cancer including laryngeal cancer is p53; however, its prognostic value in laryngeal cancer is uncertain.[336-338] Epidermal growth factor receptor (EGFR) overexpression has been found to be a marker for aggressiveness, nodal metastasis, and survival.[338,339] EGFR overexpression is also associated with radioresistance and poor local control of laryngeal cancer,[340] and therefore a tumor's EGFR status may be used to predict radiosensitivity and chemosensitivity.[338] Vascular endothelial growth factor (VEGF) positivity is associated with increased overall survival in patients irradiated for laryngeal SCC.[341] Cyclin D1 and cyclin D3 overexpression are reported to be significant predictors of disease-free survival, and determining the cyclin D1/D3 coexpression status of laryngeal carcinomas has allowed stratification of patients into prognostic groups, with patients overexpressing both cyclins having the worst prognosis.[342] Markers of epithelial differentiation such as type 2 cyclooxygenase (Cox-2) and galectin-3, may also have predictive value. Low expression of Cox-2 in laryngeal SCC is associated with aggressive biologic behavior (including invasion), whereas galectin-3 expression is associated with improved overall survival.[338] At present, much of the data regarding molecular markers are conflicting and no reliable prognostic molecular markers exist for clinical use.

Follow-Up

Follow-up after treatment for laryngeal cancer has several goals: (1) to detect recurrent disease; (2) to detect second primary tumors; (3) to assist in the ongoing rehabilitation of speech and swallowing; (4) to ensure that adequate nutrition is being maintained; and (5) to treat any other problems that may arise as a side effect of treatment such as chronic pain. The first two goals are probably less important than the other goals. In a study of the utility of follow-up after treatment (with curative intent) for laryngeal cancer, Ritoe and colleagues[343] reported that an asymptomatic tumor recurrence was found in only 2% of all routine visits and that no survival benefit came from the detection of these asymptomatic recurrences as part of the follow-up regimen. In a second study from the same institution, Ritoe and colleagues[344] also observed that screening (with a chest radiograph) to detect lung cancer in asymptomatic patients after curative treatment for laryngeal SCC did not improve survival for those who were diagnosed with lung cancer.

The National Comprehensive Cancer Network (NCCN) suggests a physical examination every 1 to 3 months for the first year after treatment, every 2 to 4 months in the second year, every 4 to 6 months in the third, fourth, and fifth years, and every 6 to 12 months thereafter.[345] Thyroid function tests should be checked every 6 to 12 months because thyroid function is reduced after larynx cancer treatment that includes radiotherapy or extensive laryngeal and thyroid surgery. Hypothyroidism may develop years after treatment, and symptoms are often vague and nonspecific—the patient who seems depressed and lethargic after treatment may be hypothyroid. The risk of hypothyroidism is 20% after RT, 50% after laryngectomy and ipsilateral thyroid lobectomy, and greater than 65% if both RT and surgery are used (see Table 107-6).[346]

Variants of Squamous Cell Carcinoma

Verrucous Carcinoma

Verrucous carcinoma (VC) is a variant of SCC characterized by a predominantly exophytic growth of well-differentiated keratinizing epithelium with pushing margins. These tumors are slow growing; however, they can cause extensive local destruction.[17] The larynx is the second most common site in the head and neck for VC, with most VC occurring on the true vocal cords.[347] HPV, particularly HPV 16 and 18, is associated with some but not all of these tumors, but the significance of this relationship is uncertain.[348]

Histologic examination of VC reveals thickened papillary projections and bulbous invaginations of well-differentiated squamous epithelium, with marked keratinization and thin fibrovascular cores (Fig. 107-15). The squamous epithelium lacks the cytologic criteria for malignancy, which distinguishes it from conventional SCC.[349] The margins of the tumor are pushing rather than infiltrating. Superficial biopsies may miss the histologic features of VC, and often patients are diagnosed only after multiple biopsies. There is often marked peritumoral inflammation, and patients may present with reactive lymphadenopathy, but pure VC does not metastasize.[350] A hybrid form of VC, which contains foci of conventional SCC, may metastasize to the cervical nodes.[351]

The preferred treatment is conservative surgical excision because VC is less radiosensitive than conventional SCC.[352] The risk of residual

Figure 107-15. A photomicrograph of verrucous carcinoma of the larynx shows hyperkeratosis, papillomatosis, and club-shaped rete ridges (hematoxylin-eosin; original magnification ×25). *(From Fliss DM, Noble-Topham SE, McLachlin M, et al. Laryngeal verrucous carcinoma: a clinicopathologic study and detection of human papillomavirus using polymerase chain reaction.* Laryngoscope. *1994;104:147.)*

or recurrent disease is higher with RT than surgery, but RT is indicated for extensive lesions, for which the only surgical treatment possible is total laryngectomy, or for patients who are poor surgical risks.[347,350,353] In one large series of VC, surgical salvage was universally successful.[352] Previously there were concerns that irradiated VC may undergo anaplastic transformation, but reviews have concluded that these cases were hybrid tumors misdiagnosed as VC.[349,351] Neck dissection is not indicated, as pure VC does not metastasize.[350] The hybrid form of VC, which may metastasize, should be treated in the same manner as conventional SCC. Overall, the prognosis for VC is excellent, with 5-year survival approximately 90%.[347,354]

Basaloid Squamous Cell Carcinoma

Basaloid squamous cell carcinoma (BSCC) is a rare and highly malignant variant of SCC. The supraglottic larynx and pyriform sinus are the most common sites for BSCC.[355] BSCC is a bimorphic tumor with both basaloid and squamous cell components.[17] The basaloid component is more prominent and consists of small cells with hyperchromatic nuclei and scanty neoplasm arranged in lobules.[356] Presence of the squamous component, which may be in situ or invasive carcinoma, differentiates BSCC from adenoid cystic carcinoma.[17] Stromal hyalinization and cystic spaces in the tumor (which may contain mucoid material) help to distinguish BSCC from conventional SCC.[357]

Patients with BSCC often present at a late stage, and both cervical and distant metastases are common.[355] Aggressive treatment with radical surgery (including neck dissection) and postoperative RT or CRT is indicated.[355,358] Basaloid SCC is generally considered to be more aggressive than conventional SCC and to be associated with a worse prognosis, although there is some disagreement in the literature regarding this.[355,358-360]

Spindle Cell Carcinoma

Spindle cell carcinoma (SPCC), also referred to as *sarcomatoid carcinoma, carcinosarcoma,* or *pseudosarcoma,* is a biphasic tumor composed of a surface squamous cell lesion (either CIS or invasive SCC) and an underlying malignant spindle cell component (which is predominant).[17,361] The histogenesis of SPCC has been debated, but current evidence suggests that it is a neoplasm of epithelial origin with mesenchymal differentiation.[362] This is an uncommon lesion, which has been reported following RT, although radiation is not thought to be a major etiologic factor. However, like conventional SCC, SPCC is strongly associated with tobacco and alcohol abuse.[361] The majority of SPCC occurs as a polypoid lesion in the glottis. Cervical metastases are common (25%) and distant metastases less so (5% to 15%).[362] The diagnosis of SPCC may be difficult, especially if the squamous component is small, or if the biopsy fails to sample that part of the tumor. SPCC may be misdiagnosed as a sarcoma such as a fibrosarcoma or MFH or as a reactive or benign proliferation of spindle cells such as nodular fasciitis.[361,362]

Surgery is the recommended primary treatment modality for SPCC because RT alone is not effective. The extent of surgery (partial vs. total laryngectomy, and neck dissection) for SPCC is similar to that required for conventional SCC at the same site and stage, and RT is often given postoperatively.[361,363,364] The clinical behavior of SPCC is similar to that of SCC, with site and stage the most important prognostic factors. The 5-year survival rate for SPCC is 63% to 94%.[361]

Adenosquamous Carcinoma

Adenosquamous carcinoma (ASC) is a rare neoplasm with histologic features of both SCC and adenocarcinoma.[17] The larynx is the most common site for this tumor in the UADT.[365] ASC arises from the basal cells of the surface epithelium that are capable of divergent differentiation.[366] The two distinct histologic components of ASC are distinct from one another. The squamous cell component, which arises from the surface epithelium, is predominant and may be either severe dysplasia, CIS, or invasive SCC. The second component, adenocarcinoma, is found deeper in the tumor.[365] ASC may be misdiagnosed as mucoepidermoid carcinoma; however, the latter tumor lacks a mucosal component.[366]

ASC is a highly malignant tumor, which is more aggressive than conventional SCC. Nearly two thirds of patients develop cervical metastases, and 23% develop distal metastases.[367] Radical laryngeal surgery with dissection of the neck is recommended; however, the prognosis is poor. Nearly half of patients experience a local recurrence, and their 5-year survival rate is 15% to 25%.[366-368]

Acantholytic Squamous Cell Carcinoma

Acantholytic SCC (ASCC), also referred to as *adenoid SCC,* is another uncommon variant of SCC and is characterized by pseudoglandular spaces or lumina resulting from the acantholysis of tumor cells.[17] Neither true glandular differentiation nor mucin production is observed in these tumors.[369] In the head and neck, ASCC arises most often in sun-exposed skin and is only rarely diagnosed in the supraglottic larynx.[370,371] Immunohistochemistry and mucin staining are important in the diagnosis of ASCC, which may be confused with adenosquamous SCC, angiosarcoma, and minor salivary gland–type tumors such as adenoid cystic carcinoma and mucoepidermoid carcinoma.[369] The treatment of ASCC is similar to that of conventional SCC. The prognosis of ASCC is similar to SCC, although some authors report that ASCC is a more aggressive tumor.[369,370,372]

Papillary Squamous Cell Carcinoma

Papillary SCC (PSCC) is an uncommon variant of SCC, which may occur as either an in situ lesion or an invasive tumor.[373] PSCC is characterized by an exophytic papillary growth pattern, composed of cores of fibrovascular stroma covered by squamous epithelium with severe atypia, increased mitotic activity, and loss of normal stratification.[17] The markedly abnormal cytologic changes observed in PSCC help to differentiate it from verrucous carcinoma in which the cytologic features of malignancy are either absent or minimal. The differential diagnoses of PSCC also include squamous papilloma and exophytic SCC. A full-thickness biopsy is crucial to allow a definitive diagnosis of PSCC.[373] Similar to conventional SCC, tobacco and alcohol are important risk factors for these tumors. PSCC may arise from squamous cell papilloma, although the true role of HPV in the pathogenesis is uncertain because the prevalence of HPV in these tumors is less than 50%.[374,375] PSCC arises from the supraglottis more commonly than from the glottis or subglottis.[373,376] PSCC may metastasize to the cervical nodes, but distant metastases are rare.[373] PSCC is treated in a similar fashion to conventional SCC and has been reported to have a better prognosis,[375-377] although some authors disagree.[378]

Uncommon Malignant Laryngeal Tumors

Although most laryngeal malignant tumors are SCCs, a wide variety of malignant tumors of other histologic types may occur in the larynx, as either a primary or a secondary tumor. For many of these tumors, the numbers reported in the literature are small. Therefore recommendations regarding treatment are often made on the basis of case reports and/or case series.

Malignant Salivary Gland Type Tumors

The larynx contains many minor salivary glands, which are submucosal and concentrated in the saccule, supraglottis (vestibular folds, aryepiglottic folds, and caudal epiglottis), and anterior subglottis.[379] Salivary gland–type tumors in the larynx are rare and constitute less than 1% of laryngeal tumors.[380] The majority of salivary gland type tumors are malignant, and the majority of these are either mucoepidermoid carcinoma or adenoid cystic carcinoma.[381] Because these lesions are submucosal, they tend to present late as large tumors.[382] The clinical features of salivary gland–type tumors does not differ significantly from those of SCC.[380] Recommendations for treatment cannot be regarded as definitive because the number of cases treated is small.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma (MEC) is a malignant epithelial tumor composed of a mixture of squamous cells, mucin-secreting cells, and cells of intermediate type.[17] This rare tumor, which accounts for one third of malignant salivary gland type tumors, is thought to arise from the intercalated ducts of seromucinous glands.[383,384] MECs are classified as either low- or high-grade carcinomas, and the histologic grade

correlates significantly with survival.[380] High-grade tumors may be difficult to distinguish from SCC on standard hematoxylin and eosin preparations. Staining for mucin may be required to confirm the diagnosis. Men are affected much more often than women.[381] These tumors are most commonly discovered in the supraglottis (especially the epiglottis).[380] Nearly half of patients with MEC present with, or eventually develop, cervical metastases.[381]

Surgery (either partial or total laryngectomy) is the primary modality for the treatment of malignant salivary gland–type tumors including MEC.[382,383,385,386] Neck dissection is indicated for N+ disease; however, there is some disagreement about the indications for neck dissection in the N0 neck: some authors have recommended an elective neck dissection in cases of high-grade MEC only,[386,387] whereas others have suggested that all patients with MEC should undergo surgical treatment of the neck given the high rate of regional metastases.[383] The use of adjuvant treatment is also uncertain. Indications for postoperative RT include close surgical excision margins, pathologically confirmed cervical metastases, and high-grade MEC.[383,386,387] Locoregional control and survival in MEC depend on the stage of the disease and histologic grade of the primary tumor.[380] Low-grade MEC has been reported to have a 5-year survival rate of greater than 95% compared with less than 30% for high-grade MEC.[388]

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma (ACC) is a distinctive type of adenocarcinoma composed mainly of small, uniform basaloid cells forming tubules, cords and/or compact masses, surrounded and intersected by cylinders of hyaline or mucoid material, giving a cribriform or lacelike pattern.[17] Like MEC, ACC is rare and accounts for one third of malignant salivary gland–type tumors.[381] ACC is thought to originate from the intercalated duct reserve cells of the terminal tubule complex.[380] Three subtypes of ACC have been described according to their histologic appearance: cribriform, tubular, and solid.[380] ACC has a propensity for perineural invasion, and for this reason pain may be a prominent symptom in ACC.[386]

In contrast with most other malignant laryngeal tumors, women and men are affected in equal numbers by ACC.[380] The majority of these tumors occur in the subglottis (60%) and the supraglottis (35%), with only occasional glottic tumors reported.[381] The mucosa overlying ACCs, which are predominantly submucosal, is usually ulcerated.[380] ACCs demonstrate distinctive biologic behavior: an infiltrative growth pattern, a propensity for perineural invasion, and a tendency for hematogenous spread.[380] Cervical lymph node metastases are uncommon; however, late recurrence with distant metastases is a common clinical scenario.[382]

Surgery is the primary modality for the treatment of ACC. Partial laryngectomy is possible, although caution should be exercised because ACC has an infiltrative submucosal growth pattern and conservative surgery may result in incomplete excision with positive margins. For this reason, some authors have recommended total laryngectomy as the standard treatment for ACC,[386] whereas others have suggested that partial laryngectomy can be used to treat patients with small, well-defined tumors amenable to complete excision with negative surgical margins.[382] Another treatment philosophy for ACC is that radical surgery should be avoided where possible because it will have no effect on the distant metastatic disease, which often develops many years after initial treatment.[383] A neck dissection is indicated only for the clinically positive neck because the risk of regional metastasis is low.[382,389]

ACC is a relatively radioresistant tumor; however, postoperative RT has been used for pathologically confirmed cervical metastases and for close surgical margins.[386,390,391] Fast neutron RT may be more effective in the treatment of ACC; however, its use is limited by the side effects on normal tissue, which is of particular importance in the larynx.[392] ACC has a tendency for late recurrence, most often with distant metastases.[382]

Neuroendocrine Tumors

After SCCs, neuroendocrine tumors of the larynx (NTL) are the second most commonly diagnosed malignancies of the larynx.[393] NTL are a group of heterogeneous neoplasms that vary from benign to highly malignant in their biologic behavior and clinical course. The WHO has classified NTL into the following types: typical carcinoid; atypical carcinoid; small cell carcinoma, neuroendocrine type; and paraganglioma.[394] Atypical carcinoid is the most common of the NTL (54%), followed by small cell carcinoma, neuroendocrine type (28%), paraganglioma (12%), and typical carcinoid (7%).[393] The larynx contains neuroendocrine cells in the epithelium of the ventricle and the subglottis, which are thought to be the cells of origin of typical carcinoids, atypical carcinoids and small cell carcinomas, neuroendocrine type.[395] However, some authors disagree, suggesting that these tumors may instead arise from pluripotential stem cells in seromucinous glands and in the squamous epithelium.[396] Paragangliomas of the larynx arise from the paraganglia of the larynx.

The clinical presentation of NTL does not differ significantly from that of SCC of the larynx and depends on the site of the primary tumor. However, several reports have described paraneoplastic syndromes associated with typical carcinoid tumors, atypical carcinoid tumors, and small cell carcinomas.[393]

Typical Carcinoid

Typical carcinoid (TC) (commonly called carcinoid) of the larynx is an epithelial tumor of low-grade malignancy composed of round to spindle cells with evidence of neuroendocrine differentiation.[394] This lesion is the least common of the NTL. Males are affected more commonly than women.[394] TCs are usually submucosal or polypoid masses found in the supraglottis.[397]

Neither RT nor chemotherapy is effective against TCs.[393] For smaller primary tumors, complete but conservative surgical excision is recommended. Total laryngectomy is reserved for extensive lesions. Elective neck dissection is not indicated because the risk of cervical metastasis is low.[393]

Although TCs are regarded as a low-grade malignancy, approximately one third of patients develop distant metastases.[398,399] The 5-year survival rate for laryngeal TCs has been reported as 48%,[400] although this may be less than expected due to the inclusion of cases of atypical carcinoids, misdiagnosed as typical carcinoids.[393]

Atypical Carcinoid

Atypical carcinoid (AC) is the most common neuroendocrine neoplasm in the larynx. Histologically, ACs are differentiated from TCs by having larger cells, more mitoses, necrosis, cellular atypia and pleomorphism, and angiolymphatic invasion.[394] ACs share some characteristics with TCs: Both tumors are more common in males, present as a submucosal or polypoid mass, and are usually found in the supraglottis.[401] Immunohistochemistry is important for the correct diagnosis of AC, which may be mistaken for a TC, paraganglioma, malignant melanoma, or medullary thyroid cancer.[394] ACs are aggressive tumors with propensity for regional and distant metastases. In one large series 43% of patients developed cervical metastases, while two thirds were found to have distant metastases.[402] A full metastatic workup is important in the management of AC and should include a complete skin examination because this tumor often metastasizes to the skin and subcutaneous tissues.[393]

Surgery is the recommended treatment. Partial or total laryngectomy is performed depending on the size and location of the primary tumor, together with bilateral neck dissections (including patients staged as N0).[393,403] Partial laryngeal resections may be performed via an open approach or endoscopically.[404] AC is regarded as a radioresistant neoplasm; however, a recent report observed a response to adjuvant RT or CRT and suggested that adjuvant RT be given for local extension, multiple nodal metastases, and extracapsular spread.[405] The prognosis for AC is poor: In one series, the 5- and 10-year survival rates were 48% and 30%, respectively,[402] while a subsequent report observed a 5-year survival rate of 46%.[400]

Small Cell Carcinoma, Neuroendocrine Type

The most malignant and second most common of the NTL is small cell carcinoma, neuroendocrine type (SCCNET).[401] Similar to the typical and atypical carcinoids, SCCNET is more common in males and usually arises in the supraglottis.[394] At presentation approximately

half of patients with SCCNET have cervical metastases, and up to 90% develop distant metastases.[406] The prognosis for SCCNET is grave, with 2- and 5-year survival rates of 16% and 5%, respectively, observed in one series[407] and a 5-year survival rate of 7.7% in a second series.[398] Due to the high incidence of disseminated metastatic disease, surgery is rarely indicated.[393] Instead, RT in conjunction with multiple-drug chemotherapy is the preferred treatment, using protocols similar to those for small cell carcinoma of the lung.[393,407]

Paraganglioma

Paragangliomas of the larynx are neuroendocrine neoplasms arising from either the superior or inferior laryngeal paraganglia.[401] These tumors are benign (with the exception of a single case of a metastasizing laryngeal paraganglioma[408]) but are included in this section to complete the discussion on laryngeal neuroendocrine tumors.

Laryngeal paragangliomas are the third most common NTL. They are three times more common in women and may be associated with paragangliomas in other sites (familial paragangliomas).[408,409] The majority of paragangliomas are found in the supraglottis, especially in the aryepiglottic fold, and are thought to arise from the superior paraganglia.[401] They appear as a well-circumscribed tan, brown, or red submucosal mass.[408] Excessive hemorrhage may result from an attempt to biopsy a paraganglioma, and if possible the diagnosis should be made preoperatively on the basis of the findings of a CT or (preferably) an MRI scan, in conjunction with an octreotide scan, to avoid a biopsy.[410]

Surgical excision with laryngeal preservation is the preferred treatment for paragangliomas. An open approach, via a lateral pharyngotomy, lateral thyrotomy, or laryngofissure, has been recommended, to allow vascular control before excision of the tumor.[410,411] Successful transoral CO_2 laser resection of a supraglottic paraganglioma has been described, but most authors advise against this technique because of difficulties with hemostasis and an increased risk or recurrence.[409,412] Subglottic paragangliomas may be excised using conservation techniques such as a cricoid split; however, total laryngectomy may be required.[409,413] A neck dissection is not indicated because paragangliomas do not metastasize to the cervical nodes.[409] If a neck mass is detected in conjunction with a laryngeal paraganglioma, there should be a high index of suspicion that either the neck mass is a carotid body paraganglioma or that the laryngeal primary tumor is another type of neuroendocrine tumor such as an atypical carcinoid.[393] Paragangliomas respond to RT, but do so incompletely.[414] The prognosis for laryngeal paragangliomas is excellent.[408]

Malignant Tumors of Soft Tissue, Bone, and Cartilage (Sarcomas)

Malignant neoplasms may arise from the connective tissue of the larynx. Fibrosarcomas were previously regarded as the most common laryngeal sarcoma, but modern pathologic techniques, especially immunohistochemistry, have demonstrated that most of these tumors were diagnosed as fibrosarcomas incorrectly and are in fact other types of malignancies, especially spindle cell carcinoma, a variant of SCC.[415,416] Fibrosarcomas may occur as a complication of RT.[417]

Chondrosarcoma

Chondrosarcomas of the larynx are rare but are the most frequent nonepithelial laryngeal neoplasm, accounting for 0.1% to 1% of all laryngeal tumors.[418] These lesions occur in adults between the ages of 50 and 80 years. Males develop this disease more commonly than females by a ratio of 3 to 4:1.[418] Chondrosarcomas usually arise in ossified hyaline cartilage, and the cricoid cartilage is the most common site for chondrosarcomas in the larynx, especially the posterior or posterolateral region of the cricoid, because these regions ossify first.[419] The thyroid cartilage is a much less common site, and epiglottic chondrosarcomas are rare indeed.[420] Chondrosarcomas are composed of neoplastic hyaline cartilage and are graded as low-, intermediate-, or high-grade lesions. A dedifferentiated variant of chondrosarcoma has also been described.[421] Most chondrosarcomas are low grade, grow slowly, and follow an indolent clinical course. High-grade and dedifferentiated chondrosarcomas have a high risk of metastases and are associated with a poorer prognosis.[419]

Patients with chondrosarcomas may present with dyspnea, stridor, dysphonia, or dysphagia. They may notice a palpable mass in the neck. These symptoms usually develop insidiously. Examination findings may include a submucosal mass, narrowing of the subglottic airway, vocal fold immobility, or arytenoid hypertelorism.[422] CT scanning is the most useful radiologic investigation in the evaluation of chondrosarcomas, but MRI can give supplementary information.[423] For histologic diagnosis a biopsy is obtained via direct laryngoscopy. The CO_2 laser may be helpful in ensuring that an adequate sample has been obtained.[424] Despite a thorough evaluation, it may still be difficult to distinguish between a chondroma and a chondrosarcoma—clinically, radiologically, or histologically. Recent reports have suggested that many chondromas have been misdiagnosed and are in fact low-grade chondrosarcomas.[421,424] In the largest published series of laryngeal chondrosarcomas, the majority were associated with chondromas on histologic examination, suggesting that chondrosarcomas may develop from chondromas that undergo malignant transformation.[419]

The treatment for chondrosarcomas is surgery: partial laryngectomy is indicated for low-grade lesions and total laryngectomy for high-grade or dedifferentiated lesions. Conservation laryngeal surgery for cricoid chondrosarcomas is challenging due to the functional sequelae of resection of part or all of the cricoid; however, both open and endoscopic approaches have been described: hemicricoidectomy,[425] total cricoid resection,[426] and TLM.[424] Reconstruction of the larynx may be achieved using grafts, local flaps, thyrotracheal anastomosis,[426] and free flaps.[427] Radiation therapy has been used to treat only a small number of cases, with long-term follow-up reported in only two patients.[428,429] Chemotherapy is not effective.[418] Chondrosarcomas have a good prognosis with a 90% survival rate at 5 years.[424] Local recurrence may be treated with a total laryngectomy or, more conservatively, with intermittent endoscopic debulking.[424,430]

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) is the most common soft tissue sarcoma in general. However, it is extremely rare in the larynx.[416] Prior RT has been implicated in the pathogenesis of some cases of MFH.[431,432] Macroscopically these tumors may be sessile or polypoid, and they are usually found in the glottis.[433] A spindle cell carcinoma may be mistaken for an MFH on histology, so the diagnosis of MFH should only be made after the appropriate immunohistochemistry has been performed.[415] Radiation therapy is not effective against MFH, which is treated surgically.[415,433-435] A neck dissection is indicated only when there is evidence of nodal disease.[436] The prognosis of MFH is variable, although this tumor usually demonstrates aggressive biologic behavior.

Liposarcoma

Primary liposarcomas of the larynx (LSL) are extremely rare. LSLs most commonly occur in males older than the age of 40 years, who often present with airway obstruction.[416] These tumors have a predilection for the supraglottis and have never been found in the subglottis.[437] The majority are low-grade tumors and follow an indolent course. For these reasons they may be misdiagnosed as lipomas initially, and the diagnosis of liposarcoma may be made only after several recurrences.[438] CT and MRI are useful in differentiating between lipomas and liposarcomas.[437] Wide local excision is the treatment of choice because simple endoscopic excision has a high recurrence rate when compared with more extensive surgery such as an open partial laryngectomy via a lateral pharyngotomy.[439] A neck dissection is not required because LSLs do not metastasize to cervical nodes.[415] The usefulness of RT and chemotherapy for these tumors is not known. The prognosis for patients with LSL is excellent, with a 5-year survival of 90%.[416]

Kaposi's Sarcoma

Kaposi's sarcoma (KS) is a vascular endothelial cell neoplasm of uncertain origin.[440] However, some have hypothesized that KS is a reactive phenomenon, with vascular proliferation stimulated by angiogenic factors released by $CD4^+$ lymphocytes or by viruses.[441] KS is classified

into three subtypes, which affect different populations: classic (older Mediterranean or Jewish men), endemic (men in equatorial Africa), and epidemic (immunocompromised patients such as those with AIDS). KS of the larynx is exceedingly rare.[440] The supraglottis (particularly the epiglottis) is the most common site for laryngeal KS.[415] Macroscopically, the tumors may be macular, nodular, or pedunculated and are a red-purple color.[440] A wide variety of treatments, both medical and surgical, have been used for KS. Local treatments include surgical excision (including TLM),[440] RT,[442] and intralesional injection of vinblastine.[443] Systemic chemotherapy[440] and immunotherapy (with interferon-α)[444] have also been reported. Often a combination of these treatments is used. Although airway obstruction may occur and require specific treatment such as a tracheotomy, KS of the larynx is usually not life threatening, and therefore the goal of treatment is the relief of symptoms such as pain, bleeding, dyspnea, dysphonia, and dysphagia.[440,441]

Malignant Hematolymphoid Neoplasms

Hematolymphoid neoplasms of the larynx are uncommon, either as primary tumors, or in association with disseminated disease.[445] Extramedullary plasmacytomas affect the larynx more often than lymphomas.[446]

Extramedullary Plasmacytoma

Plasma cell neoplasms (antibody forming B cells) usually involve the bone marrow diffusely, (multiple myeloma), but they may also occur as single lesions localized to bone marrow, a medullary plasmacytoma; to bone, a solitary plasmacytoma of bone; or to soft tissue without bone marrow involvement, an extramedullary plasmacytoma (EMP).[447] By definition, patients with EMP do not have multiple myeloma. The finding of an extramedullary plasmacytoma necessitates referral to a hematologist for a workup to exclude multiple myeloma. EMPs comprise less than 5% of plasma cell neoplasms, but more than 80% occur in the head and neck region, with approximately 5% in the larynx.[421] By 1996, approximately 90 cases had been reported.[448] Laryngeal EMP is more common in males by a ratio of 3:1 and has a peak incidence between 50 and 70 years of age.

Patients usually present with hoarseness, dyspnea, or a foreign body sensation.[449,450] Dysphagia, stridor, and pain are late symptoms associated with aggressive lesions.[448] Laryngeal EMPs are polypoid or sessile submucosal masses and occur most frequently in the supraglottis (especially in the epiglottis),[447] with vocal fold[449] and subglottic[450] EMPs less common. An adequate biopsy is crucial in the diagnosis of EMP. Because the lesion is usually submucosal, a deep biopsy must be performed to ensure that pathologic tissue has been obtained,[451] and the specimen must be sent fresh to allow the appropriate investigations to be undertaken. Immunohistochemistry, flow cytometry, and immunophenotyping are necessary to establish the diagnosis of EMP. Amyloidosis is an important differential diagnosis because amyloidosis is associated with plasma cell infiltrates (polyclonal on immunohistochemistry) and up to 40% of EMPs have evidence of amyloid on biopsy.[447]

Options for the treatment of laryngeal EMPs include surgery alone, surgery combined with RT, and RT alone.[447] Conservative surgical treatment such as TLM has been suggested for small lesions in easily accessible locations (such as the epiglottis),[452,453] but because EMPs are radiosensitive, the majority have been treated with RT.[447,450] The cervical nodes should be included in the RT fields to decrease the risk of regional failure.[450] The prognosis for patients with EMPs is good, with a local failure rate of less than 10%.[447] However, 16% to 32% of patients with EMPs later develop multiple myeloma; therefore long-term follow-up is important.[450]

Lymphoma

Primary non-Hodgkin's lymphoma (NHL) of the larynx is also rare with fewer than 100 cases reported in the literature.[454] Secondary involvement of the larynx by lymphomas from regional lymph nodes is more common.[421] Most primary laryngeal NHLs are B-cell lymphomas, most commonly diffuse large B-cell lymphoma and extranodal marginal zone B-cell lymphoma of MALT type.[455-457]

Patients with laryngeal lymphomas usually present with dysphonia, a foreign body sensation, or airway obstruction.[456] Laryngeal lymphomas are usually submucosal masses (because they arise from submucosal aggregates of lymphoid cells) without mucosal ulceration and are most commonly found in the supraglottis (especially in the aryepiglottic folds). An adequate biopsy is also critical in the diagnosis of lymphoma. Because the lesion is usually submucosal, a deep biopsy must be performed to ensure that tumor has been sampled. The specimen must be sent fresh. Immunohistochemistry, flow cytometry, and immunophenotyping are necessary to establish the diagnosis and determine the type of NHL. Once the diagnosis of lymphoma has been confirmed, a hematologic consultation should be sought. A thorough evaluation including blood work, a bone marrow biopsy, and imaging is performed for staging. Most patients with primary laryngeal NHL present with early-stage disease (Ann Arbor stage IE or IIE).[455-457]

Treatment of laryngeal lymphoma usually involves RT or chemotherapy, or a combination of the two, and the appropriate treatment regimen is selected on the basis of histologic typing. Localized RT has been the most common treatment for laryngeal NHL.[456,457] Chemotherapy with the RCHOP regimen (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone) has also been used successfully, particularly for diffuse large B-cell lymphoma.[455,458]

Mucosal Malignant Melanoma of the Larynx

In the head and neck, most melanomas are of cutaneous origin. Mucosal malignant melanomas of the UADT constitute 0.5% to 3% of melanomas from all sites, and only 4% to 7% of these arise in the larynx. Therefore primary mucosal malignant melanoma of the larynx (PMMML) is extremely rare. The majority of these tumors affect men, and the peak incidence is in the sixth and seventh decades. Most PMMMLs occur in Caucasians, but African Americans may also be affected.[459]

PMMMLs may arise from the malignant degeneration of intralaryngeal melanocytes or intralaryngeal melanocytic lesions (e.g., melanosis, nevi, lentigo).[460,461] Intralaryngeal melanocytes are located either in the basal cell layer of the epithelium, stroma of the submucosa, or minor salivary glands in the submucosa. The etiology of PMMML is uncertain, although smoking has been implicated in its pathogenesis.[462]

The supraglottis is the most common site for PMMML. A subglottic PMMML has never been reported.[459] The tumors have a variable appearance and may be nodular, sessile, or polypoid. Their color may also vary significantly, ranging from black, brown, or red-pink, to tan-gray or white.[461] Immunohistochemistry is key to the diagnosis: Immunoreactivity to S100 and HMB45 in a pleomorphic, epithelioid, or spindle cell neoplasm is diagnostic of melanoma.[463] However, histologically, PMMMLs are identical to primary cutaneous melanomas, which are the most common malignancy to metastasize to the larynx. Therefore it is vital to determine whether a melanoma in the larynx represents a metastasis from a cutaneous site, by performing a full cutaneous examination to look for a primary lesion, and by imaging the neck, chest, abdomen, and pelvis to look for metastatic disease.[461]

The recommended treatment for PMMML is wide local excision, which may be achieved using either partial or total laryngectomy, with a neck dissection for patients with nodal disease.[464,465] Adjuvant RT has been used, with a higher dose per fraction recommended.[463,464] The prognosis for patients with PMMML is poor, with a 5-year survival of less than 20%.[461,462] The incidence of local recurrence is low, although there is a high rate of regional and distant metastases to account for this.[466] Prognostic criteria used in cutaneous melanomas, such as depth of invasion, tumor thickness, and ulceration are not useful in PMMML.[459]

Neoplasms of Uncertain Behavior

Two unusual neoplasms warrant special consideration because they are classified as "borderline" lesions of uncertain behavior: inflammatory myofibroblastic tumor (IMT) and giant cell tumor (GCT).

The nature and etiology of IMT is controversial. It was orginally described as a benign, non-neoplastic proliferative lesion that could be

treated with conservative surgery and steroids.[467,468] However, subsequent genetic studies have suggested that IMT is a neoplasm, which usually behaves in a benign fashion.[469,470] The larynx (primarily the glottis) is the most common site in the head and neck for these tumors, which are composed of myofibroblastic cells with inflammatory cells and collagen. These lesions are not typically aggressive, although metastases from visceral IMTs have been reported. Conservative surgical excision is the treatment of choice.[469,470]

Giant cell tumor is a rare neoplasm composed of large multinucleated osteoclast-like giant cells and mononuclear cells; it arises from the thyroid cartilage, cricoid cartilage, or epiglottis.[471] This tumor is aggressive and locally destructive but has not been reported to metastasize. Complete surgical excision is the recommended treatment, either by partial or total laryngectomy.[472] Note that GCT is a different entity from giant cell carcinoma, which is an extremely rare undifferentiated carcinoma with a poor prognosis. The histogenesis of giant cell carcinoma is uncertain.[473]

Secondary Tumors of the Larynx

Secondary tumors of the larynx are tumors that originate in another site in the body and then spread from that site to involve the larynx. These tumors may spread from a site contiguous with the larynx by direct invasion (e.g., thyroid, oropharynx, hypopharynx, cervical esophagus, trachea) or they may spread hematogenously from a distant site, in which case the secondary laryngeal tumor is a true metastasis.

Laryngeal Involvement by Tumors from Contiguous Sites

The larynx may be invaded by malignant neoplasms arising from any of the adjacent structures. Involvement of the larynx carries a worse prognosis, which is reflected in the advanced T stage assigned to tumors of the oropharynx (laryngeal invasion = T4a), the hypopharynx (laryngeal hemifixation = T3, thyroid or cricoid cartilage invasion = T4a), the cervical esophagus (laryngeal invasion = T4), and the thyroid (laryngeal invasion = T4a). Treatment of the primary aerodigestive tract tumors is discussed in the relevant chapters of this volume.

The treatment of thyroid cancer with laryngeal invasion is discussed briefly because there has been some controversy regarding its optimal management. Well-differentiated thyroid cancers such as papillary thyroid cancer, the most common histologic type of thyroid cancer, invade the larynx in approximately 1% to 2% of cases,[474,475] and involvement of the endolarynx is associated with a worse prognosis.[475] Anaplastic thyroid cancers invade the larynx more often, but the prognosis for patients with these tumors is poor and therefore treatment is usually palliative.

For well-differentiated thyroid cancer, surgery is the primary treatment modality and plays a particularly important role in the management of extrathyroidal disease. It is generally accepted that leaving gross residual disease is associated with a poorer prognosis,[475,476] and therefore complete resection of macroscopic disease is the goal. In cases in which there is aerodigestive tract invasion, there is debate regarding how extensive surgery should be. The surgical options for laryngeal invasion include shave excision, partial laryngectomy, or total laryngectomy. Shave excision may be used if there is limited invasion of the larynx; however, if there is intraluminal tumor, a shave excision will leave macroscopic tumor.[476] McCaffrey and Lipton[477] and McCaffrey[475] have recommended a shave excision for partial-thickness cartilage invasion and complete resections for full-thickness cartilage involvement or intraluminal tumor: a cricotracheal resection when less than half of the cricoid is involved; a total laryngectomy for more extensive cricoid involvement; and a partial laryngectomy (such as a vertical hemilaryngectomy) for unilateral thyroid cartilage or paraglottic space invasion. Postoperatively, radioactive iodine and/or RT are recommended as adjuvant treatment for extrathyroidal spread in well-differentiated thyroid cancers.[478]

Metastases to the Larynx

Metastases to the larynx are rare and represent only 0.09% to 0.4% of laryngeal tumors.[445,479] Ferlito[445] reviewed 134 cases of metastases to the larynx in 1993. The majority of these tumors were either cutaneous malignant melanomas or carcinomas. The primary tumors responsible for these metastases to the larynx were (in descending order of incidence) cutaneous malignant melanoma (34%), renal cell carcinoma (16%), and cancer of the breast, lung, prostate, colon, stomach, and ovary (each <10% of the total). The metastases spread to the larynx hematogenously, via the systemic circulation or via the paravertebral venous plexus. Metastasis to the larynx is rare because the larynx itself is a small organ at the terminal part of the circulatory system and does not receive a high volume of blood flow.[479] The supraglottis is most frequently affected (in 35% to 40% of cases) because it has the richest blood supply. The subglottis (10% to 20%) and glottis (5% to 10%) are less commonly involved, but metastases in multiple subsites are common.[421]

Kleinsasser[480] has observed two types of metastases: submucosal soft tissue metastases, usually affecting the vestibular and aryepiglottic folds, and metastases to the cartilaginous framework, most often the cricoid and thyroid cartilages. When cartilage is involved, it is usually the marrow space of the ossified portion of the cartilage. Metastatic melanoma and renal carcinoma metastasize to the soft tissues, whereas breast and lung cancer metastasize to the cartilages.

Metastasis to the larynx generally reflects widespread disseminated disease, and the prognosis is grim. Treatment is almost always palliative, and supportive measures such as a tracheostomy are the most appropriate. However, if the laryngeal metastasis is solitary, then surgical treatment should be considered, depending on the biologic behavior of the primary tumor, the symptoms from the laryngeal lesion, and the patient's overall condition.[445] Prolonged survival has been reported in such cases.[481,482] Surgical options include both partial laryngeal surgery (open or endoscopic[483]), as well as total laryngectomy.[445]

CHAPTER ONE HUNDRED AND EIGHT

Management of Early Glottic Cancer

Henry T. Hoffman

Tim A. Iseli

Lucy H. Karnell

Timothy M. McCulloch

John M. Buatti

Gerry F. Funk

Key Points

- The glottis represents the site where approximately 50% of laryngeal cancers arise, and 95% of laryngeal malignancies are squamous cell carcinoma.
- Five-year relative survival is approximately 90% for T_1N_0 tumors and 75% for T_2N_0 tumors.
- Second primary tumors (lung followed by head and neck) are the most common cause of death in patients with early glottic cancer.
- Staging is based on cord mobility (T_1 normal, T_2 impaired) and spread outside the glottis (T_{1a} one cord, T_{1b} both cords, T_2 supraglottis or subglottis).
- Leukoplakia followed for 3 years will develop invasive cancer in approximately 4% without dysplasia, 10% with mild/moderate dysplasia, and 18% with severe dysplasia/carcinoma in situ.
- Diagnosis is by laryngoscopy and biopsy. Staging often includes a CT of the larynx for cartilage invasion and paraglottic space assessment and increasingly PET scan for second primaries.
- Radiotherapy is an effective treatment modality and is the most commonly used modality in North America.
- Most likely, radiotherapy has the best final voice quality in patients retaining their larynx. Failures most commonly require total laryngectomy; however, some centers are increasingly using laryngeal conservation surgery for salvage.
- Larynx-preserving alternatives to radiotherapy include transoral laser microsurgery and open laryngeal conservation surgery.
- Surgery has the advantages of having a higher rate of final laryngeal preservation, particularly in T_2 tumors, and repeatability for recurrence or second primary tumors.

> ... at the start of the 21st century, the oncologist and patient are presented with a bewildering array of choices for laryngeal cancer therapy.
>
> —Ferlito and colleagues[1]

Background

Statistics from the National Cancer Database (NCDB) provide insight into contemporary demographics and management of laryngeal cancer in the United States.[2] The most common site for laryngeal squamous cell carcinoma is the glottic larynx (Fig. 108-1). The role for surgery as single-modality therapy for advanced laryngeal cancer is diminishing as combined chemoradiation has become more common in the initial management (Fig. 108-2). Five-year relative survival was best for early-stage (stages 0, I, and II) glottic cancer (Fig. 108-3).

Analysis of this dataset demonstrated that squamous cell carcinoma is the dominant histologic type of laryngeal cancer in the United States, representing approximately 95% of cases (Fig. 108-4). Unless indicated otherwise, the remainder of the discussion in this chapter focuses on squamous cell carcinoma.[3,4]

Etiology

Squamous cell carcinoma of the larynx is strongly associated with the use of tobacco and alcohol. An increase in the prevalence of cigarette use among females in the past has been linked to a proportionate increase in the number of female patients with laryngeal cancer. Other factors implicated in the development of laryngeal cancer include

passive smoking, chronic laryngeal irritation from gastroesophageal reflux, and viral infection.[5-9]

Since 1979 gastric acid reflux has been identified as a risk factor for laryngeal and pharyngeal cancer.[10,11] Alkaline reflux has more recently been identified as a laryngeal carcinogen by Galli and colleagues.[12] These investigators identified a higher than expected number of patients with pharyngolaryngeal cancer associated with achlorhydria and presumed alkaline reflux after gastric resection. They concluded that periodic endoscopy of the upper aerodigestive tract should be performed on gastrectomized patients because of their higher risk for pharyngolaryngeal disorders in general and cancer in particular. These investigators also identified that, among patients with laryngeal squamous cell carcinoma with an intact gastric acid secreting mechanism, 81% showed abnormal acid reflux on 24-hour pH testing.

Human papillomavirus (most notably the oncogenic type 16) has been associated with head and neck cancer.[13-15] The role for human papillomavirus (HPV) infection in laryngeal oncogenesis has been supported by previous study but does not have as strong an association as has been identified with cancer of the oropharynx and oral cavity.[16,17] Initial study suggests that a difference exists in behavior between HPV and non–HPV-related squamous cell carcinoma of the upper aerodigestive tract, with a better prognosis afforded the HPV-positive cases.[18]

Differences in exposure to carcinogens or genetic susceptibility may explain the differences in the predominant types of laryngeal cancer throughout the world. Glottic cancers predominate over supraglottic cancers in the United States at a ratio of 2:1. In France the opposite occurs, where the number of supraglottic cancers exceeds that of glottic cancers at a ratio of 2:1.[19] In Finland the incidence of supraglottic cancer decreased and the incidence of glottic cancers increased between the decades 1976 to 1985 and 1986 to 1995.[20] Supraglottic cancers were more common than glottic cancers in the earlier decade (ratio of 1.4:1). Glottic cancers predominated in the later decade at a ratio of 2:1. The reason for this change in distribution of laryngeal cancers in Finland is not clear. A low exposure to alcohol and a high availability of medical services were factors Brenner and colleagues identified as important determinants to the characteristics of laryngeal cancer in Israel. These investigators linked these factors to the high proportion of laryngeal cancers treated at an early stage with an overall better outcome when compared with other countries.[21]

Laryngeal cancer in the United States: changes in demographics, patterns of care, and survival.* Laryngoscope. *2006;116[9 Pt 2 Suppl 111]:1-13.)*

Staging

The most widely accepted system for classifying cancer in the United States, as is currently promoted by the American Joint Committee on Cancer (AJCC), had its beginning in 1959 with the organization of the American Joint Committee for Cancer Staging and End-Results Reporting (AJC).[22] This staging system was first published in 1977 in the *Manual for Staging of Cancer.*[23] The staging system has evolved to its current form as it is codified in the *AJCC Staging Manual, Sixth Edition* published in May of 2002 and implemented as of January 1, 2003.[24] Major revisions made to the fifth edition in the head and neck section were directed primarily to the advanced-stage cases. the definitions for stages 0, I, and II laryngeal cancers remained unchanged, alterations to the T_3 definitions in the sixth edition have impacted on the interpretation of T_1 and T_2 classification.

The anatomic definitions and boundaries between sites, as published in the *AJCC Staging Manual,* have remained constant across the multiple editions. The glottis has been defined as the true vocal cords including the anterior and posterior commissures. Unfortunately, the definition of the posterior commissure remains vague. It is difficult to discriminate among the glottis, the adjacent supraglottis (arytenoids), and the hypopharynx (postcricoid region) in the region of the posterior commissure.[25] The superior border of the glottis is more clearly defined by a horizontal plane passing through the apex of the ventricle. The inferior limit of the glottis is defined by a line parallel to and 1 cm inferior to this plane.

Glottic cancers are staged primarily by clinical assessment of degree of vocal cord mobility (Table 108-1).[24] Cancers confined to the glottis with normal mobility are staged T_1. Subdivision of T_1 vocal cord cancers is based on extension to involve the opposite cord. A tumor limited to one vocal cord is T_{1a}. A horseshoe lesion that extends around the anterior commissure to involve both vocal cords without impairing mobility is T_{1b}. Despite consistency across all previous editions of AJCC staging manuals indicating that T_4 status is based on "tumor invasion through the thyroid cartilage … ," it has been common clinical practice to consider any extent of thyroid cartilage invasion from a glottic cancer to be cause for T_4 classification. Clinically apparent stage I glottic cancers ($T_1N_0M_0$) were reassigned stage IV status ($T_4N_0M_0$) when "microscopic invasion of adjacent cartilage" was identified.[26] Revision to the *AJCC Staging Manual, Sixth Edition* identifies that minor cartilage erosion (e.g., inner cortex) should be classified as T_3 rather than T_4.

Glottic cancers continue to be classified T_2 on the basis of two separate criteria: impaired vocal cord motion or transglottic spread beyond the glottis to involve either the supraglottis or subglottis. Although the AJCC does not discriminate between these two criteria, some investigators distinguish T_{2a} from T_{2b} cancers. T_{2a} vocal cord cancers do not impair mobility but are a higher stage than T_1 cancers by virtue of transglottic spread to involve the supraglottis or subglottis. T_{2b} cancers are sufficiently invasive to impair vocal cord mobility without causing complete fixation. Revision to the sixth edition identifies that T_3 classification results from vocal cord fixation or invasion of the paraglottic space. This clarification is helpful to resolve controversy in the interpretation of subtle differences between impaired vocal cord motion and fixation. If the arytenoid remains mobile but the membranous vocal cord is tethered by deep infiltration to the paraglottic space, the cancer is considered a T_3.

Still further clarification is necessary to address inconsistencies that persist among publications describing the paraglottic space.[12,27-29]

Table 108-1

Primary Tumor (T) Classification of Glottic Cancer

T_x	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_{is}	Carcinoma in situ
T_1	Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) with normal mobility
T_{1a}	Tumor limited to one vocal cord
T_{1b}	Tumor involves both vocal cords
T_2	Tumor extends to supraglottis or subglottis, or with impaired vocal cord mobility
T_3	Tumor limited to the larynx with vocal cord fixation or invades paraglottic space, or minor thyroid cartilage erosion (e.g., inner cortex)
T_{4a}	Tumor invades through the thyroid cartilage or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
T_{4b}	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures

From Greene F, Page D, Fleming I, et al. *AJCC Cancer Staging Manual.* 6th ed. New York: Springer Verlag; 2002.

Berman defined the borders of the paraglottic space as they have been commonly reported by others:

- Anterolateral: the thyroid cartilage.
- Inferomedial: the conus elasticus.
- Medial: the ventricle and the quadrangular membrane.
- Posterior: the pyriform sinus.[12]

This definition fails to address the controversy as to whether all, part, or none of the thyroarytenoid muscle is part of the paraglottic space.[30] An assessment by Weinstein and colleagues[31] defines the medial border of the paraglottic space as the tissue lateral to the conus elasticus at the glottic level and lateral to the quadrangular membrane at the supraglottic level. By this convention, the thyroarytenoid muscle is considered part of the paraglottic space. Others define the glottic portion of the paraglottic space as the fat deep to the intrinsic laryngeal musculature. For the purposes of T classification according to the revised AJCC criteria, it is reasonable to consider that paraglottic space invasion (T_3) occurs when the fat compartment deep to the intrinsic laryngeal musculature is involved with tumor. Impaired vocal cord mobility (T_2) (without paraglottic space involvement) may be considered when the thyroarytenoid or lateral cricoarytenoid muscles are infiltrated but not fully transgressed.

Carcinoma in situ is classified as T_{is}. Accuracy in classifying premalignant changes affecting the laryngeal epithelium is compromised by the subjective nature of the assessment and by a lack of uniformity in terminology. Some pathologists discriminate between severe dysplasia and carcinoma in situ, whereas others group them together as type III intraepithelial neoplasia.[32-34] The grading of laryngeal dysplasia as mild, moderate, and severe or as carcinoma in situ originated from a similar classification of preneoplastic diseases of the uterine cervix. Keratinizing dysplastic lesions of the upper airway are more common than in the cervix and are also more difficult to categorize. The differences that exist in the behavior of carcinoma in situ originating at these two distinctly different anatomic sites has also undermined the transfer of concepts governing uterine cervical carcinoma in situ to laryngeal carcinoma in situ.[35] Despite the clearly stated pathologic principle that high-grade dysplasia and carcinoma in situ are equivalent terms in describing abnormal laryngeal squamous epithelium, clinical management is generally less aggressive for high-grade dysplasia than for carcinoma in situ.

Table 108-2

Stage Grouping of Laryngeal Cancer

Stage 0	T_{is}	N_0	M_0
Stage I	T_1	N_0	M_0
Stage II	T_2	N_0	M_0
Stage III	T_3	N_0	M_0
T_1, T_2, or T_3	N_1	M_0	
Stage IV a	T_{4a}	N_0, N_1, N_2	M_0
T_1, T_2, T_3, or T_{4a}	N_2	M_0	
Stage IV b	T_{4b}	Any N	M_0
Any T	N_3	M_0	
Stage IV c	Any T	Any N	M_0

From Greene F, Page D, Fleming I, et al. *AJCC Cancer Staging Manual.* 6th ed. New York: Springer Verlag; 2002.

The stage grouping of primary tumor, regional lymph nodes, distant metastatic (TNM) classifications for laryngeal cancer is the same as for other head and neck mucosal sites (Table 108-2). Although the stage groupings have been revised—with the sixth edition introducing the division of stage IV into IV a, IV b, and IV c—the staging of early glottic cancer has remained constant (stages 0, I, and II).

Definitions: Early Glottic Cancer

The appropriate definition of the term *early* as it applies to laryngeal cancer has been debated. Some investigators have loosely used the term to describe laryngeal cancer in the context of management options. By this convention, a laryngeal cancer is considered early if it can be treated by partial laryngeal (conservative) surgery without a neck dissection, by endoscopic excision, or by radiotherapy alone.[36] Others apply the term *early* to stage 0, I, or II tumors and *late* to stage III or IV tumors. This definition of *early* may be inappropriate. Because the extent of disease—not the rate of growth—determines staging, the term *localized* is more accurate than the term *early.*[37] Similarly, the term *advanced* may be more appropriate than the term *late.*[38] The most accurate grouping uses the terms *localized* for any-TN_0M_0 disease, *regionally spread* or *vicinally spread* for any-$TN+M_0$ disease, and *widely disseminated* for any-T-any-NM_1 disease.[39] Convention and tradition dictate that this chapter continue to use the terms *early* to refer to lower stage (0, I, and II) and *late* to refer to higher stage (III and IV).

Diagnosis

Endoscopic Imaging

The initial evaluation of a patient with an early glottic lesion requires inspection of the larynx. The common use of flexible fiberoptic laryngoscopy to supplement indirect mirror examination now permits visualization of the majority of laryngeal cancers in a clinical setting. Videoendoscopy and videostroboscopy offer further refinement in

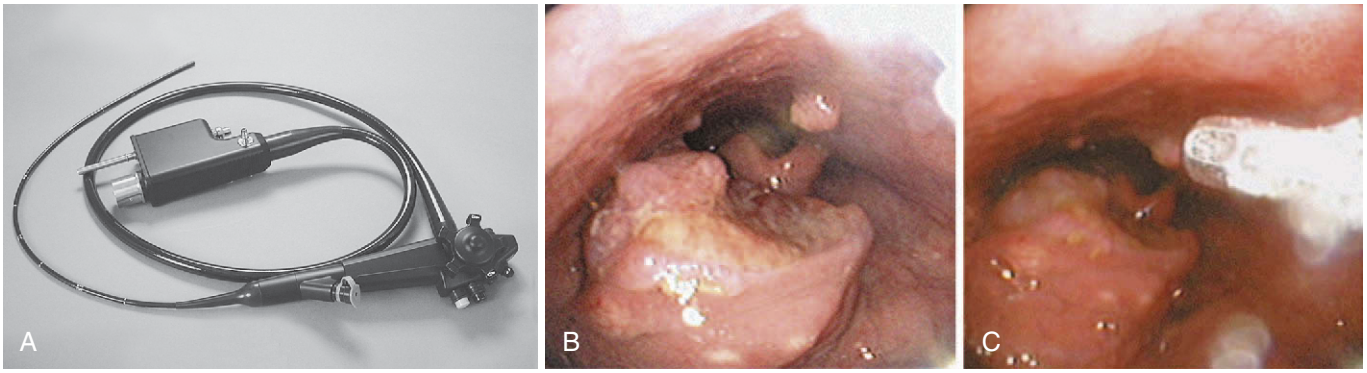

Figure 108-5. **A,** Transnasal esophagoscope (TNE) (Pentax). **B,** View of oropharynx and hypopharynx through TNE. **C,** Biopsy forceps prepared to remove posterior pharyngeal wall lesion.

assessing glottic lesions. It has become standard practice in many institutions to permanently record the appearance of all laryngeal cancers through video recording, using rigid or fiberoptic endoscopy. The capacity to refer to these permanent records documenting the extent of the original lesion often improves long-term patient care.

The development of flexible fiberoptic endoscopes designed for transnasal endoscopy has also permitted use of these instruments to evaluate the larynx and trachea.[40-43] The improved optics of these instruments—coupled with the presence of a side port that permits the use of suction, placement of biopsy instruments, and instillation of topical anesthetics—has expanded the capacity to perform in-office laryngeal evaluations (Fig. 108-5A). Although direct laryngoscopy remains the most appropriate approach to evaluate and biopsy the majority of lesions suspected of being malignant, in selected cases biopsy can be effected in the clinic (see Fig. 108-5B and C).

When videostroboscopy was introduced as a common clinical tool, enthusiasm was high for its potential to help discriminate invasive cancer from epithelial atypia on the basis of the stroboscopic appearance of the vocal fold epithelial pliability.[44,45] Subsequent experience of Colden and colleagues[46] has identified that laryngeal stroboscopy is neither reliable in distinguishing vocal fold atypia from invasive cancer nor useful in determining the depth of invasion of vocal fold cancer. These investigators did suggest that the stroboscopic appearance of a relatively normal mucosal wave indicates that a lesion is superficial and does not extensively involve the underlying vocal ligament.

Advances in technology, coupling physical and biologic analysis to endoscopy, have identified several adjuncts to complement standard imaging of the larynx at the time of direct laryngoscopy. Lugol's solution, as well as toluidine blue, have been used to stain laryngeal tissue in an effort to discriminate normal tissue from tumor.[47,48] These approaches have not met with uniform success and therefore have not been widely adopted. Fluorescent tumor markers such as tetracyclines and hematoporphyrin derivatives are preferentially absorbed by tumor cells and can be used to discriminate tumor from adjacent normal tissue by the red fluorescence they emit when exposed to ultraviolet light.[49] Additional cost and operating time, as well as problems with skin photosensitivity, have limited the usefulness of this technique. A more promising approach employing autofluorescence laryngoscopy has been reported. Zargi and colleagues[50] have employed the lung imaging fluorescence endoscope (LIFE) system to evaluate laryngeal lesions. Their preliminary work identified differences in the intensity of autofluorescence between normal and tumor tissue when exposed to blue or violet light. They also identified shortcomings in the use of the LIFE system for this purpose, noting that further technical advances are necessary to make this endeavor a useful clinical tool.

Stone and colleagues[51] reported that the fluorescence of biologic tissue actually may impede the use of Raman spectroscopic analysis to discriminate normal from malignant laryngeal lesions. These investigators have developed strategies that negate the impact of the natural biologic fluorescence to permit evaluation of the distinctive spectral signatures of tissues elicited when exposed to monochromatic laser excitation. This strategy may develop into a noninvasive tool in the early detection of cancerous and precancerous lesions.

Radiology

Chest X-Ray

A chest radiograph is necessary in the evaluation of patients with glottic cancers to assess for concurrent pulmonary disease and to screen for second primary lung cancers. The incidence of distant metastatic spread of an early glottic cancer to the lung is sufficiently rare that a preoperative chest radiograph is not generally intended to survey for that specific purpose. Annual chest x-rays should be obtained in the course of clinic follow-up examinations primarily because of the high incidence of second primary lung cancers in patients managed for laryngeal cancer.[52]

Magnetic Resonance Imaging and Computed Tomography

In our institution most early laryngeal cancers will be assessed clinically and with a fine cut computed tomography (CT) to determine invasion into or through the thyroid cartilage and to assess for spread into the paraglottic space. The appropriate role for magnetic resonance imaging (MRI) and CT in early glottic cancers is still being defined.[53] These advanced imaging studies are of questionable value in the assessment of most superficial T_1 lesions of the vocal cords. Selected T_1 lesions with anterior commissure involvement may benefit from MRI or CT imaging if extension of the tumor superiorly into the preepiglottic space or anteriorly into the thyroid cartilage is detected. The more routine use of MRI or CT is advocated in the evaluation of T_2 lesions not only to help determine tumor extent (and hence T classification) but also tumor volume. Some authors have suggested that CT or MRI of T_2 lesions may help determine radiocurability by assessing tumor volume. Other investigators have not found the size of the tumor to be useful for predicting radiocurability.[54]

Wenig and colleagues[55] contend that surgical treatment of laryngeal cancer with less than a total laryngectomy mandates preoperative MRI in almost all cases. These investigators identify that tumor involvement of the entire vocal cord or the anterior commissure, as well as the presence of vocal fold paresis, is considered an indication for the use of MRI. They relate that only the most superficial T_1 lesions of the mobile portion of the vocal cord need not be imaged because MRI will not detect the extent of these lesions. This philosophy is distinctly opposite from that of Steiner and Ambrosch,[56] who relate that advanced imaging of laryngeal cancer is fraught with artifact. Steiner and Ambrosch find little value in preoperative imaging of laryngeal cancers and relate that the most accurate assessment of tumor extent comes at the time of endoscopic laser microsurgical resection.

Debate continues as to whether CT or MRI offers the most useful information when imaging the larynx.[57] Advances in the speed with which CTs can now be done offer an advantage to this technique. In 2002 Stadler and colleagues[58] reported that use of rapid imaging spiral CTs of the larynx permits complete evaluation during the course of a

Table 108-3

Selected Surgical Procedures for Glottic Cancer

Procedure	Indications	Study
Microlaryngoscopy partial cordectomy with or without carbon dioxide laser (excisional biopsy)	T_1 midcord leukoplakia, T_{is}/microinvasion	Strong and Jako (1972) Kleinsasser (1990) Shapshay, Hybels, and Bohigian (1990)
Cordectomy complete with or without carbon dioxide laser (endoscopy)	T_1 midcord	Strong (1975) Annyas et al (1990) Shapsay, Hybels, and Bohigian (1990) Eckel and Thumfart (1992)
Cordectomy (laryngofissure)	T_1 midcord	DeSanto et al (1977) Bailey (1985)
Frontolateral partial laryngectomy	T_1 with extension to anterior commissure	Leroux-Robert (1975)
Hemilaryngectomy and extended hemilaryngectomy	T_1/T_2 with extension to arytenoid, without anterior commissure fixation (minimal)	Norris (1958) Som (1975) Mohr et al (1983)
Anterior partial laryngectomy with epiglottoplasty or with keel	T_1/T_2 with extension to anterior commissure (without arytenoid)	Tucker et al (1979) Som and Silver (1968)
Subtotal laryngectomy with cricohyoidoepiglottopexy	T_{1b}/T_2 bilateral anterior involvement; may include removal of one arytenoid	Laccourreye et al (1990) Charlin et al (1988)

single maneuver. This rapid imaging of the larynx may be accomplished as the patient performs either a modified Valsalva maneuver or phonation of the utterance "E." This functional imaging (done during the maneuver) was compared with nonfunctional imaging (done with quiet breathing) and correlated with postsurgical pathology assessments and findings at microlaryngoscopy. Although the numbers in their study were small, Stadler and colleagues conclude that functional CT imaging appears to be more accurate in determining tumor extent than nonfunctional imaging.

Positron Emission Tomography

The role for positron emission tomography (PET) is continuing to expand. Although distant metastases from early laryngeal cancers are rare, the most common cause of death in patients with early laryngeal cancer is second primary tumor.[59,60] The most common second primary tumors are lung followed by other head and neck primaries, which are more easily detected clinically and with endoscopy. It has become standard practice in our institution to order a PET scan in all but the earliest T1 laryngeal cancers.

F-18-fluoro-deoxy-glucose (FDG) PET scanning has been reported as useful in detecting subclinical recurrent or persistent cancer at a stage when it is highly curable.[61] Terhaard and colleagues[62] propose an algorithm for the follow-up of patients treated for laryngeal or hypopharyngeal cancers that emphasizes the use of PET imaging. Through a prospective study of 109 PET scans done on 75 patients with either laryngeal or hypopharyngeal cancer, these investigators concluded that an FDG PET scan should be the first diagnostic step when a recurrence is suspected after treatment with irradiation. As a result of this study, in which the majority of cases were glottic and classified as either T_1 or T_2, these investigators suggested that no biopsy is necessary if the scan is negative. In the face of a positive scan and a negative biopsy, a follow-up scan showing decreased FDG uptake would indicate that a recurrence is unlikely. Caution should be exercised in following these guidelines if other clinical indicators support the need for a biopsy. At this point in our experience, endoscopy with a biopsy to sample tissue suspicious in appearance for cancer remains the most critical means by which recurrence is evaluated.

Shortcomings of PET imaging have been noted. Most investigators suggest waiting at least 3 months after treatment to perform PET imaging because false-positive results are common if the imaging is done soon after radiotherapy is completed.[63] False positives may also result from infection, radionecrosis, or accumulation of saliva in the vallecula.[64,65] Some of these shortcomings of PET imaging are being addressed by use of pharmaceuticals other than FDG. The presence of viable tumor has been identified through PET imaging with 1-[1-^{11}C]-tyrosine (TYR). TYR PET imaging analyzes protein synthesis activity and has been reported to be successful in detecting recurrent squamous cell carcinoma of the larynx.[66] Further progress with PET imaging is anticipated with the introduction of other pharmaceuticals.

Treatment

The ideal initial management of an early glottic cancer is the one that is most likely to result in cure and to preserve a normal voice without impaired swallowing or breathing while leaving all modalities of treatment available for recurrence or second primary cancers. It is not often possible to meet all of these goals. A compromise is generally required, wherein the choice of therapy is based on the desires of an informed patient who understands the shortcomings of the alternatives. The surgeon should be aware of the options to make an informed recommendation to the patient. Ideally the patient will meet with both the surgeon and a radiation oncologist to permit identification of the full spectrum of treatment options from differing perspectives.

The following discussion focuses on specific surgical and radiotherapy techniques and concludes with a review of general management principles, focusing on the impact of management on the voice.

Surgery

Physicians' views vary on the indications for use of a specific procedure or radiotherapy technique. General guidelines for selection of an approach based on the extent of a lesion are listed in Table 108-3 and depicted in Fig. 108-6. The choice of therapeutic approach for a patient requires consideration of many other variables in addition to the anatomic extent of the cancer. Overall cure rates and laryngeal preservation

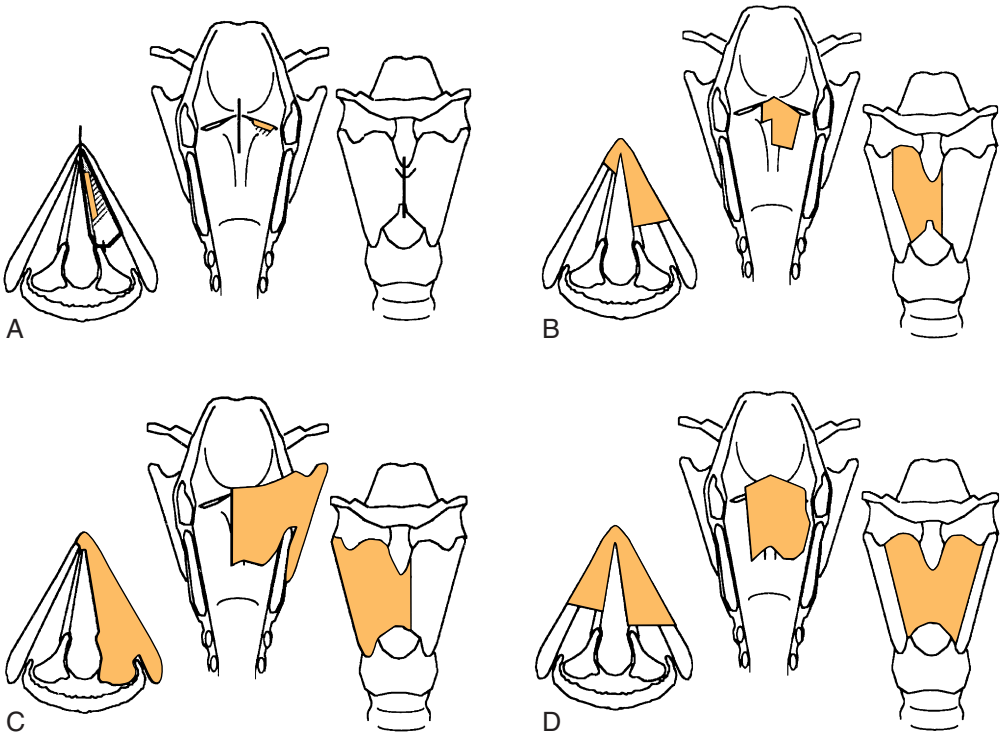

Figure 108-6. **A** through **D,** Diagrams of vertical partial laryngectomy.

figures are high for the surgical management of early glottic squamous cell carcinoma (Table 108-4).

Endoscopic Excision

The histopathologic correlate of a superficial T_1 primary cancer may reveal a lesion without deep extension beyond the superficial layer of the lamina propria.[67] Endoscopic surgical excision of such a lesion may allow for resection with a clear margin without damaging the underlying vocal ligament or vocalis muscle (Fig. 108-7).[68] However, not all T_1 glottic cancers are amenable to superficial conservative resection. Up to 20% of T_1 cancers will show normal mobility despite invasion of the vocal ligament.[69] Carcinoma in situ, which by definition does not invade past the basement membrane, is most amenable to complete excision without disruption of the underlying vocal ligament. The importance of achieving clear surgical margins at the first attempt at resection is highlighted by a review of 1467 patients treated with laser microsurgery. Patients with residual tumor at re-resection had significantly worse locoregional control regardless of clear margins at the second surgery.[70]

Biopsy

In general, discrete lesions of the vocal cords are better sampled through excisional biopsy than through small, piecemeal, random biopsies. The opportunity to effect a cure exists through excisional biopsy if the pathologic assessment shows carcinoma in situ or a minimally invasive cancer. Excisional biopsies also avoid any sampling error wherein small areas of invasive cancer may be missed within a larger field of dysplastic epithelium. Judgment should be exercised in determining the extent of dissection in performing a biopsy on patients who are candidates for irradiation. Smaller biopsies that are sufficient to confirm the diagnosis of invasive cancer impair the posttreatment voice to a lesser degree than larger excisions if irradiation is used as definitive treatment. It is useful to discuss the decision making with the patient in weighing the benefits and risks to approaching the biopsy conservatively or aggressively.

Laser Excision

Endoscopic laser excision is addressed in Chapter 109, and is not discussed here.

Open Partial Laryngectomy

The topic of open partial laryngectomy is covered well in Chapter 110 and is not addressed here.

Voice Considerations

There are two central issues when discussing voice outcomes of various treatment options for early laryngeal cancer: absolute quality of voice, which generally favors radiotherapy; and final laryngeal preservation, which generally favors surgery.[71]

Cragle and Brandenburg[72] reported that surgical treatment of early glottic cancers may produce a vocal result that is equivalent to that following irradiation. These investigators evaluated voice profiles in 11 patients treated with laser cordectomy and 20 patients treated with irradiation. Both groups had similar voice profiles, characterized by decreased maximum phonation times and increased jitter, shimmer, and signal-to-noise ratios.

Most investigators contend that, in cases of early glottic cancers, a better voice more reliably follows treatment with radiotherapy rather than with surgery.[73-77] Unlike surgery, radiotherapy does not require removal of adjacent healthy tissue to provide a clear margin around a cancer. However, vocal deterioration may result from radiotherapy and may be significant if loss of vocal cord bulk results from tumor necrosis or if fibrosis develops.

Ton-Van and colleagues[78] evaluated 356 patients with early glottic cancer and determined that the quality of voice after treatment with radiotherapy is "indisputably superior to that after conservation surgery." However, these investigators pointed out that a functional larynx was preserved in 92% of patients treated surgically compared with 81% initially treated with radiotherapy. The investigators acknowledged that these results could have been biased by management, which generally used total laryngectomy for surgical salvage. As a result of these findings, Ton-Van and colleagues[78] advocate the use of surgery as a primary mode of therapy in patients capable of safely undergoing an anesthetic. Exceptions include patients who are willing to accept a greater risk of total loss of the larynx in the effort to preserve the highest-quality voice.

For most patients with laryngeal cancer, the absolute quality of their voice may not be as important a consideration in selecting

treatment as is their general ability to communicate. For these patients, speech intelligibility may be more meaningful as a criterion to assess results rather than acoustic and aerodynamic measurements. Schuller and colleagues[80] used interviews and questionnaires to evaluate 75 patients treated surgically for early laryngeal cancers. They found that 88% of the respondents were content with the postoperative voice.

The vocal behaviors of most patients after partial laryngectomy are similar to those of patients with glottic incompetence caused by vocal cord paralysis. Leeper and colleagues[81] evaluated six patients who had undergone vertical hemilaryngectomy operations. They found that, whereas large variability was noted, the general tendencies for patients after hemilaryngectomy were (1) incomplete glottic closure; (2) vibratory action of the supraglottic structures (ventricular folds, arytenoids); and (3) high average transglottal airflow with reduced maximum phonation time.

The ability of the vocal tract to regain normal appearance and function is determined by the extent of tumor damage and by the extent of surgical resection. Benninger and colleagues[82] evaluated factors associated with recurrence and voice quality after radiotherapy for early glottic carcinomas. They identified that large excisional biopsies before irradiation increased the risk of poor voice quality.

Radiotherapy

Radiotherapy is considered effective treatment for early glottic cancer (Table 108-5). Broad comparisons between outcomes after initial treatment with either irradiation or surgery are often made without addressing the differences in the various approaches to the administration of radiotherapy or different techniques in performing the surgery.[83] Variables in the application of radiotherapy that affect tumor control include fraction size, total dose of radiation delivered, treatment duration, field size, energy of the x-rays, and method of delivery.[84-87] Rudoltz and colleagues[85] identified duration of treatment as a significant variable in predicting local control and survival in the management of early glottic cancer. Patients completing treatment within 46 days had better local control than those treated over a longer period (Fig. 108-8). Treatment applied through fractions of at least 200 cGy for the standard once-a-day, 5-day-a-week dosing also improved control rates relative to treatment with less than 200 cGy per day.[84,88] Ricciardelli and colleagues[89] also supported the use of higher per-dose fractions through a clinical study and in an in vivo tumor model. In 1993 Rudoltz and colleagues[85] reported that accelerated regimens employing higher-dose fractions were of value primarily because they allowed for shorter treatment duration.

The benefit derived from accelerated fractionation needs to be balanced against the additional morbidity induced. In a phase III study Hliniak and colleagues[90] compared an accelerated regimen (AF) of 66 Gy given in 33 fractions during 38 days (2 fractions every Thursday) with conventional regimen (CF) of 66 Gy given in 33 fractions during 45 days. A total of 395 patients with $T_{1-3}N_0$ glottic and supraglottic cancer treated between 1995 and 1998 were evaluated. More acute morbidity (acute mucositis with pain and dysphagia) was seen in the AF arm at 1 and 2 months. At 4 months after treatment all types of toxicity except skin telangiectasia were similar in both arms. Although there was no difference in the disease-free survival between the two arms, these investigators calculated that shortening of the overall treatment time by 1 week resulted in a 3% to 5% therapeutic gain ($P = 0.37$). They suggest that further shortening of the treatment time could be done within the limits of acceptable morbidity, especially if the volume of the irradiated tissue was small (as for T_1 and T_2 tumors).

Another important consideration in the radiotherapeutic management of early glottic cancer is the technique used for planning and delivery. The treatment target for an early cancer is the lesion itself

without the need to address the rare occult metastasis. Conventional techniques initially depended on the physical examination with the placement of a square open field that generally ranged from 44 cm up to 66 cm for larger T_2 lesions. Most of the published experience is based on utilization of either cobalt −60 or linear accelerators of 4 meV or less. The treatment field was traditionally defined by positioning a light field to cover the midthyroid notch superiorly to the inferior cricoid inferiorly. The posterior border of the treatment field was defined by the physician's estimate of the posterior border of the tumor. Anteriorly, the field was extended to completely cover over the anterior skin with additional margin. Careful attention to the daily placement of the field based on external anatomic landmarks was a key to accurate targeting. Treatment simulation employed plain radiographs with confirmation of appropriate targeting of the field based on portal films to check the position of the cartilaginous anatomy that is well visualized on lateral radiographs.

Despite this simple and common sense approach to treatment setup, dosimetric misses occurring because of field misplacement, as well as dose calculation considerations in the small air-filled and irregular cavity of the larynx, were problematic. Reports using higher (6 meV) energy beams (which today are more commonly available than lower energy beams) were initially associated with higher failure rates because of a lack of adequate dosimetric considerations.[91,92] With the advent of virtual simulation it has become possible to better account for the 3D anatomic considerations within the glottis. More sophisticated corrections for the air interfaces can also now be made. These advances permit better estimation of the optimal wedge used to shape the beam profile. Multiple field techniques can now be employed to assure homogeneous and accurate doses. These new techniques improve success but still depend on verification for accurate daily reproducibility and dosimetry.[93,94]

Most radiation failures of early glottic cancer represent local recurrences rather than regional or distant metastasis.[95] The ability to salvage radiation failures with partial laryngectomy or endoscopic laser resection contributes to the overall success of radiotherapy for initial treatment modality (Table 108-6).[96-101] The extent to which conservation laryngeal surgery (partial laryngectomy) rather than total laryngectomy is used to salvage irradiation failures of T_1 and T_2 glottic squamous cell carcinoma depends on multiple factors: the intensity of follow-up (designed to identify persistent tumor at an early stage), the desires of the patient, the presence of comorbidity, and the management philosophy of the treating physicians. Differing philosophies likely contribute to the variable success reported with salvage partial laryngectomy.

Toma and colleagues[102] expanded on their initial criteria to permit partial laryngectomy salvage of early glottic irradiation failures unless the tumor invaded:

- the arytenoid cartilage (except the vocal process)
- beyond the anterior half of the contralateral vocal cord
- subglottically more than 10 mm in the anterior half or 5 mm in the posterior half of the larynx
- into the thyroid or cricoid cartilage

Application of these criteria to 19 recurrent T_1 and T_2 glottic cancers treated with primary radiotherapy at their institution between 1989 and 1998 yielded three failures (recurrences), which were each successfully salvaged with total laryngectomy. These criteria may be considered as general guidelines but should not be applied to all cases for several reasons. Consideration as to anatomic differences in laryngeal size should allow a more subjective assessment of resectability than afforded by the absolute measurement of 10 mm of anterior subglottic extension as a contraindication. A large male larynx will differ from a small female larynx in applying these criteria.

Additionally, Toma and colleagues did not address the role that supracricoid laryngectomy may play in salvaging irradiation failures. Laccourreye and colleagues[103] reported successful use of supracricoid laryngectomy as a salvage procedure with a laryngeal preservation rate among 12 patients who had failed radiotherapy. The major contraindications they pointed to in use of supracricoid laryngectomy were fixation of the ipsilateral arytenoid cartilage, cricoid cartilage invasion, extralaryngeal spread of tumor, and infraglottic spread to the cricoid cartilage.

Chemotherapy

Because early glottic cancers are highly curable with conventional surgery or radiotherapy, the addition of chemotherapy to most treatment algorithms has not been strongly supported. In addition, past dogma has dictated that invasive squamous cell carcinoma of the upper aerodigestive tract is not curable with chemotherapy alone.[104] Laccourreye and colleagues reported that some of the patients with early glottic squamous carcinoma that they treated with an induction chemotherapy regimen (platinum based) had a complete response clinically and chose to forgo the further treatment that was suggested.[105] Although local recurrence was noted in almost one third of these patients, none of the patients who had local recurrence ultimately died from their disease or lost their larynx. This finding has prompted further interest in the use of chemotherapy for early laryngeal cancer to the point that prospective trials evaluating this modality are now under way.

Choosing a Treatment Modality

Carcinoma in Situ

Isenberg and colleagues[106] reviewed 2188 biopsies for leukoplakia revealing no dysplasia (53.6%), mild-moderate dysplasia (33.5%), and severe dysplasia or carcinoma in situ (15.2%). Followed for 3 years, 3.7% of patients with no dysplasia, 10.1% with mild/moderate dysplasia, and 18.1% with severe dysplasia or carcinoma in situ developed invasive squamous cell carcinoma.

Close interaction between the clinician and pathologist is necessary to manage optimally carcinoma in situ ($T_{is}N_0M_0$). Depending on the bias among several pathologists evaluating a biopsy, the same lesion may be reported as grade III intraepithelial neoplasia, high-grade dys-

plasia, or $T_{is}N_0M_0$.[107] Despite the often stated pathologic principle that high-grade dysplasia and $T_{is}N_0M_0$ are equivalent terms in describing abnormal squamous epithelium, the clinical management is generally less aggressive for high-grade dysplasia than for $T_{is}N_0M_0$. Whereas radiotherapy has commonly been supported as a reasonable treatment alternative for $T_{is}N_0M_0$, it is not recommended in the management of high-grade dysplasia.

Difficulty in discriminating between reactive processes and carcinoma in situ is underscored by a study evaluating imprecision in histopathologic diagnoses. Westra and colleagues[108] reported three cases of laryngeal $T_{is}N_0M_0$ submitted from outside hospitals that were, on review with a second opinion at their hospital, considered to be reactive atypia.

Controversy persists regarding the role for radiotherapy in the management of $T_{is}N_0M_0$. A common management approach has been to address laryngeal $T_{is}N_0M_0$ surgically when conservative endoscopic removal is possible.[109] Persistence after multiple resections or the presence of extensive involvement of multiple sites has been used as an indication for irradiating $T_{is}N_0M_0$.[110] Factors such as the anticipated need for multiple endoscopic resections, cost of treatment, voice considerations, reliability of the patient for follow-up, patient's age, and presence of comorbidities are all factors that may influence initial definitive treatment with irradiation.[111]

Issues regarding the appropriate management of $T_{is}N_0M_0$ are unresolved. Local excision and radiotherapy are effective management options.[112] Either approach requires close follow-up.

Invasive Squamous Cell Carcinoma

Selection of an appropriate treatment modality for early glottic cancers ($T_1N_0M_0$, $T_2N_0M_0$) is made difficult by the many opinions that support conflicting approaches. The simplest conceptual approach is offered by Hinerman and colleagues,[113] who identified that, in the past at the University of Florida, "Radiation therapy has been the treatment of choice for all previously untreated T_1 and T_2 vocal cord cancers." These investigators later amended this practice to prefer transoral laser excision over radiotherapy for the small subset of patients with limited T_1 midthird vocal cord lesions for whom surgical excision is expected to preserve voice quality.

Although the NCDB survey of laryngeal cancer indicates that in the United States radiotherapy is used most commonly in the management of T_1 and T_2 cancers, there are well-considered arguments for a more liberal use of surgery as the initial management.[114] Morris and colleagues,[115] through an intensive literature review, identified an overall 8.6% failure rate at the primary site for T_1 glottic cancers managed surgically (cordectomy) compared with a 16.7% failure rate among similarly staged cancers managed with radiotherapy.[116] Stronger support

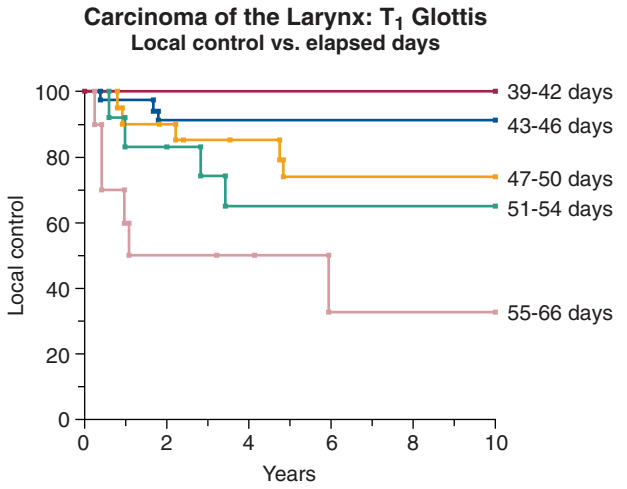

Figure 108-8. T_1 glottic carcinoma of the larynx: local control versus radiotherapy elapsed time. Local control is a function of elapsed days for patients managed with radiotherapy for T_1 squamous cell carcinoma of the glottis. *(From Rudoltz MS, Benammar A, Mohiuddin M. Prognostic factors for local control and survival in in T1 squamous cell carcinoma of the glottis.* Int J Radiat Oncol Biol Phys. *1993;26:768.)*

comes for use of surgery as the primary treatment for T_2 glottic cancers. In 1990 Howell-Burke and colleagues reported from MD Anderson that, among patients treated with primary irradiation for T_2 glottic cancers, only 74% maintained a functional larynx.[117] Some investigators contend that T_2 glottic cancers initially treated with irradiation have a higher risk that laryngeal function will be lost than when conservation surgery is the initial treatment.[118]

Further support for this concept comes from review of published recurrence rates following initial treatment of early-stage laryngeal cancer (see Tables 108-6 and 108-7). A review of these same rates identifies that the great majority of early laryngeal cancers that recur are ultimately treated with total laryngectomy. A problem leading to this need for total laryngectomy may be identified as difficulty in surveillance permitting early detection. Suzuki and colleagues[119] reported in 1994 that 60% of patients initially identified with an early laryngeal cancer are identified with an increased stage at the time of recurrence.

Barthel and Esclamado[120] reviewed management of 45 patients with early glottic cancer who were treated with primary irradiation at the Cleveland Clinic between 1986 and 1994. These investigators reported that their local control rates of 87.5% for T_1 and 75% for T_2 lesions were consistent with prior published series. Among the nine recurrences that developed, six had tumors that were (retrospectively) considered to be amenable to treatment with a partial laryngectomy. Among these six cases (all treated with irradiation), only one was successfully salvaged with conservation laryngeal surgery. These investigators concluded that patients with T_2 glottic tumors may be better treated primarily with surgery because T_2 glottic cancers have a high recurrence rate after irradiation and surgical salvage with less than a total laryngectomy was unlikely to be successful. Valuable insight is provided by a report by Jorgenson and colleagues that addresses 1005 Danish patients treated at a single referral center between 1965 and 1998.[121] The philosophy of treating all but those who had previous treatment with irradiation resulted in remarkably little selection bias regarding treatment choice, with 99% of patients receiving initial management with radiotherapy. Jorgenson and colleagues[121] identify that the presence of a stable patient base within a cachement area of 1.33 million people, coupled with excellent follow-up (only three patients were lost to follow-up), lends further credibility to this study. Among 312 T_1 glottic cancers treated with irradiation, 5-year locoregional control was 88%, which, coupled with surgical salvage, resulted in a 99% 5-year disease-specific survival. Among 233 T_2 glottic cancers treated with irradiation, 5-year locoregional control was 67.4%, which, when coupled with surgical salvage, resulted in an 88.4% 5-year disease-specific survival. These investigators identify that this high recurrence rate (one out of three) for T_2 glottic cancers resulted in an overall laryngeal preservation of 80%, which is substantially lower than the 95% organ preservation reported by Chevalier and colleagues when supracricoid laryngectomy was used as the initial treatment.[122] Based on these data, Jorgensen and colleagues raised the logical question: Why not introduce supracricoid partial laryngectomy as primary standard treatment of T_2 glottic cancer? Jorgenson and colleagues argued that part of the excellent results reported by Chevalier and colleagues reflected a selection bias that favoring surgical results by reserving supracricoid laryngectomy for the more favorable cases. Jorgensen and colleagues additionally pointed out that the voice quality is better after irradiation than after supracricoid laryngectomy. For these reasons, they have not altered their standard approach to managing T_2 glottic cancers with irradiation. They also observed that improved radiotherapy techniques, as well as the capacity to salvage irradiation failures with

supracricoid laryngectomy, will likely decrease the ultimate need for total laryngectomy further.[103]

Motamed and colleagues[123] reviewed all series of laryngeal preserving surgical salvage following localized radiotherapy failure for early laryngeal cancer. They estimated that one third of recurrences following radiotherapy are amenable to localized treatment. In this highly select group of patients the average laryngeal conservation rate was 77% following open conservation surgery and 65% following the endolaryngeal laser microsurgery. The trend favoring surgery over radiotherapy with regards to final laryngeal preservation may therefore be due to differing salvage philosophies, as well as submucosal or diffuse recurrence patterns and the difficulties in early detection of recurrence due to edema and tissue changes following radiotherapy.

The preceding studies have focused on AJCC (or the International Union Against Cancer) TNM classification as the factor determining treatment. Others have identified specific features of early glottic cancers separate from this classification system that may be helpful in assessing the likelihood of cure with radiotherapy.[124] It is useful to individually evaluate these characteristics that are either not included in the TNM staging (anterior commissure extension and large tumor bulk) or are used to discriminate T_2 from T_1 lesions (impaired vocal cord mobility and subglottic extension). Many investigators support surgery as the preferred initial treatment for patients who have such characteristics.[125]

In general, the survival outcomes for early laryngeal cancer are very good regardless of treatment modality. In a series of 410 patients treated with primary radiotherapy, Franchin and colleagues[59] showed that second primary tumors were the major cause of death. Patients who developed a second primary (most commonly lung followed by head and neck) had a 32% 10 year survival compared with 77% 10-year survival for those without a second primary tumor. In a series of 240 early-stage laryngeal cancers treated with radiotherapy followed for a median 6 years, Holland and colleagues[60] showed that 28% developed second primary tumors (6% in the head and neck) with median survival 14 months.

Laryngeal-preserving surgery, whether endoscopic or open, is repeatable, whereas radiotherapy, in general, can only be used once. Although radiotherapy is more commonly used, surgical techniques reserve the capability of using radiotherapy in treatment of more deadly second primary tumors of the head and neck, which may be more advanced at presentation or be in sites where surgical treatment is more morbid and less of an equally suitable alternative than the larynx.

The anterior commissure has been, in a contradictory fashion, either considered as a barrier to tumor spread or as an early pathway for cancer extension into the laryngeal framework.[126] Shvero and colleagues[127] related that surgical treatment is preferred for cancers arising in this region because of a higher local recurrence rate after radiotherapy with an increased risk for distant metastasis. They contend that the behavior of small cancers in this location is much different from that of other early glottic cancers.[79] Other investigators have attributed the higher rates of failure after radiotherapy for anterior commissure lesions to problems with adequate dosing.[128,129] The distance from the anterior commissure to the skin varies greatly among patients. This variability and the thick overlying thyroid cartilage have been cited as impediments to consistent dosing of radiation to this region.

Insight into poor outcomes after irradiation of cancer affecting the anterior commissure is offered through a retrospective review by Maheshwar and Gaffney of 53 patients with T_1 glottic cancer treated between 1989 and 1996 with a minimum dose of 63 Gy in 30 fractions during 6 weeks with parallel opposed fields.[130] These investigators reported an overall 20.8% locoregional recurrence rate. The recurrence rate (57.1%) with anterior commissure involvement was much higher than the recurrence rate (15.8%) when the anterior vocal cord was involved but did not include the anterior commissure. They hypothesized that a lack of pretreatment CT imaging may have contributed to their poor results. Without this advanced imaging, they may have understaged the group of anterior commissure cancers, which have a high chance of cartilage involvement and hidden tumor bulk. Although some investigators relate that modern radiotherapy techniques with improved dosimetry have adequately addressed these concerns, Maheshwar and Gaffney[130] report in their study that they had addressed the potential to underdose the anterior commissure by adding wax bolus to the region during treatment.

T_{2b} cancers and those with subglottic extension generally have a larger tumor volume that may contribute to the lower cure rates with radiotherapy.[131,132] Many contend that surgery as a single modality is more effective than radiotherapy for managing these larger "early" glottic lesions. Questions persist about the capacity of a management plan that uses definitive radiotherapy coupled with salvage by partial laryngectomy to provide equivalent rates of laryngeal preservation.[69]

One final factor weighing against radiotherapy is the absence of definitive histologic specimen. From the early days of laryngeal conservation surgery it has been known that up to 20% of biopsy proven cases will have no residual cancer found on definitive resection.[133] Such cases improve results in both radiotherapy and surgical outcome studies and would not require radiotherapy to the unaffected residual tissues.

A systematic review of the world's literature (including the Cochrane Controlled Trials Register, as well as MEDLINE, EMBASE, CINAHL, and Cancer Lit, up to October 2000) identified three randomized clinical trials (RCTs) comparing treatment of patients with stages I and II glottic cancer with either irradiation or surgery.[134] One trial was excluded because of insufficient numbers of patients[135] and another because of the combination of suboptimal radiotherapy dosimetry, small numbers of patients with glottic cancer, and improper randomization.[136]

The most relevant RCT was an Eastern European multicenter trial to which 234 patients with early laryngeal cancer were randomly assigned, starting in 1979. They were treated with open surgery, radiotherapy, or a combination of radiotherapy and chemotherapy (prospodine) after stratification by anatomical site (glottis or supraglottis) and by tumor stage (T_1 or T_2).[137] The published results (which did not report the number of events or patients at risk in each treatment arm) identified 5-year survival rates of 100% after surgery and 91.7% after radiotherapy for T_1 tumors. For T_2 tumors the 5-year survival rates were 97.4% after surgery and 88.8% after radiotherapy. Although these higher survival rates for patients receiving surgery were not statistically significant, the 5-year disease-free survival rates of 78.7% for surgery and 60.1% for radiotherapy were significant ($P = 0.036$). In subsequent review, Dey and colleagues[134] questioned the validity of these results because they believed the patients in the study were inadequately staged

before being randomly assigned, that the radiotherapy may have been suboptimal, and that the follow-up was poor. Dey and colleagues concluded from their systematic review that uncertainty remains as to the comparative benefits and societal costs of these different treatment modalities.

A large survey employing Canadian and American data sets to assess outcome as a function of differing management philosophies acknowledged that "current practice is based on reports from individual institutions recommending differing treatment policies."[138] These investigators opine that a clear advantage to one approach will be difficult to identify because randomized trials comparing surgical and nonsurgical treatment of glottic cancer will never be conducted because of entrenched beliefs. Although it is clear from the review by Dey and colleagues that RCTs have been done addressing early laryngeal cancer, none has yet compared the effectiveness of endolaryngeal resection with either radiotherapy or open surgery.

Summary

Selection of a treatment modality for early glottic cancers should be determined after a careful discussion of options with the patient. Ideally patients should have a discussion with both a radiation oncologist and a surgeon experienced in laryngeal conservation surgery (open or laser). Radiotherapy and careful follow-up employing surgical salvage offers a similar chance for a cure as that provided by treatment with surgery and most likely provides the best voice quality in patients retaining their larynx. The major shortcomings of radiotherapy include the need for prolonged treatment, the higher risk of requiring a total laryngectomy for salvage, and limitation in repeatability in the event of a second primary head and neck tumor. Second primary tumors are the most common cause of death in early laryngeal cancer. T1 cancers with anterior commissure involvement or large tumor bulk and T2 cancers most likely have higher final laryngeal preservation following initial surgical treatment rather than irradiation. The major shortcomings of surgery include exposure to a general anesthetic and most likely worse voice quality, although with higher final laryngeal preservation. Potential swallowing impairment, as well as other comorbidities, should be considered when recommending an approach. Close follow-up is important to detect second primary tumors and treat selected early recurrence using laryngeal-preserving techniques.

CHAPTER ONE HUNDRED AND NINE

Transoral Laser Microresection of Advanced Laryngeal Tumors

Michael L. Hinni

John R. Salassa

Bruce W. Pearson

Key Points

- Transoral laser microsurgery (TLM) permits both small and large laryngeal tumors to be resected. The limits of resectability are based on access and functional consequences and not on extent or T stage.
- Piecemeal resection of cancer permits precise tumor mapping and may improve local control over traditional "en bloc" resections. It further permits larger tumors to be removed through endoscopes that could otherwise not accommodate the physical volume.
- TLM offers numerous functional advantages including fewer tracheostomies, no fistulas, earlier swallowing, and sensation.
- TLM can replace traditional conservation laryngeal operations.
- TLM can fit well into multimodality therapy strategies.

Terms and Definitions

Transoral laser microsurgery (TLM) is a surgical treatment strategy for primary cancers of the mouth, pharynx, and larynx. In TLM, the instrument of excision is a carbon dioxide (CO_2) laser beam, an operating microscope imparts the perspective, and the natural passageways of the upper aerodigestive system provide the access.

Two features distinguish TLM from open surgery[1]: healing is allowed to occur by secondary intention[2] and the tumor block can be subdivided into manageable units by the laser (in situ).

TLM is clearly a conservation strategy, but it is not a reconstructive one. "Piecemeal" removal is a distinguishing feature of TLM—and a key source of controversy. Tumor transection endows important diagnostic dimensions to TLM, and magnification exploits the difference in visual appearance between normal tissue and cancer.

Safe TLM requires two conditions: adequate exposure through the mouth and a tangible specimen.

TLM is an excision, not vaporization. A specimen is the basis of meaningful frozen section margins. Individual specimens may be small, but, in aggregate, the resected tissue volume parallels that of an open operation.

In many ways, TLM is a misleading name. Transoral laser microsurgery is not totally transoral—open surgery is still required for nodes in the neck. TLM is not entirely laser, either—it depends on endoscopic cautery, vascular clipping, and occasionally blunt and sharp dissection. Finally, TLM is not exclusively surgical—radiotherapy may be offered (for neck indications, but never to finesse margins).

The aim of TLM is to improve cure and function through patient selection and technical excellence. The goal is the cure rate of open surgery and the functional promise of a tissue-conserving treatment like radiotherapy, all of this with less morbidity, at lower cost.

"Advanced" (as in "advanced laryngeal tumors") is a confusing term. In the context of laser surgery, it once meant any tumor larger than T1a glottic. In traditional discussions, it used to mean cancer with a fixed cord. The staging system suggests a different connotation—positive neck nodes. What is clear is that laryngeal cancer is not one disease. It is many different diseases. And unless we digress and clarify the descriptors of the different laryngeal cancers, all discussions of treatment are ambiguous. The answer to the question, "Does an advanced case qualify for TLM?" is "It depends. What do you mean by advanced?" Let's look at the classifications.

Is it cancer? Laser surgery manages everything along the histologic spectrum, but this chapter only relates to the worst actor, invasive squamous cell carcinoma. The Ljubljana taxonomy[3] is probably the closest thing we have to an internationally accepted classification of epithelial hyperplastic laryngeal lesions (EHLL). For the most benign, "simple hyperplasia," acanthosis predominates. "Abnormal hyperplasia" is next, and basal proliferation is the hallmark. "Atypical hyperplasia" features dysplasia and atypia. Fourth is carcinoma in situ (CIS), cytologic neoplasia on an intact basement membrane. All these can be laser resected, but TLM is a higher strategy for a higher challenge, group five, neoplasia with subepithelial penetration (i.e., invasive squamous cell cancer).

Is it TLM? An excellent classification for laser cordectomies has been developed by the European Laryngological Society.[4] It names five types: subepithelial, subligamental, transmuscular, total, and extended cordectomy. The first three are elegant one-piece excisional biopsies, and a laser may be used on them. TLM (and the strategy of depth determination) comes into play for the last two.

What site? Before "multidisciplinary" committees imposed a theoretic anatomic classification (glottic, supraglottic, and subglottic) on

laryngeal cancer, surgeons included clinical behavior in the sorting system. For 50 years, laryngeal cancer was "intrinsic" or "extrinsic."[5] Intrinsic was "interior region" cancer, primarily glottic in origin, and slow growing, and its nodes were generally late.[6] TLM treats most of these, but not all. Extrinsic cancer was more supraglottic, originating around the laryngeal opening or its pharyngeal surface. It had a higher rate of metastases and was more lethal. TLM treats the local disease, but not the metastases.

Now the official categories are glottic, supraglottic, and subglottic, whereas "transglottic" is used to describe tumors that span the ventricle. However, in the anterior larynx, glottic and subglottic cancers behave similarly.[7] Subglottic cancer often turns out to be glottic, with descent. The height of the glottis is controversial (5 mm high, 10 mm high), or excluded posteriorly (sparing the posterior commissure). None of the sites is off limits to TLM.

In discussing local extent, clinicians often reduce their spoken references to "early" and "advanced" laryngeal cancer, the traditional dividing line being vocal cord motion. In these terms, TLM is primarily an "early" cancer treatment, as opposed to the "advanced" group.

The tumor, node, metastasis (TNM) staging system[8] uses T_X, T_{is}, T_1 (a and b in the glottis), T_2, T_3, T_{4a}, and T_{4b} to define a local tumor, expanding 3 regions to 18 "extents." And this is just for the local disease (T). Nodes multiply the possibilities by 7. Metastases multiply the possibilities by 3, for more than 300 possibilities. Some are suitable for TLM. Some are not. No one knows where we should place the dividing line, or where "advanced" should start (or end). The staging system does encourage a summary format, stage 1, stage 2, stage 3, and stage 4, but the neck dominates this classification. If the neck is positive, everything is stage 3 or 4 (advanced), even if the primary is miniscule.

The staging of laryngeal cancer is not linked to any particular therapy and has significant limitations. TNM staging leaves out historic factors (age, previous treatments, habits, work, duration of and number of symptoms, literacy, religious beliefs, distance from treatment facility, etc.) and leaves out comorbidities. Both symptom severity scores and comorbidity scales have been shown to improve the accuracy of TLM.[9] TNM also ignores complex patient factors (e.g., exophytic vs. endophytic, keratinized vs. ulcerated, stridor, obesity vs. cachexia, forced expiratory volume, ejection fraction, hemoglobin, protein levels, blood sugar, liver function tests). These and other limitations of TNM staging pose challenges to the treating physician.

This leaves the doctor with the problem of how to interpret the term "advanced" in the context of TLM. It makes little sense to link advanced to a higher TNM stage (3 or 4) if patients with T_1 and T_2 local cancers will be included (all that is required to make a T2 cancer "stage 3" is for someone to feel a node in the neck). For example, the 2002 American Joint Committee on Cancer (AJCC) TNM staging of larynx cancer states that stage III includes T_1, T_2, or T_3 N_1(or T_3 N_0), where N_1 is a single node smaller than 3 cm. The AJCC also lists stage IVA to include T_1, T_2, T_3, or T_{4a} N_2 (or T_{4a} N_1 or N_2), where N_{2a} is a node between 3 and 6 cm in size, on the same side; N_{2b} is multiple nodes smaller than 6 cm, on the same side; and N_{2c} is bilateral or contralateral nodes smaller than 6 cm in size.

This chapter is primarily about the treatment of the local diseases by TLM. Therefore we need to classify local diseases and to help distinguish those for whom TLM is an option and those for whom it is not.

Five Types of Local Laryngeal Cancer

From the surgeon's standpoint, local laryngeal cancer comes in five different "flavors," each one more damaging (to function) and more difficult to cure. Severity relates to what stock local excision would be required for complete removal. What would that impose on the patient, in terms of voice, swallow, and nasal breathing? This does not indicate the treatment is surgery. It does ensure that the appropriate local option for surgery is identified, especially to the patient, when the selection among various modalities is made. Each flavor can thus be defined by one of five classic excisions, which ascend in severity from laryngoscopic biopsy to total laryngectomy. Each excision removes a customary block, from one nodule to the whole larynx and its coverings, and each has a formal technique. We have a published record for each of local control rates from 98% to 80%. The expected functional outcome ranges from normal voice, swallow, and breathing down to tracheoesophageal puncture (TEP) voice and stomal breathing. Each of these five categories can be named as follows: very early, early, intermediate, advanced, and very advanced.

1. Very Early
   Exophytic midcordal T_{1a} carcinoma. Encompassed by transoral excisional biopsy removal. Includes one-piece subepithelial cordectomy (stripping), subligamental[4] partial cordectomy, and midcordal transmuscular cordectomy.

2. Early
   Two subtypes, glottic and supraglottic.
   a. Early Glottic
      T_{1a}, T_{1b}, and T_{2a} true cord carcinoma whose formal external excision would be a vertical partial laryngectomy,[10,11] or hemilaryngectomy.[12,13] The European Laryngological Society's total cordectomy and extended cordectomy[10] concepts probably fit here.
   b. Early Supraglottic
      T1 supraglottic carcinoma fitting within a supraglottic laryngectomy block.[1,14,15]

3. Intermediate
   Laryngeal cancer that fits within a supracricoid partial laryngectomy block.[16,17] Thus T_2 glottic carcinoma (T_2 by spread to the supraglottis), T_3 glottic (T_3 by thyroid cartilage erosion from the anterior commissure—mobility is preserved), T_2 supraglottic (T_2 by descent to involve the vocal cords), or T_3 supraglottic cancer (if T_3 by involvement of the preepiglottic space PES).[18-20]

4. Advanced
   T_3 glottic carcinoma (T_3 by unilateral cord fixation and invasion of the paraglottic space or the thyroid ala) is the prototype because it is lateralized and fits within a near-total laryngectomy.[21] Lateralized invasive T_{2b} glottic carcinoma qualifies if the T_{2b} is by impaired mobility of one vocal cord. Also, advanced glottic carcinoma includes T_2 supraglottic carcinoma, where T_2 means involvement of the vallecula or the medial pyriform wall, and T_3 supraglottic carcinoma, where T_3 means unilateral cord fixation with invasion of the paraglottic space or the thyroid ala.

5. Very Advanced
   Bilateral anterior T_3 glottic carcinoma invading both ventricles, bilateral posterior T_3 supraglottic cancer invading the postcricoid region, or T_{4a} glottic or supraglottic carcinoma, which means the cancer has invaded into adjacent structures outside the larynx—the strap muscles, the thyroid gland, the tongue beyond the immediate base, the trachea, or the esophagus. The minimum excision these cancers would require is at least a wide field total laryngectomy (T_{4b} is incurable by surgery). T_{4b} means gross distant extension. But this is virtually unheard of in cancers with no prior treatment. Examples include direct extension into the prevertebral space or the mediastinal structures or encasing the carotid.

Now we can examine TLM in the context of the clinical severity of the local disease. Others can judge the use and validity of the approximate term *locally advanced.*

Acronyms

CHEP Cricohyoidoepiglottopexy.[22] Reconstruction for supracricoid partial laryngectomy (SCPL).

CHP Cricohyoidopexy.[23,24] Reconstruction for SCPL.

HSL Horizontal supraglottic laryngectomy.

NTL Near-total laryngectomy.[25,26] Frontoanterior VPL with epiglottoplasty, SCPL, and NTL have at various times all been called *subtotal laryngectomies.*[27-30]

PES Preepiglottic space.

SCPL Supracricoid partial laryngectomy. Frontoanterior VPL with epiglottoplasty, SCPL, and NTL have at various times all been called *subtotal laryngectomies.*[27-29]

TLM Transoral laser microsurgery.

TEP Tracheoesophageal puncture, tracheoesophageal prosthesis.[31,32]

VPL Vertical partial laryngectomy. Includes the vertical frontoanterior and frontolateral[10,11,33,34] partial laryngectomies, and hemilaryngectomy.

Laser Surgery and Transoral Laser Microsurgery in the Treatment of Early, Intermediate, and Advanced Cancers

Laser surgery is not new in larynx cancer. Davis and colleagues[35]; Jako and colleagues[36]; Strong[37]; and Vaughan and assessites[38] all treated selected tumors during the 1970s and early 1980s.

Through the 1980s and 1990s, Motta and others[39] and Steiner[40,41] pioneered a new concept: tumor transection in situ. Consider the implications. If infiltrative cancer could be safely resected in pieces, tumor depth could be determined in situ. Incremental resection would become possible—as in Mohs' chemosurgery.[42] (Mohs treated cancer successfully in more sites than just the skin.) One could "follow the tumor" (i.e., custom tailor the excision to each individual patient). If tumors could be subdivided into manageable subunits, early, intermediate, and even some advanced laryngeal cancers might be candidates.

Of course, transoral cordectomy provided outstanding results long before the laser was added. Suspension[43-46] and the microscope were the keys, not a laser. What the laser added was questionable—costs for new equipment, time to set up, regulations in the operating room, thermal injury hazards, maintenance issues, anesthesia issues, more suction, filters, retraining requirements, and new credentialing. And what the laser gave up was considerable—the tactile feedback of cold steel microinstruments, the ability to cut around corners, the plume-free operating site, the char-free pathology specimen, operating room space, an unencumbered microscope, and the precision of a cut path versus a vaporization path.

But in the 1980s and 1990s, a sustained experience of endoscopic laser surgery for larger than T_{1a} glottic cancers was growing in Germany.[40,41,47-51] This raised additional questions among traditionalists. They had concerns about exposure, hemostasis, reconstruction, margins, and wound healing. The greatest concern, however, was tumor transection. Steiner cut right through laryngeal cancer—in situ—through a laryngoscope! The claimed advantage was visualization and confirmation of tumor depth. How did the skeptics respond? First, they were asked to compromise access and work through smoke with an endoscope, with no convincing evidence this was meaningful. Then they were asked to give up orientation and violate the principle of en bloc resection—with no laboratory evidence this was safe!

Other concerns fueled the discussion. After a laser supraglottic resection, there was no reconstruction! Open supraglottic laryngectomy always led to aspiration if one failed to repair the gap between the glottic unit and the tongue base.[15,52,53] After laser SCPL, there was no cricohyoidopexy. Yet this was essential in open SCPL.[19,24] There were so many additional issues a laser did not address (e.g., bleeders over 2 mm, ossified cartilage, neck nodes).

Furthermore, the obvious problems of access were troubling. Big tongues, small mandibles, capped teeth, mild trismus, and other challenges all lay in waiting, even for the most resourceful of operators. Very early midcordal T_{1a} carcinomas may have been fine. But early cancers would require greater exposure, intermediates more, and so on. Some would be too big to extract through an endoscope. A growing plethora of "laser laryngoscopes" raised suspicion that the problem of access remained unsolved.

Another challenge would be quality control from the pathology department. In cancer operations, negative margins are compulsory. If laser specimens were vaporized, the pathologist would have no margins to read. If they were excised with a laser, margins would at best be charred. If they were excised in several pieces, positive margins would be meaningless!

In North American practices, these considerations delayed TLM. This occurred despite much of the pioneering work originating in North America—the entire organ serial section studies from New Haven,[54] Philadelphia,[55] and Toronto[56,57]; the development of the CO_2 laser itself at American Optical Corporation by Strong[58] and associates in 1965; and the pioneering clinical laryngology of Strong[37]; Jako,[36] Vaughan,[38] Davis,[35] and Ossoff[59] and their coworkers; and Shapshay.[60] But the German centers were leaders in the collaborative development of all the ancillary laryngologic instrumentation needed to capitalize on the technique. They pushed their experience well beyond the concerns recited earlier, tracked their results, and continue to report on their experience.[41]

In 1996 the authors of this chapter began to study this body of work more closely, and subsequently we took numerous steps to incorporate TLM into our practices. This effort provided new perspectives on laryngeal cancer management and the initial selection of therapy. Now we seek to share what we have learned.

Theoretic Basis of Transoral Laser Microsurgery

TLM does violate a time-honored dictum of surgical oncology—en bloc resection. A typical glottic or supraglottic cancer (above T_1) is likely to be extracted in three to six separate pieces!

En bloc has always been a prudent tactic to avoid unseen physical dispersion of viable malignant cells in a wound. When a scalpel penetrates cancer, the cells exposed will be alive. Viable cancer cells may adhere to the blade. Nothing prevents the surgeon from inadvertently transferring unseen cancer to an adjacent site in the wound. If unseen cell transplantation does occur during open surgery, and then we close the wound, how could tumor not recur? In open traditional surgery, this is why we isolate cancer in an unbroken package of normal surrounding tissue—to prevent contact between cancer and a scalpel or a scissor. This way, maybe we can avoid transplanting living malignant cells from the cancer back into the patient.

Rethinking this chain of events in laser microresections raises a new question. What would be the apparatus of physical transplantation? Cancer cells do not adhere to a beam of light. There is no physical carrier to transplant the tumor. Then again, grasping forceps and the suction cautery tips are used in TLM. They could do it. But assuming no tearing of the specimen, how would exposed cancer cells be viable? Cells revealed by laser energy are thermocoagulated, not viable. Finally, in the TLM paradigm, we do not close the wound. An unseen cancer cell falls on a thin layer of coagulum, not a healthy tissue surface. This layer is gradually sloughed, not incubated.

These are theoretic reasons we postulate that laser surgery permits local cancer ablation without en bloc resection. Is there any laboratory or clinical data? Werner and colleagues showed (for CO_2 laser incisions) that the lymphatic vessels of the wound margin are sealed immediately, and lymphatic vessels remain sealed for about 10 days after laser surgery.[61] And we also have 20 years of European clinical data.[62-65] Steiner and colleagues[41,64-67] have been performing TLM since the early 1980s. He and his colleagues have observed a low local recurrence rate (2% to 10%), a high survival rate, and a low rate of complications.[66,67] They have not seen an increase in late neck or distant metastases during follow-up of more than 10 years. The incidence of cure by TLM is the same as the best results reported for open conservation surgery. Put another way, open surgery follows the principle of block resection but produces no more local cures than TLM! TLM allows laser tumor subdivision, but local failure occurs with the same low incidence as in traditional open conservation surgery.

If tumor transection can be safely accomplished (it is not automatic, care is still important), we have an attractive new technique to determine the depth of cancer invasion before we commit to the plane of excision. If we misjudge and cleave too close to the tumor, this is

just another form of tumor transection. We can extend the excision, incrementally. All we have lost is some time.

If tumors can be divided in situ, the tumor itself ceases to be a factor in obstructing our vision. Complete removal always requires that we expose the entire mucosal margin of the tumor. Now we can achieve that goal in a mosaic of views, unrestricted by the bulk of the disease.

If tumors can be extracted in pieces, the internal diameter of the laryngoscope does not set the limit on how large a tumor we can resect. The limit becomes the exposure for each step and our disciplined attention to specimen orientation. Mohs[42] transected cancers in situ successfully, and his attention to orientation was uncompromising.

Later in this chapter we summarize our TLM results, as well as those of others.[67] We have documented a low incidence of failure at the primary site and also reported the ultimate causes of death. Our conclusion is that ultraradical treatment of the primary is not justifiable in a disease for which the main causes of death are advanced neck recurrences, distant metastases, second primaries, and serious general diseases. In modern times, quality of life is increasingly salient. In related diseases like hypopharyngeal cancer (TLM treats pyriform cancer, too[68]), 5-year survival rates have stood between 15% and 30% for decades. Aggressive combined therapy (chemotherapy, radiotherapy, and radical surgery) have not improved the poor prognosis. Again, if we can effect local control with conservation laser surgery, the argument in favor of radical ablation clearly declines.

Transoral Laser Microsurgery Compared with Open Conservation Surgery

Open operations approach intralaryngeal carcinoma from its "blind side." The surgeon cannot see the primary cancer until he or she has opened the neck, divided the fascia, separated the strap muscles, opened the framework, and penetrated the lumen at a critical point, determined by the local anatomy. Once exposed, field margins are oozy, not laser cut. Structures within the field relocate with the surgery, instead of maintaining a fixed position. The tumor margins are diminutive, not magnified, and the headlamp is illuminated, not microscope superilluminated. For safety and reproducibility, open operations closely replicate a named excision block, chosen without the benefit of intraoperative depth information. For example, supraglottic laryngectomy removes the superstructures above the cords, which produces a predictable wound, requires a characteristic reconstruction, and can be repeated for numerous supraglottic cancer patients, despite the fact each has unique anatomy, distinctive preoperative findings, and slightly different tumor characteristics. Because the neck will be opened, the timing of a node dissection is determined. The neck dissection is continuous with the primary wound, so steps must be taken to prevent a fistula. Because the framework is elevated to the tongue base and both swell, airway safety demands a temporary tracheotomy. Supraglottic laryngectomy supports the principle of en bloc resection, but this was necessitated by the scalpel, not the cancer. It assists teaching, but for gross anatomy, not for the microanatomy and micropathology. Open supraglottic laryngectomy provides the access needed for reconstruction, but the open surgery necessitated the reconstruction.

By approaching laryngeal carcinoma through the mouth, TLM requires no disassembly for access. The laryngeal framework continues to support the airway. A tracheotomy is usually superfluous in a supraglottic TLM. The strap muscles retain their swallowing contribution. Through the endoscope, the operator confronts the authentic primary right from the beginning of the resection, with no disassembly of the patient just to reach the cancer. The laryngoscope stabilizes the field. The magnification and brilliant illumination unveil important subtleties (e.g., dysplasia at a margin). With no disturbance of the neck, and no connection of a neck wound with a laryngeal wound, pharyngocutaneous fistulae disappear from the list of potential complications.

During TLM, diagnosis continues.[69] Wherever the local tumor extends, the microscope and the laser try to follow. Magnified tissue appearances acquire new significance. Some tumors change the vascular patterns in the mucosa. Deeper in, invasive cancer tends to appear pale and dysmorphic. Tissues give up subtle information about their consistency as they are retracted. Cancer is stiff or soft (soft can progress to friability and bleeding). Beyond the tumor, the expected microarchitecture is striated muscle, fat, seromucinous glands, fibrous perichondrium, (ossified) cartilage, or bone. Fat looks yellow and lobulated; mucous glands are pale and lobulated but more noticeably vascular. Muscle is striated. Fibrous tissue is white and dry. Ossified cartilage and bone carbonize to a dominoes-like appearance. The undersurface of the strap muscles is loose and areolar.

TLM is a natural ally of combined treatment. Once the tumor is out, the locoregional microvasculature is still undisturbed—the best milieu for postoperative radiotherapy. And complete three-dimensional resection under the microscope has minimized the chances of a positive margin.

During the weeks after TLM, the endolaryngeal wound heals by secondary intention (in many ways similar to a tonsil bed). The framework resists stenosis because it remains intact. The thermal damage from laser resection is superficial (after electrocautery, it is deeper). No local flaps are mobilized or transposed, so there is no chance to bury residual tumor. "Second look" endoscopies become a meaningful way to revisit the primary site.

Months later, persistent granulation may signal the need for endoscopic removal, to improve voice. Follow-up laryngoscopy also allows the removal of small, ossified cartilage sequestra, which sometimes develop after laser resection has been carried down to the framework. Reepithelialization seems to forecast recovery but does not completely eliminate all risk of recurrence. Not even a negative second look excludes later recurrence. An overhanging anterior glottic scar may hide an unsuspected nubbin of residual tumor—still a salvageable circumstance, by simple laser resection, if discovered in time by this tactic. Before recommending TLM, discuss the willingness of the patient to return for a "second look."

Instrumentation and Techniques of Transoral Laser Microsurgery

Instruments

We use a floor-model CO_2 laser console that can generate an output beam of 1 to 50 W or a hand-held hollow CO_2 fiber (Omni-Guide). The latter device permits some cutting at angles. Two modes, pulsed and continuous, are possible. Pulsed mode produces the fastest vaporization and the least adjacent thermal injury—the least char, hence the best clear recognition of the texture at the cut surface. But any vessel larger than an arteriole will bleed, and the bleeding must be arrested with electrocautery. Pulsed mode at low power (2-3 W) is ideal for glottic mucosa. One can maintain control over the cut (working slowly), avoid collateral heat (especially unintended thermal injury to the anterior commissure), and also avoid a "hole" of unintended depth (by pausing). For most normal laryngeal incisions, we use continuous mode at around 6 W of power. This setting provides excellent hemostasis but not enough char to upset the pathologists. Most mucosa bleeds too much in pulsed mode. Continuous mode results in a little more coagulation (about 50 to 100 µm).

The overall spectrum of power in laryngeal work is wide—1 W (focused, pulsed mode, for fine cutting of cordal mucosa), to 20 W (defocused, continuous mode, to vaporize friable semi necrotic centers inside bulky cancer, one of the few justifications for vaporization).

Besides mode and power, four more variables influence the effect:

- Speed: How quickly one moves the beam. Thermal transmission takes some time.
- Focus: Defocus the beam to create a superficial cautery effect but turn up the power, especially for broad forward advancement. Defocusing reduces the density of the power.
- Target tissue: Normal tissue (moist, not running wet) cuts best. Wet tissue (fluid is visible) cuts slowly, with a lot of thermal artifact from the boiling that has to take place first.

- Bleeding: Flowing blood stops laser surgery cold. It has to be ended (with electrocautery) before the excision can continue. Bleeding tissue just takes refuge under an expanding black char ball. Paradoxically, a beam set for the least char may impose the greatest char, by requiring the use of electrocautery.

An articulated arm brings the laser beam to the microscope body. From here we direct it with the joystick on a Sharplan Acuspot 712 micromanipulator. The frame of the micromanipulator bears a gimbaled half-silvered mirror through which we see the target and with which we manipulate the laser beam. The narrowness of the micromanipulator frame is important. Anything wider than the microscope body will conflict with the introduction of instruments (22 to 23 cm long). Unimpeded maneuvering and hemostasis at the primary site demand a clear path alongside the microscope for the grasping forceps and suction cautery tubes.

If the hollow Omni-Guide CO_2 fiber is preferred, the micromanipulator can be removed from the microscope granting greater visibility and increasing the working space. The company can provide both straight and angled introducing fiber carriers. Occasionally we use both the micromanipulator (for precise tremor-free work) and the fiber.

The CO_2 cutting beam is invisible, at 10,600 nm (far infrared). The wavelength of visible light is 400 nm (violet) to 700 nm (red). The surgeon observes a red spot on the target produced by an integral red Helium Neon (HeNe) beam at 632.8 nm (visible red). A video camera is mounted on the microscope as in otologic microsurgery. A monitor displays the operative field, so the operating room nurses can anticipate and assist.

More than anything else, laser microresection requires sophisticated skills in direct laryngoscopy. Much of this is experience, but part of it is an understanding of the laryngoscopes. Narrow tubular endoscopes (i.e., narrow side-to-side) overcome difficult exposure best. The tongue is incompressible (a fluid) and confined by the arch of the mandible. It can only be distorted. Wherever the scope contacts the tongue, it employs strong pressure and deforms it such that a straight path to the anterior commissure results. The narrower an endoscope, the more it can sink into the tongue, and the more the tongue can squeeze around the sides.

A narrow vertically oval instrument like the Hollinger anterior commissure laryngoscope is the optimal tool to overcome difficult anterior visualization. But a narrow monocular laryngoscope is too narrow to accommodate the side-by-side dual optical pathways of an operating microscope. A Dedo anterior commissure laryngoscope overcomes this limitation. It provides just barely enough width to accommodate a microscope. The Zeitels Endocraft laryngoscope[70] maintains this advantage and adds a useful tip enhancement for glottic work—less bevel. A blunt tip is better for holding aside the false cords. Regular tips actually cover the anterior commissure by the time the rest of the barrel reaches distal enough to lateralize the false cords. Zeitels' scope also features proximal slots along the sides to improve access for the instruments. Special modifications load both the Dedo and the Zeitels instruments with extra light and need extra suctions carriers. Laser plume is the most troublesome limitation to clear vision during TLM, so the optimum allocation of suctions is important.

Storz and colleagues[66,67] have developed a specific assortment of laryngoscopes for TLM. Their standard adult laser laryngoscope (8661 CN) has a dome-shaped cross-section, a lip at the tip (anterior commissure), and an unobtrusive suction channel incorporated into the upper wall of the blade and the handle. For larger tumors, distending laryngoscopes are the best. Two we have considered indispensable are the Weerda distending operating laryngoscope (8588 L) and the Weerda/Rudert distending supraglottiscope (8588 E). These instruments are wider, independently adjustable, and fitted with great suction tubes. The upper blade features flare at the side to help hold the tongue out of the way. The lower blade mounts on a strong left proximal C arch (8588 L) or a strong ring (8588 E) to provide minimal encroachment on instrument access.

The best vallecular laryngoscope is probably the Lindholm instrument (8587 A). The essential laser laryngoscopes for difficult access and subglottic access are the Steiner models. These are long and thin. The "half dome" subglottiscope (8661 DN) sinks into a large tongue the best, and the suction channel is incorporated into the handle. The flat-bodied subglottiscope (8661 E) gets past prominent incisor teeth the best, and a separate suction can be clipped.

We protect the incisors by fashioning a custom splint of heated Aquaplast (PS-1685), a thermoplastic substance that sets to a hard stable cap and diffuses the pressure over five or six teeth (WFR/Aquaplast Corp., Wyckoff, N.J.). Sometimes we provide external counterpressure to the larynx with a band of tape across the table to provide downward pressure to the larynx.

You can never have too much suction for plume evacuation—suction tubes on the laryngoscopes, suction tubes on the grasping instruments, suction in the insulated cautery, and plain dedicated suction tubes. Support each one with a separate suction line. Then add special suction tubes for blood. We prefer plain suction tubes for cleanup and gentle tissue manipulation and insulated suction-cautery tubes for flowing blood (two of each). Insulated (model 8606) suction cauteries come in various diameters—the insulation is necessary to prevent them from sparking out to the endoscope. Prevent suction trauma (and worse, sticking to a friable specimen and tearing it) with a small relief hole in the tubing or at the sucker tip. We recommend at least three separate suction lines per case.

Larger vessels sometimes require something more targeted than suction cautery. Insulated model 8663 alligator forceps will pick up a small bleeder around a corner for electrocoagulation. Control the lateral vascular pedicles coming into the supraglottis with insulated MicroFrance CE 0459 bipolar cautery-forceps (specify 22.5-cm length). Place titanium clips on named arteries such as the superior laryngeal and the anterior cricothyroid arteries. Delayed secondary hemorrhage would be a formidable complication in a patient with no tracheotomy. Stop this problem before it arises by using laryngeal vascular clip applicators (model 8665 works well).

Bouchayer fenestrated forceps (8662 R or L) are excellent grasping instruments for small cordal specimens. But to secure the grip we need on the larger specimens we manipulate in TLM, normal laryngeal microinstruments are too delicate. Saw-tooth grasping forceps meet the need. Use one (model 8662 EL, FL, GL, or HL) to maintain a stable grip on tumor subunits. Use two to advance by double grasping. The L denotes a suction channel.

Controlled resection is only as certain as the stability we create for the micromanipulator. A rock-steady microscope stand, like a Universal S3, serves our Zeiss OPMI 111 well. Reduce the wrist and finger movements you transmit to the system with adjustable armrest stabilizers on a pneumatic chair (like the Möller-Wedel Combisit E). Adjust the microscope and the patient to a comfortable position for you (as in otologic microsurgery) instead of the other way around.

During TLM, operating laryngoscopes require frequent redirection. This is why a rack-and-pinion chest table (like the Storz Göttingen model) is worthwhile. It permits efficient breakdown and redirection of the suspension system, which affords the operator the opportunity to quickly re-establish a different stable vantage point several times per case. Coupled with table-height and tilt adjustment (controlled from the head end of the table too), the operator can repeatedly re-establish the optimal line of sight.

Techniques

To enhance endoscopic exposure of the anterior commissure, one can laser-transect the ventricular bands (i.e., the inferior free margin of the false cord or upper lip of the ventricle) from their anterior anchorage on the framework of the larynx. But this diminishes the contribution undisturbed false cord tissues might have made to voice (exposure of the anterior commissure for lasering presupposes that the anterior glottic contribution to voice will be lost).

Do not rely completely on the pathologist. Study the mucosal margin around the tumor yourself. The operator enjoys the advantage over the pathologist when it comes to dodging a falsely negative margin reading. The pathologist will only see some of the margin—a rolled edge, with its telltale vascular network empty and collapsed. The surgeon gets to view the living margin under brilliant illumination, extended by traction, and further described by its vascular patterning.

Once beneath the mucosa, follow the cancer in an orderly way. Use your knowledge of cross-sectional anatomy. Use the telescopes to inspect beyond the tumor. Use the power of laser surgery to resect one piece at a time and maintain constant orientation. Replace finger palpation with instrument palpation. Pull the tumor into the field with grasping forceps. Finish an area before changing the tension and exposure in favor of another.

For laryngeal cancers that we choose to remove in sections, the plan of TLM is to complete each subresection a block (or view) at a time. Use transection at the edge of the field to find the healthy tissue plane and deliver all the cancer that will be taken in that established view. Tumor transection defines the plane of separation from the rest of the cancer. Consider marking it with ink. This surface will be the plane we need to place within the next view we "capture," to maintain a continuous resection. Like a Rubik's cube, as each new tumor subcomponent is delivered, an adjacent component becomes more accessible.

As each subunit is resected, three obligations are paramount:

1. Maintain continuous orientation to the cancer. Recognize what has been completed and what next to expose. Know what remains to be done.

2. Orient the resected specimen for the pathologist. The deep margin is the margin of interest, not the margin released from the rest of the tumor, which is known to be cancerous. It usually remains unmarked or bears the specific color we use to designate tumor transection surfaces.

3. Ink the deep surface margins and the peripheral margins, which are expected to be negative, with the previously agreed on study color (usually blue).

Any time TLM is applied to intermediate or advanced cancer, some patients will present with significant disease in the subglottic larynx. This can be a challenging location for exposure. Among the most helpful ploys are a small endotracheal tube, proper choice of the endoscopes, top-to-bottom sequencing of the resection, and special positioning of the larynx. Tip the larynx up by elevating the thyroid cartilage with the laryngoscope blade and depress the cricoid with cross-table taping. Most patients with subglottic cancer have glottic cancer. Excise the glottic component first and exposure is automatically improved for the subglottic disease. When cancer descends to the inferior margin of the thyroid cartilage, include the cartilage margin itself in the resection. It is possible to encounter (and recognize) the Delphian node when laser resections extend forward through the lower margin of the thyroid cartilage. Resection with the cricothyroid soft tissues provides an opportune method to identify an important mode of extralaryngeal nodal spread, a finding that usually calls for further treatment of the nodes in the neck.[70] Laser resection and histopathologic study of the Delphian node should probably be a routine part of any significant subglottic resection.

TLM is not just a simple combination of already familiar techniques. It forces us to reconsider the detailed anatomy of the larynx—to learn it "inside out." Otolaryngologists introducing TLM into their practice should watch someone do it. Take a course. Be prepared to train an assistant and a scrub nurse too. If facilities permit, fresh frozen cadaver dissection has merit. Some of the goals would be to distinguish the greater horn of the hyoid versus the upper edge and cornu of thyroid cartilage, the preepiglottic fat versus the glands around the ventricle, the distribution of the superior laryngeal artery and its main branches,[26] the form and attachments of the conus elasticus, and other parts of the neck.

If you biopsy a cancer at a separate sitting, use this opportunity to evaluate your preparedness and equipment for TLM. Determine whether your exposure will be adequate. When it comes to making the transition from study and observation to practice and application, start with small cancers and edentulous patients, the easiest to expose. Then work your way up.

Pathology Issues

TLM tends to be a "one-surgeon" operation. But it is by no means a one-doctor operation. An interested, enthusiastic, and involved frozen-section pathologist is an essential partner. Multiple specimen blocks require mutual understanding and clear communication. The step-section technique works nicely for a single block (like a T1a glottic specimen). It is not appropriate for the usual multiblock TLM case.[2]

When a tumor has been subdivided in situ, as already noted in this chapter, not all raw borders are margins. We have outlined one way to ink the margin in question on the specimen (Davidson Marking System). Another is to cut separate margin specimens from the wound. You may be surprised at how easily a specimen becomes disoriented. Orientation is often lost by the time the specimen reaches the lips! If you want the pathologist to work from the primary specimen itself, ink the margin in situ before the specimen is detached. In complex resections, ink the site of detachment, too, so that the subsequent readings will be easier to track. If you prefer, cut specific separate margin specimens from the wound. Then all the pathologist has to do is evaluate the entire submitted specimen. Is it yes or no? Is tumor present or not? The surgeon's responsibility is to avoid three errors—errors of sampling, errors of communication, and errors of identification. Sampling is the art of providing a dead specimen and getting the pathologist to tell you what will happen with the adjacent living tissue still present in the patient. Communication means providing the pathologist with key information, like whether the patient was irradiated before. Identification means keeping track of the sites of the sources of the biopsies. Use hemo clips, maps, lists, and inks of different colors. Number the specimens and link them to a map or a color. Make sure you and the cytopathologist share the same site names.

Transoral Laser Microsurgery in Relation to Each of the Five Clinical Categories of Laryngeal Cancer

Very Early Laryngeal Cancer

Very early laryngeal cancers provide a good initiation to laser laryngology, but the laser is just a "stand-in" for microforceps and cautery with little tangible advantage. Expert laryngologists commonly cure midcordal T1a glottic lesions by transoral laser excision. But all they perform is a simple excisional biopsy. Suspension microlaryngoscopy is a key asset. But the secret to the high cure rate in "very early" cancer is patient selection, skillful laryngoscopic exposure, careful en bloc excision, and negative margins. The advantage lies not with a laser, but with the nature of the disease. Very early glottic cancers are an exceptional neoplasm, being small, localized, and off the anterior commissure. No new principles were really required and no old principles were really challenged.

Early Laryngeal Cancer

"Early" laryngeal cancer comprises two groups, loosely similar to previously untreated T1B and T2A glottic cancer and previously untreated T1 supraglottic cancer: (1) glottic cases falling within the purview of an open vertical partial laryngectomy and (2) supraglottic cases falling within the boundaries of a supraglottic laryngectomy.

Transoral laser microresection clearly meets or exceeds expectations in early laryngeal cancer:

- The cure rate matches the open operations (vertical partials and supraglottics) while the morbidity and functional losses decline.[67]

- TLM does not require a temporary tracheotomy to treat early cancer. Hospital time contracts to 3 days[72] and costs fall.[73]

- Radiotherapy may outperform open VPL for voice in early glottic cancer, but only if cure is obtained. TLM provides the same high cure rate of VPL, but a better voice than VPL.[74] The major advantages of TLM relate to the efficiency of cure (obtained with only one treatment) and speed of completion (treatment is finished at the

same direct laryngoscopy and biopsy the patient would require to start radiation treatment).

- Radiotherapy may surpass open supraglottic laryngectomy (HSL) in resisting aspiration (but it loses on cure and efficiency). TLM preserves better swallowing[75] than HSL and, unlike radiotherapy, requires no diminution of lubrication or taste.

- Over a lifetime, up to 25% of laryngeal cancer patients develop a second cancer.[76] Half involve the upper aerodigestive system. Patients who opted for TLM retain every possible option for the second cancer (including radiotherapy and laser surgery). Patients who accepted radiotherapy—and even prevailed—have narrowed their de facto future options to surgery in an irradiated field.

The conduct of TLM in early laryngeal cancer proceeds as follows. Intubate for general anesthesia with a small laser-approved endotracheal tube. (To minimize trauma, consider doing it yourself.) Our tubes have two balloons filled with water. Set up the laser for parfocal operation, for the smallest microspot (0.25 mm), and for continuous mode. Ask for 3 W power if you are a beginning laser surgeon, more as you learn to work faster. Establish the initial laryngoscopic exposure and the video image. Protect the face with a wet towel.

For early glottic cancer, use the laser, retract with suction, and outline the tumor margins. Then subdivide the lesion into a "middle plus anterior" and a "posterior" subunit.[66] Identify the depth of infiltration into the thyroarytenoid muscle and the extent onto the arytenoid. Laser-resect the posterior block. Resuspend the laryngoscope and transect the remaining tumor between the "middle" and "anterior" block. Laser-resect the middle block so that all that remains is the front. Reconfirm the depth by frozen section. Finally, reposition the laryngoscope and resect the anterior block. Traction with Bouchayer forceps works well to clarify the resection line at the anterior commissure.

In anterior commissure cancer, the voice is usually bad due to the disease. Voice after TLM for anterior commissure cancer is usually no worse.[72] However, the mechanism is different. Extensive resection of anterior commissure/anterior glottic cancers changes the glottis to a keyhole shape. It also bares the inner aspect of the thyroid cartilage. Healing on the inner aspect of cartilage will produce thin mucosa on a solid base, cartilage or fibrous scar with tethered restriction points. Thus we obtain stiffness. And stiffness produces hoarseness. Also, the intact thyroid cartilage will brace open the defect to produce an anterior glottic gap. And a gap produces breathiness.

In some cases, breathiness can be reduced with phonosurgery (e.g., cartilage implantation[77]) to reduce the anterior glottic gap. The correction of hoarseness caused by stiffness awaits future advances. The principal strategy now is the intelligent preservation of uninvolved tissues and the avoidance of unnecessary desiccation of the normal tissues left behind (TLM preserves glandular elements better than radiotherapy).

For early supraglottic cancer (confined to the supraglottis—the glottis and both arytenoids are free), split the suprahyoid epiglottis[78,79] vertically in the midline (even if this transects cancer crossing the midline). Identify the hyoid bone. Cut the vallecula and expose more hyoid to each side. Pass down the thyrohyoid membrane and clearly identify the upper margin of the thyroid cartilage. Plan to capture the bilateral supraglottic vascular pedicles with insulated grasping forceps or the bipolar cautery forceps. In most cases, it is prudent to clip (with two or three hemoclips) the internal branch of the superior laryngeal artery. Resect suprahyoid tissues before infrahyoid tissues, in planned subsections, proximal to distal. Above the plane of the thyroid alar margin, you will not harm the glottis. Below this plane, improve your access and vision by having resected all of the suprahyoid tissues on both sides. When resecting the false cords, take advantage of the angled suction protectors (model 8596) to shield the vocal cords. Insert the "baffle" into the ventricle or above the anterior commissure. In every supraglottic case, the surgeon should work to resect all of the preepiglottic space.

Intermediate Laryngeal Cancer

Earlier we defined "intermediate" laryngeal cancer to be one that would require SCPL to be encompassed by an open operation. Most "intermediate" glottic or supraglottic cancers can be treated by laser microresection, open SCPL, or radiation with surgical salvage. The problem with radiation and salvage is that intermediate cancers that fail radiotherapy are not cured by conservation operations. SCPL has a better record of local control,[24,80] but patient selection and surgical execution require tremendous sophistication. SCPL pushes function to the limit—it is probably the most extensive open resection one can do and still restore swallowing and an internalized airway (i.e., the tracheotomy is temporary).

Experience refutes the allegation that TLM cannot encompass intermediate cancers. When an anterior commissure lesion is too big for a vertical partial (but too mobile for a near total or total laryngectomy),[72] TLM provides a logical resection. TLM clearly rivals open SCPL for functional results. The morbidity is more than we see after TLM for early cancer, but clearly less than we expect after open SCPL for intermediate cancer.[81] Case selection may be more forgiving than it is for open SCPL because of the intraoperative diagnostic advantage of TLM.

Full exposure of intermediate cancer is only slightly more difficult than for early cancer. The larger challenge is continuity and orientation. Start with early cases to master exposure. Then progress to intermediate cases and the greater manipulative and directional tests they offer. Intermediate anterior glottic cancers typically involve the thyroid cartilage but spare the arytenoids. Of course, anterior laryngeal resections can include large pieces of the thyroid cartilage and the subglottis. Ossified framework can be devitalized with heat and outlined for endoscopic resection with Jackson laryngeal scissors (Pilling).

If motion on one side of the anterior glottis is at all impaired (T2b), look for extraconical cancer during TLM. And bear in mind that once external to the conus, the tumor descends to escape outside the larynx (through the cricothyroid triangle).[82] Borders of the cricothyroid triangle are the inferior margin of the thyroid cartilage, the lateral edge of the cricothyroid ligament, and the medial border of the cricothyroid muscle. An "intermediate" cancer found to extend outside the larynx can be managed by TLM. However, early in one's experience it might be better to open the neck and permit the formal resection of, say, a near-total laryngectomy, which includes strap muscles and the thyroid isthmus and lobe.[83] The price is the permanent stoma that accompanies NTL, but this is better than recurrent cancer.

TLM can also treat T_2 supraglottic cancers if the reason for "T_2" is invasion of the glottis or the medial pyriform wall. Once, a total laryngectomy was rationalized in these cases (by the notion that the tumor exceeded the limits of a supraglottic laryngectomy). That was why SCPL was a real advance. When TLM is feasible for T_2 supraglottic cancer, TLM becomes the next advance. Note that the patient undergoing TLM for intermediate cancer reaps the additional benefit of continuing diagnosis. Under brilliant magnification and stable exposure, little extensions of unexpected cancer[84] are likely to be recognized and removed. So are erythroplasia and keratosis, future sites of origin of the next cancer. When TLM cannot be done for intermediate cancer, the attempt to perform a laser excision may demonstrate why transoral laser and open SCPL are both unsafe (in that patient).

Intermediate TLM risks glottic stenosis. The maximum safe preservation of intralaryngeal mucosa and cricoid cartilage resists it. Preemptive suppression of reflux with antacid medical regimens also makes sense. If you anticipate losing an arytenoid at TLM, do a tracheotomy at the time of the laser surgery. Take advantage of the view (no endotracheal tube) and protect (to the degree possible) the patient against initial aspiration with a cuff.

TLM may generate the most logical resection for intermediate cancer, but the wound is still left to granulate and contract by itself. Open SCPL calls for a strong cricohyoidopexy.[85] The return of swallowing after TLM implies cricoarytenoid elevation is accomplished by other means. Perhaps this is preservation of the strap muscles—no suprahyoid dissection, no circumhyoid suturing.

The risk of a fistula after TLM for intermediate laryngeal cancer is nil because the neck dissection never connects to the primary site.

Advanced Laryngeal Cancer

"Advanced" laryngeal cancers are glottic, supraglottic, transglottic, aryepiglottic, or even medial pyriform cancers distinguished by two

fundamental features: (1) permeation of the paraglottic space (therefore advanced cancers impair the motion on one side) and (2) a clearly lateralized disposition (advanced cancers seem to permeate the "hemilarynx").

The block to encompass such a cancer corresponds to a near-total laryngectomy.[83] NTL is a complete supraglottic laryngectomy plus an extended hemilaryngectomy, combined to include all of one paraglottic space and all of its contiguous neighbors (i.e., thyroid lobe and isthmus, hemicricoid, arytenoids, pyriform, anterior commissure and subglottis). However, much contralateral anterior glottis is necessary to encompass the cancer. Patients undergoing NTL retain a lung-powered voice—a prosthesis-free tracheopharyngeal fistula voice—but their stoma is permanent.

What saves these patients from being classified as "very advanced" are the following characteristics.

1. Most of the subglottic mucosa within the cricoid, certainly all of it on the "good" side, is free of cancer.

2. The contralateral ventricle is clear of cancer.

3. The contralateral vocal cord is only involved in the superficial mucosa and the most anterior glottic musculature.

4. The posterior commissure and postcricoid regions are completely clear.

To recognize patients with "advanced" laryngeal cancer, we have to be able to identify and exclude the "very advanced" cancers, for which near-total laryngectomy would not be safe. "Very advanced" means the only dependable ablative option is total laryngectomy and the preferred voice strategy is TEP. Typical "very advanced" laryngeal cancers are midline and bilateral, not lateralized. For example:

1. Massive "horseshoe" glottic/subglottic cancers (both ventricles and both muscular vocal cords are cancerous).

2. Significant subglottic cancers (generally involve the cricoid bilaterally and often present with airway obstruction).

3. Posterior commissure/postcricoid cancers (both arytenoid complexes are involved).

Near-total laryngectomy is the most logical open "block" for advanced cancers. But NTL requires a specialized lateral laryngotomy. The challenge is to enter the lumen without encountering cancer and without compromising the future speaking shunt. In many candidates, it would be easier to outline the block from within the lumen of the larynx. And the laser would be the ideal tool. More subglottic mucosa could be saved (which improves the tapered capacity of the inferior shunt—the tracheocricoid entry into the speaking shunt). More interarytenoid soft tissue could be saved (which contributes to the shunt's voicing and valving capacities). Occasionally, it might be recognized that both arytenoids were actually clear. That is, the cancer was "intermediate," not "advanced," and a logical laser supracricoid operation could be performed. This would confer an important advantage for the patient—no permanent tracheotomy.

Generally, we find "advanced" cases cannot be treated by TLM because reconstruction is required. The value of TLM lies not in complete excision, but in prereleasing the crucial tissue that really needs to be excised—this can define whether the cancer actually rises to the level of a near-total laryngectomy. Prerelease occurs with visible direction from familiar endolaryngeal landmarks, and it avoids the cancer itself. Then the surgeon can perform open delivery through the neck. No concerns about the site of entry, where the true margins lie, or where unseen submucosal cancer might extend. Perhaps the pharyngeal augmentation flap (to be turned down from the ipsilateral side to participate in the shunt[83]) can be precut with the laser as well. Voice shunt reconstruction would then be a simplified assembly with precut margins, no mucosal bleeding, and the least chance of cautery damage

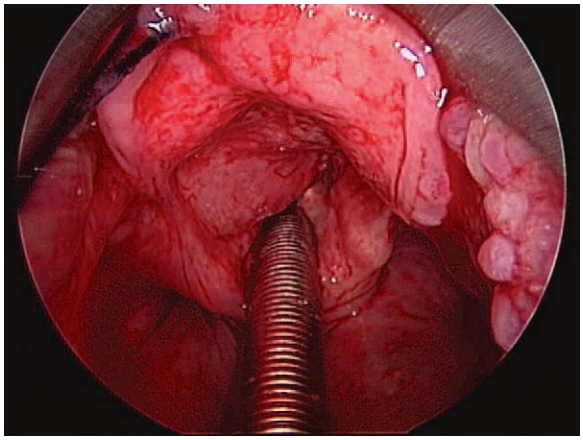

Figure 109-1. Preoperative T_4 transglottic squamous cell carcinoma (cartilage penetration).

to the nerve supply or the muscular components of the shunt. The exception is when both arytenoids and cricoarytenoid joints—or at least the posterior half of the arytenoids can be preserved. In this situation, complete tumor excision is possible via TLM, generally with acceptable functional consequences (Figs. 109-1 through 109-3).

Very Advanced Laryngeal Cancer

TLM has no apparent application in the "very advanced" category of laryngeal cancer. The exception might be the emergency treatment of neglected cancer with airway obstruction.[86]

Total Laser Microresection and Neck Dissection

The neck nodes are treated by open surgery or postoperative radiotherapy. We can carry out a neck dissection at the same sitting as TLM on the primary, but laser endoscopic surgery cancels the argument to perform a node dissection now because "the neck is already violated" (to access the primary). A better time might be weeks later. One unproven hypothesis suggests later is better because the micrometastases "in transit" at the time of the TLM will have had time to lodge in the nodes. A more practical reason would be to wait until a patient with serious comorbidities has recovered from the primary resection, or until after an elderly patient has regained swallowing after a laser supraglottic laryngectomy, or until after we know exactly what the pathologist has to say about the invasive nature of the primary cancer. Because a "second look" is possible after TLM, this might be a suitable time to operate on the deferred neck. With respect to the patient with a very low tolerance for complications, we have already mentioned that staging the primary and the neck surgery at separate sittings reduces the chance of a pharyngocutaneous fistula to zero.

Total Laser Microresection and Radiotherapy

TLM undoubtedly works best as a primary treatment. But surgeons who can offer TLM are not always consulted when the initial therapy is being selected. About half of our anterior commissure patients had already received previous treatment by the time we were called on to consider laser surgery.[72] Therefore surgeons will be confronted with patients who seek TLM for radio recurrent disease.

Prior radiotherapy complicates the planning of TLM and increases the morbidity attributable to delayed wound healing. It diminishes the accuracy of clinical judgment and the specificity of preoperative imaging. Radio recurrent cancer is often submucosal and sometimes discontinuous.[87] These factors complicate the decision to even attempt TLM. If TLM is undertaken, magnification does help disclose atypical patterns of spread. But magnification comes with its own danger—the temptation to cut normal-looking margins too close.

In our anterior commissure series,[72] 5 of 16 patients with intermediate laryngeal cancers received postoperative radiotherapy. The

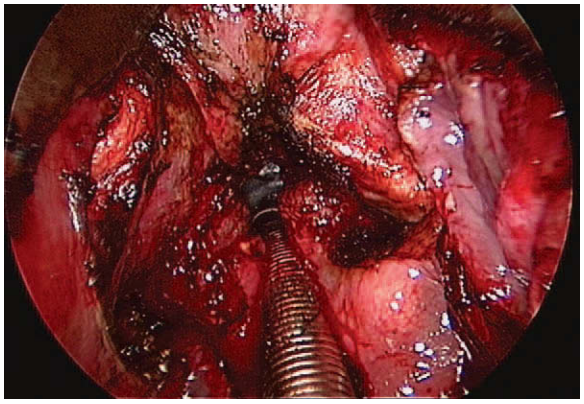

Figure 109-2. Extensive TLM resection removing left and anterior thyroid cartilage, both true vocal cords, supraglottic structures and preepiglottic space, and some strap muscle, but preserving cricoid ring and both posterior arytenoids.

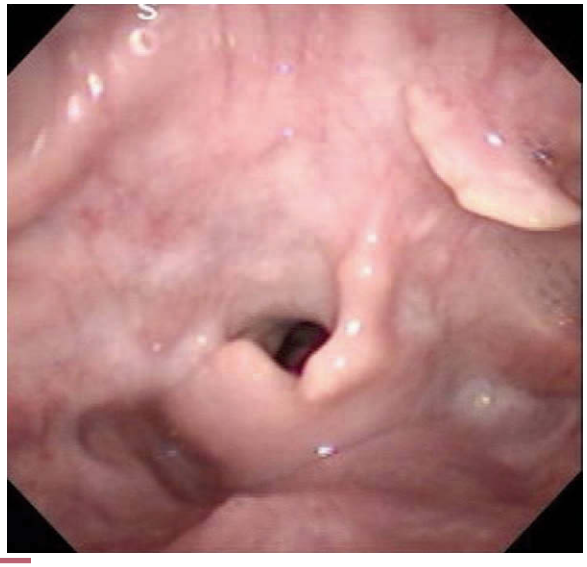

Figure 109-3. One year post-transoral laser microresection (and radiotherapy). Feeding tube has been removed and there was no tracheostomy.

indication was suspected disease in the neck, never a positive margin at the primary site. A positive margin at the laser site is an indication for further surgery, not radiotherapy.

TLM gives us a way to remove the primary without first disturbing the neck. After TLM, postoperative radiation faces the novel circumstance that no one has first disturbed the microcirculation with an open operation. Maybe the obligation to include the primary site in the radiotherapy fields is more questionable after TLM, when margins were clear and radiotherapy is being given for neck indications. TLM patients tend to heal as quickly as patients with open surgery. But more importantly, the risk of a complication (necrosis, a fistula, an infection in the neck) is diminished. Therefore TLM may be a more logical choice for the excisional component of combined therapy. Indicated radiotherapy will not likely be delayed by the prior performance of a TLM.

Complications of Transoral Laser Microresection

The complications of stray laser light include unwanted burns. Tiny pinpoint burns to normal laryngeal or pharyngeal mucosa are not rare, as the beam can easily pop the endotracheal cuff. Burns to facial skin, or worse, to the eyes or the airway are extremely rare but potentially devastating. We use small, wet precut toweling strips to cover fields beyond the target site, and angled suction protectors shield the cords. Cover the face and eyes of the patient with wet toweling after you position the laryngoscope. The microscope itself will save the operator's eyes from harm, but all other personnel need protective eyewear in the operating suite. Give the laser pedal to the surgeon (only) and the cautery pedal to the assistant (only). Control the concentration of oxygen in the airway (below 30% FiO_2), and use a double-cuffed laser endotracheal tube with saline in each cuff to maintain the seal confining the oxygen to the distal trachea.

Prolonged endoscopic displacement of the tongue causes obvious, sometimes severe, lingual contusion, swelling, and subsequent dysphagia, with or without long-term lingual dysesthesia. Chipped or loosened teeth follow difficult intubations or forceful endoscopic suspension in the dentulous patient. Sponges used to protect mucosa easily drift out of sight to be left behind when an endoscope is repositioned. Arteries can bleed voluminously into the wound in the larynx, particularly in the patient recently taking platelet inhibitors. All of these complications threaten the airway—with swelling, foreign bodies, or blood.

Many patients undergoing TLM require no tracheotomy. However, every consideration should be given to one in the intermediate and advanced cases where the role of a tracheotomy may be different. Here are some potential indications:

- To bypass expected edema from prolonged pressure on the tongue base in a lengthy case with difficult exposure.
- To bypass the specter of serious hemorrhage in the supraglottic region in the absence of airway protection.
- To avoid the impediment to exposure an endotracheal tube can pose, especially in the subglottis.
- To allow cuffed resistance to laryngotracheal aspiration in a patient with susceptible lungs.

Sudden secondary bleeding—without a tracheotomy—is probably the most dangerous risk.[88] The best treatment is avoidance: never trust the cautery to provide sustained control of a named artery (like the superior laryngeal), clip named arteries, and never trust the standard mouth guards to protect the teeth. Also, cover the upper incisors with thermosetting plastic and cool it with ice water. We use the small square of double-folded Aquaplast, the same material used to fashion rhinoplasty splints. As much as possible, the surgeon should pick up the tempo of the TLM to avoid prolonged tongue pressure. Do not be slowed down by inadequate plume suction, a weak laser beam, or a medium power beam weakened by defocusing. Learn to adjust the power and focus to the optimal settings for pace. Lengthy surgery risks tissue stasis and deep vein thromboembolism. Consider timed repositioning and apply antiembolism devices to all but the "very early" cases.

TLM imposes obvious limitations on reconstruction, but, in practice, the fact that the wound must heal by secondary intention is usually an advantage. The surface we will eventually be following in the office will be recovered by indigenous mucosa, not a skin graft, regional flap, or irradiated mucosa. This should improve our ability to monitor for local recurrence. Secondary intention healing involves contraction and granulation tissue, of course, but the preserved laryngeal framework does a surprisingly good job resisting contraction and stenosis is not common. Beware the patient with reflux. Reflux slows healing, which encourages fibrous stenosis. Be prepared to give proton-pump inhibiting medications on minimal evidence. Leaving the wound unreconstructed may yield two additional benefits: free cancer cells (if any) will fall on a slightly more inhospitable surface than the one we "bury" by reconstruction in open operations; and, at a future date, not having buried that surface, we preserve the possibility of a second chance through the discovery of persistent cancer at a "second look."

Whenever the inner surface of the cartilage is exposed by TLM, a sizeable granuloma is almost inevitable. Small osseocartilaginous sequestrae will perpetuate a granuloma until they are removed. At the anterior commissure, extensive resection leads to a rounded open anterior glottic defect. The opening produces breathiness. The walls consist of thin new mucosa, directly applied to the cartilage. The stiffness begets hoarseness. Prevention involves the optimal preservation of laryngeal mucosa,[89] plus the recognition and removal of any cartilage that undergoes laser thermal devitalization. Treatment of the breathiness draws on one's phonosurgical experience.[77] The stiffness is so far resistant to intervention.

TLM incurs new expenses. The institution incurs new costs, for training and equipment, and increased demands are made on the cytotechnicians and frozen-section pathologists. Some patients require a "second look" laryngoscopy (a few patients require more than one "second look"). Other patients will seek phonosurgical procedures (Fig. 109-4A and B). Some patients will receive postoperative radiotherapy (but their indications will be the same as in open surgery, so this cannot be considered an extra cost). TLM requires more travel for some patients because of its limited availability in the United States (although travel for radiotherapy is also common, and the time required away is considerably longer). Despite these extra costs, TLM reduces costs considerably.[72,73] Unfortunately, in practice, many patients do not receive TLM until after they have already incurred the expense of a previous therapy (that has failed). If TLM gains broader acceptance as an initial option, the potential for expense reduction may further improve.

TLM is a more difficult skill to transfer to the residents than is open surgery. The subtleties of orientation defer the assignment of part to the resident, part to the consultant. TLM tends to be a one-person, start-to-finish operation. There is not the usual sharing of duties possible with open surgery or the formal laboratory experience familiar to ear surgeons who prepared themselves on the temporal bone. TLM requires new judgment from laryngeal surgeons with respect to case selection and more advanced skills in laryngeal endoscopy because of the challenges of proper exposure. There are additional procedures to master including second-look direct laryngoscopies, new phonosurgical procedures, and the artful management of the complications noted earlier.

Contraindications to Transoral Laser Microresection

Extensive tumor spread to the neck (e.g., great vessels, esophagus, thyroid gland) is an absolute contraindication to TLM. So is inability to expose (with caveats if the upper teeth are the only impediment). The patient might consider the extraction of (carious) teeth, especially if it might save an open approach and a separate dental charge. Radiotherapists advise patients who have cancer to have pretreatment extractions. Preparation would include receiving patient consent and the taking of a dental impression.

TLM should not be advised for unresectable cancer, advanced cancer needing reconstruction, patients with functional disorders after extensive partial resections (like severe persistent aspiration or secondary stenosis), or the patient with overwhelming comorbidities. TLM is not very successful in any palliative role. It will usually prove unhelpful at the primary site in a patient with an N_3 neck or distant metastasis. A fixed (not impaired) cord is a relative contraindication to TLM, as is recurrent cancer in an irradiated "bed."

TLM has the potential to attract more patients with unrealistic expectations (e.g., those with advanced or very advanced laryngeal cancer after chemoradiation failure) or patients with major systemic comorbidities hoping to avoid a needed open operation for cancers that are advanced or very advanced. Sometimes a patient seeking TLM has built up too much faith in "the laser myth" while denying the realities of his or her predicament. TLM cannot repair tissues or functions already lost to cancer, radiotherapy, or previous surgery. It cannot restore tissues currently compromised by cancer. TLM cannot bring back lubrication, it will not reverse soft tissue or chondro-osseous necrosis, and it does not improve edema or painful soft tissue induration after radiotherapy.

Results of Transoral Laser Microresection

After an open operation or radiotherapy, laryngeal cancer reappearing at the original site is properly designated as "local persistence" or "recurrence." Local recurrence is disease that reappears after the initial treatment program has been completed. In TLM a "second look" is often a planned second phase of treatment. The discovery of residual cancer

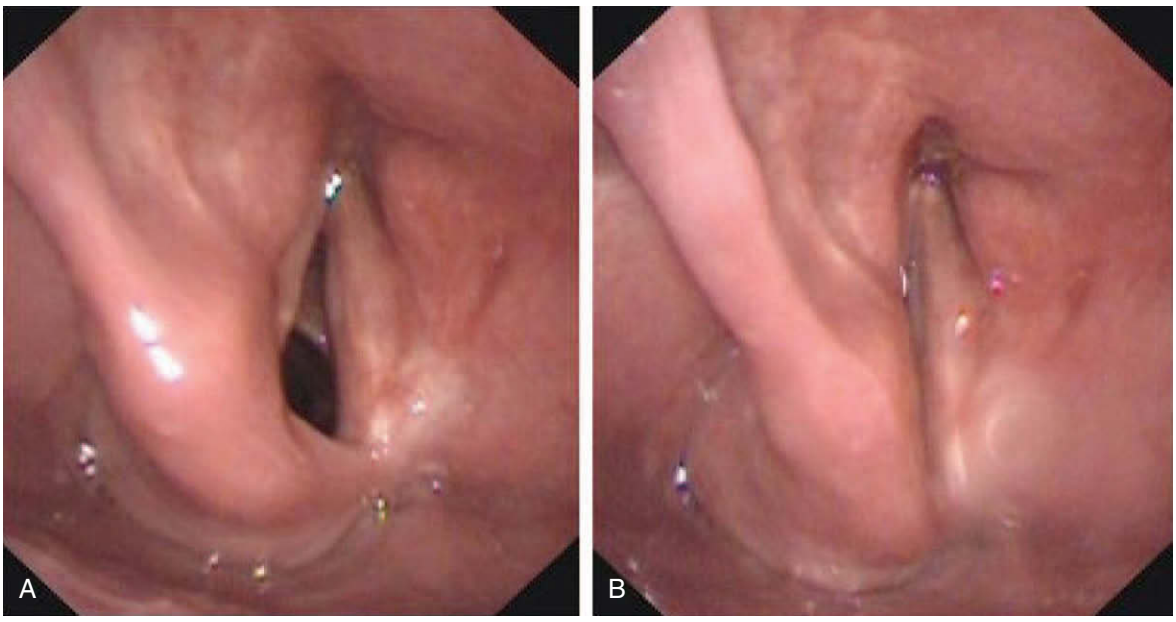

Figure 109-4. **A,** Open view of post-transoral laser microresection larynx for T_3 (fixed R true vocal cord requiring removal of right arytenoid) after open phonosurgical reconstruction (Gortex). **B,** Closed view. Patient does not use a feeding tube.

amenable to cure by laser resection at the time of the second look should not be listed as "local persistence" or "recurrence." These are diagnoses one would logically withhold until after a second-look strategy has been completed (or after one has been refused). This convention would be similar to the standard for chemotherapy, where persistent cancer at the primary site is not considered a failure if only the first cycle has been given.

In our recent publication on TLM for advanced laryngeal cancer the results of 117 patients were presented. These results were compared with the chemotherapy and concurrent radiotherapy and the radiotherapy-only arms of the RTOG 91-11 study.[90] The overall and T stages were similar with fewer T2s in the TLM group (8% vs. 12%). In the TLM series, at 2 years the percentage of patients with an intact larynx after treatment was 92%. The 2-year local control and locoregional control rates were 82% and 77%, respectively. The 2-year disease-free and overall survival rates were 68% and 75%, respectively. The 5-year Kaplan-Meier estimates were local control, 74%; locoregional control, 68%; disease-free survival, 58%; and overall survival, 55%. Most patients in our series did not receive adjuvant radiotherapy. These results compare favorably with those published in the RTOG 91-11 trial.[91] We concluded that TLM with or without adjuvant radiotherapy is a valid treatment for select advanced staged laryngeal cancers.

Göttingen Group Results

After first observing TLM by Wolfgang Steiner and Petra Ambrosch in 1996, and later by Heinrich Rudert in Kiel, Germany, the authors attempted to emulate these techniques in their own practices. Around that time, a comprehensive report on the results of TLM was given by Steiner and his colleagues at the European Federation of Oto-Rhino-Laryngological Societies (EUFOS) in Budapest. Because many North American laryngologists remain unfamiliar with this important presentation and, because our own combined experience in more than 900 TLM patients seems congruent with this original work, we have tried to summarize Steiner's data here.

His reports were based on 606 patients treated from 1979 to 1986 in Erlangen-Nurnberg or 1986 to 1993 in Göttingen. The last Erlangen entry was in January 1994, and the last Göttingen entry was in December 1995. The only exclusions were patients with simultaneous second primary cancers, thus not treatable for cure. Of the patients, 360 had early glottic cancer, 43 had early supraglottic disease, 147 had late glottic carcinoma, and 56 had late supraglottic cancer. The T distributions were pT_{is}; 45 patients, pT_1; 228 patients, pT_2; 231 patients, pT3; 69 patients and pT4; 33 patients. As might be expected, the T_{is} and T_{1a} cases did extremely well and will receive no further comment.

Attempting to reclassify all of Steiner's glottic cases as "very early" (pT_{is} or pT_{1a} for 236 patients) and "early" (pT_{1b} pT_{2a} for 124 patients), there were 18 recurrences (15%) in the 124 "early" cases. Among the 26 pT_{1b} glottic cancer patients, 5 local tumors recurred. Of the 98 patients with pT_{2a} glottic cancers, 13 experienced recurrences. Combining the very early and early patients, there were 35 recurrent cancers among 360 TLMs. Of these 35 recurrences, 5 occurred more than 5 years after initial treatment (thus possibly were second primaries).

Of the 35 patients, 27 were salvaged by functional surgery, mainly by transoral laser microreresection. Eight patients proceeded to laryngectomy. Of the 360 (0.5%), 2 died from the glottic cancer. Six developed neck metastases, three with their primary controlled and three with recurrent cancer at the primary site. During the course of their follow-up, 23 patients (6.4%) developed second primaries and 16 (5%) died of their second primary. The commonest cause of death in the whole group was intercurrent disease—64 patients (17.5%). The 5-year Kaplan-Meier survivals were 87% for the "very early" glottic group and 83% for the "early" cases. TLM preserved voice in 352 of the 360 patients (98%) and was judged to be of satisfactory quality in 90%. One patient bled. No one needed a tracheotomy.

Steiner reported 43 previously untreated patients with supraglottic cancers. Of these, 18 (42%) underwent TLM to the primary only. Of the 43 patients, 23 (53%) also had open surgery on their neck. Two (5%) received postoperative radiotherapy. Again, trying to apply our clinical definitions to Steiner's supraglottic cases, we judged none to be "very early," 10 to be "early," and 33 to be "intermediate." Only four (9.5%) developed a local recurrence (or second primary) within 5 years, and three of these were salvaged by functional operations (one open supraglottic laryngectomy and two transoral laser reresections). No patients lost their larynx. Five (12%) died from their supraglottic cancer—one who refused treatment of a local recurrence, one who was never controlled in the neck, and three with distant metastases. In addition, five (11.3%) developed second primaries, two (5%) ultimately fatal. Six supraglottic patients (14%) died of intercurrent disease, while in one patient the cause of death was unknown. As in the glottic cancer patients, intercurrent disease placed ahead of laryngeal cancer as a cause of death. The 5-year Kaplan-Meier overall survival was 73%.

Of the 43 patients undergoing laser supraglottic resection, 36 (84%) required a feeding tube. One received a tracheotomy at the time of the laser surgery, and one needed a tracheotomy postoperatively. Two patients with dyspnea (5%) required assistance, including one of the temporary tracheotomies. The other was managed by lasering. Two with aspiration required treatment, one by tracheotomy to allow a cuffed tube and the other by conservative means. Two patients (5%) had bleeding, and one of these had to be returned to surgery for cautery under general anesthesia.

TLM was used for glottic cancer staged T_{2b} and above in 147 patients in Steiner's report. There were 93 pT_{2b} glottic cancers, 40 pT_3, and 14 pT_4. Using our clinical classification, this was about 93 early or intermediate and 54 intermediate or advanced. Ninety (61%) were TNM stage 2, 38 (26%) stage 3, and 19 (13%) stage 4. Ninety-five (65%) of the 147 glottic patients received laser treatment of the primary (only). Thirty-two (22%) were treated with TLM at the primary site plus open surgery in the neck. Four more (3%) underwent TLM and radiotherapy. Eight (5%) had laser microresection, neck surgery, and postoperative radiotherapy. All in all, 40 patients (27% of the "T_{2b} and above" glottic cancer patients) underwent neck dissections, mainly selective dissections of levels 2 and 3. Twenty patients (14%) received radiotherapy after surgery.

Among the 147 patients treated by TLM for early/intermediate/advanced glottic cancer, there were 45 local recurrences (including possible second primaries). The 5-year Kaplan-Meier survival overall was 59%. During 40 months, the recurrence rates broken out by clinical stage ran as follows: 28 of the 93 patients with early and intermediate glottic cancer and 17 of the 54 intermediate to advanced. Seven patients developed neck metastases in addition to their recurrence at the primary site. One grew nodal disease without a primary recurrence. Three (2%) patients acquired distant metastases.

In the entire 147 patients undergoing TLM for T_{1b} early or T_2 intermediate or T_3 advanced glottic cancer, 45 developed local recurrences. In 21, this led to a total laryngectomy, 8 of whom also received postoperative radiotherapy. Four patients received open vertical partial laryngectomies. Ten were salvaged by TLM, and six more were salvaged by TLM and radiotherapy. Four of the patients who developed local recurrences received palliative care only. Thirteen of the 93 early/intermediate cases and 12 of the 54 patients with intermediate/advanced cancer died from their glottic disease. Thus 25 of the 147 patients (17%) with larger tumors died. Only 11 of the 25 died of local/locoregional recurrence. One died from regional recurrence alone, and 13 died from distant metastases. The number of second primaries was 14 (9.5%), with only 1 in the head and neck. Ten patients (7%) died of a second primary and 29 (20%) died of intercurrent disease. Once again, intercurrent disease beat glottic cancer treated by TLM as the cause of death in these patients.

Steiner's report to EUFOS included 56 patients with higher TNM stage supraglottic cancer. One had pT_1 local disease, 7 had pT_2, 29 had pT_3, and 19 had pT_4. Therefore 48 of 56 patients had pT_3 or pT_4 supraglottic cancer. Eight (14%) underwent only TLM. One (2%) had TLM and radiotherapy. Of the 56 supraglottic TLM patients, 47 (84%) also received neck surgery, mainly of selective dissection of levels II and III. Twenty six (46%) had neck surgery only; 21 (37.5%) had postoperative radiotherapy as well. In the whole group of 56

patients with higher-stage supraglottic cancer, 22 (39%) had radiotherapy after surgery. Of the 56, 11 (19.5%) developed local recurrences (or second primaries). Eleven patients developed neck metastases, five with their primary controlled and six with recurrence at the primary site (locoregional recurrence). Of these, three also developed distant metastases.

No local recurrence was salvaged with an open partial laryngectomy. Three were salvaged with radiotherapy and six patients required a total laryngectomy. Two also received postoperative radiotherapy. Two patients with recurrence received palliative treatment only. The overall 5-year Kaplan-Meier survival for these patients with higher-stage supraglottic cancer (where the primary was treated by TLM) was 50%.

In Steiner's 1996 series, 48 patients had pT_3 or pT_4 supraglottic cancers. Complications in this group included three patients with early stenosis. One was lasered. Two required a permanent tracheostomy. Five patients suffered significant aspiration, leading to total laryngectomy in three. One responded to a temporary cuffed tracheotomy, and one accepted a gastrostomy tube. Four patients experienced bleeding that required endoscopic coagulation under general anesthesia.

In the pT_3/pT_4 supraglottic cancer group, 11 recurrences (or second primaries) (23%) appeared. Six patients with recurrence (12.5%) were laryngectomized (two with postoperative radiotherapy). Nine second primaries (16%) arose, four in the head and neck. Of these patients, seven (12.5%) died from their second primary. Six patients (11%) died of intercurrent disease. Of the 13 (23%) patients who died from supraglottic cancer, 4 died from local recurrence, 5 of regional recurrence, and 4 from distant metastasis. Notice that if TLM failed locally in pT_3 or pT_4 supraglottic cancer, half the patients required a laryngectomy (6 of 11 or 55%). And again, intercurrent disease and second primary cancers combined to cause death as often as locally advanced supraglottic cancer treated primarily with TLM.

For interested readers, Steiner also reported his TLM results for pyriform cancer to EUFOS.[68] Of 103 previously untreated patients with hypopharyngeal cancer, mainly pyriform, 63 patients had pT_2 cancers and 14 had pT_3. Sixty percent had proven neck disease. Steiner excluded patients with simultaneous second primaries, very advanced neck disease (N3), or distant metastases (i.e., not treatable for cure). All patients underwent TLM, but 75% also had neck surgery and 50% had postoperative radiotherapy. Of these 103 patients, 93 were controlled locally—there were only 10 local recurrences during a 44-month mean follow-up period. The 5-year Kaplan-Meier survivals mirrored supraglottic cancer (69.2% for combined stage I and II, 52.5% for stage III and IV), validating Krishaber's classic differentiation of "intrinsic" versus "extrinsic" disease. More laser surgery, open surgery, and radiotherapy were used to address failure. Eighteen patients (17%) died from pyriform cancer. Nearly as common (as causes of death) were intercurrent disease (16, or 15%) and second primaries (13 deaths among 16 second primaries or 13% of the total group).

Conclusions

TLM is not cancer surgery through a keyhole. In fact, it has oncologic advantages. The diagnostic component supports accurate verification of the tumor extent. The patient receives not the largest resection, but the most logical resection. The strategy of "follow the tumor" reduces the risk of undertreatment. Tissues adjacent to the resection site do not require dissection, which ensures preservation of the local microcirculation—the optimum precondition for adjuvant radiotherapy. And TLM leaves behind an open resection site—no chance to bury residual cancer cells, and all the better in follow-up.

TLM offers meaningful functional advantages—fewer tracheotomies, no fistulae, less disfigurement, less pain (nurse's observations), earlier swallowing, and a lower risk of overtreatment. It also carries certain socioeconomic advantages—reduced treatment costs from the shorter length of stay and the low rate of retreatment (for local control). TLM is a repeatable treatment (radiotherapy is not). And TLM anticipates the real problem of second primaries. After TLM, all treatment options remain.

Some things have changed with the introduction of TLM and some have not (e.g., time spent in the operating room—it takes us just as long to perform a transoral resection as an open one). More time is spent on the resection and the frozen sections, while less time is spent on open approaches and closures. The indications for and performance of neck dissection remain the same. The only variation is the greater opportunity to stage the neck. The indications for adjunctive radiotherapy remain the same, and, of course, so does the need for expert anesthesia and skilled postoperative care.

In the United States, opinions once held that TLM should never be done because it contravened oncologic principles—transected cancer, burned specimen margins, and replaced brilliant reconstructive techniques with healing by secondary intention. Now TLM is receiving more and more attention. Block excision can be seen as just a tactic to spill no viable cancer in the wound, and TLM as a strategy that supports this goal, but with a different tactic. It turns out that pathologists can read laser microresection specimens well. There are more specimens to study, and the surface coagulation is only several cells deep—less than what electrocoagulation will sometimes produce in an open surgery specimen. Secondary intention healing is no longer seen as a disadvantage because TLM selects patients for whom secondary intention healing provides excellent results.

Of course, not all change is progress. Predictions that laser surgery would (or should) produce miracles because laser technology was new, easier, faster, and bloodless were clearly exaggerations. TLM is a demanding endoscopic intervention and a complex resection, with no savings in time and its own special set of challenges. Bleeding does occur, and it can stop the laser in its tracks. Cautery and hemoclips remain entirely necessary. Laser surgery does require us to invest in new equipment and accept new safety regulations. Laboratory evidence of oncologic efficacy still lags, but it may be a bit late for animal evidence, given the excellent cure rates reported in actual human application.[66,67,78] Detailed documentation of quality-of-life outcomes is starting to become available. The TNM system retains its due respect as a reporting system, but we feel we have better concepts to guide initial treatment selection. Some will claim long-term multi-institutional cooperative trials have supported other modalities in the United States[92,93] and not TLM, but our own experience suggests that properly selected patients with advanced lesions can be managed by TLM with equal or superior rates of control and function. TLM does not rule out chemotherapy or radiation whenever they can add to the outcome. Radiotherapy cannot be used until a direct laryngoscopy and biopsy have been done, and this is usually a perfect opportunity for laser microresection.

Cartilage involvement and subglottic extension were once thought to constitute contraindications to TLM, but this turns out not to be so. Margins are not unobtainable just because the thyroid cartilage is involved. Laser microresection of the arytenoid was predicted to cause inevitable intolerable aspiration, but, again, this proves to be an overstatement. Subglottic resection is challenging, but now special techniques and special endoscopes[70,94] are available to overcome the limits on exposure.

TLM is eminently suited to the treatment of laryngeal cancer because squamous carcinoma starts in the epithelium and the epithelium is accessible through the mouth. The tumor needs to be accessible to endoscopy, but it does not need to be completely exposed in a single field of view. The cancer will need to be completely resected, with negative margins, but it will not need to be removed in one single piece. The resection site will need to have the time and conditions to heal by secondary intention and the support to resist stenosis—but it will not require primary closure. T stage in and of itself does not rule out TLM as worthy of consideration. In a series of laryngeal cancers involving the anterior commissure,[72] transoral laser excision was valid in selected carcinomas staged pT_2b, and a small number of pT_3 and pT_4 anterior commissure cancers were also treated successfully. This led to our focused study on advanced laryngeal cancer.[91]

In patients with very early laryngeal cancer, suspension microlaryngoscopies and laser excisional biopsies might best be considered "beginners TLM." When possible, it avoids 6 weeks of radiotherapy.

In early glottic cancer, TLM virtually replaces conventional VPL and hemilaryngectomy in our practice. We have experienced the same for early supraglottic cancer. TLM basically puts conventional HSL out

of business. (The minimum prerequisite is at least one mobile arytenoid cartilage.)

TLM challenges supracricoid laryngectomy, and it replaces partial laryngeo-pharyngectomy (Ogura's "PLP"[71]). Laryngeal cancer extension outside the framework contraindicates TLM, but in cases of doubt this decision can be made during treatment because endoscopic surgery can always be converted to open surgery. The need for reconstruction is considered a relative contraindication to TLM. But the vertical closures familiar in HSL and SCPL have not proven necessary in patients treated by TLM.

TLM now also has a role to play in advanced laryngeal cancers, but the arytenoid complex must be preserved bilaterally in part or in total to resist aspiration.

TLM has no role in very advanced laryngeal cancer, except possible palliative relief of airway obstruction until definitive open laryngectomy.

Transoral laser microsurgery is clearly one of the important treatment options for squamous cell cancer of the larynx. Advantage is taken of the operating microscope, laser micromanipulators and the new CO_2 fiber, and advanced laryngoscopic instrumentation to provide the most logical tumor resection, the least loss of normal tissue, and the best opportunity to follow tumor extension beyond what was visible in the office and to the scanners. With fewer tracheotomies, shorter hospitalizations, and no limitation on additional treatment, laser resection seems to combine the promise of the "light scalpel" with endoscopic advances and the realities of laryngeal cancer. For many patients, transoral laser microresection can provide the optimum combination of cure and quality of life.

Appendix on the Clinical Classification Used in This Chapter

"Early" and "advanced" were ancient designations intended to differentiate whether the cord was fixed. Fixation meant advanced, which meant total laryngectomy. Early glottic cancer had two operations: resection via direct laryngoscopy or laryngofissure and cordectomy. Early meant a low volume of cancer and a reasonable prospect of cure by radiotherapy. Advanced meant radiation usually failed, and surgery would usually be required. But sometimes radiotherapy worked and avoided a total laryngectomy.

Some early cancers were so favorable that they could be cured by a biopsy. This could falsely inflate treatment results—irradiation after an excisional biopsy would invariably produce a "cure." Therefore this subgroup was given its own category, namely "very early."

Conservation surgeons recognized that some cases with a fixed cord could have less than a total laryngectomy. These types of cancers kept the name advanced, but those cancers that everyone agreed had no chance with anything less than a total laryngectomy came to be called "very advanced."

A clinical classification of local laryngeal cancer thus evolved. There were four categories, very early, early, advanced, and very advanced. Early could be handled by classic conservation operations like the vertical and horizontal partials. Advanced was defined as lateralized cancer pervading one paraglottic space and sparing enough mobile innervated glottic tissue on the contralateral side to make a voicing shunt. The cord was fixed, but advanced could be controlled by a near-total laryngectomy.

Naturally, some laryngeal cancers fell in between a supraglottic laryngectomy and a near-total laryngectomy. We called them "intermediate" (between early and advanced). As it happens, these cancers fit the supracricoid partial laryngectomy block quite nicely.

Key Points

- Four principles of organ-preservation surgery help provide consistent oncologic and functional outcomes: local control; accurate assessment of the 3D extent of tumor; cricoarytenoid unit as the basic functional unit of the larynx; and resection of normal tissue to achieve an expected functional outcome.
- Indirect laryngoscopy and staging operative endoscopy are critical to planning conservation laryngeal surgery. Vocal fold fixation must be distinguished from arytenoid fixation, which implies cricoarytenoid joint invasion and is a contraindication to conservation laryngeal surgery.
- The overall health of the patient must be assessed. Patients must tolerate some degree of aspiration in the postoperative period. Pulmonary function tests are rarely used. Instead, if a patient is active in daily life and can walk up two flights of stairs without being winded, he or she may be a candidate for a conservation laryngeal procedure.
- Open organ-preservation options for glottic carcinomas include vertical partial laryngectomy (VPL) and supracricoid partial laryngectomy with cricohyoido-epiglottopexy (SCPL-CHEP).
- The classic VPL and its extensions all share a common approach, which includes a vertical transaction through the thyroid cartilage and paraglottic space, as well as a "blind" entry into the larynx through a narrow exposure.
- Functional results with VPL are variable depending on the extent of resection and the type of reconstruction, which varies from imbrication laryngoplasty, to strap muscle flap, to epiglottic laryngoplasty.
- Oncologic results for VPL are excellent with T_1 glottic carcinomas, but VPL should be avoided with advanced T_2 lesions and all T_3 and T_4 glottic lesions.
- The main use for SCPL-CHEP has been in selected T_2 and T_3 glottic carcinomas, with local control rates greater than 90%. The SCPL-CHEP does not resect the entire supraglottis, so for transglottic tumors, the supracricoid partial laryngectomy with cricohyoidopexy is preferred.
- Functional results with SCPL-CHEP are predictable due to the identical resection and reconstruction in all cases. Long-term dysphagia is rare.
- Organ-preservation options for supraglottic carcinomas include the supraglottic laryngectomy and the supracricoid partial laryngectomy with cricohyoidopexy (SCPL-CHP).
- Supraglottic laryngectomy has produced excellent oncologic results for T_1 and T_2 supraglottic carcinomas with local control rates greater than 90%, but outcomes are extremely variable with advanced lesions.
- Voice results for supraglottic laryngectomy are typically excellent, although a certain degree of temporary dysphagia is to be expected, with more severe dysphagia expected with extended procedures.
- SCPL-CHP is indicated for supraglottic carcinomas in which there is glottic level involvement, pre-epiglottic space involvement, decreased vocal fold mobility, or limited thyroid cartilage invasion.
- The oncologic success of the SCPL-CHP is attributed to the en bloc resection of bilateral paraglottic spaces, the preepiglottic space, and the entire thyroid cartilage.
- Contraindications to the SCPL include (1) subglottic extension greater than 10 mm anteriorly and 5 mm posteriorly; (2) arytenoid fixation; (3) massive preepiglottic space involvement with involvement of the vallecula; (4) extension to the pharyngeal wall, vallecula, base of tongue, postcricoid region, and interarytenoid region; and (5) cricoid cartilage invasion.
- Transoral Robotic Surgery (TORS) is a new technique that offers an alternative to open and transoral laser approaches for the treatment of glottic and supraglottic carcinomas.

A variety of open surgical approaches are available. When applied for the appropriate indications, they have an excellent ability to control laryngeal cancer while conserving laryngeal function. Conservation laryngeal procedures are historically the original "organ-preservation" techniques; the first hemilaryngectomy for malignancy was performed by Billroth in 1874.[1] Long before nonsurgical approaches were available to attempt to preserve the entire structure of the larynx, innovative surgical techniques were being used to remove enough of the larynx to allow for local control of the malignancy while preserving adequate structure to allow the larynx to function.[2] There exists a spectrum of laryngeal malignancies for which there is a complementary spectrum of conservation laryngeal procedures available. This chapter reviews the open conservation laryngeal procedures in the organ-preservation surgical paradigm available for managing the spectrum of selected glottic, transglottic, and supraglottic carcinomas. These techniques allow for the maintenance of physiologic speech and swallowing without the need for a permanent tracheostoma. The modern head and neck surgeon must have a comprehensive understanding of both surgical and nonsurgical organ-preservation strategies to allow for the most comprehensive care in the treatment of the patient with laryngeal cancer.

Although the origins of conservation surgery of the larynx are more than a century old, during the second half of the past century, the conservative options were limited to vertical hemilaryngectomy and supraglottic laryngectomy. The inherent limitations of these procedures in terms of indications led to these procedures losing favor among many physicians with experimental approaches, with chemotherapy and radiation dominating the management of advanced laryngeal cancer. Then, in the last decade of the 20th century in the United States, the introduction of supracricoid partial laryngectomies, as well as the introduction of endoscopic laser resections, created a renaissance in surgical organ preservation for laryngeal cancer. At present, this surgical renaissance in organ-preservation surgery for laryngeal cancer has evolved into an acceptable standard of care for the 21st century.

The common thread in the history of conservation laryngeal surgery is that these procedures were first developed outside the United States and then imported to its shores. Improvements in antibiotics and anesthetic techniques fostered the development of conservation laryngeal surgery.[3] Vertical hemilaryngectomy, which was first described by Billroth[1] in Germany and popularized in Europe by Leroux-Robert and Portmann,[4] was refined in the United States by Som,[5] Norris,[6] and Conley.[7] A French surgeon named Huet described a procedure in which a portion of the supraglottis was excised without the upper portion of the thyroid cartilage in 1938.[8] Later, a Uruguayan surgeon named Alonso extended this procedure to resect the upper portion of the thyroid cartilage together with the supraglottic structures, thereby defining the supraglottic laryngectomy.[9,10] The supraglottic laryngectomy was popularized in Europe by Bocca[11] and in the United States by Ogura,[12] Som,[5] and Kirchner.[13] The supracricoid laryngectomies originally were described in 1959 by the Austrian surgeons Majer and Reider[14] approximately one decade after Alonso had described the supraglottic laryngectomy.[9] The supracricoid laryngectomies were later promoted in Europe by Labayle[15] and Piquet and associates[16] and were imported to numerous institutions in the United States during the 1990s.[17]

The first of two major classes of techniques that developed was the vertical partial laryngectomy, in which entry into the endolarynx is through a vertical thyrotomy, the most notable example of which is the vertical hemilaryngectomy. The second major class of techniques is the horizontal partial laryngectomy, in which endolaryngeal entry is made through a transverse or horizontal thyrotomy (i.e., supraglottic partial laryngectomy). During the 1960s through the 1980s, innovative surgeons[18-23] reported numerous small series of patients in which the indications and extent of resection of these basic techniques were extended in an attempt to manage larger lesions. The commonalities among these series were (1) the relatively small numbers of patients; (2) variable local control rates compared with the strict previous indications for the procedure that was being extended; and (3) complex reconstructions requiring cartilage and mucosa rotation flaps with variable functional results.[18-25] These variable results made it difficult for other surgeons to use these extended procedures in the treatment of larynx cancer. Despite these innovations of the pioneers of conservation laryngeal surgery, the techniques that most surgeons became facile with, as reflected by the large numbers of series in the literature, were the standard vertical hemilaryngectomy and standard supraglottic laryngectomy. A common surgical solution in the United States for lesions considered too large for these standard conservation laryngeal procedures was total laryngectomy, with the innovations being in the area of alaryngeal speech and speech shunt development.[26,27]

In many European countries, laryngectomy, with its concomitant permanent stoma, was considered an anathema to be avoided when possible, and a different approach evolved. In 1959 in Austria, Majer and Reider[14] reported on a new horizontal partial laryngectomy technique in which the entire thyroid cartilage, true cords, false cords, and all or a portion of the epiglottis and preepiglottic space were resected. The reconstruction was with a pexy either between the cricoid and hyoid (cricohyoidopexy) or between the cricoid and the remaining epiglottis and hyoid (cricohyoidoepiglottopexy). This procedure, known as the supracricoid partial laryngectomy, allowed for a complete resection of the preepiglottic and paraglottic spaces and of the surrounding cartilage and soft tissue, resulting in higher local control in glottic, supraglottic, and transglottic cancers that equaled total laryngectomy, resulting in speech and swallowing without a permanent tracheostomy. Unlike the plethora of extensions of the vertical partial laryngectomy and the supraglottic laryngectomy, the supracricoid laryngectomies were repeated in many patients by numerous European centers during the 1970s through the 1990s with consistently excellent local control and functional results.[16,28-37]

Conservation Laryngeal Surgery Today

Although conservation surgery of the larynx had its origins in the 19th century, the standard of care in the 21st century dictates that when vertical partial laryngectomy, supraglottic laryngectomy, or supracricoid laryngectomy are alternatives for a given patient, these options should be discussed with the patient. In most cases, it is the general otolaryngologist–head and neck surgeon who makes the diagnosis of laryngeal cancer, and therefore these are frequently the physicians who first counsel the patients concerning their treatment options. Standard of care dictates that a discussion based on the literature be given to the patient concerning both surgical and nonsurgical approaches to organ preservation. In our opinion, one scenario might be that a physician might rationalize that because "I don't do these procedures," he or she might send the patient to the radiation therapist—but this may not be in the best interest of the patient. Alternatively, in our opinion the physician diagnosing a laryngeal cancer that does not have the expertise to offer all surgical and nonsurgical options could refer the patient to a multidisciplinary center that can triage patients to either surgery or nonsurgery on the basis of the needs and desires of the patient.

An analogy can be made with free tissue reconstruction surgery. If a patient has a large jaw carcinoma and the superior option from the oncologic and functional perspective is a free flap, we would not offer him or her a lesser surgical procedure or chemotherapy and radiation. The patient would be sent to a surgeon with a special expertise in free flap surgery. This is possible because, in the past 20 years, a cadre of head and neck subspecialists have cropped up that have a particular interest and expertise in performing free flap surgery. In fact, over the past decade we have witnessed a similar phenomenon in the United States in the area of organ-preservation surgery for laryngeal cancer. In our opinion, a similiar situation exists in which some head and neck surgeons have special expertise in open and endoscopic approaches for laryngeal organ preservation in the face of laryngeal cancer.

The focus of this chapter is to provide the general otolaryngologist–head and neck surgeon with an introduction to these techniques. This information is important because it is the responsibility of the general otolaryngologist–head and neck surgeon to understand the indications for the full spectrum of open and endoscopic organ-preservation surgical approaches and either gain the expertise to perform these procedures or refer the patient to surgeons who have this special expertise.[38]

During the 1970s and 1980s, the functional and oncologic results after supraglottic laryngectomy were reported in numerous series in

the United States, defining the role of this technique among the plethora of surgical and nonsurgical options available for supraglottic carcinoma.[39-41] During the same period and into the 1990s, the role of vertical partial laryngectomy for glottic carcinoma has been re-examined because of advances in nonsurgical and laser endoscopic approaches to similarly staged disease.[3,42] In the 1990s the supracricoid laryngectomies were imported to numerous institutions in the United States, and the European functional results have been reproduced.[17,43,44] The supracricoid laryngectomies have broadened the spectrum of reliable techniques available to the conservation laryngeal surgeon.[3]

At present, a renaissance is occurring in the United States in the area of conservation laryngeal surgery. Many factors have fostered the rekindled interest in conservation laryngeal surgery, including (1) a clearer understanding of the three-dimensional extent of laryngeal carcinoma, which has stemmed from numerous clinicopathologic studies and from advances in radiologic techniques; (2) numerous long-term studies of outcome after the application of a broad spectrum of techniques; and (3) the introduction of new techniques during the past 2 decades. Today, there are a variety of techniques available for selected laryngeal malignancies, with predictable functional and oncologic outcome based on analyses in the literature of many patients. The full spectrum of surgical techniques allows the surgeon to consistently offer patients, with selected lesions, excellent local control that will result in speech and swallowing without the need for a permanent tracheostoma. This may provide the patient with an alternative to nonsurgical organ-preservation modalities. There are organ-preservation principles to which the surgeon must adhere to maximize both oncologic and functional outcome. Conservation laryngeal surgery is precision surgery,[45] and to achieve successful oncologic and functional results, the conservation laryngeal surgeon should have a firm grasp on the clinical assessment of laryngeal cancer and a complete understanding of the surgical techniques. The art of correctly staging the lesion as one appropriate for a conservation laryngeal procedure requires an in-depth knowledge of both the static and dynamic anatomy of the larynx and how the tumor relates to it.

Anatomy, Physiology, and Tumor Spread

In 1966 Bocca elegantly stated that, "often cancer seems to have limits, while the surgeon seems to have none. We should make efforts to force upon our knife the same limits as those which surrounding tissues or structures force upon cancer and its spread."[11] Bocca's eloquent statement underscores that successful outcome in conservation laryngeal surgery is predicated on a thorough knowledge of the pertinent surgical anatomy and on an understanding of the behavior of the malignancy in a particular anatomic site. Much of what is known concerning the three-dimensional spread of malignancy through the larynx has been derived from clinicopathologic studies in which the entire larynx was sectioned. These whole organ section studies are the basic science foundation for clinicians performing conservation laryngeal surgery.

The surgical anatomy of the larynx can be understood in terms of the skeleton and connective tissue barriers, the spaces delineated by these structures, and the soft tissue structures, which include the fat, musculature, vessels, nerves, and adnexa that fill these spaces. The skeleton of the larynx (Fig. 110-1) is dominated by the thyroid cartilage, which articulates posteriorly and inferiorly through the inferior cornua with synovial joints on the posterolateral aspects of the cricoid cartilage. A thick tendon originates from the superior cornua and attaches to the lateralmost aspect of the "crown" of the larynx, the hyoid bone. Anteriorly there is a notch, and the lateral aspect of the laminae is traversed by the oblique line, which is the point of attachment of the strap musculature. The extension of cancer into the thyroid cartilage tends to occur in areas of ossification of the cartilage.[46] The mode of invasion into the ossified bone has been attributed to osteoclast formation,[47] extension along collagen bundles,[48] or through areas of high vascularity.[49] The most common site of invasion of the thyroid cartilage was at the angle,[50] although other sites of predilection for carcinoma invasion are the points of attachment of the cricothyroid membrane and the anterior origin of the thyroarytenoid musculature.[48] The perichondrium provides an excellent barrier to invasion, and once the carcinoma is within the cartilage, the cancer can extend throughout the cartilage behind an intact perichondrium, precluding surgical cuts through the cartilage, as is done in some partial laryngectomies.[51] Nakayama and colleagues[52] noted that a large proportion of patients staged clinically as T_3 actually had thyroid cartilage invasion when the specimens were analyzed by whole organ sectioning, and they noted that in these patients with T_3 glottic cancers, any combination of two factors including significant degree of calcification of the cartilage, tumor length greater than 2 cm, and anterior commissure involvement resulted in a higher incidence of cartilage invasion (71% to 92%).

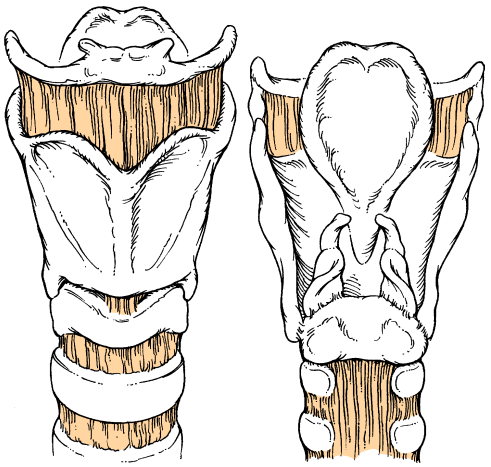

Figure 110-1. Skeletal structure of the larynx.

The cricoid cartilage is the only circumferential ring in the airway, and preservation or reconstruction of its ring-shaped structure allows for decannulation after conservation laryngeal surgery. The arytenoid cartilages sit atop the cricoid, to which they are attached by a synovial joint. The two muscular processes of the arytenoid cartilages are oriented posteriorly and laterally, and the vocal cord tendon originates from the tip of the vocal process and spans anteriorly to the thyroid cartilage. The most common site of cricoid cartilage invasion by carcinoma is at its posterior superior border, and the most common site of arytenoid invasion is at the points of attachment of the joint capsule.[53]

The epiglottis, with its numerous fenestrations, originates from the tendinous attachment on the thyroid cartilage, fanning out from its most inferior point known as the petiole to a widened superior aspect above the hyoid. The carcinoma on the infrahyoid surface of the epiglottis readily extends through the fenestrations of the epiglottic cartilage through blood vessels[49] and the ducts of the seromucinous glands.[54] The hyoid bone is almost never involved by supraglottic carcinoma. Kirchner[55] noted no cases of hyoid bone invasion in 55 supraglottic carcinomas evaluated by whole organ section, although in Kirchner's series,[55] two patients had cancer up to the periosteum, one of which could be palpated at the level of the thyrohyoid membrane and one which had vallecula mucosa involvement. Among 172 patients with supraglottic carcinoma reported by Timon and colleagues,[56] only four patients had hyoid bone invasion, and a common feature of all of these patients was vallecula mucosal involvement. Preservation of the hyoid bone helps with swallowing postoperatively. Understanding this concept is essential and makes it possible to perform supracricoid laryngectomy with cricohyoidopexy in selected transglottic tumors. These authors concluded that it is sound to preserve the hyoid bone in cases without palpable submucosal vallecula carcinoma or vallecula mucosal involvement.[55,56]

There are numerous condensations of fibrous tissue that traverse the three-dimensional anatomy of the larynx. Some of the modern knowledge of these structures comes from the pioneering work of Tucker and Kirchner, both of whom studied whole organ sections of larynges and analyzed this anatomy.[57-59] The conus elasticus (Fig. 110-2) spans from each vocal cord down laterally to the cricoid cartilage. The conus elasticus provides a temporary barrier for the spread of early glottic carcinoma, but ultimately, for larger cancers, it serves as

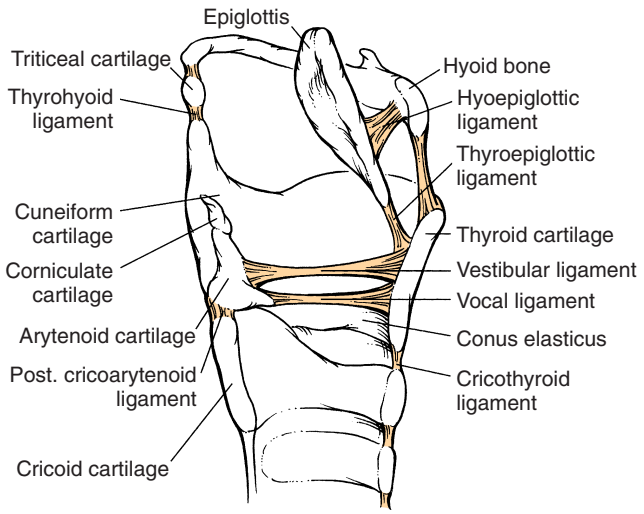

Figure 110-2. Conus elasticus.

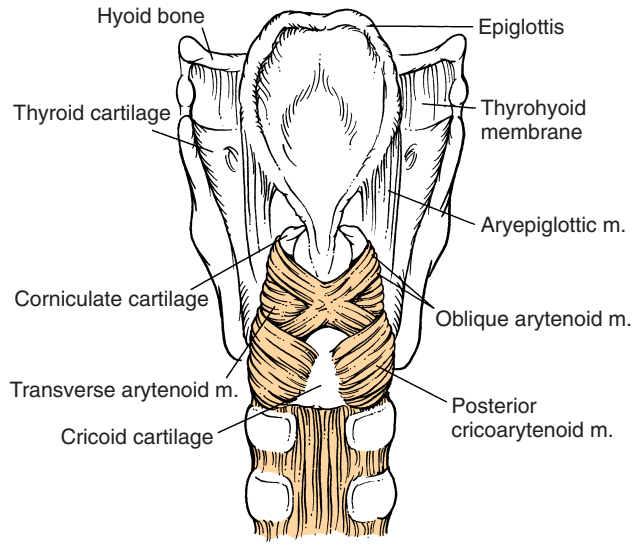

Figure 110-3. The thyrohyoid membrane.

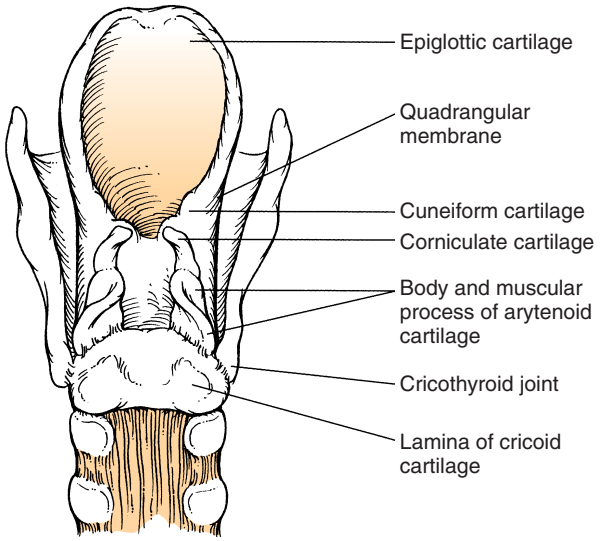

Figure 110-4. The quadrangular membrane.

the gateway to the subglottic and extralaryngeal spread of carcinoma.[60] Posteriorly, it is also attached to the arytenoid, providing stability to the arytenoid and the vocal tendon. The vocal tendon, which essentially is a medial condensation of the conus elasticus, attaches anteriorly to the thyroid cartilage at the Broyles ligament or the anterior commissure tendon.[61] Although the anterior commissure tendon is devoid of perichondrium, the ligament constitutes a dense fibrous attachment to the cartilage and sends slips of fibrous tissue superiorly to the thyroepiglottic ligament. Kirchner and Carter[60] have noted that the anterior commissure tendon is a point of dense adhesion of fibrous tissue, and it is rare for an early glottic cancer with anterior commissure involvement to erode into the thyroid cartilage here. However, the anterior commissure tendon provides access to cartilage invasion for larger cancers, which spread superiorly or inferiorly.[60] Anteriorly, there is a superior inferior condensation of the conus elasticus called the cricothyroid ligament, which is a central structure and does not spread out laterally to provide a connective tissue barrier along the circumference of the cricoid.[50] This is different than its superior counterpart, the thyrohyoid membrane. The thyrohyoid membrane drapes along the entire circumference of the thyroid cartilage superiorly and spreads upward to the hyoid bone (Fig. 110-3). Extension out of the larynx through the thyrohyoid membrane alone is rare and is typically seen when cancer exits the larynx through the upper portion of the thyroid cartilage.[50] The quadrangular membrane (Fig. 110-4) originates from the top of the arytenoid posteriorly and from the lateral aspect of the epiglottis anteriorly and then extends inferiorly like a curtain to an inferior condensation of fibrous tissue, which spans between the inferior aspect of the arytenoid posteriorly and the petiole of the epiglottis anteriorly. The hyoepiglottic ligament was recently elegantly described by Zeitels and Kirchner,[62] who showed this structure to be a resilient barrier to malignant spread from the supraglottis to the tongue base when the cancer is confined to the laryngeal membranes and does not clinically invade the suprahyoid epiglottis.

The skeleton and fibrous tissue barriers demarcate a number of spaces within the larynx. The superiormost space is the preepiglottic space (Fig. 110-5), which is filled with fat and traversed by blood and lymphatic vessels.[63] Kirchner and Carter[60] noted that carcinoma tends to invade within the preepiglottic space with a "pushing edge," which is almost "encapsulated" after it reaches the elastic tissue membranes in the preepiglottic space, contributing to the oncologic safety in saving the hyoid bone during supraglottic surgery. The boundaries of this space are the vallecula mucosa and the hyoid superiorly, the thyrohyoid membrane and the thyroid cartilage anteriorly, and the epiglottis posteriorly. Posterolaterally, on either side, the preepiglottic space is bounded by the superior portions of the paraglottic space.[64]

There is a paraglottic space on either side of the larynx (Fig. 110-6). Superiorly, the medial boundary is the quadrangular membrane, whereas inferiorly, the medial margin is the conus elasticus. It originates superiorly within the aryepiglottic fold, where it fades to a peak. The paraglottic space makes up the substance of the true and false cords and within it are the thyroarytenoid musculature and the mucosa-lined, air-filled space known as the *ventricle* and its superior extension, the *saccule.* Inferiorly, it follows the conus elasticus down to the top of the cricoid cartilage. Anteriorly, it abuts the preepiglottic space and the anterior third of the thyroid cartilage, and the posterolateral boundary is the mucosa of the medial aspect of the pyriform sinus. The paraglottic space traverses the supraglottis, glottis, and subglottis laterally within the larynx. Rather than having a distinct barrier to superior-inferior spread, cancer seems to be impeded in its course through the paraglottic space to varying degrees by the hourglass shape of the space, which is made by the indentation of the ventricle and saccule.[65] One additional space is Reinke's space, which actually is a potential space under the true vocal cord mucosa and provides no barrier to invasion.

The behavior of carcinoma in the supraglottis is modified by the soft tissue, connective tissue barriers, and the skeleton of the larynx (Fig. 110-7). Kirchner[57] showed, in an analysis of whole organ sections, that supraglottic carcinomas that overlie the epiglottic cartilage have a

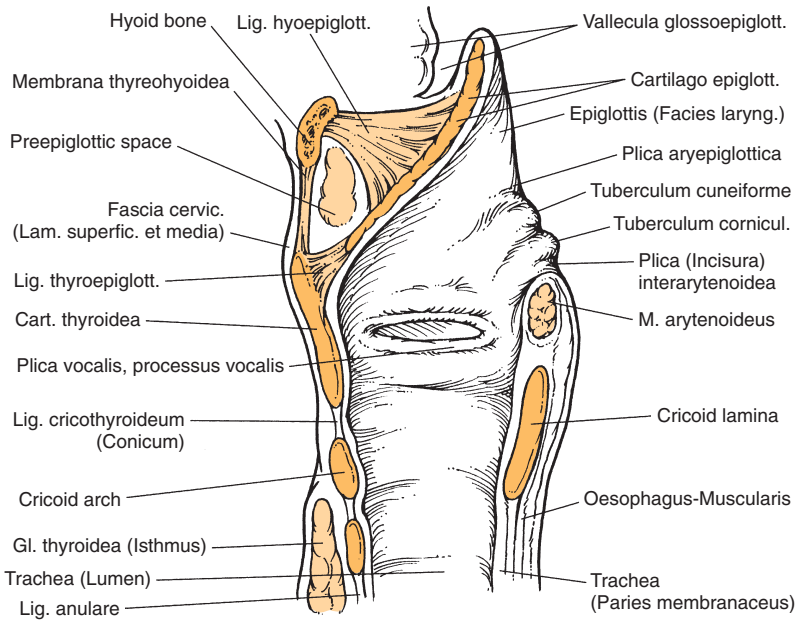

Figure 110-5. The preepiglottic space.

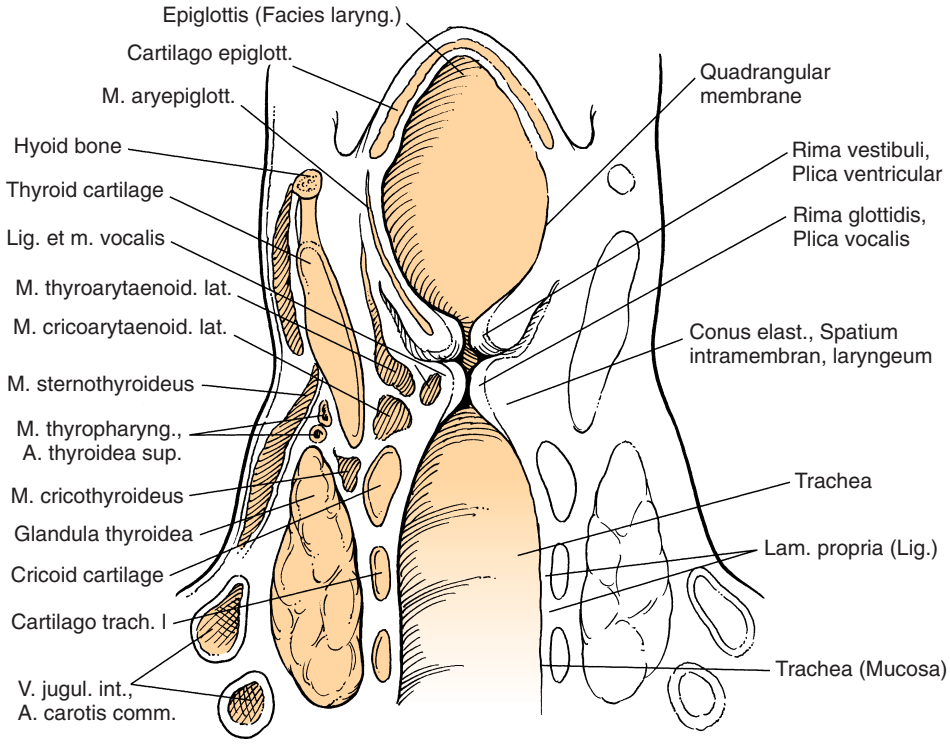

Figure 110-6. The paraglottic space.

tendency (9 of 10 cases) to extend into the preepiglottic space, at least microscopically, through the fenestrations in the epiglottic cartilage. In addition, Bridger,[54] working with the whole organ section collection at Johns Hopkins, showed that seromucinous tubuloalveolar glands extend through the fenestrations and provide a route of spread of cancer into the preepiglottic space. Although it had been suggested in the past that embryologic fusion planes somehow provide protection against inferior spread of carcinoma from the supraglottis to the glottis, a recent study that evaluated all of the series of whole organ sections in the literature revealed that the incidence of spread of supraglottic carcinoma to the glottic level is between 20% and 54%.[65] This study indicated that there was a statistically significant relationship between the presence of abnormal cord mobility or involvement of carcinoma below the false cord and glottic level extension, most commonly through the paraglottic space.[65]

Carcinomas at the glottic level tend to begin at the junction of the anterior one third and posterior two thirds of the vocal cord. They readily pass through Reinke's space to the tissues below. Early studies by Pressman,[66] with submucosally injected dyes and radioisotopes, indicated that barriers existed between the two sides of the glottis and the supraglottis. Welsh and colleagues[53] demonstrated that as dye concentration increases, these barriers become less effective. For early lesions,

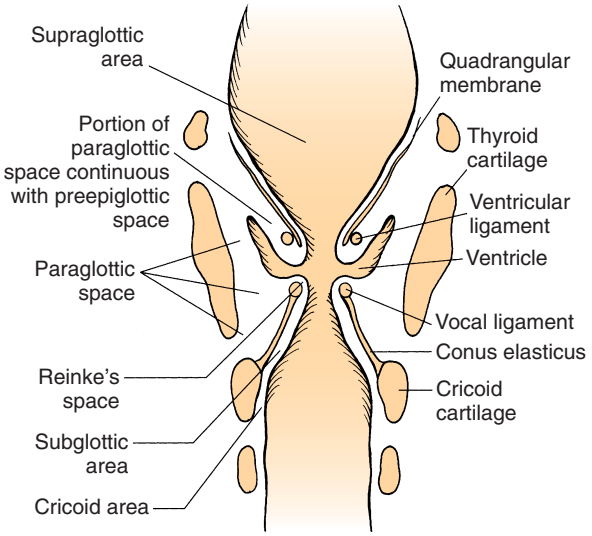

Figure 110-7. Connective tissue barriers within the larynx.

the conus elasticus provides a barrier to extension; as the lesion enlarges, this barrier becomes less pertinent.[67]

The sensation to the supraglottis is supplied by the superior laryngeal nerves, whereas the glottis and subglottis are innervated by the recurrent laryngeal nerve. The neural structures play an important role in timely postoperative functional rehabilitation.[68] Whenever possible, the main trunks of the superior and recurrent laryngeal nerves and the hypoglossal nerves, bilaterally, should be preserved during conservation laryngeal surgery.

Certain aspects of physiology of the larynx are pertinent to successful application of conservation laryngeal surgery. Hirano and colleagues,[69] in a whole organ analysis of the normal larynx, noted that 50% to 65% of the entire adult airway is located posterior to the tips of the vocal processes and concluded that the posterior larynx is the respiratory airway and the anterior portion is the phonatory airway. This is because all of the musculature that opens and closes the glottic chink, the lateral cricoarytenoid musculature, changes the position of the vocal processes during speech and swallowing. The arytenoids are responsible for opening the airway for breathing and for closing during swallowing and speaking. The vocal cords provide vocal quality during phonation; therefore loss of one or both vocal cords results in hoarseness, but preservation of at least one arytenoid and an intact circumferential ring at the level of the cricoid is sufficient for speech and swallowing without a tracheostomy.[70-75]

Principles of Organ-Preservation Surgery

The otolaryngologist–head and neck surgeon must adhere to certain key principles to determine a patient's eligibility for a conservation laryngeal surgery. The advent of the supracricoid laryngectomy makes us direct our focus away from the vocal fold and concentrate on the cricoarytenoid unit as the essential functional unit of the larynx. The organ-preservation principles are formulated to help provide consistent oncologic and functional outcomes.[76] These can then be compared with current nonsurgical organ-preservation options to allow the patient and physician to make educated decisions regarding treatment. Adopting these principles will enable the surgeon to maximize oncologic and functional outcomes for a number of glottic, supraglottic, and transglottic malignancies.

First Principle: Local Control

Local control is the most important principle. Survival from the index cancer is compromised if there is a local failure after radiation therapy or surgery to the supraglottis and glottis.[77] Early detection of the primary site recurrence may be difficult for a number of reasons. Medical and surgical organ-preservation modalities alter the topography of the larynx and make definitive evaluation of recurrent cancer difficult. Symptoms may be attributed to the treatment intervention or recurrent tumor, although increasing pain, persistent ear pain, and dysphagia are ominous signs. Repeat endoscopy and biopsy of the original primary site is warranted. Computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) may also be helpful in explaining recurrent or persistent cancer. Organ-preservation laryngeal procedures should be used only when resection of the tumor can be accomplished comfortably with local control rates approximating those of total laryngectomy.

Second Principle: Accurate Assessment of the Three-Dimensional Extent of Tumor

The second principle of organ-preservation surgery is to be able to confidently predict the extent of tumor. A comprehensive appreciation of laryngeal anatomy and function is necessary. The inability to accurately predict the extent of tumor in a conservation laryngeal procedure may lead to total laryngectomy when another organ-sparing approach may have been possible.

Third Principle: Cricoarytenoid Unit Is the Basic Functional Unit of the Larynx

The cricoarytenoid unit is the basic functional unit of the larynx. The cricoarytenoid unit consists of an arytenoid cartilage, the cricoid cartilage, the associated musculature, and the superior and recurrent laryngeal nerves for that unit. Preservation of at least one functional cricoarytenoid unit makes it possible to consider an organ-preservation procedure. This is a foreign concept to most surgeons who perform vertical partial laryngectomy and supraglottic laryngectomy. The surgeons, along with the T-staging system for laryngeal cancer, focus on the vocal fold rather than on the cricoarytenoid unit. The paradigm shift from the vocal fold to the cricoarytenoid unit is essential for the head and neck surgeon to be able to use the full spectrum of organ-preservation surgeries. It is the cricoarytenoid unit, not the vocal folds, that allows for physiologic speech and swallowing without the permanent need for a tracheostoma after supracricoid laryngectomy.

Fourth Principle: Resection of Normal Tissue to Achieve an Expected Functional Outcome

This principle may seem counterintuitive because we are talking about "conservation laryngeal surgery." What we are conserving is the function of the larynx, not necessarily all the regions of the larynx that are uninvolved with cancer. This resection of normal tissue is necessary to achieve consistent functional outcomes in terms of speech and swallowing. A reliable reconstruction for each organ-preservation surgical choice that is proven with regard to speech and swallowing outcome should make the surgeon feel more at ease when comparing nonsurgical and surgical organ-preservation results for a patient. Reconstructions based on the extent of tumor resection for clear margins alone often result in novel reconstructions and the surgeon's trepidation regarding functional outcome. A better approach is to perform a standard resection where a consistent functional outcome is known.

Preoperative Evaluation

The preoperative evaluation includes an oncologic assessment of the primary site, regional nodes, and distant sites. In addition, it includes an assessment of the patient's ability to medically undergo the surgery and postoperative treatment. Finally, patient and family insight, emotional state, and ability and willingness to undergo the postoperative rehabilitation should be considered.

Clinical Evaluation of the Primary Site

Before examining the larynx, the physician should listen to the patient speak and breathe. The degree of airway impairment and the voice quality should be assessed. Glottic carcinomas that affect the phonatory structures tend to cause hoarseness; supraglottic cancers frequently are above the cords and cause a muffled "hot potato" voice as they enlarge. Hoarseness from a supraglottic carcinoma may indicate impairment of cord mobility as a result of arytenoid involvement or glottic level involvement. Next, both sides of the neck should be palpated for nodal disease. The thyroid cartilage itself should be palpated for irregularities,

as should the areas directly above and below the thyroid cartilage. A bulge or mass at the level of the thyrohyoid membrane may indicate massive preepiglottic space invasion. A mass at the level of the cricothyroid ligament may indicate a Delphian lymph node, which indicates subglottic extension of the malignancy.[78] Indirect mirror or fiberoptic laryngoscopy is used to assess the larynx and surrounding structures. The important gross pathologic characteristics that need to be evaluated are airway impairment, endophytic versus exophytic, superficial spread versus deep invasion, mucosal structures involved, arytenoid and vocal cord mobility, and extensions out of the endolarynx.

The clinical assessment of laryngeal mobilities provides excellent insight into the three-dimensional extension of carcinoma within the larynx. Mobility of the vocal cord itself, without attention to arytenoid mobility, is adequate when planning for management that is directed to the entire organ such as total laryngectomy or radiotherapy. Biller and Lawson[79] and Ogura's team[80] have noted that assessment of arytenoid mobility and cord mobility is important in the preoperative planning for conservation laryngeal surgery, particularly when the vocal cord itself is fixed. Assessment of vocal cord mobility is best clinically assessed during indirect laryngoscopy by having the patient speak or breathe deeply, whereas arytenoid mobility is best assessed by having the patient cough gently.

Cancers involving the glottis and supraglottis have different effects on vocal cord mobility and arytenoid mobility. Impaired mobility from glottic carcinoma may be a result of superficial thyroarytenoid invasion or bulk on the surface of the cord in an exophytic lesion.[67] Hirano and others[81] assessed the degree of thyroarytenoid muscle invasion in glottic carcinoma and found fixed cords had deeper invasion into the musculature than impaired cords. Numerous studies have demonstrated that glottic carcinoma associated with a fixed vocal cord most commonly results from extensive invasion of the thyroarytenoid muscle.[81-83] In some patients, subglottic extension with fixation to the cricoid cartilage and lateral extension with adherence to the thyroid cartilage resulted in fixation of the cord[82] and invasion of the lateral cricoarytenoid musculature and the cricoarytenoid joint.[83] At the supraglottic level, cancer invasion into the thyroarytenoid musculature at the glottic level is less likely, and the most common cause of cord fixation, noted by Hirano and others,[81] was deep arytenoid cartilage invasion superiorly. Montgomery[84] and Ogura[85] assessed vocal cord and arytenoid mobility, independently, in preparation for conservation laryngeal surgery of the supraglottis. Brasnu and colleagues,[86] in a whole organ section series, noted two types of impairment in arytenoid mobility—namely the "weight impact" of the tumor—in which the arytenoid motion seems impaired superiorly causing "pseudofixation" versus actual fixation from the malignant involvement of the intrinsic laryngeal musculature, the cricoarytenoid joint, or both (Fig. 110-8). They are distinguished by careful evaluation of the vocal fold; if any motion of the cord is noted in the presence of what seems to be arytenoid fixation from a supraglottic cancer, this is "pseudofixation."[86] This information is valuable to the conservation laryngeal surgeon because it is unlikely that a larynx with a "pseudofixed" arytenoid has cricoarytenoid joint and musculature involved, whereas these areas are involved in more than two thirds of patients when "true fixation" of the arytenoid is present. We have found that the fiberoptic scope has use in the assessment of vocal cord mobility in the presence of exophytic supraglottic carcinomas because the tip of the scope can be manipulated past the lesion to look at the structures below. The clinical implication is that careful assessment of the vocal cord and arytenoid mobilities is essential when planning for conservation laryngeal surgery to attempt to understand which deep structures are invaded and which in turn may improve the likelihood of applying the appropriate surgical technique.

Figure 110-8. Entire section through the cricoarytenoid joint with fixation of the true cord and the arytenoid revealing cricoarytenoid joint invasion.

The final aspect of the physical examination of the primary site is performed during direct laryngoscopy during general anesthesia. The direct laryngoscopy allows for biopsy of the lesion to be performed and for a thorough visual evaluation of the larynx and surrounding structures with the routine use of the operating microscope or rigid endoscopes. Palpation of the lesion and surrounding structures with endoscopic instrumentation can yield valuable information concerning submucosal extent of disease. Palpation of the vallecula with a finger and of the posterior floor of mouth provides a critical assessment of submucosal extent of disease in these areas from supraglottic carcinoma.

After this clinical assessment, the conservation laryngeal surgeon should have a clear understanding of the extent of the lesion and have in mind which surgical or nonsurgical options are optimal for the patient.

Radiologic Evaluation of the Primary Site

Although imaging studies are frequently available before the clinical evaluation of the primary site, the best role of these studies is to corroborate the clinical findings noted on indirect and direct laryngoscopy and to corroborate clinical evidence of deep growth of lesions. This is because although there are specific findings that are particularly useful to assess with imaging studies, there are limitations to the value of these studies, and they may either overpredict or underpredict tumor in certain situations. One caveat is that when evaluating particularly small lesions or the superficial extension of a large lesion, CT[87] or MRI may demonstrate little abnormality. This is because these modalities are insensitive to superficial mucosal masses. Another pitfall is seen in those with large exophytic lesions. When lesions have large extensions into the airway, they may sit up against adjacent mucosal sites such as the pyriform sinus, tongue base, floor of mouth, lateral pharyngeal wall, or ventricle or saccule. Although the point of the attachment of the cancer may be small and discrete, the scan may deceptively indicate that all mucosal surfaces are involved. In these patients the endoscopist has a better view of the lesion, and the clinical examination takes precedence over the radiologic evaluation. Valsalva maneuver performed during the CT scan may be useful if these issues cannot be resolved at endoscopy.[88] Occasionally, tumors may be isodense (CT) or isointense (MRI) with the surrounding tissues, which at times may overestimate or underestimate the size of the lesion noted on the clinical examination.[89] In these patients the radiologist and surgeon should work together to find the true extent of tumor.

Laryngeal imaging studies have been useful in a number of areas. Occasionally, the bulk of the lesion extends submucosally into the subglottis. In these patients, MRI more so than CT can be useful to demonstrate the direct invasion or secondary thickening or asymmetry caused by the lesion in this area. Coronal T_1-weighted MRI scans are particularly elegant in demonstrating submucosal transglottic spread. The cricoarytenoid area is best evaluated with axial scans, and sclerotic changes on CT are indications of perichondrial or direct arytenoid cartilage involvement.[88,90] Sagittal MRI has been shown to be a sensitive and specific test for varying degrees of preepiglottic space invasion.[91] Because the cartilages of the larynx calcify starting in the second decade in an inhomogeneous fashion, loss of calcification of the cartilage on CT is an unreliable indicator of tumor extension.[92] MRI has been shown to be highly sensitive to cartilage invasion, particularly if fat-suppressed and postgadolinium scans are performed. Enhancement

into cartilage on postgadolinium fat-suppressed scans is highly sensitive to invasion, but it suffers from reduced specificity because inflammation and chondronecrosis will show similar findings. Kirchner[93] noted that the most common site of thyroid ala invasion from glottic carcinoma is the lower edge, and questionable isolated involvement of the superior aspect of the thyroid cartilage may represent random calcification patterns within the cartilage. We agree with Kikinis and colleagues[94] that MRI has been more useful for evaluating tumor extension into or through laryngeal cartilages. Fluorodeoxyglucose (FDG) PET has gained popularity among physicians in the staging and surveillance of head and neck cancer.[95] Its most promising role in larynx cancer appears to be in the delineation of posttreatment effect (medical organ-preservation strategies) from recurrent tumor. The role of FDG PET in organ preservation for the larynx paradigm is currently being assessed in a prospective study.

T Stage

The larynx by convention is divided into three discrete parts for the purpose of T staging. The supraglottis begins inferiorly at the lateral angle of the ventricle. Although the supraglottis extends superiorly up to the tip of the epiglottis, the vallecula mucosa is part of the oropharynx. The glottis begins at the lateral angle of the ventricle, and it extends 1 cm inferiorly at the midcord level. The subglottis begins at the inferior aspect of the glottic level and extends to the inferior aspect of the cricoid cartilage. Although this partitioning of the larynx is somewhat artificial, it allows for a staging system that, despite its shortcomings, allows for comparison of treatment modalities and prognostication.[96] Although the T-staging system is useful when comparing modalities that encompass the entire larynx such as radiotherapy or total laryngectomy, it lacks the precision necessary to determine whether conservation laryngeal surgery may be performed at all and, if so, which particular procedure is indicated. Within each of the four T stages, at each site there is a spectrum of lesions for which a variety of conservation laryngeal procedures may be used with successful outcome. When planning for conservation laryngeal surgery, numerous factors that go beyond the level of detail required in the T-staging system should be evaluated. The factors that are clinically important include the precise extent of mucosal involvement, the depth of invasion of the malignancy, and the vocal cord and arytenoid mobilities. Although it has frequently been stated that millimeter margins are adequate for conservation laryngeal surgery, the caveat to this axiom is that for any given conservation laryngeal technique, millimeters of tumor extension within the larynx may preclude performing that technique and may result in intraoperative conversion to total laryngectomy. The conservation laryngeal surgeon should describe the lesion in more detail than the T-staging system to allow for application of the appropriate conservative laryngeal technique.

Overall Clinical Assessment

The primary medical issues important to the conservation laryngeal surgeon are the patient's ability to successfully tolerate the general anesthesia required to perform the procedure, the patient's lack of severe systemic medical problems that may dramatically impair wound healing, and the patient's pulmonary reserve to tolerate the postoperative course. The standard criteria are available for assessing anesthesia-related risks before surgery and should be used. Systemic illnesses that may predispose to poor wound healing include severe nutritional depletion, medications associated with organ transplantation, diabetes mellitus, and gastroesophageal reflux.

The degree to which the severity of pulmonary disease is used in the decision to proceed with conservation laryngeal surgery remains controversial in the literature. The real question is how well the patient will tolerate some degree of aspiration during the early postoperative period.[97] The amount of postoperative aspiration varies with the type of surgery contemplated. Vertical hemilaryngectomy sparing arytenoid typically causes little impact on swallowing function, whereas extensions of standard or extended supraglottic laryngectomy may result in increased dysphagia and aspiration risk.[98] Some authors advocate pulmonary function tests routinely for all patients,[99] whereas others use clinical evaluation such as walking up two flights of stairs without getting short of breath.[1,97] The percutaneous gastrostomy tube has been useful for patients who require long periods of no nutrition by mouth.[100] The literature actually leaves a fair amount of leeway for the clinician in terms of the pulmonary workup and in terms of how to use this information in clinical decision making. We rarely use pulmonary function testing preoperatively, unless requested by a medical consultant or anesthesiologist in preparation for a general anesthetic. If the patient has chronic obstructive lung disease but can walk up two flights of stairs without being winded and is active in his or her daily life, then the risks, benefits, and alternatives of conservation laryngeal surgery are discussed with the patient. If the pulmonary status indicates severe impairment of activity and a likelihood of morbidity or mortality after the procedure, we do not recommend conservation laryngeal surgery for that particular patient. In actual practice, each surgeon should know, over time, the limitations of a particular surgical technique in "their hands." Using this approach, there rarely will be patients who need functional laryngectomy for intractable aspiration, although there will also be many patients who have had their larynges spared with conservation laryngeal surgery.

An important factor in patient selection is the patient's insight into the problem and the ability of the patient to play an active role in his or her rehabilitation. The issue of age has been discussed often in the literature. Some authors have strict age criteria for performing partial laryngeal surgery.[101] Others have stated that it is the biologic age and the patient's overall constitution that is more important than the chronologic age.[1,100,102] In addition, conservation laryngeal surgery is a "team endeavor," and if the patient and family prefer to "sit on the sidelines" rather than be actively involved in the rehabilitation process, it is our experience that the patient will likely have a protracted course with increased morbidity. In our institutions, the assessment of the patient's willingness and ability to be rehabilitated is a joint decision among the speech pathologist, otolaryngologist, patient, and family. Although we do not obtain preoperative modified barium swallow, all patients are assessed by a speech pathologist, and the rehabilitation is discussed with the patient. The sine qua non for a cooperative and functional patient postoperatively is extensive preoperative counseling by the surgeon and speech pathologist. The patient and family should understand that much work is required on their part for rehabilitation. Some patients may choose alternative nonsurgical approaches to their problem or even total laryngectomy to avoid the swallowing rehabilitation required for some conservation laryngeal procedures.

The literature is replete with nonsurgical strategies for the preservation of the larynx for all stages of laryngeal carcinoma. All surgical and nonsurgical therapies have expected sequelae, risks, and complications, which are balanced by the ability of a given technique to control the malignancy. The two central issues of great importance to the patient, his or her family, and the physician are (1) the quality of life and (2) cancer control. The clinician weighs each factor carefully in advising a patient on which modality is preferred in a particular case. It is tempting for clinicians to apply their value system to what is good for a patient, although when making recommendations, it is clinicians' ethical and legal responsibility to offer patients the risks, benefits, and alternatives to the variety of treatment options that are available for their cancer.

Surgical Techniques

The next section reviews the various conservation laryngeal techniques available for the management of the spectrum of laryngeal carcinomas. The discussion is limited to open surgical approaches in which the functional goal is speech and swallowing without a permanent tracheostomy. The main category of surgical technique is introduced with a review of the literature analyzing the oncologic results, basic surgical technique, key surgical points, extensions of the procedure, expected functional outcome, and complications.

Indications and Contraindications

The indications for particular surgical techniques, presented in the literature, have varied over time. Indications frequently vary, depending

on the stage of development of the technique. When a technique is first introduced, most surgeons advocate conservatism in its application.[2,9] Later, pioneering surgeons attempt to cautiously extend the use of techniques, frequently on the basis of applications of their surgical skills combined with their knowledge of surgical anatomy and by necessity without the benefit of long-term oncologic follow-up evaluation.[103,104] The final stage in the development of a technique, according to Daly,[105] is reevaluation followed by acceptance of the technique on the basis of reported results. Before the last stage of development, the indications for a particular technique are usually parochial and based on the anecdotal experiences at a particular institution or the pronouncement of a pundit in the field. Reliance on the literature for indications and contraindications is, therefore, frequently not helpful because surgeons usually attempt to use techniques for a large spectrum of tumor stages. To address this problem, we have provided, for each technique, a thorough literature review in terms of oncologic results, functional outcome, and complications. The surgeon can use this information when advising patients concerning the risks, benefits, and alternatives for a particular surgical procedure.

Conservation Laryngeal Surgery for the Lesions Originating in the Glottic Level

Vertical Partial Laryngectomies

All vertical partial laryngectomies share a common approach, which includes a vertical transection through the thyroid cartilage and paraglottic space. The extent of resection is decided on the basis of the preoperative and intraoperative assessment of the tumor extent. Although this vertical approach provides useful and expeditious access to the endolarynx, they all share a common characteristic, which is "blind" entry into the larynx through a narrow exposure.[106] Depending on the extent of the primary lesion, the initial vertical cut may be close to or distant from the cancer. This point should be considered when these procedures are used.

Vertical Hemilaryngectomy

ONCOLOGIC RESULTS. Among the series in the English language literature in which local control has been reported in terms of the T stage, the local recurrence rates for T_1 lesions ranged from 0% to 11%, with five of six series having a local control of greater than 90% (Table 110-1). In one large series of 248 patients, the local control was 93% (104 of 112) for patients with malignancy confined to the true cords without anterior commissure involvement.[106] In that same series, patients with anterior commissure involvement without impaired mobility or extension beyond the glottis had local failure rate of 25% (8 of 32). When the anterior commissure is involved, the most common site of recurrence is the subglottis, as demonstrated in a series in which 14% (8 of 58) of patients with anterior commissure involvement had vertical hemilaryngectomy failure; in 7 of 8 of these patients, the recurrence was in the subglottis.[107] When the anterior commissure is involved by cancer, a wide surgical margin is indicated in the subglottis. Another factor that portends poor local control is extension beyond the confines of the glottis or impaired mobility.

Mohr and others[108] reported the highest local control in the literature for T_2 glottic carcinoma after extended vertical hemilaryngectomy, but they included only T_2 lesions with impaired mobility and excluded lesions that extended beyond the midventricle (only five patients) or beyond 5 mm into the subglottis because of the known high local failure rate for these lesions.[108] Subglottic extension has been associated with cricoid cartilage invasion, which is not resected in the standard vertical hemilaryngectomy.[109] Extension into the supraglottis through the ventricle should alert one to the possibility of thyroid cartilage invasion, which may account for the higher local recurrence in this patient group.[108] The difficulty in managing T_2 glottic carcinoma with vertical hemilaryngectomy was noted in a number of series that had local failure greater than 20%,[41,106,110] and six of the eight series in the English language literature that correlated local recurrence with T stage reported a local recurrence rate of greater than 14% (Table 110-2). One cause for impaired cord mobility is varying degrees of thyroarytenoid muscle invasion within the paraglottic space, which, in our opinion, may account for the higher local failure rates in vertical hemilaryngectomy in which the paraglottic space is routinely transected.[67]

The local control after the management of T_3 glottic carcinoma with vertical partial laryngectomy has yielded variable local failure rates ranging from 0% to 46%, with four of the eight series reporting local failure rates of greater than 36% (Table 110-3). This finding may be related to the fact that many cases may be understaged[52] and may have thyroid cartilage invasion, which is routinely partially resected during vertical hemilaryngectomy.

Our analysis reveals that consistently excellent oncologic results can be expected for T_1 glottic carcinomas involving the mobile membranous vocal cord, although once the anterior commissure is involved or if there is extension beyond the glottis or impaired cord mobility, vertical hemilaryngectomy should be used cautiously. On the basis of

our review of the oncologic results in the literature, they do not recommend vertical hemilaryngectomy for those with advanced T_2 lesions or any T_3 or T_4 glottic carcinomas.

SURGICAL TECHNIQUE. A tracheostomy routinely is performed. A horizontal skin incision is used that is separate from the tracheostomy site. The midline raphe between the strap muscles is dissected from the cricoid cartilage to just above the superior aspect of the thyroid cartilage. When feasible, we prefer to resect the window of thyroid cartilage adjacent to the vocal cord, allowing reconstruction through imbrication laryngoplasty.[111] The external thyroid perichondrium is scored in the midline with a blade, and the perichondrium is elevated as a single flap in continuity with the strap musculature. This is done with an elevator such as a Freer and by cutting the perichondrium sharply with a knife at its superior and inferior attachments to the thyroid cartilage. A variety of techniques have been described in which varying amounts of ipsilateral thyroid cartilage is excised, ranging from no cartilage[112] to the entire ipsilateral ala.[41] We use the technique described by Pleet and colleagues,[111] in which a window of cartilage is outlined with a marker lateral to the level of the true vocal cord. The inferior aspect of the resected cartilage begins approximately 5 mm above the inferior aspect of the thyroid cartilage, and the resected portion is approximately 1.5 cm in height.[113] It extends from the midline to the posterior aspect of the thyroid cartilage. At this point the midline thyrotomy and other cuts are made with a knife, drill, or saw, depending on the degree of calcification of the thyroid cartilage and the preference of the surgeon. A No. 15 blade is used to make a midline vertical cricothyrotomy.

At this point the patient is paralyzed, the cords are held apart from below with a mosquito clamp, and a No. 12 blade is used to gently transect the anterior commissure, as in laryngofissure and cordectomy. The true and false cords are separated sharply up to the level of the petiole of the epiglottis. The cancer is visualized. The soft tissue resection is accomplished with a No. 15 blade for the anterior and posterior cuts. A right-angled Beaver blade or small right-angled scissors are useful for the posterior cut.

A variety of reconstructive options exist including no replacement of the glottic level allowing healing to occur by secondary intention, strap muscle flap with thyroid cartilage preservation,[112] and skin flaps.[7] In imbrication laryngoplasty,[111] we elevate a composite flap that includes the superior portion of the thyroid cartilage and the undermined false cord (Fig. 110-9).[113] This flap of vascularized, innervated false vocal cord is stabilized by the imbrication of the cartilage. It allows

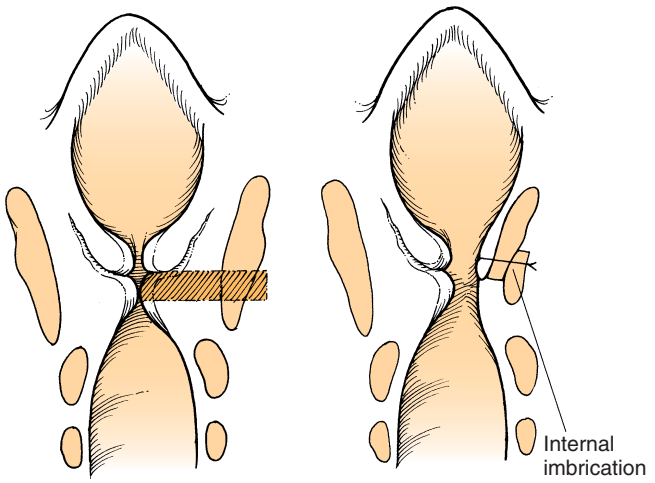

Figure 110-9. Imbrication laryngoplasty—reconstructive technique.

for soft tissue coverage from the false cord, but the inset of the superior thyroid cartilage on the inferior remnant also ensures medialization of the mucosal surface, which may improve phonation when compared with no reconstruction.[113]

EXTENDED PROCEDURES. A number of extensions of the standard procedure have been described.

FRONTOLATERAL VERTICAL HEMILARYNGECTOMY. Frontolateral vertical hemilaryngectomy has been used for lesions that approach or involve the anterior commissure or opposite true vocal cord anteriorly.[6] In this case the vertical thyrotomy is made through the thyroid lamina of the less involved side, allowing for removal of the anterior angle of the thyroid cartilage, anterior commissure, and a portion of the contralateral true vocal cord.

POSTEROLATERAL VERTICAL HEMILARYNGECTOMY. Posterolateral vertical hemilaryngectomy is used for cancers that extend posteriorly to involve the ipsilateral arytenoid mucosa.[5] The thyrotomy approach is the same as the standard operation, and the modification lies in the posterior extension of the resection to encompass part or all of the ipsilateral arytenoid cartilage and mucosa.

EXTENDED VERTICAL HEMILARYNGECTOMY. A number of procedures have been described in which extensive resection is accomplished through a vertical approach. Common characteristics include resection of the entire ipsilateral hemilarynx with the option of resecting the superior aspect of the cricoid cartilage. A variety of reconstructions have been proposed for these radical resections including sparing a posterior strip of the ipsilateral thyroid cartilage and fashioning a new hemilarynx, strap muscle reconstruction,[112] or pyriform sinus mucosal flap advancement into the hemilaryx.[108]

FUNCTIONAL OUTCOME. The functional outcome after the standard vertical hemilaryngectomy is some degree of permanent hoarseness, which varies with the reconstructive technique. A more impaired voice tends to accompany no reconstruction, whereas the best voice was associated with replacement of the glottis with an adjacent false cord flap.[113] Hirano and colleagues[114] compared the vocal function after a variety of reconstructions and noted that poor outcome was least often associated with free mucosal grafts, although this report did not evaluate the imbrication technique. Blaugrund and colleagues[115] noted that the supraglottic structures were responsible for voicing postoperatively predominantly in patients in whom one arytenoid was resected but also in patients in whom both arytenoids were spared. The supraglottic voicing was rougher and associated with a lower fundamental frequency than glottic voicing. Chronic dysphagia is not associated with the standard vertical hemilaryngectomy with or without resection of the vocal process, and 92% (11 of 12) of patients resumed a normal postoperative diet within 1 month.[98] It is not clear from the literature how extended vertical hemilaryngectomy affects function in terms of speech and swallowing.

KEY SURGICAL POINTS.

1. As in cordectomy, always tack the petiole of the epiglottis back into position with a 3-0 Vicryl stitch so that the epiglottis will not prolapse posteriorly postoperatively, obscuring the view of the glottis.

2. Also as in cordectomy, suture the anterior commissure on the noninvolved side anteriorly at the external thyroid perichondrium with a 4-0 Vicryl stitch so that the cord will be in normal position and the vocal tendon will have proper tension.

COMPLICATIONS. Uncommonly, wound complications such as seroma or hematoma might occur. Again, as in cordectomy, fistula is uncommon. In extended procedures, there is a higher incidence of complications including delay in decannulation, stenosis, and long-term dysphagia.[79] Persistent airway edema can be managed expectantly or with laser laryngoscopy.

Epiglottic Laryngoplasty

ONCOLOGIC RESULTS. Epiglottic laryngoplasty was first described by the Czechoslovakian surgeon Sedlacek,[116] then reported by Kambic and colleagues[117] in Yugoslavia, and later popularized in the United States by Tucker and associates.[118] The history of the development of this technique is classic for conservation laryngeal surgery in general; it was first developed in Europe and later imported and popularized in the United States. The term *epiglottic laryngoplasty* refers to the reconstruction, which is done by undermining the epiglottis and advancing it inferiorly and laterally to reconstruct the larynx after vertical hemilaryngectomy or anteroinferiorly to reconstruct after a bilateral vertical partial laryngectomy. The entrance into the larynx, like in all vertical partial laryngectomies, is through two vertical thyrotomies: one just anterior to the posterior aspect of the thyroid cartilage on the more involved side, and the other can be anywhere from a midline thyrotomy when the reconstruction is applied to the standard vertical hemilaryngectomy or symmetrically placed on the opposite thyroid ala for extensive bilateral lesions. In the most extensive resection, both cords, true cords, and one arytenoid may be resected. Tucker and colleagues[74] reported on a series of patients who underwent the procedure with a minimum follow-up period of 2 years and in which there were no local recurrences among four T_{1a}, 8 T_{1b}, and 11 T_3 cancers and one recurrence in eight (12.5%) T_2 cancers. Tucker[119] noted a 50% local recurrence rate for lesions with greater than 6 mm of subglottic extension anteriorly.

SURGICAL TECHNIQUE.[118] A tracheostomy is performed. We describe the procedure in which both thyroid ala are resected to manage a bilateral lesion. The midline raphe of the strap muscles is identified. The thyroid perichondrium is incised in the midline. The perichondrium is elevated in continuity with the overlying strap musculature. The vertical thyrotomies are made 3 to 4 mm anterior to the posterior aspect of the thyroid cartilage on the more involved side and placed more anteriorly on the less involved side. A transverse cricothyrotomy is performed. Right-angled scissors are used to transect the soft tissue of the paraglottic space on the less involved side through the previously made thyrotomy. The resection on the involved side can resect the arytenoid, taking care to preserve the posterior arytenoid mucosa. The epiglottis is undermined to the level of the vallecula, which is not transgressed (Fig. 110-10). It is advanced inferiorly and sutured to the cricothyroid membrane or cricoid cartilage and laterally to the thyroid cartilage remnants. The external thyroid perichondrial flap and strap muscles are then sewn across the midline.

KEY SURGICAL POINTS.

1. At least one functional arytenoid should be saved, and care should be taken not to damage the cricoarytenoid joint during the resection.

2. The preepiglottic space is dissected away from the anterior surface of the epiglottic cartilage, and this dissection should be brought up through the median hyoepiglottic ligament to allow for the epiglottis to be advanced far enough inferiorly.

3. No internal mucosal stitches are necessary, although the inferior suture line should be under no tension to prevent dehiscence.

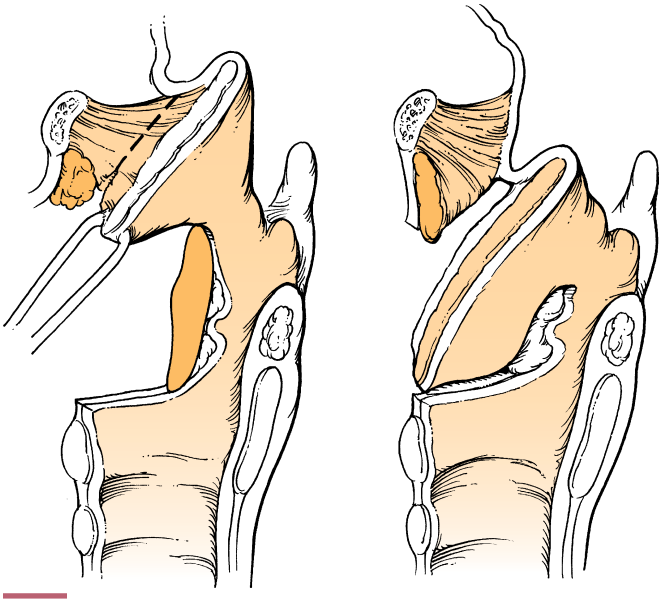

Figure 110-10. Epiglottic laryngoplasty—undermining of the epiglottis in the preepiglottic space before closure.

EXTENDED PROCEDURES. One extension of the epiglottic laryngoplasty has combined the procedure of the supracricoid partial laryngectomy with cricohyoidoepiglottopexy as described by Guerrier and colleagues,[29] in which an epiglottic advancement flap and pexy of the cricoid and the hyoid are performed.

FUNCTIONAL OUTCOME. In Tucker and associates'[118] original description, all patients were taking food by mouth from 1 to 18 days after decannulation, although as in all conservation laryngeal procedures in which one arytenoid is resected, some degree of temporary dysphagia is to be expected. Other authors have encountered increased degrees of postoperative aspiration and an extremely breathy voice, which they attributed to the wide anterior posterior dimension of the airway that prevents appropriate sphincteric function of the posterior glottis.[120] Nong and others[121] have responded to this problem by modifying the procedure by use of a number of endolaryngeal flaps to reconstruct the neolarynx to decrease aspiration and breathiness while preserving respiration.

COMPLICATIONS. Reported complications have included delayed decannulation from postoperative aspiration and mild upper airway obstruction.[118]

Horizontal Partial Laryngectomies

Horizontal partial laryngectomies are so called because the initial entry into the laryngeal lumen is through a transverse or horizontal cut. This incision is distant from the cancer, which allows for safe entry into the endolarynx followed by inspection of the lesion before making additional incisions. Although in the past the term *horizontal partial laryngectomy* has been used by some authors interchangeably with supraglottic partial laryngectomy, this is one type of horizontal technique that is used for supraglottic carcinomas. During the past 2 decades, the supracricoid partial laryngectomy with cricohyoidoepiglottopexy, another horizontal technique with use for managing selected glottic carcinomas, has been developed.

Supracricoid Partial Laryngectomy with Cricohyoido-Epiglottopexy

ONCOLOGIC RESULTS. The supracricoid partial laryngectomy with cricohyoido-epiglottopexy allows for resection of both true cords, both false cords, the entire thyroid cartilage, both paraglottic spaces bilaterally, and a maximum of one arytenoid. Speech and swallowing without a permanent tracheostomy are achieved. The technique's main use has been for the management of selected T_2 and T_3 carcinomas of the glottis, although it has been reported that it was used for T_{1b} and

selected T_4 glottic carcinomas. There were no local recurrences among nine patients with T_1 glottic carcinomas (one T_{1a} and eight T_{1b}).[72] The local control for T_2 lesions is 4.5% (3 of 67).[122] The local recurrence for selected T_3 glottic carcinomas was 10% (2 of 20).[123] Piquet and Chevalier[47] reported the local recurrence for a group of 104 (T_1, 12; T_2, 77; T_3, 15) previously untreated patients to be 5%, although local recurrence was not reported by T stage in this series. One of the reasons for the consistently low local recurrence rates may be the complete resection of the entire thyroid cartilage and the bilateral en bloc resection of the paraglottic spaces.

Transglottic lesions have been defined as carcinomas that extend across the laryngeal ventricle, involving the true and false cords.[124] Although the exact origin of these cancers is frequently unclear, the origin is attributed to the site in which the epicenter of the tumor resides. In carcinomas with transglottic extension, the local recurrence after conservation approaches that use extended vertical hemilaryngectomy or extended supraglottic laryngectomy has yielded a local failure rate of 23% (7 of 30).[125] One caveat is that the supracricoid laryngectomy with cricohyoidoepiglottopexy does not result in a complete resection of the supraglottis, and therefore we prefer to perform supracricoid laryngectomy with cricohyoidopexy for transglottic extension.

SURGICAL TECHNIQUE.[72] After the creation of a U-shaped incision in line with the tracheostomy site, which will be placed later in the procedure, the superior flap is elevated to approximately 2 cm above the hyoid bone, exposing the underlying strap muscles. Next, the sternothyroid and the thyrohyoid muscles are transected individually, from medial to lateral, along the superior aspect of the thyroid cartilage. The sternohyoid muscle is elevated inferiorly, allowing for the exposure of the sternothyroid muscle. Typically, there is a blood vessel that pierces the deep strap musculature to the more superficial layer that should be ligated at this point bilaterally. The sternothyroid muscle is then carefully transected along the inferior edge of the thyroid cartilage. Care is taken at this point not to cut the underlying thyroid gland. The constrictor muscles are then transected along the posterior and superior-lateral aspect of the thyroid cartilage, and the pyriform sinus mucosa is elevated off of the internal surface of the thyroid cartilage bilaterally, as is done in a total laryngectomy. A Freer elevator is used to disarticulate the cricoarytenoid joint bilaterally, taking care to protect the recurrent laryngeal nerves. The recurrent laryngeal nerves are never actually visualized. The isthmus of the thyroid gland is transected and ligated. At this point, a blunt finger dissection of the cervicomediastinal trachea is done to the level of the carina, as is done in a tracheal resection and anastomosis, to close the tracheal defect. A transverse cricothyrotomy is performed just above the cricoid cartilage, and the endotracheal tube is removed from above and placed into the cricothyrotomy. The larynx is then entered through a transverse transepiglottic laryngotomy. The scissors are oriented obliquely and inferiorly to allow transection of the epiglottis at the level of the petiole, if the lesion is amenable to such an approach, and to allow for entry just above the false cords and preservation of as much epiglottis as possible.

The endolaryngeal excision is now performed on the non–tumor-bearing side first, and the incision is brought down in the sagittal plane with a scissors at the junction between the false cord and arytenoid. The transection is carried inferiorly just posterior to the ventricle and then through the vocal process of the arytenoid. Special care is taken to avoid entering the cricoarytenoid joint with the scissors. Just above the cricoid cartilage, the orientation of the scissors changes to allow connection of this incision, through the cricothyroid muscle, to the previously made cricothyrotomy. The larynx is opened up on its anterior spine like a book (Fig. 110-11). The cut on the tumor-bearing side may be made through just posterior to the ventricle again or may transect all or part of the arytenoid cartilage. This incision can be done by cutting the subglottic mucosa with a No. 15 blade and following posteriorly and superiorly to the level of the arytenoid. Nonetheless, the posterior arytenoid mucosa should be spared so that it can be used in the endolaryngeal reconstruction to cover the cricoarytenoid joint area on the cricoid. This forms a cushion, postoperatively, against which the remaining arytenoid will abut to allow for closure of the larynx.

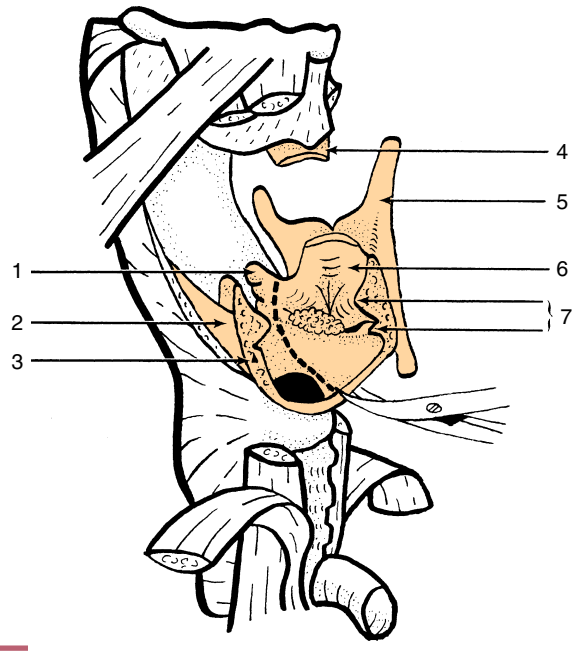

Figure 110-11. Supracricoid partial laryngectomy with cricohyoidoepiglottopexy—exposure of malignancy. *1,* arytenoid; *2,* internal thyroid perichondrium; *3,* vocal process; *4,* inferior aspect of transected epiglottis; *5,* thyroid cartilage; *6,* petiole of the epiglottis; *7,* false and true vocal cords.

The reconstruction is begun by pulling the arytenoid cartilages forward with 3-0 Vicryl suture material by placing a stitch just at or just above the vocal process and sewing them (or the posterior arytenoid mucosa in the case of unilateral arytenoid resection) anterolaterally to the cricoid cartilage. In this way, the arytenoid will not prolapse backward postoperatively. Impaction of the cricoid to the hyoid is performed with three centrally placed 2-0 Vicryl sutures on a 65-mm round needle. The first stitch is placed circumferentially, submucosally around the cricoid cartilage, in the midline. The stitch is then passed through a few millimeters of inferior epiglottic cartilage, submucosally, so that when the stitch is tied down, the epiglottic mucosa will be approximated to the cricoid mucosa. Next, the same first stitch is passed back into the preepiglottic fat and up around the hyoid bone and deep into the tongue base. This large needle allows the suture to be passed deeply into the tongue base, submucosally, while it is carefully palpated with a finger on the tongue base mucosa to pull it back and have a bulge of tongue-base tissue over the airway postoperatively (Fig. 110-12). Before tightening the sutures, the two lateral sutures are pulled taut, which places the trachea in its postoperative position, and the tracheostomy is performed in line with the skin incision. With the two lateral cricohyoidoepiglottopexy sutures under tension, the central pexy stitch is tied, followed by the two lateral stitches. The strap muscles are closed as a second layer closure with 3-0 Vicryl. A cuffed tracheostomy tube is put into place. The skin wound is closed in two layers, taking special care to separate the tracheostomy site from the remainder of the wound with a subcutaneous stitch placed between the skin and the underlying strap muscles above the tracheostomy site.

Key Surgical Points

1. During the exposure, elevate the skin flaps to approximately 2 cm above the hyoid bone to prevent tethering of the skin in the closure postoperatively.

2. When disarticulating the cricoarytenoid joint, be careful not to injure the recurrent laryngeal nerve.

3. When making the vertical prearytenoid incision just posterior to the ventricle, be careful not to enter the cricoarytenoid joint.

4. Always save the posterior arytenoid mucosa in the case of a transected arytenoid cartilage, and sew this mucosa anteriorly to the cricoid cartilage during the closure.

5. The three tongue base sutures should be placed precisely 1 cm apart and arched up deeply into the tongue base. We use a 2-0 Vicryl on a 65-mm needle.

6. Perfect alignment between the cricoid cartilage and the hyoid bone should be created to reduce the risk of dysphagia postoperatively.

7. Submucosal stitches in the inferior aspect of the epiglottic remnant should be performed to avoid posterior rotation of the epiglottis that may cause airway compromise postoperatively.

8. Gentle internal palpation of the upper esophageal sphincter with a finger will allow for assessment of hypertonia, which should prompt the consideration of cricopharyngeal myotomy except in the presence of gastroesophageal reflux.

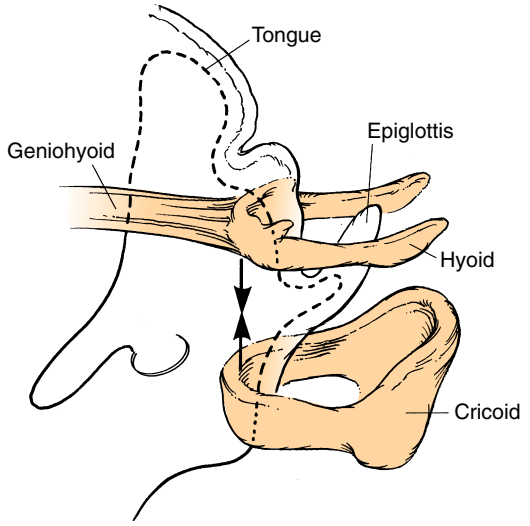

Figure 110-12. Supracricoid partial laryngectomy with cricohyoidoepiglottopexy—laryngoplasty using circumferential cricoid, hyoid, epiglottic, and tongue base sutures.

9. The dissected inner thyroid perichondrium should be gently sewn anteriorly with one 3-0 Vicryl stitch after the creation of the cricohyoidoepiglottopexy to reposition the pyriform sinus in a closer approximation to normal.

10. Always put the tracheostomy in line with the main incision, and always pull up the trachea before placing the tracheostomy so that it will be in line with the incision postoperatively.

EXTENDED PROCEDURES. Extensions of the basic technique include resection of one arytenoid. Anterior subglottic extension may be managed with resection of the anterior arch of the cricoid,[126] which is closed with a pexy between the first two tracheal rings and the hyoid or a tracheohyoidoepiglottopexy.

FUNCTIONAL OUTCOME. Temporary dysphagia immediately postoperatively is to be expected, but long-term dysphagia is rare. Review of the functional results in the world literature revealed a range of days to removal of nasogastric tube postoperatively from 9 to 50 days (Table 110-4). The need for removal of the larynx for intractable aspiration was low and ranged from 0% in 4% of seven studies and ranged from 1% to 4% in the remaining three studies (see Table 110-4). These results compare favorably with the functional laryngectomy rate for aspiration noted after supraglottic laryngectomy (Table 110-5). The vocal quality after supracricoid partial laryngectomy has been studied in a prospective fashion, and by the sixth month, speech parameters of phrase grouping and number of words per minute were similar to normal speakers, although the mean fundamental frequency was lower and wider than normal, suggesting some voice instability postoperatively.[127] In addition, we found that the degree of voicelessness parameters increased, suggesting difficulties in achieving consistent neoglottic closure during speech.[127]

COMPLICATIONS. In one series, the only complication was progressive hyoid necrosis, resulting from underlying severe vasculitis.[72] Three patients in Piquet's series had neolaryngeal stenosis develop requiring placement of a Montgomery T-tube for 3 months.[47]

Conservation Laryngeal Surgery for Lesion Originating in the Supraglottic Level

The management scheme at most institutions managing supraglottic carcinoma has included surgical and nonsurgical approaches. Table 110-6 categorizes patients with supraglottic carcinoma, from a number of large series, treated in the United States by various approaches including partial laryngectomy, total laryngectomy, or radiotherapy alone.[40,97,128,129] The range of percentages of patients undergoing primary surgical management varied from 47% to 90%. When the authors analyzed the number of patients undergoing total laryngectomy

in these series, they noted that the range was from 42% to 66%. Although numerous surgical series have had overall local recurrence rates including all T stages of less than 5%[39,40,97,130,131] in most series (Table 110-7), most patients undergoing primary surgical treatment of the supraglottis underwent total removal of the larynx (see Table 110-6). The conservative surgical option among the patients in Table 110-7 (with the exception of five patients in the Mayo series who were treated with transoral epiglottectomy) was standard or extended supraglottic partial laryngectomy. The main use of the standard supraglottic laryngectomy is for those with selected T_1 and T_2 supraglottic carcinomas,[5] whereas its extensions are used for those with highly selected T_3 and T_4 cancer.[132]

Horizontal Partial Laryngectomies

Supraglottic Laryngectomy

ONCOLOGIC RESULTS. When series of supraglottic laryngectomy from the United States were analyzed, it was noted that the local recurrence varied from 0% to 12.8%, with seven of eight of the large series having a local control of 90% or higher.[5,39,40,97,130,133-135] When local recurrence after supraglottic laryngectomy was analyzed by T stage, one saw consistently high local control for selected T_1 and T_2 lesions but an extremely variable success rate for those with T_3 and T_4 lesions, with local recurrence rates as high as 75% for the former and 66.7% for the latter (Table 110-8). It is not clear from the literature which patients with specific T_3 or T_4 lesions were at highest risk for recurrence; therefore until this is evaluated further in the literature, supraglottic laryngectomy should be performed with caution for those with highly selected T_3 and T_4 lesions of the supraglottis. Lee and colleagues[40] noted improved local control among intermediate-sized supraglottic carcinomas with the addition of postoperative radiotherapy after supraglottic laryngectomy, although the tradeoff for local control seemed to be decreased functional results after extended supraglottic laryngectomy and radiotherapy in that series. Nonetheless, supraglottic laryngectomy provides consistently excellent oncologic results among patients with selected T_1 and T_2 lesions. Our recent analysis of the extension of supraglottic carcinoma to the glottic level revealed a statistically significant increase in glottic involvement for those with lesions with impairment of the vocal cord or involvement of the ventricle.[65] These findings support the contentions that extension below the false cord and impaired cord mobility are contraindications for supraglottic laryngectomy.[84]

SURGICAL TECHNIQUE. We perform an apron incision, in line with the tracheostomy, and routinely perform bilateral modified neck dissection. The main trunk of the superior laryngeal nerve should be spared bilaterally in the nonextended supraglottic laryngectomy. The fascia between the strap muscles at the level of the superior aspect of the thyroid cartilage is divided. In addition, the fascia between the strap muscles is divided inferiorly, and the thyroid isthmus is transected and ligated routinely. The intervening fascia between the strap muscles is left intact. The sternohyoid and the thyrohyoid muscles at the superior border of the thyroid cartilage are divided, with care taken laterally to avoid damaging the superior laryngeal nerves. The constrictor muscles are sharply cut at the posterior and superior edge of the thyroid cartilage laterally all the way to the top of the superior cornua. The superior edge of the thyroid cartilage is scored with a knife, and a Freer elevator is used to elevate the periosteum off of the thyroid cartilage. The external thyroid cartilage perichondrium is elevated halfway down the cartilage from the superior edge to allow for the transverse thyrotomy to be made at the level just above the anterior commissure. The pyriform sinuses are then freed up bilaterally for endolaryngeal tumors, as is done in total laryngectomy, and unilaterally for tumors that involve the pyriform sinus. A tracheostomy is then performed. The next step in the procedure depends on whether the tumor involves the endolarynx alone or is in the vallecula.

The following is the standard technique for T_1 and T_2 endolaryngeal supraglottic carcinomas. If the tumor has not involved the vallecular mucosa and if it was not palpable beneath the vallecula mucosa in the pre-epiglottic space, then it is oncologically sound to spare the hyoid bone, and it is skeletonized from below with an electrocautery. The horizontal thyrotomy is made through the thyroid cartilage at the appropriate level with a sagittal saw. The vallecula is entered, and the epiglottis is pulled externally with an Allis clamp. The resection is done close to the epiglottis, sparing both arytenoids. The cut is made anterior to the arytenoid cartilage bilaterally in a superior-to-inferior direction with one scissor blade in the laryngeal lumen and one scissor blade between the thyroid cartilage and the previously elevated internal thyroid perichondrium (Fig. 110-13). This will allow sparing of the pyriform sinuses bilaterally. The cut is brought down to the level of the ventricle, at which point the transection is made through the ventricle at right angles to the previously made transection in front of the arytenoid. The specimen is then removed for frozen section analysis.

The reconstruction is accomplished by first sewing either the remnant of false cord mucosa or the lateral aspect of the floor of the ventricle to the external perichondrium at the corresponding level of the remaining thyroid cartilage. The stitch should be placed to reposition the anterior commissure into normal position if necessary. There have been numerous reports in the literature on various techniques for closure and laryngoplasty after supraglottic laryngectomy.[55,136,137] The technique we use is similar to the closure used in supracricoid laryngectomy. The concept is to provide mucosa-to-mucosa closure while creating a prominence of tongue-base tissue right over the central aspect of the larynx and the laryngeal inlet. This is done by passing stitches submucosally deep into the tongue base. Three 1-0 Vicryl stitches are used as in supracricoid laryngectomy (Fig. 110-14). The first stitch is placed circumferentially around the remnant of the thyroid cartilage, taking care to remain submucosal and to not damage the anterior commissure. The stitch is then arched high up around the hyoid and submucosally deep into the tongue base, using the entire circumference of the needle. Two additional stitches are placed 1 cm lateral; again, care is taken to pass the stitches around the entire circumference of the remaining inferior thyroid ala, subperichondrially on the internal surface of the thyroid cartilage, so that the thyroarytenoid musculature is not tethered by the stitch. Each of these stitches is passed around the hyoid bone, if it is present, and submucosally deep into the tongue base. The two lateral stitches are held tight by the assistant while the central stitch is tied down. The two lateral stitches are then tied. The periosteum with the overlying inferior strap muscle flap is sewn superiorly to the suprahyoid musculature. The skin flaps are closed, with special care to separate the tracheostomy site from the remainder of the neck wound with a semicircular running 3-0 Vicryl stitch placed sub-

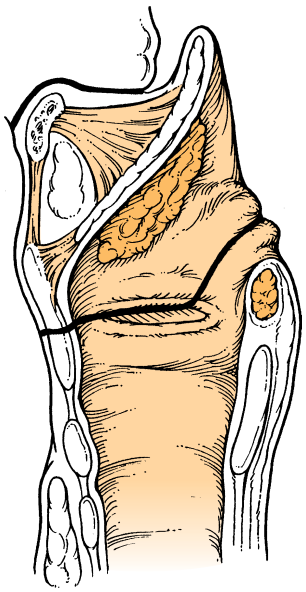

Figure 110-13. Supraglottic laryngectomy—superior to inferior of the false cord, to the level of the ventricle, anterior to the arytenoids.

cutaneously in the upper flap to the strap muscles above the tracheostomy site.

Key Surgical Points

1. We locate the main trunk of the internal and external branches of the superior laryngeal nerve routinely at the time of bilateral modified neck dissection (Fig. 110-15). This is accomplished by dissection of the fat pad, which is anterior to the carotid artery, inferior to the hypoglossal nerve, and lateral to the superior laryngeal nerves. The superior thyroid artery runs through this fat pad and is transected proximally and distally to perform this dissection. This procedure also requires removal of the lymphatics, which travel adjacent to the larynx, allowing the main trunk of the superior laryngeal nerves to be spared bilaterally.

Figure 110-15. Superior laryngeal lymph node dissection—exposure of the superior laryngeal nerve at the time of modified neck dissection. *A,* internal jugular vein; *B,* omohyoid muscle; *C,* sternocleidomastoid muscle. *1,* hypoglossal nerve; *2,* carotid artery; *3,* superior laryngeal nerve; *4,* transected proximal and distal ends of the superior thyroid artery.

2. The superior aspects of the pyriform sinus are dissected from the inner aspect of thyroid cartilage when they are not involved by the malignancy.

3. The superior aspects of the arytenoid are spared, unless the malignancy is directly involving this area.

4. The hyoid bone is not spared when the malignancy involves the vallecula or tongue base.

5. The greater cornua of the hyoid is resected in those with marginal lesions.

6. The tongue base sutures are placed in the midline and 1 cm off of the midline, avoiding damaging the hypoglossal nerves and the lingual arteries.

EXTENDED PROCEDURES. There are two basic extensions of the supraglottic laryngectomy: (1) resection of one arytenoid or the upper part of the pyriform sinus and (2) resection of a portion of the tongue base.[32] Modifications of the standard procedures can be accomplished systematically by the following two approaches.

ARYTENOID, ARYEPIGLOTTIC FOLD, OR SUPERIOR MEDIAL PYRIFORM INVOLVEMENT FROM SUPRAGLOTTIC CARCINOMA. Skeletonize the hyoid bone, and free up the lateral cornua of the hyoid if it is to be resected. Only free up the internal thyroid perichondrium on the uninvolved side. Enter the endolarynx through the vallecula on the uninvolved side or through the thyrotomy inferiorly if the vallecula is involved. Cut anterior to the uninvolved arytenoid and through the false cord. Bring the resection around the upper pyriform on the involved side, which is transected at the level of the ipsilateral true vocal

cord. When the pharyngoepiglottic fold is involved, resect a generous margin of the posterior tonsillar pillar and a portion of the ipsilateral tongue base. If the posterior tonsillar pillar and tongue base have been unilaterally resected, close this portion of the defect separately, taking care to advance the tongue base posteriorly. Close the tongue base with three large stitches.

BASE OF TONGUE EXTENSION FROM SUPRAGLOTTIC CARCINOMA. Enter inferiorly through the thyrotomy. Do not skeletonize the hyoid bone. If necessary, free up the twelfth nerves and move them out of the line of resection. Cut above the hyoid bone and do not skeletonize. Make the tongue base resection under direct visualization from below with a 2-cm margin. The resection should leave at least 1 cm of tongue base posterior to the circumvallate papillae to allow for adequate function postoperatively. The closure is with the submucosal tongue base sutures.

FUNCTIONAL OUTCOME. Although there is some variability in vocal quality after supraglottic laryngectomy combined with radiotherapy, among patients who have undergone decannulation within the first 3 postoperative weeks, microstrobolaryngoscopic findings reveal normal vibration of the cords and normal vibration amplitudes, and results of sonographic evaluations are normal, with some abnormalities related to removal of the resonance space above the cords.[68] One study, which assessed the subjective voice qualities, found that 87% of patients had normal-to-mild breathiness and that 67% had mild or no evidence of hoarseness.[138]

The stages of wound healing and stabilization may take months, although a reasonable measure of progression of swallowing rehabilitation, in the literature, has been the point at which the patient no longer relies on tube feedings for nutrition. Hirano and colleagues[139] noted that 84% (32 of 38) of patients had removal of the nasogastric tube within 30 days postoperatively, whereas some patients required tube feeding for 3 months. Padovan and Oreskovic[68] noted that complete rehabilitation takes at least 3 months, and this may be prolonged in irradiated patients. The factors that Hirano and colleagues[139] found to be significantly related to duration of nasogastric intubation were extent of removal of the arytenoid and asymmetric removal of the false cords, whereas resection of the hyoid and tongue base was not related to swallowing outcome. Flores and colleagues[100] also noted that arytenoid resection was associated with failure to attain swallowing function and that resection of the hyoid and tongue base did not worsen swallowing outcome. Although Flores and others[100] could not find a significant correlation between transection of one versus two superior laryngeal nerves and swallowing outcome, it is interesting to note that all nine patients who failed to swallow had at least one superior laryngeal nerve resected, and there were no patients in this series with the nerves spared bilaterally with which to make a comparison. Although Padovan also agreed that arytenoid preservation is important in swallowing outcome, his group stressed the importance of bilateral preservation of the superior laryngeal nerve to achieve timely swallowing function.[68] This nerve can be visualized after modified neck dissection, and when the pyriform sinus is not involved by the malignancy, the main trunks of the internal and external branches of the superior laryngeal nerve frequently can be spared bilaterally. Staple and Ogura,[140] in a cineradiographic study of 36 patients who had undergone supraglottic laryngectomy, emphasized the association of impaired neuromotor function of the tongue through the hypoglossal nerves and significant degrees of aspiration.

Impaired swallowing function has been associated with extended supraglottic laryngectomy.[40,98,100] The literature was reviewed, and the results from series that assessed the extreme adverse outcomes of permanent gastrostomy, functional laryngectomy, and death resulting from aspiration pneumonia were tabulated in Table 110-5. The series of patients undergoing supraglottic laryngectomy without extended procedures[5,102] seem to be less likely to undergo functional laryngectomy compared with the series that included extended procedures.

COMPLICATIONS. The reported fistula rate after supraglottic laryngectomy has been 0% to 12.5%.[133] Other reported complications, reported in large series, include aspiration pneumonia (0% to 10.8%),[99,141] inability to decannulate the tracheostomy (0% to 5.5%),[102,133] and tracheocutaneous fistula.[5]

Supracricoid Laryngectomy with Cricohyoidopexy

ONCOLOGIC RESULTS. Supraglottic carcinomas that are not amenable to supraglottic laryngectomy because of glottic level involvement either through the anterior commissure or the ventricle, preepiglottic space invasion, decreased cord mobility, or limited thyroid cartilage invasion frequently will be resectable with supracricoid laryngectomy with cricohyoidopexy. These lesions are not rare, and in one study, the incidence of spread of supraglottic carcinoma to the glottic level was between 20% and 54% in the literature.[65] Glottic level invasion should be suspected when there is either impaired cord mobility or extension of carcinoma to the ventricle.[65] In a series of selected supraglottic carcinomas, Laccourreye and colleagues[72] found there were no local recurrences in 68 patients (T_1, 1; T_2, 40; T_3, 26; and T_4, 1) with a minimum follow-up period of 18 months. Laccourreye and colleagues[142] later reported on 19 patients with gross pathologic invasion of the preepiglottic space, with a minimum follow-up period of 5 years, and noted a local control of 94.4% (18 of 19). Chevalier and Piquet[143] reported on their series of 61 consecutive cases of supraglottic carcinoma managed with supracricoid laryngectomy with cricohyoidopexy and noted a local recurrence rate of 3.3% (2 of 61). They attributed the oncologic success to the en bloc resection of the bilateral paraglottic spaces, the preepiglottic space, and the entire thyroid cartilage. Contraindications to the procedure include (1) subglottic extension greater than 10 mm anteriorly and 5 mm posteriorly because of the potential for cricoid cartilage involvement; (2) arytenoid fixation; (3) massive preepiglottic space invasion with involvement of the vallecula; (4) extension to the pharyngeal wall, vallecula, base of tongue, postcricoid region, and interarytenoid region; and (5) cricoid cartilage invasion.[72]

SURGICAL TECHNIQUE.[72] The approach and many of the steps are the same as in supracricoid laryngectomy with cricohyoidoepiglottopexy, although in this procedure, the entire epiglottis and preepiglottic space is resected. A U-shaped incision is made in line with the tracheostomy site, which will be placed later in the case, and the superior flap is elevated to approximately 2 cm above the hyoid bone, exposing the underlying strap muscles. The incision is made up to the mastoid tip to accommodate the bilateral modified neck dissections that are done in the case of supraglottic carcinoma. The sternothyroid and the thyrohyoid muscles are transected individually from medial to lateral, along the superior aspect of the thyroid cartilage. The thyrohyoid muscle is elevated inferiorly, allowing for the exposure of the thyroid muscle. As in supracricoid laryngectomy with cricohyoidoepiglottopexy, there is a blood vessel that pierces the deep strap musculature to the more superficial layer, which needs to be ligated bilaterally. The sternothyroid muscle is then carefully transected along the inferior edge of the thyroid cartilage. Care is taken not to cut the underlying thyroid gland, which will cause undue bleeding and obscure the surgical field. The constrictor muscles are then transected along the posterior and superior-lateral aspect of the thyroid cartilage, and the pyriform sinus mucosa is elevated off of the internal surface of the thyroid cartilage bilaterally, as is done in total laryngectomy. A Freer elevator is used to disarticulate the cricoarytenoid joint bilaterally, taking care to protect the recurrent laryngeal nerves. The recurrent laryngeal nerves are never actually visualized, although the area posterior and lateral to the inferior cornua of the thyroid cartilage is respected and avoided. The isthmus of the thyroid gland is transected and ligated. A blunt finger dissection of the cervicomediastinal trachea is done to the level of the carina, as is done in a tracheal resection and anastomosis to close the tracheal defect. A transverse cricothyrotomy is performed just above the cricoid cartilage, and the endotracheal tube is removed from above and placed into the cricothyrotomy. Now, rather than entering the larynx through a transverse transepiglottic laryngotomy and transecting the epiglottis as is done in supracricoid laryngectomy with cricohyoidoepiglottopexy, we resect the entire epiglottis and preepiglottic space. To do this, the superior aspect of the transected sternothyroid and sternohyoid muscles are elevated off of the thyrohyoid membrane. The upper aspect of the preepiglottic space is dissected off of the inferior aspect of the hyoid bone with an electrocautery unit. The dissection is done medially to create an opening in the vallecula just large enough to allow the epiglottis to be pulled externally and grasped with an Allis

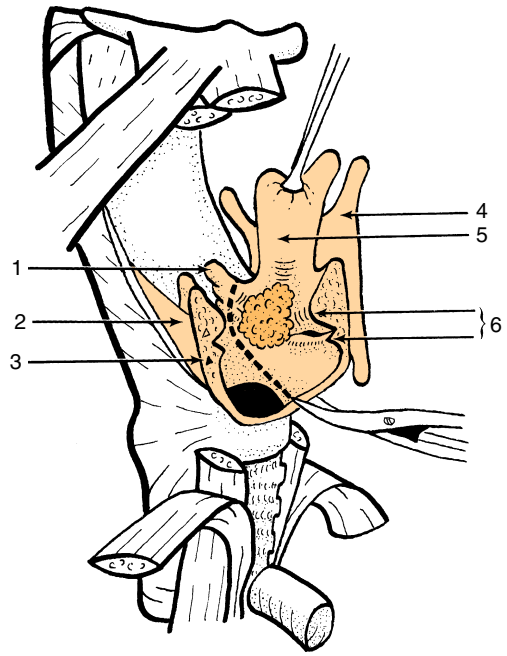

Figure 110-16. Supracricoid partial laryngectomy with cricohyoidopexy—exposure of malignancy. *1,* arytenoid; *2,* external thyroid perichondrium; *3,* vocal process; *4,* thyroid cartilage; *5,* epiglottis; *6,* false and true cord.

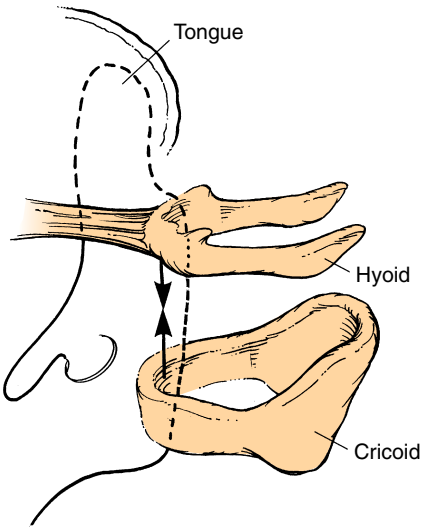

Figure 110-17. Supracricoid partial laryngectomy with cricohyoidopexy—laryngoplasty using three circumferential cricoid, hyoid, and tongue base stitches.

clamp. One scissor blade is placed in the endolaryngeal lumen, and one blade is placed externally. The cut is made in a superior-to-inferior direction to allow for resection of the entire preepiglottic space, although the cut is made medial to the main trunk of the internal branch of the superior laryngeal nerve to keep this intact. The scissors are advanced with one blade in the lumen and the other between the elevated internal thyroid perichondrium and the thyroid cartilage. This cut is made anterior to the pyriform sinus, which remains intact posteriorly.

The endolaryngeal excision now is performed on the non–tumor-bearing side first, in the same fashion as in supracricoid laryngectomy with cricohyoidoepiglottopexy. The incision is brought down, in the sagittal plane, with a scissor blade at the junction between the false cord and arytenoid. The transection is carried inferiorly just posterior to the ventricle and then through the vocal process of the arytenoid. Special care is taken to avoid entering the cricoarytenoid joint with the scissors, avoiding cricoarytenoid ankylosis. Just above the cricoid cartilage, the orientation of the scissors changes to allow connection of this incision, through the cricothyroid muscle, to the previously made cricothyrotomy. The larynx is opened up on its anterior spine like a book, which allows for direct visualization of the lesion (Fig. 110-16). The cut on the tumor-bearing side may be made just posterior to the ventricle or may transect all or part of the arytenoid cartilage. This can be done by cutting the subglottic mucosa with a No. 15 blade and following posteriorly and superiorly to the level of the arytenoid. The posterior arytenoid mucosa should be spared to be used in the endolaryngeal reconstruction and to cover the cricoarytenoid joint area on the cricoid. This forms a cushion, postoperatively, against which the remaining arytenoid will abut to allow for closure of the larynx. The patient will have severe swallowing impairment postoperatively unless this posterior arytenoid mucosa is spared.

The reconstruction is begun by pulling the arytenoid cartilages forward with 3-0 Vicryl suture material by placing a stitch just at or just above the vocal process and sewing them (or the posterior arytenoid mucosa in unilateral arytenoid resection) anterolaterally to the cricoid cartilage. In this way, the arytenoid will not prolapse backward postoperatively. The impaction of the cricoid to the hyoid is performed with three centrally placed 2-0 Vicryl sutures on a 65-mm round needle. The first stitch is placed circumferentially, submucosally around the cricoid cartilage, in the midline. The stitch is placed submucosally in the subglottis. Next, the same first stitch is passed up around the hyoid bone and deep into the tongue base. This large needle allows the suture to be passed deeply into the tongue base, submucosally, while it is carefully palpated with a finger on the tongue base mucosa, to pull it back and have a bulge of tongue base tissue over the airway postoperatively (Fig. 110-17). A self-release needle should not be used because it may become embedded in the tongue base musculature. Before tightening the sutures, the two lateral sutures are pulled taut, which places the trachea in its postoperative position, and the tracheostomy is performed in line with the skin incision. With the two lateral cricohyoidoepiglottopexy sutures under tension, the central pexy stitch is tied, followed by the two lateral stitches. The strap muscles are closed as a second layer closure with 3-0 Vicryl. A cuffed tracheostomy tube is put into place. The skin wound is closed in two layers, taking special care to separate the tracheostomy site from the remainder of the wound, with a subcutaneous stitch placed between the skin and the underlying strap muscles above the tracheostomy site.

KEY SURGICAL POINTS. The key surgical points are the same as those in supracricoid laryngectomy with cricohyoidoepiglottopexy.

EXTENDED PROCEDURES. The extension of the basic technique, as in supracricoid laryngectomy with cricohyoidoepiglottopexy, is the resection of one arytenoid.[72]

FUNCTIONAL OUTCOME. When the world literature is analyzed, variability was noted in the duration of tube feedings with a range from 13 days[142] to 365 days (Table 110-9).[28] The percent of patients undergoing functional laryngectomy for intractable aspiration varied from 0% to 10.8% (see Table 110-9). In the large series, with more than 65 patients analyzed, the need for functional laryngectomy remained less than 5%, which may indicate that experience is of value in achieving successful functional results.[31,35,72] Dysphagia is more common after supracricoid laryngectomy with cricohyoidopexy when one arytenoid is resected.[73,143] Success in postoperative swallowing results has been attributed to careful attention to preoperative patient selection, intraoperative technique, and postoperative rehabilitation.[144]

The duration and frequency characteristics of normal speakers was compared with 14 patients who had undergone supracricoid laryngectomy with cricohyoidopexy.[145] The findings in that study revealed that although the average F_0 among the supracricoid laryngectomy group was within normal range, the operated group was significantly less efficient in jitter, shimmer, maximum phonation time, and phase

grouping.[145] The authors attributed these findings to the instability of the neoglottis, resulting from the wide surgical resection and the fact that the neoglottis allows for air escape during phonation.

COMPLICATIONS. Among the extremely rare complications reported in the literature are rupture of the cricohyoidopexy,[146] pneumonia caused by severe gastroesophageal reflux,[115] chondroradionecrosis,[142] and glottic stenosis.[142]

Organ-Preservation Surgery Spectrum for Glottic and Supraglottic Cancer

Organ laryngeal preservation surgery is based on three fundamental keys. The surgeon needs to be able make an accurate assessment of the patient as a surgical candidate, be able to accurately assess the origin and extent of the lesion, and have a thorough understanding of the available surgical techniques and preoperative issues. Figures 110-18 and 110-19 are schematic representations of the surgical disease spectrum of glottic and supraglottic carcinomas, respectively.[76] Below the schematics are a number of possible variables. These are important clinical factors that have a bearing on the application of organ-preservation surgery of the larynx. There are representative examples of carcinomas from the smallest on the left to the largest on the right. Every other schematic is blank, enabling the surgeon to consider placement of a lesion in its appropriate space, designating the appropriate organ-preservation surgeries available. This schematic allows the surgeon to formulate an organ-preservation surgical plan by comparing the tumor to known lesions while accounting for certain key organ-preservation variables. It is meant to be used as a helpful teaching aid in learning the concepts of organ-preservation surgery for larynx cancer.

Intraoperative Conversion to Total Laryngectomy

Accurate preoperative staging is critical to avoid intraoperative conversion to total laryngectomy including an accurate prediction of the surface extension and the depth of invasion. In general, the problem occurs when there are close margins intraoperatively that necessitate resection of structures that are necessary for the postoperative functional reconstruction. Whole organ section studies reveal that deep and superficial lesions are commonly surrounded by a penumbra of microinvasion carcinoma, carcinoma in situ, and dysplasia.[109] Deep invasion is best appreciated preoperatively during the clinical evaluation, which includes visualization of mobility, palpation during direct laryngoscopy, and radiologic studies. The surface invasion is best evaluated by indirect and direct endoscopy. The penumbra of surface changes surrounding the deeply invasive carcinoma may be particularly difficult to assess clinically because of natural tendency to focus on the obvious cancer during endoscopy and because of the difficulty in assessing subtle mucosal changes on a mucosal surface, which is tangential to direct vision with the naked eye or the microscope. If either subtle granularity or erythema is noted in a critical area on the mucosal surface that would obviate the conservation technique that is contemplated, it should undergo microscopic biopsy at the time of endoscopy. We do not perform random microscopic biopsies of normal-appearing mucosa because the excoriations of these sites may lead to confusion at the time of the definitive resection.

One area that results in conversion to total laryngectomy when dealing with supraglottic laryngectomy is extension to the glottic level. In the past, it has been suggested that supraglottic carcinoma rarely, if ever, extended to the glottic level. A recent analysis of whole organ sections of laryngeal carcinoma and a literature review have revealed that the true incidence of glottic level extension from the supraglottis is between 20% and 54%.[65] The most common route of extension is the paraglottic space. Surgeons relying on the previously held assumption that the carcinoma is unlikely to extend to the glottis, regardless of the proximity of the cancer to the glottis, may need to convert to total laryngectomy in 25% of patients.[13]

The area in glottic carcinoma for which involvement may result in intraoperative conversion to total laryngectomy is invasion of the cricoarytenoid joint. Fixation of the joint is an indication that the joint capsule, the joint itself, or the surrounding musculature is involved by carcinoma.[147] This should be fully assessed, and the joint involvement should be predicted to avoid the necessity of intraoperative conversion to total laryngectomy when performing either vertical partial laryngectomy or supracricoid laryngectomy.

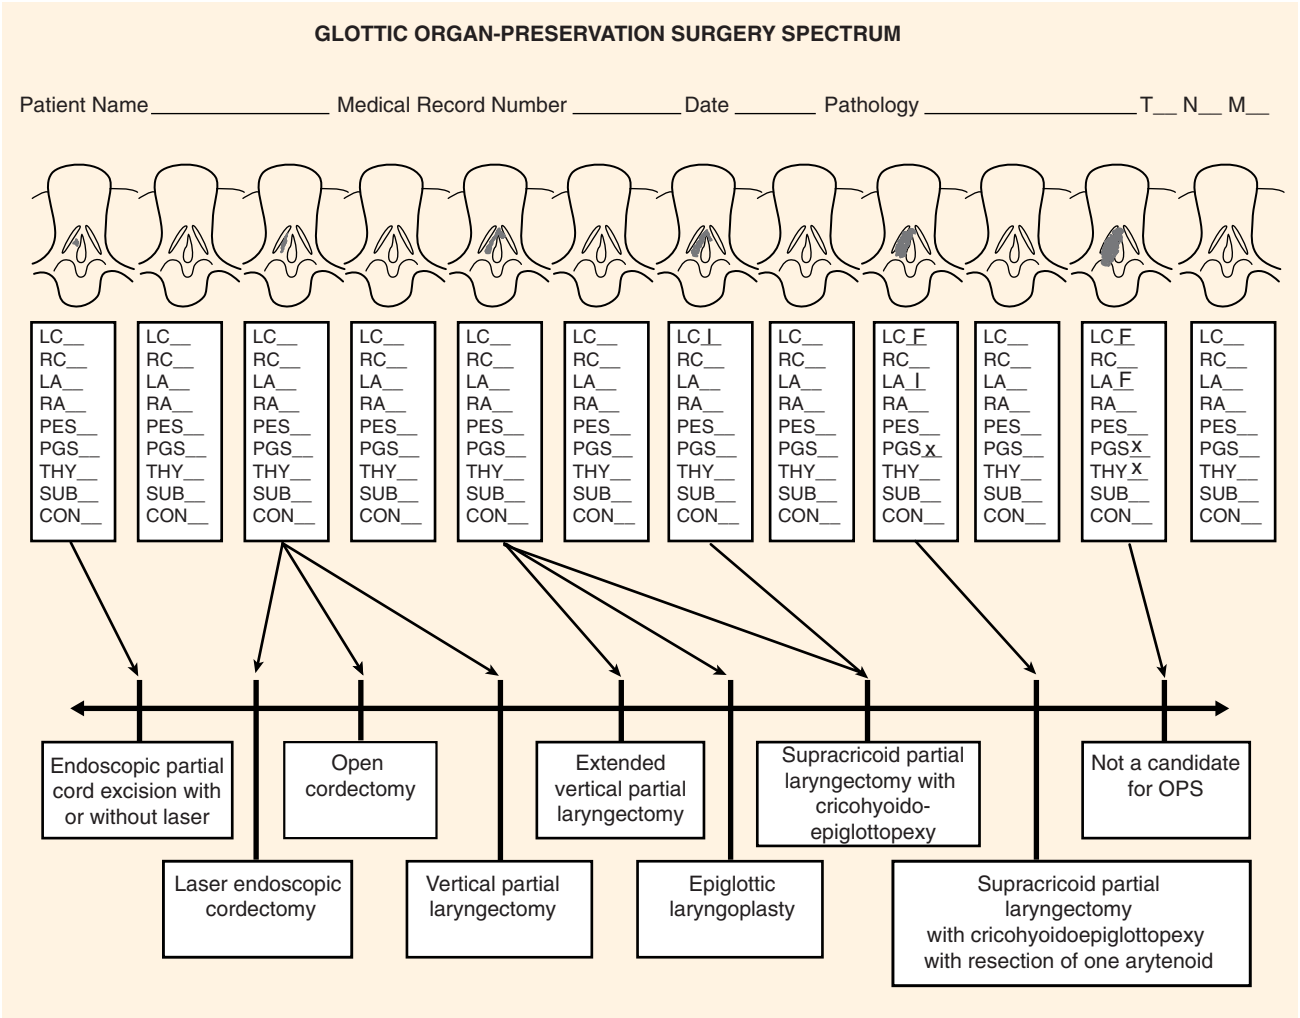

Figure 110-18. Glottic organ-preservation surgery spectrum. *LC,* left vocal cord mobility; *RC,* right vocal cord mobility; *LA,* left arytenoid mobility; *RA,* right arytenoid mobility; *PES,* preepiglottic space involvement; *PGS,* paraglottic space invasion; *THY,* early radiologic evidence of thyroid cartilage invasion; *SUB,* subglottic extension greater than 1 cm at midcord, or greater than 0.5 cm at posterior cord level; CON tumor and non-tumor contraindications. At the top of the form is a series of schematic diagrams of the larynx with additional descriptors in the text box below. At the bottom of the form is the spectrum of organ-preservation surgeries that are applicable. Representative cancers are shown in a spectrum from least extensive on the left through most extensive on the right. The mucosal extent is documented on the schematic. Mobility is documented with either a "blank" for normal mobility, "i" for impaired mobility, and "f" for fixation. An "x" documents involvement of the preepiglottic space, paraglottic space, thyroid cartilage, and a tumor- or non-tumor–related contraindication. This form may be used in surgical planning by drawing the lesion into a blank laryngeal schematic, in the appropriate place on the spectrum. *(From Weinstein GS, Laccourreye O, Brasnu D, et al.* Organ Preservation Surgery for Laryngeal Cancer. *San Diego: Singular Publishing Group; 2000.)*

The best approach to avoid intraoperative conversion to total laryngectomy is preoperative planning. The surgeon has a wide spectrum of conservative techniques available with consistent functional and oncologic outcome in the literature. We do not advocate conversion from one type of conservation laryngeal surgery intraoperatively to another to avoid total laryngectomy. In our opinion, this conversion will lead to poor oncologic and functional outcome. Rather, to avoid intraoperative conversion to total laryngectomy, the procedure of choice should be decided on preoperatively, and this should be the technique that affords the safest oncologic margins for that particular lesion. Nonetheless, the surgeon always should obtain consent from the patient for the possibility of intraoperative conversion to total laryngectomy, with the understanding that in rare instances, removal of the entire larynx may be necessary. The patient who cannot accept this option is not a good candidate for conservation laryngeal surgery.

All patients undergoing attempts at conservation laryngeal surgery must give their consent for possible total laryngectomy. Careful preoperative planning can help to reduce the incidence of conversion to total laryngectomy. If the patient cannot accept this possibility or if the surgeon feels that there is a distinct possibility for total laryngectomy, the patient should be encouraged to pursue an organ-preservation medical strategy if appropriate.

Current Organ-Preservation Paradigm for Laryngeal Cancer

The trial conducted by the Department of Veterans Affairs Laryngeal Cancer Study Group 1991 compared induction chemotherapy (cisplatin plus fluorouracil) followed by radiation versus surgery (total laryngectomy) and radiation for advanced laryngeal cancer.[148] The conclusion from this study was that induction chemotherapy followed by radiation was able to preserve the larynx while not affecting survival. This provided an alternative to total laryngectomy for these patients with advanced laryngeal cancer. Recently, the Radiation Therapy Oncology Group (RTOG) Trial 91-11 was performed to examine the contributions of chemotherapy and radiation therapy to medical larynx-preserv-

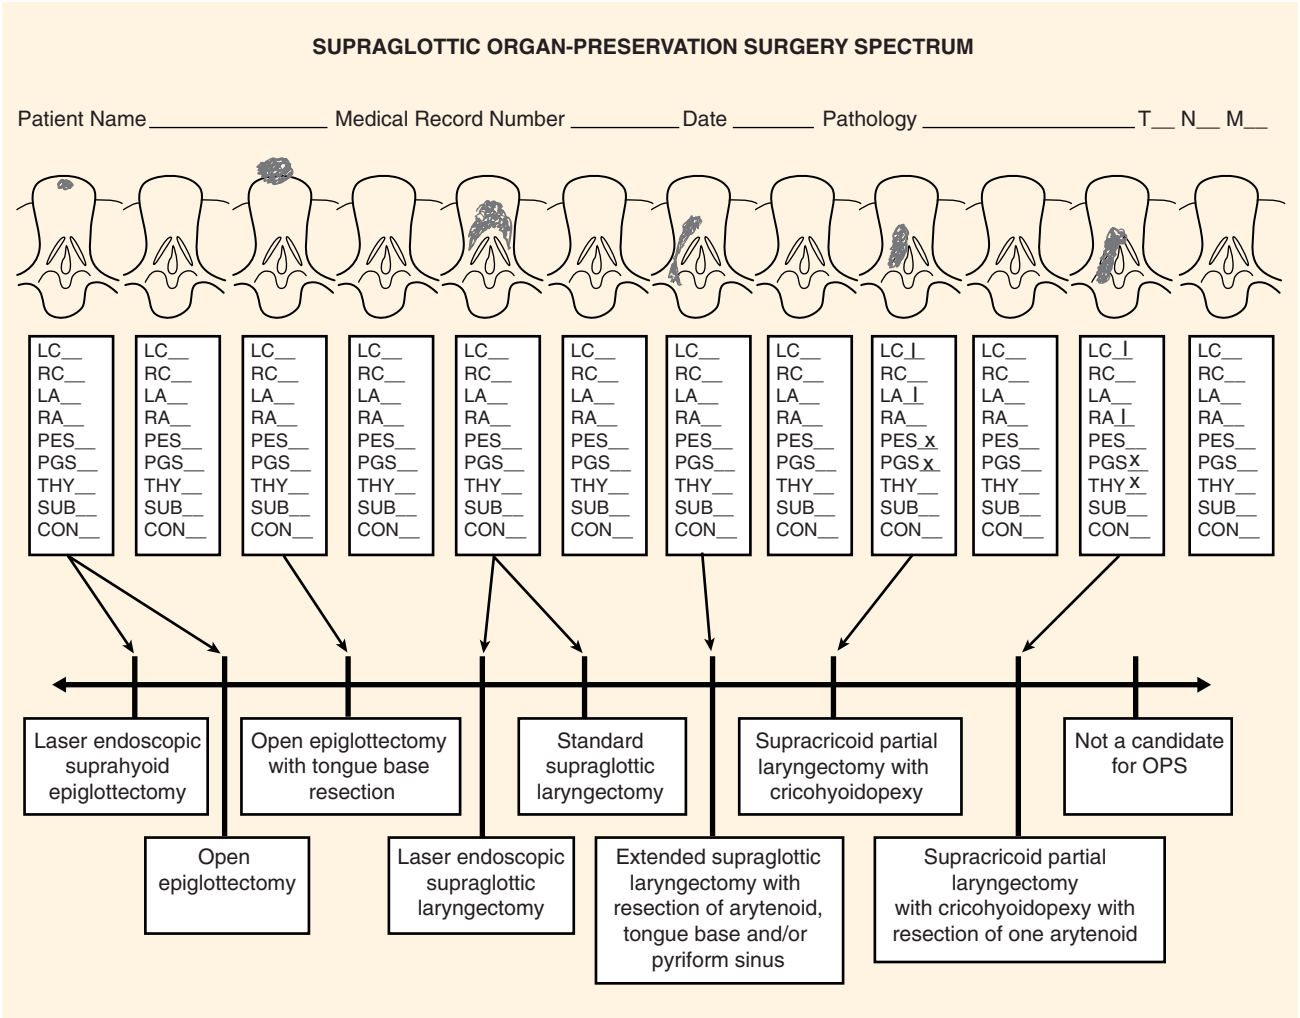

Figure 110-19. Supraglottic organ-preservation surgery spectrum. *LC,* left vocal cord mobility; *RC,* right vocal cord mobility; *LA,* left arytenoid mobility; *RA,* right arytenoid mobility; *PES,* preepiglottic space involvement; *PGS,* paraglottic space invasion; *THY,* early radiologic evidence of thyroid cartilage invasion; *SUB,* subglottic extension greater than 1 cm at midcord, or greater than 0.5 cm posterior cord level; *CON,* tumor and non-tumor contraindications. At the top of the form is a series of schematic diagrams of the larynx with additional descriptors in the text box below. At the bottom of the form is the spectrum of organ-preservation surgeries that are applicable. Representative cancers are shown in a spectrum from least extensive on the left through most extensive on the right. The mucosal extent is documented on the schematic. Mobility is documented with either a "blank" for normal mobility, "i" for impaired mobility, and "f" for fixation. An "x" documents involvement of the preepiglottic space, paraglottic space, thyroid cartilage, and a tumor- or non-tumor–related contraindication. This form may be used in surgical planning by drawing the lesion into a blank laryngeal schematic, in the appropiate place on the spectrum. *(From Weinstein GS, Laccourreye O, Brasnu D, et al.* Organ Preservation Surgery for Laryngeal Cancer. *San Diego: Singular Publishing Group; 2000.)*

ing regimens.[149] The conclusion from this study was that concurrent chemotherapy and radiation was superior to both induction chemotherapy followed by radiation and radiation alone for larynx preservation in patients with stage III and stage IV disease (T_2, T_3, or T_4 not extending to tongue base or through cartilage). The study states that radiation with concurrent cisplatin should be the standard of care for the previously staged patients.

The study fails to recognize that organ-preservation surgical strategies for laryngeal cancer have gained widespread acceptance throughout the past decade.[150-155] These strategies offer an alternative to concurrent cisplatin and radiation for similarly staged lesions (T_2, T_3, and selected T_4). The majority of the patients in the RTOG 91-11 trial were staged as T_3 tumors. Previously, the only surgical option available to most of these patients was a total laryngectomy. With the worldwide acceptance of organ-preservation surgical approaches (in particular, supracricoid laryngectomy), these patients now have an established surgical alternative to concurrent cisplatin and radiation with defined oncologic and functional outcomes.[38,156-161]

It is incumbent on all physicians caring for patients with laryngeal cancer to understand all of the available options for treatment. Correct staging is absolutely essential to this and requires an interpretation of dynamic laryngeal function that at present can only be made by direct examination of the larynx. This mandates the need for a head and neck surgeon's examination and interpretation of the larynx. The discussion held before treatment must include all organ-preservation approaches available for that patient's particular tumor. The ability of the patient to choose from these options allows for a tailoring of treatment that best suits the patient's needs and wishes. These options should be to the benefit of the patient with larynx cancer and should not be preferentially excluded.

Conservation Laryngeal Surgery and Radiotherapy

Essential differences exist between nonsurgical organ-sparing modalities versus conservation laryngeal surgery. In nonsurgical approaches the clinician accepts that when treating those with larger lesions within the spectrum of malignancy that more patients will have local

recurrence and rely on surgical salvage when possible, which frequently is total laryngectomy.[77] The advantage to this approach is that for the patients without local recurrence, the entire larynx is spared, and it is inferred that for those patients, the functional outcome is maximized. The approach of the conservation laryngeal surgeon is the opposite. When managing progressively larger lesions within the spectrum of malignancies, the procedure is chosen from the spectrum of conservation laryngeal procedures that then maximize local control while progressively removing more laryngeal tissue. The loss of functional anatomy usually manifests as permanent hoarseness when the glottis is resected and as temporary dysphagia when the supraglottis is resected. Long-term severe dysphagia for conservation laryngeal surgery is rare (see Tables 110-4, 110-5, and 110-9). The conservation laryngeal approach to organ preservation accepts decreased laryngeal function for the entire population of patients to decrease the morbidity and mortality associated with local recurrence. The nonsurgical approach to organ preservation accepts the sequelae of local recurrence in an effort to preserve anatomic structure for selected patients.

Although functional outcome after conservation laryngeal surgery is well documented in the literature, this has not been the case of the nonsurgical organ-sparing regimens for intermediate-stage to high-stage lesions. Outcomes in terms of vocal quality, long-term dysphagia, reliance on long-term enteral feeding, and need for tracheostomy need to be evaluated in future studies for the nonsurgical approaches to verify that preservation of anatomic structure ensures improved functional outcome.

Surgical salvage with conservation laryngeal surgery has been well documented in the literature. Early diagnosis of failure after radiotherapy for laryngeal carcinoma is often difficult because of posttherapeutic edema, erythema, and changes in laryngeal mobilities.[162] This often leads to late discovery of the recurrence, leaving most patients who are eligible for surgical salvage needing to undergo total laryngectomy.[131,163] Patients with failure at the glottic level who were amenable to vertical hemilaryngectomy in the preradiation period and in whom the tumor has not enlarged may undergo the procedure and expect a local control rate of 83.3% (15 of 18).[164] Although in the DeSanto and colleagues[131] series, 80% (24 of 30) of patients with supraglottic carcinoma who underwent radiotherapy and failed would have been theoretically amenable to supraglottic laryngectomy before radiotherapy, only 30% (9 of 30) underwent conservation laryngeal surgery for postradiation failure. Sorensen and colleagues[165] reported poor oncologic and functional results after supraglottic laryngectomy for radiation failure and advocated total laryngectomy in these patients. Lavey and Calcaterra[166] have stated, after a review of the literature, that vertical hemilaryngectomy should be contraindicated in the radiation failure case if (1) the tumor involves the arytenoid; (2) there is greater than 10 mm of subglottic extension anteriorly and greater than 5 mm posteriorly; and (3) cartilage invasion into the thyroid or the cricoid is present. Shaw[167] stated that supraglottic laryngectomy is contraindicated in the postradiation failure setting unless (1) the primary tumor is small; (2) the recurrence is located anteriorly; and (3) the carcinoma has never involved the anterior commissure. One alternative for larger lesions is to use either supracricoid laryngectomy with cricohyoidopexy or cricohyoidoepiglottopexy as the salvage procedure, which has a reported local control of 83.3% (10 of 12).[168]

It seems that supracricoid laryngectomy may be ideally suited to treat early (T_1 and T_2) glottic radiation failures. The en bloc resection of the entire thyroid cartilage and its contents along with a significant portion of the anterior subglottic mucosa makes it particularly attractive in those with anterior commissure recurrences. Often, the only salvage modality offered to these patients is total laryngectomy. The role of supracricoid laryngectomy in salvage of glottic radiation failures will be explained as more institutions use the technique.

Management of metachronous primary tumors is an important consideration. Roberts and colleagues[169] reported that the average annual risk for a second malignant neoplasm developing after a glottic carcinoma was 3.1% a year over the ensuing 10 years. Seventy-one percent of these second lesions occurred in the upper aerodigestive tract or in the lungs.[169] The physician should also consider the future management of second primary malignancies when planning treatment for the patient with primary cancer.

Postoperative Management Issues

Although postsurgical management varies from institution to institution, the central issues generally center on the timing of tracheal decannulation and on the approach to swallowing rehabilitation. In this section we discuss our approach to these management issues. We deflate the tracheotomy tube as early as possible postoperatively. In the absence of contraindications such as ventilator dependence, we drop the tracheostomy cuff on day one. Second, we remove the tracheostomy early, and our first attempts at decannulation are between days 3 and 5. The tracheostomy should be kept in for prolonged periods if there is laryngeal edema or salivary stasis. As a rule, patients undergoing vertical partial laryngectomies or supracricoid laryngectomies can be decannulated sooner than those undergoing supraglottic laryngectomies. Swallowing rehabilitation is not begun until the tracheostomy is removed, the stoma is closed, and the patient is swallowing his or her saliva. The larynx should always be visualized with indirect laryngoscopy before decannulation. If there are any ensuing airway problems, the tracheotomy tube should be immediately replaced. Although stridor is the sentinel sign of laryngeal airway impairment, other signs such as sweating or agitation should be carefully evaluated even in the absence of audible stridor. Finally, the speech pathologist is central to the speech and swallowing rehabilitation and is consulted early postoperatively.

Future Developments

In addition to open surgical approaches, endoscopic transoral laser microsurgery (TLM) has become widely accepted as a means of conservation laryngeal surgery. Results of TLM for glottic and supraglottic carcinoma have been widely reported, and proponents of this technique cite its advantages including organ and function preservation, avoidance of a tracheostomy, low morbidity, and shorter periods of hospitalization.[170-172] However, TLM may be limited by line of site visualization of the operative field, which may lead to the inability to obtain adequate exposure for resection of laryngeal carcinomas. This is because laryngoscopes are used to expose the operative field in conjunction with operating microscopes, which are positioned outside the oral cavity, allowing the surgeon to visualize a limited operative field that is in line with the microscope.

In an effort to overcome these limitations, preclinical transoral experiments with the *da Vinci* Robotic Surgical System (Intuitive Surgical, Inc., Sunnyvale, Calif.) in mannequin and cadaver models revealed that exposure of the laryngopharynx might be possible using mouthgags rather than laryngoscopes, with the prediction that this may also apply in the human clinical setting.[173,174] The *da Vinci* Robotic Surgical System consists of a robotic cart next to the patient with three arms, two placed laterally for the instruments and the middle one for the endoscopic camera. The surgeon controls the instruments through a separate console, which provides the surgeon with a three-dimensional view and translates the movements of the surgeons hands at the console to the robotic arms positioned in the patient's oral cavity. The robotic arms employ "wristed" instruments that allow 7 degrees of freedom and 90 degrees of articulation, providing the surgeon with improved dexterity and precision for transoral approaches. In addition, 0-degree and 30-degree endoscopes are available to allow visualization that cannot be obtained with the line-of-site view obtained with operating microscopes. Weinstein and colleagues[175-177] have reported the efficacy of transoral robotic surgery (TORS) for performing supraglottic laryngectomy and glottic microsurgery in the canine model, as well as a supraglottic partial laryngectomy in three human patients. They noted excellent visualization, minimal blood loss, and shorter operating times than traditional laser resection. Negative surgical margins, avoidance of tracheostomy, and a normal diet were achieved in all patients.

Multiplaner transection with monopolar cautery, using instruments that mimic normal hand movements including caudal to cranial transection, was seen to be advantageous over traditional laser excision, which is limited by "line-of-site" resection with carbon dioxide laser, no caudal to cranial resection possible, and no axial plane resection possible. As clinical experience has expanded, TORS for supraglottic and glottic resections has continued to have the advantages of improved visualization, shorter operating times, minimal blood loss, and excellent functional outcomes. With continued experience, TORS has the potential to be an integral part of the armamentarium for the conservation laryngeal surgeon.

Summary

In 2003 Forastiere and colleagues in their landmark report of a prospective trial comparing concurrent chemotherapy and radiation to other nonsurgical treatment for advanced laryngeal carcinoma concluded: "Radiotherapy with concurrent cisplatin should be considered standard care for patients desiring laryngeal preservation whose cancer is within the categories of disease studied in this trial, and laryngectomy should be performed only as salvage therapy. We believe that in most patients with laryngeal cancer, the disease can be managed without a primary surgical approach."[149] In a letter to the editors of the New England Journal of Medicine, Weinstein, Myers, and Shapsay responded to Forastiere and colleagues with this statement: "When patients with early or advanced laryngeal cancer are candidates for surgical approaches that preserve the larynx, it is the standard of care to discuss the surgical and nonsurgical organ-preserving options with the patient and allow the patient to participate in the choice of appropriate treatment."[178] Although the latter statement concerning the role of organ-preservation surgery was made by surgeons, this opinion has been expressed by nonsurgeons as well. In 2006 the practice guidelines for laryngeal preservation of the American Society of Clinical Oncologist (ASCO) were created by a multidisciplinary group, which included radiation oncologists, head and neck surgeons, and medical oncologists.[179] This ASCO multidisciplinary panel concluded that for both early and advanced laryngeal cancer surgical and nonsurgical options should be considered as standard options.[179] We agree with the contention of the ASCO laryngeal cancer practice guidelines, and the purpose of this chapter has been to provide an overview to clinicians involved in the diagnosis and treatment of laryngeal cancer to fully understand the surgical organ-preservation options.

A spectrum of conservation laryngeal procedures that allow for management of the broad spectrum of laryngeal carcinomas is available. The vertical partial laryngectomy, supraglottic laryngectomy, and supracricoid laryngectomy are accepted worldwide with established oncologic and functional outcomes. No single surgical approach is a panacea, and a conservation laryngeal surgeon may only perform a few of each technique to manage a large number of laryngeal carcinomas. Accurate understanding of the anatomy and physiology of the larynx and the behavior of neoplasm in a particular site is necessary to assess the three-dimensional extent of the malignancy preoperatively. A thorough understanding of the whole organ section literature is paramount for success in conservation laryngeal surgery. The conservation laryngeal surgeon uses a variety of surgical approaches to allow for the preservation of a functional larynx. The functional goals of conservation laryngeal surgery are speech and swallowing without a permanent tracheostomy. The acute functional sequelae vary but typically include temporary dysphagia and a tracheostomy. Among the procedures that have gained acceptance in multiple centers, including vertical hemilaryngectomy, supraglottic laryngectomy, and supracricoid laryngectomy, the rate of severe dysphagia requiring functional laryngectomy for aspiration has been low. The most common long-term functional sequela of conservation laryngeal surgery is hoarseness. If the choice of surgical procedure is based on sound principles gleaned from large series of patients reported in the literature, successful oncologic results in terms of local control are attainable. Open surgical approaches for laryngeal preservation afford the surgeon the opportunity to perform laryngoplasty to maximize functional outcome.

CHAPTER ONE HUNDRED AND ELEVEN

Total Laryngectomy and Laryngopharyngectomy

Christopher H. Rassekh

Bruce H. Haughey

Key Points

- Total laryngectomy remains as the standard by which other forms of treatment for advanced primary laryngeal carcinoma are evaluated. It should still be considered as a primary treatment modality for selected patients.
- Total laryngectomy is also occasionally indicated for advanced thyroid cancers or tumors of the oropharynx and/or neck that invade the larynx.
- The special subset of patients with laryngeal cancer who require a total laryngectomy instead of organ preservation therapy present management issues that are particularly complex.
- Higher complication rates can be expected in the setting of preoperative radiotherapy and chemoradiotherapy with longer and more complex salvage procedures. Pharyngocutaneous fistula is much less common in nonirradiated patients. Closure of the pharynx should be done in a meticulous fashion.
- Other factors that may predispose to complications include positive margins, technical errors, diabetes mellitus, hypothyroidism, and poor nutritional status.
- Total laryngectomy is also important for management of chronic aspiration as a result of diseases that render the larynx incompetent.
- Rehabilitation of swallowing and voice with tracheoesophageal speech allows a reasonably good quality of life after total laryngectomy for most patients.
- The tracheal stoma is the hallmark of total laryngectomy. Effective ways to create and manage an adequate stoma are available.
- Total laryngopharyngectomy is used for more advanced laryngeal and pharyngoesophageal carcinomas.
- Prognosis with hypopharyngeal carcinoma is poor compared with laryngeal carcinoma, but functional organ preservation rates are also poor, and although controversial, surgery incorporating adequate reconstruction for swallowing and voice is the best choice for many patients.
- The key to successful management of total pharyngeal defects following laryngopharyngectomy is free flap reconstruction. Fasciocutaneous flaps have significant advantages over visceral flaps.

Total Laryngectomy

Historical Development

Although Patrick Watson of Edinburgh often is credited with performing the first total laryngectomy in 1866, there is no recorded proof that the operation actually was done by him. Research into Watson's own article[1] apparently answers this question; Watson stated he performed only a tracheotomy while the patient was alive and then did a postmortem laryngectomy of the syphilitic larynx. Billroth of Vienna, on December 31, 1873, carried out the first total laryngectomy for a patient with laryngeal cancer. One month earlier, he had performed a vertical cricothyrotomy and local intralaryngeal excision of this patient's lesion. Gross pathologic recurrence necessitated further radical ablation,[2] but the total laryngectomy was punctuated by considerable bleeding, coughing, and arousal from the anesthetic. The patient died 7 months after surgery,[3] but Bottini of Turin in 1875 performed a total laryngectomy on a patient who survived for 10 years. In 1880 the operative or early postoperative mortality rates were approximately 50%.

This high mortality rate led Gluck of Germany to develop a two-stage procedure in which the tracheal separation was performed first, such that a healed tracheocutaneous stoma was present when the laryngectomy and pharyngeal closure were performed 2 weeks later. In the 1890s, with his pupil Sorenson, he then developed a successful single-stage operation, similar to contemporary techniques, in which the larynx was removed from above downward. Solis-Cohen, advancing from partial laryngectomies in the 1860s, reported at the 1892 Philadelphia County Medical Society Meeting carrying out a total laryngectomy by use of similar Gluck-Sorenson techniques, although Frederick Lange of New York apparently reported performing the first total laryngectomy in the United States in 1879.[3,4] Radiation therapy was popular for treatment of patients with laryngeal cancer during the first half of the twentieth century, although with improvements in surgical and anesthetic technique and a recognition of radiation therapy's

limitations, surgery (including total laryngectomy) still maintained a prominent role in the second half of the century. In the past two decades, there has been an increased focus on organ preservation. For intermediate and advanced-stage tumors, concurrent chemotherapy and radiotherapy have become part of the standard of care,[5] particularly for those patients who are in some way unsuitable for organ preservation surgery such as transoral laser or robotic excision. However, total laryngectomy as a primary treatment modality is still relevant for many patients. The attention on chemoradiation has resulted in an increase in salvage total laryngectomy and laryngopharyngectomy procedures, complicated by a greater potential for complications due to the tissue damage following chemoradiotherapy.

Indications for Total Laryngectomy

Malignant Disease

With the spectrum of organ preservation surgery that is now available,[6] the need for total laryngectomy as the only surgical option for those with laryngeal cancer has decreased. Organ preservation surgery includes specific procedures for supraglottic and glottic cancer. There are two major organ preservation surgical strategies, transoral (endoscopic) and open. Transoral procedures range from the very limited endoscopic resections that most head and neck surgeons can accomplish to extensive laser procedures that require greater surgical experience and specialized instrumentation,[7,8] covered in Chapter 109. Open procedures include the more conventional vertical partial laryngectomy group of procedures and horizontal supraglottic partial laryngectomy group. In the early 1990s, a group of open operations called the supracricoid partial laryngectomies became more popular. The supracricoid partial laryngectomy with cricohyoidopexy (SCPL-CHP) for selected supraglottic carcinomas and the supracricoid partial laryngectomy with cricohyoidoepiglottopexy (SCPL-CHEP) for selected glottic carcinomas have extended the spectrum of tumors that can be managed surgically while avoiding total laryngectomy.[9] More information about organ preservation surgery and nonsurgical organ preservation are covered in Chapters 110 and 112. In addition to the increased number and success of open procedures for organ preservation, even in the setting of prior radiotherapy, the continually improving instrumentation and experience of endoscopic transoral resections continues to improve, which reduces the need for total laryngectomy.[10-14] Organ preservation surgery can safely be used after radiotherapy but with a higher complication rate.[15]

Another operation that avoids total laryngectomy is the "near-total laryngectomy."[16] This procedure is not strictly an organ preservation operation because it does not maintain an airway without a tracheostome. Essentially, it can be viewed as a total laryngectomy with an epithelialized voice fistula.[17] Nonsurgical treatment for patients with laryngeal malignancy also is established as primary treatment in some centers. Management includes definitive radiation alone with surgery for salvage for patients with primary lesions up to T3 or neoadjuvant chemotherapy and radiotherapy, with total laryngectomy reserved for those with unresponsive tumors. The frequently cited Veterans Affairs study[18,19] randomly assigned patients with advanced laryngeal cancer to chemotherapy and radiotherapy or total laryngectomy. Although present, the increased survival in the surgical arm was not significant. Criticisms of the study prompted a head and neck intergroup trial that randomly assigned patients to three groups and compared radiation alone versus concurrent versus sequential chemotherapy with radiotherapy. This study has recently been published and demonstrates that concurrent chemotherapy with radiotherapy is superior to sequential chemotherapy followed by radiotherapy or radiation alone in terms of local control and organ preservation.[20] However, there was no surgical arm to this study, thereby falling short of establishing a new standard of care. Furthermore, using primary concurrent chemoradiation therapy, the 5-year results for both disease-free survival (39%) and laryngectomy-free survival (46%) show that this method leaves the majority of patients either dead or absent their larynx at 5 years.[21] Therefore, this leaves much room for improvement in treatment of laryngeal cancer. Other studies have shown that if nonsurgical organ preservation is to be used, concurrent chemotherapy with hyperfractionated radiotherapy is more effective than radiotherapy alone[22] and that hyperfractionated radiotherapy is more effective than standard radiation alone.[23] Newer trials are investigating the impact of induction chemotherapy to assess tumor response. A complete (or near complete) response to chemotherapy then selects the patients for concurrent chemotherapy and radiotherapy.[24] No biologic marker yet identified can reliably predict which patients are better treated surgically. This is also the topic of investigations in concurrent studies.[25] Because the survival of the two treatment strategies is equivalent, quality-of-life issues are of paramount importance. Recently, a study demonstrated that in the intergroup trial, patients who had total laryngectomy after radiotherapy had a high complication rate including a risk of pharyngocutaneous fistula of up to 30%, highest in the concurrent chemotherapy group.[26] Studies that have evaluated the quality of life after nonsurgical management of advanced laryngeal cancer do suggest that organ preservation is associated with improved quality of life.[27,28] Although the details of such studies are beyond the scope of this chapter, the results indicate that more extensive analysis of the quality of life is important. These studies are difficult to accomplish because many patients are not available after the study, and the quality of life of the survivors might be significantly different than those of the patients who have died, particularly if they died of local complications related to uncontrolled primary site disease. Total laryngectomy still remains a viable option as the primary surgery for advanced cancer or as salvage surgery after radiotherapy and finally for a group of less common conditions. Overlap between these indications occurs. For example, a patient with radionecrosis of the larynx may be found to have residual tumor on permanent sections and, as such, the surgery was salvage in hindsight. Similarly, a tumor that fails radiotherapy may also be causing chronic aspiration and may be too large to allow for any sort of organ preservation surgery. This sort of patient has three (or more) of the following indications for undergoing the procedure.

Indications

1. Advanced tumors with cartilage destruction and anterior extralaryngeal spread; particularly presenting initially with laryngeal dysfunction (including vocal cord paralysis), airway obstruction, or severe aspiration (these patients are not good candidates for "organ preservation" because the organ already has been damaged and will not likely function even if preserved anatomically).[29]

2. Posterior commissure or bilateral arytenoid/cricoarytenoid joint tumor involvement, as is sometimes seen in advanced supraglottic tumors.

3. Circumferential submucosal disease with or without bilateral vocal cord paralysis.

4. Subglottic extension with extensive invasion of the cricoid cartilage.

5. Radiotherapy or chemoradiation failures including those who have also had partial laryngectomy failure.

6. Completion laryngectomy for failed conservation or extensive endoscopic surgery.

7. Hypopharyngeal tumor originating at or spreading to the postcricoid mucosa.

8. Massive neck metastases or thyroid tumors (usually recurrent) invading both sides of the larynx from outside the laryngeal skeleton.

9. Advanced tumors of certain histologic types that are incurable by endoscopic resection, chemotherapy, or radiotherapy (e.g., adenocarcinoma, spindle cell carcinoma, soft tissue sarcomas, minor salivary gland tumors, large cell neuroendocrine tumors); chondrosarcomas of the thyroid cartilage.

10. Extensive pharyngeal or tongue base resections in patients who are at high risk for aspiration problems.

11. Radiation necrosis of the larynx, despite tumor control, unresponsive to adequate antibiotic and hyperbaric oxygen management. This condition can be painful and also predispose patients to aspiration, and often tumor is found when total laryngectomy is performed.

12. Severe irreversible aspiration, with the laryngectomy used for complete separation of the air and food passages. This indication should be rare, considering the variety of other separation or closure procedures available.

Patient Selection and Workup

The following patient requirements should be met before a total laryngectomy is performed.

1. Candidate for general anesthesia; consider severe comorbid conditions as a relative contraindication.

2. Informed consent including realistic understanding of total laryngectomy state and lifestyle after surgery (including the risk of drowning and the need to avoid swimming and certain risky activities and the lack of sense of smell in the event of fire, smoke, or toxic fume exposure).

3. Sufficient performance status, especially dexterity, to allow basic self-care of stoma.

The workup required for a total laryngectomy includes the anesthetic-related assessment of general health (not elaborated here) and specific tests relevant to the larynx. Assuming the patient has a laryngeal carcinoma, the following are required:

1. History (especially details of any previous radiation) and physical examination.

2. A comprehensive head and neck examination, especially the neck, for detection of cervical metastasis.

3. Biopsy proof of malignancy and careful endoscopic assessment of tumor location; use of both microscopic and telescopic endoscopy can help determine the need for total laryngectomy and can also help determine which patients are likely to have extensive subglottic extension or submucosal extension in the hypopharynx.

4. Synchronous primary tumor screening including bronchoscopy, esophagoscopy, and/or barium swallow, chest radiography, and chest computed tomography (CT) in selected cases.

5. Metastatic screen when indicated.

6. Neck CT for assessment of cartilage or pre-epiglottic space invasion in those with advanced or radiation-recurrent lesions and for assessment of radiologically detectable neck metastasis. PET and MR scan may also be useful.

7. In the laboratory evaluation, diabetes and hypothyroidism should be evaluated and managed appropriately because they increase the risk of complications. A nutritional screen is also indicated. Evaluation for the potential for postoperative alcohol withdrawal is also important.

The role of metastatic workup is detailed in other chapters, as are indications for different imaging studies.

Surgical Technique (see Key Indicator Video on website)

Resection

Proper patient positioning provides access to the anterior part of the neck for the surgeon and the assistant. Positioning is best achieved by placing the patient on a table fitted with a head holder, allowing the head to be cantilevered out but remain well supported. This also assists bilateral neck dissection, which is often performed "in-continuity" and allows surgeons to position themselves all the way around the head. The table is turned 180 degrees from the anesthesiology team to further assist access to the patient. Before the operation day, airway management is planned with the anesthesiologist so that an agreement is reached regarding timing of tracheotomy and intubation. In the unobstructed larynx the anesthesiologist may pass an orotracheal tube with anesthetic induction, which may be removed at subsequent tracheotomy or left in situ until tracheal transection is performed at the end of the laryngectomy. With an obstructed airway or in a case in which intubation may displace malignant tissue into the lower airway, a preliminary tracheotomy with the patient under local anesthesia is performed. The tracheotomy skin incision is made at the intended site of the final stoma. The stoma can be placed in the line of the incision (long flap) or 2 to 3 cm inferior to the incision (Fig. 111-1, A and B). The advantage of the former is that creation of the stoma is more

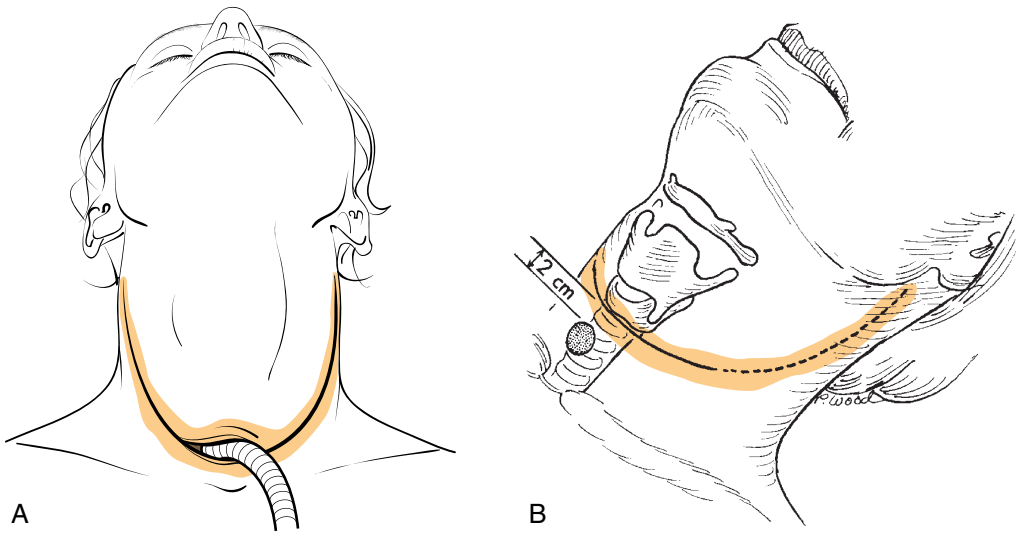

Figure 111-1. Incision options for total laryngectomy and total laryngopharyngectomy. **A,** Long apron flap without separate incision for tracheostomy from mastoid tip to mastoid tip intersecting the midline at approximately the level of the cricoid cartilage, usually about 2 cm above the sternal notch in the midline. **B,** Short apron flap with separate tracheostome incision 2 to 3 cm inferior to the flap incision. A U-shaped incision (not shown) is rarely used, but feasible when neck dissection is not performed.

reliable and avoids a bipedicled bridge of skin between the flap incision and the tracheostomy incision, which can result in stenosis of the stoma. The advantage of the latter is that in the event of pharyngocutaneous fistula, which requires diversion, the stoma is less likely to be involved in the resulting wound. The latter consideration is perhaps more important in previously irradiated patients because the risk of fistula in primary total laryngectomy is low. This configuration also avoids the technical nuances of bilateral, three-point closures at the stoma necessitated by exteriorizing the lower cut tracheal end through the laryngectomy skin incision. In the long flap approach, the three-point closure is performed after the inferior aspect of the stoma is completed, elongating it with the technique shown in Fig. 111-6. This is somewhat more difficult to accomplish with the stoma created 2 to 3 cm into the inferior flap because the trachea is not anchored to the lateral aspect of the dissection. Ultimately, the comfort level of the surgeon determines the choice of incision.

Every attempt should be made to enter the trachea with a horizontal cut at the ultimate level intended for tracheal transection, but in the event that a tracheotomy already is in place, the tracheal transection will be 2 cm inferior to the existing tracheotomy site (if possible). A precurved or flexible reinforced cuffed tube then is passed into the trachea, and adequate ventilation is confirmed. The cuff of the tube is prepped into the field so that the tube can be removed intermittently for suture placement during creation of the stoma.

For access to the larynx itself, a curved, horizontal neck skin incision is preferred because of its minimal intersection with the pharyngeal closure and its potential for extension laterally into a neck dissection incision. Once the incision is deepened through, but not beyond, the platysma, flaps are elevated superiorly and inferiorly in the subplatysmal plane until there is exposure above to the upper border of the hyoid bone and below to the cervical trachea. The anterior jugular veins and the prelaryngeal Delphian node are left undisturbed on the specimen, as are the strap muscles. The sternocleidomastoid muscle then is identified along its anterior border on each side. The investing layer of cervical fascia is incised longitudinally from the hyoid above to the clavicle below. The omohyoid then is divided, which allows entry to the loose areolar compartment bounded laterally by the sternomastoid muscle and carotid sheath and medially by the pharynx and larynx contained in the visceral compartment of the neck. Appropriate neck dissections are performed. The extent of neck dissection is beyond the scope of this chapter, but a few points merit mention. For supraglottic carcinoma, the minimal neck dissection to be performed is selective neck dissection, stations II and III bilaterally. It is extended to level IV and possibly IB and V if lymphadenopathy indicates the need. For advanced glottic carcinoma with supraglottic involvement, the same procedure is recommended. Unilateral (ipsilateral) neck dissection can be considered for T3 glottic carcinoma. For patients who have previously been irradiated, evidence still supports selective neck dissection.[30,31] In general, both neck dissections can be pedicled at the thyrohyoid membrane area and the resection can easily be done en bloc.

The strap muscles then are divided inferiorly from their sternal origins and elevated to expose the thyroid gland (Fig. 111-2, A). Controversy exists with regard to thyroidectomy as part of a total laryngectomy. Studies note that involvement of the thyroid gland is rare.[32] However, when there is nodal disease in the jugular chain from glottic or subglottic cancer, the thyroid is at high risk because of the paratracheal and parapharyngeal lymphatics associated with the thyroid. Also, in patients who have invasion of the thyroid or cricoid cartilage in close proximity to the thyroid gland, the gland may become directly involved by the tumor. The risk to the thyroid is highest with transglottic cancers that extend more than 1 cm subglottic.[32-34] In some cases, both lobes of the thyroid should be removed because of these risk factors. When the lobe of the thyroid is to be removed, the superior and inferior thyroid vascular pedicles are therefore ligated and divided, as is the middle thyroid vein. The lobe(s) to be preserved then is (are) dissected off the laryngotracheal skeleton from medial to lateral, thereby preserving blood supply to the remaining thyroid and parathyroid parenchyma by way of inferior thyroid vessels (the superior thyroid artery can be preserved also if oncologically sound, but this is not necessary). An effort should be made to preserve the vascularity to the parathyroid glands, but if a parathyroid gland is noted that is poorly vascularized after the procedure, this can be reimplanted into the neck musculature as is done for parathyroidectomy in thyroid cancer. Next, after dividing and ligating the upper and lower extent of the anterior jugular veins, the superior aspect of the hyoid bone is skeletonized by detaching the mylohyoid, geniohyoid, digastric sling, and hyoglossus in sequence from medial to lateral (see Fig. 111-2, B). "Cold" knife dissection should be used lateral to the lesser cornu, avoiding excess electrical stimulation or direct damage to the hypoglossal nerve. Caution is advised for supraglottic cancers that involve the aryepiglottic fold, pyriform sinus, or vallecula because too much skeletonization of the hyoid bone and thyrohyoid membrane area may put the surgeon in close proximity to the deep extent of the tumor, which might result in a close or positive margin histologically. This is not a concern with completely endolaryngeal cancers. The sternohyoid and thyrohyoid muscle attachments on the lower border of the hyoid bone remain undisturbed. Further laryngeal cartilage skeletonization now is performed if the tumor does not extend outside the pyriform fossa. The posterior border of the thyroid cartilage lamina is rotated anteriorly by upward traction, allowing sharp release of the constrictor muscles from the inferior to the superior cornu (see Fig. 111-2, C). Above the superior cornu, the laryngeal branch of the superior thyroid artery should be identified, ligated, and divided before it penetrates the thyrohyoid membrane.

The pharyngotomy incisions and definitive laryngeal removal now are performed. To avoid contact with the neoplasm or cutting through its submucosal extensions, the pharynx is entered contralateral to the tumor. If superior extension to the tongue base is present, lateral pharyngotomy behind the thyroid cartilage is performed, and by use of a headlamp, the extent of tumor is inspected. A safe 2-cm margin of normal-looking mucosa then is preserved with further cuts from below, progressing superiorly behind the thyrohyoid membrane, around the hyoid bone, and then transversely across the vallecula or tongue base. By contrast, if the disease is confined below the level of the hyoid, entry by way of the vallecula is feasible with a direct anteroposterior approach (Fig. 111-3) in the horizontal plane of the upper hyoid border. Strict maintenance of this plane, avoiding excessive inferior traction on the hyoid itself, precludes violation of the pre-epiglottic space. Once the mucosa is breached, the epiglottis' tip is identified, grasped with an Allis forceps if tumor free, and gently pulled anteriorly out of the pharyngotomy. A view of the endolarynx and pharynx now is possible to assess tumor extent and to plan appropriate mucosal cuts (see Fig. 111-2, D).

With a Mayo scissors, bilateral, inferiorly direct cuts are made, releasing the lateral pharynx from the larynx. The inside scissors blade is on mucosa, and the outside blade is on constrictor musculature. As these vallecula-to-pyriform sinus incisions are made, the larynx is further angled anteriorly out of the wound until it is released to the apices of the pyriform sinuses. The postcricoid mucosa is exposed and incised sharply in the transverse direction connecting the inferior extent of both lateral incisions across the lower half of the cricoid lamina. A plane of blunt dissection initially behind the posterior cricoarytenoid muscle, but from there down between the trachea and longitudinal esophageal muscle, is then opened until the desired level of tracheal transection is reached. Optimum exposure of the trachea at this stage is achieved by further lateralization of the preserved thyroid lobe and then followed by knife transection of the trachea itself. This cut is bevelled upward from anterior to posterior (see Fig. 111-6, A), with special care not to encroach on any subglottic tumor extension. If the latter is present, a 1.5- to 2-cm margin of healthy-appearing trachea should be resected in continuity with the larynx to avoid stomal recurrence.[35] If a preliminary tracheotomy had not been performed, the oral endotracheal tube is next withdrawn from the tracheal stump and a new, cuffed, flexible tube is inserted for connection to new anesthesia tubing. As an alternative, the steps can be altered slightly as indicated by the pathology. As long as there is not extensive subglottic spread, preliminary tracheotomy assists the resection greatly. This is performed after dissection of the thyroid gland and skeletonization of the thyroid cartilage. The trachea is entered 2 cm below the inferior extent of tumor, and careful inspection is performed on entry. The endotracheal tube is withdrawn, and the trachea is further incised laterally with a

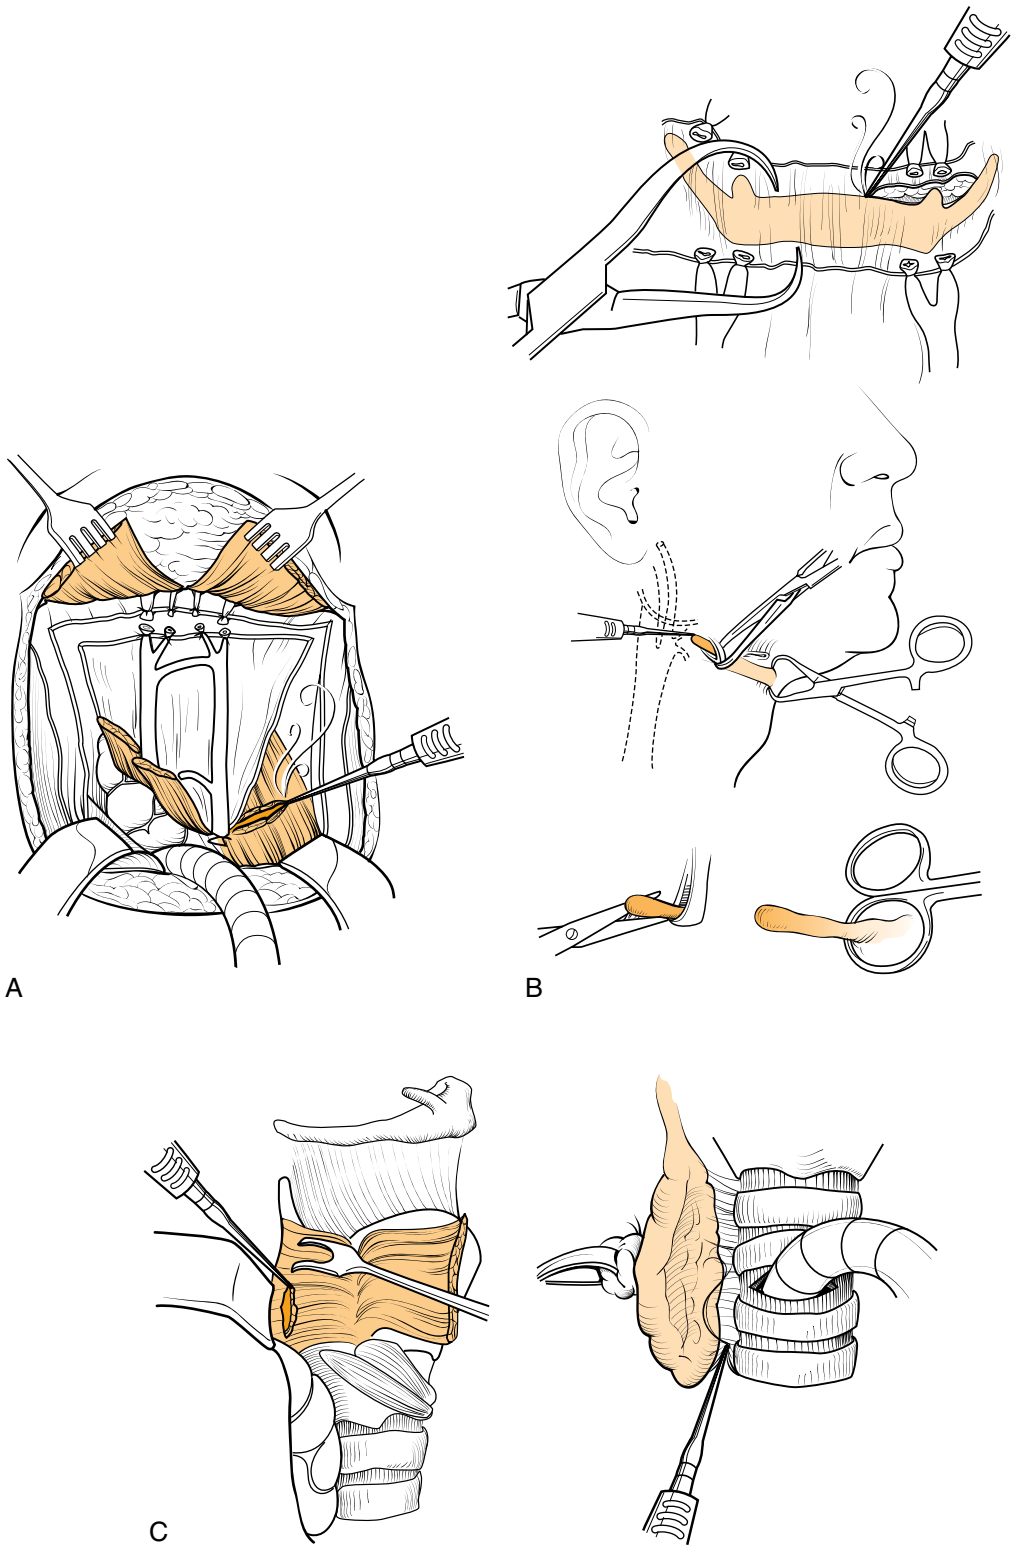

Figure 111-2. Skeletonization of the larynx. **A,** Division of the strap musculature after elevation of a subplatysmal flap. The omohyoid is divided inferiorly, usually during the neck dissection. The sternothyroid and sternohyoid muscles are divided inferiorly to expose the thyroid gland and trachea. **B,** Division of suprahyoid musculature. This is performed staying close to the superior aspect of the hyoid bone. Cautery is avoided lateral to the lesser cornu to avoid injury to the hypoglossal nerve. In this area the hyoid is retracted in such a way as to distract the greater cornu inferiorly, and a scissor is used to release the cornu staying right on the bone. **C,** Division of constrictor musculature along the lateral aspect of the thyroid cartilage and dissection of the thyroid. If the thyroid is to be resected, it is elevated and the dissection proceeds directly to the tracheoesophageal groove. If the thyroid is to be preserved, the lobe is dissected away from the tracheoesophageal groove after division of the isthmus. Electrocautery dissection is useful to minimize bleeding in this area. The degree of skeletonization depends on tumor extent. Once the thyroid cartilage is skeletonized, the superior laryngeal neurovascular bundle can be divided to decrease bleeding during the resection.

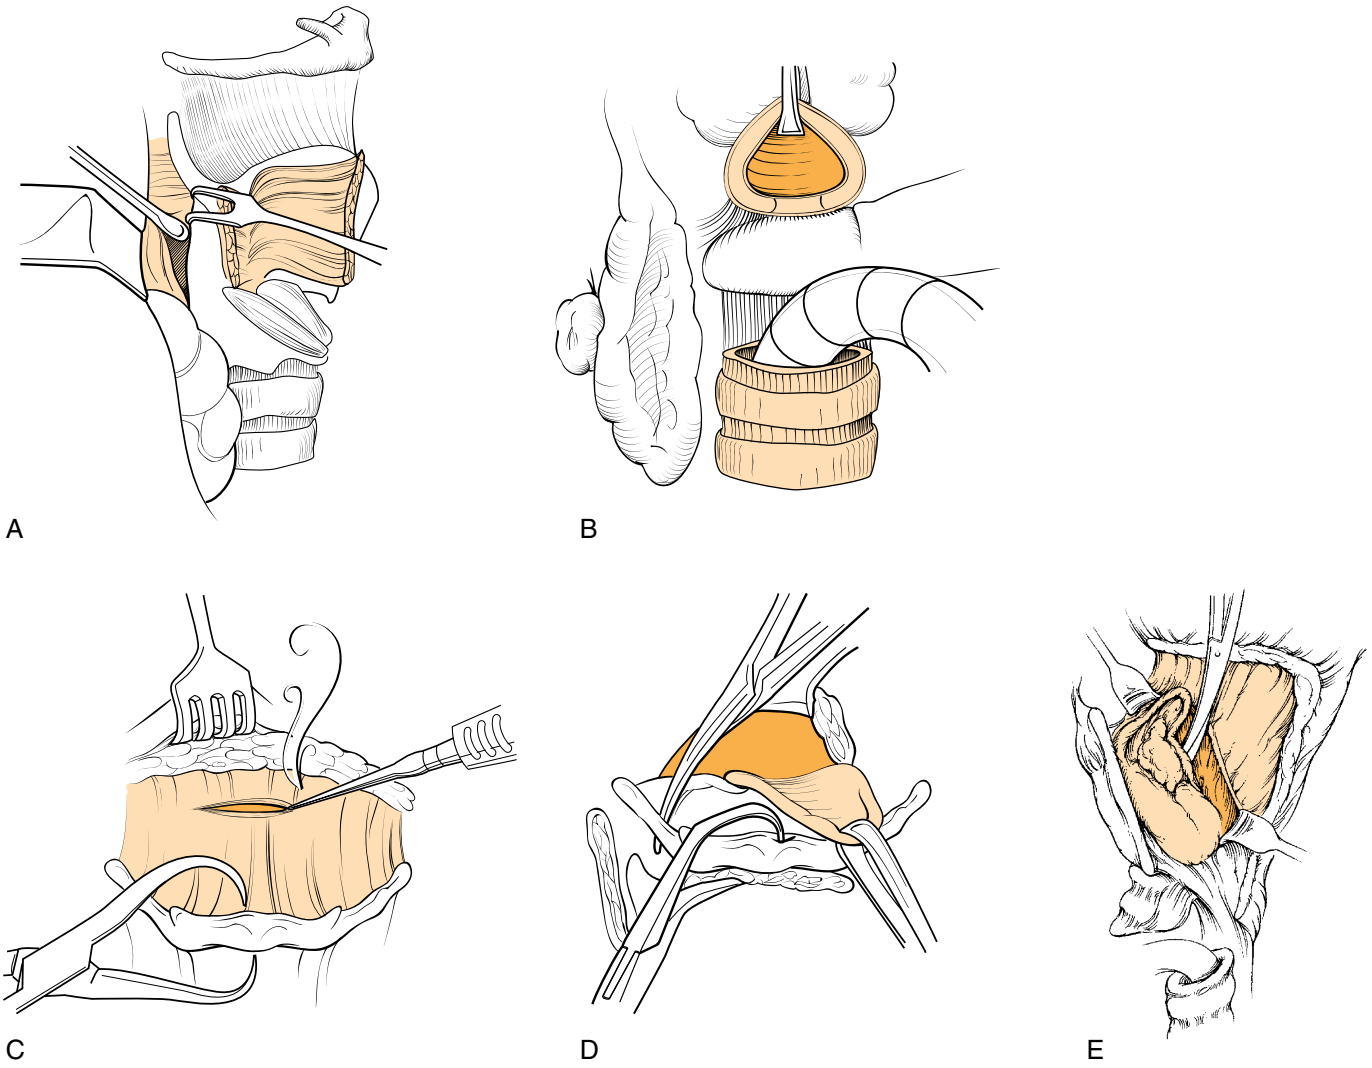

Figure 111-3. Entry into larynx. **A,** Use of a Freer elevator to mobilize the pyriform sinus and internal perichondrium from the thyroid cartilage. This should not be performed if the pyriform sinus is likely to be involved by the tumor. **B,** The trachea is transected, and the ligamentous attachments are divided permitting dissection of the trachea away from the upper esophagus up to the level of the posterior cricoarytenoid musculature. This cut is beveled as shown in Figure 111-6. This step is delayed if there is concern about significant subglottic extension. **C,** Dissection follows the hyoepiglottic ligament to the epiglottis and vallecula to avoid entry into the pre-epiglottic space. **D,** If clinically uninvolved, the vallecula is entered on the nontumor side, and if it is not involved, the tip of the epiglottis is grasped. **E,** The pharyngoepiglottic fold cuts are extended. If uninvolved, the previously preserved pyriform sinus mucosa is preserved by transecting the mucosa close to the aryepiglottic fold. This is accomplished by placing one scissor blade in the lumen and the other between the previously released internal perichondrium and the thyroid cartilage. This leaves the larynx pedicled only on the mucosa of the anterior esophageal inlet, which can be transected under direct vision preserving as much mucosa as is oncologically sound. If the trachea was not previously transected, it is done at this time to release the specimen.

beveled cut (see Fig. 111-6, A). A reinforced tube is placed and a sterile connector passed through the drapes to connect to the circuit. The trachea is then transected by making a notched incision in the posterior wall. This is taken down to the esophageal musculature. Once the ligamentous attachments and the recurrent laryngeal nerve are divided, blunt dissection can be performed up to the level of the posterior cricoarytenoid musculature. Then, when the surgeon enters the larynx and completes the mucosal cuts from superiorly along the aryepiglottic folds, the specimen is pedicled on the postcricoid mucosa only, and this assists the final transection, which can reduce the blood loss. The surgeon places a pack in the pharynx and neck while inspecting the specimen for orientation and margin assessment (Fig. 111-4). After the specimen is passed from the table, it is carefully inspected for adequacy of resection, and a pathologist's frozen section study of the patient's entire cut margins including trachea, tongue, and pharyngeal mucosa is requested. The tracheal margin is critical because there are patients in whom submucosal occult microscopic disease spreads down the trachea, despite relatively normal-looking mucosa. Excising all disease helps prevent stomal recurrence. The wound is thoroughly irrigated, all clots are removed, and hemostasis is achieved.

If a primary tracheoesophageal puncture is to be performed, creating the tracheostome before pharyngeal repair may be considered because it enables definitive positioning of the trachea relative to the esophagus and skin before a puncture site is selected. A pair of right-angled forceps then is passed into the esophagus, with the tip elevating the posterior tracheal wall at the intended puncture site (see Fig. 111-7). A tracheoesophageal stab incision is made, exposing the forceps tip, and with these, a catheter is grasped, pulled into the pharynx, and then fed down the esophagus. This is secured to the anterior chest wall skin with an op-site and suture. The previously described resection technique clearly needs to be modified according to the extent of tumor spread. A common variation is the "wide-field" laryngectomy, in which overlying neck skin is resected in continuity with the larynx and thyroid gland (see Fig. 111-8). This method is sometimes prudent for tumors that

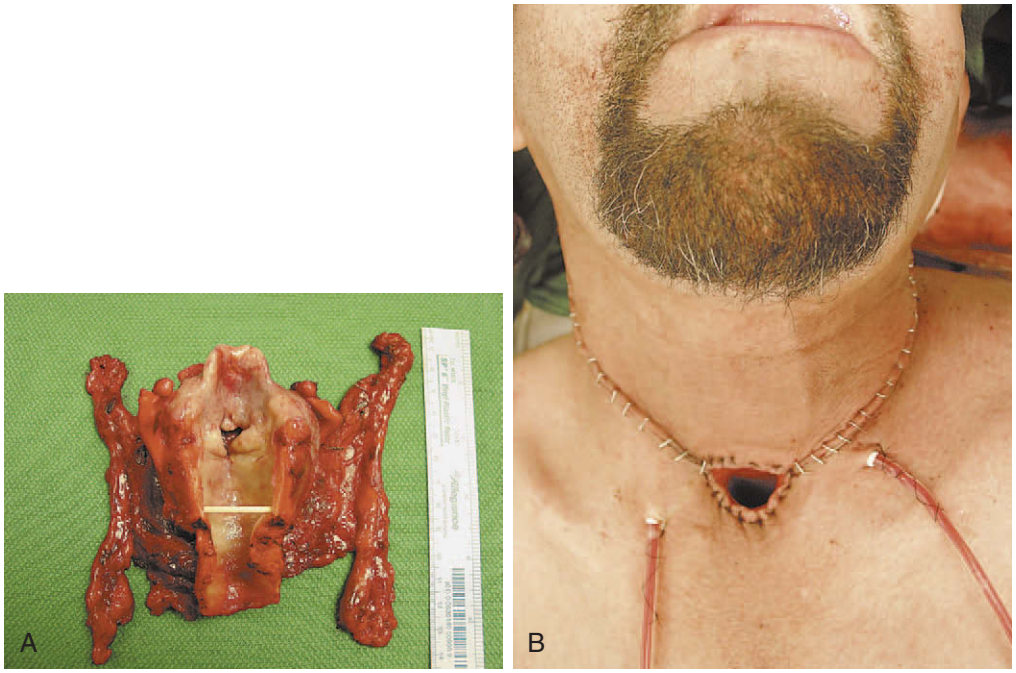

Figure 111-4. Specimen and resulting wound. **A,** Total laryngectomy specimen in continuity with bilateral selective neck dissections. **B,** Final closure with stoma in long flap approach.

have invaded soft tissue outside the laryngeal skeleton but usually requires pedicles of free flap to close the neck and create a stoma.

Repair and Reconstruction

Pharynx

Pharyngeal reconstruction is currently performed by direct closure or flap augmentation. Configurations for a direct repair are T shaped or linear (horizontal or longitudinal) (see Fig. 111-5). Selection of closure type is based on an assessment of the shape and size of the pharyngeal defect, elasticity of remaining tissue, and simulated wound approximation before suturing. The least-tensioned apposition of wound edges is the best; it is usually T shaped and results in minimal or no horizontal pharyngeal shelf formation.[36] However, a straight closure is less prone to technical failure in patients with abundant pharyngeal mucosa for closure.

The pharyngeal wall is closed in a single layer. A running or interrupted closure, according to the surgeon's preference, is used with particular attention to inversion of the mucosal edges into the pharynx. This inversion is achieved with an absorbable stitch that runs horizontally through the submucosa, without penetration of the mucosal surface. A longer retained material such as polyglycolic acid (3-0) is used and is adequate for irradiated tissue. Large series of stapled closures have also been reported.[37] Although some advocate closure of the pharyngeal muscle, this is not necessary. Reinforcement of the suture line with muscle sutures may be performed in selected cases where the mucosa has been compromised by radiation, but it is not a substitute for good mucosal closure. One study[38] has shown that a mucosal closure alone is sufficient for sound healing. Closure of muscle can lead to difficulty with tracheoesophageal speech.[39] and dysphagia. Some surgeons recommend a closure of the muscle over the suture line with a constrictor myotomy performed laterally and myotomy inferiorly along

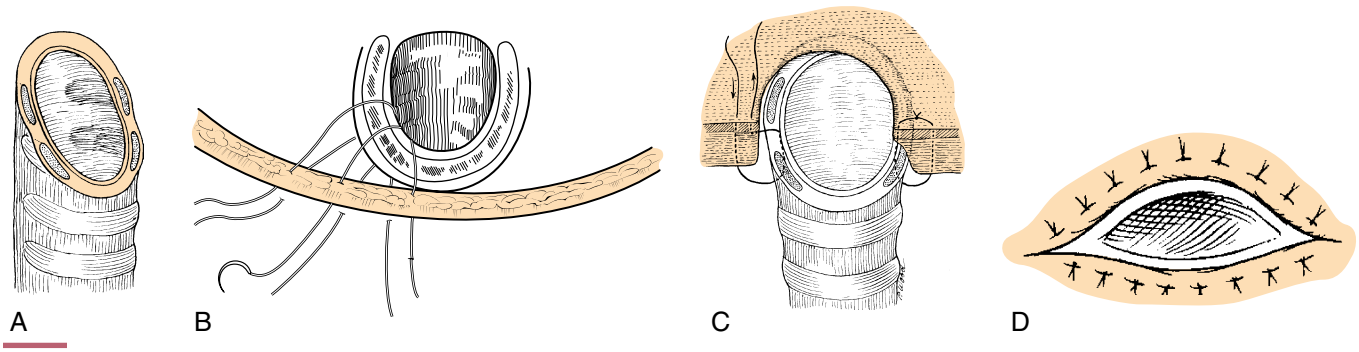

Figure 111-6. Steps to avoid stenosis in creation of tracheostoma (long flap incision). **A,** Bevel the tracheal cut such that more posterior wall is preserved. This is done by curving a scissor upward as the anterior tracheostomy is extended laterally. The posterior wall is transected with a V-shaped incision in the mucosa to lengthen it and prevent scar contracture. **B,** Elongate the anterior edge of the stoma by placing sutures from midline outward, proceeding farther along the skin than the trachea and by continuing this well onto the lateral portion of the trachea. **C,** Bury the exposed tracheal cartilage with a half-buried vertical mattress suture from far on the skin around the tracheal cartilage and then back through the near edge of the skin tying the suture on the skin. To minimize granulation tissue, an effort should be made to place these sutures submucosally. Absorbable sutures are preferred. 2-0 Vicryl is advisable for the central suture, and 3-0 Vicryl is used for the remainder. **D,** Final closure including appearance of stoma using long-flap approach and the stoma technique described in **A** through **C.** Note the quite ample diameter of the stoma that results from suture placement in the manner described.

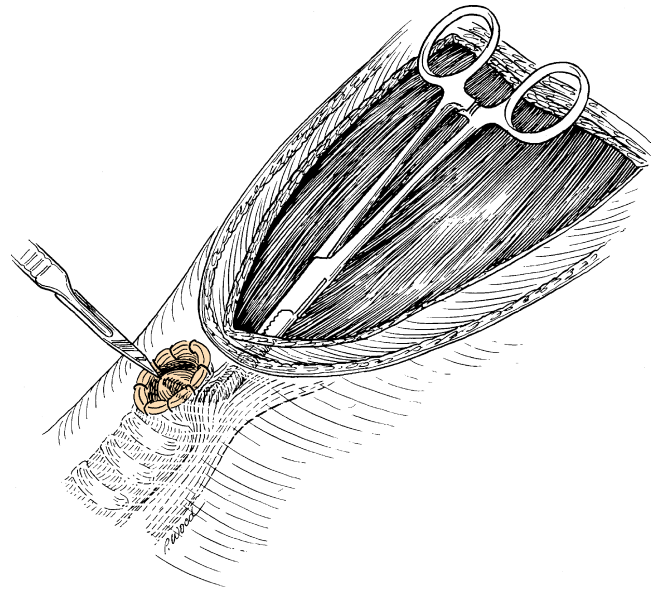

Figure 111-7. Technique of tracheoesophageal puncture. See text for description of technique.

the lateral aspect of the esophagus, sometimes called a cricopharyngeal myotomy (somewhat of a misnomer given that the cricoid has been removed). This technique reinforces the closure with a second layer but avoids the circumferential effect of the muscle closure.

If there is insufficient pharyngeal wall to close over a 36-French (F) dilator, a flap repair should be considered to increase the circumferential dimension of the neopharynx. Hui and colleagues[40] addressed the question of the width of the pharyngeal wall remnant relative to postoperative dysphagia and concluded that a remnant as small as 1.5-cm wide was sufficient to avoid dysphagia, although the study included only one patient with a remnant as small as 1.5 cm. Reconstructive options include a myocutaneous flap, a muscle flap, or a microvascular free flap. In extremely difficult patients, a controlled salivary fistula can be created to avoid catastrophic wound problems. In such patients, the flap will allow a vascularized bed that will ultimately allow removal of the conduit that is placed.

Tracheal Stoma

For the long flap approach, the stoma is inserted into the center of the lower flap with a central suture of 2-0 Vicryl excising an ellipse of skin if needed. In the short flap, the permanent end-tracheal stoma is created by excising a shield-shaped skin island from the lower neck flap in the midline, just above the sternal notch. Any excess adipose tissue or bulky sternomastoid muscle or tendon is excised deep to the skin flap to minimize tracheostenosis. The central suture is then secured to the lower aspect of the shield-shaped defect. The circumferential suture line should provide support for the trachea and accurate skin-mucosa apposition without cartilage exposure. These sutures should be placed beginning in the center and each subsequent suture placed lateral to the prior one. For each suture, the surgeon proceeds farther along the skin edge than the mucosal edge, which serves to pull the trachea outward. In addition, the trachea is not sewn in a circular fashion. By bringing the lateral trachea down to the inferior flap, the inferior aspect of the stoma is elongated, producing a more horizontally based trapezoid (shield) shape that avoids the circumferential stenosis or slitlike vertical stomas, which may result in a need for revision. This is best achieved by a modified ("half-buried") vertical mattress suture that traverses (1) skin (peripherally); (2) cartilaginous tracheal wall (extramucosally); and (3) skin (centrally).

So, to summarize, we have Figure 111-6, which demonstrates that the three ways to maximize stoma size are (1) "bevel the trachea"; (2) "elongate the base"; and (3) "cover the cartilage." A 2-0 Vicryl is used for the central suture and a 3-0 Vicryl for the remaining inferior sutures. A trifurcating suture can be used (either 3-0 or 4-0 Vicryl) where the superior flap comes into contact with the lateral aspect of the stoma bilaterally (in the long flap approach). Absorbable sutures are preferable because suture removal is undesirable in the stoma region.

Postoperative Management and Complications

Apart from routine postsurgical care, the specific treatment of early postlaryngectomy patients includes the following monitoring: systemic vital signs, fluid balance, oxygenation, wound drain vacuum retention and output, and neck flap viability. Postoperative treatment includes ventilator assistance, as per respiratory status; tracheostomy tube care (cleaning, cuff pressure checks); airway humidification; bronchodilator treatments or chest physical therapy; suture line care three times daily; and nasogastric or tracheoesophageal fistula tube feeding once bowel sounds are present. Drains are removed when output is less than 25 mL/day for 2 consecutive days, and oral feeding is normally begun 7 days after surgery in the nonirradiated patient. Laryngectomees previously radiated are fed 12 to 14 days in most cases because edema precludes earlier assessment of the safety of the wound. Timing of feeding in total laryngectomy can be individualized depending on individual patient considerations.

Figure 111-8. Wide-field laryngectomy defect for radiation recurrent tumor including anterior neck skin, thyroid, sternomastoid, and selective neck node resection.

Early Complications

Early complications usually occur during the patient's postoperative hospitalization.

Drain Failure

Drains unable to hold a vacuum represent a serious threat to the wound. Usually there is either a leak in the pharynx or the skin and stoma closure that needs to be promptly detected and sealed.

Hematoma

Although rare, a hematoma requires prompt intervention to avoid pressure separation of the pharyngeal repair and compression of the upper trachea. The patient is returned to the operating room; the clot is evacuated, and any detectable bleeding is controlled. New drains are inserted because blockage of the original ones with clot is inevitable.

Infection

A subcutaneous infection after total laryngectomy is recognized by increasing erythema and edema of the skin flaps 3 to 5 days after surgery. Associated odor, fever, and elevated leukocyte count occur. If an infected collection is present, the wound is opened during sterile conditions and the pus is evacuated and cultured. Dead space between the neopharynx and skin flap is managed with repeated antiseptic gauze packing until healed. Antibiotic coverage is modified according to culture results, and a pharyngocutaneous fistula is suspected if wound discharge continues or increases. A chyle fistula should be ruled out if neck dissection was performed.

Pharyngocutaneous Fistula

Patients with poor preoperative nutritional status and positive surgical margins and those with diabetes are at high risk for fistula development.[41] Early studies[35,42] did not show a significantly increased fistula rate in patients who have had preoperative radiotherapy, but subsequent studies seem to refute this.[26,41,43-45] A fistula begins as a major accumulating salivary leak from the pharyngeal closure into the subcutaneous space beneath the skin flaps and may be encouraged by a tight distal hypopharyngeal closure. Its existence often is heralded by increased turbid drain output and by erythema and edema around part of the wound closure, which, on opening, drains purulent material and saliva.

Such fistulas may occur 1 to 6 weeks postoperatively, depending on the presence or absence of previous radiation, and communication from the skin to the pharynx is confirmed by a methylene blue swallowing test or a Gastrografin swallow radiograph. Persistent or recurrent tumor always should be ruled out.

Initial management is by regular, antiseptic gauze fistula-track packing, dressings, and antibiotic therapy, as well as by giving the patient nothing by mouth. An active drain can often be converted to a passive drain to allow diversion of the saliva and prevention of salivary collection. A pressure dressing is sometimes useful. Conservative therapy attempts to allow the fistula to close from the inside toward the skin. A useful adjunct is to "sterilize" the fistula from within by administering 10 mL of 0.25% acetic acid by mouth or an antibiotic or other antiseptic preparation, three to four times daily. If the previously described measures are unsuccessful in sealing off the pharynx from the neck, operative closure should be considered. Although spontaneous closure may occur up to 6 weeks after onset, most patients prefer a more rapid resolution so that oral feeding may begin.

An excellent option for fistula closure before complete epithelialization is a pedicled muscle flap (pectoralis, trapezius, or latissimus dorsi) slipped between the pharyngeal and skin defects. Such flaps endow excellent blood flow and antibacterial benefits to an avascular, infected bed.[46] A control pharyngostome catheter suction system, as described in the discussion of surgical technique, also may be used to direct saliva away from the carotids. Further surgery at this stage also should correct any benign pharyngeal stricture distal to the fistula. Another option is a salivary bypass tube, which allows saliva to pass by the pharyngeal defect. This can be used in conjunction with a flap. Control of esophageal reflux is also an important aspect of preventing and managing pharyngocutaneous fistula.

Wound Dehiscence

Wound dehiscence may accompany a tensioned skin closure, the postradiation state, wound infection, fistula, or poorly designed ischemic neck flaps. Local wound care should suffice for healing by secondary intention, but if the carotid becomes persistently exposed, vascularized muscle flap coverage is advisable.

Late Complications

Stomal Stenosis

If the stoma is created as described earlier, this complication is uncommon. This approach can be used in revision as well. In patients with small tracheas or a propensity for stenosis, women have a higher likelihood of fistula.[47] Revision, when necessary, can be done with V-Y advancement flaps, Z-plastys, and a "fish-mouth" stomaplasty. Excision of cartilage remnants is preferable to radical excision and laryngectomy tube placement, but in some cases prolonged use of a laryngectomy tube will be required.

Pharyngoesophageal Stenosis and Stricture

Tumor recurrence should be suspected, but once excluded by endoscopy and biopsy, outpatient dilation is usually effective. An adequate lumen (36 F) is necessary not only for swallowing and nutrition but also for tracheoesophageal speech production. If dilatation is unsuccessful, flap reconstruction is preferable.

The high incidence of wound complications as a result of salvage laryngectomy has prompted some surgeons to transfer vascularized tissue to help minimize short-term and long-term problems. The results from these series suggest that it is possible to decrease the incidence of complications, but the rate of fistula is still high.[48,49] Unfortunately, the same patients that are at the highest risk for severe and chronic wound complications are often those who are not ideal candidates for free tissue transfer. Although the rate of fistula may be as high as 50% in some patients who have undergone intensive chemoradiation, this policy would result in unnecessary flap reconstructions in some patients if applied to all salvage cases.

Hypothyroidism

Preoperative or postoperative radiotherapy plus hemithyroidectomy is usually sufficient to induce a low thyroid state.[50-52] Thyroid function tests every 1 to 2 months after completion of all treatment indicate when supplemental thyroid medication is required.

Rehabilitation

Swallowing

Oral intake usually is commenced 7 days after surgery, although waiting until after 14 days is advisable if the patient has had preoperative radiotherapy. In a Brazilian study, 625 laryngectomees were fed 3 days after surgery and showed no increase in complications. They were able to avoid use of a nasogastric tube altogether.[53] Further study has replicated this finding,[54] but in reality, feeding patients this early is not always feasible because of postoperative edema. Because of this, length of hospital stay was found not to be significantly affected by early oral feeding in one study.[55] In general, once the patient can swallow saliva, it seems reasonable to consider oral feeding. The literature shows that most pharyngocutaneous fistulas occur at or just after postoperative day 7. In uncomplicated cases with minimal edema, it may be possible to be certain there is no fistula sooner than that. Our experience has been that we do tend to feed people who have previously been irradiated later and more carefully. Because of this, the recognition of the fistula has sometimes been delayed well beyond a week. It is our experience that fistula is more common after radiotherapy. Regardless of the timing of oral feeding, the key is recognition of the fistula if it does occur. A higher index of suspicion of pharyngocutaneous fistula should be maintained in patients with edema or prior radiotherapy or in patients with comorbid conditions such as diabetes mellitus, renal insufficiency, or on immunosuppressive agents. Every effort should be undertaken to avoid positive margins not only for cancer control but also because the presence of tumor can result in fistula. A gastrostomy may be of benefit in likely to have a pharyngocutaneous fistula or dysphagia postoperatively. Once a soft diet is tolerated, the patient may advance to normal intake, but edentulous patients should be especially cautious about solid food.

If dysphagia prevents adequate caloric or fluid intake, pharyngeal stricture, tumor recurrence, stenosis, or tongue weakness may be responsible. A modified barium swallow test[56] or manofluorography[57] helps diagnose which component or components of the swallowing tract or mechanism are faulty. Radiation fibrosis of the neck, causing pharyngeal stenosis some months or years after completion of treatment, should be counteracted by regular dilatation. Neuromuscular paralysis or weakness may be either preexisting or iatrogenic from radiotherapy or from surgical damage to the hypoglossal nerve. In these patients, except those with radiation neuritis, time and speech therapy exercises assist recovery.

Occasionally, circumferential spasm of the pharyngoesophageal segment may be sufficient to cause dysphagia, in which case Botox A injections or myotomy may be helpful.[58,59]

Voice

Electro-Mechanical Devices

These devices are useful in the early, postoperative phase, before it is safe for the healing pharyngeal wall to be insufflated. Some patients also use them for permanent communication. Their major disadvantages are the monotonous, mechanical sound production; poor intelligibility; and the need for a cumbersome external device.

Esophageal Speech

Although esophageal speech is mastered only by a few patients,[60] a good esophageal speaker eventually may undertake public speaking engagements. Air charging is achieved by thrusting the tongue back and forcing a bolus through the cricopharyngeus. The air bolus then is regurgitated through the pharyngoesophageal segment, which vibrates to produce sound. Spasm of the pharyngoesophageal musculature or fixed stricture may prevent acquisition of this technique, as may poor patient motivation. The former may be managed by botulinum toxin injection.[56]

Tracheoesophageal Speech

This method is the most commonly employed technique of voice restoration following total laryngectomy. The principle behind tracheoesophageal speech is diversion of exhaled air into the pharynx by way of a permanent, surgically constructed tracheoesophageal fistula. The pharyngoesophageal segment above the fistula vibrates, producing a neovoice. Singer and Blom[61] and Panje[62] have developed prosthetic devices that allow airflow to the pharyngoesophagus and prevent salivary leak into the trachea. Tracheostomal occlusion is either digital or by wearing a valved stoma button that flaps shut with forceful exhalation. The tracheoesophageal puncture (TEP) may either be done primarily at the time of laryngectomy or as a secondary procedure when wound healing is complete. Primary TEP has been shown to be more effective overall and it has been demonstrated that it can be done safely even in the setting of prior radiotherapy.[63] Many surgeons place the appropriate diameter tube through the TEP site for early postoperative nutrition. Our experience has shown that primary TEP in nonirradiated patients is preferred if the patient has a good understanding of the process and is counseled appropriately. Some patients cannot grasp this complexity at the time of primary total laryngectomy. Other patients who have received high doses of radiotherapy and are at increased risk for wound problems are probably best allowed to heal before performing TEP. Also, patients who have primary total laryngectomy for subglottic cancer will require high-dose postoperative radiotherapy to the stoma and are probably best allowed to heal the stoma before placing any foreign body. Manipulation of peristomal tissue and vibratory excursion of pharyngoesophageal mucosa ensues once phonation training begins. Both may cause excessive edema, unless thorough tissue recovery from radiation has occurred. A stoma at least 1 cm in diameter is required. Refer to Chapter 113 for further details of tracheoesophageal speech and prosthesis management. We perform both primary and secondary tracheoesophageal puncture by incising over a Crawford clamp and then passing a catheter under direct vision. Recently, transnasal esophagoscopy has made it possible to do tracheoesophageal puncture in the clinic under local anesthesia.[64] Tracheoesophageal speech is a major factor in improving quality of life in laryngectomy patients and is the preferred method for rehabilitation.[65]

Nevertheless, long-term problems with the puncture site do occur. Leakage and granulation tissue can be troublesome, as can yeast infection. Leakage can be treated by increasing the diameter of the prosthesis, but in some cases it requires closing the tract.

Ultravoice

A speaking device built into a denture is another option for patients who are unable to acquire tracheoesophageal speech.[66]

Total Laryngopharyngectomy

Total laryngopharyngectomy includes associated circumferential pharyngectomy. The vertical extent of the pharyngectomy may be from the nasopharynx above to the cervical esophagus below, depending on tumor location and spread. Advanced squamous carcinoma of the hypopharynx or cervical esophagus with pharyngeal extension is the most common clinical entity requiring this operation (Fig. 111-9).

Historical Development

Total laryngopharyngectomy was a logical extension of total laryngectomy. Thus after Billroth's landmark total laryngectomy in 1873, von Langenbeck removed a larynx plus much of the pharynx and cervical esophagus in 1875. Czerny, who had assisted Billroth in the first total laryngectomy, performed the first total laryngopharyngectomy in 1877.[67] According to Macbeth,[67] little had been done to reconstitute the pharynx until the 1920s, when Trotter introduced the concept of skin flaps turned in from the neck to form a posterior pharyngeal wall at stage 1, followed by circumferential tubing for stage 2. Gluck, operating in the late 19th century, also is credited with discovering this concept,[69] in which bilateral, laterally based neck skin flaps were used.

Once the complications of sepsis and perioperative mortality had been minimized, attention turned to better reconstruction. Wookey[70] in Toronto published a series of total laryngopharyngectomies followed by a unilaterally based skin flap reconstruction. Since then, advances have centered on more sophisticated forms of single-stage reconstruction, with the resectional techniques for the larynx and pharynx remaining standard.

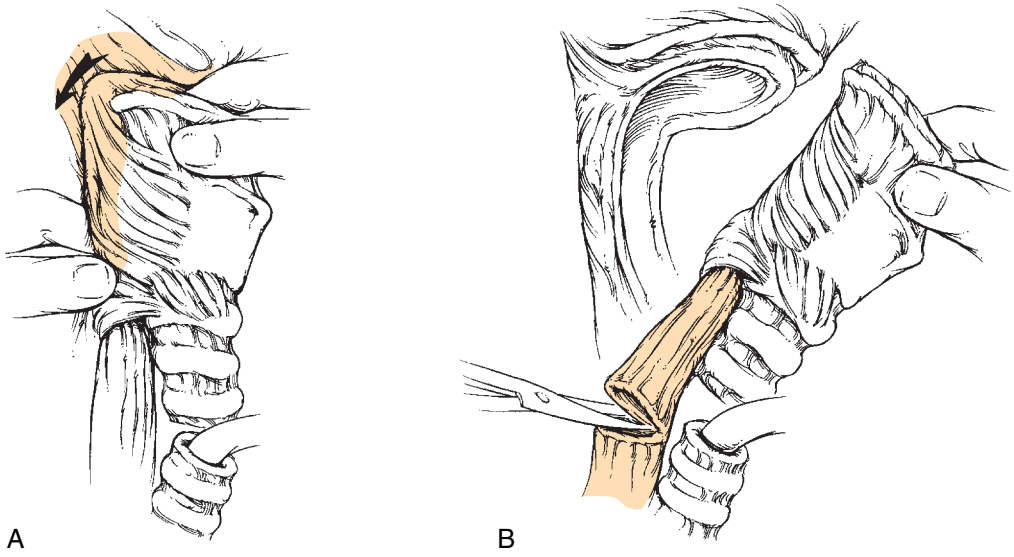

Figure 111-9. Total laryngopharyngectomy. **A,** The retropharyngeal dissection has been performed. **B,** Now superior and inferior cuts that are cirumferential will complete the resection.

Indications

Assuming surgery is advised, patients with advanced tumors of the hypopharynx with the following features require total laryngopharyngectomy.

Pyriform Sinus Carcinoma

Posterior pharyngeal spread of the tumor across the postcricoid region beyond the midline posteriorly or extension into the esophageal inlet necessitates circumferential pharyngectomy. The larynx, even if not directly involved, is sometimes sacrificed because it loses its dynamic pharyngeal support for swallowing or it becomes denervated. Total pharyngeal resection and reconstruction with laryngeal preservation have been described but require superb patient performance status. This result is the exception rather than the norm in the hypopharyngeal cancer population. Laryngeal spread, especially if it involves the posterior cricoarytenoid muscle to cause abductor paralysis, as indicated previously, nearly always necessitates total laryngectomy.

Again, some patients may be suitable candidates for near-total laryngectomy,[17] but these patients also usually require flap reconstruction of the pharynx. Alternatively, supracricoid hemilaryngopharyngectomy[71] has been advocated for select patients with carcinoma of the pyriform sinus. More recently, Steiner's group has reported on a series of endoscopically excised hypopharyngeal tumors with creditable survivorship.[72] The goal of treatment of any patient requiring surgery of the laryngopharynx is to achieve cancer control and restore airway, swallowing, and speech. The authors believe this goal is achievable with appropriate reconstruction even in patients undergoing total laryngopharyngectomy.[73]

Organ preservation rates are lower in hypopharyngeal carcinoma than in laryngeal carcinoma with a chemoradiation strategy.

Carcinoma of Posterior Hypopharyngeal Wall

When carcinoma of the posterior hypopharyngeal wall extends anteriorly into the pyriform sinuses or inferiorly below the level of the arytenoids, total laryngopharyngectomy is necessary.

Postcricoid Carcinoma

Postcricoid carcinoma usually is seen late, after spread downward into the esophageal inlet has occurred. In these patients, total laryngopharyngectomy is required, especially if there is vocal cord paralysis caused by infiltration of the posterior cricoarytenoid muscles or cricoarytenoid joints.

Patient Selection and Workup

The same general patient considerations apply as outlined for total laryngectomy. Special features of the preoperative workup of patients with hypopharyngeal cancer include nutritional assessment and supplementation, careful scan staging of local and distant disease extent, and endoscopy with mapping biopsies. Then an assessment of resectability is made (carotid artery, vertebral column, and extensive neck metastatic involvement is common), followed by complete evaluation of potential donor sites for pharyngoesophageal reconstruction. Preoperative calcium and thyroid hormone levels are assessed as a baseline for postoperative management.

Surgical Technique

Resection

Patient positioning and anesthetic considerations are the same as for those undergoing total laryngectomy with the addition of donor sites such as the forearm, lateral thigh, or abdomen prepared for flap harvest or, in patients with gastric pull-up, stomach mobilization. The neck dissection usually is performed first; the specimen is pedicled medially on the pharyngeal wall from the hyoid level down to the cricopharyngeus. Suitable arterial stumps (lingual, facial, superior thyroid, transverse cervical) are preserved, provided no oncologic compromise results, to allow a microvascular free tissue transfer. Similarly, the external jugular, anterior jugular, internal jugular tributaries, or transverse cervical vein may be kept, unless a classic radical neck dissection is necessary. If esophageal resection well inferior to the thoracic inlet is required to obtain clear margins, a total esophagectomy and visceral transposition may be the best reconstruction, obviating the need for recipient vessel preservation and avoiding the potential leakage of saliva or refluxate into a suture line near the great vessels. In such cases a mediastinal tracheostomy may also be necessary to assist tracheal resection.

The initial dissection steps for laryngopharyngectomy are the same as for total laryngectomy, except that mobilization of the larynx, pharynx, and cervical esophagus as a unit is performed by extending the lateral dissection into the retropharyngeal and retroesophageal space. This actually makes this operation much simpler because the pyriform mucosa is not dissected free. The skeletonization of the larynx is not performed laterally, so the dissection can be done bluntly once the deep cervical fascia is divided medial to the carotid artery along the prevertebral fascia adjacent to the lateral masses of the vertebral bodies. Careful observation is maintained for spread beyond the buccopharyngeal and prevertebral fasciae into the prevertebral muscles or vertebral

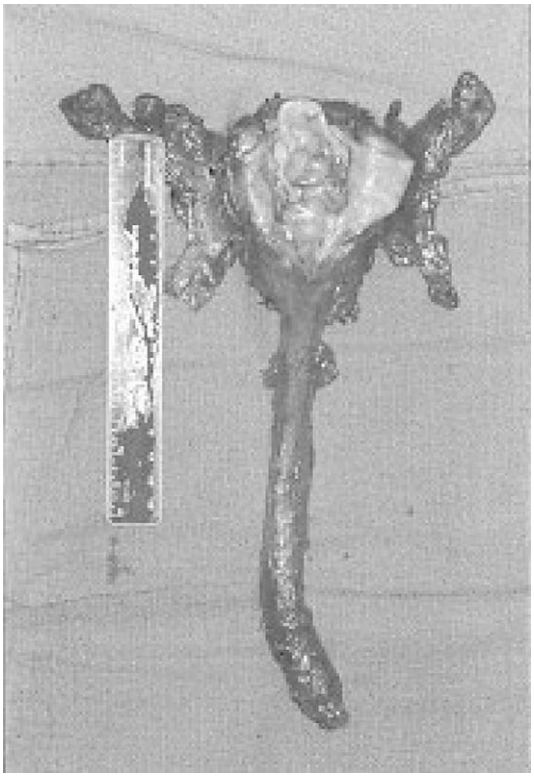

Figure 111-10. Total laryngopharyngoesophagectomy specimen en bloc with bilateral neck dissections and thyroidectomy. This patient had one hypopharyngeal tumor and a second, distal esophageal tumor.

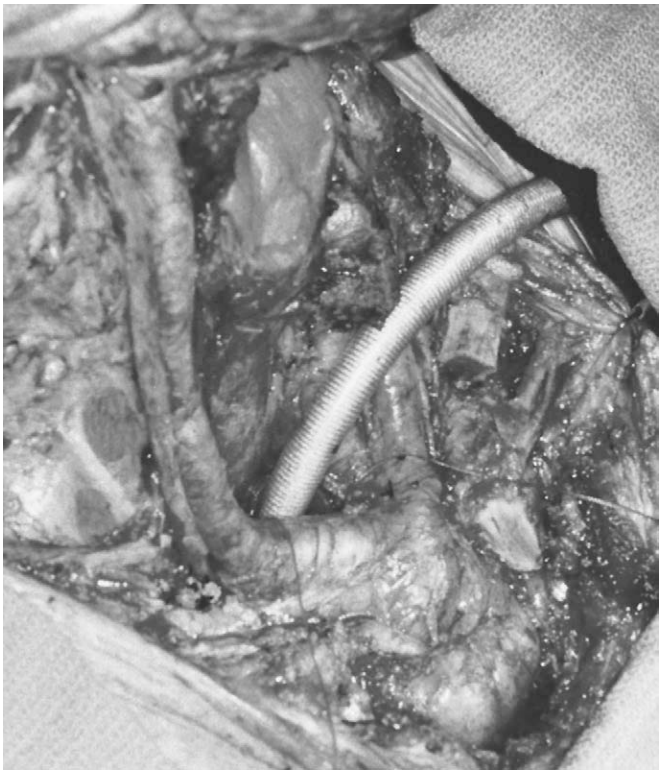

Figure 111-11. Superior mediastinal resection defect including heads of clavicles and sternal manubrium. All node-bearing tissue is excised, preserving brachiocephalic and common carotid arteries. Ventilation tube enters cut tracheal stump.

bodies. The prevertebral fascia itself is a moderately resistant barrier to tumor spread, but it is resected in continuity with the specimen if necessary. Some surgeons would discontinue resection once prevertebral fascia involvement was proven.[74]

Once the pharynx, larynx, and upper cervical esophagus are circumferentially mobilized, the thyroid gland should be dissected free from its vascular pedicles to be removed with the specimen. The parathyroid glands contralateral to the tumor's epicenter often may be preserved but may have to be removed to ensure clearance of the surrounding paratracheal nodes. If there is no oncologic risk, parathyroid reimplantation into a muscle bed is effective to avoid long-term hypocalcemia.

The pharynx is entered above the hyoid contralateral to the site with the most superior spread. Piriform sinus tumors may extend superiorly into the base of the tongue, thereby requiring a wide margin of resection during direct observation. In such patients, performing a contralateral lateral pharyngotomy improves the view without inhibiting a subsequent total laryngopharyngectomy if deemed necessary. Then pharyngeal mucosal cuts are continued horizontally around and onto the posterior pharyngeal wall at least 2 cm above the highest extent of the lesion, such that the entire upper pharynx and larynx are free. Then the trachea is transected, followed by the cervical esophagus at a level appropriate to the tumor extent. The operation can be summarized in three steps: (1) mobilizing a large tube that includes the larynx and pharynx; (2) cutting the superior end of the tube (base of tongue and pharyngeal walls); and (3) cutting the inferior end (esophagus). If total esophagectomy is to be performed, blunt dissection of the esophagus continues from above downward until the inferior esophageal dissection from the abdomen is encountered (Fig. 111-10). Superior mediastinal adenopathy is dealt with by use of a manubrial resection approach (Fig. 111-11).

Reconstruction

An extensive history and voluminous surgical literature deals with reconstruction of circumferential pharyngeal defects. We prefer to use a tubed skin flap such as the radial forearm flap (Figs. 111-12 and 111-13),[75] but a jejunal free transfer is an alternative. If the esophageal resection extends well below the thoracic inlet, a visceral transposition (gastric pull-up) is used, thus avoiding anastomoses in the mediastinum. Quality of life after high pharyngogastric anastomosis is poor in our experience. With adequate access created by sternectomy, a tubed free skin flap reconstruction endows other major advantages such as avoiding thoracoabdominal transgression. Further details of hypopharyngeal reconstruction are given in Chapter 105.

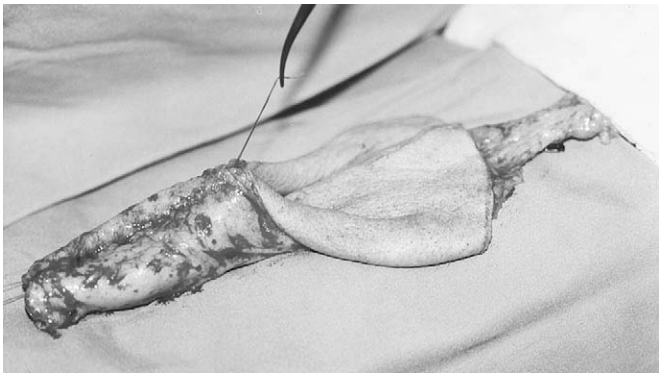

Figure 111-12. Radial forearm flap pretubed on the forearm before transfer to the neck. Note proximal skin paddle to be folded through 180 degrees, separated by a de-epithelialized transverse strip and inset in one stage to provide neck coverage.

Postoperative Management and Complications

Postoperative Management

The same management applies as that described for total laryngectomy, although one or more neck dissections and abdominal or extremity

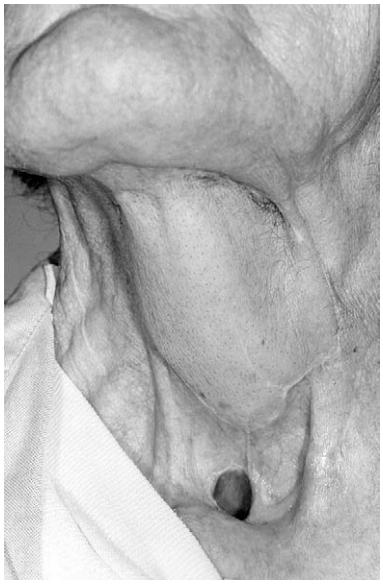

Figure 111-13. Postoperative result at 2 years. Patient maintains normal diet, and skin paddle pliability assists neck movement. Contour of tubed neopharyngeal component is visible deep to radial skin paddle.

donor sites frequently are used, and this greater magnitude of surgery necessitates special attention to pulmonary function, fluid nutritional balance, and local wound conditions in the neck, thorax, and donor site. Regular postoperative checks of calcium, magnesium, and phosphorus levels are necessary, and supplementation with calcium, magnesium, and 1, 25-dihydroxycholecalciferol usually is required.

Early Complications

Early fistula formation is more common than in patients undergoing total laryngectomy alone and needs especially aggressive management because of the mediastinitis risk. When a fistula or infection in the neck is detected, the wound is opened widely and left open with the track packed and is directed to pass away from the carotids and microvascular pedicle. A tight, distal closure of the pharyngoesophageal reconstruction is a prime cause of early fistula formation. Leaking pharyngeal or esophageal anastomoses, especially if secreting gastric or jejunal tissue has been used for reconstruction, may need to be controlled with pharyngostome formation and, if healing is poor, should be reinforced with fresh, vascularized, nonirradiated flap tissue (e.g., pectoralis or trapezius muscle flaps).

Late Complications

Stricture

Strictures are more common at the inferior, esophageal end of the pharyngeal reconstruction than superiorly, where the recipient lumen of the pharynx is wider. A stricture causing dysphagia may develop some weeks or months after surgery or after radiotherapy is complete.

Whether the reconstruction is skin or viscera, the principles of stricture management are the same as for patients after total laryngectomy alone: repeated, outpatient dilatation once tumor recurrence is excluded by endoscopy and biopsy, progressing to surgical revision if the latter is unsuccessful or poorly tolerated.

During this decade, a strategy that uses a salivary bypass tube in combination with a radial forearm free flap has been reported to be encouraging in pharyngoesophageal reconstruction. Another innovation that has been reported is the topical application of mitomycin C just after dilation.[76]

Functional Swallowing Problems

The jejunal free flap frequently maintains its contractility after transposition to the neck. This has been shown to cause functional dysphagia in some patients if the food bolus is delivered simultaneously with circumferential contractions.[56] Regurgitation of food is a recognized complication of the gastric transposition procedure, and it usually is caused by loss of the gastric reservoir or narrowing at the pylorus rather than anastomotic stricture and may be variable in its severity.

Frequent, mechanically blenderized meals eaten slowly usually are sufficient to maintain nutrition. It is possible that a passive segment of a tubed skin flap is superior for swallowing, although no prospective comparison studies have been performed.

Rehabilitation

The considerations in swallowing are the same as those noted previously in the discussion of functional swallowing problems after total laryngectomy.

Voice

Despite the interposition of circumferential visceral, skin, or myocutaneous tissue, voice may be attained with a tracheoneodigestive tract fistula technique. The stomach,[77] the jejunum, and skin or myocutaneous flaps are capable of sufficient vibration to produce intelligible speech.[71] Detailed analysis of voice characteristics after radial forearm flap reconstruction has been documented.[78] A tracheoesophageal puncture procedure may be safely performed as a primary procedure if the fistula tract does not communicate with the main resection site. In some patients, a strip of mucosa can be preserved and a pedicled or free flap can be sutured to the edges. If it is not oncologically sound to preserve a strip of mucosa, and the flap is too bulky to make a complete tube, then the skin of a myocutaneous flap can be sutured to the prevertebral fascia and this can allow for a watertight closure. An example is when a free flap fails and a salvage flap such as a pectoralis major myocutaneous flap modification is used. The flap is sutured to the mucosa or the fascia in these two situations in a "horseshoe" fashion.[79] Although such a procedure is difficult in obese patients, thinner patients can be successfully reconstructed in this way. In all of these situations rehabilitation of voice is feasible with tracheoesophageal speech.

Summary

A review of contemporary indications, techniques, and rehabilitation for patients undergoing total laryngectomy or total laryngopharyngectomy is presented. Total laryngectomy is the most cost-effective treatment option for advanced laryngeal cancer.[80] Total laryngopharyngectomy is the most effective treatment for hypopharyngeal carcinoma today.[81] Most patients requiring these operations have head and neck cancer, and the scope of the chapter is limited to the relevant clinical details of operative and perioperative events. Readers are referred elsewhere to consider the effectiveness of these operations in cancer control.

CHAPTER ONE HUNDRED AND TWELVE

Radiation Therapy for Cancer of the Larynx and Hypopharynx

Alice Cheuk

Parvesh Kumar

Key Points

Laryngeal Cancer

Early-Stage Glottic Cancer (T_1-T_2 Lesions)

- Definitive radiation therapy offers several advantages over a primary surgical option, including superior quality of voice outcome and the ability to treat subclinical lymphatic nodal disease without the need for a neck dissection with equivalent outcomes to surgery. Initial and ultimate local control outcomes for T_1 and T_2 disease are noted in Tables 112-1 and 112-2, respectively.
- Prognostic factors predicting outcome with radiation therapy include impaired vocal cord mobility,[7] anterior commissure involvement, total dose/dose per fractions/and overall treatment time,[8] tumor bulk,[6] pretreatment and post-treatment hemoglobin levels,[9] p53 and p21 molecular markers,[10-11] and concurrent smoking.[12]
- The rate of chronic long-term complications with definitive radiation therapy is very low (<5%).

Advanced-Stage Glottic Cancer (T_3-T_4 Lesions, N+)

- Primary surgical treatment is recommended for large bulky tumors in which concurrent chemoradiation therapy is unlikely to achieve local control of disease, or for those patients with a poor presenting quality of voice outcome or a destroyed epiglottis, resulting in an irreversibly compromised swallowing function with a high probability of aspiration (outcomes noted in Table 112-3).
- For organ preservation therapy, definitive concurrent chemoradiation therapy is recommended for nonbulky tumors for which local control can be achieved with a nonsurgical approach.

Supraglottic Cancer

- Treatment principles for early and advanced stage supraglottic cancers are the same as for glottic cancers, except that lymphatic nodal stations should be included in the radiation volume even for early stage disease. Outcomes after treatment are noted in Tables 112-6 and 112-7.

Subglottic Cancer

- Subglottic cancers are extremely rare. Early-stage lesions can be definitively treated with radiotherapy alone (66-70 Gy at 2.0 Gy/fx), whereas advanced stage tumors should be treated with surgery followed by radiation therapy with or without chemotherapy.

Hypopharyngeal Cancer

Early-Stage Hypopharyngeal Cancer

- Treatment principles for early-stage lesions are the same as for glottic cancers, except that lymphatic nodal stations should be included in the radiation volume. For T_1 lesions, ultimate local control rates are 87%-95% (Table 112-9). For T_2 tumors, ultimate local control rates are 74%-91% (Table 112-9).

Advanced-Stage Hypopharyngeal Cancer

- Low volume disease should be managed with definitive radiation therapy (with or without chemotherapy) to avoid sacrificing the larynx associated with a primary surgical approach.
- Treatment principles involving surgical and organ preservation approaches are similar to advanced-stage glottic cancer.
- The 5-year local control rates range from 20%-50%, whereas overall survival varies from 20%-35%.

Overview

Of the millions of species on planet Earth, none has the ability to communicate as effectively as Homo sapiens. Of course, central to this ability to communicate is the larynx. Besides directly assisting the human voice, the larynx is indirectly involved in other critical functions such as swallowing. Hence it is not surprising that cancer of the larynx is a devastating diagnosis for a patient not only because of its potentially life-threatening implications but also due to the numerous implications on the individual's quality of life. The American Cancer Society estimated that 12,250 cases of laryngeal cancer were diagnosed in 2008 and that 3670 deaths resulted from this disease.[1] Cancer of the hypopharynx, though rare with 2500 new cases estimated every year, has similar implications on the individual patient's well-being and quality of life.

Treatment of the larynx and hypopharynx should achieve two major goals: cure of the cancer and preservation of organ function to maintain quality of life. In one extreme, an aggressive surgical approach that would leave the patient with gross deformities and functional impairment is not optimal; on the other hand, advocating chemoradiation therapy for a patient with a larynx that is not worth preserving is equally futile. Cure can usually be achieved in early-stage larynx and hypopharynx cancers, but the prognosis is still relatively poor for advanced-stage disease, with 5-year overall survival ranging from 15% to 50%. For these reasons, the involvement and coordination of a multidisciplinary team including ear, nose, and throat surgeons; radiation oncologists; medical oncologists; and appropriate supportive staff (i.e., nurses, dieticians, social workers, speech and swallowing therapists) is vital to determining the best management for each patient, in order to maximize cure and preserve quality of life.

In determining the most optimal therapy for an individual patient, careful attention should be paid to patient-related factors (e.g., baseline quality of voice and swallowing function, weight loss, comorbidities, duration of symptoms to gauge the "tempo" of the cancer, age, performance status, hemoglobin levels, family support system, patient's motivation to complete the proposed treatment); tumor-related factors (e.g., volume and extent of disease, nodal disease, tumor grade); and treatment-related factors (e.g., the likely acute/chronic toxicities of the therapy and their impact on the quality of life, duration of treatment). A careful "holistic" approach that takes into account these factors is necessary for the optimal treatment of each patient's cancer.

In order to achieve succinctness and clarity, this chapter is organized as follows:

1. Review of pertinent anatomy
2. Key points in initial evaluation and workup of patients
3. Overview of treatment options and radiation techniques
4. Innovations and future direction in treatment

Anatomic Considerations

A fundamental knowledge of laryngeal and hypopharyngeal anatomy is necessary to allow the clinician to understand how (1) a particular cancer affects function to produce signs and symptoms; (2) patterns of local invasion and lymphatic and distant spread differ for individual cancers of the larynx and hypopharynx; and (3) the extent of tumor within the larynx and hypopharynx determines treatment selection. For the radiation oncologist, knowing the relation of the laryngeal and hypopharyngeal structures to bony landmarks is critical in radiation treatment planning.

The hypopharynx extends from the superior aspect of the hyoid bone, which corresponds to the level of the vallecular floor, to the inferior border of the cricoid cartilage. The three subsites of the hypopharynx are (1) the paired pyriform sinuses, (2) the postcricoid area, and (3) the posterior and lateral hypopharyngeal walls.

The larynx is intimately related to the hypopharynx; it is situated anteriorly to the hypopharynx, at approximately the same cervical levels. Anatomically, the larynx extends from the tip of the epiglottis at the level of the lower border of the C3 vertebra to the distal extent of the cricoid cartilage at the level of the C6 vertebra. The larynx is subdivided into three anatomic regions: the supraglottis, the glottis, and subglottis regions. The supraglottic region includes (1) the epiglottis, (2) the aryepiglottic folds, (3) the arytenoids, (4) the false vocal cords, and (5) the ventricle. The glottis consists of the true vocal cords and the anterior and posterior commissures. Importantly, the anterior commissure is usually within 1 cm of the skin surface, an important consideration for radiation treatment planning. The lower boundary of the glottis extends 5 mm below the free margin of the vocal cords, or to the horizontal plane 1 cm below the apex of the ventricle. The vocal cords attach to the thyroid cartilage at what is visualized to be the "figure-of-eight" on a lateral plain film. The subglottis extends from the lower boundary of the glottis to the inferior margin of the cricoid cartilage. These anatomic boundaries are readily visualized on plain lateral x-ray films (Fig. 112-1).

Figure 112-1. Plain simulation film.

From a radiographic perspective, it is important to note that the thyroid, cricoid, and most of the arytenoid cartilages are composed of hyaline cartilage, which begins to ossify when a person is about 20 years old. The epiglottis, corniculate, and cuneiform cartilages and the apex and vocal process of the arytenoids are made up of elastic cartilage, which does not ossify and therefore is not radiopaque.

Lymphatic Drainage

Knowledge of the lymph node levels in the neck in relation to bony landmarks, as well as surgical landmarks, is important for the radiation oncologist when planning radiation portals. Level I nodes are above the hyoid bone, below the mylohyoid muscle and anterior to the back portion of the submandibular gland. This corresponds to the submental and submandibular triangles. Level II nodes are located from the skull base to the lower body of the hyoid bone inferiorly, posterior to the back of the submandibular gland, and anterior to the posterior extent of the sternocleidomastoid muscle. The jugular chain lymph nodes, which run from the mandible down to the carotid bifurcation, are included in this level. Level III nodes extend from the lower body of the hyoid to the inferior margin of the cricoid, also anterior to the

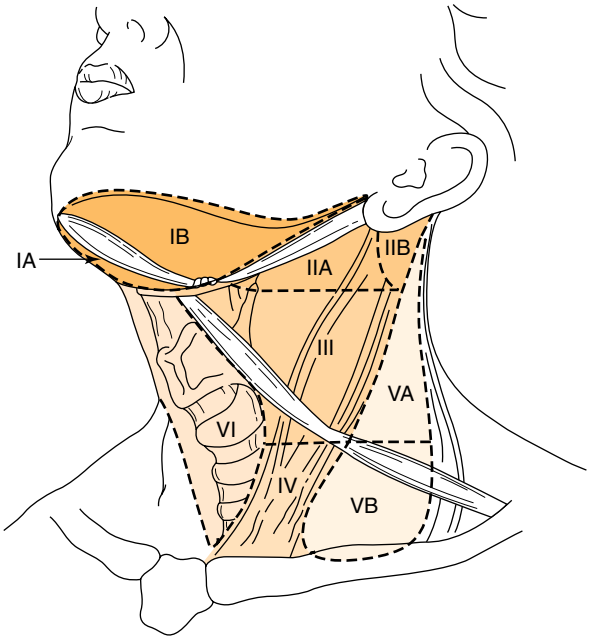

Figure 112-2. Lymph node levels of the neck. *(Adapted from Harish K. Neck dissections: radical to conservative.* World J Surg Oncol. *2005;3:21.)*

posterior margin of the sternocleidomastoid muscle, corresponding to the region from the carotid bifurcation to the omohyoid muscle. Level IV lymph nodes are bordered superiorly by the lower border of the cricoid cartilage and inferiorly by the clavicles and are anterior to the posterior margin of the sternocleidomastoid muscle, which corresponds to the region from the omohyoid muscle to the clavicle. Level V lymph nodes run from the skull base to the level of the clavicle in the region posterior to the sternocleidomastoid muscle; this area is the posterior triangle bounded by the SCM anteriorly, the trapezius posteriorly, and the omohyoid inferiorly. Level VI lymph nodes are between the lower body of the hyoid bone and the suprasternal notch, otherwise known as the anterior compartment between the carotid arteries (Fig. 112-2).

Clinical Presentation and Evaluation

Clinical Presentation

Larynx

SUPRAGLOTTIS. The most common presenting symptoms of carcinoma of the supraglottis are sore throat and odynophagia. Often a neck mass may be the first sign of carcinoma of the supraglottis because of the high incidence of lymph nodal metastases. Unilateral otalgia occurs because of referred pain from the involvement of the vagus nerve and the auricular nerve of Arnold (a branch of cranial nerve X). Hoarseness is usually not an initial symptom, and it occurs with invasion of the vocal cords. Weight loss, dyspnea, foul breath, and aspiration occur with advanced disease.

GLOTTIS. The most typical presenting symptom of early-stage vocal cord cancer is hoarseness. The symptoms of advanced disease include sore throat, localized pain as a result of cartilage invasion, otalgia, and dyspnea as a result of airway compromise.

SUBGLOTTIS. Carcinoma of the subglottis is relatively asymptomatic during early stages. With advanced-stage disease, dyspnea becomes the predominant symptom as a result of narrowing of the airway; other less common symptoms include hoarseness, odynophagia, and hemoptysis.

Hypopharynx

Secondary to anatomic location, patients with hypopharyngeal cancers often present at more advanced stages than other head and neck cancers. Typical presenting symptoms include hoarseness, odynophagia and/or dysphagia, a sore throat, otalgia, weight loss (20%), and neck masses. In more advanced stages, patients may also complain of hemoptysis and stridor as the airway becomes involved.

Diagnostic Evaluation/Workup

The diagnostic evaluation of a patient who is suspected of having cancer of the larynx should begin with a mandatory history and physical examination. The mainstay of the physical examination is the flexible fiberoptic endoscope, which allows for excellent visualization of the infrahyoid epiglottis and anterior commissure; these regions may be difficult to see with indirect laryngoscopy. Several key clinical pearls should be remembered when performing the examination. In addition to determining the tumor extent, assessment of the mobility of the vocal cords is absolutely critical because this determines staging and is an important factor when deciding between treatment modalities. For lesions in the supraglottis, careful palpation and an examination of the base of tongue should be performed to determine involvement. Because hypopharyngeal carcinomas can often present as skip lesions with disease distant from the primary site, a thorough examination is imperative to localize all areas of disease. The neck should be carefully palpated to determine the size, number, pliability (mobile, partially mobile vs. fixed), and location (ipsilateral, bilateral, or contralateral) of lymph node metastasis. Fixed lymph nodes may warrant preoperative radiation therapy (RT) versus preoperative chemoradiation therapy in order to make surgical resection more feasible.

Routine laboratory tests include a complete blood count and liver function tests. If the liver function tests or serum alkaline phosphatase are abnormal, further studies (e.g., computed tomography [CT] of the abdomen, bone scans) may be indicated.

Imaging studies include a chest radiograph (a CT scan should be considered for patients at high risk of metastasis to the chest) and a CT scan with contrast enhancement of the head and neck region. The CT scan should be performed before the biopsy whenever possible because postbiopsy edema may overestimate tumor extent. CT slices 3-mm thick should be obtained at 3-mm intervals throughout the larynx. The relative usefulness of CT scanning versus magnetic resonance imaging (MRI) remains controversial. MRI is more useful for delineating the soft-tissue extent of the primary tumor and cartilage invasion, whereas CT scanning is better for evaluating early bone invasion and the remainder of the laryngeal anatomy. The disadvantages of MRI are longer scanning time and motion artifact. For patients who are at moderate to high risk for harboring distant metastases, fluorodeoxyglucose positron emission tomography scan is recommended. This is particularly important for patients with hypopharyngeal cancer and for laryngeal cancer associated with bulky (N2-3) nodal disease.

Examination under anesthesia with direct laryngoscopy and biopsy of the tumor is the most important step in the diagnosis of carcinoma of the larynx and hypopharynx. In advanced-stage disease, a panendoscopy (bronchoscopy and esophagoscopy) should be performed to rule out synchronous tumors, if suspected.

If RT is considered, patients should be referred for a thorough dental evaluation and extractions, if necessary, before treatment. This is imperative because xerostomia, which frequently results from radiation, predisposes patients to dental carries, particularly those with poor oral hygiene initially. In addition, if dental work needs to be performed, especially tooth extractions, it should be done before treatment because healing of the mandible is impaired after radiation, leading to increased chances of infection and osteoradionecrosis.

Staging

Laryngeal and hypopharyngeal cancers are staged according to the American Joint Commission for Cancer Tumor Node Metastasis system. The sixth and most recent version of the staging system published in 2002 can be found in other chapters. In contrast to staging in other sites, the staging for tumors in the larynx is based on involvement of anatomic structures and not on the size of the lesion. Staging in the hypopharynx is based on size and subsite involvement in early stages. Note that in both the larynx and hypopharynx, fixation of either

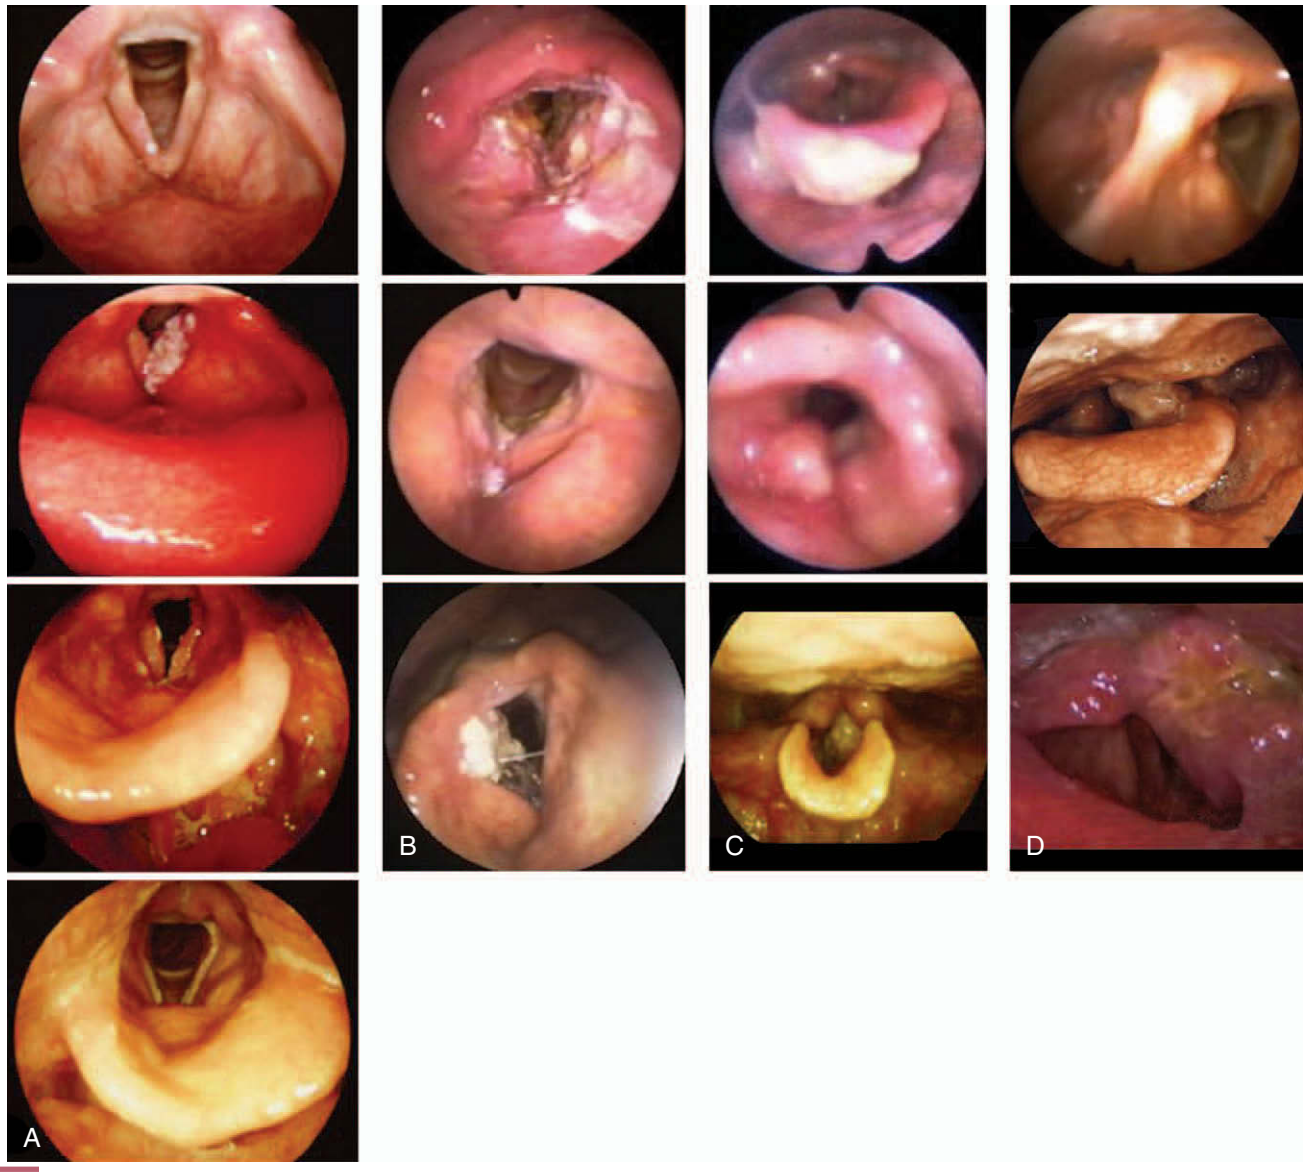

Figure 112-3. **A,** T_1 Glottis. **B,** T_2 Glottis. **C,** T_1 Supraglottis. **D,** T_1 Hypopharynx. *(From* Foote RL. Radiotherapy alone for early-stage squamous cell carcinoma of the larynx and hypopharynx. Int J Radiat Oncol Biol Phys. *2007;69(2 Suppl):S31-S36.)*

vocal cord automatically stages the tumor as a T3, regardless of the tumor bulk. T4 disease is the same in all glottic subsites and hypopharynx, reflecting invasion outside of thyroid cartilage or beyond. Nodal staging is the same as that in other head and neck malignancies (with the exception of the nasopharynx). The ability to visualize the stage of the disease from an anatomic framework, rather than memorizing lines of description in text, is useful. Direct laryngoscopy images of early T-stage laryngeal and hypopharyngeal cancers are shown in Figures 112-3A-D.

Treatment Options, Radiotherapy Techniques, Dose-Fractionation Schemes, Outcome, Prognostic Factors, and Complications

Overall Management

Recognizing that management of patients with laryngeal and hypopharyngeal cancers involves a combined modality approach involving the radiation oncologist, the head and neck surgeon, and the medical oncologist, we also recommend consultation with other specialists such as the dentist for clearance before radiotherapy (especially if the mandible is likely to be in the radiation field), dietician, and speech and swallowing therapist to assist the patient's rehabilitation and recovery from the malignancy and treatment sequelae.

Management of the Neck

We do not devote much consideration to the management of the neck in this chapter because it is covered extensively elsewhere in this textbook. As a matter of principle, nonbulky nodal disease (i.e., ≤3 cm) can be generally managed with either RT alone or chemoradiation therapy with surgery reserved for salvage therapy. However, bulky nodal disease (i.e., >3 cm) generally requires a combined-modality approach involving either preoperative or postoperative RT, or definitive chemoradiation or radiotherapy alone followed by a planned (generally limited) neck dissection, especially if the patient still has palpable lymphadenopathy after full doses of irradiation. Hence when we speak of "early-" versus "advanced-" stage disease, we are usually referring to the "T-stage" versus "N-stage" disease.

Laryngeal Cancers

Early-Stage Glottic Cancer (T_1 or T_2)

Early-stage laryngeal cancer can often be cured with either RT or surgery. No randomized trials have directly compared surgery with RT,

but published series report similar local-regional control rates for both treatment approaches. Selection of a treatment modality for an individual patient depends on a number of factors including number of prior surgical procedures (e.g., "surgical stripping," laser excisions), quality of voice, and location of the lesion. For example, laser excision of a lesion in the region of the anterior commissure can result in permanent hoarseness as a sequela of surgery. On the other hand, the same laser excision of a mid-vocal-cord lesion often leaves patients with excellent quality of voice without the need for 6 to 7 weeks of daily radiotherapy treatments. Conversely, a patient who has already failed a number of prior surgical interventions (e.g., "surgical strippings," laser excisions) is unlikely to achieve the "same old" natural quality of voice when treated with definitive RT. Generally, the advantages of RT include the following:

1. Avoidance of surgical morbidity such as poor quality of voice (i.e., chronic hoarseness) and anesthesia risks
2. Maintaining surgery as a salvage treatment option
3. Treatment of subclinical lymphatic nodal spread without the need for a neck dissection

The main contraindication to definitive RT is the likelihood of noncompliance to daily treatments for 6 to 7 weeks because of decreased local control associated with radiotherapy treatment breaks.

Radiation Techniques and Dose-Fractionation Schemes

Multiple-dose fractionation schemes have been used to treat patients with T_1 and T_2 glottic carcinoma, with total dose equaling 66 to 70 Gy at 2.0 Gy/fraction (fx) per day, 63 Gy at 2.1 Gy/fx per day, or 60.75 Gy to 65.25 Gy at 2.25 Gy/fx per day, 5 days per week.[2-4] At the Department of Radiation Oncology, University of Southern California (USC) Keck School of Medicine (KSOM), patients with T_{cis}, T_1 (including verrucous carcinoma), and small T_2 lesions are treated to 66.0 Gy at 2.0 Gy/fx. Patients with T_2 lesions are treated to a total dose of 70 Gy at 2.0 Gy/fx. These dose-fractionation schemes are used at USC because of the ease of tolerability (i.e., rarity of treatment related interruptions) in our experience and excellent local control rates. Doses less than 2.0 Gy/fx should not be used to treat early-stage glottic tumors because of the extended interval of RT, which enhances tumor repopulation rates, leading to inferior local control rates.[5,6] Although altered-dose fractionation schemes (i.e., hyperfractionated or accelerated radiotherapy) can be used to treat patients with unfavorable early-stage glottic cancers (e.g., bulky T_2 lesion), the treating radiation oncologist should only embark on this path if he or she has experience in using these alternative-dose fractionation schemes.

At USC, a three-dimensional conformal RT (3-D CRT) approach is used to treat patients with early-stage laryngeal carcinoma. A planning CT scan is done with the patients in a supine treatment position, with the head hyperextended and immobilized with an individually made face mask. For T_1 and very early T_2 lesions, two small opposing lateral fields, usually measuring $5 \times 5\,cm^2$ to $6 \times 6\,cm^2$, are used (Fig. 112-4). The fields typically extend from the upper thyroid notch superiorly to the lower border of the C6 vertebral body inferiorly. The anterior border of the field should flash at least 1 cm in front of the skin surface at the level of the vocal cords (approximately C4). The posterior border of the field should include the anterior portion of the vertebral bodies. During fluoroscopic simulation (if possible) of the fields, the patients should be asked to swallow to monitor the superior extension of the glottis to ensure that it is still within the radiotherapy field because sometimes a patient may actually swallow during the radiation treatment. During treatment planning, radiation dose homogeneity, especially in the anterior commissure region, using wedges should be achieved to prevent overdosing or underdosing (Fig. 112-5). The lymph nodes are not treated in patients with T_{cis} and T_1 disease because of the virtually nonexistent incidence of lymphatic nodal metastases. The incidence of lymphatic nodal involvement varies from 5% to 15% with T_2 disease. Generally, for T_2 lesions, we recommend treatment of at least the first-echelon lymph nodes (subdigastric and midjugular, or lower levels II and III), especially in a patient with bulky disease.

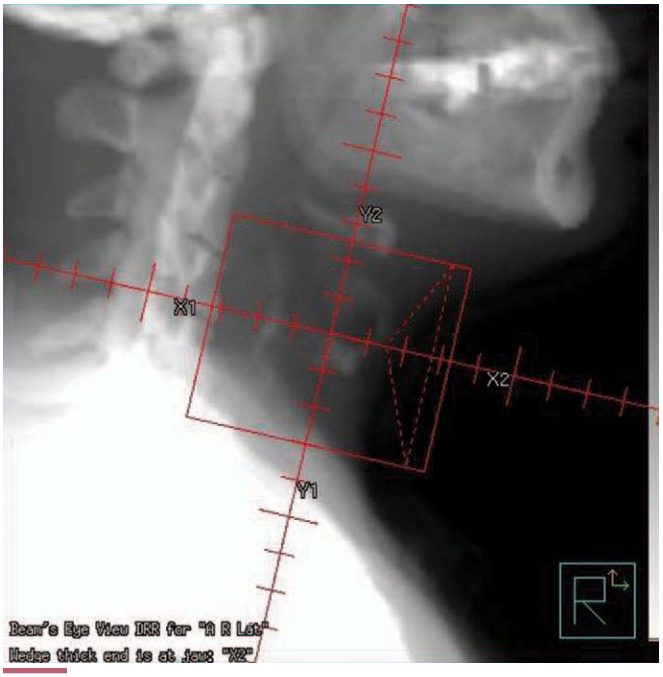

Figure 112-4. Simulation film of a T_1 glottis cancer.

Outcome and Prognostic Factors

For T_{cis} and T_1 lesions, local tumor control rates vary between approximately 85% and 95% at 5 years (Table 112-1). With surgical salvage, ultimate local control rates between 95% and 99% at 5 years can be achieved. For T_1 verrucous carcinoma, similar high local control rates have been reported with definitive RT. For T_2 glottic lesions, initial local control rates vary between 70% and 90% at 5 years with RT alone (Table 112-2). Following surgical salvage of radiotherapy failures, ultimate local control rates between 80% and 96% at 5 years can be achieved for T_2 lesions.

Various prognostic factors have been identified for early-stage glottic cancers including the following:

1. Impaired vocal cord mobility[7]
2. Anterior commissure involvement presumably due to underdosing of this region during treatment in the non-3-D CRT era
3. Total dose/dose per fraction/overall treatment time[8]
4. Tumor bulk (visible lesions as opposed to subclinical)[6]
5. Pretreatment and post-treatment hemoglobin levels[9]
6. p53[10] and p21 molecular markers[11]
7. Concurrent smoking[12]

Anterior commissure involvement has been shown in older studies to be associated with lower tumor local control rates. However, in the era of 3-D CRT with computer treatment planning, which can detect and thus limit underdosing of the anterior commissure region, this prognostic factor is no longer significant. Fraction sizes of less than 2.0 Gy result in inferior local control rates and therefore should not be used. Studies have also shown that extending treatment times beyond approximately 42 days results in inferior outcomes secondary to accelerated repopulation by tumor cells.[8] In a study of 91 patients with T_1N_0 squamous cell carcinoma of the glottis treated with definitive radio-

therapy, both overall treatment time (i.e., ≤42 days vs. > 42 days) and dose per fraction (i.e., <200 cGy vs. ≥200 cGy) predicted for local control. Typically, a loss of approximately 1.4% (0.4% to 2.5%) in local control occurs for every day of a treatment break or overall extension of treatment time. Multiple studies have shown an adverse effect of low pretreatment and/or post-treatment hemoglobin levels (Hgb) on outcome in early- and advanced-stage laryngeal cancer.[9] For example, in a study from Fox Chase Cancer Center that analyzed 109 patients with T_1 or T_2 glottic cancers treated with definitive RT, pretreatment Hgb levels less than or equal to 13 g/dL adversely affected both 2-year local control rates and overall survival (66% vs. 95% and 46% vs. 88%, respectively) on multivariate analysis.

Complications from Radiation Therapy

Because the treatment fields for early-stage glottic cancer are small, patients typically experience few side effects from RT. Common side effects include skin erythema and/or hyperpigmentation, desquamation, hoarseness, sore throat, and resultant dysphagia. These effects are self-limiting, manifesting approximately 2 to 4 weeks into therapy and usually resolving within 6 to 8 weeks after the completion of treatment. Hypothyroidism is also a possible consequence of radiation, and therefore patients should have thyroid function testing before treatment and every 6 to 12 months. Hypothyroidism rates as high as 30% to 40% have been reported in the literature after radiation.[13] Hormonal replacement can be given to replete thyroid hormone levels. More serious though rarer late sequelae from RT include laryngeal arytenoid edema and laryngeal arytenoid necrosis. In patients who have been irradiated for carcinoma of the glottis, the incidence of mild to moderate laryngeal edema persisting for more than 3 months after RT is about 15.4% to 25%.[14] The incidence of severe laryngeal edema is about 1.5% to 4.6%,[15-18] and this increases with greater total dose, field size, dose per fraction, and T stage of the lesion.[16,18,19] Initially these patients should be managed conservatively with voice rest, abstinence from alcohol and cigarettes, and careful, close follow-up examinations. Antibiotics and low-dose steroids (i.e., 2 mg po bid) may be used when there is suspicion of infection or when the edema is severe enough to significantly compromise the airway. However, if the edema is progressive and unresponsive to conservative measures and recurrent disease is strongly suspected, biopsies should be carried out to rule out malignancy as the underlying cause. Salvage surgery is performed if biopsies are positive. Late laryngeal arytenoid necrosis after RT is rare, with a reported incidence of about 0.5% to 1.8% for glottic cancer.[15,20,21]

Advanced-Stage Glottic Cancer (T_3 or T_4, Stage III or IV)

Overall Considerations: Balancing Cure, Organ Preservation, and Quality of Life

Historically, resectable locally advanced carcinoma of the glottic larynx (i.e., T_3 and T_4 and/or N_2 and N_3 disease) has been generally treated with combined surgery and postoperative RT. However, a primary surgical approach requiring a total laryngectomy has the disadvantage of loss of organ function such as voice and swallowing. Hence during the past several decades, various primary nonsurgical approaches have been explored to achieve cure of locally advanced disease and preserve the larynx so as to maintain organ function. These therapeutic approaches have consisted of radiotherapy alone or a combination of chemoradiation therapy. Currently, concurrent chemoradiation therapy has evolved to become the "standard of treatment" for patients with locally advanced laryngeal cancer who otherwise would require a total laryngectomy. For patients whose primary lesion is amenable to conservation laryngeal surgery, the choice is between chemoradiation and the former. The authors advise against the use of such a "generic" reflexive chemoradiation approach that does not individualize therapy for each patient. For example, a patient presenting with a large-volume laryngeal glottic carcinoma with significant epiglottic destruction and poor voice quality is unlikely to have reversal of these symptoms let alone eradication of local disease; hence a primary surgical approach consisting of a total laryngectomy followed by postoperative RT with or without chemotherapy would be more optimal for the patient in this setting.

Hence we recommend a primary surgical approach in the following settings:

1. Large, bulky tumors in which concurrent chemoradiation is unlikely to achieve local control of disease.

2. Poor presenting quality of voice, which is unlikely to reverse with a primary nonsurgical therapeutic approach.

Table 112-3

Postoperative Head and Neck/Glottic Trials with Chemoradiation

Study	High-Risk Population			Outcomes			
				LC	DFS	OS

German ARO 96-3[25]	1) + LN ≥ 3 2) + ECE 3) + margins	5-yr	RT CT/RT	72.2% 88.6%	50.1% (PFS) 62.4%	48.6% 58.1%	(p = 0.11)

3. A destroyed epiglottis resulting in an irreversibly compromised swallowing function with a high probability of aspiration.

Primary Surgical Approach: Adjuvant Therapy

At USC, we prefer to use postoperative versus preoperative radiotherapy in the setting of a primary surgical approach based on results of the Radiation Therapy Oncology Group (RTOG) 7303 and the "inherent" advantages of adjuvant treatment.[22] RTOG 7303 was a randomized trial comparing preoperative (50 Gy) versus postoperative (60 Gy) RT in advanced-stage, operable supraglottic larynx and hypopharynx cancers. The 10-year locoregional control was significantly improved in the postoperative versus the preoperative group (70% vs. 58%, respectively). Additionally, the rate of complications was much higher in the patients undergoing preoperative RT (9%) versus the postoperative group (5%). On the basis of the results of this RTOG study and the inherent advantage of having pathologic information after surgery, postoperative RT is preferred over preoperative RT. At USC, the role of preoperative RT is limited to shrinking locally advanced disease considered to be unresectable.

Although locoregional tumor control rates with total laryngectomy followed by postoperative RT are relatively high, some patients with high-risk disease features still do poorly with adjuvant radiotherapy alone. Hence several randomized trials have evaluated the role of adding concurrent chemotherapy to adjuvant RT following surgery for locally advanced head and neck cancer including primary laryngeal tumors. These studies include RTOG 9501, European Organization for the Research and Treatment of Cancer (EORTC) 22931, and the German ARO 96-3 study (Table 112-3).[23-26] All three of these randomized trials showed that adjuvant concurrent chemoradiation therapy is better than radiotherapy alone for local control and disease-free survival in patients with high-risk disease following surgery. In the RTOG 9501 trial, 459 patients with high-risk locally advanced head and neck cancer defined as any T-stage disease with two or more involved lymph nodes, positive extracapsular extension (ECE), and/or positive mucosal margins of resection were randomized to either RT alone (60 to 66 Gy at 2.0 Gy/fx) or the same RT with concurrent cisplatin (100 mg/m^2 on days 1, 22, and 43). At 2 years, local control rates (82% vs. 72%, p = 0.01, respectively) and disease-free survival (35% vs. 25%, p = 0.04, respectively) were significantly better among those who underwent adjuvant chemoradiation therapy versus radiotherapy alone, respectively. However, there was no statistical difference in overall survival between the two arms (45% vs. 35%, p = 0.19, respectively). In the EORTC 22931 trial, high-risk disease was defined as any patient with a pT_3 or pT_4 tumor with any nodal stage, or a pT_1/pT_2 tumor with N_2 or N_3 disease, or pT_1/pT_2 and N_0 or N_1 disease with involved mucosal margins, positive ECE, perineural invasion, and/or vascular emboli. In the EORTC trial, 334 patients were randomized to RT alone (66 Gy at 2.0 Gy/fx) or the same RT with cisplatin (100 mg/m^2 on days 1, 22, and 43). At 5 years, local control rates (82% vs. 69%, p = 0.007, respectively) and progression-free survival (PFS) (47% vs. 36%, p = 0.02, respectively) and overall survival (53% vs. 40%, p = 0.04, respectively) were significantly better among those who underwent adjuvant chemoradiation therapy versus radiotherapy alone, respectively. The German ARO 96-3 trial included 440 high-risk patients with three or more involved lymph nodes, ECE and/or involved mucosal margins of resection who were randomized to either RT alone (66 Gy at 2.0 Gy/fx) or the same RT with concurrent cisplatin (20 mg/m^2 on days 1 to 5 and 29 to 33) with 5-fluoruracil (600 mg/m^2 on days 1 to 5 and 29 to 33). As with the other two trials, adjuvant concurrent chemoradiation therapy as compared with RT alone improved local control rates (72% vs. 89%, p = 0.00259, respectively) and PFS (50% vs. 62%, p = 0.024, respectively) at 5 years. However, there was no statistical difference in overall survival between the two arms (49% vs. 58%, p = 0.11, respectively) at 5 years.

Hence at USC, patients with locally advanced laryngeal cancer who are found to have low-risk disease (i.e., ≤1 involved lymph nodes, no extracapsular extension and/or negative mucosal margins of resection) after surgery are treated with adjuvant radiotherapy alone (66 Gy at 2.0 Gy/fx). Those patients with high-risk locally advanced head and neck cancer are treated with adjuvant concurrent cisplatin (100 mg/m^2 on days 1, 22, and 43) and radiotherapy (at least 66 Gy at 2.0 Gy/fx). However, treating physicians should be forewarned that acute severe toxicity (e.g., mucositis, epidermatitis, dysphagia, odynophagia) associated with concurrent adjuvant chemoradiation therapy is usually twice that of using adjuvant radiotherapy alone. Hence patients undergoing concurrent adjuvant chemoradiation therapy require considerable nutritional (e.g., dietary consultation/intervention, PEG placement as needed) and rehabilitative support. Certain patients with high-risk disease (e.g., the very elderly, those with poor KPS and/or nutritional status) may not be good candidates for adjuvant concurrent chemoradiation therapy; in these cases, concurrent chemotherapy with adjuvant radiotherapy may not be possible. Therefore a more prudent approach

may be to proceed with adjuvant radiotherapy alone rather than risk not being able to complete the planned course of adjuvant chemoradiation therapy alone!

Organ Preservation Approaches: Combining Chemotherapy with Radiation Therapy

The main disadvantage of a primary surgical approach is the loss of organ function. Although progressive surgical reconstructive techniques such as tracheoesophageal punctures allow patients who undergo total laryngectomies to phonate, voice quality is suboptimal and patients often express dissatisfaction with the results. For example, in a study evaluating the significance of organ preservation, 20% of people would elect to maintain their voice at the expense of decreased survival.[27] Hence therapeutic options that would allow patients to preserve their larynx without compromising survival have been explored for the past several decades.

Because RT alone for the treatment of advanced laryngeal cancer provided poor results, focus has been turned to adding chemotherapy with radiation in attempts to preserve the larynx and maintain survival for the past several decades. The first randomized study to evaluate a surgical versus nonsurgical approach was the Veterans' Administration (VA) Laryngeal Preservation Trial.[28] This trial randomized 332 patients with stage III and IV (excluding T_1N_1 lesions) between surgery (total laryngectomy) followed by postoperative RT versus induction chemotherapy with fluorouracil and cisplatin, followed by definitive RT. At 2 years there was a 64% laryngeal preservation rate in the chemoradiation group, but no difference in overall survival (OS) at 68% between the two treatment arms; hence OS was equivalent with the chemoradiation arm but with almost two thirds of the patients retaining their larynx. However, one of the criticisms of the VA Laryngeal Preservation Trial was the lack of a radiotherapy-alone arm. So the Head and Neck InterGroup Laryngeal Preservation Trial (RTOG 9111) was designed. This was a three-arm phase III trial that randomized patients with stage III and IV laryngeal cancer to standard RT alone (70 Gy in 35 fractions) versus induction cisplatin (100 mg/m^2 on days 1 and 22) with 5-fluorouracil (FU) (1000 mg/m^2 daily continuous infusion for 5 days for two cycles) followed by the same standard RT, or concurrent cisplatin (100 mg/m^2 on days 1, 22, and 43) with the same RT.[29] The primary end point of laryngeal preservation was 83.6% in the concurrent chemoradiation therapy arm, compared with 70.5% ($p = 0.0029$) in the induction chemotherapy arm and 65.75% ($p = 0.0018$) in the RT-alone arm at 5 years. The 5-year rates of local regional tumor control were also significantly improved in the concurrent chemoradiation therapy arm (68.8%) compared with the induction chemotherapy arm (54.9%, $p = 0.0018$) or the RT-alone group (51%, $p = 0.0005$). The 5-year overall survival was similar in all three groups (54.6% in the concurrent chemoradiation arm, 59.2% in the induction chemotherapy arm, and 53.5% in the RT-alone group). The laryngectomy-free survival (in which either a laryngectomy or death from any cause constituted a treatment failure) was also similar between the concurrent chemoradiation arm (46.6%) and the induction chemotherapy arm (44.6%), but both were better than the RT-alone group (33.9%).[30] Hence on the basis of the Head and Neck Intergroup Laryngeal Preservation trial, concurrent chemoradiation therapy is considered a viable alternative to a primary surgical approach for advanced laryngeal carcinoma. *However, the RTOG Intergroup trial did not typically include large bulky tumor or "advanced T4 lesions," so caution must be exercised in extrapolating the results from these trials to "blankety" recommending concurrent chemoradiation for advanced laryngeal cancers.*

Additionally, achieving better locoregional tumor control and larynx preservation with concurrent chemoradiation therapy comes with a price of increased toxicity; the rate of severe toxicity (acute and late effects) was significantly higher with concurrent chemoradiation therapy (82%) as compared with RT alone (61%).[29] Hence, as with adjuvant chemoradiation therapy, these patients require extensive nutritional and rehabilitative support.

Review of quality-of-life (QOL) factors comparing surgery against larynx-preserving treatment reveals that there is no statistically significant difference in overall QOL scores between the two groups.[31] There was a trend toward better social functioning in the chemoradiotherapy group, but significantly greater dissatisfaction with dry mouth. The surgery group had significantly greater problems with taste and smell, coughing, and use of painkillers. From a cost-effectiveness standpoint, the cost of total laryngectomy followed by RT is approximately $3000 less than organ-preserving chemoradiation strategies.[32]

Organ Preservation Approaches: Combining Targeted Biologic Agents with Radiation Therapy

Incorporation of targeted biologic agents into the multimodality treatment of advanced head and neck cancers remains investigational. Recently, a phase III multinational, randomized trial comparing RT alone using various dose-fractionation schemes (i.e., 70 Gy in 35 fractions, 72.0-76.8 Gy at 1.2 Gy/fx bid and 72 Gy in 42 fxs [concomitant boost technique]) or with same concurrent RT with cetuximab for stage III or IV nonmetastatic squamous cell carcinoma of the oropharynx, hypopharynx, and larynx was completed.[33] Cetuximab is a monoclonal antibody against the epidermal growth factor receptor that is abnormally overexpressed in head and neck squamous cell carcinomas. Chemotherapy was not used in this trial because concurrent chemoradiation had not become the standard of treatment at the time the trial was designed. This study revealed improved 2-year local control rates (41% vs. 50%, respectively) and 3-year overall survival (45% vs. 55%, respectively) with the cetuximab/RT arm. However, a few caveats need to be appreciated regarding this trial. The majority (60%) of patients enrolled in this trial had oropharyngeal primaries. The local control benefit was limited to patients with oropharyngeal primaries, and the overall survival benefit was limited to patients with oropharyngeal primaries treated with a concomitant boost technique (72 Gy in 42 fxs). Moreover, the role of targeted biologic agents in the setting of chemoradiation therapy is unknown. This role is currently being addressed in RTOG 0522, which randomizes patients with stage III and IV head and neck squamous cell carcinomas to RT (72 Gy in 42 fxs using an accelerated fractionation scheme with concomitant boost) and cisplatin with or without cetuximab. Therefore given the above caveats, results from randomized trials are necessary before targeted biologic agents can be incorporated into the chemoradiation therapy treatment of laryngeal cancer. Moreover, the authors caution against the substitution of targeted biologic agents for chemotherapy agents with radiotherapy in the absence of randomized data.

Most Optimal Radiotherapy Dose-Fraction Scheme

The most optimal radiation dose fractionation scheme to use concurrently with chemotherapy remains unknown. Hyperfractionated irradiation uses higher total doses of radiation in the same time interval as standard fractionated (once-daily) irradiation to achieve at least the same local control but theoretically with reduced late toxicity. Accelerated fractionated radiotherapy aims to deliver the same total dose of irradiation as standard fractionated (once-daily) radiotherapy but in a shorter time interval to improve local control with theoretically the same late toxicity. RTOG 0129, which was recently closed to accrual, randomized locally advanced head and neck cancer (larynx and nonlarynx sites) patients to standard radiotherapy (70 Gy in 35 fractions given once a day) or accelerated fractionated RT with concomitant boost ([AFX-C] 72 Gy in 42 fractions at 1.8 Gy/fx with a concomitant boost at 1.5 Gy/fx during the last 12 fractions) with concurrent cisplatin (100 mg/m^2 every 3 weeks × 3 on days 1, 22, and 43) in both arms. The basis for the AFX-C arm was RTOG 9003,[34] which was the largest randomized trial to evaluate various dose fractionation schemes for head and neck squamous cell carcinomas. This was a four-arm randomized trial that compared standard fractionated radiotherapy (70 Gy in 35 fractions at 2.0 Gy/fx given once a day) with hyperfractionation (81.6 Gy in 7 weeks at 1.2 Gy/fx given twice daily), accelerated fractionation (67.2 Gy in 6 weeks at 1.6 Gy/fx twice daily including a 2-week break after 38.4 Gy), or AFX-C scheme (72 Gy in 42 fxs at 1.8 Gy/fx with a concomitant boost at 1.5 Gy/fx during the last 12 fractions). The 2-year local regional control rate was the best in the AFX-C arm (54.5%) compared with the standard fractionation arm (46.0%), so it was chosen as the experimental arm for RTOG 0129.

However, the price for this greater local control in the AFX-C arm was higher grade ≥3 toxicity (58.8% vs. 35% for standard RT). Hence we recommend using standard fractionated radiotherapy (1.8 or 2.0 Gy/fx once daily) with or without chemotherapy until the results of RTOG 0219 show otherwise.

Radiation Therapy Techniques: General Principles

Recently, technical advances in the delivery of irradiation such as 3-D CRT and intensity modulated radiation therapy (IMRT) have allowed for better homogeneous delivery of radiation doses, more precise delivery of radiation dose to the tumor and normal tissues so as to minimize dose to the surrounding critical organs (e.g., spinal cord, salivary glands) and thus reduce late toxicity (e.g., xerostomia), and the escalation of radiation dose to improve local-regional control of tumor.[35-38] The choice of whether to use 3-D CRT, IMRT, or a combination of both depends on a number of factors including the extent of disease in the head and neck area and the experience of the radiation oncologist in using the specific technology. Typically, IMRT is used to deliver radical doses of irradiation to the primary tumor and involved lymph nodes with the aim of limiting high doses to the salivary glands and other critical organs. For example, in a patient with extensive bilateral pathologic neck disease including levels I-III, it would not be wise to use IMRT because salivary glands are unlikely to be spared the high doses of irradiation due to their proximity to the involved neck disease. In fact, a number of investigators have reported a high risk of neck recurrences following IMRT among patients who were probably not the most suitable patients for this type of highly precise delivery of irradiation.[39-41] Additionally, IMRT also presents with the further challenge of determining how "hot" to run your primary tumor dose and how "cold" to run your involved lymph nodes for the treating radiation oncologist.[42] Of note, there have been no phase III randomized trials that have compared 3-D CRT with IMRT in head and neck cancer. As a general principle, high doses of irradiation are delivered to the areas of gross and/or resected disease and the involved lymphatic nodal regions (i.e., ≥60 Gy at 2.0 Gy/fx), whereas lower doses (i.e., 50-54 Gy at 2.0 Gy/fx) are used for the next echelon of uninvolved lymph nodes and subclinical microscopic disease (Table 112-4).

At the University of Southern California, a 3-D CRT approach is used among patients who present with either pathologic or subclinical *extensive* neck disease in whom limiting dose to the salivary glands is considered to be too risky due to concern for marginal miss of disease. Occasionally, a combination of 3-D CRT may be employed initially for the treatment of gross and subclinical disease followed by an IMRT boost to the regions of gross and/or resected disease, which allows for dose escalation while sparing higher doses to the surrounding critical organs. At USC, daily amifostine (Ethyol) is used for salivary gland protection when a significant portion of the salivary gland(s) is to be irradiated.[43]

Radiation Therapy Techniques: Patient Setup and Dose-Fractionation Schemes

Patients are immobilized in the supine position with thermoplastic immobilization masks. For patients undergoing a 3-D CRT approach, irradiation of advanced laryngeal carcinoma is accomplished using opposed lateral shrinking fields that encompass the primary tumor and the upper cervical lymph nodes, which are matched with an anterior AP field (i.e., "three-field" technique) (Fig. 112-6A-E). Ideally, the upper and lower fields should be set up using a "half-beam" technique so that the potential overlap in the spinal cord region can be dosimetrically reduced. Therefore this setup uses one isocenter, which becomes the inferior border of the lateral fields and the superior border of the anterior low-neck field. Nonetheless, a safety spinal cord block should still be placed either in the inferior-posterior portion of the lateral upper neck fields or the upper midcenter position of the lower neck field so that any areas of gross disease are not blocked. Typically the superior border of the initial field should cover the level II lymph nodes as appropriate and indicated, which requires that the field extend to the base of skull. In cases where there is suspected cranial nerve involvement, a margin above the base of skull must be left to encompass the appropriate foramen. The lower border of the lateral fields should encompass the larynx, usually at or below the level of C5 (the bottom of the cricoid cartilage) depending on disease extent. The guiding principle is that all areas of gross disease with at least a 2.0-cm margin in the initial volume should be included in the lateral fields. A single anterior field is used to irradiate the lower neck. This also encompasses the supraclavicular and infraclavicular regions and should be wide enough to cover at least the medial two thirds of each clavicle. After a dose of 40 Gy (at 2.0 Gy/fx) is delivered to the upper neck/opposed lateral fields, the posterior border is moved to the midvertebral bodies and the posterior necks are supplemented with electrons to shield the spinal cord from higher doses of irradiation so as not to exceed dose tolerance. Usually, at a dose level of 50 to 54 Gy, additional blocking is added to the opposed lateral upper neck fields so that the "boost field #1" is treated to 60 Gy encompassing the areas of resected or gross disease with generally a 1.5-cm margin. After 60 Gy, the upper neck opposed lateral fields are further reduced with more blocking so that the final "boost field #2" is treated to 70 Gy encompassing areas of gross disease, positive mucosal margins, and/or extracapsular extension with a 1.0-cm margin. Sometimes, a final boost field #3 is also necessary for dose escalation to 74 to 76 Gy level. The lower neck AP field is treated to a dose of 50 Gy delivered to a depth of 3 cm to adequately treat the uninvolved lymph nodes. If an emergent tracheostomy was performed, then the stoma (which is usually encompassed in the lower neck AP field) needs to be treated to at least 56 Gy, which can be achieved by giving an extra *en face* electron boost dose of 6 Gy.

When there is extensive subglottic involvement and/or positive lymph nodes in the low neck or supraclavicular fossa, a mini-mantle field technique can be used. In this technique, matching anteroposterior and posteroanterior fields are used, with the patient in the hyperextended position to achieve homogeneous dose distribution and to prevent unnecessary irradiation to the lips and oral cavity. The mini-mantle field extends superiorly from the mastoid processes to the lower neck area to include the supraclavicular and infraclavicular fossae. Typically, the mini-mantle field is treated to 40 Gy, after which the patient is switched to a three-field plan as described earlier (i.e., two parallel opposed lateral fields that are half-beam junctioned with an AP anterior field) and a shrinking field technique is used to treat the patient to definitive radiation doses.

Table 112-4

Recommended Standard Radiation Dose-Fractionation Schemes

Region at Risk	Total Dose (Gy at 2.0 Gy/fx Once Daily)
Gross primary and/or gross lymphatic nodal disease	≥66-70
Resected primary and/or lymphatic nodal disease*	≥60-66
Next-echelon uninvolved lymphatic nodal station	50-54

*Positive margin and/or ECE.

Outcomes and Prognostic Factors

Typically, locoregional tumor control rates are influenced by the ability to control both the primary tumor and nodal adenopathy, whereas overall survival is mostly influenced by the extent of nodal disease, which is a predictor and harbinger of metastatic disease. Local control rates for T_3-T_4 lesions treated with definitive chemoradiation therapy vary between 70% and 80% (Table 112-5). Laryngeal preservation rates range from 50% to 75% using either RT alone or chemoradiation therapy. Local control rates for advanced glottic lesions treated with

Table 112-5

Outcome with Definitive Chemoradiation Therapy for Locally Advanced Laryngeal Cancer

Trial	Primary Tumor Site	Patients (*n*)	Local Control	2-Yr Overall Survival	Larynx-Preservation Rate
Department of Veterans Affairs Laryngeal Cancer Study Group[28]	Larynx	332	Surgery, 93% Induction CT, 80%	68% in both arms	Surgery, N/A Induction CT, 64%
GETTEC[78]	Larynx (T_3)	68	Surgery, 87.5% Induction CT, 75%	Surgery, 84% Induction CT, 69%	N/A 42%
RTOG[29,30]	Larynx	547	RT, 56% CT→RT, 61% CT/RT, 78%	RT, 75% CT→RT, 76% CT/RT, 74%	RT, 70% CT→RT, 75% CT/RT, 88%
2006 ASCO Update		515	RT, 51% CT→RT, 54.9% CT/RT, 68.8%	RT, 53.5% (5-Yr) CT→RT, 59.2% CT/RT, 54.6%	RT, 65.7% CT→RT, 70.5% CT/RT, 83.6%

CT, chemotherapy; CT→RT, induction CT followed by RT; CT/RT, concurrent CT and RT; RT, radiation therapy.

total laryngectomy and postoperative radiation with or without chemotherapy range from 70% to 88%. Overall survival for stage III or IV disease ranges from 35% to 50% at 5 years. Recognizing that the majority of patients with advanced laryngeal carcinoma have other tobacco and/or alcohol related comorbidities, the significantly lower overall survival rate reflects deaths caused by other noncancerous-related conditions. A treatment algorithm for the management of glottic carcinomas is presented in Figure 112-7.

As with early-stage glottic cancer, the prognosis of patients with advanced laryngeal disease is affected by hemoglobin levels, extent of nodal disease, and elapsed treatment days. For example, in a retrospective review of 306 patients with stage III to IV glottic or supraglottic cancer, van Acht and colleagues[44] showed that both local control and overall survival were affected by pretreatment hemoglobin levels.

Complications from Radiation Therapy

Not unexpectedly, both the acute and late side effects are more frequent and severe with advanced-stage glottic cancer as compared with early-stage disease due to multiple factors including larger field sizes, higher total doses, and combined modality therapy including surgery and/or chemotherapy. For example, data from RTOG 9111 showed that 77% of patients in the concurrent chemoradiation arm experienced grade ≥3 acute toxicity compared with only 47% in the RT-alone group. Furthermore, both acute and late sequelae were determined to be 82% in

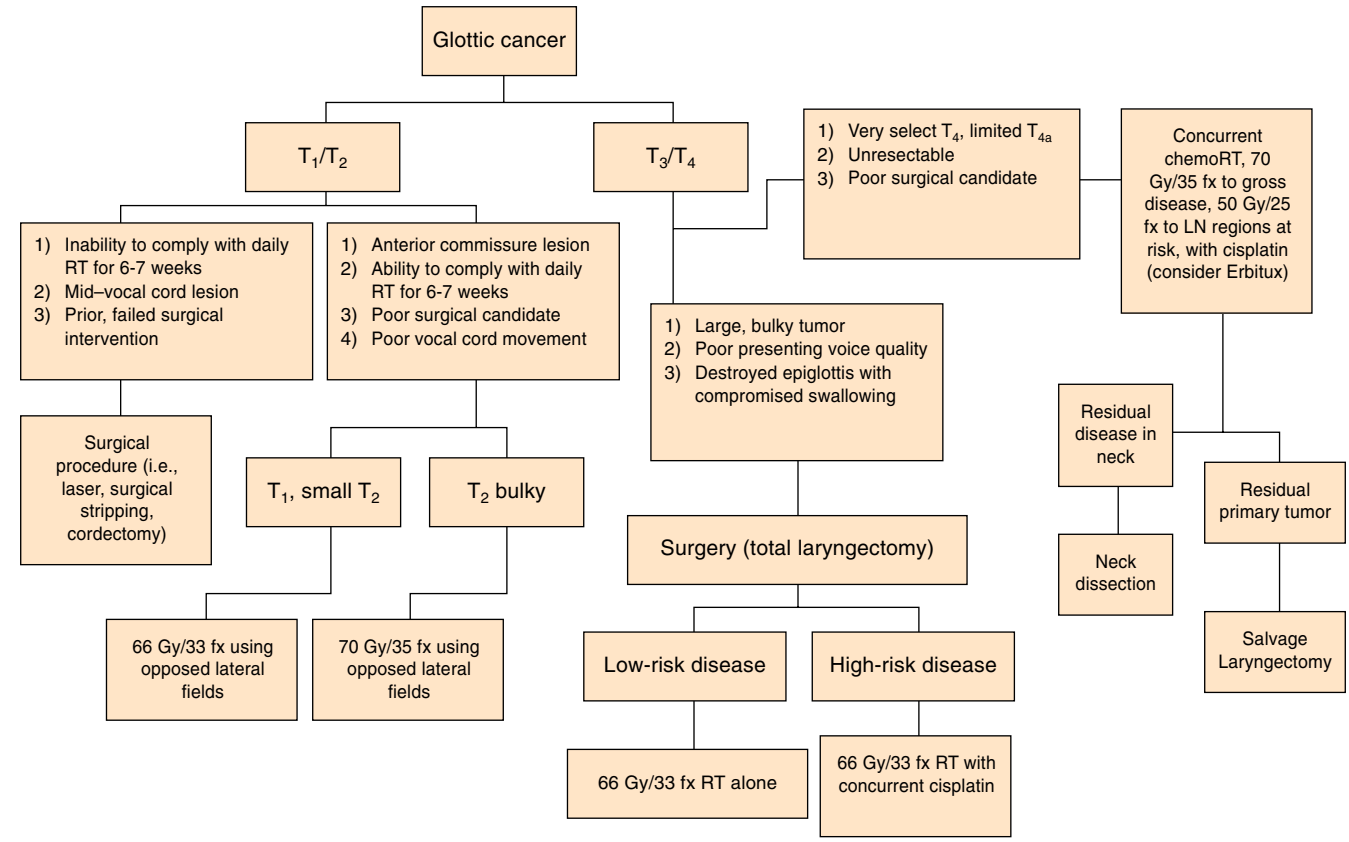

Figure 112-7. Treatment algorithm for glottic carcinomas.

the concurrent chemoradiation arm versus only 61% in the RT-alone group.[29]

Acute common side effects that are transient include skin erythema and desquamation, oral mucositis, and xerostomia with accompanying changes in taste. These acute side effects are self-limiting and need to be treated symptomatically with the aim of maintaining adequate liquid and nutritional intake so that radiotherapy treatments can be continued without significant interruptions. We do not recommend the prophylactic placement of a percutaneous esophagogastrectomy tube (PEG) unless the patient has already lost more than 10% of the baseline body weight or is unable to maintain nutritional intake by mouth due to the effects of the cancer or other reasons. In our experience the prophylactic placement of a PEG decreases the motivation for the patient to maintain oral intake during the radiotherapy treatment and quite often results in the patient becoming chronically PEG dependent. However, in order to support the patient during periods of decreased oral intake, we recommend aggressive intravenous fluids for up to three to five times per week. In addition, the use of radioprotectors such as amifostine also ameliorate the acute toxicity of radiotherapy such as mucositis and xerostomia.[43] Late sequelae from radiotherapy therapy include xerostomia and neck fibrosis, especially exacerbated by surgery. Rare late sequelae include mandibular osteoradionecrosis or arytenoid necrosis and chronic laryngeal edema.

Early-Stage Supraglottic Cancer

Many of the same general management principles used to treat early-stage glottic cancers also apply to the management of supraglottic lesions and are therefore not repeated in this section; however, the unique and salient features in the treatment of supraglottic cancers are highlighted. As with early-stage glottic cancers, early-stage $T_{1\text{-}2}$ supraglottic cancers can be treated with either radiotherapy alone or supraglottic laryngectomy, with excellent local control and preservation of voice. However, unlike T_1 glottic cancers, T_1 supraglottic lesions and certainly T_2 cancers require treatment of the next-echelon, uninvolved lymphatic nodal regions because of their propensity for subclinical metastases, and thus the risk of xerostomia is more significant in this setting and is a potential disadvantage to using radiotherapy. Conversely, not every patient with early-stage supraglottic disease is a candidate for supraglottic laryngectomy. From an anatomic standpoint, supraglottic laryngectomy is contraindicated under the following conditions:

1. More than minimal extension into the medial wall of the pyriform sinus
2. Involvement of the postcricoid region
3. Arytenoid fixation or bilateral arytenoid involvement
4. Impaired vocal cord mobility or fixation
5. Invasion of the thyroid or cricoid cartilage
6. Extension into the infrahyoid epiglottis or into the ventricle within 5 mm of the anterior commissure and/or the true vocal cord(s)
7. Extension into the base of the tongue to involve both lingual arteries and/or extension anterior to the circumvallate papillae

Of course, from a functional standpoint, elderly patients or those with poor lung function who may have difficulty swallowing and consequent complications of aspiration are also not good candidates for conservation surgery.

Radiation Techniques and Dose-Fractionation Schemes

The dose-fractionation schemes for early-stage supraglottic cancers are similar to those for early-stage glottic cancer as indicated earlier in the chapter. However, because of the propensity for lymphatic nodal

metastases for even T_1 and obviously T_2 lesions, the treatment volume should include any involved regional lymphatic nodes and the uninvolved next-echelon lymphatics.

At USC, we treat T_1 tumors with 66.0 Gy in 2.0 Gy/fx, again with a shrinking field technique with the final total dose delivered to the tumor with a 2.0-cm margin. The treatment volume should include the involved lymph nodes and the next-echelon uninvolved lymphatics. The involved lymph nodes should be treated with radical doses of radiation depending on the size of the disease (i.e., ≤1 cm with 60.0 to 66.0 Gy, >1 to 2 cm with 66 Gy and >2 cm with at least 70 Gy at 2.0 Gy/fx), and the uninvolved lymphatics should be treated with 50 Gy at 2.0 Gy/fx. For T_2 lesions, we recommend doses of at least 70 Gy at 2.0 Gy/fx. Several investigators have reported using alternative-dose fractionation schemes for T_2 lesions. Hinerman and colleagues[45] used a twice-daily hyperfractionated schedule for a total dose of 74.4 to 76.8 Gy at 1.2 Gy/fx with a minimum daily interfraction interval of 6 hours. Other investigators such as Wang and Montgomery[46] at the Massachusetts General Hospital have used an accelerated, fractionated radiotherapy schedule with a total dose of 67.2 Gy at 1.6 Gy/fx, twice a day, 5 days per week, with a 2-week rest after 38.4 Gy. We recommend caution using these alternative fractionation schedules unless the treating radiation oncologist has experience with these types of schemes because these patients require considerable support during their treatment because of acute toxicity.

The choice of treatment technique depends on multiple factors including the extent of the disease and the experience of the treating radiation oncologist. At USC, two parallel opposed fields using a 3-D CRT approach are used for T_1N_0 lesions, whereas a classic three-field technique (described previously) is used to treat $T_{1\text{-}2}$, N+ disease with successive shrinking fields.

Outcome and Prognostic Factors

Local control after RT for T_1 supraglottic carcinoma is excellent, ranging from 88% to 100%. For T_2 lesions, local control after RT varies from 73% to 89% (Table 112-6). Overall survival for stage I and II supraglottic cancers is 60% to 73%, comparable with the survival data for early-stage glottic tumors. Prognostic factors for glottic tumors also apply to supraglottic lesions.

Complications from Radiation Therapy

Compared with patients undergoing radiation for early-stage glottic tumors, patients undergoing radiation for early supraglottic lesions experienced more side effects from radiation secondary to the use of typically larger fields.

Advanced Supraglottic Cancer

The same principles used to select the optimal management for advanced glottic carcinoma also apply to advanced supraglottic cancers. *Hence we recommend a primary surgical approach for large, bulky tumors in which concurrent chemoradiation therapy is unlikely to achieve local control of disease; poor presenting voice quality that is unlikely to reverse with a primary nonsurgical therapeutic approach; or a destroyed epiglottis resulting in an irreversibly compromised swallowing function with a high probability of aspiration.* For T_3 lesions with mobile vocal cords, a supraglottic laryngectomy can be considered, with or without the addition postoperative RT depending on the risk status of the disease. However, as with glottic lesions, total laryngectomy is the preferred treatment for more advanced lesions with bilateral vocal cord involvement and compromised airway. When surgery is used as the primary definitive therapy, postoperative RT is added to reduce the risk of locoregional failure. Postoperative RT is indicated when there is tumor at or close to the surgical margins, cartilage invasion, involvement of the soft tissues of the neck, extensive subglottic infiltration, lymphatic nodal metastasis, extracapsular nodal extension, and perineural, lymphatic, or vascular invasion. Indications for adding chemotherapy to postoperative irradiation include other risk factors such as two or more involved lymph nodes, extracapsular extension, and/or positive surgical margins.

Concurrent chemoradiation therapy is a reasonable treatment option for patients with nonbulky, locally advanced supraglottic cancers. Typically, results with RT alone for locally advanced supraglottic cancers are suboptimal. Harwood and colleagues[47] and Karim and colleagues[48] reported local control rates of 56% (39 patients) and 63% (38 patients), respectively, with T_4 disease.

Table 112-6

Local Control after Radiotherapy for Early-Stage Supraglottic Carcinoma

Series	Stage	Patients (*n*)	Local Control
Fletcher et al (1980)[79]	T_1	24	88%
	T_2	56	79%
Ghossein et al (1974)[80]	T_1	17	94%
	T_2	64	73%
Wall et al (1985)[81]	T_1	38	89%
	T_2	132	74%
Wang and Montgomery (1991)[82]	T_1	23	89%
	T_2	79	89%
Nakfoor et al (1998)[83]	T_1	24	96%
	T_2	73	86%
Skyes et al (2000)[84]	T_1	65	92%
	T_2	136	81%
Hinerman et al (2002)[85]	T_1	22	100%
	T_2	125	86%
Johansen et al (2002)[86]	T_1	154	64%
	T_2	86	62%

Radiation Techniques and Dose-Fractionation Schemes

The same general techniques used to treat advanced glottic cancers also apply to advanced supraglottic cancers. The total dose used to treat T_3 to T_4 supraglottic tumors using standard, once-daily fractionated RT is at least 70 Gy at 2.0 Gy/fx. Higher total doses (up to 76 Gy) may be used for bulky or nonresponding disease with either IMRT or stereotactic radiosurgery techniques. Please refer to Table 112-4 regarding our recommendations for radiation doses. The treatment volume should include any gross or resected regions of disease, as well as any involved regional lymphatic nodes and the uninvolved, next-echelon lymphatics. Please refer to the section on advanced glottic cancer for general principles regarding dose-volume recommendations.

Outcome and Prognostic Factors

As discussed previously, locoregional tumor control rates are approximately 80% with concurrent chemoradiation therapy, 60% with induction chemotherapy followed by RT, and 55% with RT alone for stage III and IV disease.[28,29] For selected T_3 and T_4 lesions, local control rates with RT alone vary between 46% and 76% and 43% and 91%, respectively (Table 112-7), and approximately two thirds of the failures can be salvaged by surgery (Table 112-8). Overall survival rates range from 37% to 50%.

Subglottic Cancers

Primary carcinomas of the subglottis are rare. As a result, RT data about the management of subglottic carcinoma is sparse. Paisley and colleagues[49] reported their retrospective analysis of 43 patients with subglottic cancer who were treated with primary RT alone. Overall, the initial local control was 56% with RT alone, with an ultimate local control rate of 81.4% with surgical salvage. When analyzed by T stage,

the initial local control rates for T_1, T_2, T_3, and T_4 lesions with primary RT alone were 63.6%, 66.7%, 50%, and 41.7%, respectively. With surgical salvage, the ultimate local control rates for T_1, T_2, T_3, and T_4 lesions were improved to 91%, 100%, 75%, and 58.3%, respectively. Most subglottic lesions are relatively advanced at the time of diagnosis and are managed by primarily with surgery followed by postoperative RT. However, definitive RT offers a viable alternative to surgery for the management of subglottic carcinomas. Overall survival rates range from 45% to 60% for stage I and II subglottic tumors and 30% to 45% for stage III and IV lesions. Our recommendations for dose-fractionation-volume for early- and advanced-stage subglottic cancers are similar to those of glottic carcinoma.

Hypopharyngeal Cancers

Overall Management Considerations

Because of the unique "anatomic intimacy" between the hypopharynx and the larynx, a primary surgical approach for the management of the hypopharynx typically requires sacrifice of the larynx; hence hypopharyngeal carcinomas, especially early- and intermediate-stage "low-volume" lesions, should be managed with definitive radiotherapy with or without chemotherapy whenever possible.

Early-Stage Hypopharynx

Early-stage hypopharyngeal carcinoma can be effectively managed with RT alone and is generally the preferred treatment modality due to the advantage of laryngeal organ preservation.

Radiation Techniques and Dose-Fractionation Schemes

The dose-fractionation schemes for early-stage hypopharyngeal cancers are similar to those for early-stage glottic cancer as indicated earlier in the chapter and Table 112-4. However, because of the propensity for lymphatic nodal metastases for even T_1 and obviously T_2 lesions, the treatment volume should include any involved regional lymphatic nodes and the uninvolved next-echelon lymphatics. Bilateral upper and lower necks need to be treated even in early-stage disease. A three-field technique as described earlier for glottic cancers is used, but some subtle yet important differences exist between the field designs for the hypopharynx. The inferior border of the lateral fields (and hence the superior margin of the lower neck field because one isocenter is used) is placed as low as possible on the neck without passing through the shoulder in order to give a margin on the inferior extent of disease. For posterior pharyngeal wall lesions, the posterior extent of the off-cord field is placed at the posterior third of the vertebral bodies as opposed to splitting the vertebral bodies in half to ensure an adequate margin on the tumor.

As with glottic cancers, T_1 lesions should be treated to at least 66 Gy at 2.0 Gy/fx using a shrinking field technique. For T2 lesions, a minimum total dose of 70 Gy at 2.0 Gy/fx should be used.

Table 112-7

Local Control after Radiotherapy for Advanced-Stage Supraglottic Carcinoma

Series	Stage	Patients, *n*	Local Control
Fletcher et al (1980)[79]	T_3	29	62%

Outcome and Prognostic Factors

In general, hypopharyngeal cancers carry a poorer prognosis when compared with laryngeal tumors. Local control rates range from 74% to 90% for T_1 disease and from 59% to 79% for T_2 disease (Table 112-9).[50-52] The use of hyperfractionated radiotherapy may improve local control rates for early-stage disease. Mendenhall and colleagues[51] reported local control of 94% in patients with T_2 pyriform sinus cancers treated with twice-a-day RT. Wang[52] reported a 5-year actuarial local control rate of 76% in patients with T_2 pyriform sinus cancer treated with split-course accelerated RT. Garden and colleagues[50] reported a local control rate of 89% for early-stage hypopharyngeal carcinoma. Overall survival is 30% to 35% for stage I and II hypopharyngeal carcinoma.

Complications

Because large fields are used to treat even early-stage disease, side effects experienced by patients undergoing radiation for early-stage hypopharyngeal tumors are similar to the effects experienced by advanced-stage laryngeal cancer patients.

Advanced-Stage Hypopharynx

As with laryngeal cancers, we recommend concurrent chemoradiation therapy only for those patients with low- or moderate-volume disease in whom speech and swallowing functions have not been already irreversibly compromised. Otherwise, we recommend a primary surgical approach followed by postoperative RT because of the high risk of local failure. An analysis by Frank and colleagues[53] found that patients with hypopharyngeal cancer who received postoperative irradiation had only a 14% rate of locoregional failure as compared with 57% in those treated with surgery only, despite the fact that patients treated with combined-modality therapy had more advanced disease. Indications for adding chemotherapy to postoperative irradiation typically include two or more involved lymph nodes, extracapsular extension, and/or positive surgical margins.

Voice-preserving strategies have been examined for this disease site as well. The European Organization for the Research and Treatment of Cancer (EORTC) conducted a voice-preservation study of patients with hypopharyngeal carcinomas, EORTC 24891, which revealed that an induction chemotherapy followed by radiation did not compromise survival and allowed laryngeal preservation in 35% of patients.[54] The details of this study are discussed later in "Outcome and Prognostic Factors." Hence combining chemotherapy with RT offers an alternative to patients with advanced-stage disease. However, based on the results of RTOG 9111 and other trials[55,56] we recommend concurrent chemoradiation therapy as compared with induction chemotherapy followed by definitive irradiation.

Radiation Techniques and Dose-Fractionation Schemes

The same general techniques used to treat advanced glottic cancers also apply to advanced supraglottic cancers. The total dose used to treat T_3 and T_4 hypopharyngeal cancer tumors using standard once-daily fractionated RT is at least 70 Gy at 2.0 Gy/fx. Higher total doses (up to 76 Gy) may be used for bulky or nonresponding disease with either IMRT or stereotactic radiosurgery techniques. Please refer to Table 112-4 regarding our recommendations for radiation doses. The same general techniques used to treat patients with early-stage hypopharyngeal cancers can be applied to treat patients with advanced-stage disease. Due to the typically large size of these lesions, maintenance of adequate margins around the gross tumor and areas of high-risk disease requires either a "mini-mantle" field arrangements as previously described or an IMRT technique.

Outcome and Prognostic Factors

As mentioned previously, hypopharyngeal cancer has the worst prognosis of any head and neck cancer. The 5-year local control rates range from 20% to 50% and overall survival rates from 18% to 35% for stage III and IV lesions. In the EORTC 24891, 202 patients were randomized to either immediate surgery followed by postoperative RT (50 to 70 Gy) or induction cisplatin (100 mg/m^2 on day 1) and 5-fluorouracil (1000 mg/m^2 daily on days 1 through 5) for three cycles followed by RT (70 Gy at 2.0 Gy/fx once daily). The locoregional failure rates were similar for both the surgery arm (31%) and the induction chemotherapy arm (40%). Survival rates were equivalent in the two treatment groups at 5 years (35% for the surgery arm vs. 30% for the induction chemotherapy arm), but patients in the chemotherapy group had a 5-year voice preservation rate of 35%. However, only 5% of the patients in this EORTC trial had T_4 disease. In combining chemotherapy with RT, we recommend a concurrent approach as the current "nonsurgical" standard of treatment.

The same factors that influence prognosis in laryngeal cancer affect outcome in hypopharyngeal tumors.[8,10,11,54,55] In addition, some data indicate that lesions in the postcricoid region have worse local control rates.[56]

Complications

Because similar fields are used to treat advanced hypopharyngeal tumors and laryngeal cancers, the same complications are experienced by this population of patients. Esophagitis leading to difficulty in maintaining oral intake and xerostomia are of particular concern when treating these patients.

Radiation Therapy for Recurrent Disease

The majority (80%) of the recurrences in head and neck cancer occur within the first 2 to 3 years after treatment, and prognosis of these patients is poor, with median survival of approximately 6 months.[57] Moreover, most of these recurrences are locoregional, so these patients still can be approached with a "curative" salvage therapy. In fact, up to 10% of patients with recurrence from their head and neck cancers can enjoy long-term control with aggressive therapy. Surgical salvage is preferred, but in many cases the recurrent disease is unresectable.

The management of patients with recurrent head and neck cancer is anything but "standard" and requires a thoughtful individualized approach for each patient on the basis of numerous factors including the following:

1. Time interval from the completion of prior curative therapy to the recurrence
2. Patient's performance status
3. "Surgical" versus "nonsurgical" disease and candidate

RTOG 9610 addressed the efficacy and safety of re-irradiation in patients for unresectable recurrence or secondary primaries in the head and neck within previously radiated fields. In this study, 86 patients were enrolled and treated with 4 weekly cycles of concurrent RT delivered in 1.5 Gy fractions twice daily, separated by at least 6 hours, to a total dose of 60 Gy, with concurrent 5-FU and hydroxyurea.[58] There was a week break between each weekly cycle. Estimated 2-year and 5-year overall survival was 15.2% and 3.8%, respectively. Grade IV toxicity was experienced by 17.7% of patients, and 7.6% experienced grade V toxicity (death). Three patients were alive at 5 years.

There is often the mistaken notion that patients with recurrent head and neck cancer should be treated "focally" with smaller fields to the areas of gross recurrent disease. However, quite often, the area of gross recurrent disease represents only the "tip of the iceberg" and "spot-welding" would only put the patient at risk for future recurrences in areas that are not irradiated. It is imperative to study the dosimetry from previous radiation and document doses to critical structures such as the spinal cord, mandible, and larynx (arytenoids, vocal cords). At the University of Southern California, patients with recurrent head and neck cancer are treated "comprehensively" using a continuous hyperfractionated radiotherapy scheme to 7700 cGy at 110 cGy/fx twice daily. The volume of irradiation includes the areas of recurrent gross disease and adjacent uninvolved lymphatic nodal regions. An "off-cord" three-field arrangement from the start of the re-treatment is typically used to keep the spinal cord dose below tolerance levels. IMRT is used in select situations to boost areas of gross disease in order to further limit dose to surrounding critical structures. In a recent report of our experience using this approach, we showed that comprehensive re-irradiation using a continuous hyperfractionated scheme is feasible and tolerable in the majority of patients.[59]

Future Strategies and Directions

Alternative Chemoradiation Therapy Strategies: The "RADPLAT" Approach

Another strategy for the treatment of advanced laryngeal and hypopharyngeal cancers involves the use of supradose intra-arterial cisplatin (100 mg/m^2 on days 1, 8, 15, and 22 with sodium thiosulfate rescue) and concurrent RT (68 to 74 Gy).[60] This strategy, termed "RADPLAT," has the advantage of "targeting" the chemotherapy to avoid the toxic systemic effects of intravenous chemotherapy while still sensitizing the effects of concurrent RT. The RADPLAT approach has been evaluated in locally advanced head and neck cancers including a multi-institutional trial of 67 patients with T4 disease.[61] In this RTOG trial (#9615), the RADPLAT approach was shown to be feasible in 87% of patients with a very high (80%) pathologic complete response rate and acceptable acute toxicity. Similar results were also shown in a study of 25 pyriform sinus cancer patients with stage III (24%) and stage IV (76%) disease who were also treated with the RADPLAT therapy.[62] Seventeen patients presented with bulky nodal disease, whereas 10 were diagnosed with T_4 lesions. At a median follow-up interval of 42 months, none of the 25 patients had experienced a local recurrence at the primary site, and only one patient relapsed regionally in the lymph nodes, which was subsequently salvaged with surgery. Moreover, the larynx preservation rate was 88%.

Emerging Technologies: CyberKnife Stereotactic Radiotherapy

In patients with head and neck cancer, local failure of disease not only adversely affects a patient's quality of life but also has a significant negative impact on overall survival. Escalation of radiotherapy doses represents one method of potentially reducing local failure rates and improving overall survival. However, escalation of radiotherapy doses beyond the "standard doses" (i.e., 70 to 76 Gy) using conformal radiotherapy techniques is not possible without causing significant increased acute and late sequelae. Additionally, not all patients with recurrent head and neck cancer are eligible to receive further re-irradiation for multiple reasons including maximal radiation dose to critical structures. One recent method of radiation dose escalation and re-treating recurrent head and neck cancer is CyberKnife (CK) stereotactic radiotherapy (SRT). The CK is a lightweight 6-MV photon linear accelerator mounted on a robotic arm that has the capability to deliver image-guided SRT with a "sharp" dosimetric dose profile. Since 2002, we have used CK SRT to treat more than 200 head and neck cancer cases for curative and palliative intent. Recently, we reported our results using CK SRT for management of recurrent head and neck carcinoma in the infratemporal fossa.[63] In this series, all patients with a prior history of chemoradiation therapy underwent further surgical debulking followed by CK SRT and cetuximab for their recurrent disease. CK SRT was well tolerated by all patients without any acute or late toxicity with moderate local control of recurrent disease.

CHAPTER ONE HUNDRED AND THIRTEEN

Vocal and Speech Rehabilitation Following Laryngectomy

Frans J. M. Hilgers

Michiel W. M. van den Brekel

Key Points

- Surgical prosthetic voice restoration is the best possible option for patients to regain oral communication after total laryngectomy and is considered the "gold standard" for voice rehabilitation of laryngectomized individuals.
- Surgical prosthetic voice restoration, in essence, is always achievable in patients fit enough to tolerate total laryngectomy and motivated to regain optimal oral communication.
- Surgical prosthetic voice restoration requires a multidisciplinary team approach (physician, speech therapist, oncology nurse) in order to obtain optimal results.
- If a good prosthetic voice deteriorates, prompt clinical consultation is required. Patients should be instructed accordingly.
- The vast majority of problems in prosthetic voice restoration are relatively simple and immediately solvable by a trained physician, speech-language pathologist, or nurse.
- Reconstruction of the pharynx (e.g., with free revascularized or pedicled flaps) does not preclude surgical prosthetic voice restoration.

History of Alaryngeal Voice and Speech

Historically the start of postlaryngectomy voice rehabilitation was surgical and prosthetic. The patient who underwent the first total laryngectomy (TL) for cancer, by Billroth in 1873, used an artificial larynx in order to speak. As eloquently described by Billroth's colleague Gussenbauer in 1874, the patient could be understood from one side of the ward to the other.[1] Considering that patient wards in those days were huge, holding up to 40 beds, this must have been an impressive achievement. This first artificial larynx, essentially a tracheotomy tube with a pharyngeal extension (Fig. 113-1), allowed pulmonary-driven speech. It contained a valve mechanism to prevent aspiration, a special membrane to act as a heat and moisture exchanger, and a reed to act as a vibrating tone generator. The only futile component of the initial artificial larynx was the tone generator in the form of a reed. Apparently, in preparing this device before the operation, it was not anticipated that diverting pulmonary air into the pharynx could produce mucosal vibrations and thus sound, which actually could interfere with the monotonous tone of the reed, potentially leading to diplophonia. The main reasons for abandoning artificial larynges in those early decades were the many wound-healing complications with these bulky devices in an era without proper anesthesia and antibiotics.[2] The discovery that with air insufflation the pharynx can act as a tone generator has undoubtedly helped to stay away from surgical voice restoration options for a long period of time.[3]

Over the past three decades, voice rehabilitation after TL has changed considerably. Until the late 1970s, there were only three options for audible postlaryngectomy voicing (i.e., esophageal voice, electrolarynx voice, and a surgical shunt between the trachea and the neopharynx). Besides these three options, there were the barely audible but sometimes still quite intelligible options of buccal and whispered voicing.

In the late 1970s and early 1980s, surgical procedures (e.g., Asai's, Staffieri's, and Amatsu's techniques) to create a functional tracheoesophageal fistula and thus allow tracheoesophageal voicing were initially popular but have since declined.[4-6] After the first enthusiastic reports about the good voice that could be achieved, many head and neck specialists became disappointed about troublesome aspiration problems. In essence, one could say that if the patient had a good voice, he or she would aspirate, and when there was no aspiration, the patient had no or only a strained voice. Although in many countries these techniques were more or less completely abandoned, in others they led to a quest for solving the aspiration problem.[7-12] The solution was found in the development of presently available voice prostheses, which have in common a surgically created tracheoesophageal fistula and the containment of a one-way valve mechanism.[13] These prostheses keep the tracheoesophageal connection open, allow the passage of pulmonary air into the esophagus in order to produce pharyngeal vibrations and sound, and prevent aspiration by automatic closure of the valve when the pulmonary air pressure drops. These devices have proven to be both functional and reliable.[14]

Some historical reflections are important at this point. Although Singer and Blom have been credited with initiating modern voice prostheses development, the first paper on a useful prosthetic device (Fig. 113-2) actually originated in Poland, where Mozolewski (1917-2007) in 1972 published his results with 24 patients.[15] This publication in Polish with abstracts in Russian and English probably went unno-

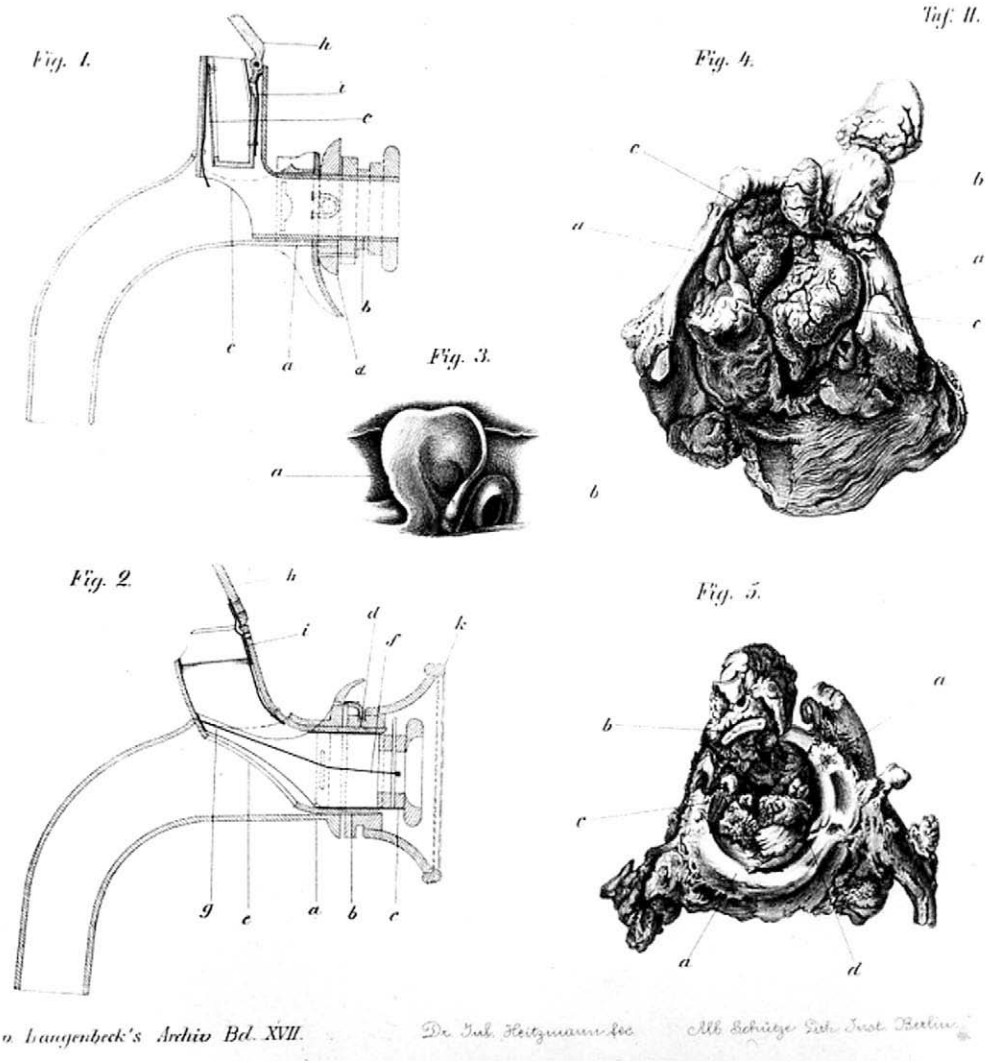

Figure 113-1. Drawings from the original paper by Gussenbauer. Note the almost complete obstruction of the subglottic space within the cricoid cartilage. On the left are the first and second versions of the artificial larynx. In the center the postoperative situation is depicted, with a pharyngostoma to hold the pharyngeal extension of the artificial larynx (note that the epiglottis was not removed). *(From Gussenbauer C. Ueber die erste durch Th. Billroth am Menschen ausgefuerte Kehlkopf-Extirpation und die Anwendung eines kuenstlichen Kehlkopfes.* Arch Klin Chir. *1874;17:343-356.)*

Figure 113-2. Photograph of the original hand-made indwelling Mozolewski voice prosthesis, which, unlike the present voice prostheses, was inserted in a pharyngocutaneous fistula just above the tracheostoma. *(Photograph courtesy of Prof. Dr. Czeslawa Tarnowska, Szczecin, Poland.)*

ticed. However, Mozolewski and colleagues[16] remained active and in 1975 published a report in *Laryngoscope* about a postlaryngectomy surgical arytenoid vocal shunt procedure as an alternative to the popular Asai procedure. Subsequently, they presented both their surgical and prosthetic methods at a conference in Boston in May 1978. After these initial reports, however, Blom and Singer have put prosthetic voice rehabilitation on the world map and diligently and tenaciously instructed and educated numerous clinicians. Since the introduction of the first Blom-Singer prosthesis in 1980, many other brands have been introduced and further developed: Panje, Groningen, Herrmann, Traissac, Algaba, Provox, Nijdam, and Voicemaster, many of which are still available.[7-12,17-19]

Physiology of Alaryngeal Voice and Speech

Prosthetic voice is pulmonary driven, as is laryngeal voicing. Sound is produced by comparable mucosal vibrations in the pharyngoesophageal segment.

For a good understanding of voice and speech rehabilitation after TL, the basic principles of normal laryngeal voice and speech production should be kept in mind. In order to be able to speak, it is necessary to have airflow, a sound source, and a cavity in which the sound will be

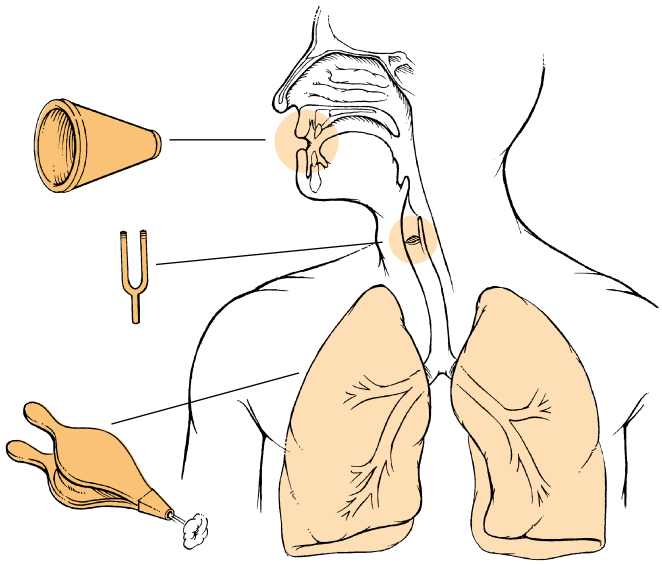

Figure 113-3. Necessary for normal speech are a bellows (i.e., pulmonary airflow), a sound source (i.e., vocal folds with vibrating mucosa), and a vocal tract, in which the articulators transform the laryngeal sound into intelligible speech. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

transformed into intelligible speech. Normally, the airflow is provided by pulmonary exhalation, which through the well-known Bernoulli effect causes vibrations of the mucosa in the voice box and thus a sound source. The sound thus produced will be transformed into intelligible speech in the mouth, nose, and throat cavities by articulation (e.g., by movements of the muscles present in that area, together forming the vocal tract, schematically shown in Fig. 113-3).

After TL the vocal tract is only slightly changed because the removal of the hyoid bone and the larynx alters the position of the tongue base, possibly influencing speech intelligibility. The most obvious change, however, is that the voice box as the natural sound source is replaced by the pharyngoesophageal (PE) segment, which has a significant impact on voice quality.[20] And without any additional measures, the disconnection of the airway and the PE segment makes the lungs unavailable as an air source.

Esophageal Voice and Speech

A potential source of air can be air injected into the esophagus and/or stomach. By expelling this air, it is possible to set the mucosa in the PE segment into vibration, which acts as a sound source. With the sound thus produced, intelligible speech can be formed in the intact vocal tract. This so-called esophageal speech is schematically depicted in Figure 113-4. A drawback of this method is that relatively little air is available (≈80 mL), in contrast to the liters of air in the lungs available before the operation. Therefore the phonation time is short, about 1 to 2 seconds compared with more than 20 seconds in laryngeal voicing. Additionally, for many patients this technique is difficult to acquire and rehabilitation often takes months. Success rates in the literature vary substantially, partly because of the lack of a good definition of voice quality. No more than 40% to 60% of the patients acquire reasonable speech and only 10% develop a really good voice.[21]

Electrolarynx Voice and Speech

Another method is the use of a tone generator, which consists mostly of an electrically driven instrument called an *electrolarynx*. These devices generate vibrations that pass through the skin toward the throat (schematically depicted in Fig. 113-5). Sound generated in this way is transformed in the vocal tract into intelligible speech. The advantage is that most patients acquire this speech rapidly, but the drawbacks are a monotonous, robot-like sound and the necessity to always have one hand occupied while using it.

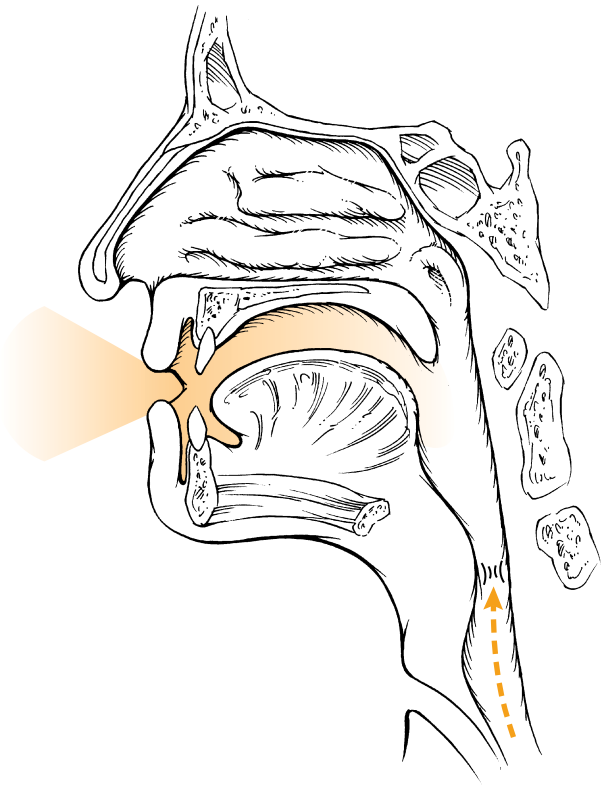

Figure 113-4. Esophageal speech. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

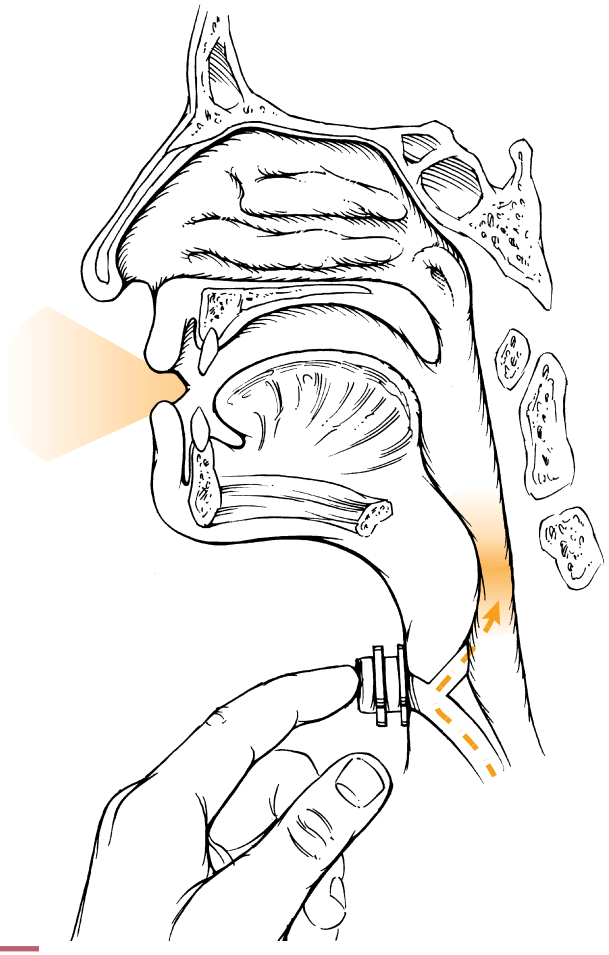

Figure 113-6. Prosthetic voice rehabilitation: The *dashed line* indicates the pulmonary air, by occlusion of the stoma through the prosthesis diverted into the pharyngoesophageal segment, where mucosal vibrations generate the sound for speech production in the vocal tract. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

Tracheoesophageal Voice and Speech

The limitations of esophageal and electrolarynx speech outlined previously have initiated the development of the so-called voice prosthesis, essentially a one-way valve allowing air to pass from the trachea into the PE segment and preventing aspiration. Through a minor surgical procedure, either primarily at the time of the laryngectomy or secondarily at a later date, a tracheoesophageal fistula is created, allowing implantation of this device. After closure of the stoma, just like before the operation, air from the lungs creates vibration, in this case in the mucosa in the throat (schematically depicted in Fig. 113-6).[22-24] Even after extensive resections and reconstructions of the throat, this method is applicable, whereas esophageal speech in these cases is hardly ever successful.[25] The recovery of oral communication is so rapid (in most cases a useful voice develops within 2 weeks) and the success rate of the prosthetic method is so high (in the magnitude of 90%) that this rehabilitation technique has developed into the "gold standard" and recovery of speech after TL has become quite predictable.[26,27]

Tracheoesophageal speech, like normal laryngeal speech, is pulmonary driven and thus is closest to normal. The availability of the pulmonary air allows maximum phonation times (MPT) that in many patients are approaching normal values; mean MPTs of 16 to 17 seconds are no longer the exception.[28] Even in most COPD patients, pulmonary capacity is still sufficient to allow for good voicing.[29] As already mentioned, the sound is produced in the PE segment by mucosal vibrations generated by the pulmonary air.[22,24] An important issue to stress at this point is that there is no gender difference in postlaryngectomy anatomy and physiology of the new sound source.[23] This means that male and female voices do not differ in fundamental frequency, which is approximately 100 Hz. Thus female voices often sound too low, whereas male voices are fine.[24,30] This is one of the remaining issues to address in the future.[31] Although it may sound like a superfluous remark, one has to keep in mind that the pharynx also constitutes the alimentary tract, so after laryngectomy the PE segment has a dual function: a sound generator and a passageway for food. This should never be forgotten when problems occur with voice prostheses and when solutions are searched for: What could be beneficial to one function might be detrimental to the other one.

Types of Voice Prostheses

Indwelling and Nonindwelling Prostheses

In general, two types of TE voice prostheses can be distinguished: nonindwelling and indwelling devices. The first voice prostheses that became available in the United States were of the nonindwelling type (Blom-Singer duckbill and Panje prostheses),[11,12] whereas the first European prostheses were indwelling devices (Mozolewski and Groningen)[10,15] (Fig. 113-7).

The nonindwelling TE voice prostheses can be removed and replaced by the patient. The indwelling TE voice prostheses stay in place permanently and must be removed and replaced by a clinician experienced in the method. The need for prosthesis replacement occurs at the end of the device's life span, which is usually determined by leakage of fluids through the prosthesis into the airway or an increased airflow resistance of the prosthesis. Because indwelling devices may have a more robust construction, their life spans are generally longer than those of their nonindwelling counterparts. Furthermore, indwelling devices have the distinct advantage in that the patient's dexterity plays a lesser role in the daily maintenance of the device; this mainly consists of internal cleaning with a brush and/or a flushing device without the need of regularly replacing the prosthesis. Even with increasing age or decreasing general health status, or both, a useful (prosthetic) voice can be preserved.[14,32] The obvious disadvantages of indwelling prostheses are that patients need a clinician for the replacement and hospital or clinic visits remain necessary. However, nonindwelling devices can also cause problems, forcing the patients to consult their clinicians. Thus the difference in the need for clinical aftercare is far from "all or nothing." Furthermore, as with indwelling devices, a regular checkup of the fistula/stoma region is necessary because of the need for early detection of possible adverse side effects (e.g., hypertrophy, infection, widening of the TE fistula) and for oncologic follow-up, irrespective of the prosthesis used. Therefore from the beginning of the modern prosthetic rehabilitation era in most of Europe, there was a strong preference for indwelling devices.[9,10,32-34] Today's most widely used indwelling prostheses in Europe, the Provox® and Provox® 2 system, are shown in Figures 113-8 and 113-9, respectively.

The evolution of voice prosthetics in the United States has been somewhat different from that in most of Europe. The American development has been influenced by speech-language pathologists (SLPs), who from the beginning favored delaying the insertion of the prosthesis. Instead, the preference has been to create a tracheoesophageal fistula and stent it with a rubber (feeding) catheter either primarily or secondarily. The insertion of the voice prosthesis is done only after wound healing is completed. The disadvantage of this approach is the tendency for the fistula to have associated edema and irritation and not to have reached its final length when the prosthesis is fitted 10 to 12 days later. In contrast, when the insertion of the prosthesis is done at the time of laryngectomy, as was originally described by Annyas and colleagues,[35] a second fitting can be avoided and the estimate of the length of the prosthesis is more accurate (almost always 8 mm). Nonetheless, others prefer inserting a feeding tube through the fistula at the time of the laryngectomy, which has the advantage of avoiding an indwelling feeding tube attached to the nose. Usually, the patient is ready to take oral feeds when the tube is removed 10 to 12 days later for placement of the prosthesis. For patients who were treated previously with radiation therapy, this length of time for tube feeding is preferred. Although insertion of the prosthesis during the postoperative phase may be difficult for some patients, the majority of them tolerate this well.

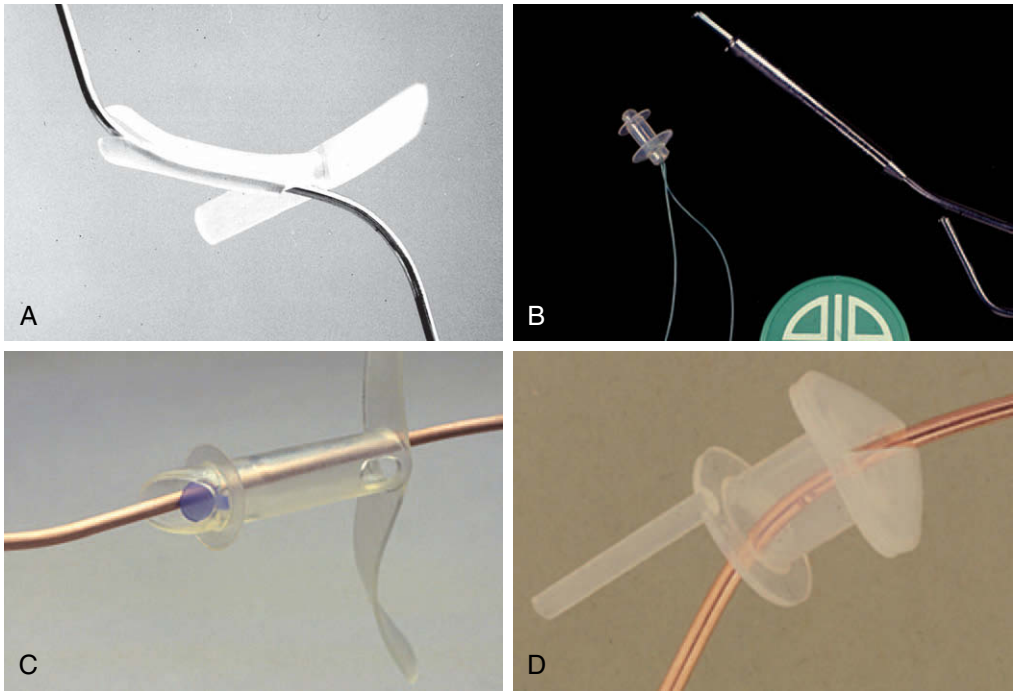

Figure 113-7. **A,** The original Blom-Singer duckbill prosthesis (1979/80) without a retention flange. **B,** The Panje prosthesis (1981), which had a retention flange, and a safety strap from the start. **C,** The later low-resistance version with a retention flange (1982). **D,** The indwelling Groningen prosthesis, which had a sturdy retention flange–valve combination, ensuring proper retention, even when inserted at the time of tracheoesophageal puncture (primarily or secondarily). For the Mozolewski prosthesis, see Figure 113-2.

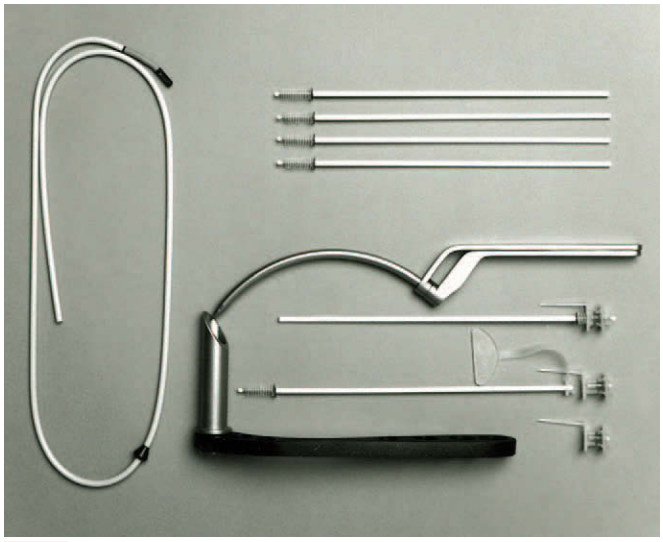

Figure 113-8. The Provox® voice rehabilitation system. From bottom to top, a pharynx protector for use during a primary TEP procedure, the voice prostheses in three sizes (6, 8, and 10 mm shaft length), a brush for internal cleaning, a plug for temporary occlusion of the prosthesis in case of leakage through the prosthesis, the trocar and cannula for primary and secondary TEP, and to the left a disposable guide wire for retrograde insertion during TEP procedure, or for prosthesis replacement (both Provox® and Provox® 2).

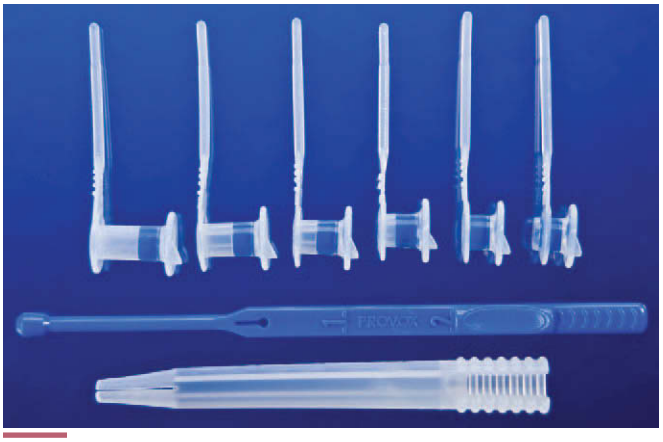

Figure 113-9. The Provox® 2 anterograde replacement system, with five different shaft lengths (4.5, 6, 8, 10, 12.5, and 15 mm) and the loading tube with inserter.

However, the alternate approach of inserting the prosthesis immediately at the time of the laryngectomy as described earlier has been reported to be quite satisfactory with a low complication rate.[9,32,35,38-41] Additionally, consideration should be given to the psychological advantage for patients to start voicing immediately after removal of the feeding tube. The recent trend by some centers to start oral intake soon after the laryngectomy in nonirradiated patients, within 24 to 48 hours, coordinates well with the early insertion philosophy.[42] Therefore it is not surprising that the immediate insertion method is gaining popularity in the United States, with SLPs still being the main responsible clinicians for the rehabilitation of postlaryngectomy voice and speech rehabilitation.

Surgical Aspects of Alaryngeal Voicing

Problem solving and prevention starts at the time of TL.

As with any other surgical technique and prosthetic appliance, problems and complications must be taken into account. Proper handling of the occasional problems is mandatory in order to maintain oral communication for the rest of the laryngectomy patient's life. Because the prognosis for many laryngectomized individuals is good, many of them have a long enough life expectancy and it is necessary for medical professionals to provide care specific for communication over the long

term. Hence investing in a good protocol to ensure optimal handling of adverse events is worthwhile for both patients and clinicians.

Standard Total Laryngectomy

For the indications and surgical aspects of TL, see Chapter 111. In the following section, specific aspects of surgical prosthetic voice rehabilitation are discussed.

Surgical Techniques and Refinements

Primary prosthetic voice restoration is presently the method of choice for optimally reestablishing postlaryngectomy oral communication.

Primary prosthetic voice restoration, meaning tracheoesophageal puncture (TEP) and immediate insertion of a voice prosthesis at the time of TL, is the method of choice for many experienced medical professionals (see Fig. 113-12, B; video clip available on website).[13,36] This enables the easiest and most comfortable voice rehabilitation because the patient is still under general anesthesia when the first prosthesis is inserted. No stenting of the fistula with a nasogastric feeding tube is necessary because the device itself is used to stabilize the puncture site.[37] The TEP can almost always can be done as a primary procedure, even when the circumference of the neopharynx has to be reconstructed, provided the esophagus is still present at the level of the trachea.[25] Only when the proximal esophagus is dissected off the trachea, as in the gastric pull-up procedure, is there a need to delay the TEP for 4 to 5 weeks.[25] In those cases, secondary TEP is performed after the completion of wound healing and before possible postoperative radiotherapy (see also discussion of the role of radiotherapy in the Prosthetic Voice Rehabilitation and Radiotherapy section).

With the currently available devices, voice prostheses (if available and affordable)[43-46] can be applied, irrespective of the method of closure of the pharyngeal mucosa and the extent of the pharyngeal constrictor muscle defect. However, with a few refinements in the surgery of TL, several postlaryngectomy problems such as hypertonicity of the pharyngoesophageal (PE) segment and a poor contour of the stoma can be avoided or diminished.

Refinements of standard TL techniques for optimizing prosthetic voice restoration results are:

1. A short myotomy of the upper esophageal sphincter to prevent hypertonicity of the PE segment
2. Suturing of the trachea in a separate fenestra in the inferior skin flap to create a stable stoma
3. Sectioning of the sternal heads of the sternocleidomastoid muscles to prevent a "deep" stoma
4. Pharyngeal mucosa closure without tension (T shape) to prevent pseudo-vallecula formation

1. Prevention of hypertonicity of the PE segment
Hypertonicity of the PE segment is the most frequent reason for failure to develop fluent prosthetic speech, as well as esophageal speech.[47,48] The cause is excess tone in the constrictor pharyngeus muscles forming the wall of the PE segment. In patients with this problem, this tonicity is exacerbated after inflation of air and thus blocks the flow of air through the PE segment, preventing mucosa vibrations and thus sound production. Although there are several surgical solutions described in the literature, we believe the best option to prevent this problem is to perform a short anterior positioned myotomy of the circular proximal upper esophageal sphincter (cricopharyngeus) muscle in every patient (Fig. 113-10; video clip available on website), unless palpation during surgery reveals that this muscle is completely relaxed.[49] After this myotomy and prosthesis insertion, the surgeon can still close the pharynx (mucosa and constrictor muscles) in the preferred manner.

2. Creation of an optimally contoured stoma
Ideally, the patient has a stable stoma with the same diameter as the trachea or only slightly narrower in order to have easy access to the voice prosthesis and to avoid a cannula to stent the stoma for adequate respiration. Reasons for stoma stenosis can be a dehiscence of the trachea from the skin because of infection and traction, sectioning of the last tracheal cartilage "ring" and diminishing its internal stability, or contraction of the tracheocutaneous suture. A reliable technique is to suture the trachea into a separate fenestra in the lower skin flap (Fig. 113-11).[50] This fenestra should have approximately the same size and diameter as the trachea, and the cranial trachea ring should remain intact. This latter aspect is the most important point of the creation of a stable stoma: the collagen fibers in the trachea cartilage are distributed in such a manner (dense and parallel on the outside and loose and intermingled on the inside) that the cartilage acts as a "spring" trying to widen the trachea.[51] If the cartilage is cut, these spring forces are lost and the trachea will collapse, resulting in a smaller stoma. Meticulous suturing of the skin to the trachea mucosa and optimally covering the bare trachea cartilage is important to prevent local infection and fibrosis. The small strip of skin (8 to 10 mm) cranially is surprisingly vital and only rarely breaks down, even in irradiated patients. The advantage of this technique is that trifurcations in the wound are avoided, which is not the case if the stoma is created in the TL skin incision itself. Obviously, in some cases in which the trachea has to be sectioned lower down, it is not long enough to be sutured in a separate fenestra and the entire inferior skin flap is necessary to be able to form a stoma. But even in these cases, with an intact last tracheal ring it should be possible to decannulate the patient following the procedure. The absence of a cannula results in less irritation of the trachea and stoma (i.e., less coughing and strain, improved wound healing).

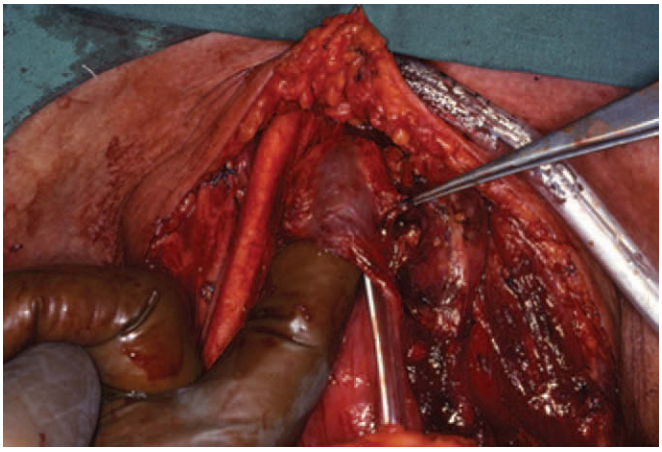

Figure 113-10. Myotomy of the cricopharyngeal muscle to prevent hypertonicity of the pharyngoesophageal segment (video clip available on website).

3. Prevention of an excessively deep stoma
A deep stoma is problematic for the later application of additional rehabilitation devices that potentially rely on peristomal attachment such as a heat and moisture exchanger (HME) or an automatic speaking valve (ASV). Sometimes a deep stoma is unavoidable (e.g., when more than 3 to 4 trachea rings are removed). However, most "deep" stomas are caused by the protrusion of the sternal heads of the sternocleidomastoid muscles (SCMMs) (Fig. 113-12; video clip available on website). Therefore the solution is to cut the sternal attachment of the SCMMs during the operation and before skin closure. This generally results in a flat peristomal area, making attachment of external devices considerably easier. Functional side effects from resected SCMMs have not been observed.

4. Pharyngeal mucosa closure
Meticulous closure of the pharyngeal mucosa is important to avoid unnecessary wound healing problems. Importantly, any undue tension on the suture line should be avoided. This means that purely

Figure 113-11. **A,** Creation of a stoma in a separate fenestra in the lower skin flap, with subsequent meticulous skin to mucosa suturing covering the intact tracheal cartilage. **B,** An immediate postoperative example of a primary tracheoesophageal puncture with immediate insertion of the voice prosthesis (in most cases an 8-mm long prosthesis is sufficiently long) (video clip available on website).

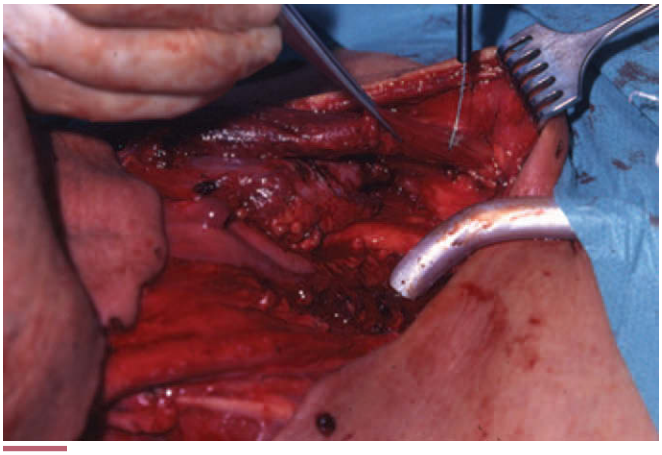

Figure 113-12. Cutting of the sternal attachment of sternocleidomastoid muscle on the left; the right side is already sectioned (video clip available on website).

vertical or horizontal closure of the pharyngeal defect seldom is possible. To avoid undue tension, the closure should be T shaped, with a variable length of the horizontal and vertical bar of the T (Fig. 113-13). If the trifurcation is reinforced with an extra submucosal stitch, there is no increased fistula formation. Most experts agree that this closure also avoids pseudo-vallecula formation, which seems to occur more frequently when a pure vertical closure is used as a standard.

Postoperative Management

Alimentary Care

Postoperative management initially involves nutritional intake through a feeding tube and stoma care. Early removal of the feeding tube, even as soon as the second postoperative day, and the commencement of a liquid oral diet seems feasible without an increased fistula rate.[42] After 8 days, mostly a soft, solid, normal diet can be resumed.

Pulmonary Care

Stomal care consists of the immediate postoperative application of an HME attached by a peristomal hydrocolloid adhesive and housing (Fig. 113-14). The early use of an HME avoids noisy external humidifiers while the patient easily adjusts to the breathing resistance of the HME, which is somewhat lower than the normal upper respiratory tract resistance.

Secondary Prosthetic Voice Rehabilitation

Secondary prosthetic voice rehabilitation is a simple endoscopic technique with antibiotic prophylaxis; in failed esophageal speakers hypertonicity is more likely to be present and might require secondary treatment (e.g., chemodenervation [Botox], myotomy).

In relation to prevention of problems with secondary tracheoesophageal puncture (TEP) and immediate prosthesis insertion (also in this case the method of choice; two video clips of standard and alternative methods are available on the website), there are several issues worth mentioning. If the patient is a failed esophageal speaker, there is a chance that the cause for this failure is hypertonicity of the PE segment.[48] This means that the medical professional and the patient have to anticipate further treatment before optimal fluent voicing can be achieved (see later for secondary hypertonicity treatment). With respect to the endoscopic technique when using a standard rigid esophagoscope, it is important to ensure the puncture is made high in the trachea (approximately 5 to 10 mm from the mucocutaneous border). This position makes the daily maintenance of the device by the patient (cleaning with a brush, or flushing, or both) and replacement by the medical professional in the outpatient clinic easiest. Further, the puncture should be done with a sharp trocar, preferably not with a scalpel incision or too wide of a fistula tract may result. As in primary TEP, the length of the prosthesis still can be mostly 8 mm, although slightly more often a longer prosthesis has to be used; the thickness of the party wall can be judged well through palpation through the stoma onto the esophagoscope. However, special measuring devices or prepuncture ultrasound can also be used. Because the prosthesis can be inserted immediately, patients can resume an oral diet almost immediately after the procedure and can begin voice and speech rehabilitation the same day. Finally, in order to prevent local infection, as in all "clean-contaminated" head and neck surgery, broad-spectrum antibiotic prophylaxis should be applied during TEP.

Prosthetic Voice Rehabilitation and Radiotherapy

Radiotherapy up to the normal doses of 70 Gy in 7 weeks and its equivalents, as well as planned postoperative radiotherapy, are not contraindications for TEP and immediate prosthesis insertion.

Many surgeons are reluctant to perform a TEP in patients needing a TL for a recurrence after chemoradiotherapy or in patients with advanced disease needing postoperative radiotherapy. In cases of radiation failure, the potential for an increased risk of complications, especially fistula development, may bias one to avoid creating a fistula. Nevertheless, there is enough evidence in the literature that this controlled fistula formation does not increase the incidence of wound complications and that, as such, TEP with immediate insertion of a voice prosthesis is a safe and reliable method.[14,32,39] The only warning is that after radiotherapy, one should wait 6 weeks to let the radiation side effects heal before performing a TEP (Box 113-1).

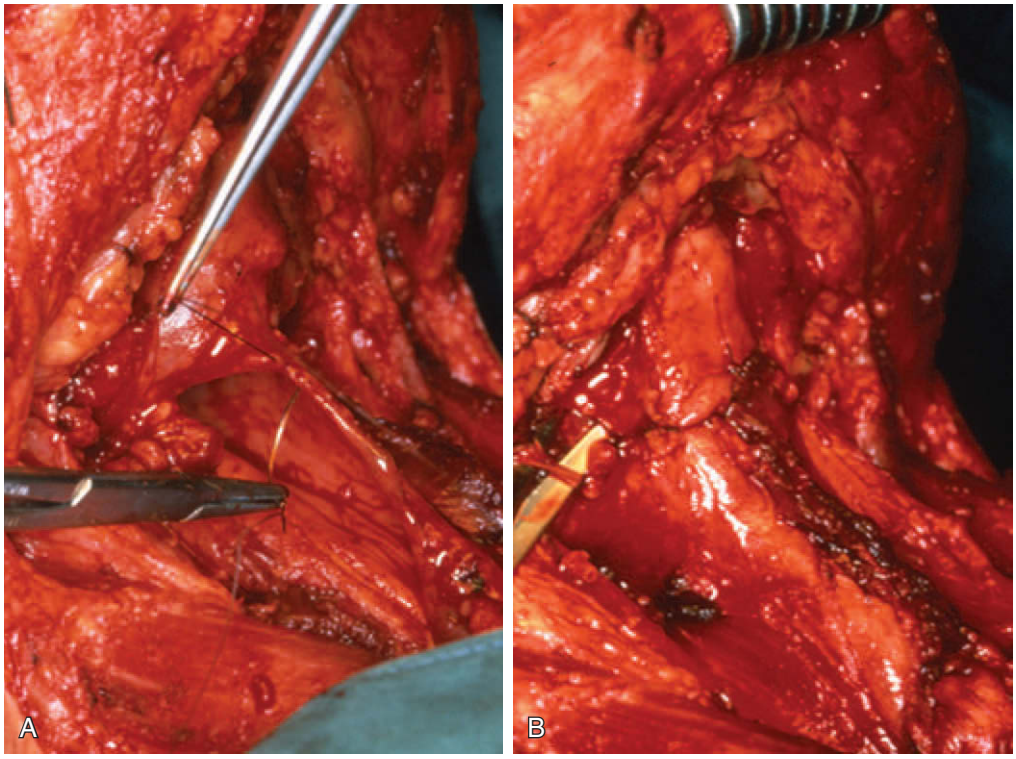

Figure 113-13. Mucosa and constrictor pharyngeus muscle closure in T shape to avoid pseudovallecula formation. **A,** Closure of the pharyngeal defect in a T-shaped manner. **B,** Pharynx after closure of the middle and inferior constrictor pharyngeus muscles. Suture these to the suprahyoid musculature. The instrument on the right side of the neck is identifying a plexus pharyngeus branch, which should be left intact.

Prosthesis Replacement and Maintenance

Indications

Voice prostheses are semipermanent implants with a limited life span. Leakage of fluids through the voice prosthesis is the most frequent reason for replacement of the device.

Silicon rubber voice prostheses, irrespective of the brand applied, are semipermanent devices that have a limited life span. The life span of prostheses shows considerable variation; in the literature mean device life spans of 4 to 5 months are found in the Western world, but much longer device life spans (10 to 18 months) are described in the Mediterranean and United States.[14,32,41,52-59] However, it is more important to look at the median device life span, which is a better reflection of the clinical practice, because the mean is often strongly influenced by a limited number of patients with long-lasting prostheses, sometimes up to 11.5 years.[14]

The main reason for replacement is leakage of fluids through the prosthesis, which signals incomplete closure of the valve. Although patients can temporarily apply a plug into the prosthesis to prevent aspiration, eventually replacement is necessary. For indwelling prostheses, this means an outpatient clinic procedure, which is easy because of the availability of anterograde replacement procedures.[34,60] The most common reason a valve starts to leak is because of growth of *Candida* species on the valve mechanism, which prevents its proper closure.[61] Measures to limit this *Candida* growth such as using antifungal drugs (e.g., Nystatin, Diflucan) are debated, but there is limited clinical evidence about their effectiveness.[62,63] A better option is to check the patient's diet and advise the consumption of probiotics such as certain yogurts that have proven effective in both in vitro and in vivo studies.[64-67]

A second reason for early prosthesis failure is the inadvertent opening of the valve due to a negative pressure created in the esophagus during deep breathing and swallowing. Especially during deep breathing, a negative pressure is created inside the thorax and thus also inside the esophagus. Normally this is of no consequence because the upper esophageal sphincter is preventing air from flowing into the esophagus. But with a voice prosthesis present under the level of the sphincter, the valve can open and air can be sucked in. Consequently, these patients often complain of disturbing aerophagia. The easier opening of the valve, perhaps in conjunction with a delayed closure, causes leakage to occur more readily. Increasing the airflow resistance of the valve could limit this problem but would create a voicing problem. Recently a special voice prosthesis (Provox ActiValve) that eliminates both the problem of *Candida* growth on the valve mechanism and the inadvertent opening by negative pressure became available.[68] This was accomplished by creating a valve mechanism made of Teflon-like material, insensitive to *Candida* growth, with built-in magnets to counteract the underpressure in the esophagus. This device appears to offer a good long-term solution for *Candida* and negative pressure–related short prosthetic life spans. In a group of patients who required an early replacement of their standard voice prosthesis after a median of 21 days, insertion of the modified device led to a median life span of 336 days.[69]

Internal blockage of the valve itself preventing proper voicing is a rare problem, and blockage is caused mostly by interference of the mucosa with the valve function. This issue and other indications for prosthesis replacement such as leakage around the device and local fistula problems are discussed as follows.

Replacement for Valve Incompetence—Transprosthetic Leakage

With any prosthesis replacement, the proper length of the device should be carefully checked even if there is "only" leakage through the prosthesis.

In case cleaning the valve with a brush or flushing device does not solve transprosthetic leakage, replacement of the device is required.[34,52,60] The preventive action to be taken in any replacement is carefully checking the length of the valve, even if there is no sign of periprosthetic leakage. By gently pulling at the tracheal flange with a hemostat, it is easy to assess whether the length is still good or the prosthesis has become too long in relation to the mostly gradually decreasing length of the fistula. The ability to move the device up to 2 to 3 mm in an anteroposterior

Figure 113-14. Use of a heat and moisture exchanger (HME) in a peristomal hydrocolloid adhesive **(A)** is safe for the healing incision, hygienic, and obviously less noisy than an external humidifier **(B).** And depending on the local health insurance system, it also may be a more cost-effective prevention and treatment of possible postoperative pulmonary sequels. Most HMEs are capable of retaining 60% of the extra water loss through a stoma, which in 24 hours is 500 mL more than in normal nasal breathing.

direction is not only tolerable but indicates that there is little or no pressure from the flanges on the mucosa. More than 3 mm in movement is an indication to downsize the prosthesis one level (e.g., from 8 to 6 mm). Care should be taken not to create a fit that is too tight, which may cause pressure of the flanges on the mucosa, leading to edema and further tightness or even tissue necrosis (see later discussion). In patients needing frequent replacements (weeks up to 2 months), one could consider the application of a Provox ActiValve, as described earlier.

Replacement for Valve Discrepancy—Periprosthetic Leakage—Too Long Prosthesis

Periprosthetic leakage is usually the result of subsiding postsurgical edema, for which downsizing of the device is recommended.

Valve-fistula discrepancy leads to periprosthetic leakage. In most instances this is a result of the natural gradual decrease of the thickness of the tracheoesophageal party wall. Subsiding surgical edema and tissue inflammation leads to a shorter fistula tract causing a once well-fitting prosthesis to become too long. This can result in piston-like movement of the prosthesis within the fistula tract, causing liquids to be squeezed around it. Because subsiding edema and inflammation are normal in the healing process, they are not considered to be complications and the solution is simply to insert a shorter prosthesis.[14] One should avoid downsizing more than one level at once in order to prevent excessive tightness, as previously described.

Box 113-1

Pros and Cons of Primary Indwelling Voice Prosthesis Insertion

The retrograde insertion technique, preferably using a special trocar, cannula, and guidewire, diminishes the risk of separation of the tracheoesophageal party wall. To some extent, the device stabilizes this wall.

The tracheal and esophageal flanges of the device give optimal protection of the TE fistula against leakage of saliva and gastric fluids.

There is less irritation of the tracheostoma and pressure on the fistula tract compared with a feeding tube taped to the skin of the neck.

There is no postoperative interference with a cannula or heat and moisture exchanger, or both.

Early postoperatively, patients can quickly become familiar with the care for their voice prosthesis as instructed by the nurses or other professionals (e.g., speech pathologists, surgeon).

There is no need for fitting the prosthesis in the early postoperative phase at a time when the stoma may still be sore from healing, and the patient's mental and physical status is not yet optimal.

Around the tenth postoperative day, there can be an immediate focus on voicing itself, which can give a tremendous psychologic boost to the patient.

Postoperative radiotherapy is not a contraindication and most patients develop a useful voice before the start of radiation treatment.

The first TEP prosthesis replacement is usually months later when wound healing is completed, surgical edema has subsided, and patients are generally in a better physical and mental state.

This approach allows the speech pathologist to maintain an active role in the multidisciplinary rehabilitation team.

The only disadvantages to the early insertion of voice prostheses are the necessity to use nasogastric feeding tube during the early postoperative period and the expectant but temporary deterioration of the voice during the postoperative radiotherapy phase. For the latter issue, the reassuring role of the speech pathologist is important because most patients retain a useful voice that will regain its original quality in the majority of individuals. The advantage of being able to communicate using the restored voice through this difficult period of treatment outweighs any disadvantage related to its quality.

Nonindwelling Voice Prostheses

With the exception of aspiration, the use of nonindwelling prostheses does not necessarily lead to other complications encountered with the indwelling types. Because of the more flimsy retention collars, nonindwelling prostheses are more prone to fall out of the tracheoesophageal fistula tract.[70] Because the majority of patients with nonindwelling devices can change the prostheses themselves, the advantage is self-management of problems with valve leakage. Consequently, if cleaning of the device fails to restore the valve, the prosthesis can be discarded and a new valve inserted. However, the spectrum of problems with the tracheoesophageal fistula can be encountered with nonindwelling prostheses, too, and patients should be instructed to consult their SLP or head and neck surgeon whenever their normal voice deteriorates. The solutions to address the problems are essentially the same as mentioned for the indwelling prostheses, as outlined next in the troubleshooting section.

Troubleshooting Prosthetic Voice

Adverse events occur in approximately one third of the patients, but such concerns require replacement of the prosthesis in only about 1 out of 10. Clinics supporting patients with voice prostheses should adopt a protocol for handling all known adverse events, and patients should be instructed to report their problems in a timely fashion.

As with any surgical and prosthetic method, complications and adverse events must be taken into account. However, most problems can be solved using routine diagnostic procedures and solutions. The occurrence is relatively common because one third of patients in a large series occasionally had problems.[14,71] Nonetheless only 10.7% of 318 patients followed for more than 5 years required prosthesis replacement because of an adverse event.[14] The complication rate is higher for patients who have had radiotherapy, but not to the extent that it would prohibit the use of voice prostheses. On the contrary, prosthetic voice rehabilitation is successful in the majority.

Patients with voice prosthesis problems, which often gradually develop, tend to postpone the visit to the clinic until "the last minute." Therefore it is important for any clinic dealing with TL patients to have a comprehensive straightforward protocol for dealing with all the known complications and adverse events. If this protocol is known by the clinicians in charge of this patient group, dealing with these occasional problems is hardly more time consuming than dealing with the regular replacement procedure needed for a leaking valve. Clinicians should instruct patients to seek clinical attention as soon as they notice a change in their voice. The sooner a problem is identified, the easier it can be corrected.

Atrophy of the Fistula/Party Wall or Too Wide of a Fistula

Atrophy of the party wall occurs in about 3% of the prosthesis replacements in 18% of the patients, ultimately leading to temporary fistula closure in 6% and to permanent closure in 1 of 318 patients.[14] Although many studies have revealed that radiotherapy does not significantly influence the outcome of prosthetic voice rehabilitation,[14,39,57,72-74] it is correlated with a higher incidence of complications during follow-up including atrophy.[14] Gradual thinning of the tracheoesophageal tissues is a naturally occurring process. Only in a minority of cases does it lead to such a short fistula tract that the shortest voice prosthesis (4 to 4.5 mm length) is still too long to ensure proper sealing of the fistula. The problem of atrophy becomes more difficult to handle if there is also a substantial widening of the fistula tract. A fistula tract that is too wide can also be caused by infection or (pressure) necrosis or making too long of an incision when creating the fistula tract. All of these causes can to some extent be avoided using a good technique and early intervention.

Algorithm to Solve Atrophy/Periprosthetic Leakage

An algorithm for periprosthetic leakage not solvable with a shorter device follows: 1a. Shrinkage; 1b. Washer; 2. Purse-string suture; 3. Augmentation; 4. Surgical closure.

If the party wall is thinner than 4 mm, there is a fair chance that a 4- or 4.5-mm prosthesis is not able to seal the fistula enough to prevent *periprosthetic* leakage. If this algorithm is followed, few patients will need the last option (i.e., closure of the TEP).

1a. Shrinkage: Although still a valid option, this is seldom applied today because it is cumbersome for the patient. Removal of the prosthesis and letting the fistula shrink for a few days is effective but requires a feeding tube and a cuffed cannula to prevent aspiration. Therefore the next option is preferred.

1b. Silicon washer: This is a thin silicon disk (we use a custom-made device: outer diameter 18 mm, inner diameter 7.5 mm, thickness 0.5 mm) punched out with a tailored punch. The washer can easily be moved behind the tracheal flange and around the shaft of the prosthesis with the help of two hemostats (like pulling a button through a buttonhole). The washer is not intended to compensate for a prosthesis that is too long but to adhere to the mucosa by surface tension; hence it should not be thicker than 0.5 mm (Fig. 113-15). This is a reliable and easy first solution for most of the "leakage around" cases, as shown in a 3-year clinical study of 32 patients.[75] Under optimal circumstances with a physician in the background, application of this washer probably can be carried out by a qualified SLP or oncology nurse as well. If the application of the washer fails to solve the periprosthetic leakage, the patient needs one of the next options.

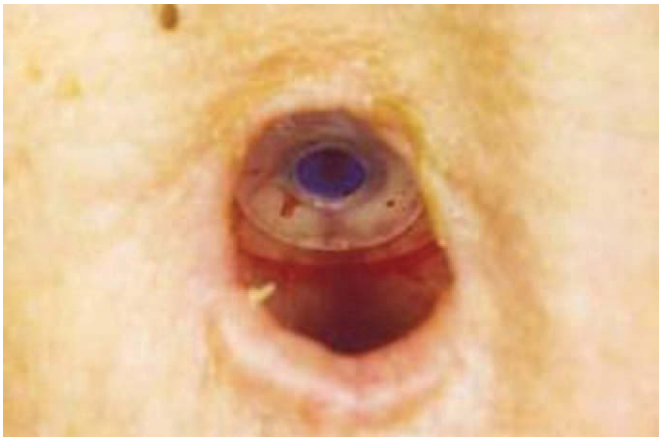

Figure 113-15. Example of a thin (0.5-mm thick) silicon washer behind the tracheal flange of the voice prosthesis blocking periprosthetic leakage in case of atrophy or scarification of the tracheoesophageal fistula.

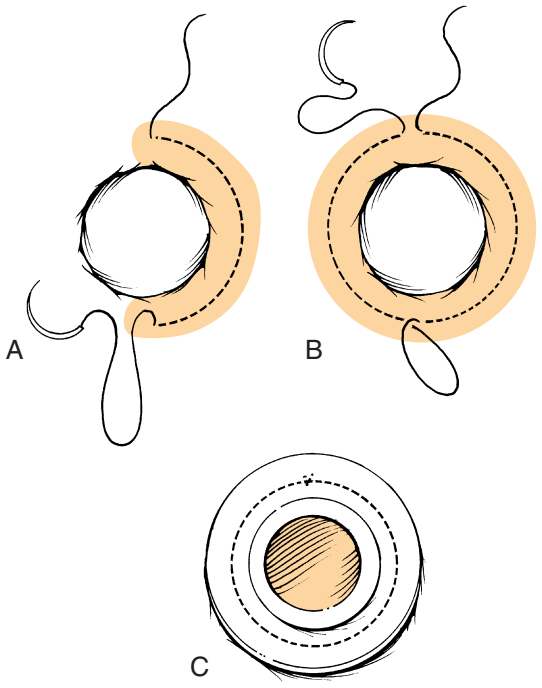

Figure 113-16. Purse-string suture: A 3-0 atraumatic Vicryl suture is inserted at 12 o'clock, curved submucosally to 6 o'clock **(A),** inserted again, and curved submucosally on the other side to 12 o'clock **(B).** After insertion of a new prosthesis, the suture is gently tightened pulling the tissues against the shaft of the prosthesis and preventing further leakage around the device **(C).** The suture should be left to degrade spontaneously, potentially enabling tissue augmentation. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

2. Purse-string suture: If the tissues are not too atrophic and the fistula is not too wide, a purse-string suture using 3-0 atraumatic vicryl is an effective and quick physician's solution. After removal of the prosthesis, the suture is started at 12 o'clock with the needle curving submucosally at a distance of 1 to 2 mm from the edge of the fistula

until 6 o'clock. Next, the needle is inserted at 6 o'clock and curved submucosally on the other side until 12 o'clock (Fig. 113-16). Sometimes three steps are easier to make (i.e., from 12 to 4, from 4 to 8, and from 8 to 12 o'clock). After placing the suture, a new prosthesis is inserted and the suture is gently tightened to pull the mucosa against the prosthesis. This procedure is always successful in the short term, and by letting the suture degrade spontaneously, it can have a tissue-augmenting effect, solving the problem also in the long term. However, if repeating this procedure once or twice does not have the intended permanent effect, the next step in the algorithm should be considered. Jacobs and colleagues[76] recently published a refinement of this method (they "buried" the suture knot submucosally, probably enhancing the efficiency of the method) and the positive long-term results that can be obtained.

3. Augmentation of party wall: Permanent augmentation of the party wall with a nondegradable product like bioplastic is highly successful and described in several papers.[77,78] The same effect can be achieved with injection of autologous fat or GAX collagen, but bioplastic probably gives the best permanent effect and is safe to use in everyday clinical practice.[79,80] Another option might be the use of granulocyte-macrophage colony-stimulating factor to induce a sterile inflammation to augment the fistula tract.[81]

4. Fistula closure and later secondary puncture: If all measures mentioned previously fail or in case there is a too wide of a fistula with a lack of tissue to be tightened around the prosthesis or augmented, fistula closure is unavoidable. Because most fistulas are completely epithelialized after 6 months, they must be dissected and closed in three tissue layers.[82] This can be best achieved by approaching the fistula from above, separating the esophagus and trachea until just caudally of the fistula, sectioning the fistula, closing the esophageal side in two layers and the tracheal side in one, and closing the skin in layers. If the tissues are fibrotic, one can consider swinging the sternal head of the SCMM in between the trachea and esophagus or using a fascia graft to enforce the esophageal and tracheal suture lines.[82] Generally, repuncture with immediate prosthesis insertion can be carried out after 6 weeks.

Sometimes larger fistulas cannot be closed in this way and tissue augmentation/addition must be performed by using a properly tailored pectoralis major muscle-fascia flap, occasionally using a split-skin graft, fixed with tissue glue, for coverage on the tracheal side. Unintended widening of the TE fistula is often related to unsuccessful local TE fistula closures via the tracheostoma. These cases can be difficult to treat. If the esophageal side cannot be closed primarily, the mucosa can be sutured to the fascia of the PM flap and that side of the defect will epithelialize secondarily. A skin island on the flap is often too bulky and is rarely necessary. Seldomly, more extensive surgery must be applied (e.g., free radial forearm flap, gastric pull-up). No standard procedure for these situations exists—a tailored approach is required.

Scarification of the Fistula

Scarification of the fistula is something seen mostly if the TEP is not punctured (e.g., with a trocar and cannula) but done through a vertical incision. This can result in an incompletely round fistula tract with a retraction on a certain spot. Patients then complain that the periprosthetic leakage always comes from the same spot (e.g., leakage at 11 o'clock). In this case the same algorithm as provided earlier is applicable: first a washer can be tried,[75] next a purse-string suture, and then tissue augmentation, with the latter method being used more readily because only the small retracted scar region has to be augmented. Permanent closure in these situations is therefore less common because mostly there is no clear atrophy of the fistula.

Infection of the Fistula

Infection of the fistula can be treated with a broad-spectrum antibiotic without removing the prosthesis; one should make sure that the device is long enough in the swollen fistula, and if needed a longer prosthesis should be inserted.

Local infection is occasionally seen in approximately 10% of the patients. Treatment is usually simple. Because local infection leads to swelling of the tissues, it is important to decrease the resulting pressure of the flanges onto the mucosa. If the prosthesis was originally fitted well, this means that in such a case the prosthesis must be replaced with a longer device. More often than not, one has to upsize at least two sizes (e.g., from 6 mm to 10 mm) to allow for a proper fitting in the infected fistula. In case of a local infection, temporary removal of the prosthesis should be avoided because that will most likely lead to a permanent closure of the TEP, leaving the patient unnecessarily speechless for a certain period. Broad-spectrum antibiotic treatment in most cases solves the infection. Subsiding of the swelling will eventually make the prosthesis too long and potentially prone to periprosthetic leakage, but this can take several months, and by that time the device likely has to be replaced for transprosthetic leakage anyway.

Hypertrophy of the Fistula

Two forms of hypertrophy of the fistula tissues exist:

1. Anterior hypertrophy.
   This consists of excessive fibromatous or granulating mucosa, potentially leading to complete overgrowth of the tracheal flange. Anterior hypertrophy is seen mainly in patients requiring a trachea cannula, which can exert pressure on the prosthesis, or in patients with prostheses that are too short and drawn inward. Obviously, the prosthesis should be of the correct size and the use of a cannula should be avoided. If this is not possible, a stoma plasty should be considered.[83] Sometimes it is necessary to remove the excessive tissue because it bulges too far forward into the trachea, decreasing the airway too much. For this, any form of electrocautery or (laser) resection can be used.

2. Posterior hypertrophy or esophageal pocket.

Posterior hypertrophy (i.e., formation of an esophageal pocket) leads to strained voicing and slight bleeding during brush cleaning; once diagnosed it is easily correctable by inserting a long prosthesis to "fistulize" the excess tissue of the pocket.

This phenomenon is sometimes incorrectly called a *separation of the party wall.* It forms an important problem in daily practice because it is not always obvious and its diagnosis is often delayed. These patients typically complain about a deterioration of their voice (more strained) and getting some blood at their brush while cleaning the inside. Often even an overt esophageal pocket is formed with eventually complete mucosa overgrowth on the backside of the prosthesis. Once suspected, it is easy to diagnose by careful inspection of the fistula with a thin (flexible) endoscope through the prosthesis, or after removal of the prosthesis it can often be seen directly. The solution is also simple: Inserting a longer prosthesis (at least two sizes longer), which encompasses the excess tissue in between the flanges, will immediately restore the patient's voice and lead to "fistulizing" the excess tissue. Anterograde insertion can be accomplished in most cases, but it is wise to overshoot the device (i.e., push the complete prosthesis into the esophagus and then pull the tracheal flange in situ with a hemostat to ensure the proper position of the esophageal flange on the backside) (Fig. 113-17). Seldomly, the traditional retrograde insertion method must be applied, and rarely this procedure must be carried out under general anesthesia (only if the fistula tract cannot be probed atraumatically).

Partial Prosthesis Extrusion

A prosthesis that is too short can cause pressure necrosis of the tracheoesophageal party wall, which should be avoided at all times. If a false passage develops, this can be solved by inserting a long enough prosthesis to bridge the defect and cover the false passage.

The riskiest complication is (partial) extrusion of the prosthesis. This adverse event has only been seen when a prosthesis that is too short has exerted too much pressure on the tissues, leading to local necrosis. This type of prosthesis can result from downsizing too rapidly or from a local infection. In any case, a prosthesis that is too short must be removed and replaced with a longer prosthesis to solve the problem. The new

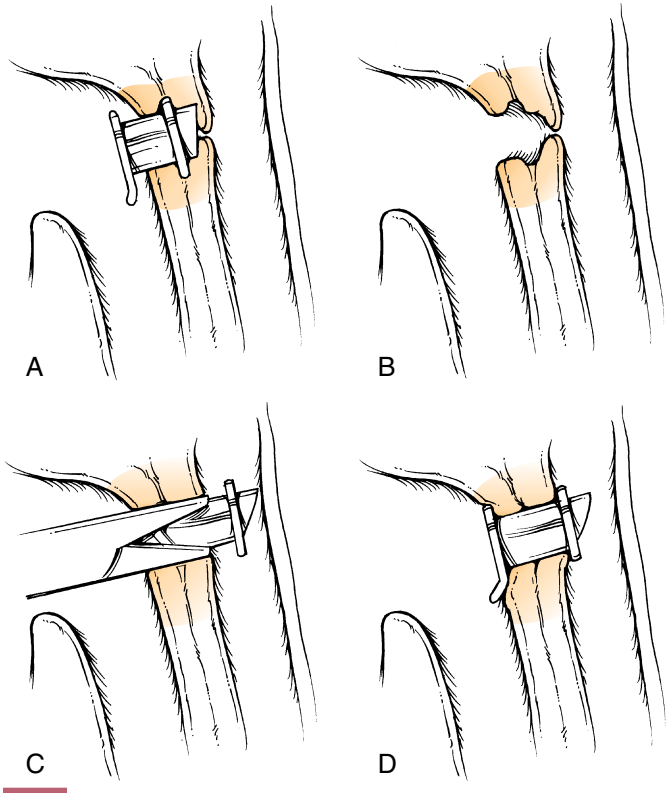

Figure 113-17. Esophageal pocket treatment: removal of the prosthesis and insertion of a sufficiently long prosthesis smoothing out the pocket. **A,** Prosthesis with esophageal flange retained in the esophageal pocket. **B,** Esophageal pocket after removal of the prosthesis. **C,** Overshooting the prosthesis into the esophagus to make sure that the esophageal flange will be in the esophageal lumen. **D,** The prosthesis correctly in place, "bridging" the extra tissue and smoothing out the pocket. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

prosthesis covers both the thickened fistula tract and the false passage. In all cases encountered, complete spontaneous healing has occurred. Sometimes excessive tissue must be removed to ensure proper fit of the new, longer prosthesis. A course of broad-spectrum antibiotics should be prescribed. Although this is potentially dangerous because of the risk of aspiration of the device "on its way out," pressure necrosis with partial prosthesis extrusion can usually be solved by replacing the too-short prosthesis with a longer device.

If the prosthesis is completely extruded and the patient cannot indicate its whereabouts, it is important to check whether the dislodgment has occurred toward the trachea or into the esophagus. In this situation a proper flexible endoscopy of the trachea and, if negative, radiologic examination (thorax and/or abdomen overview) must be conducted. If the prosthesis is trapped in the bronchial tree, it must be removed endoscopically. If the device is located in the alimentary tract, spontaneous passage can be expected in most cases.

Some Nonprosthesis-Related Problems

Hypertonicity of the Pharyngoesophageal Segment

Hypertonicity of the PE segment is the most important reason for failure to acquire fluent prosthetic speech, and chemodenervation with botulinum toxin type A (Botox) is the preferred treatment method.

Hypertonicity, although not a complication of prosthetic voicing, is still worth mentioning because it is the most important reason for failure to develop fluent speech. As already described, performing a short myotomy of the upper esophageal sphincter can be considered the most effective preventive measure to be taken during TL. However, if hypertonicity exists and intensive speech therapy is not capable of solving this, the condition warrants treatment. The easiest and least invasive option available is chemodenervation with botulinum toxin.[84,85] After proper identification of the hypertonic PE segment with videofluoroscopy, marking the segment on the skin, 100 MU of Botox (or for the alternative brand Dysport, 400 MU) is injected in the constrictor pharyngeus muscle area, preferably using a hollow electromyography needle. Interestingly, once a good result has been achieved, the effect is long lasting, in contrast to other clinical conditions in which Botox is used.[84,85] Apparently, once the patient has experienced fluent speech, through some kind of biofeedback, the effect is maintained. This phenomenon is sometimes even seen after the temporary denervation with Lidocaine injection, which should be used as a diagnostic procedure in all cases of hypertonicity. Since the availability of Botox, surgical myotomy is hardly ever necessary, although it is still an option. Care should be taken to perform a myotomy of the complete constrictor and cricopharyngeus muscle groups and to avoid fistula formation, especially in radiated patients.[86-88]

Hypotonicity of the Pharyngoesophageal Segment

Hypotonicity of the PE segment leads to a whispery and even aphonic voice and potentially can be treated surgically by creating an SCMM sling as an internal pressure band to prevent the excessive bulging of the distended PE segment.

Although not a complication of voice prostheses, hypotonicity of the PE segment can be a disturbing condition because the patient cannot produce a good sound and only has a whispering, aphonic voice. Mostly, there is no pitch detectable in the voice of patients with this condition. The sometimes extreme distension of the PE segment is caused by an inadvertent complete denervation of the constrictor muscles, which is why plexus pharyngeus neurectomy, once popular as a means to prevent hypertonicity of the PE segment,[89] should be considered with caution. Until recently, only through application of some external pressure (digital or with a special pressure band) could this problem be treated.[48] However, now an interesting surgical technique for treating hypotonicity exists (i.e., using an SCMM sling as an internal pressure band).[90] This results in clear improvement in the voice, especially because of an increase in the maximum phonation time and dynamic range.

Voice and Speech Therapy

Postlaryngectomy voice and speech rehabilitation in many countries is the domain of the SLP, but it should be stressed that optimal results are only achievable with good teamwork between the SLP and head and neck surgeon. Especially in situations where the rehabilitation process does not develop smoothly, a close collaboration among all team members leads to a quicker and better solution of the underlying problem. If clinical evaluation does not lead to a diagnosis and solution, videofluoroscopy is the best diagnostic method to analyze possible voicing problems (a video clip is available on the website).[24,49,91] For those who are interested in studying rehabilitation in head and neck cancer patients, especially TL patients, in more depth, the books by Doyle and Keith and Ward and van As-Brooks are recommended.[92,93] Some interesting reading about perceptual and acoustic research on postlaryngectomy voice and speech can be found in the publications of van As-Brooks and colleagues.[20,94]

Pulmonary Care and Rehabilitation

An HME should be an integral part of the rehabilitation protocol of laryngectomized individuals, not only in order to restore (in part) pulmonary physiology, but also to optimize prosthetic voicing.

Introduction

"Rehabilitation after TL requires more than improving voice alone",[95] and pulmonary rehabilitation is an essential and vital part of the comprehensive rehabilitation protocol after TL. Because of the short circuiting of the upper respiratory tract, TL significantly disrupts normal pulmonary physiology.[96] The disconnection of the upper and lower airways has repercussions for the conditioning—warming,

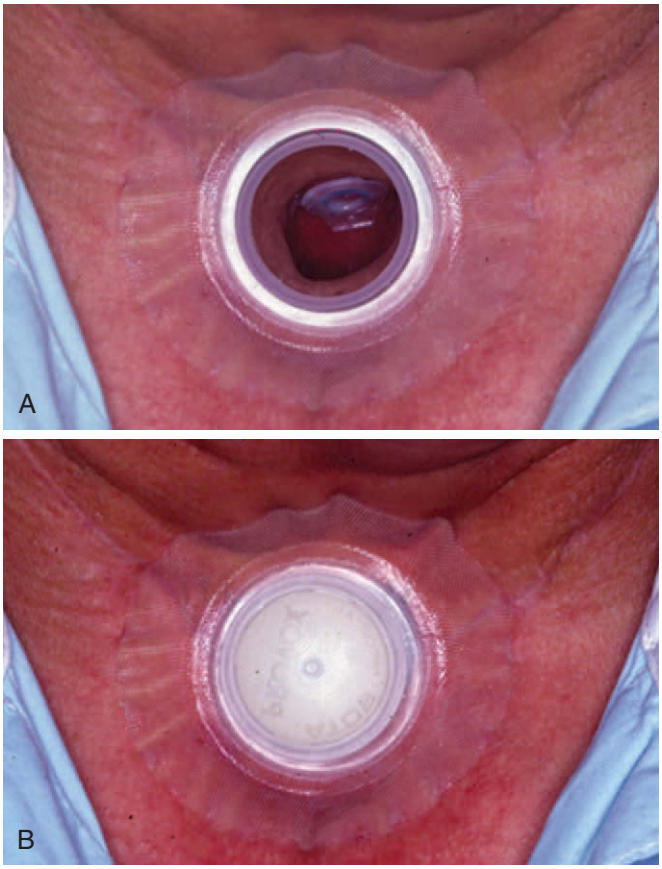

Figure 113-18. Pulmonary rehabilitation using a peristomal adhesive **(A)** with a heat and moisture exchanger **(B),** preferably applied 24/7 for optimal effectiveness, optimizing pulmonary climate.

humidifying, and filtering—of inhaled air, which is thereby precluded. There is also a loss of breathing resistance, which theoretically has a negative impact on pulmonary physiology, although less than has been postulated in the past.[97] Recent tracheal climate measurements have clearly shown that temperature and humidity decrease significantly after TL.[98-100] Especially at the end of the inspiration, both temperature (28° C instead of 32° C) and relative humidity (70% to 80% instead of 100%) are seriously below normal physiologic values. Consequently, many laryngectomized patients suffer from respiratory problems, of which involuntary coughing, excessive phlegm production, forced expectoration, and dyspnea are the most pronounced complaints.[101] These symptoms develop and tend to increase during the first 6 months postoperatively and probably well beyond that period, but later seem to stabilize. Frequently, there is an increase in respiratory symptoms during cold and wet seasonal periods. Moreover, these problems can have a serious impact on many aspects of daily life, including increased fatigue and sleeping problems, compromised voice quality, disrupted social contacts, and heightened psychological distress.[101]

Furthermore, an objective impairment of the pulmonary function of laryngectomized patients can be expected as well. The technique of pulmonary function assessment requires special attention: testing should not be performed with an intratracheal cuffed cannula, but with an extratracheal device (e.g., HME adhesive).[102] If an intratracheal cuffed cannula is used, the flow-volume loop is influenced by the internal diameter of the cannula, which is smaller than that of the trachea, resulting in lower (incorrect) values. This phenomenon does not play a role when using an external peristomal adhesive attachment. Pulmonary function studies have shown that the pulmonary function values of laryngectomized patients are significantly lower than the (age, sex, height, and race adjusted) predicted values.[29]

Heat and Moisture Exchangers

Treatment Aspects

In an attempt to restore some of the lost "nose" functions, HMEs have been introduced.[103] With these devices, placed over the stoma through special peristomal adhesives (Fig. 113-18), it appears possible to reduce the diurnal loss of water through the exhaled air (500 mL) by approximately 60%. In the aforementioned climate studies, both at standard (23° C) and cold (4° C) environmental conditions with a standard HME the intratracheal relative humidity appears to be restored to the physiologic level of 100%, although at a slightly lower temperature under room temperature conditions (under cold conditions there is a significant increase in intratracheal temperature).[98-100] In several studies the positive influence of an HME on respiratory problems (i.e., restoring intratracheal humidity) could be clinically established.[104-106] The results of the various clinical studies indicated that the regular use of an HME leads to significant improvement of the respiratory and the related psychosocial problems of laryngectomized patients. Significant reductions were found in the mean daily frequency of sputum production, stoma cleaning, and forced expectoration. Consequently several aspects of daily life (e.g., feelings of fatigue and malaise and sleeping problems) improved. Interestingly, in all studies carried out so far, the use of an HME also positively influenced voice quality. Positive HME effects also could be established objectively: A significant improvement over time in the inspiratory flow-volume values has been observed.[104]

Prevention Aspects

HMEs can prevent the development and reduce the severity of respiratory symptoms when used as soon as possible following TL, as was established in a study comparing pulmonary complaints in a regular user and a nonuser group at 3 and 6 months postoperatively.[107] Long-term use of HMEs also appears to prevent and significantly decrease pulmonary infection rates, as was demonstrated in a recent randomized study.[108] This coincides with the present clinical experience that severe tracheitis, which before the "HME era" was regularly encountered during winter, now seems to be a disease of the past. The few cases still seen are only in patients who are not compliant with HME use.

From these and other studies, it can be concluded that the only effective nonpharmaceutic treatment of pulmonary problems in laryngectomized patients is the regular use of an HME. Of vital importance is that all clinicians involved in the treatment of laryngectomized individuals—head and neck surgeon, SLP, and oncology nurse—are aware of the profound pulmonary physiologic changes TL brings about and of the necessity to prescribe HMEs for the prevention and treatment of the otherwise inevitable pulmonary problems patients will suffer from.

Compliance Aspects

The recent development of more specialized systems has reduced problems with peristomal attachment and airtight stoma closure necessary for voicing, which has resulted in an improved compliance rate.[109,110] An interesting side effect of these specialized devices is a reportedly better intelligibility of the prosthetic speech, which is brought about by a longer maximum phonation time and a wider dynamic loudness range.[28,109] However, still more development is necessary to optimize the peristomal or intrastomal attachment of these indispensable medical devices such as HMEs and automatic speaking valves (see later).

Early Postoperative Pulmonary Hygiene

Another step forward in recent years is that through the availability of colloid adhesives these HMEs can be used from the first postoperative day onwards, even with the stitches still in situ, as discussed earlier in the section on postoperative management and pulmonary care. Also as described earlier, it is virtually always possible to create a stable tracheostoma that does not need a cannula to be kept open, and this colloid adhesive can easily be glued to the peristomal skin (Fig. 113-19). Also, when patients still need a cannula to keep the stoma open, some systems allow the simultaneous application of an HME.[111] This makes external

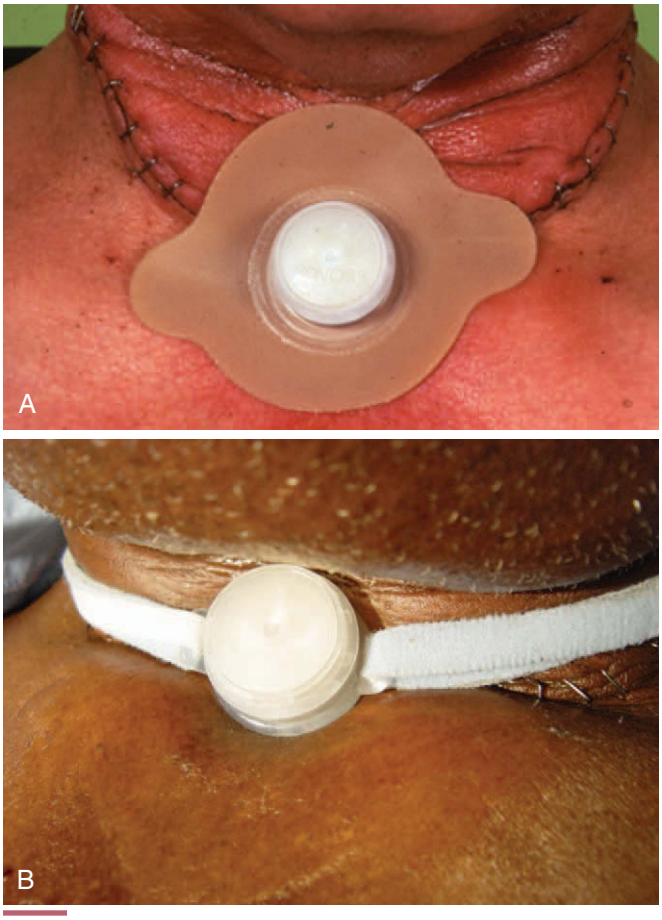

Figure 113-19. Early postoperative application of a heat and moisture exchanger using a colloid adhesive **(A)** or special cannula **(B).**

humidification superfluous, and depending on the local insurance situation, this mostly also appears to be cost-effective. This custom has several other definitive advantages: the patient has optimal stoma protection as early as possible, noisy external humidification is avoided, the patient gets used to the HME early (no problem with the airflow resistance of the device because this is lower than the preoperative upper airway resistance), the stoma has a well-cared appearance for the family and other visitors, and spreading of sputum during coughing is diminished.

Another advantage of using an HME immediately postoperatively concerns the early onset of voice rehabilitation. Often, patients are somewhat reluctant to start with speech therapy because it can be difficult to "digitally" close the not yet ideally healed stoma, which may still be sore. By applying an HME, the patient can start speech therapy and properly close the stoma digitally and hygienically, without undue pressure on the healing stoma.

Hands-Free Speech

A drawback of prosthetic speech is that the patient needs to occlude the stoma with a finger. Not only does this lead to the uncomfortable occupation of one hand, but also increases the "visibility" of the patient's handicap (i.e., being pointed at in conversation). This is still the case when the patient is using an HME. Applying an automatic speaking valve (all of which presently incorporate an HME) can solve this problem.[112-114] Although the success rate is still quite moderate with approximately 25% of daily users, with more modern and technically advanced devices (Fig. 113-20) it seems possible to increase the percentage of patients who can successfully apply an automatic speaking valve and HME as an additional rehabilitation tool for specific occasions such as shopping and social visits.[115]

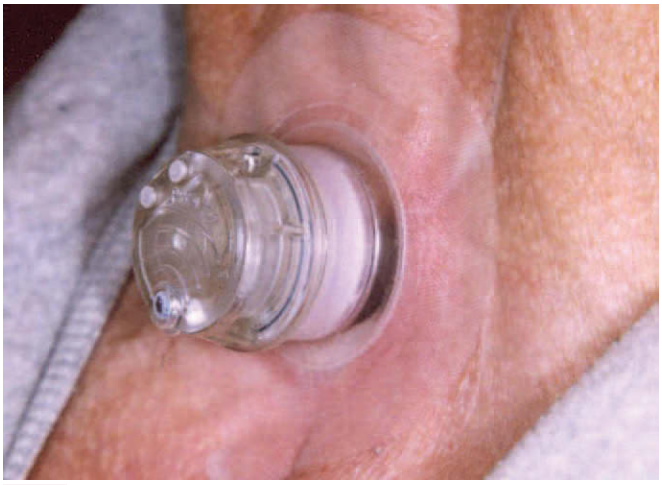

Figure 113-20. Patient with an automatic speaking valve to enable hands-free speech.

Conclusions of Pulmonary Rehabilitation

The use of an HME can effectively reduce the physical and psychosocial problems after TL. Continuous use of an HME, both day and night, is advisable to obtain an optimal pulmonary rehabilitation effect. With the availability of special colloid adhesives, early postoperative application is feasible and early pulmonary hygiene and voicing are improved. Early postoperative application also improves short- and long-term compliance with the use of HMEs because digital stoma occlusion is greatly assisted. Ideally, a combination of an HME and an automatic valve should used. It must be emphasized again that an HME is a medical device that should be prescribed with proper counseling of patients in order to obtain optimal results.

Olfaction Rehabilitation

Deterioration of the sense of smell seems an inevitable consequence of TL.[21] This bothering side effect of the operation is caused by disconnection of the upper and lower airways, which results in breathing through a tracheostoma in the neck, and thereby absence of nasal airflow. Therefore, odor molecules are no longer passively reaching the olfactory epithelium* and patients are effectively anosmic despite the fact that the olfactory system is essentially intact (Fig. 113-21). Over the years, several studies have established this problem, without finding a solution for this nuisance. Most patients actually seem to accept this problem, probably because of proper counseling before the surgery and the lack of an effective rehabilitation method.[21,116] The absence of complaints about this problem is surprising in view of the many patients visiting the otolaryngology practice when they experience a sudden or gradual loss of the sense of smell. In laryngeal patients this is apparently considered to be an unacceptable symptom of what is often suspected to be a sign of a serious underlying illness.[117]

In order to prove that the sense of smell is essentially intact if there would be a nasal airflow, the larynx bypass is a useful instrument.[118-120] This device consists of a mouthpiece, a tube, and an attachment possibility of that tube to the stoma (Fig. 113-22). By connecting the mouth with the stoma and subsequently breathing in through the nose, a nasal airflow is provoked. This allows odor testing, and it could be shown that in most laryngectomized individuals the sense of smell is

*Two types of smelling exist: passive and active. Passive smelling is a bonus of normal nasal breathing: During inhalation through the nose, odor molecules can reach the olfactory epithelium in the upper regions of the nasal cavity and provoke an olfactory stimulus. This often results in active smelling or sniffing in order to identify the odor and its source. After TL, passive smelling is mostly absent and only few patients have some spontaneous capability of active smelling.

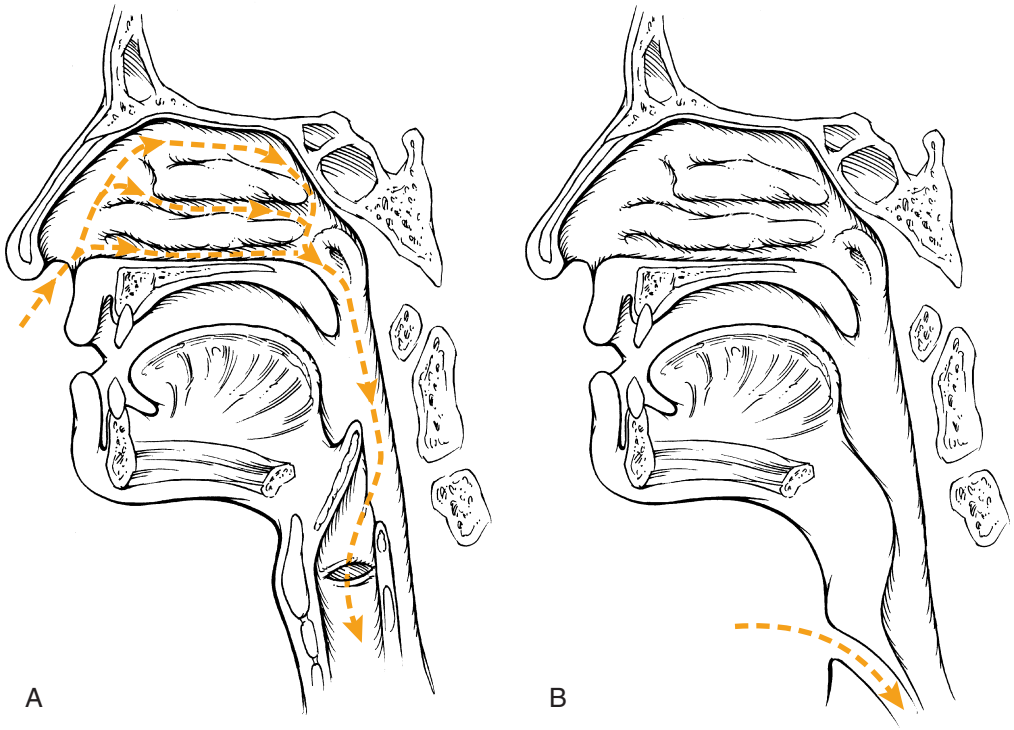

Figure 113-21. **A,** Normal nasal breathing and passive smelling. **B,** Stomal breathing without a nasal airflow, resulting in anosmia. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

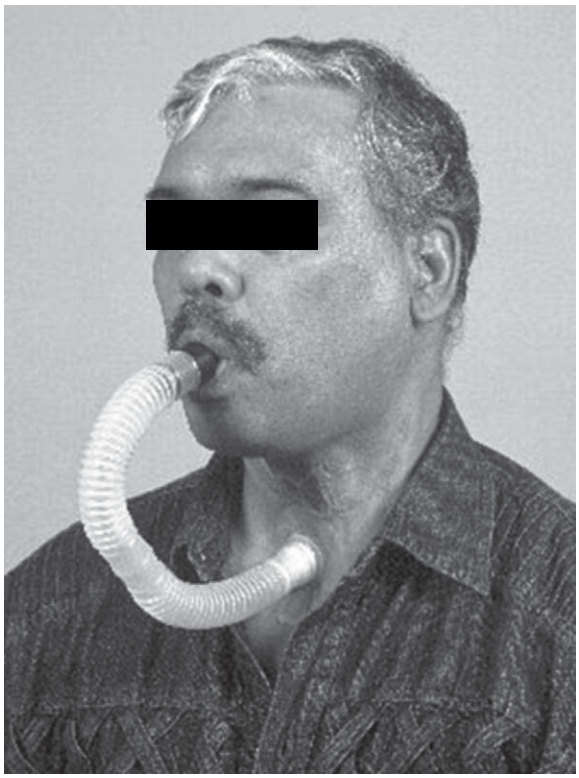

Figure 113-22. Larynx bypass, connecting the oral cavity with the stoma. Breathing through the nose results in nasal airflow and allows olfaction again.

intact. However, for obvious reasons, this is not a useful instrument to rehabilitate the olfactory acuity in everyday life.

Recently, this problem has been studied in depth, and again the magnitude of this problem was established.[116] On the basis of two odor tests and standardized questionnaires, it was found that more than two thirds of a cohort of 63 laryngectomized individuals were effectively anosmic (nonsmellers). Careful observation of the patients, who scored positive on one or both of the odor tests (smellers) revealed that they used their facial muscles more often. Furthermore, most of these patients were using their smell technique unconsciously and had discovered it all by themselves.

Analyzing the observed movements of the facial muscles, the conclusion was that some movements actually result in a nasal airflow, which allows the odor molecules to reach the olfactory epithelium again. Refining these observed movements led to the conception of a nasal airflow inducing maneuver (NAIM) or so-called "polite yawning" technique.[121] This technique induces a rapid increase in volume of the oral cavity while keeping the lips closed airtight. The potential vacuum, prompted by the expansion of the oral cavity, has to be filled. The result is an airflow through the nasal cavity (Fig. 113-23). By repeating this maneuver rapidly, a pumping effect is created and a sufficient airflow through the nose is established in order to smell again.

The effectiveness of the NAIM was established in an intervention study and subsequently confirmed in a follow-up study.[121,122] Approximately half of the patients were able to smell again after one half-hour training session. Also, 25% of the patients in this series, who were already able to smell with a personal technique, indicated an improvement. After instruction by the speech pathologist, they were much better able to initiate a nasal airflow and could much better smell at will. Recently, these results were confirmed and it also became clear that a longer and intensified rehabilitation period further increases long-term olfaction rehabilitation results.[123,124] A comprehensive book on olfaction rehabilitation was published recently, and this information is also available on the Internet (www.hoofdhals.nki.nl/olfaction/Start.aspx).[125]

Conclusions of Olfaction Rehabilitation

Olfaction rehabilitation in laryngectomized individuals should form an integral part of the rehabilitation program, deserving as much attention

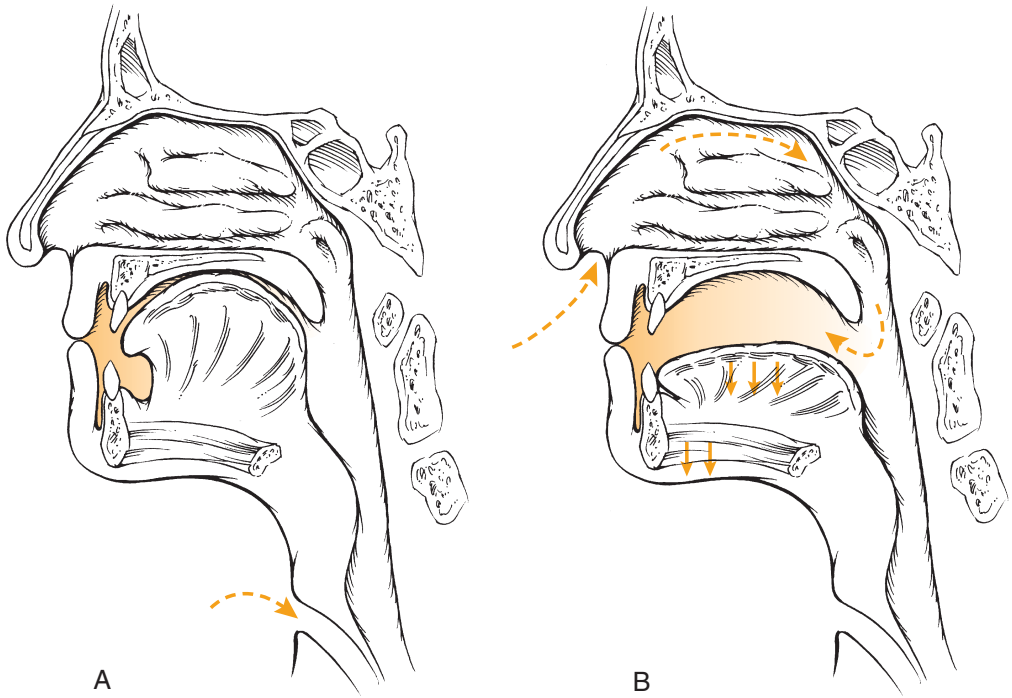

Figure 113-23. Schematic illustration of the nasal airflow inducing maneuver or "polite yawning" technique for olfaction rehabilitation after total laryngectomy. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

from the multidisciplinary team as the other two postlaryngectomy fields of interest (i.e., voice and speech rehabilitation and pulmonary rehabilitation). For head and neck surgeons it is important to know when counseling potential TL patients that this once seemingly insolvable problem now can be rehabilitated effectively by the SLP. The nasal airflow inducing maneuver or polite yawning technique forms an excellent instrument for the SLP to address this disturbing problem, resulting in a clear improvement not only in olfaction, but also in taste perception, and thus in an improved quality of life.

Quality of Life after Total Laryngectomy

With any oncologic treatment it is important not only to address the various (local, regional, and distant) control rates of the disease, but also to study the effects of the treatment on quality of life. Especially with an oncologic treatment as effective as TL, the long-term sequelae of the treatment are important to take into consideration when counseling patients. Clinicians are increasingly shying away from surgical, organ-sacrificing treatments like TL and favoring organ-preservation chemoradiotherapy treatments (CRTs). However, organ preservation is still not synonymous with function preservation and CRT has not always led to improved functional results, especially in advanced larynx cancer.[126,127] Data indicates that CRT has even decreased long-term cure rates.[128]

With all the postlaryngectomy rehabilitation options available, it is important to weigh the pros and cons of the various treatment options carefully. Wayne Koch[27] eloquently discussed quality-of-life issues in laryngectomized versus chemoradiated patients in a review, stating: "Tracheoesophageal puncture has made high-quality voice restoration readily available to most individuals who must undergo TL. Although none of these patients would voluntarily choose to undergo a TL if not faced with a life-threatening condition, at least some achieve better quality of life, including better vocal function, after treatment and rehabilitation (than chemoradiated patients). Although far from perfect, TL with tracheoesophageal puncture affords both quality and quantity of life to a group of individuals who currently have no alternative but to undergo debilitating surgery in an effort to extend their lives." Adding pulmonary and olfaction rehabilitation to this description, the present comprehensive postlaryngectomy rehabilitation possibilities to establish and maintain an acceptable quality of life are clear.

CHAPTER ONE HUNDRED AND FOURTEEN

Diagnosis and Management of Tracheal Neoplasms

Chadrick Denlinger

G. Alexander Patterson

Key Points

- Ninety percent of primary tracheal tumors in adults are malignant.
- The incidence of tracheal squamous cell cancers and adenoid cystic tumors is equivalent, and together they account for 75% of all primary tracheal tumors.
- The 5-year survival for resectable squamous cell cancers is 45% and is influenced by the presence of positive mediastinal lymph nodes.
- The 5-year survival for adenoid cystic carcinoma is 55% and is not significantly affected by the presence of positive resection margins or pulmonary metastasis.
- Half of the trachea can be safely resected and anastomosed primarily.
- Unresectable tracheal tumors have a poor prognosis but can be palliated with several different types of bronchoscopic treatment modalities.

Overview

Primary tracheal tumors are relatively uncommon with an estimated annual incidence of two cases per 1 million people.[1,2] Therefore an understanding of these neoplasms is based predominantly on small case series from large referral centers. Tracheal tumors are categorized as either primary or secondary depending on whether they arise within the trachea or secondarily involve the trachea from metastatic disease or local invasion. Primary tracheal tumors are further subdivided into benign or malignant lesions. In adults 90% of primary tracheal tumors are malignant, but in children 80% are benign.[1] Primary tracheal tumors are most often treated with multimodality therapy including surgical resection and radiation.[3] Currently, the disease-specific and all-cause mortality for primary malignant tracheal tumors are 73% and 79%, respectively.[4]

Secondary tracheal tumors are, by definition, malignant and involve the trachea either by direct extension or hematogenous metastases. Direct extension occurs most commonly from cancers arising in the lungs, esophagus, thyroid, and mediastinum, in order of decreasing frequency. Distant metastases from renal cell carcinomas, sarcomas, breast cancer, colon cancer, and melanomas have been reported. Optimal management for this diverse group of tumors depends on their location, natural history of the primary, and patient comorbidities. Surgical resection offers a chance for cure for patients with lung or thyroid cancers that involve the trachea by direct extension. However, the vast majority of secondary tracheal tumors are treated with palliative intent.

Historical Review

Morgagni described the first primary tracheal neoplasm, a fibroma, in 1761. Over 100 years would pass before experimental attempts at tracheal resection with primary end-to-end reconstruction would be described.[6] Kuester performed the first human tracheal resection and primary reconstruction in 1884. Before the 1960s, it was generally believed that tracheal resection was limited to four tracheal rings, about 2 cm, because greater resections would place undue tension on the anastomosis and prevent adequate healing.[7] Because of the presumed limits of resection and primary anastomosis, efforts at prosthetic replacement of the trachea were undertaken. In 1950 Belsey[7] reported his initial attempt with tracheal reconstruction after resection of an adenoid cystic carcinoma using fascia lata reinforced with stainless wire. Pearson and colleagues[8] used heavy Marlex mesh for tracheal replacement in seven patients and reported excellent function of the airway in three patients for several years. Neville and colleagues[9] reported extensive experience with the use of a solid silicone tube to replace the trachea; others, however, have reported unacceptable morbidity and mortality with this nonporous material.[10] Over the past several decades, a variety of other foreign materials, nonviable tissue, autogenous tissue, tissue engineering, and transplantation techniques have been attempted, but successful tracheal replacement remains elusive.[11]

Fortunately, the development of techniques for tracheal mobilization[12-14] made it possible to perform extensive tracheal resections, involving 50% of the tracheal length, with primary reconstruction. Using these techniques, tracheal replacement is uncommon. For the rare occasion when primary anastomosis cannot be performed and replacement is necessary, promise lies with tracheal allotransplantation, but long-term immunosuppression requirements will obviously limit its potential uses.[15]

For secondary tumors involving the trachea and carina, surgical techniques have been developed to address those with the potential for

Table 114-1

Classification of Tracheal Tumors

Epithelial Neoplasms	Mesenchymal Neoplasms
Benign	**Benign**
Squamous cell papilloma	Fibroma
Papillomatosis	Hemangioma
Pleomorphic adenoma	Granular cell tumor
	Schwannoma
Malignant	Neurofibroma
Squamous cell carcinoma	Fibrous histiocytoma
Adenoid cystic carcinoma	Pseudosarcoma
Carcinoid	Hemangioendothelioma
Mucoepidermoid carcinoma	Leiomyoma
Adenocarcinoma	Chondroma
Small-cell undifferentiated carcinoma	Chondroblastoma
	Lipoma
Secondary Malignancies	**Malignant**
Invasion by adjacent malignancy	Leiomyosarcoma
Metastases	Chondrosarcoma
	Paraganglioma
	Spindle-cell sarcoma
Non-neoplastic Tumors	Lymphoma
Tracheobronchopathia osteochondroplastica	Malignant fibrous histiocytoma
Amyloidosis	Rhabdomyosarcoma
Inflammatory pseudotumor	Melanoma

cure (thyroid and bronchogenic). Advances in therapeutic bronchoscopy offer options for patients who are not candidates for surgical resection. Endoscopic débridement, laser treatment, photodynamic therapy (PDT), cryosurgery, brachytherapy, and tracheal stents can provide palliation for patients with incurable disease.

Primary Tracheal Tumors

Primary tumors of the trachea are uncommon, but a variety of benign and malignant neoplasms have been described (Table 114-1). In recent reports, men and women are equally affected by tracheal tumors, and the peak age of diagnosis is 50 to 59 years. Primary tumors can originate from any layer of the tracheal wall and histologically are classified as either epithelial or mesenchymal tumors. Although primary tumors can be found anywhere in the trachea, the proximal and distal thirds of the trachea are most frequently affected, as is the membranous wall. A few large surgical series of primary tracheal tumors have been reported (Table 114-2).[16-19]

Staging

Neither an American Joint Committee on Cancer nor a Union Internationale Centre le Cancer staging system currently exists for primary tracheal tumors. However, a tumor node metastasis (TNM) system has been proposed on the basis of a single institution's retrospective review of 99 patients with primary tracheal tumors. T1 and T2 tumors were defined as tumors confined within the trachea that are less than 2 cm or greater than 2 cm, respectively. T3 tumors extend beyond the trachea but do not involve any surrounding structure. T4 tumors extend into surrounding structures such as the esophagus or great vessels. In addition, patients are either N0 or N1 and M0 or M1 depending on the absence or presence of lymph node or distant metastasis, respectively.[20]

Benign Primary Tracheal Tumors

Uncommon in adults, benign primary tracheal tumors are usually well circumscribed, round, soft, and smaller than 2 cm. On chest computed tomography (CT) scanning, these lesions typically are seen as smooth, homogeneous tumors that do not extend through the tracheal wall. The presence of calcium within the lesion suggests a benign histology.[21]

Squamous Papilloma

Squamous cell papillomas are superficial, sessile, or papillary masses consisting of a connective tissue core covered by squamous epithelium. In children, squamous papillomas are the most common tracheal neoplasm. In adults, these lesions are rare and associated with heavy cigarette smoking. Although these lesions can be found throughout the respiratory tract, approximately 90% to 95% are isolated to the larynx.[12,22,23] Eleven percent of the patients had papillomatosis in the trachea in addition to the larynx, but only 1.2% had disease isolated to the trachea. Presence of the disease below the larynx has been linked to the presence of a tracheostomy.[22] Papillomatosis is caused by human papillomavirus (HPV) types 6 and 11,[23] transmitted from mother to fetus during childbirth.[24] Despite being a benign tumor, papillomatosis frequently recurs and is difficult to completely eradicate. Fortunately, it usually regresses spontaneously after puberty. Numerous therapies have been used including microdébridement, nebulized or intralesional injection of cidofovir, PDT, pulsed dye laser, and indole-3-carbinol.[25,26] Recently, the carbon dioxide laser has shown promise in the treatment of papillomatosis.[7] Adjuvant treatment with α-interferon has been used.[27]

Papillomas undergo malignant transformation to squamous cell carcinoma and verrucous carcinoma, a phenomenon apparently more commonly seen with HPV 11,[28] that occurs with an incidence of 1.6% to 4%.[25,29]

Granular Cell Tumor

Granular cell tumors were first described by Abrikosoff in 1926[30] as a myogenic tumor, but more currently these tumors are understood to be neurogenic in origin. There appears to be no gender predilection, but the majority of granular cell tumors occur in African Americans. They rarely are seen in children. Approximately 50% of granular cell tumors occur in the head and neck region and 10% appear in the larynx, but the cervical trachea is rarely affected.[31] Multicentric tumors occur in 20% of patients, and these tumors tend to be biologically more aggressive.[32] Granular cell tumors are not encapsulated and tend to invade locally, despite being benign. Seventy-three percent of these tumors are intraluminal, and the remainder are either extraluminal or mixed.[33] Malignant degeneration occurs in 1% to 2% of all granular cell tumors, but this has never been reported in children.[34,35] Bronchoscopic resection of tumors smaller than 8 mm has been recommended.[34] Granular cell tumors larger than 8 mm have a high likelihood of transmural involvement and recurrence following bronchoscopic resection, and these should be managed with segmental tracheal resection.

Chondroma

Chondromas are the most common benign mesenchymal tracheal tumors, occurring most often in older men.[17-19,36] These cartilaginous tumors are hard, broad-based, and covered by intact mucosa. The most common site of origin is the internal aspect of the posterior cricoid lamina,[37] but they are evenly distributed throughout the length of the

trachea. Calcification is radiographically seen in 75% of patients, although this will not distinguish chondromas from malignant chondrosarcomas, into which chondromas may degenerate on the basis of anecdotal evidence.[38] Endoscopic resection may be used for palliation but leads to recurrence, and thus segmental tracheal resection is recommended.

Leiomyoma

Tracheal leiomyomas originate from the smooth muscle of the tracheal wall and most commonly arise from the membranous portion of the lower third of the trachea.[39] These tumors typically grow as smoothly contoured, broad-based polypoid masses. Intraluminal growth can cause symptomatic airway obstruction. Death from bleeding has been reported during bronchoscopic excision, and this treatment modality has been recommended only for patients with pedunculated tumors.[40] Segmental tracheal resection is recommended for leiomyomas in order to prevent local recurrence following incomplete resection.

Hemangioma

Hemangiomas of the airway occur in adults and children. In adults, cavernous hemangiomas develop in the larynx, whereas capillary hemangiomas originate in the subglottic trachea. Tracheal hemangiomas occur more often in young children and are actually the most common obstructive subglottic mass in this patient population.[32] These lesions are asymptomatic at birth, but most will cause stridor within the first 6 months of life. Cutaneous hemangiomas are present in half of the affected infants.

In the airway, capillary hemangiomas develop within the submucosa and are covered by normal respiratory epithelium. They are typically located on the posterolateral aspect of the subglottic trachea, are smooth, bluish in color, and project into the airway from a sessile base. Most of these spontaneously regress by 2 to 3 years of age and close observation is advocated when possible. In highly symptomatic patients, a tracheostomy may be required temporarily. Regression following treatment with steroids, interferon, or laser ablation has been reported, although surgical resection may be associated with less stricture formation.[41]

Miscellaneous Benign Primary Tumors

A variety of other benign tracheal tumors have been reported including adenomas, myoepithelial cell tumors, lipomas, fibromas, schwannomas, neurilemomas, hemangiomas, paragangliomas, fibrous histiocytomas, neurofibromas, chondroblastomas, benign mucoepidermoid tumors, angiofibromas, xanthomas, myoblastomas, hamartomas, glomus tumors, intratracheal goiters, and chemodectomas. All combined, these tumors represent less than 10% of all primary tracheal tumors. Treatment for these diverse tumors is generally surgical excision, although some may be successfully managed with endoscopic resection.[39]

Malignant Primary Tracheal Neoplasms

In adults, the majority of primary tracheal tumors are malignant. Typically, malignant lesions have a shorter duration of symptoms than benign lesions, are larger in size, and exhibit an irregular surface. In most series, approximately 75% of all primary malignant tracheal neoplasms are histologically either squamous cell carcinoma or adenoid cystic carcinoma.[3,18,19,42,43] Historically, malignant tumors were much more common in men than women and squamous cell histology was most prevalent. More recently, however, the incidence of tracheal squamous cell carcinomas has declined, while the incidence of adenoid cystic carcinomas has increased. At the same time, the distribution between genders has nearly equalized.[1,4,19] The most frequent presenting symptoms are cough (72%), dyspnea (66%), hemoptysis (39%), stridor (39%), and hoarseness (31%), but the presence or absence of these symptoms has no prognostic implication.[44]

Squamous Cell Carcinoma

Until the 1980s, squamous cell carcinomas were the most common primary malignancy of the trachea, but the incidence of this disease has decreased significantly since then (Fig. 114-1).[4,44,45] Men are twice as likely to develop this cancer than are women, and the mean age of patients is 60 years.[46] A history of cigarette smoking is found in 90%, and synchronous or metachronous respiratory tract malignancies occur in 30% of these patients.[46] These tumors demonstrate exophytic growth with ulceration. Sputum cytology results are positive for cancer in nearly one half of patients. The lateral tracheal wall is often involved by these tumors, although when a squamous cell carcinoma involving the membranous tracheal wall is found, invasion from a primary esophageal tumor should always be considered.

Squamous cell cancers of the trachea are lethal, biologically aggressive tumors that grow rapidly and metastasize early. In a large series of squamous cell and adenoid cystic tracheal tumors by Gaissert and colleagues,[42,46] 33% of patients had tumors that were unresectable at presentation, and this percentage declined over the past 4 decades. Of those with resected squamous cell tumors, 27% had positive mediastinal lymph nodes. Hospital mortality averaged 7% in the series reviewing a 4-decade experience but improved to 3% in the last decade.

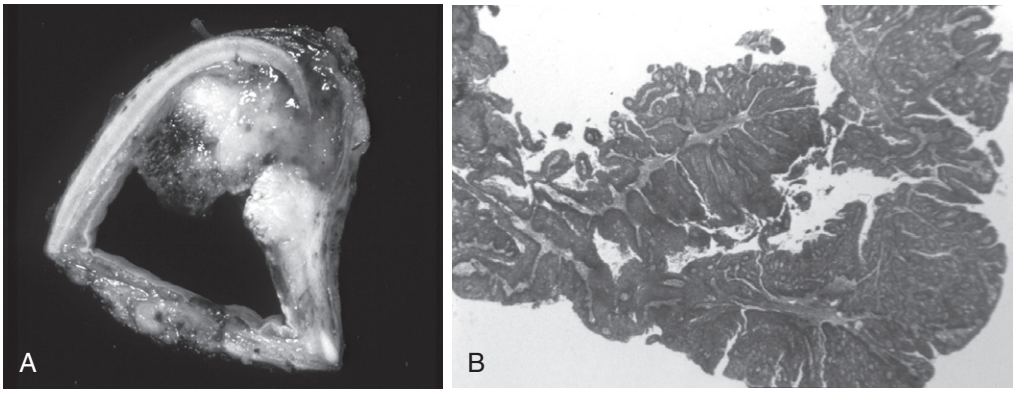

Figure 114-1. **A,** Cross section of trachea through a tracheal squamous cell carcinoma. The bulk of the mass is intraluminal, with focal growth through the tracheal cartilage and into the adventitial soft tissue. **B,** Histopathologic examination of tracheal squamous cell carcinoma showing a papillary growth pattern, with constituent atypical squamous cells (hematoxylin and eosin, ×40). *(Reprinted with permission from Patterson GA, Campbell DB. Clinical-pathologic conference in thoracic surgery: basaloid squamous carcinoma of the trachea.* J Thorac Cardiovasc Surg. *2000;120:187-193.)*

Median survival was 38 months for patients with resectable tumors but only 8.8 months for unresectable patients. The 5-year survival rates for these two groups were 39.1% and 7.3%, respectively. The presence of invasive carcinoma at the resection margins correlated with poorer prognosis, although the number of patients in this category was too small to reach statistical significance. Mediastinal lymph node involvement had the strongest prognostic implication following surgical resection in this review, but this finding was consistent among other case series. The 5-year survival for patients with negative mediastinal lymph nodes was 48.4% compared with 12.5% of patients with positive lymph nodes.[46] Conversely, a large French review found that the presence of positive lymph nodes had no impact on long-term survival, which had an overall 5-year survival rate of 47%.[19]

Radiation therapy has been used to palliate patients with unresectable squamous cell carcinomas. In a series by Grillo and Mathisen,[17] the median survival of patients with tracheal squamous cell carcinomas treated with radiation alone was 10 months, which was greater than survival among untreated patients. In addition, better survival has been observed in patients treated with surgery and radiation compared with either surgery alone or radiation with or without chemotherapy.[4] Similarly, Jeremic and colleagues[47] reported a series of tracheal squamous cell carcinomas treated with 60 Gy of radiation. The median survival was 24 months, and 5-year survival was 27%. The presence of metastasis in the mediastinal lymph nodes portended a poor survival.[47]

Adenoid Cystic Carcinoma

Adenoid cystic carcinomas, previously referred to as *cylindromas,* were first described by Billroth in 1859. These tumors can be seen in all age groups with equal distribution between men and women, but the peak incidence occurs in the fourth or fifth decade. They usually arise in the trachea or main bronchi and thus are frequently symptomatic, although many patients experience symptoms for more than a year before the diagnosis is secured. There is no association with sex, race, or cigarette smoking. Adenoid cystic carcinomas are nonencapsulated, slow-growing, low-grade malignant tumors that originate from the epithelium of the glands lining the mucosa of the respiratory tract. Adenoid cystic carcinomas are known to push mediastinal structures aside rather than invade them (Fig. 114-2). Despite growing slowly, these tumors unfortunately show a predilection for perineural, submucosal, and distant metastatic spread. Surgical resection margins are frequently microscopically positive well away from grossly apparent tumor. In these circumstances, adjuvant radiation therapy is used and commonly associated with long-term survival.[46,48] Lymphatic metastases are relatively uncommon (13% to 19%), but hematogenous metastases develop in 44%.

Treatment consists of surgical resection with preoperative radiation frequently given for large tumors. Surgical resection is possible in only 75% of patients at the time of their initial presentation due to extensive radial and longitudinal growth.[46] The indolent but persistent

Figure 114-2. Computed tomography cross-sectional image of a tracheal adenoid cystic carcinoma displacing mediastinal structures rather than invading them.

nature of adenoid cystic carcinomas conveys long-term survival rates of 33% and 10% at 5 and 10 years, respectively, in unresectable patients.[46] Survival is improved following surgery to 54% and 33% at 5 and 10 years.[46] Although controversial because of the prolonged survival seen even with unresectable disease, pulmonary metastases are not considered a contraindication to tracheal resection in otherwise operable patients. Mean survival in patients with pulmonary metastases was only 37 months.[19,48] Unfortunately, late local recurrences often occur, leading to death in patients thought to be completely resected. Overall mean and median survival rates as high as 85 and 60 months, respectively, have been reported.[48]

Adenoid cystic carcinomas are responsive to radiation therapy.[42] Radiation therapy usually commences approximately 4 weeks after surgical resection. Before initiating radiation, bronchoscopy is performed to assess adequacy of healing. Regnard and colleagues[19] reported adjuvant radiotherapy significantly improved survival in patients with an incomplete resection (positive margins).

Other Malignant Primary Tracheal Tumors

Besides adenoid cystic carcinoma and squamous cell carcinomas, a variety of other malignant tracheal tumors have been reported. All combined, these tumors represent approximately 25% of primary tracheal tumors.[3,18,19] In a recent large, single-institution review of all primary tracheal lesions, 90 of 357 patients had histology that was neither squamous cell nor adenoid cystic carcinoma.[3] Of this diverse

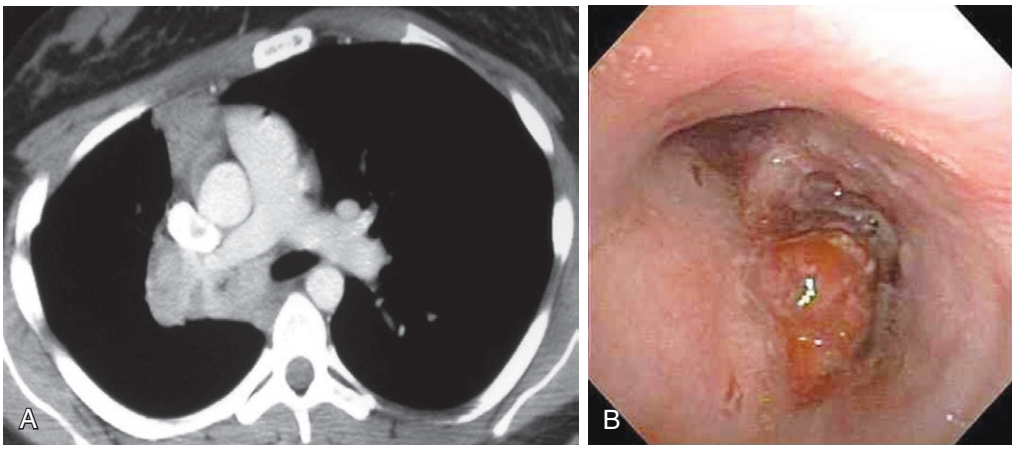

Figure 114-3. **A,** Computed tomography cross-sectional imaging of a carcinoid tumor involving the right mainstem bronchus. Note the enhancement with intravenous contrast administration. **B,** Bronchoscopic view of the same carcinoid tumor.

group, carcinoids and mucoepidermoid carcinomas are the most frequent. Less commonly seen malignant primary tracheal tumors are seen in Table 114-1. Survival at 10 years was 94% for benign tumors. Long-term survival is also frequently observed in patients with uncommon malignant tracheal tumors following resection. Gaissert and colleagues[3] reported a 10-year survival rate of 83% for carcinoid tumors and 5-year survival of 60% for bronchogenic tumors, 100% for mucoepidermoid tumors, and 78% for sarcomas.

Carcinoid Tumors

Carcinoid tumors develop from the argyrophilic Kulchitsky's cells that are present in the airway mucosa. Carcinoids are considered part of a spectrum of neuroendocrine tumors that include small cell lung cancers. These tumors have been subcategorized as neuroendocrine grade I (typical carcinoid), grade II (atypical carcinoid), and grade III (small or large cell undifferentiated neuroendocrine carcinoma).[49] Typical carcinoids, which occur 10 times more frequently than atypical carcinoids, grow slowly and infrequently metastasize.[3] Atypical carcinoids demonstrate aggressive biologic behavior and are characterized by malignant histologic features including nuclear abnormalities, mitotic activity, and necrosis. The majority of patients with atypical carcinoids have lymph node or distant metastases at the time of diagnosis. Small cell carcinoma of the trachea is rare and usually unresectable when diagnosed.

The diagnosis of carcinoid tumors depends on histologic confirmation that can often be obtained by bronchoscopic biopsy. These tumors tend to bleed profusely, so biopsy in the operating room using a rigid bronchoscope may be preferred. The typical bronchoscopic appearance has been described as "mulberry-like" (Fig. 114-3).

The treatment of choice for tracheal carcinoids without mediastinal lymph node involvement is surgical resection, which has been associated with an 83% 10-year survival rate.[4] Aggressive atypical carcinoids are often treated as small cell lung cancers, and responses to chemotherapy and radiation therapy have been seen. Small cell carcinoma of the trachea has an extremely poor prognosis despite management with combined chemotherapy and radiation.

Mucoepidermoid Carcinoma

At bronchoscopy, mucoepidermoid carcinomas of the trachea appear as pink, polypoid masses that can be confused with a carcinoid tumor. Mucoepidermoid carcinomas are derived from minor salivary gland tissue of the proximal tracheobronchial tree. On the basis of mitotic activity, level of necrosis, and nuclear pleomorphism, these tumors are classified as low or high grade. Low-grade tumors behave in a benign fashion, whereas high-grade mucoepidermoid carcinomas progress rapidly. Bronchoscopic biopsy provides the diagnosis and optimal treatment requires surgical resection. Long-term survival is common (100% 5-year survival) when these tumors are completely resected, but unresectable tumors have a poor prognosis with no patients surviving 5 years.[4] Adenosquamous carcinomas are pathologically similar to mucoepidermoid carcinomas and have an aggressive course.

Secondary Tracheal Tumors

Secondary tracheal tumors arise either from direct extension from the primary tumor or from metastatic spread to the airways. Direct tumor extension from adjacent organs is more frequent than metastatic spread and most commonly occurs from tumors of the lung, esophagus, thyroid, mediastinum, and head and neck. Of the tumors that involve the trachea by direct extension, only lung and thyroid have any chance for cure with surgical resection.[34,50] Optimal surgical management of thyroid tumors that secondarily involve the trachea remains controversial. Some favor shaving the tumor off the trachea at the time of a thyroidectomy given the relatively slow-growing nature of most thyroid malignancies and the availability of radiotherapy for local control.[12] Others have supported tracheal resection for thyroid tumor invasion, noting adherence to oncologic principles and the fact that these operations can be performed safely.[51-53] Grillo and Zannini[54] reported effective palliation and occasional cure with aggressive tracheal resection, particularly when the trachea is invaded by well-differentiated thyroid cancer. Complete resection has been associated with a 5-year survival of 78%, which compares favorably with incompletely resected patients who have a 44% 5-year survival rate. However, the results of this one particular study must be evaluated with the understanding that complete resections were attempted in all of these patients, and therefore incompletely resected tumors likely represented more aggressive disease.[55] Some have advocated cervicomediastinal exenteration when necessary, with resection of the involved trachea, larynx, and esophagus, esophageal replacement by colon or stomach, and formation of an end tracheostomy for cure.[56] Anaplastic thyroid cancer and lymphomas with extension to the trachea should not be treated by surgical resection.

Carcinoma of the lung invades the trachea either by proximal extension of a primary tumor within a mainstem bronchus or from involved paratracheal or subcarinal lymph nodes. Aggressive tracheal and carinal resections are warranted in patients without mediastinal lymph node involvement.

Invasion of the trachea by esophageal carcinomas, mediastinal malignant neoplasms, or head and neck cancers are not considered for surgical resection because they have not been shown to benefit from surgical intervention and their outcome is universally poor. Therapy for these tumors is palliative, and management options include radiotherapy, chemotherapy, stents, and other endoscopic techniques.

The most common metastatic tumors to the airway include renal cell carcinoma, sarcomas, breast cancer, and colon cancer. Melanomas can represent a primary tumor of the trachea or more commonly can be metastatic to the trachea. Rarely tumors of the uterus, testes, and

adrenal gland have reportedly metastasized to the trachea. Metastatic tumors involving the trachea can cause airway compromise by direct invasion and endoluminal obstruction or by extrinsic compression of the trachea. Determining the cause of the obstruction is crucial in directing treatment. Metastatic lesions to the trachea are incurable and treated palliatively.

Diagnosis

Symptoms, Signs, and Physical Examination

Tracheal masses are often not diagnosed until months or years after the onset of symptoms and are frequently large when discovered. Tracheal masses grow silently and do not produce symptoms until the lumen of the airway is narrowed by approximately 75%.[32] Adding to the typical delay in diagnosis is the fact that tracheal tumors are extremely uncommon, and the initial symptoms often mimic those of common disorders such as asthma or chronic bronchitis.

The most common symptom in a patient with a tracheal tumor with significant airway narrowing is exertional dyspnea. Other common symptoms of tracheal lesions include stridor, wheezing, cough, difficulty clearing secretions, recurrent pneumonia, hemoptysis, and hoarseness. Hoarseness is usually the result of reduced air flow across the vocal cords, although it can also indicate recurrent laryngeal nerve involvement. Systemic symptoms including weakness, weight loss, and dysphagia may be seen with metastatic tumors and are a poor prognostic sign.

Physical examination in a patient with a tracheal tumor may be unrevealing, but stridor, wheezing, bronchial breath sounds, increased accessory muscle use, signs of obstructive pneumonia, or subtle alteration in the timber of the voice may be present with significant narrowing of the airway. A clue that the symptoms are caused by a tracheal lesion rather than pulmonary disease is the inspiratory and often paradoxic nature of dyspnea, which is exacerbated by lying down. A history of another primary neoplasm in the setting of airway obstructive symptoms suggests direct extension or metastatic spread and should prompt evaluation.

Radiographic Evaluation

In general, the diagnosis of a tracheal tumor requires a high index of suspicion and appropriate confirmatory radiographic studies. A posteroanterior and lateral chest radiograph will identify an obstructing tracheal lesion in one quarter to one half of the cases.[32] Findings on a plain chest radiograph suggesting a tracheal tumor include the presence of a mass and narrowing, distortion, or disruption of the tracheal air column (Fig. 114-4). Direct extension from an adjacent primary may be detected.

Chest CT scans are an important part of the evaluation of a tracheal tumor. In addition to demonstrating the degree of luminal compromise, CT is excellent for assessing mediastinal tumor extension and nodal or metastatic disease (Fig. 114-5). Inspiratory and expiratory CT scans can help clarify dynamic states such as tracheomalacia, and spiral CT with three-dimensional reconstruction is useful in the evaluation and management planning of complex lesions involving the carina.

In many patients a CT scan can suggest the histologic type of the tumor. The presence of fat and calcification within a tracheal mass is virtually pathognomonic of a hamartoma.[32] Marked enhancement of a tracheal lesion after intravenous contrast administration suggests a carcinoid tumor.[57]

In other patients, CT scans may provide clues to the benign or malignant nature of a tracheal tumor. Features suggestive of a benign lesion by CT scan include an intraluminal tumor with limited spread along the tracheal wall, a well-circumscribed lesion with a smooth or lobulated appearance, and a size usually smaller than 2 cm.[58,59] Calcification suggests a cartilaginous lesion, but it does not rule out malignancy. Features suggestive of a malignant tracheal lesion include an irregular surface with extension over variable lengths of the trachea, extramural extension into the mediastinum, lesions larger than 2 cm, circumferential tracheal involvement, and enlarged mediastinal lymph nodes.[59]

CT scans are unreliable for delineating the submucosal spread of disease, and thus they will underestimate the longitudinal dimensions of a tumor. This is particularly true for adenoid cystic carcinoma, which has a propensity for submucosal spread well beyond the limits of the gross pathologic tumor. Furthermore, because adenoid cystic carcinomas tend to grow slowly and push mediastinal structures away rather than invade them, the CT finding of a loss of fat planes between the tumor and mediastinal structures is a poor predictor of actual invasion with this tumor.[32]

Figure 114-4. Careful examination of the tracheal air column seen in this standard posteroanterior chest radiograph demonstrates an oval mass nearly obstructing the trachea *(arrows)*.

Magnetic resonance imaging (MRI) has been used in the evaluation of tracheal tumors. Coronal, axial, and oblique sagittal planes can demonstrate the superior or inferior extent of a tumor and its relationship to adjacent mediastinal structures. One area in which MRI has shown promise recently has been in the detection of tracheal invasion by thyroid carcinoma.[60] MRI offers some advantage over CT when vascular or cardiac invasion is suspected and to determine whether a lesion has a pedicle or broad-based attachment.[59]

Pulmonary Function Testing

Pulmonary function tests can suggest an upper airway obstruction and occasionally can lead to the diagnosis of a tracheal lesion. Characteristic findings include a significant reduction in peak expiratory flow rate, FEV_1 and FEV_{25-75}, with relative preservation of vital capacity.[11] Significant improvement in symptoms, as well as pulmonary function test values, have been observed after tracheal and bronchial stent placement for stenosis.[11]

Bronchoscopy

Bronchoscopy represents the mainstay of diagnosis for tracheal tumors and is a necessary step in the examination of patients with these neoplasms. Capabilities for rigid bronchoscopy are essential, particularly in those with proximal tracheal tumors. Biopsy and manipulation of a tracheal tumor with flexible bronchoscopy are potentially hazardous because they may precipitate bleeding or total obstruction of an already compromised airway. The combination of flexible and rigid bronchoscopy allows biopsy of the tumor, precise measurement of tracheal length, identification of tumor extension, and determination of the proximity of the tumor to the larynx or carina. Mucosal extension of the tumor may be suggested by evidence of inflammation or erythema above or below the lesion.

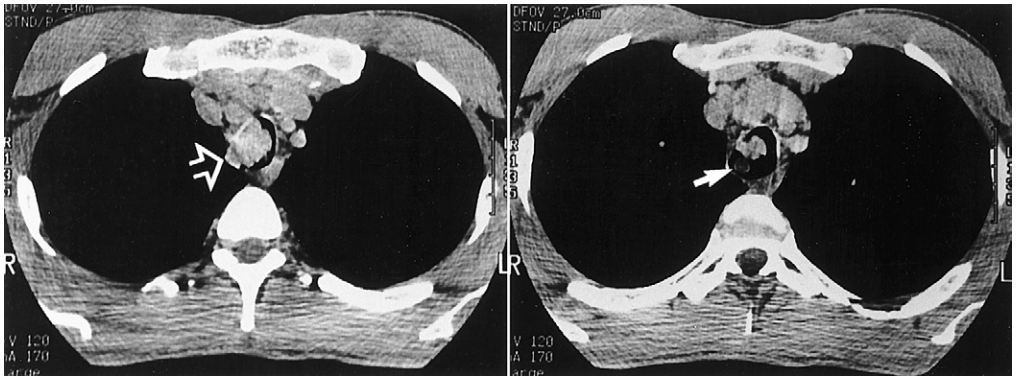

Figure 114-5. Two images from the computed tomography scan of a patient with what proved to be a tracheal hamartoma demonstrate the degree of tracheal luminal obstruction by the tumor and its attachment to the right lateral tracheal wall. Although the right lateral tracheal wall is deformed by the tumor *(open arrow),* there is no invasion beyond the wall. Fat *(closed arrow)* within the tumor suggests the diagnosis of hamartoma.

Our preference for initial evaluation is transnasal or transoral flexible fiberoptic bronchoscopy using topical anesthesia and intravenous sedation. Patients with nonobstructing distal tracheal tumors can be intubated after the induction of general anesthesia and then can undergo biopsy and evaluation with the flexible bronchoscope. Patients with large proximal tracheal tumors are best treated by the induction of general anesthesia with inhalational agents and intravenous sedatives followed by the evaluation of the airway with a rigid bronchoscope. Rigid bronchoscopy is preferred when tracheal tumors are causing subtotal obstruction because ventilation can be maintained through the bronchoscope. In addition to maintaining ventilation, the rigid bronchoscope can be used to dilate and core out the malignant lesion, providing stabilization of the airway. Tumor bleeding, although a concern, is rarely a problem with rigid bronchoscopy because the bronchoscope can be used to apply pressure to the site; alternatively, cautery or laser treatment can be used to control bleeding.

Treatment

Appropriate treatment of a tracheal tumor begins with a careful assessment of the overall situation. Coexistent medical disorders, especially cardiopulmonary disease, should be evaluated and optimized. Pneumonia should be cleared, and the airway should be stabilized, if necessary, with rigid and flexible bronchoscopic techniques. Importantly, tracheal tumors once symptomatic can rapidly progress to critical airway obstruction. Tracheal luminal diameters less than 10 mm are typically asymptomatic, even with activities, although exertional dyspnea usually manifests at a tracheal diameter of 8 mm and worsens rapidly with any further decrease in diameter. Stridor is present at rest when the tracheal diameter is narrowed to 5 mm or smaller. Acute decompensation can occur with minimal edema or secretions.

Primary Malignant Tracheal Tumors

The majority of adult tracheal tumors are malignant, and when feasible, surgical excision with circumferential tracheal resection and primary end-to-end reconstruction represents the best therapy. Limitations to resectability include the invasion of critical mediastinal structures and involvement of such an extensive length of trachea that reconstruction would be impossible. Patients with tracheal squamous cell carcinoma who are potential candidates for resection require mediastinoscopy. If metastatic disease is detected in superior mediastinal nodes, the likelihood of complete resection and long-term survival is remote. In these patients, resection should not be undertaken. These patients are treated better with combination chemoradiotherapy. If the results of the mediastinoscopy are negative, resection should proceed immediately. Anterior mobilization of the lower cervical and entire thoracic trachea will already have been accomplished by the mediastinoscopy. In contrast, the presence of metastatic disease in regional mediastinal nodes in patients with adenoid cystic carcinoma does not have a clear impact on survival rate and should not preclude resection. Furthermore, Pearson and colleagues[18] have noted that many patients with adenoid cystic carcinoma remain asymptomatic from pulmonary metastases for years, and thus patients with synchronous pulmonary metastases should not be considered inoperable.

Anesthetic Management

Patients with tracheal tumors present major challenges in airway management. Before surgical resection of tracheal tumors, flexible and rigid bronchoscope techniques are used to stabilize the airway, if necessary. Surgery should then be undertaken in a short time span to prevent the tumor from reobstructing the airway. A mixture of inhalational and intravenous sedation is used, allowing spontaneous ventilation while the airway is secured. Tracheostomy is unwarranted and detrimental in patients with tracheal tumors because stomal placement may interfere subsequently with ideal positioning of the tracheal anastomosis.

After intubation, the next challenge in airway management occurs during tracheal division and reconstruction. After transecting the trachea, ventilation can be maintained by one of three methods: (1) advance the endotracheal tube down into the distal trachea across the transected portion of the airway; (2) pass a small jet ventilation catheter either down the endotracheal tube or across the sterile field and into the distal airway; or (3) directly intubate the distal airway using a sterile, wire-reinforced endotracheal tube connected to sterile, corrugated plastic ventilator tubing brought across the field. For patients with distal tracheal lesions, it may be necessary to intubate the left or right mainstem bronchus individually, with intermittent inflation of the opposite lung if the oxygen saturation decreases as a result of persistent blood flow through the atelectatic lung (shunt). These patients require close monitoring with digital pulse oximetry and frequent arterial blood gases. Cardiopulmonary bypass is hazardous and unnecessary in nearly all patients.[51]

Surgical Management: Tracheal Resection and Primary Reconstruction

A low-collar incision provides access to the cervical and the upper two thirds of the intrathoracic trachea. If necessary, additional exposure can be obtained by adding a partial or complete sternotomy. Tumors of the distal third of the trachea are approached through a right posterolateral thoracotomy (usually at the fourth interspace). When the carina is involved, a median sternotomy may be preferable for exposure (Fig. 114-6).[13,18]

When using a cervical incision, the patient is positioned with the neck fully extended using an inflatable pad behind the shoulders. A transverse collar incision is made 1 to 2 cm above the clavicular heads, and subplatysmal skin flaps are created extending from the superior aspect of the thyroid cartilage to the clavicular heads. The strap muscles are separated in the midline, exposing the anterior trachea. The trachea is then mobilized and brought into the incision, and the site of resection can be determined by bronchoscopically visualizing a needle being

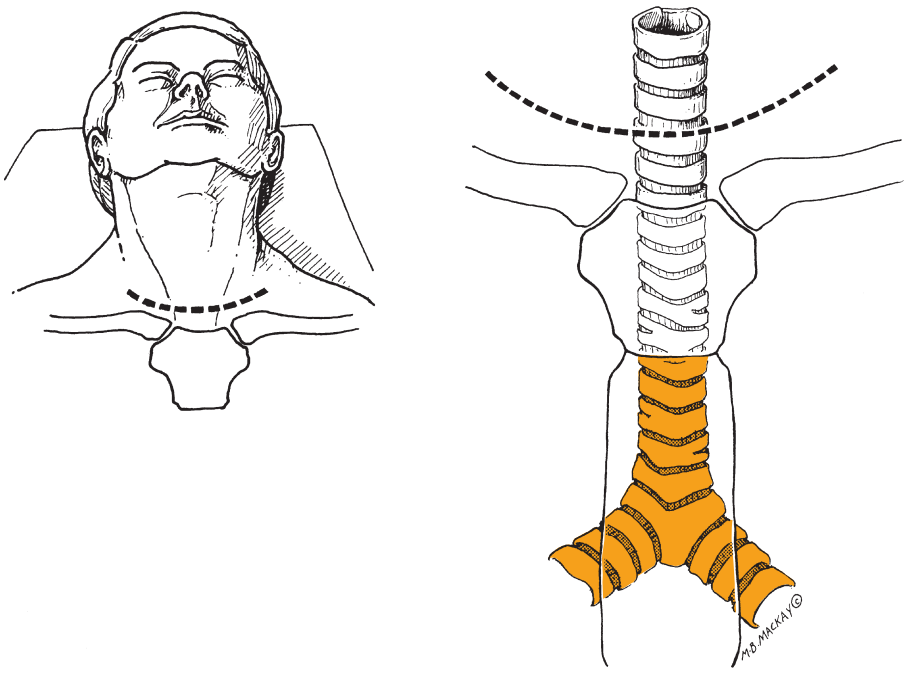

Figure 114-6. Location of cervical incision used for cervical and upper one half to two thirds of the mediastinal trachea *(unshaded area).* The distal trachea and carina *(shaded area)* requires either a median sternotomy or right posterolateral thoracotomy. *(Modified from Griffith Pearson F, Cooper JD, Deslauriers J, et al.* Thoracic Surgery. *New York: Churchill Livingstone; 2002:407.)*

passed through the anterior tracheal wall. During mobilization of the trachea, care is taken to preserve the blood supply, which enters laterally. In patients with benign tumors, the dissection is kept immediately adjacent to the trachea and no attempt is made to isolate or identify the recurrent laryngeal nerves. Resections for malignant tumors require identification and preservation of the recurrent laryngeal nerves, if possible. If one recurrent laryngeal nerve is involved with tumor, it should be sacrificed. Sacrifice of both recurrent laryngeal nerves requires concomitant tracheostomy and a subsequent vocal cord-lateralizing procedure. Paratracheal nodes are excised with malignant tumors to the extent possible without compromising the blood supply to the remaining trachea.

Care is taken during resection to prevent anastomotic tension. In optimal circumstances, approximately half the trachea can be resected and a primary anastomosis can still be performed without undue tension,[13] but advanced patient age and prior mediastinal radiation may impose restrictions on tracheal resections because of the loss of tissue resiliency. Before complete division and resection of the involved airway, stay sutures are placed in the remaining proximal and distal ends to assist alignment and to gauge tension. The proximal endotracheal tube is pulled back and the distal trachea is intubated for ventilation. Resection margins should be assessed by intraoperative frozen section. Unfortunately, it may not be possible to determine the necessary extent of resection until after the airway is open.

After completion of the tracheal resection, the patient's neck is flexed by deflating the pad behind the patient's shoulders and a primary anastomosis constructed using a continuous running absorbable suture on the posterior membranous portion and interrupted simple absorbable suture to close the anterior cartilaginous portion of the trachea (Fig. 114-7). After placement of the posterior membranous sutures, the patient's oral endotracheal tube is readvanced across the anastomosis and the distal endotracheal tube is removed. The anterior tracheal wall sutures are then placed. All intrathoracic anastomoses should be wrapped to interpose tissue between the suture line and adjacent pulmonary or systemic vessels. Frequently, either pedicled pleura or pericardial fat is used, although omentum is recommended when there has been previous mediastinal irradiation.[42] A drain is usually placed alongside the anastomosis and brought out through a separate stab incision in the neck. If there is any doubt about the viability of the anastomosis, a Montgomery T-tube can be placed across it. The incision is then closed by reapproximation of the strap muscles, the platysma, and the skin (see Fig. 114-7).

To reduce tension on the anastomosis, cervical flexion is maintained with a heavy (No. 2) monofilament "guardian" stitch between the chin and the anterior chest wall. It is left in place for approximately 7 days and is usually removed after confirmation of anastomotic healing by bronchoscopy (Fig. 114-8).

Preferably, and if deemed appropriate, the patient is extubated in the operating room. However, the presence of edema may preclude this, and an uncuffed endotracheal tube should be used in these situations. The patient is taken to the intensive care unit for postoperative management. Yearly follow-up bronchoscopy should be performed for life, particularly in patients with adenoid cystic carcinoma, because recurrences have been identified more than 25 years after tracheal resection.

Release Maneuvers

If it becomes apparent that the necessary amount of tracheal resection will place the anastomosis under tension, various mobilization and release techniques can be performed to provide additional tracheal length. For resections involving the cervical trachea, the easiest maneuver is simple neck flexion and dissection along the anterior trachea in the neck and mediastinum. An additional 2 to 3 cm of tracheal length can be obtained by performing either a suprathyroid[12] or suprahyoid[14] laryngeal release. These procedures allow the larynx to drop down, thus providing additional mobility and tracheal length. Of the two procedures, the suprahyoid is preferred because it involves a lower incidence of swallowing complications postoperatively. For thoracic tracheal and carinal resections, these release maneuvers are generally not useful. In these cases, dissection of the left main bronchus along its anterior surface (taking care to avoid lateral blood supply) will provide slightly more mobility and is easily performed. Intrapericardial hilar release maneuvers are also used and can be effective in obtaining an additional 2 cm of tracheal length by elevating the carina. The right hilar release is performed by making a U-shaped incision in the pericardium beneath the inferior pulmonary vein and incising the intrapericardial septum, which joins the lateral aspect of the atrium and inferior vena cava to the pericardium (Fig. 114-9). The performance of the maneuver on the

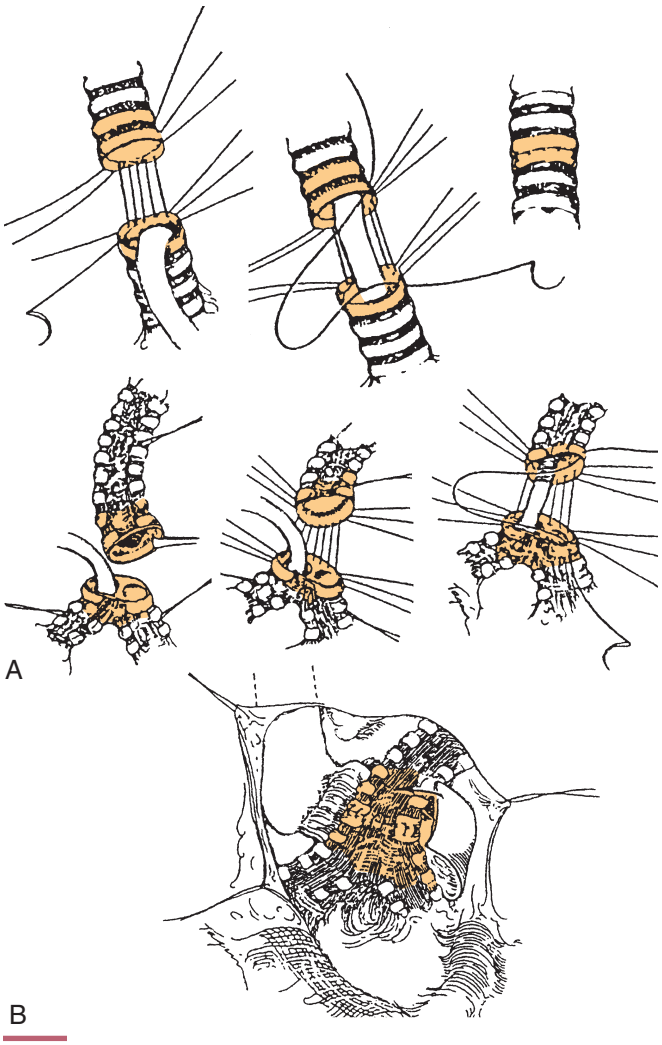

Figure 114-7. **A,** A tumor of the upper trachea has been excised, and the proximal and distal ends of the trachea are mobilized (although not circumferentially, as suggested in this diagram). Interrupted simple sutures are placed with the knots on the outside. Ventilation is accomplished initially across the field with intubation of the distal airway. Subsequently, as the anastomosis nears completion, the endotracheal tube is advanced across the anastomosis. **B,** A tumor of the distal trachea is excised, and ventilation is maintained by selective intubation of the left mainstem bronchus across the field. After suture placement, the endotracheal tube is advanced across the anastomosis and into the left mainstem bronchus. The completed anastomosis is wrapped with a pleural flap. *(Modified from Grillo HC. Reconstruction of the trachea. Experience in 100 consecutive cases.* Thorax. *1973;28:667.)*

left is basically the same, except there is no intrapericardial septum to divide and the ductus arteriosus should be transected. Although seldom necessary, an additional 2.7 cm of tracheal length can be obtained through division of the proximal left mainstem bronchus and reimplantation into the bronchus intermedius. Obviously, this increases the complexity and the potential morbidity of the operation. Even more mobility can be obtained by incising the pericardium around the hilar airway. While this release maneuver can be performed on the right, the left mainstem bronchus is relatively fixed by its relationship with the aortic arch.

Subglottal Resections

Tumors that involve the subglottal region require precise surgical intervention to prevent permanent recurrent laryngeal nerve damage and vocal cord injury. In selected patients, tumors of the subglottal airway can be managed by excision of the anterior cricoid arch and the posterior cricoid plate leaving its perichondrium in place. A primary thyrotracheal anastomosis is then performed, usually within 1 cm of the inferior border of the vocal cords with preservation of the recurrent laryngeal nerves (Fig. 114-10).[8] Resectional management of well-differentiated thyroid carcinomas invading the trachea may require complex reconstruction.[61]

Although rarely necessary, techniques for cervical exenteration have been described. Occasionally these techniques may be useful in the palliation of strangulating tumors. Rarely, this drastic technique can be curative.[42]

Carinal Resections

Tumors involving the carina present major technical challenges. Again, the need for a tension-free anastomosis is critical. In carinal resections, tumors involving more than 4 cm of tracheal length usually preclude resection. The complexities of carinal resection and the options for reconstruction were well reviewed by Grillo in 1982 (Fig. 114-11).[62] After carinal resection, the simplest technique for reconstruction involves approximating the medial walls of the right and left mainstem bronchi to fashion a new carina and then anastomosing this to the distal trachea (Fig. 114-12). This technique is applicable only with small tumors, which require limited tracheal resection. The fixation of the left mainstem bronchus by the aorta limits the ability to approximate the ends of the airway in most patients. More commonly, the trachea is anastomosed end-to-end to one of the mainstem bronchi, and the other mainstem bronchus is sutured into the lateral wall of the trachea above the first anastomosis (Fig. 114-13).

Benign Tracheal Tumors

Most benign tracheal tumors are readily managed with segmental tracheal resection and primary anastomosis. Patients with pedunculated or exophytic tumors or those with benign tumors in anatomic locations that might make resection difficult are potential candidates for endoscopic resection. Current methods of endoscopic resection include coring out and biting off the tumor with a rigid bronchoscope and biopsy forceps, cautery excision, cryoablation, and laser photocoagulation. Benign tumors most amenable to these techniques include lipomas, hamartomas, papillomas, fibromas, and small (≤8 mm) granular cell tumors. The base of the tumor should be ablated to reduce the incidence of recurrence, and patients with recurrence detected on a follow-up bronchoscopy should be considered for resection.

Palliative Treatment of Unresectable Malignant Tracheal Tumors

Therapeutic Bronchoscopy

Endoscopic procedures including dilation, mechanical débridement, laser vaporization, PDT, cryotherapy, brachytherapy, or stenting can provide palliation of unresectable tracheal tumors. For endotracheal lesions, the optimal choice of endoscopy technique depends on the individual tumor's characteristics, and often a combination offers the best approach.[63] Dilation of the narrowed segment, if caused by an endobronchial component, can be dilated by passage of rigid bronchoscopes of increasing size, use of bougies, or, alternatively, balloon dilation. Gentle passage of the rigid bronchoscope past the lesion should be performed to prevent creation of false passage. Dilation, although effective, is temporizing and rarely used as the sole treatment of unresectable endobronchial tumors. One can use the rigid bronchoscope to remove large pieces of an obstructing neoplasm by running the scope against the wall of the trachea and slicing off the tumor. This is referred to commonly as *coring out* of the tumor or *mechanical débridement*. Bleeding is controlled with compression by the rigid bronchoscope supplemented with epinephrine-soaked sponges if necessary. Laser vaporization has been used in combination with the rigid bronchoscope for lesions that are quite vascular such as metastatic renal cell carcinoma. Laser vaporization can be used alone as a treatment of unresectable tracheal neoplasms, but this is more time consuming. Besides being hemostatic, an additional advantage of laser vaporization is that it can

be performed through a flexible bronchoscope, thus avoiding general anesthesia. The most frequently used laser is the neodymium:yttrium-aluminum-garnet (Nd:YAG).[64] Complications with laser vaporization include airway perforation, bronchopulmonary artery fistulas, airway fires, and skin burns.

PDT is an option for endotracheal tumors, but because the mucosal edema may exacerbate airway stenosis, this therapy is not recommended for highly obstructive lesions. For PDT the patient is given a photosensitizer, dihematoporphyrin ether (DHE), intravenously, which is retained longer in tumor cells but is also taken up by normal cells. After 2 days the patient is treated with an argon dye laser system (630 nm). The DHE absorbs the light energy, radical oxygen species are produced, and the tumor cells necrose. PDT results in a wider radial extent of necrosis compared with mechanical débridement or laser vaporization and therefore results in a more durable palliation.[65-67] Bronchoscopies to remove necrotic mucosa are usually performed on days 1 and 3 following treatment. Subsequent treatments can be performed if residual tumor persists. PDT, like laser vaporization, is hemostatic and therefore can be used for highly vascular tumors. The disadvantages of PDT are photosensitivity of the patient for up to 8 weeks after DHE injection, scar and stricture formation with multiple treatments, and possibly fistula formation.[67]

Cryotherapy involves a probe placed with either rigid or flexible bronchoscopes to freeze tumor cells, resulting in necrosis. Thus cryotherapy is similar to PDT in that it does not provide immediate relief and can initially worsen the obstruction. Repeat bronchoscopy is necessary over the course of the next few days to débride the necrotic exudate. Also similar to PDT, cryotherapy provides extensive radial necrosis, and thus the number of repeat treatments may be lessened. Its major disadvantage lies in its complexity, time requirement, and a lack of familiarity with the procedure among most surgeons.

Brachytherapy delivers high amounts of localized radiation therapy to the tumor with endotracheal catheters that are placed with flexible bronchoscopy. Large, bulky lesions do not respond well to this treatment, but it has been used on unresectable tumors with a curative intent. It is frequently used in combination with mechanical core-out or laser therapy and provides better palliation than either used alone. Usually iridium-192 is used to deliver 2 Gy/min over several minutes to provide 7 to 15 Gy at a setting. A total of two to four fractions at 1-week intervals are delivered.[68] Brachytherapy has a few significant complications including radiation bronchitis (10%), stenosis (1% to 3%), and massive hemoptysis (5% to 20%).[68] One study found local failure, persistent malignancy, delivery of laser photocoagulation, and direct contact of the endobronchial brachytherapy applicator, and the tracheobronchial walls at the vicinity of the great vessels were the most indicative indicators of a massive hemoptysis.[69]

Tracheal tumors that cause airway obstruction by extrinsic compression are best palliated with endoluminal stents. Patients requiring palliation with tracheal stents typically have short life expectancies with a recent series showing a mean survival of 8 months after stent placement.[70] Stents have been used with adjuvant chemotherapy and radiation, and they have also been used in combination with other endoluminal treatment modalities. Two types of stents currently available are silicone and metal expandable stents. Silicone stents, which are

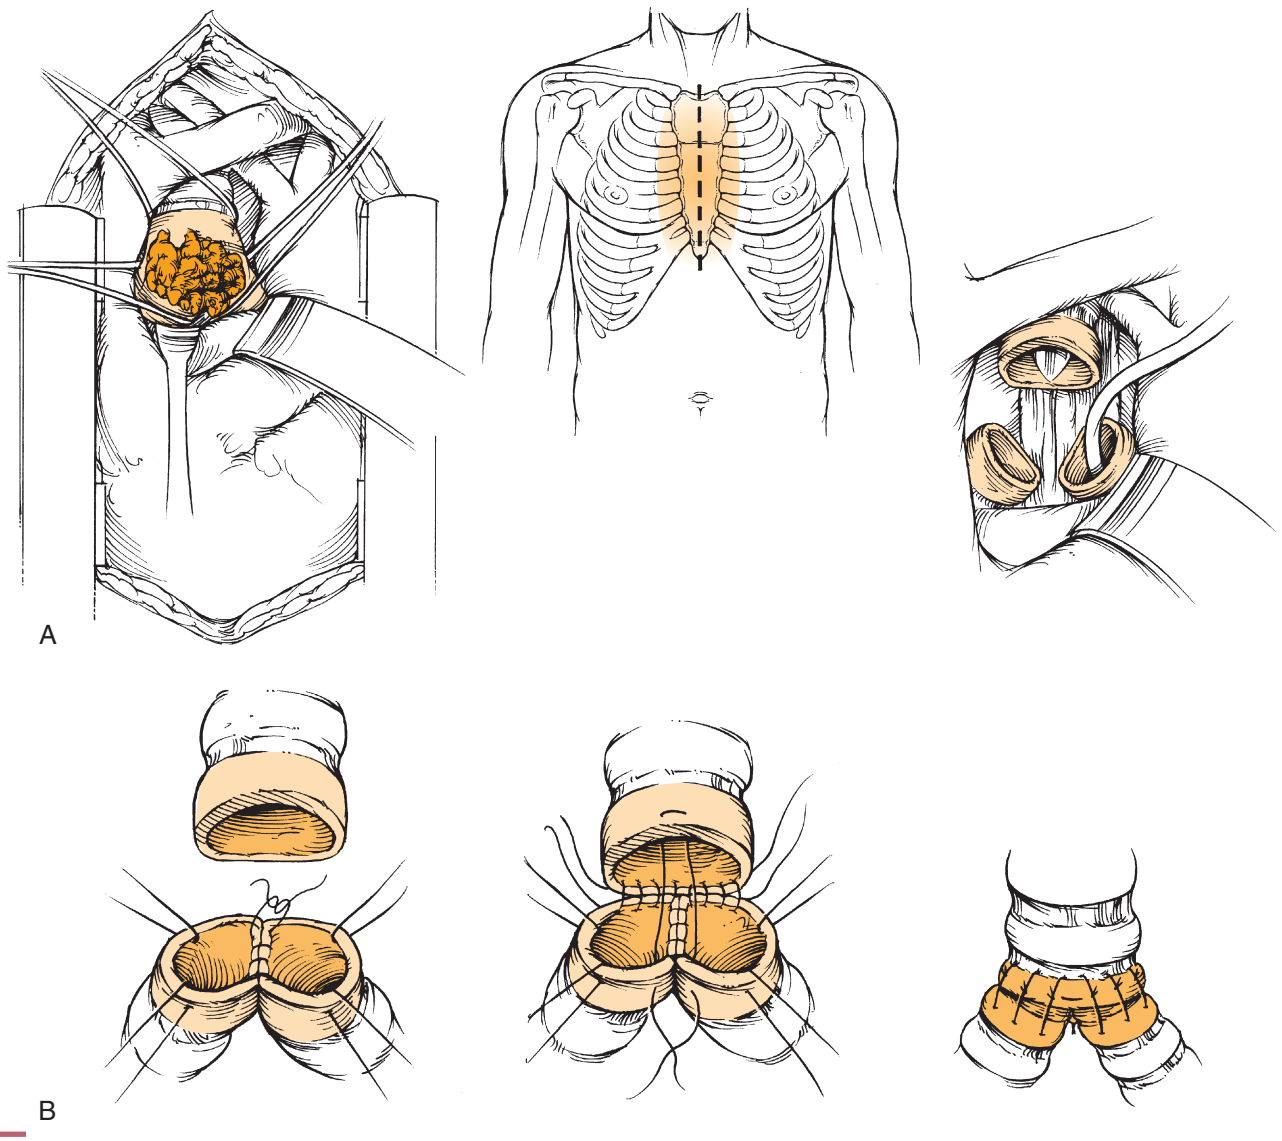

Figure 114-12. **A,** A tumor at the carina is excised. Ventilation is accomplished with a small jet ventilation catheter brought across the field and directed down the left mainstem bronchus. **B,** The medial walls of the right and left mainstem bronchi are anastomosed to form a new carina, which is then sutured to the distal trachea. *(Redrawn from Urschel HC Jr, Cooper JD.* Atlas of Thoracic Surgery. *New York: Churchill Livingstone; 1995.)*

available in cylindrical or bifurcated forms, are somewhat more difficult to place than expandable metal stents because they require rigid bronchoscopy. These stents are easy to remove or reposition because they do not incorporate into the surrounding tissues. Unfortunately, for the same reason, silicone tubes are known to spontaneously dislodge and migrate. Newer models of silicone stents are available with external studding to help reduce the risk of dislodgement. In comparison, expandable metal stents can be placed with a flexible bronchoscope. They incorporate firmly into tissues and thus are difficult to remove or reposition. Complications associated with airway stenting include stent migration, erosion, ingrowth of granulation tumor, and impaired secretions clearance.

Results

Hospital mortality rates for primary tracheal tumor resection have ranged from 5% to 15%.[18,19,42,71] Regnard and colleagues[19] reported morbidities of anastomotic failure (12%), pneumonia (6.3%), and aspiration (13.9%). The highest postoperative mortalities occurred in patients undergoing carinal resection and tracheal reconstruction attempts. Regnard and colleagues[19] reported 5- and 10-year survivals of 47% and 36%, respectively, for resected squamous cell carcinomas and 73% and 57% for resected adenoid cystic carcinoma, respectively.

Hospital mortality for patients who underwent tracheal resection for the invasion of a well-differentiated thyroid carcinoma in one series was 9%.[50] Of the 34 patients in this series treated with surgical resection, only 2 patients had airway recurrence, and 50% of patients remained alive for between 1 month and 14.5 years postoperatively (average, 5.3 years). In a series of 60 tracheal resections for thyroid cancer reported by Ishihara and colleagues,[55] complete resection was possible in 56.7% of patients. Complete resection was associated with improved long-term survival rate (78.1% at 5 years) compared with those who had an incomplete resection (40% at 5 years). Yang and colleagues[72] resected the tumors in eight patients with well-differentiated thyroid carcinoma invading the trachea, and at follow-up ranging from 14 to 183 months, five remained free of disease (three of these were followed up for more than 10 years).

Results for patients with primary lung cancer undergoing carinal resection reveal a 10% operative mortality and 5-year survival of 42%. Patients with no lymph nodes involved have a 51% 5-year survival, whereas those with positive results for mediastinal lymph node disease have only a 12% 5-year survival rate.[73]

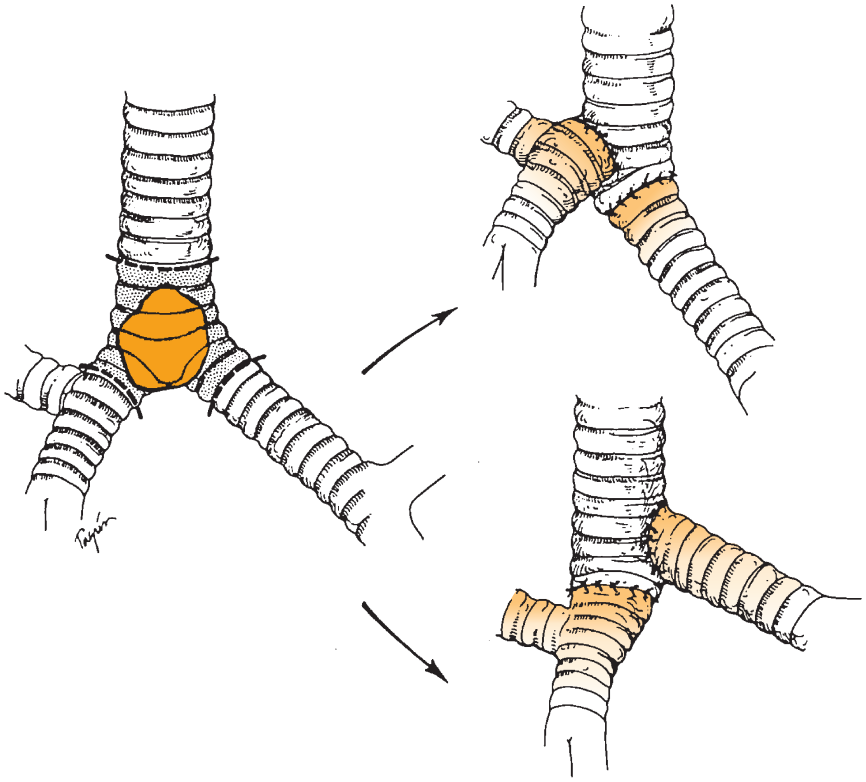

Figure 114-13. Carinal reconstruction after resection. The trachea is anastomosed end-to-end to either the left (most commonly) or the right mainstem bronchus, and the other bronchus is placed into the lateral wall of the trachea above the first anastomosis. *(Modified from Grillo HC. Tracheal tumors: surgical management.* Ann Thorac Surg. *26:112, 1978.)*

Complications

Regnard and colleagues[19] identified four factors that were significantly associated with the development of postoperative complications: an increasing length of resection, the need for laryngeal release, laryngotracheal or carinal resection as opposed to standard tracheal resection, and squamous cell histology.

Common problems after tracheal surgery include atelectasis, retained secretions, pneumonia, and swallowing dysfunction with aspiration. Aspiration is most likely to be a problem in patients with recurrent laryngeal nerve dysfunction and in those who underwent a release procedure of the upper airway (superior laryngeal or suprahyoid technique). In many patients, the problem resolves within a few weeks, either spontaneously or with swallowing modification techniques. Vocal cord dysfunction may be transient or permanent, depending on the nature of the injury to the recurrent laryngeal nerve. Dysfunction of one vocal cord usually produces hoarseness and an impaired cough. Bilateral cord dysfunction can cause airway obstruction requiring tracheostomy.

Wound infections, particularly in the cervical area, are rare. Prompt opening and complete drainage of the wound is essential. Intrathoracic infections are potentially much more serious, particularly when an anastomotic dehiscence produces an air leak or a space within the mediastinum. Urgent and wide drainage is critical to prevent the development of mediastinitis.

Anastomotic dehiscence usually occurs as a result of excessive tension or compromised tracheal blood supply. Excessive tension occurs with overzealous tracheal resection or inadequate mobilization. Ischemia is more likely to occur in patients with previous irradiation to the area and in those who undergo extensive nodal dissection or circumferential mobilization of the airway. Acute separation can be resutured if it occurs early and if there is no necrosis or ischemia.[54] Otherwise, a tracheostomy or T-tube can be inserted across the defect.

An uncommon but lethal complication of airway surgery is tracheal-innominate or tracheal-pulmonary artery fistula formation. Fistulas can result from pressure against the innominate artery by a postoperative tracheostomy tube or by direct abrasion of the anastomosis against the innominate or pulmonary artery. To protect against fistula formation at the airway anastomosis, dissection near the brachiocephalic artery should be performed on the trachea, leaving adjacent soft tissue undisturbed on the artery itself. This will prevent most fistulas. If the artery is bared, vascularized soft tissue such as a pedicled strap muscle should be interposed between the artery and the anastomosis. Within the thorax, soft tissue, like the thymus or pericardium, should be placed between the pulmonary artery and an airway suture line. Some patients will have a "herald" bleed, and prompt exploration with bronchoscopy and opening of the wound may save these patients. Unfortunately, most patients who develop this complication suffer a sudden, fatal hemorrhage into the airway.

Late complications include the development of granulation tissue or stenosis at the anastomosis. Exuberant granulation tissue can often be extracted endoscopically with a biopsy forceps. Occasionally, granulation is a result of infection or necrosis of underlying cartilage and can be a particular problem if it involves the cricoid. When the cricoid is involved, the infection can slowly progress over many months and definitive management often requires operative débridement. Anastomotic stenosis developed in 5% of patients who survived tracheal or carinal resection and reconstruction in the series by Grillo and Mathisen.[17] Symptomatic stenoses occurred in 14% of patients in the series reported by Regnard and colleagues,[19] and it occurred significantly more frequently among patients who had postoperative locoregional complications such as tracheal dehiscence or mediastinitis. Anastomotic stenoses can often be managed with endoscopic techniques including dilation and T-tube placement. Attempts at resection should be delayed for 4 to 6 months after the initial surgery to allow the acute inflammation to subside.[74] As noted by Grillo and colleagues,[74] the difficulties of tracheal reconstruction increase markedly with each attempt at repair, and thus conditions should be optimal. Every effort should be made at the time of the initial resection and

reconstruction to avoid complications that could lead to an anastomotic stenosis.

Summary

Primary tracheal tumors are rare, and in adults, most tumors are malignant. More than 80% of malignant tracheal tumors are either squamous cell carcinoma or adenoid cystic carcinoma. Tracheal tumors are best managed by resection with end-to-end anastomosis. Great care should be taken to avoid excessive tension on the anastomosis by limiting the extent of the resection and, in addition to cervical flexion, performing appropriate release procedures as needed. Anastomotic ischemia is avoided by limiting the area of circumferential dissection, carefully preserving the lateral blood supply, and being judicious in the extent of the paratracheal lymph node excision.

Adjuvant radiotherapy is probably of benefit after resection of squamous cell and adenoid cystic carcinoma, particularly in those with positive resection margins. Radiotherapy as primary management for malignant tracheal tumors is reserved for patients medically unfit for an operation, those with unresectable airway tumors, and those with metastatic disease. Overall, the 5-year survival rate for patient with adenoid cystic carcinoma (73%) is much greater than for those with squamous cell carcinoma (47%). Management for tumors involving the trachea secondarily is in general palliative, although aggressive tracheal resection for invasive thyroid carcinoma and bronchogenic carcinoma offers a chance for cure.

CHAPTER ONE HUNDRED AND FIFTEEN

Penetrating and Blunt Trauma to the Neck

David B. Hom

Robert H. Maisel

Key Points

- With penetrating neck trauma, emergent surgical exploration is necessary for any immediate life-threatening signs or symptoms (expanding hematoma, nonexpanding hematoma in the presence of hemodynamic instability, hemomediastinum, hemothorax, hypovolemic shock).
- For the stable patient, the choice of treatment for penetrating neck trauma remains controversial. Classifying the neck zone involvement (zone I, II, or III), mechanism of injury, and velocity of the projectile are helpful in determining the risk of major injury. Zone I and zone III injuries usually require arteriography on all stable patients. Because hemorrhage is the leading cause of death for penetrating neck injuries, hemodynamic and neurologic status should always be monitored closely for at least 48 to 72 hours.
- In blunt neck trauma, symptoms can present with a delayed onset and be easily underdiagnosed. Thus careful observation should be made for individuals with significant blunt neck trauma in order to monitor for progressive signs and symptoms of injury.

As the incidence of violent trauma rises in our society, the rate of penetrating trauma to the head and neck also grows. Presently, penetrating neck injury comprises 5% to 10% of all trauma cases. All penetrating neck wounds are potentially dangerous and require emergency treatment.

In the neck, multiple vital structures are vulnerable to injury in a small anatomic area and are not protected by bone. Such vital structures of the neck can be divided into four groups: the air passages (trachea, larynx, pharynx, lung); vascular (carotid, jugular, subclavian, innominate, aortic arch vessels); gastrointestinal (pharynx, esophagus); and neurologic (spinal cord, brachial plexus, peripheral nerves, cranial nerves [CNs]). Signs or symptoms listed in Box 115-1 should alert the otolaryngologist that injury to any of these structures has occurred.

Physical Properties of Penetrating Objects

Knowledge of the physical properties and ballistics of the penetrating object can help determine a management plan and predict the risk of injury. The location of penetration also predicts risk and helps in planning for management.[1] The magnitude of injury is determined by the kinetic energy that is transferred from the projectile to the target tissue: $KE = \frac{1}{2}M(V_1 - V_2)^2$. *KE* is the kinetic energy of the projectile, *M* is the mass of the projectile, V_1 is the initial velocity on contact, and V_2 is the exit velocity. Thus differences of projectile velocity transform into kinetic energy by the second power.

Handgun

Civilian handgun injuries are traditionally from projectiles with low-muzzle velocity (90 meters per second [m/s]). An impact velocity of 50 m/s penetrates skin, and an impact velocity of 65 m/s will fracture bone. These slow-velocity projectiles have been known to push aside vital structures such as arteries. Penetrating wounds caused by small-caliber handguns have a less damaging effect than other projectiles of higher velocity.

Guns are classified by projectile type, speed, and caliber (diameter of muzzle bore). Bullets that travel greater than 610 m/s are considered high-velocity projectiles. Handguns or pistols (.22 caliber to .45 caliber) have muzzle velocities from 210 to 600 m/s. Caliber is a term interchangeable with the designation of the cartridge (i.e., .22-caliber pistol). Handguns can develop up to 1000-foot pounds of energy. A .44-caliber magnum, which has a large powder charge, can create even more hypervelocity. Thus injury from this gun can cause tissue destruction comparable with that caused by a rifle bullet, a larger projectile.

The yaw of the bullet describes the deflection of the projectile around the axis of travel. If the yaw is minimal (not tumbling), with the bullet entering perpendicular to the body surface, the bullet will pass through the tissues with little energy transmitted. A tumbling bullet causes injury in a wider path. The projectile can follow tissue planes and may not injure vital structures. A bullet also can deflect from bones of the mandible or cervical spine. Unfortunately, civilian gunshot wounds increasingly involve heavier projectiles with higher-velocity handguns. In all cases a full inspection of the entire naked body and palpation of the head is necessary to reveal all entrance and exit wounds. This information may be useful in predicting damage.

Low-velocity bullets are usually lead shielded and often leave a radiographic track. A diagnosis based on physical signs of injury, after full and careful organ system evaluation, is often sufficient for these injuries if all presentations are normal. Radiographic confirmation or surgical exploration should follow any uncertainty or deterioration of physical signs.

Box 115-1

Signs and Symptoms of Penetrating Neck Trauma

Airway
Reparatory distress
Stridor
Hemoptysis
Hoarseness
Tracheal deviation
Subcutaneous emphysema
Sucking wound

Rifle

Most military rifles have a jacket of strong metal, usually copper, that surrounds a lead projectile. This permits smoother and longer flight because of less drag and less aerodynamic compression. Similarly, because of the lack of deformation, these military bullets create a clean hole with a through-and-through wound without a lead track to follow. The M16 military rifle has a bullet that is designed to tumble, and therefore it causes more tissue injury. It is against the terms of the Hague Convention of 1908 for military projectiles to include expanding bullets such as hollowpoint, softnose, or dumdum bullets. These soft-tip bullets expand on contact and cause greater soft-tissue injury. They create a large wound cavity, may not cause an exit wound, and may fragment, with partial projectiles causing injury far from the primary direct path. Hunting rifles use these expanding bullets, and therefore the civilian wounds caused by these projectiles can be more devastating than a comparable wound inflicted by a military weapon.

Most military rifles have a muzzle velocity of 760 m/s. High-velocity missiles (>610 m/s) not only tear tissue but transmit energy to surrounding tissue. A cavity of up to 30 times the size of the missile may be created and pulsate over 5 to 10 ms, with several waves of contraction and expansion of the tissue (Fig. 115-1).[2] This may explain the finding of a punctured viscus without direct penetration and should

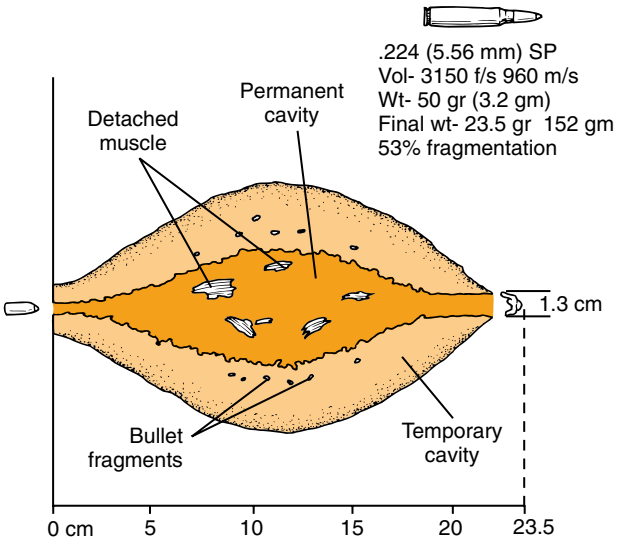

Figure 115-1. Characteristic wound profile of a high-velocity, soft-point rifle bullet. Note characteristic large temporary and permanent cavities with massive tissue disruption. The wound profile of a conventional copper-jacketed, high-velocity bullet would reveal a similar temporary cavity. *(From Fackler M, Bellamy R, Malinowski J. The wound profile: illustration of the middle-tissue interaction.* J Trauma. *1988;28(Suppl):21.)*

alert the surgeon to examine the trachea and esophagus, even when a bullet wound is 2 inches away (Fig. 115-2).

High-energy missiles are not easily deflected and cause significant destruction along their path because the energy is absorbed by the surrounding tissue. Deer rifles fire a projectile designed to mushroom on impact, causing a large amount of tissue destruction within a small area.

The mortality from all high-velocity rifle injuries inflicted directly on the neck is significant. These patients usually do not survive and are not available for study. In view of the expected severity of injury, all known victims of high-velocity rifle injuries who survive on reaching the hospital merit strong consideration for surgical exploration. For stable patients, angiograms should be considered before surgery. In helping to determine if mandatory surgical exploration or further preoperative diagnostic tests are necessary, knowledge of the size and velocity of the intruding missile is helpful.

Shotguns

The severity of shotgun wounds is largely dependent on the distance between the weapon and the victim, the type of weapon used, and the size of the projectile (shot). Pellets tend to scatter as they travel on the basis of the distance to impact and the interior muzzle diameter (choke) of the shotgun. At close range the entire charge can act like a single missile with a KE similar to a high-velocity bullet.[3] At further distances, birdshot pellets scatter and act as multiple individual missiles. With larger pellets such as buckshot, significant injuries can occur from individual pellets up to 150 yards away with a standard-length barrel. A sawed-off shotgun leads to early spraying of the shot. Shotguns are low-velocity weapons (muzzle velocity of 300 m/s).

Birdshots are pellets with a diameter less than or equal to 3.5 mm (0.13 inch) and are categorized as No. 4 shot or smaller. Buckshots have a diameter greater than 3.5 mm and have a greater range, causing significant injury up to 150 meters. This is in contrast to birdshots, which have a 12-m maximum range of serious injury (Tables 115-1 and 115-2). Each pellet injury from a buckshot blast is similar to a bullet injury from a handgun. Buckshot wounds are usually more serious than handgun bullet wounds because of the number of missiles involved.

The gauge of the gun determines how much shot can be included in a single shell. The actual shot varies from 00 buckshot (for deer hunting, which has eight and one half pellets per ounce with a larger

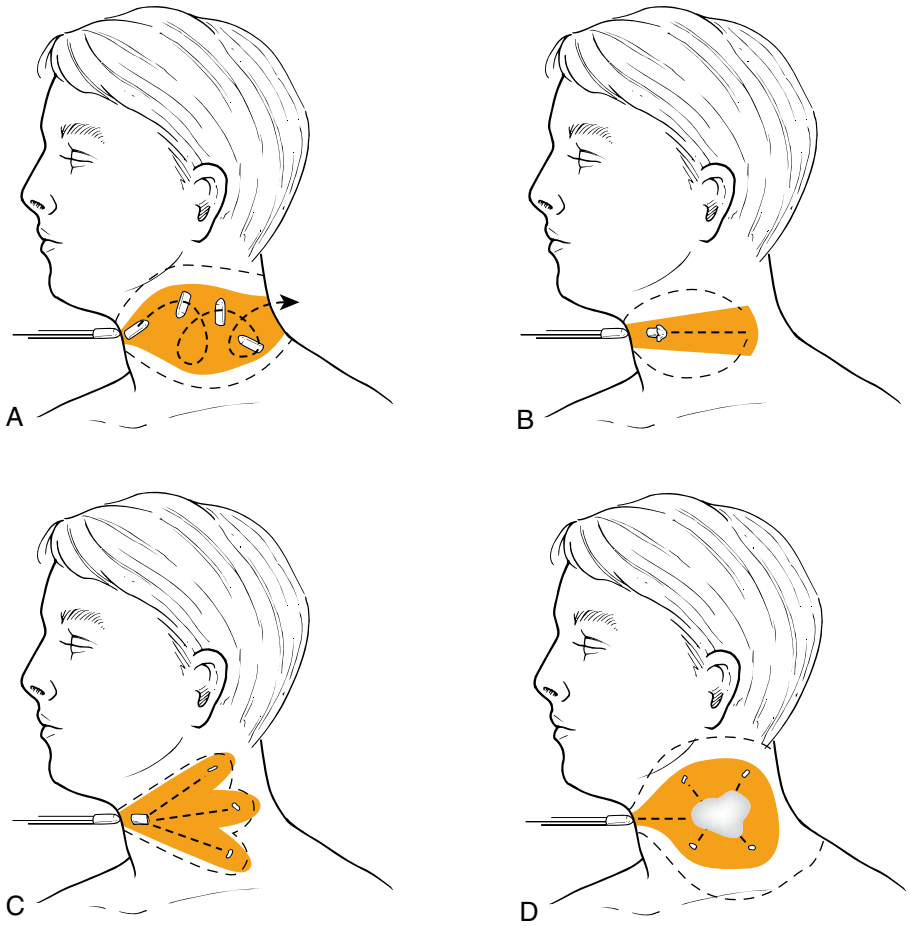

Figure 115-2. Types of injuries caused by different missiles. Both temporary cavity *(dotted line)* and permanent cavity *(stipple area)* are large. **A,** Tumbling missile. **B,** Expanding bullet. **C,** Fragmenting bullet. **D,** Self-exploding bullet. *(From Holt GR, Kostohryz G. Wound ballistics of gunshot injuries to the head and neck.* Arch Otolaryngol. *1983;109:313.Copyright 1983, American Medical Association.)*

tissue impact) up to 12 buckshot (which has 2400 pellets per ounce, has little destructive ability, and is used for target shooting). An 8 buckshot with 400 pellets per ounce is used for shooting small game such as rabbits and birds.

At close range, shotgun injuries cause as much damage as rifle injuries because of the massive blast effect to the tissues. When the distance between the shooter and the recipient is more than 6 m, the details of gauge, shot, powder load, and the choke of the gun become more important. Wadding from the shotgun blast also should be searched for and removed from the wound to prevent infection. Radiography is useful for revealing pellets in unexpected locations such as the intracranial, intrathoracic, or intraorbital cavities. Magnetic resonance imaging (MRI) may be even more valuable than computed tomography (CT) for the stable patient because metal scatter artifact does not occur.

Knife and Stab Injuries

Knife, ice-pick, cut-glass, or razor-blade injuries usually proceed along more predictable pathways. However, what appears to be a single-entry wound may be from multiple stab wounds. The history of the attack may be of some help to the physician in determining whether the blow was overhand or underhand, whether both the attacker and the recipient were standing, and other similar details. Compared with gunshot wounds to the neck, cervical stab wounds have a higher incidence of subclavian vessel laceration.[4] This is because stabbings to the neck often occur in a downward direction with the knife slipping over the clavicle and into the subclavian vessels.[5] In gunshot wounds the direction of the projectile is more perpendicular to the neck; thus the clavicle can protect the subclavian vessels. In regard to spinal injuries, neck stab wounds have a lower incidence than cervical bullet wounds.[5]

Mandatory versus Elective Exploration

Penetrating neck injuries should be differentiated into two basic presentations depending on whether or not they are immediately life threatening. The signs of immediate life-threatening injuries include massive bleeding, expanding hematoma, nonexpanding hematoma in the presence of hemodynamic instability, hemomediastinum, hemothorax, and hypovolemic shock. In all of these instances, immediate surgical exploration is mandatory. On the other hand, hemodynamically stable patients who present with non–life-threatening features can undergo thorough imaging investigations to determine the extent of injury.

For the stable patient, the choice of management remains controversial: either mandatory exploration for all penetrating neck wounds or selective exploration with observation. Retrospective studies have supported both mandatory surgical exploration and selective surgical exploration.[6,7] For the selective surgical approach, it is emphasized that the clinical status of the patient should be monitored closely by frequent observation and medical examination using diagnostic radiology and surgical endoscopy. In civilian injury this is often possible, but in times of war or civilian catastrophe, resources such as radiography and observation beds may not be available for large numbers of casualties.

Until World War II, the mortality of penetrating neck wounds ranged from 7% to 15%. By the end of the Vietnam War, it was reduced to 3% to 6% (Table 115-3).[7] However, mortality remains high if major vascular structures (carotid or subclavian arteries) or the cervical spinal cord is injured. During the Vietnam War, it was customary to explore all patients with penetrating neck wounds below the platysma layer under general anesthesia, regardless of preoperative findings. The idea of mandatory exploration was also advocated by Fogelman and Steward in 1956 for civilian injuries. This philosophy was followed until the mid-1980s by most general trauma centers in large cities in

the United States. However, it was realized that in many instances significant injuries to major structures did not occur. This reasoning led some surgeons to follow a more selective approach for these injuries. However, advocates for mandatory exploration believe that exploration has time-proven success. Each of the proponents gives arguments that support their views, both medically and economically (Table 115-4).

Classification

Anatomically, the neck can be divided into three major zones in order to aid in the decision making for diagnostic tests and timing of surgery (Fig. 115-3).[1] Zone I is below the cricoid and represents a dangerous area because the vascular structures in this zone are in close proximity to the thorax. The bony thorax and clavicle act to protect zone I from injury, as do other bony structures at the base of the neck. This osseous shield also makes surgical exploration of the root of the neck difficult. In zone I, injuries to the right side are often approached through a median sternotomy, whereas injuries to the left side are often managed by a left anterior thoracotomy to control the hemorrhage. Zone I has a fairly high mortality rate of 12%.[8] Mandatory exploration is not usually recommended for zone I injuries; angiography is usually suggested to ensure that the great vessels are not injured.

Zone III is located above the angle of the mandible. This area is also protected by skeletal structures and is difficult to explore because of the skull base and the need to divide or displace the mandible. The necessity for craniotomy in exploration and control of high carotid injury in this location makes zone III treacherous. Recognizing injuries to many of the cranial nerves exiting the skull base in zone III is important because these injuries may be indicative of injuries to the great vessels due to their close proximity. An abnormal neurologic examination would suggest the need for angiography in the stable patient.

In view of the difficult surgical approaches to zone I and zone III, most authors agree that all patients with such injuries who are stable and without evidence of acute airway obstruction, significant bleeding, or expanding hematoma should be evaluated with angiography, with consideration of barium swallow. For zone III injuries, frequent intraoral examination should be performed to observe for edema or expanding hematoma within the parapharyngeal or retropharyngeal spaces.

Zone II penetration is the most frequently involved region (60% to 75%), and injury in this zone has created a great deal of controversy in the American literature over the past 25 years.[9] Experts are having an ongoing debate about the use of mandatory exploration versus selective exploration with serial examination, endoscopic tests, and angiography. In zone II, isolated venous injuries and isolated pharyngoesophageal injuries are the most common structures missed clinically in the preoperative evaluation. A substantial number of patients can be selectively managed depending on signs, symptoms, and direction of the trajectory. When patients are stable and lack physical signs of obvious major neck injury, they are evaluated by diagnostic radiologic

Table 115-2

Classification of Birdshot Shotgun Wounds

Type	Range*		Injury	Mortality (%)
	Standard Barrel	Sawed-off Shotgun		
0	Long >12 m	>4 m	Superficial—pellets in skin only	0
I	Long >12 m	>4 m	Penetrates only subcutaneous tissue	0-5
II	Close 5-12 m	2-4 m	Penetrates beyond deep fascia	15-20
III	Point blank <5 m	0-2 m	Extensive tissue damage	85-90

and endoscopic techniques. All patients are admitted for observation. A hospital with a comprehensive trauma service with experienced personnel doing careful and repeated physical examinations and with 24-hour availability of radiologic and endoscopic capability is necessary.[5] The leading cause of death from penetrating neck injuries is hemorrhage from vascular structures. In a study by Stone and Callahan, vascular injuries in the neck accounted for 50% of deaths.[10]

One article emphasizes the increased lethal potential of transcervical penetrating neck wounds when the projectile crosses the midline. In this study all 11 patients with transcervical gunshot and shotgun wounds sustained vascular or aerodigestive injuries and longer hospital stays (14 days) compared with patients with other gunshot wounds (6.6 days). We believe that transcervical injuries should be reported separately from zone I, II, and III injuries because they tend to be more severe.[11]

Initial Management

The initial care of patients with penetrating neck injuries should follow the basic tenants of trauma care. The emergent management of all penetrating neck trauma requires (1) airway establishment, (2) blood perfusion maintenance, and (3) clarification and classification of the severity of the wound. In the emergency department, satisfactory control of the airway is established by intubation, cricothyroidotomy, or tracheostomy. Direct transcervical tracheal intubation is safer than oral or nasal intubation when the oral cavity, pharynx, or larynx are traumatized and filled with blood. In the setting of a gunshot wound, it may be difficult to fully evaluate the cervical spine until the airway is controlled. Multiple blind intubation attempts will risk enlarging a lacerated piriform sinus wound and extending it iatrogenically into the mediastinum. Similarly, a tracheal tear may be exacerbated by extending the neck, which distracts the proximal and distal segments. The airway must be established and the hemodynamic status stabilized before transporting the patient to the angiography suite. Large-bore intravenous lines are placed, even when the patient is not hypotensive, so that fluids can be rapidly introduced if necessary. Particularly in zone II, hemorrhage or an expanding hematoma will respond to direct pressure and should not be managed by indiscriminate clamping through the wound. Under no circumstances should a penetrating neck wound be probed because clot dislodgement and uncontrollable bleeding can occur.

Every patient with significant neck trauma should have routine anterior and lateral neck and chest radiographs. When a pneumothorax is identified by a radiograph or physical examination, a chest tube should be inserted emergently. In the rare circumstance of an exsanguinating oral hemorrhage, a tracheostomy must be performed immediately and the pharynx must be packed. In high-volume trauma hospitals, the emergency department usually has an operating theater intended for emergent patients on whom control of a major vessel hemorrhage must be performed immediately. Physical findings of vascular injury are pulse deficit, active bleeding, expanding hematoma, bruit, murmur, neurologic deficit, or hypotension. Patients with acute injury to the spinal cord may present with hypotension without tachycardia (spinal shock). Cranial nerve injury is not common; however, when it is evident, documentation of the deficit is helpful in evaluating the direction of the projectile and possible injury to adjacent structures. For instance, if a hypoglossal nerve injury is present, one should be suspicious for a possible carotid artery injury. Horner's syndrome (pupil constriction, upper eyelid ptosis, skin flushing, and absence of sweating on the affected side) may indicate injury to the carotid artery or to structures along the sympathetic chain. Under controlled circumstances, the patient is taken to the operating room, where a wide-apron incision is made from the mastoid tip to the midline of the neck at the cricoid level for definitive exploration.

Table 115-3

Mortality of Penetrating Neck Trauma in Wartime and Current Civilian Practice

Incident	Injuries *(n)*	Mortality (%)
Civil War	4114	15
Spanish-American War	188	18

Table 115-4

Mandatory versus Selective Management of Neck Wounds

Consideration	Mandatory	Selective
Diagnosis	Potential life-threatening injuries can be missed by the preoperative workup.	Most major injuries can be diagnosed preoperatively; routine exploration can miss some injuries.
Skill and resources	Selective management requires more skill, manpower, experience, and judgment; additional special diagnostic procedures are also required.	Selective care will reduce unnecessary explorations by a surgeon inexperienced with trauma.
Hospital stay	Length of stay is similar for observation and negative exploration.	No advantage of negative exploration.
Delay	If occult injuries are delayed, morbidity and mortality will increase.	Delay has not been shown to significantly increase morbidity and mortality of occult injuries.
Patient care	Active observation requires continuous availability of experienced trauma medical staff for monitoring the patient.	Selective management emphasizes the concept of collaboration among trauma team members and reduces unnecessary surgical exploration.

Adapted from Obeid F, Haddad GS, Horst HM, Bivins BA. A critical reappraisal of a mandatory exploration policy for penetrating wounds of the neck. *Surg Gynecol Obstet.* 1985;160:517.

Diagnostic Evaluation

When the patient's stability allows, an orderly history and physical examination including a full examination of the unclothed body to look for entrance or exit wounds should be performed. In the conscious patient a full neurologic examination should be done and a chest radiograph taken. The radiograph should be examined to rule out hemothorax, pneumothorax, or pneumomediastinum. The latter would suggest a punctured viscus and demands further evaluation. Subclavian vessel injury may be first recognized by an abnormal chest radiograph. All patients should be managed assuming potential cervical spine fractures until they undergo radiographic evaluation. On radiographs, all cutaneous wounds can be marked with radiopaque objects to aid in evaluating the site of the injury.

Most trauma centers suggest that personnel and equipment be available 24 hours a day for flexible endoscopy or arteriography, with accessibility for immediate neuroradiologic interpretation.

A hospital trauma team should include an otolaryngologist as part of the surgical team to help evaluate and repair the aerodigestive tract and explore the nerves and branches of the carotid artery in the neck. Patients with significant bleeding or an expanding hematoma need immediate attention with probable emergent exploration in the operating room.

Several series of cases have shown examples of injuries being misdiagnosed, both by angiography and during direct exploration.[12] False aneurysms, external carotid branch lacerations, arteriovenous fistulas, and viscus-vessel fistulas have all been described despite the presence of sophisticated personnel and experienced examiners. Approximately 30% of patients with carotid artery injury present with a neurologic deficit.[13] Arterial injury or propagation of a thrombus into the skull can lead to cerebral ischemia. One third of the population cannot tolerate complete unilateral carotid occlusion.

The debate over the merits of mandatory versus selective exploration continues. Meyer and colleagues[14] have reviewed their data and suggest that mandatory exploration is appropriate. Others have used similar data to suggest the advantages of selective exploration.[9,14] Among patients explored routinely, 50% to 70% have negative explorations with some morbidity and some cosmetic deformity.[15,16]

Several surgeons claim that mandatory exploratory operations are the gold standard against which all other procedures should be measured. The rare case of a patient under observation suffering from an underdiagnosed hemorrhage with complications is cited to encourage exploration. However, prospective studies have failed to prove that either choice is clearly better. Many level I trauma centers have become more encouraged by selective management (Figs. 115-4 and 115-5). Table 115-5 shows the accuracy of selective evaluation techniques with the caveat that using rigid and flexible esophagoscopy together can be more accurate than the use of either one alone.[17] In cases where the cervical spine has not been cleared, flexible endoscopy is helpful for evaluating injuries of the pharynx and esophagus. Contrast infusion CT scanning can aid in the surgical decision making for zone II penetrating neck injuries.[18]

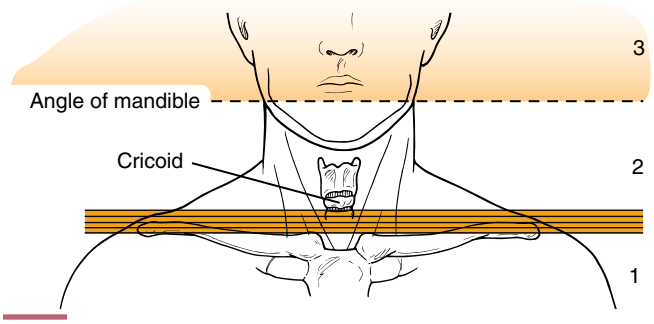

Figure 115-3. The three zones of the neck are seen on this frontal view. The *shaded area* represents the portion that some authors consider zone I but that others label zone II. *(From Carducci B, Lowe RA, Dalsey W. Penetrating neck trauma: consensus and controversies.* Ann Emerg Med. *1986;15:208.)*

Angiography

Angiography is the most urgently performed diagnostic technique because once the airway has been secured by intubation or tracheostomy, hemorrhage can be life threatening. A positive angiogram may mandate an immediate trip to the operating room, but evaluation of the upper digestive tract in the radiology suite may be useful if time and the patient's condition permit. Zone I and zone III injuries usually require routine preoperative arteriography on stable patients because their surgical approach is more difficult than zone II injuries. In addition, when wounds involve both sides of the neck with zone I and zone III injuries, four-vessel angiography (bilateral carotid and vertebral arteries) should be considered in stable but symptomatic patients.

Zone II wounds are usually easily accessible and a low risk for exploration. Zone II injuries may be evaluated by selective angiography or exploration. Certain indications for an angiogram in zone II injuries include a stable patient who has persistent hemorrhage or neurologic deficits compatible with adjacent vascular structure damage (Fig. 115-6).[19] An example of this is a Horner's syndrome indicative of sympathetic nerve plexus injury or hoarseness indicating a recurrent laryngeal nerve injury. This neurologic picture suggests that the carotid sheath has been violated, and vascular integrity needs confirmation by angiography, as well as frequent close observation to detect for a lacerated carotid artery, intimal tear, or pseudoaneurysm (Fig. 115-7).[20] Arteriography can be accurate diagnostically with good technique and with an experienced radiologist. Patients with negative arteriography

and positive physical signs still need exploration. If there is radiographic evidence that a bullet has changed location due to gravitational or positional change of the patient, removal of the bullet should be considered. This is because a migratory bullet can increase the risk of embolic phenomenon.[21]

For asymptomatic zone II penetrating neck injuries, the usefulness of angiography remains controversial. One study showed no statistically significant difference in sensitivities between a clinical examination and angiography for the detection of vascular injury. This study concluded that the clinical examination for zone II injuries may be sufficient to detect significant vascular lesions unless the trauma is in close proximity to the major vessels.[22] Other studies have supported the use of angiography for stable asymptomatic patients (Fig. 115-8).[23] Some have suggested the increasing role of computed tomographic angiography

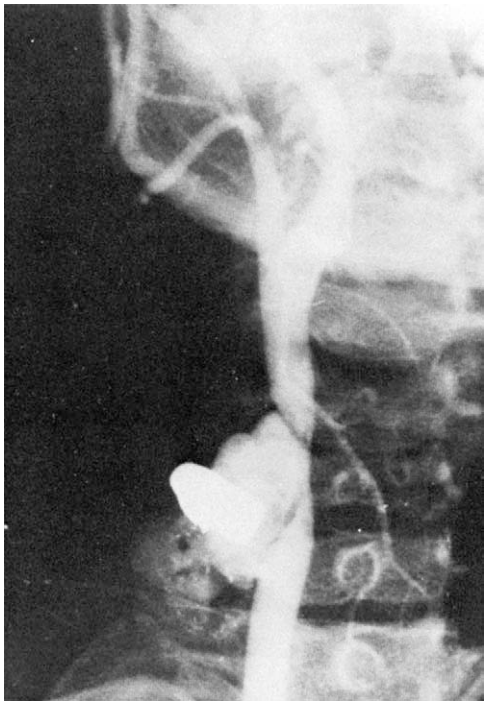

Figure 115-6. Arteriogram demonstrating common carotid artery injury in a 26-year-old man with small hematoma and normal neurologic examination. *(From Hiatt JR, Busuttil RW, Wilson SE. Impact of routine arteriography on management of penetrating neck injuries.* J Vasc Surg. *1984;1:860.)*

(CTA) as a fast, minimally invasive screening method to evaluate penetrating neck injuries in hemodynamically stable patients.[24]

Management of Vascular Penetration

Zone I vascular perforation requires thoracic surgery. Although a low cervical incision may result in sufficient exposure, a mediastinotomy extension or a formal lateral thoracotomy may be necessary.

Zone III injuries at the skull base can be temporized by pressure, but once delineated, access to the injury may require mandibulotomy in the midline similar to exposure for a parapharyngeal space tumor. A temporary arterial bypass of the carotid artery may be placed until the lacerated or aneurysmatic vessel can be approached safely.

For controlling distal bleeding from the internal carotid in zone III, Perry[26] has described passing a No. 4 Fogarty catheter through a Pruitt-Inahara shunt. By passing the Fogarty catheter beyond the injury and inflating the balloon to occlude the lumen, the shunt can then be advanced beyond the injury (Fig. 115-9).[25] After removing the Fogarty catheter, proximal shunt placement is performed. To evaluate patency and vascular flow of the artery repair, Doppler probe measurements are conducted with consideration for angiography.

All veins in the neck can be safely ligated to control hemorrhage; if both internal jugular veins are interrupted by the injury, an attempt to repair one is appropriate. All external carotid artery injuries are easily managed by suture ligation because collateral circulation is good. Common carotid or internal carotid injury in zone II is explored once the diagnosis is made by an approach along the anterior border of the sternocleidomastoid muscle. To find the carotid artery in cases where the vessel is no longer pulsating (i.e., hematoma injury or proximal interruption), the external carotid branches may be followed retrograde from the facial artery at the submandibular gland or from the superior thyroid artery at the superior cornu of the thyroid cartilage.

Techniques of lateral arteriorrhaphy for vascular repair (Fig. 115-10) have been suggested.[26] End-to-end anastomosis or autogenous grafting is recommended when stenosis is evident by arteriography.

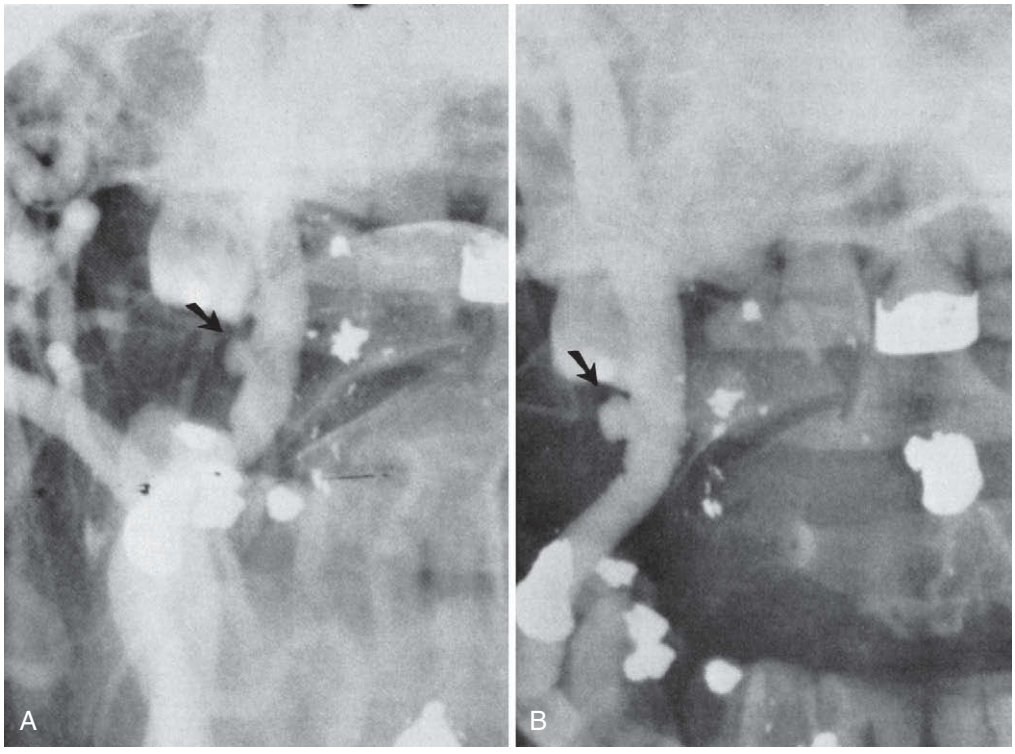

Figure 115-7. A, Anteroposterior view arteriogram of the right common carotid artery reveals a contained extravasation of the internal carotid artery near the base of the skull *(arrow)*. Cranial nerve deficits at the jugular foramen (X to XII) accompany this injury. **B,** A follow-up arteriogram of the internal carotid artery 1 week later shows enlargement of the pseudoaneurysm. *(From Scalfani S, Panetta T, Goldstein A, et al. The management of arterial injuries caused by penetration of zone II of the neck.* J Trauma. *1985;25:871.)*

Ligation of the common or internal carotid injuries is generally reserved for irreparable injuries and in patients who are in a profound coma state with bilateral fixed and dilated pupils. Delayed complications from unrepaired vascular injuries include aneurysm formation, dissecting aneurysm, and arteriovenous fistulas.

More recently, interventional radiologists have used angiographic techniques to treat vascular injury. In some instances, embolization procedures can help control arterial disruption.[27] For arterial injuries in zone III, transcatheter arterial embolization can be an effective modality to obtain hemostasis. Penetrating injuries in zone III have a higher incidence of multiple vascular injuries involving the internal carotid artery, internal maxillary artery, and external carotid artery.[27] In areas of difficult vascular access at the skull base, detachable balloons or steel coils can be placed for carotid occlusion.[28] Embolized bullets also can be retrieved by angiographic techniques. The possible complications of interventional angiography include blood vessel injury, inadvertent balloon detachment, ischemic events, pseudoaneurysm formation, and treatment failure.

Achieving hemorrhage control of penetrating vertebral artery injuries can be challenging given their anatomic relationship with the bony structure of the cervical spine and mandible. Because these vertebral artery injuries often result in both neurologic and hemodynamic sequelae, they are frequently associated with higher morbidity and mortality rates. Because their surgical management can be complex, endovascular treatment approaches have been promising.[29]

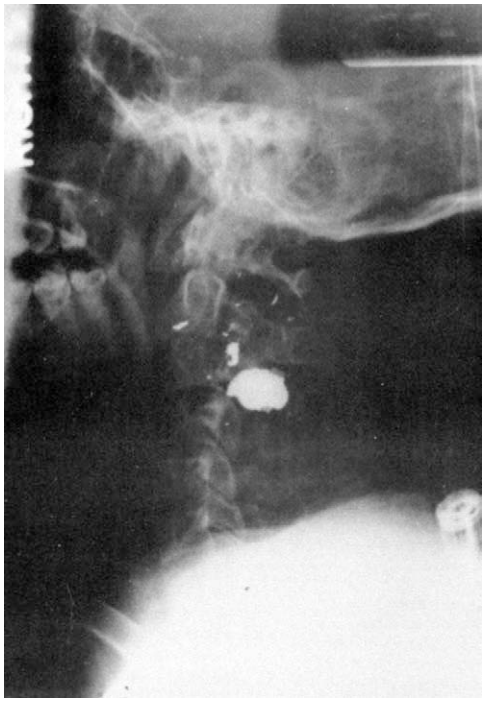

Figure 115-8. This patient had a high cervical cord resection with quadriplegia. No vascular injury was recognized. *(From Ordog GJ, Albin D, Wasserberger J, et al. 110 bullet wounds to the neck.* J Trauma. *1985;25:238.)*

Digestive Tract Evaluation

In the patient with a possible esophageal perforation, most radiologists recommend Gastrografin swallow as a first-order contrast study because barium extravasation radiographically distorts soft tissue planes for other studies and is more toxic. Reports in the literature are mixed[7,12] regarding which of these methods is more reliable in demonstrating a perforated esophagus or pharynx. A negative Gastrografin study should be followed by a barium swallow if suspicion remains high.[12]

Many studies report the use of flexible esophagoscopy to circumvent the need for general anesthesia during rigid endoscopy. However, several authors have reported a missed perforation near the cricopharyngeus, as well as the hypopharynx, where flexible endoscopy is least satisfactory due to mucosa redundancy. Missed esophageal tears (Fig. 115-11) represent most of the delayed injuries and, when they progress to mediastinitis, morbidity and mortality are considerable.[30] Meyer and colleagues[14] found a significant incidence of missed esophageal injury in their prospective endoscopic, contrast radiographs, and subsequent mandatory exploration studies. Some surgery services mandate neck exploration for patients who have air in the soft tissues of the neck despite yielding normal endoscopy results. At the time of exploration to rule out pharyngeal and esophageal injuries, a nasogastric tube can be gently pulled up to the level of the neck and methylene blue infused through the nasogastric tube to help localize the injury site. The combination of flexible endoscopy and rigid esophagoscopy to examine the entire cervical and upper thoracic esophagus has also been reported. No perforations were missed in those series using both techniques on all patients. If suspicion of a pharyngeal perforation remains unconfirmed by examination or even by exploration, the patient is given no food and is observed for several days. Fever, tachycardia, or widening of the mediastinum on serial chest radiographs requires that repeat endoscopy or neck exploration be considered. When an esophageal injury is found early, management involves a two-layer closure with wound irrigation, débridement, and adequate drainage. After repair of the mucosa perforation, a muscle flap may be interposed over the esophageal suture line for further protection.[31] One study showed the value of a muscle flap placed in the bed of a traumatic esophageal and tracheal wound to minimize the risk of a tracheoesophageal fistula (Fig. 115-12).[19] If an extensive esophageal injury is present,

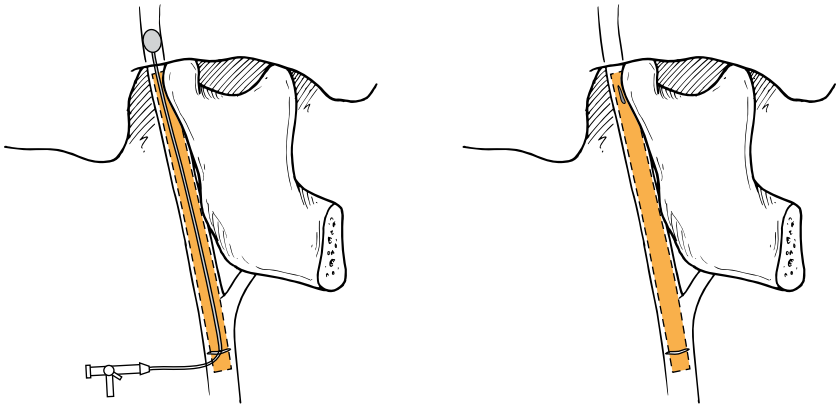

Figure 115-9. No. 4 Fogarty catheter method with shunt placement in an attempt to control bleeding of internal carotid artery near skull base. *(Modified from Perry M. Injuries of the carotid and vertebral arteries. In: Bongard FS, Wilson SE, Perry MO, eds.* Vascular Injuries in Surgical Practice. *Norwalk, Conn: Appleton & Lange; 1991.)*

it may necessitate a lateral cervical esophagostomy and later definitive repair.

Many surgeons perform direct laryngoscopy, bronchoscopy, and rigid esophagoscopy under anesthesia for penetrating injuries of the neck with air in the soft tissues, hemoptysis, hematemesis, or other suspicious clinical findings. Direct laryngoscopy and rigid bronchoscopy can be combined with flexible airway examination to recognize and stent a lacerated trachea temporarily. In the setting of a cervical spine fracture, rigid esophagoscopy may have to be omitted. Definitive management for any airway compromise is always essential.

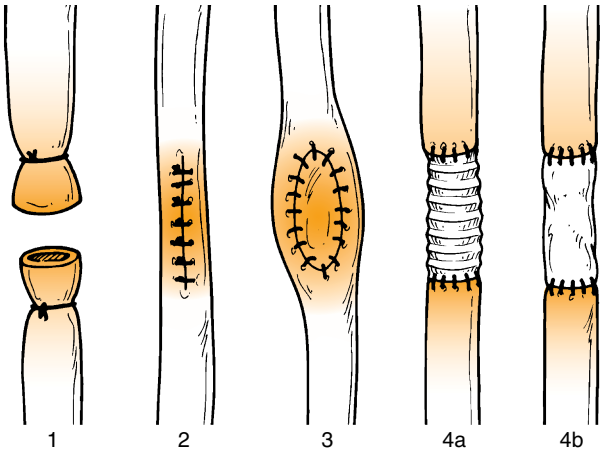

Figure 115-10. Types of vascular repairs: **1**, vessel ligation; **2**, vessel wall repair; **3**, vessel patch graft; **4a**, synthetic vessel graft; **4b**, autogenous vessel graft. *(From Dichtel WJ, Miller RH, Feliciano DV, et al. Lateral mandibulotomy: a technique of exposure for penetrating injuries of the internal carotid artery at the base of the skull.* Laryngoscope. *1984;94:1142.)*

If the clinical examination is benign, follow-up examination is done frequently (at least three times every 24-hour shift) by a physician recording his or her observations. Frequent monitoring of vital signs, as well as examination of the neck and the entry wounds by the nursing staff, is also crucial. A 48- to 72-hour observation period should be used to monitor for changes in physical findings or vital signs that mandate urgent attention. Most vascular injuries that need attention present within 48 hours. Careful appraisals show that the patient with a negative physical examination and normal radiograph and endoscopy will most likely have a negative neck exploration, and no significant injury will be discovered. Direct observation can thus be recommended.[9]

Management of Laryngotracheal Injury

Laryngeal mucosal lacerations from penetrating injury should be considered to be repaired early (within 24 hours) because the time that elapses before repair can affect airway scarring and voice.[32]

Significant glottic and supraglottic lacerations and displaced cartilage fractures need surgical approximation. Endoscopy and CT will differentiate between the patients who need only observation (small laceration, shallow laceration, nondisplaced fracture) and those that require a thyrotomy or open fracture reduction and mucosal approximation. A soft laryngeal stent may be necessary for badly macerated mucosa.

Simple tracheal lacerations that do not detach a tracheal ring or encroach on the airway can be repaired without a tracheostomy. More severe disruptions (gunshot wound directly to the trachea) imply more soft tissue injury and a 6-week tracheostomy either below or through the tracheal injury is the safest procedure. Later the stenosis may require sleeve resection, but if the stenosis is soft, it can often be managed by a T-tube tracheostomy tube.

Blunt Neck Trauma

Blunt neck injuries can occur from motor vehicle accidents and sports injuries. A blunt force may result in laryngeal, vascular, and digestive

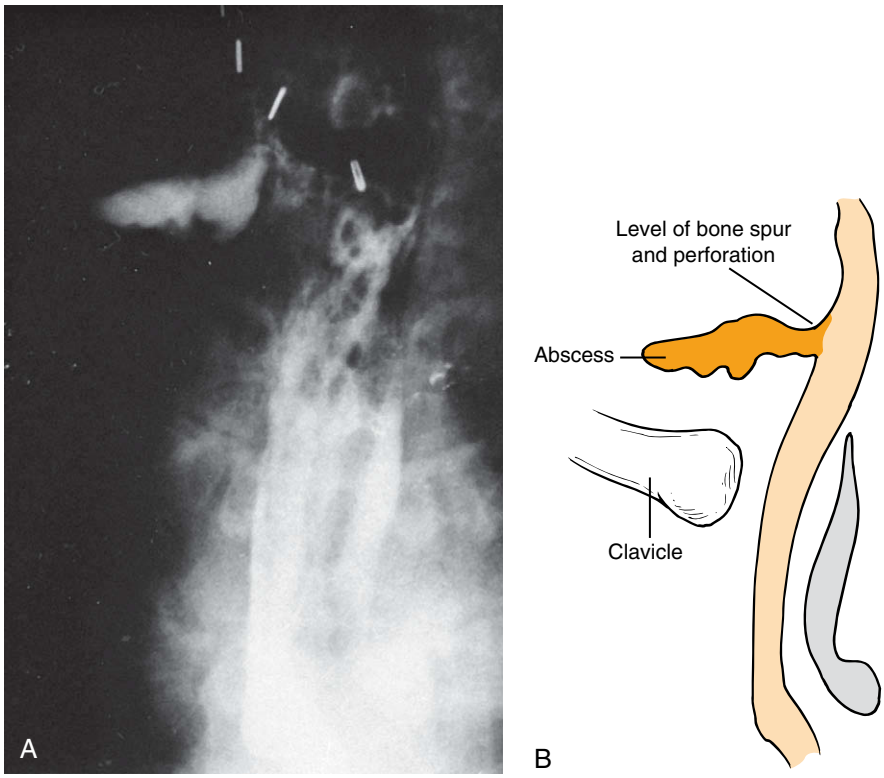

Figure 115-11. This perforation occurred from blunt trauma. Cervical esophageal perforation from flexion-hyperextension injury. **A,** Esophagogram showing perforation at the level of the C5-6 vertebrae. **B,** Level of bone spur and perforation. *(From Splener CW, Benfield JR. Esophageal disruption from blunt and penetrating external trauma.* Arch Surg. *1976;111:663-667. Copyright 1986, American Medical Association.)*

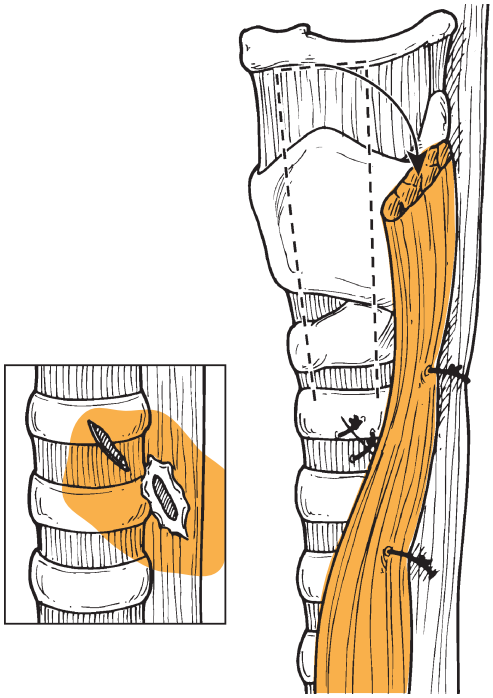

Figure 115-12. Interposition of strap muscle between esophageal and tracheal repair. *(From Miller RH.* The Surgical Atlas of Airway and Facial Trauma. *Philadelphia: WB Saunders; 1983.)*

injuries and be easily underdiagnosed because their onset can be delayed. In addition, occult cervical spine injury may be present with blunt neck trauma.[33]

For these reasons, careful observation should be made for individuals with blunt neck injury because their signs and symptoms may be delayed in onset involving the airway, vascular, digestive, and neurologic systems. This is especially apparent in patients who have multisystem trauma in which blunt laryngotracheal injuries can be frequently overlooked. Due to slow progression of airway edema from laryngotracheal trauma, airway obstruction may not occur until several hours after the injury. Thus monitoring for delayed signs and symptoms of airway injury should be carefully watched for as described in Box 115-1 in the beginning of this chapter. CT may be helpful to determine degrees of injury to the larynx and vessels.[34,35] Blunt injury to the cervical vessels can lead to thrombosis, intimal tears, dissection, and pseudoaneurysm. Treatment options for blunt artery injuries are based on the mechanism, type of injury, and location. Treatments for blunt artery injuries include surgery, anticoagulation, and observation. Surgical intervention for blunt vascular injuries includes ligation, resection, thrombectomy, and stent placement.

Summary

Emergent surgical exploration is indicated for any immediate life-threatening signs or symptoms from penetrating neck trauma (i.e., massive bleeding, expanding hematoma, nonexpanding hematoma in the presence of hemodynamic instability, hemomediastinum, hemothorax, hypovolemic shock).

For the stable patient, the choice of treatment remains controversial. Knowledge of the neck zone involvement (I, II, or III), mechanism of injury, and velocity of the projectile are helpful in determining the likelihood of vital structure injury. Presently, many trauma centers manage stable patients with non–life-threatening penetrating neck trauma with selective exploration; however, this must be supported by on-site angiography, flexible and rigid endoscopy, and closely monitored physical examinations. High-velocity missiles inflict a significantly greater amount of damage than low-velocity projectiles. Zone I and zone III injuries usually require arteriography on all stable patents. Stable patients with zone II injuries may require angiography. Because hemorrhage is the leading cause of death for penetrating neck injuries, hemodynamic and neurologic status should always be monitored closely for at least 48 to 72 hours.

In blunt neck trauma, injuries can involve the laryngeal, cervical, vascular, and digestive structures. Symptoms can present in a delayed fashion and be easily underdiagnosed. For these reasons, careful observation should be made for individuals with significant blunt neck trauma in order to monitor for progressive signs and symptoms of laryngeal, cervical, vascular, and digestive injury.

CHAPTER ONE HUNDRED AND SIXTEEN

Differential Diagnosis of Neck Masses

Amy Chen

Kristen J. Otto

Key Points

- Neck masses are common in the general population and represent a wide array of pathologies.
- The likelihood for any given neck mass diagnosis is most closely related to the patient's age.
- Inflammatory neck masses are the most common neck masses in pediatric and young adult age groups.
- Congenital neck masses are rarely seen in older adults, and the possibility for malignancy must be thoroughly investigated in this group of patients.
- The unknown primary squamous cell carcinoma of the neck represents a special entity and diagnostic paradigm. A specific protocol must be followed when patients with unknown primary squamous cell carcinoma of the neck are being evaluated, with the main goal of locating the primary lesion in a mucosal site.

A mass in the neck is an extremely common clinical finding in patients of all age groups. Neck masses are often the result of inflammation caused by self-limited processes such as viral infections, although the differential diagnosis of a neck mass actually encompasses the entire spectrum of pathology from congenital to infectious to neoplastic. The list of all conditions associated with neck masses is too sizable to list in this chapter, but with a detailed understanding of the anatomy and what constitutes an abnormality, the evaluation of any neck mass can be approached systematically. This chapter focuses on the important examination findings, diagnostics, and workup of the most common etiologies associated with neck masses. Treatment of masses of the neck is not discussed in this chapter.

History and Physical Examination

Age is a crucial element of the history-taking when evaluating a patient with a neck mass. For the purposes of the workup, patients can be broken up into several age groups: pediatric (0 to 15 years old), young adult (16 to 40 years old), and older adult (older than the age of 40) (Fig. 116-1). The difference in relative probabilities of congenital versus inflammatory versus neoplastic neck masses within these groups makes their differentiation important. In the pediatric population inflammatory masses are more common than those of congenital origin, and congenital masses are more common than neoplastic neck masses. The same can be said for the young adult population, although, as the patient ages, the risk for a neck mass of congenital origin decreases as the risk for a neoplastic process increases. The major distinction can be made in the older adult population, where consideration for neoplasia should be highest on the differential diagnosis list.[1] With the exception of masses that occur in the thyroid, 80% of adult neck masses are neoplastic and 80% of those are malignant. In a child, however, more than 90% of neck masses are benign.[2,3] Other important elements of the history include the time course to presentation, risk factors for immunodeficiency, and prior trauma, travel, irradiation, or surgery. Associated symptoms are also important and can help differentiate neck mass etiology and origin. Of these, fever, dysphagia, weight loss, otalgia, hearing loss, and respiratory difficulty are just a few.

Physical examination is a key component to the workup of an unknown neck mass and should not be limited to palpation of the mass itself. The physician must remember to perform a full head and neck examination including evaluation of all mucosal surfaces of the head and neck. A key adjunct to visual inspection of the head and neck and aerodigestive tract mucosa is fiberoptic laryngoscopy, which should be used in most instances of evaluating an unknown neck mass. The clinician should remember that primary lesions may be submucosal in the head and neck. Thus palpation of mucosal sites such as the floor of mouth and tongue base are also important. Other adjunctive examination findings such as a bruit may point toward a vascular origin. The otolaryngologist must always make a point to evaluate the patient's airway status during fiberoptic examination. Airway evaluation will be crucial for eventual surgical planning and will also delineate the patient's need for emergency airway intervention.

Diagnostic Imaging of the Neck

The preferred imaging modality in the workup of a neck mass may differ on the basis of patient age, time course to presentation, and the clinical suspicion of the examiner (Table 116-1). In a child with suspected infectious adenopathy, ultrasound can be used to differentiate a fluid-filled abscess from a solid lymph node and help in the eventual treatment protocol.[3] Ultrasound imaging is helpful in the diagnosis of pediatric neck masses because it does not require the use of sedation or general anesthesia as do the more detailed imaging modalities such as computed tomography or magnetic resonance; it is inexpensive and allows the patient to avoid ionizing radiation. Ultrasound is useful for soft tissue imaging, the differentiation of cystic versus solid masses,

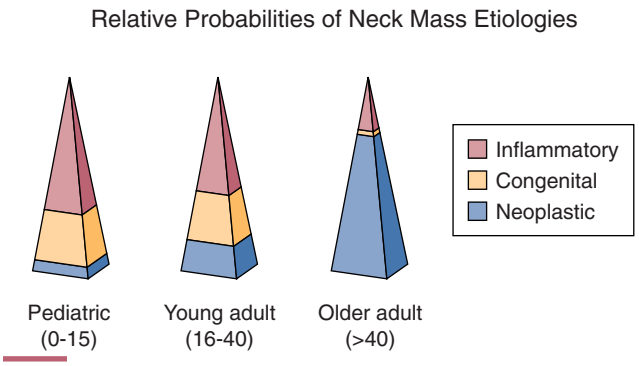

Figure 116-1. Breakdown of neck masses by age.

Table 116-1

Imaging of Neck Masses

Modality	Basic Indications
Ultrasound	Good for pediatric neck masses, thyroid masses. Differentiates cystic versus solid.
Computed tomography	Workhorse imaging modality for adult neck masses. Provides three-dimensional relationships, excellent detail of mucosal disease and involvement of adjacent bone.
Magnetic resonance imaging	Superior soft tissue delineation. Good for lesions of the salivary glands and tongue (where dental amalgam may obscure the view on a CT). Modality of choice for determining nerve enhancement. Consider for thyroid imaging in cases necessitating radioiodine.
Radionuclide scanning	Useful for midline lesions in children—differentiates functioning from nonfunctioning tissue.
Positron emission tomography	Useful for staging of head and neck malignancies. Can be used in cases of unknown primary malignant neck masses or treated neck disease.
Angiography/magnetic resonance angiography/computed tomography angiography	Useful for lesions encasing the carotid and vascular lesions. Conventional angiography should be considered for preoperative assessment in cases of potential carotid artery sacrifice or where embolization is required.
Plain radiograph	Generally should not be considered in the workup of a neck mass.

thyroid pathology, and salivary gland pathology,[4] but it is extremely limited in providing detail regarding soft tissue invasion and approximation to bone.

Computed tomography (CT) is the workhorse imaging modality for adult neck masses. CT provides excellent resolution of both soft tissue and bone and, when used in conjunction with iodinated intravenous contrast, allows for superior delineation of vascular lesions. Neck masses can be evaluated for invasion of surrounding soft tissue and bone, airway compression, and perineural and perivascular invasion. CT also allows for determination of jugular vein occlusion in the case of infectious neck masses. CT locates masses within or outside of glands or nodal chains and provides three-dimensional relationships.[4] In the workup of an adult with a suspected unknown primary metastatic neck node, CT gives excellent detail regarding head and neck mucosal sites.

Magnetic resonance imaging (MRI) is the most superior imaging modality for soft tissue detail, although it is less readily available and more expensive than the choices described previously. MRI is useful in pregnant women because it does not require radiation, and it is also a good choice for cases of well-differentiated thyroid malignancies where radioiodine therapy is to be used because iodinated contrast is not necessary.[4] MRI is the best choice of imaging when perineural spread is to be determined. CT and MRI are often complementary imaging tools for the workup of an adult with a suspected head and neck malignancy.[5]

Radionuclide scanning can be of help in the workup of an anterior or midline neck mass, particularly in the pediatric population. Radionuclide scanning gives the added benefit of differentiating functioning from nonfunctioning tissue and thus can be considered in the workup of a lingual thyroid or thyroglossal duct cyst, where the presence of normal functioning thyroid tissue must be determined before any consideration for surgical excision. Radionuclide imaging can also be considered in the workup of salivary gland pathology because lesions can be localized to within or outside of the major salivary glands.[3]

Positron emission tomography (PET) is a useful imaging adjunct in the workup of head and neck malignancies, but it should not be considered standard for first-line evaluation. PET can differentiate persistent disease from postradiation effects, particularly when it is used in conjunction with contrast-enhanced CT to evaluate treated nodal disease,[6] and can occasionally detect metastatic nodal disease equivocal on CT or MRI. PET is also helpful in the diagnosis of distant metastatic disease for patients with known head and neck malignancies.

In cases of suspected vascular lesions, arteriography can be helpful, both from diagnostic and therapeutic viewpoints. Arteriography can identify lesions with carotid infiltration and can help in differentiating the origin of paragangliomas. The use of arteriography in a preoperative setting can also allow for balloon occlusion testing in cases of possible carotid artery sacrifice or embolization of tumor feeding vessels. CT arteriography (CTA) and magnetic resonance arteriography (MRA) are also both readily available and allow for excellent vascular imaging clarity. They have the added benefit of reducing the risk of the invasiveness of arteriography. In general, these tests can be considered for basic imaging of vascular lesions, but when an intervention such as balloon occlusion or embolization is necessary, traditional arteriography is the gold standard.

Plain radiographs are of little use in the workup of a neck mass in any population and, in general, should not be considered in the face of the excellent imaging modalities discussed earlier. A plain radiograph of the chest (CXR), however, is an important tool for comprehensive staging in the case of a suspected malignancy of the head and neck. CXR should accompany the other diagnostic imaging modalities in these patients.

Initial Workup of the Unknown Neck Mass

The correct clinical management course of a neck mass will often be determined by information gleaned from the history and physical examination, as well as the imaging. The most important first step is making a diagnosis. In the pediatric and young adult populations, where inflammatory neck masses are common, an antibiotic trial is a reasonable starting point for patients with suspected infectious adenopathy. In general, antibiotics may be given for several weeks, after which time the differential diagnosis should be reconsidered and further workup may be necessary. Typically, unilateral, enlarging, or asymmetric masses; masses located in the supraclavicular fossae; masses associated with other worrisome symptoms; and masses not associated with prior infectious symptoms should be further investigated. If, during the

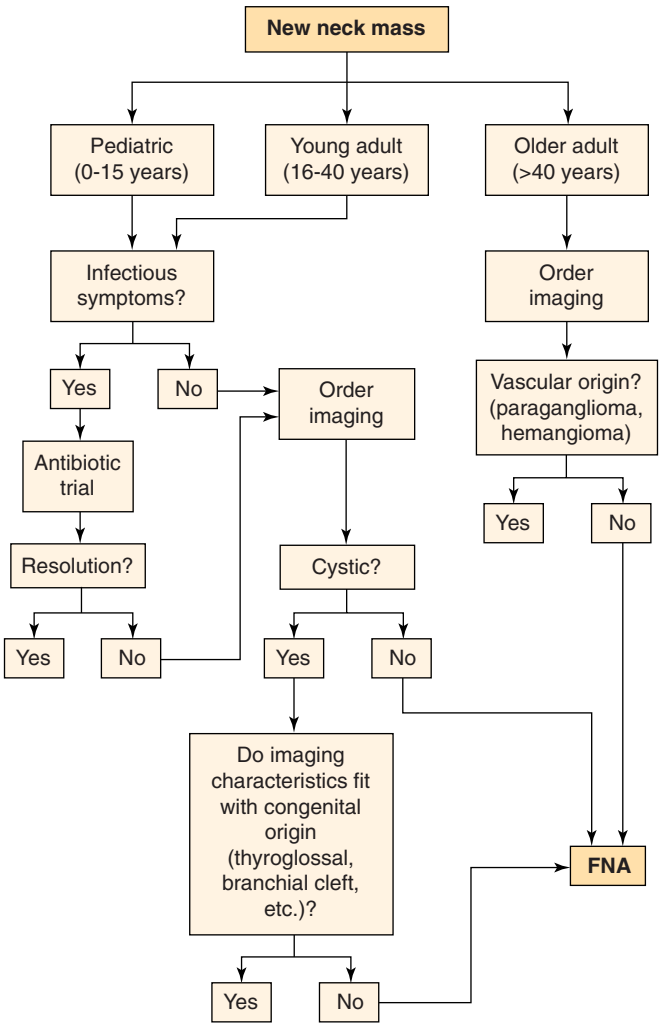

Figure 116-2. Diagnostic schema for a new neck mass.

antibiotic trial, the mass progresses or the patient develops new symptoms, the management paradigm should be reconsidered as well. Imaging of the neck mass is a good starting point to better define the mass and the structures it involves.

If a patient has failed an antibiotic trial, or in any case of an adult with a new neck mass, biopsy should always be considered as an essential step in making a diagnosis. The gold-standard biopsy modality in the workup of a neck mass is fine-needle aspiration (FNA) (Fig. 116-2). The sensitivity and specificity of FNA for both pediatric and adult head and neck masses have been reported to be approximately 97% when diagnostic material is obtained.[7-9] FNA should always be done before the consideration of any open procedures. FNA can be used for both cytology and culture (in cases in which a suspected infectious neck mass does not respond to conventional antibiotic therapy). If an FNA is unsuccessful or if sufficient information is not obtained from an initial FNA, the FNA should be repeated before open biopsy. Multiple aspirations using a thin needle (usually 25-gauge) are necessary. The FNA should be performed in the presence of an experienced cytopathologist to ensure ideal slide preparation and thus useful diagnostic information.[8,9] Studies comparing the sufficiency, accuracy, and diagnostic outcome of FNAs performed by cytopathologists versus those performed by clinicians have actually shown that cytopathologists' FNA attempts yield significantly more useful diagnostic information than those of clinicians.[8] Cells obtained by FNA can be analyzed for microbiologic, molecular, and cytogenetic properties if these techniques are useful in the diagnosis.[5,8,9] If an FNA has been unsuccessful or has failed to reveal useful results after several attempts, a core needle biopsy should be considered.[3,5,9] FNA may miss the true lesion in cases where a neck mass is especially bloody, necrotic, or fibrotic, and specific diagnostic information may be unattainable in lesions where complex tissue architecture is necessary.[7] Open biopsy of neck masses should only be considered as a last resort for diagnosis. In the case that squamous cell carcinoma is identified in the neck during open biopsy, the surgeon should be prepared to proceed with a comprehensive neck dissection. This possibility should be part of the patient's preoperative counseling.

Once the diagnosis is made, it will be necessary to determine whether the particular diagnosis warrants further investigations. The best example of this is the case of an unknown primary malignancy of the neck. A detailed diagnostic protocol must be adhered to in the workup of an unknown primary malignancy in the neck. A variety of pathologic entities can manifest with the primary presentation being an enlarged metastatic cervical lymph node. Among these, adenocarcinoma, thyroid malignancies, poorly differentiated carcinoma, and melanoma are seen on occasion, but squamous cell carcinoma is the most common.[3,5] The detailed workup required in the evaluation of the unknown primary squamous cell carcinoma of the neck is discussed later in this chapter.

Unknown Neck Mass: Differential Diagnosis

Inflammatory Neck Masses

Inflammatory neck masses represent the most common and ubiquitous neck masses across all age groups.

Lymphadenopathy/Lymphadenitis

Inflammatory lymphadenopathy can occur in response to any infectious or inflammatory process in the head and neck and is typically a self-limited process lasting days to weeks. Lymph nodes will enlarge and become tender in the face of infection or inflammation, then typically subside without treatment. Occasionally lymph nodes will become necrotic in the face of bacterial or viral infection, and an abscess forms. These nodes can be differentiated by ultrasound or CT. *Staphylococcus* and *Streptococcus* are the organisms most commonly cultured from neck abscesses.[3,4,10] Diffuse lymphadenopathy is common in patients with human immunodeficiency virus, but a growing or dominant mass should raise suspicion for lymphoma.[11]

Granulomatous Diseases

The clinician should keep a multitude of granulomatous processes in mind when evaluating a neck mass. Diagnosis of most of these will rely on associated signs and symptoms, history of exposure or travel, and, of course, FNA biopsy. These entities include tuberculosis, atypical mycobacterial infections, actinomycosis, cat-scratch disease, and syphilis. FNA is the preferred biopsy technique because open procedures may create nonhealing wounds.

Sialadenitis/Sialolithiasis

Inflammation, infection, and/or blockage of the parotid or submandibular glands or their ducts can produce neck masses. The infected parotid or submandibular gland will present as a warm, tender, enlarged gland. Systemic symptoms such as fevers and chills may be present. Often, the examiner will be able to express purulent material from the duct draining the gland. This diagnosis typically does not require imaging, and treatment is with antibiotics, hydration, warm compresses, massage, and sialagogues.

Patients with sialolithiasis will experience periodically enlarged and painful glands, often in association with eating. Ultrasound imaging will typically detect salivary stones either within the glands or the ducts. Chronic sialolithiasis can lead to salivary stasis and eventually sialadenitis. Treatment is with hydration, massage, and sialagogues.

Congenital Neck Masses

The list of congenital causes may be considered in the differential diagnosis both for children and adults with neck masses. Caution, however, should be exercised before assuming a cystic mass in a patient in the older adult population is of congenital origin. In these instances, malignancy must be considered first and foremost, and congenital

diagnoses entertained only once malignancy has been ruled out. A thorough description of the embryology and anatomy of the congenital masses of the neck is beyond the scope of this chapter but is crucial to guiding appropriate and accurate surgical therapy.

Thyroglossal Duct Cysts

Anomalies of the thyroglossal duct are seen commonly in the pediatric population; they are second in frequency only to lymphadenopathy. Remnants of the thyroglossal duct are actually found in approximately 7% of the population, but only a small number of these ever become symptomatic.[12] Because the thyroid begins as a diverticulum within the tongue musculature and descends caudally to finally situate itself low in the neck anterior to the larynx and trachea, it is possible to see remnants of the duct and thyroglossal duct cysts anywhere along this course. The tract of the thyroglossal duct can descend either anterior or posterior to the hyoid bone. Thyroglossal duct cysts usually become evident in childhood as a midline neck mass, often one that is fluid filled and elevates in the neck with tongue protrusion or swallowing. Occasionally, thyroglossal duct cysts present as an infected midline mass. Incision and drainage should generally be avoided in this circumstance because eventual surgical eradication is made more difficult. Needle aspiration, together with antibiotics, is the recommended treatment option for infected thyroglossal duct cysts. Patients should be taken for proper surgical excision once the infection is cleared.

Before consideration for surgical excision, patients must undergo a complete workup of thyroid function to rule out median ectopic thyroid. The workup should consist of thyroid function studies and either ultrasound (to confirm thyroid location) or radionuclide scanning. If a solid mass is discovered during excision of a thyroglossal duct cyst, the diagnosis of median ectopic thyroid should be entertained. If frozen section analysis confirms normal thyroid tissue, the surgeon should confirm the presence of thyroid tissue in the expected location before proceeding.

Performing the proper surgical treatment for thyroglossal duct cysts relies directly on knowledge of the embryologic pathway of the thyroid gland. The Sistrunk procedure, the preferred method of surgical excision, involves excision of the entire pathway of the thyroglossal duct. The patient is placed in the supine position with the neck extended. A horizontal neck incision is planned overlying the cyst. The cyst is dissected free from the surrounding soft tissue and is taken in continuity with the pyramidal lobe of the thyroid (if present) to ensure comprehensive inferior pathway removal. Dissection is then carried superiorly toward the hyoid bone. Often, a proximal tract can be identified. The tract is taken, with a cuff of soft tissue surrounding it. Once the dissection reaches the hyoid bone, the central portion of the bone is taken in continuity with the dissected soft tissue. The bone must be excised due to the inconsistent nature of the tract in relation to it. The final step of the procedure involves following the tract to the level of the tongue base and then amputating the entire tract with suture ligation.

If median ectopic thyroid is identified during thyroglossal duct cyst excision, the proper surgical management is debatable. If there is normal thyroid tissue present in the expected location, the Sistrunk procedure should be performed. If the ectopic focus is the only normal thyroid tissue, it should either be left alone or possibly repositioned laterally in the neck. Thyroid hormone suppression should be considered in these cases to control the size of the ectopic focus for either functional or cosmetic benefit.[12]

Branchial Cleft Anomalies

Approximately 30% of pediatric neck masses are the result of anomalies of branchial clefts; they can present as cysts, sinuses, or fistulae.[12] They are common both in the pediatric and young adult populations. The specific site in the neck where a branchial cleft anomaly occurs is dependent on the brachial arch from which it is derived. Anomalies of the second arch are by far the most common (representing 95% of all branchial cleft anomalies) and typically manifest as a lateral neck swelling associated with an upper respiratory tract infection.[4,12] When these lesions present as infected neck masses, it is important to manage the infection first, although attempts should be made to avoid incision and drainage as in the case of thyroglossal duct cysts.

Particular mention should be made of anomalies of the first branchial arch because these often present a diagnostic and treatment dilemma in the pediatric population. Despite the fact that these anomalies account for only 1% of branchial cleft anomalies,[12] their association with the facial nerve can make management difficult. First arch anomalies come in two types and typically present as cysts, sinuses, or fistulae located between the external auditory canal and the angle of the mandible. Type 1 first branchial cleft anomalies are duplications of the external auditory canal and often have attachments to the skin of the external auditory canal or to the tympanic membrane. These lesions contain ectodermal elements only and typically run lateral to the branches of the facial nerve. Type 2 first branchial cleft anomalies, however, contain ectoderm and mesoderm. These anomalies can often contain cartilage elements. Type 2 first branchial cleft anomalies often course deep to the facial nerve and its branches.

The proper surgical treatment for anomalies of the first branchial cleft includes excision of the entire cyst, fistula, or sinus tract, which often involves superficial parotidectomy and dissection of the facial nerve branches. Complete surgical excision of first branchial cleft anomalies associated with the ear canal requires resection of ear canal skin. If the tract of the anomaly courses medial to the tympanic membrane, a separate procedure is often required to remove the middle ear component.

The most common of the branchial cleft anomalies, accounting for greater than 95%, are those originating from the second arch.[12] Second arch anomalies present as swellings or draining tracts anterior to the sternocleidomastoid muscle. The course runs lateral to the internal carotid artery and enters the pharynx at the tonsillar fossa (the product of the second branchial pouch). Surgical excision is performed by a horizontal incision in the neck overlying the cyst or skin tract. In the case of sinuses and fistulae, skin excision is required to ensure complete eradication. The tract is then followed superiorly to the entry into the pharynx at the tonsillar fossa. Suture ligation occurs at this point. Often, a stair-step incision is required to follow the tract along its entire course.

Anomalies of the third and fourth branchial arches are extremely uncommon. Cysts of these arches can present with airway obstruction, especially if they become infected. The course of anomalies of the third arch is deep to the internal carotid artery. They pierce the thyrohyoid membrane with the superior laryngeal nerve and enter the pharynx at the pyriform sinus. Fourth branchial arch malformations are even rarer and have a variable course depending on the side where they occur. On the left, they course into the mediastinum and around the arch of the aorta, medial to the ligamentum arteriosum. On the right, they follow a tract around the subclavian artery. Fourth arch anomalies ascend into the neck deep to the internal carotid artery, can be intimately associated with the thyroid gland, and enter either the pyriform sinus or the cervical esophagus. Third and fourth branchial cleft malformations present as swellings or sinuses in the low neck anterior to the sternocleidomastoid muscle border, or they can even present as intrathyroid cysts. Excision of these anomalies is rarely necessary but requires excision of the entire course of the tract. Often, hemithyroidectomy is performed simultaneously. Pharyngoscopy and esophagoscopy can be helpful in pinpointing the pharyngeal communication point.

Dermoid Cysts

Dermoid cysts are the result of trapped rests of epithelial elements along the natural lines of embryonic fusion. These cysts contain both ectodermal and endodermal elements. They present as median or paramedian masses that slowly enlarge due to the accumulation of sebaceous contents. They are typically diagnosed before the age of 3.[4,12] Infection within dermoid cysts is rare.

Teratomas

Teratomas, on the other hand, contain elements from all three germ layers. Teratomas of the head and neck comprise less than 2% of all teratomas, but the common head and neck subsites are the neck and nasopharynx.[12] These lesions are usually diagnosed in the prenatal or

early neonatal period, as rapidly enlarging masses. They may present with polyhydramnios caused by esophageal obstruction, or they may cause airway compression. Some neonates will require immediate intubation.

Lymphangiomas

Lymphangiomas are benign hamartomatous lesions of lymphatic vessels and channels. They are soft, compressible masses located most commonly in the posterior triangle of the neck but are also seen in the oral cavity, axilla, and abdomen. Half of all lymphangiomas are present at birth, and 90% are present by the age of 2.[4] They can often enlarge with upper respiratory infections or with hemorrhage into the cystic spaces. Airway intervention is necessary on occasion. These lesions are often diagnosed by physical examination, but ultrasound or CT may be helpful in determining the extent of infiltration into surrounding tissues.

Hemangiomas

Hemangiomas represent congenital lesions of endothelial cells, which always present in the first few months of life. Hemangiomas commonly occur in the head and neck. They are soft, compressible, bluish-purple lesions associated with a bruit or thrill. There are three growth phases to hemangiomas, making their management predictable in most cases. A rapid expansion phase can last 6 to 12 months, followed by a stable phase in which minimal growth or change occurs. The final phase is one of involution, which usually begins by 24 months. Tumor regression is complete in 50% of children by age 5, and nearly all tumors regress by ages 10 to 12.[13]

Primary Neoplasms of the Neck

Unlike those lesions that manifest themselves as metastatic cervical lymph nodes, there are also several neoplastic processes that occur primarily in the neck.

Lymphoma

Lymphoma represents the only primary neoplasm seen in cervical lymph nodes and accounts for approximately 4% of new cancer diagnoses in the United States each year.[8] Lymphomas are the most common head and neck malignancies in the pediatric population and are the second most common overall head and neck malignancy, second only to squamous cell carcinoma.[2,3,14] Lymphoma can be classified as either Hodgkin's or non-Hodgkin's types. Eighty percent of patients with Hodgkin's disease have cervical nodal disease, whereas only about 33% of those with non-Hodgkin's disease have involved cervical lymph nodes. Non-Hodgkin's lymphoma, however, is approximately five times more common than Hodgkin's disease in the head and neck. Greater than 90% of non-Hodgkin's lymphomas are of B-cell origin, while the remainder are of T-cell origin. There is also a strong link between non-Hodgkin's disease and the human immunodeficiency virus.[11,14]

CT represents the best and most appropriate imaging modality for patients with lymphoma; both for the purposes of staging and follow-up. FNA can be helpful for identifying a clonal lymphocyte population in a neck mass, although frequently, nodal tissue is required, by open biopsy, to confirm a diagnosis by flow cytometry.[2] The clinician should pay attention to associated symptoms because these may raise clinical suspicion and assist in the ultimate diagnosis of lymphoma. The so-called "B" symptoms (those symptoms that, when found, upstage the patient) are unexplained fever, unexplained weight loss, and night sweats. These symptoms, when present, make the likelihood of systemic disease much greater.[14]

Thyroid Neoplasms

Thyroid neoplasms represent the most common neoplastic anterior neck masses in all age groups. The incidence of benign thyroid nodules increases with age so that approximately 40% of the population older than the age of 40 have at least one thyroid nodule detectable by ultrasound. Thyroid nodules are approximately four times more likely to occur in women. More than 90% of all thyroid nodules are benign, but the incidence of malignancy within a thyroid nodule increases with the extremes of age—either the very young or the very old. The incidence of malignancy is also increased in men with thyroid nodules.[15] In the pediatric population, a lateral neck mass (lymph node metastasis) is the most common presenting sign of well-differentiated thyroid carcinomas, whereas thyroid masses are the more common presenting sign in adults.[3] As with other neck masses, thyroid nodules should be evaluated with FNA biopsy. Ultrasound imaging is extremely useful for masses of the thyroid because it can provide detail about the thyroid gland itself, as well as the surrounding nodal chains.

Neoplasms of Salivary Glands

Salivary gland tumors represent 1% of all head and neck masses. Among salivary gland neoplasms, 80% arise primarily in the parotid glands, 15% arise in the submandibular glands, and the remainder arise in the sublingual and minor salivary glands. In adults, 80% of parotid lesions are benign; the majority of these are mixed tumors, or pleomorphic adenomas. The incidence of malignancy in salivary gland neoplasms increases as the lesions appear in the smaller glands, such that 50% of submandibular masses are malignant and greater than 75% of sublingual masses are malignant.[16] In children, salivary gland neoplasms are rare, but a greater percentage (35%) are malignant. Hemangiomas represent the most common benign lesions of the parotid glands in children.[3,16] Mucoepidermoid carcinomas are the most common salivary gland malignancies in all population groups.

Although diagnostic imaging is probably not essential for small lesions located in the major salivary glands, both CT and MRI can offer useful information regarding lesions of the salivary glands. Both CT and MRI can help to distinguish tumor invasion, associated adenopathy, and extension into the deep lobe of the parotid and to differentiate deep lobe lesions from tumors of the parapharyngeal space. MRI is the best imaging modality to pinpoint facial nerve enhancement.[17]

Because surgical excision is the management of choice for most salivary gland tumors, there is some debate regarding the necessity and utility of preoperative FNA. FNA can be used for all types of salivary gland tumors and has a sensitivity for distinguishing benign from malignant salivary gland tumors of approximately 95%. FNA is likely useful for preoperative counseling of patients and for assisting in determining the appropriate comprehensiveness of surgical resection.[18]

Neurogenic Neoplasms

Schwannoma is the most common solitary neurogenic tumor of the neck. These lesions occur in patients who are 20 to 50 years old, and 25% to 45% of extracranial schwannomas occur in the neck. The parapharyngeal space is a common cervical location for tumors of neurogenic origin, and for this reason the tumors may clinically mimic salivary gland lesions as they grow laterally. Schwannomas can occur in the cranial nerves, sympathetic trunk, or spinal nerve roots.[19] These lesions are best imaged by CT or MRI; they are enhancing and will often demonstrate areas of cystic degeneration.[19] When located in the carotid sheath, schwannomas will displace the internal and external carotid arteries anteriorly, a feature distinguishing them from carotid body tumors. These lesions can be difficult to diagnose by FNA because FNAs typically reveal bland spindle cell cytology and can be confused with other soft tissue tumors.[20] Schwannomas can manifest as cranial nerve deficits of the involved nerves and are typically painful on attempts at FNA biopsy.

Other neurogenic neoplasms of the neck include neurofibromas and malignant peripheral nerve sheath tumors. Neurofibromas should be considered in their association with von Recklinghausen's disease (NF-1). Most patients with NF-1 present with diffuse or plexiform neurofibromas. There is a 2% to 6% incidence of malignant degeneration into or de novo generation of malignant peripheral nerve tumors for patients with neurofibromas associated with NF-1.[19]

Neurogenic tumors can also present in the form of lesions of neuroblastic origin. The list of pathologies includes neuroblastoma, ganglioneuroblastoma, and ganglioneuroma. Neuroblastoma represents the most common extracranial solid tumor in children and causes 8% to 10% of all childhood malignancies. Although primary cervical neuroblastomas are seen rarely, cervical metastases from intra-abdominal neuroblastomas are the more common presentation in the head and neck.[19]

Another neural entity seen with relative frequency in the neck is the neuroma. Neuromas occur at sites of neuronal injury and represent an inflated response to the injury manifested histologically by fibrous tissue, regenerating axons, and Schwann cells, in a disorganized mass. Neuromas are encountered commonly in the neck at the cut end of the greater auricular nerve after neck dissection or parotidectomy.[3,19]

Paragangliomas

Paraganglia are collections of cells of neuroectoderm origin that secrete catecholamines. They have an important functional role during embryogenesis, when they serve as the major source of catecholamines. After birth, most paraganglia rests disappear, with the exception of the adrenal medulla and the sites around the autonomic nervous system. In the adult the function of the paraganglia is to help the autonomic nervous system respond to stressors such as hypercapnia, hypoxia, or decreasing pH.[21]

In the head and neck, tumors of the paraganglia and paragangliomas occur in three main locations: carotid body, jugulotympanic region, and vagus nerve. These are highly vascular, slow-growing, mostly benign lesions, with less than 10% thought to be malignant.[21] Although most are single and sporadic, approximately 10% occur in an inherited pattern (autosomal dominant) or are associated with a syndrome (multiple endocrine neoplasia IIA or IIB, or von Hippel–Lindau disease) and 10% occur as multicentric lesions in the same patient.[21]

Paragangliomas have differing presentations on the basis of their location in the head and neck. Carotid body tumors typically present as a painless, slowly enlarging neck mass. The classic diagnostic features are a mass that is mobile horizontally, but fixed vertically, and a mass with an associated bruit or vascular thrill.[3,21] As these lesions enlarge, they may also cause cranial nerve or sympathetic chain neuropathies. Vagal paragangliomas will have a similar presentation but may have an increased incidence of hoarseness, pharyngeal fullness, or dysphagia at presentation.[3,21] Paragangliomas of the jugulotympanic region tend to have otologic symptoms at presentation (hearing loss, pulsatile tinnitus, fullness), as well as lower cranial nerve deficits. These lesions do not usually present primarily as neck masses.[21]

The major distinction between carotid body tumors and vagal paragangliomas is that seen on angiography. The classic *lyre's sign* or splaying of the internal and external carotid arteries indicates a carotid body tumor. Vagal paragangliomas tend to displace both vessels anteriorly, rather than splaying them. Angiography can also be a useful tool when preoperative embolization is to be considered for larger lesions, especially those of the carotid body.

More commonly, MRI is used as an important diagnostic tool for lesions of the paraganglia. Paragangliomas have a distinct "salt and pepper" appearance on T1-weighted MR images due to their vascular flow-voids. They are hyperintense on T2 images. Often, the position of the lesions with respect to the internal and external carotid arteries can also be determined from MRI, so this is the imaging of choice for these lesions. CT can be helpful in determining bony skull base erosion and can thus assist in the diagnosis of those of jugulotympanic origin.[21-22] These lesions should be diagnosed by physical examination and imaging, and FNA should, in general, not be performed.

Lipomas

Lipomas represent the most common subcutaneous soft tissue tumor of adults. They commonly occur in the posterior neck but can occur throughout the neck and face. They are slow-growing, benign tumors composed of adipocytes, with a firm to rubbery consistency on palpation.

Special Consideration: Unknown Primary Squamous Cell Carcinoma of the Neck

As with any patient with a neck mass, the most important starting point in the workup of a patient with an unknown primary head and neck squamous cell carcinoma is a thorough physical examination (Table 116-2). This examination should consist of careful inspection and palpation of all mucosal subsites of the oral cavity and oropharynx, as well as fiberoptic endoscopy. During endoscopy, particular attention should be paid to the nasopharynx, tongue base and tonsillar fossae, and hypopharynx.

Table 116-2

Steps in the Workup of an Unknown Primary Squamous Cell Carcinoma of the Neck*

1. Complete physical examination (inspection and palpation) of all head and neck subsites	Oral cavity Oropharynx Thyroid Salivary glands Face/scalp/neck skin
2. Fiberoptic endoscopy examination	Nasal cavity Nasopharynx Oropharynx Hypopharynx Larynx
3. Fine-needle aspiration	
4. Primary imaging	Head and neck (computed tomography or magnetic resonance imaging) Chest (radiograph or computed tomography)
5. Secondary imaging	Positron emission tomography
6. Panendoscopy/mucosal site sampling	Include laryngoscopy, bronchoscopy, esophagoscopy, and ipsilateral tonsillectomy. Pay close attention to the tongue base and hypopharynx.

*Each step should be followed in order until a primary diagnosis is made.

Next, imaging of the head, neck, and chest must be obtained. The clinician should keep in mind that when patients present with metastatic adenopathy in the low neck or supraclavicular fossae, there is an increased risk that the primary lesion will be located below the clavicles. Prognosis is extremely poor for this group of patients.[5] Imaging of the head and neck should be in the form of CT or MRI. CT of the chest should be performed. Clinicians have been increasingly interested in using PET scans to detect unknown primary malignancies of the head and neck. Results show that PET might help to pinpoint specific areas of increased metabolic activity in a small subgroup of patients with unknown primaries, but PET is also fraught with a significant number of false-positive results.[23] PET can be considered an adjunct to the complete workup of patients with an unknown primary head and neck squamous cell carcinoma. It should be performed before panendoscopy and biopsy to potentially provide a site to target and also to prevent false-positive results that might be seen in the face of tissue that has been recently instrumented and biopsied.

Once a complete battery of imaging has been completed, the patient should undergo panendoscopy and directed biopsies under general anesthesia. The examination should also include thorough palpation of the oropharyngeal subsites including the tongue base, tonsillar fossae, and glossotonsillar sulci. An ipsilateral tonsillectomy should be performed in patients who have not had previous tonsillectomy or in those with adequate lymphoid tissue remaining. Directed biopsies of the nasopharynx, tongue base, and hypopharynx should also be performed. The ipsilateral tonsil has been found to harbor the occult primary in 20% to 40% of cases of unknown primary squamous cell

carcinoma of the neck as reported in several series in the literature. The next most common subsite is the base of tongue.[5,23]

If the primary tumor has still not been identified after the thorough workup discussed earlier, the patient should be referred for nonsurgical management of the unknown primary. If the primary lesion is identified in the workup, treatment of the neck mass will be given according to the principles of treatment of the primary site.

Summary

Neck masses are extremely common and represent a wide variety of both head and neck and systemic pathologic entities. The most important element in the workup of an unknown neck mass is the exclusion of malignancy. As such, malignancy will be much more common in the older adult with a neck mass, particularly one that is painless, enlarging, and asymmetric. A thorough head and neck examination is the mainstay in the diagnosis of most neoplastic neck masses. In the pediatric population, inflammatory masses will present most commonly, but one should always be aware of the potential for a congenital mass to mask itself as an infectious adenitis. In these patients multiple recurrent neck infections should increase one's clinical suspicion and prompt imaging of the neck.

Finally, the otolaryngologist should always be aware of the airway in patients presenting with neck masses. Although formal airway evaluation is not always essential, the potential for airway compromise should be kept in mind before any further investigations. In the case of any clinical suspicion or overt airway symptoms, fiberoptic endoscopy should be performed and one should be ready for immediate intervention.

CHAPTER ONE HUNDRED AND SEVENTEEN

Ultrasound Imaging of the Neck

Mikhail Vaysberg

David L. Steward

Key Points

- High-resolution ultrasound is the best imaging modality for nodular thyroid disease.
- Sonographic features of thyroid nodules suggesting malignancy include microcalcifications, irregular borders, extrathyroidal extension, and increased vascularity.
- Thyroid nodules with suspicious sonographic features or greater than 1 to 1.5 cm in size should undergo ultrasound-guided, fine-needle biopsy.
- Ultrasound is the most sensitive tool for detection and localization of persistent or recurrent thyroid cancer in the neck.
- Repeat neck ultrasound to look for metastatic lymphadenopathy is indicated preoperatively in patients with cytologically diagnosed thyroid cancer.
- Ultrasound is a sensitive tool for parathyroid adenoma localization, providing greater anatomic detail than radionuclide imaging.
- Ultrasound is useful for submandibular and parotid salivary gland neoplasms, especially when combined with ultrasound-guided, fine-needle biopsy.
- Sonographic features suggestive of metastatic lymph nodes include absence of echogenic hilum, round shape, cystic component, irregular borders, and jugular vein indentation.
- Ultrasound-guided, fine-needle biopsy reduces sample error and nondiagnostic rates when compared with palpation alone.
- To assist sonographic imaging of the needle tip during fine-needle biopsy, the bevel of the needle should be facing up toward the ultrasound transducer.

Basics of Ultrasound

Over the past 30 years sonographic imaging technology has undergone tremendous change. As a result of excellent resolution and portability, it has gained popularity as an office-performed procedure adding another dimension to physical examination and going beyond physicians' proprioception. Understanding of anatomy and disease pathophysiology remains the key in any radiologic study, yet one is required to understand the principles and physics of ultrasound (US) technology in order to maximize the information provided.

Sonographic technology is based on the properties of the acoustical wave. The energy by a US transducer is transferred to molecules of a medium. The molecules vibrate in a series of rhythmic, mechanical compressions generating a number of longitudinal waves like a ripple in the water. Each wave has a particular number of cycles per second that determines its *frequency*. One cycle per second is equal to 1 Hz; 10^6 cycles/second is equal to 1 megahertz (MHz). Audible sound has a frequency between 20 and 20,000 Hz, whereas US has a frequency greater than 20,000 Hz.

The sonographic signal is generated at the level of the transducer that contains crystals with piezoelectric properties. These crystals are linearly arranged and their properties permit conversion of electrical energy into US energy and vice versa. As US waves propagate through tissue, a small percentage of the energy (echo) is reflected back to the transducer. The US image is formed by the returning wave, and the strength of the image is proportional to the strength of the returning wave. Substances with a greater density produce stronger "echoes." Structures of different densities are easier to distinguish from one another.

Multiple tissue interfaces emit various sonographic echoes and permit generation of readable images. High-frequency waves provide better images because of higher reflection, but they are restricted to the evaluation of the superficial structures caused by rapid energy loss. Because of the superficial location of most head and neck structures, clinical US uses fluctuating frequencies between 5 and 10 MHz or 7 and 12, 13, or 16 MHz. This range combines the penetration of lower frequencies and higher resolution of higher frequencies. The frequency of the sound changes when it is reflected from a moving object. The change in frequency is known as the *Doppler shift* and can be used to determine the flow of red blood cells as they course through vessels.

One should be familiar with terminology used in US imaging. *B-mode sonography* refers to a gray-scale mode, where *Doppler* sonography is used for assessment of blood flow and is color coded. *Echogenicity* defines the appearance of tissues on the US image relative to its ability to reflect the US wave. *Anechoic* means no return signal; it represents complete penetration of the energy through a structure, appearing black. An *isoechoic* object has similar echogenicity to surrounding tissue. *Hypoechoic* tissue has lower echogenicity than reference tissue, appearing darker. *Hyperechoic* tissue is brighter compared with the reference structure due to higher echogenicity.[1]

Utility and Limitations

The majority of structures and pathologies in the neck are located within 5 cm distance from the skin surface. With high-resolution sonographic technology, virtually all extracranial structures can be accurately assessed, though the primary utility is imaging of thyroid, parathyroid, and salivary glands, as well as lymph nodes. Magnetic resonance imaging (MRI) or computed tomography (CT) scans generally offer no additional information regarding size, margin, or malignant potential.[2] Being relatively inexpensive, office-based US technology is readily available, portable (size of laptop computer), quick and easy to perform, and harmless to the patient. It also allows real-time diagnostic imaging and image-guided fine-needle biopsy to be performed at the same visit. It does not involve ionizing radiation or require intravenous contrast.

Ultrasonography should be the first imaging modality for evaluation of thyroid nodular disease. The limitations of US include difficulty assessing deep soft tissue and bony invasions and inability to penetrate through bone or cartilage. It cannot reliably evaluate perineural spread, involvement of the skull base, or parapharyngeal/retropharyngeal/mediastinal nodes.[4]

Operator dependence is one of the major limitations of ultrasonography. Mastering office-based sonography by a surgeon who knows the anatomy, patient, and disease eliminates reliance on someone else's reporting, provides better real-time preoperative localization, assesses related lymphadenopathy, permits single operator consistent follow-ups with image-based documentation, assists more accurate specimen acquisition, and adds another dimension to physical examination.[3,5,6]

Brief Description of Technique

The patient is placed in a semi-reclined or fully reclined position with mild neck extension. The monitor is placed near and at the same level as the patient. The examiner should be able to view the monitor and perform the scan without undue stretching or twisting. Convention dictates the orientation of the transducer relative to the patient. Transducers have an embedded indicator that must be directed cephalad during scanning in the sagittal plane and directed toward the patient's right during scanning in the transverse plane. The examiner's hand is stabilized on the patient's skin, with the transducer held between the thumb and first two fingers. The transducer is advanced with constant skin contact with mild consistent pressure. For better acoustic coupling, the skin is covered with aqueous gel. Patient position should not be considered to be static; changes in position are often necessary to improve the quality of the image, to assess a particular structure, or to discriminate mobile from fixed reflectors. The dynamic examination is one of the advantages of real-time US imaging.

It is important to develop a readily replicated, systematic approach for the examination of neck structures. We prefer to use B-mode (gray-scale) scanning in the transverse/axial plane primarily. Starting inferiorly in the lateral neck, the probe is tilted inferiorly to visualize the subclavian vessels and then steadily advanced in superior direction with the carotid along the medial aspect of the field of view. The examination is then repeated on the contralateral side.[6,7]

For central compartment evaluation, one half of the trachea should be visible on the medial aspect of the screen and the great vessels visible laterally, proceeding inferiorly to superiorly. A light touch will minimize compression of the jugular vein. Longitudinal/sagittal imaging is less intuitive; thus it is mostly reserved for confirmation and sizing in the cranial-caudal dimension of selected pathology once it is identified. For subtle changes in position, the probe can be slightly tilted back and forth, which allows more precise movement than sliding the probe along the skin surface. Color Doppler imaging can be used to assess vascularity, though most vessels are readily distinguished in gray scale. Once an image is localized in real time, the image can be frozen, labeled, sized, saved, and printed for the patient's file (Fig. 117-1).[8]

Thyroid Ultrasound

Neck US is widely accepted as the optimal modality for evaluation of thyroid nodularity. The thyroid gland, one of the easiest neck structures to image with US, should be homogeneous and of intermediate gray scale. It is considered the reference echogenicity for comparison with other structures. Solid hyperfunctioning thyroid nodules tend to be mildly hyperechoic with respect to the surrounding gland. Fluid-filled or cystic nodules tend to be hypoechoic, similar to vascular structures. Cystic nodules can be differentiated from vessels as one scans from inferior to superior because nodules will appear and then disappear, whereas vessels will continue in one direction or another. Doppler imaging can be used to assess vascularity of the gland overall or a discrete nodule. Untreated Graves' patients demonstrate increased vascularity throughout a relatively homogeneous thyroid gland. In contrast, Hashimoto's thyroiditis usually appears heterogeneous with splotchy ill-defined hypoechoic areas; the micronodular pattern represents lymphocytic infiltrations. As the disease progresses, it results in generalized gland atrophy and fibrosis-induced hypoechoic lobulation that may mimic nodularity. The diseased gland is often associated with benign-appearing reactive lymph nodes frequently located inferior to the gland.

US provides the most accurate sizing of nodular disease for surveillance, and its sensitivity for detection of thyroid malignancy approaches 80% to 90% in experienced hands.[9,10]

In the setting of a multinodular thyroid, it is important to carefully evaluate each nodule individually and target which sonographic features increase the predictive value of fine-needle aspiration (FNA) for carcinoma. Although there is no single pathognomonic sonographic feature, the constellation of findings may suggest malignancy: microcalcifications, intranodular intrinsic vascularity, absent "halo sign," extraglandular extension, and irregular or microlobulated margins (Fig. 117-2, Box 117-1). Unless purely cystic, the presence of cystic component within a lesion does not diminish risk of carcinoma, and is common in papillary carcinomas. One should be aware of inspissated colloid as a common misinterpretation for microcalcifications. The presence of a comet-tail or ring-down artifact posterior to the echogenic foci is seen with colloid (Fig. 117-3). We still perform a biopsy of the largest nodule in spite of benign sonographic features, but will select other nodules for biopsy that appear suspicious independent of size alone.[11,12]

In addition to evaluation of the thyroid gland, cervical lymph nodes must be carefully examined, especially in patients suspected of having malignancy.[13] Sonographic identification of round, enlarged, hypoechoic, solid or cystic lymph nodes with microcalcifications and absent echogenic hilum should raise suspicion of papillary or medullary thyroid carcinoma (Fig. 117-4). They should undergo fine-needle biopsy. Lymphatic drainage accompanies vascular supply with levels III, IV, and VI being predominantly involved. Lymphadenopathy as high as cervical level II is not uncommon due to the pathway of superior thyroid vascular pedicle,[14] and level V due to transverse cervical vessels. Metastatic nodes are often seen posterior to the carotid along the inferior thyroid artery.

Ultrasonography can be used not only for initial preoperative localization of malignant thyroid disease, but can play an important role for determination of residual or recurrent disease. Neck US may be the most sensitive tool for detecting recurrent differentiated thyroid carcinoma, especially in combination with thyroglobulin measurement. Patients may be considered to be disease free when US evaluation of the neck is negative, TSH-stimulated thyroglobulin is undetectable, and antithyroglobulin antibodies are absent.[15]

Parathyroid Ultrasound

Hyperfunctioning parathyroid adenomas are responsible for approximately 90% of cases of primary hyperparathyroidism. Due to early recognition of disease with asymptomatic hypercalcemia noted on routine renal panels, many diagnoses are made while adenomas are relatively small. Surgical therapy remains the best treatment for this disease. Thus the localization of the pathologic gland constitutes the main challenge. With an experienced and motivated sonographer, high-resolution US can reliably localize solitary adenomas to correct side and location (right vs. left and superior vs. inferior) in about 90% of cases, which supersedes sensitivity of sestamibi scan and provides greater anatomic detail.

US techniques for localization of parathyroid adenomas deserve specific mentioning. Normal-sized parathyroid glands (<40 mg) are not

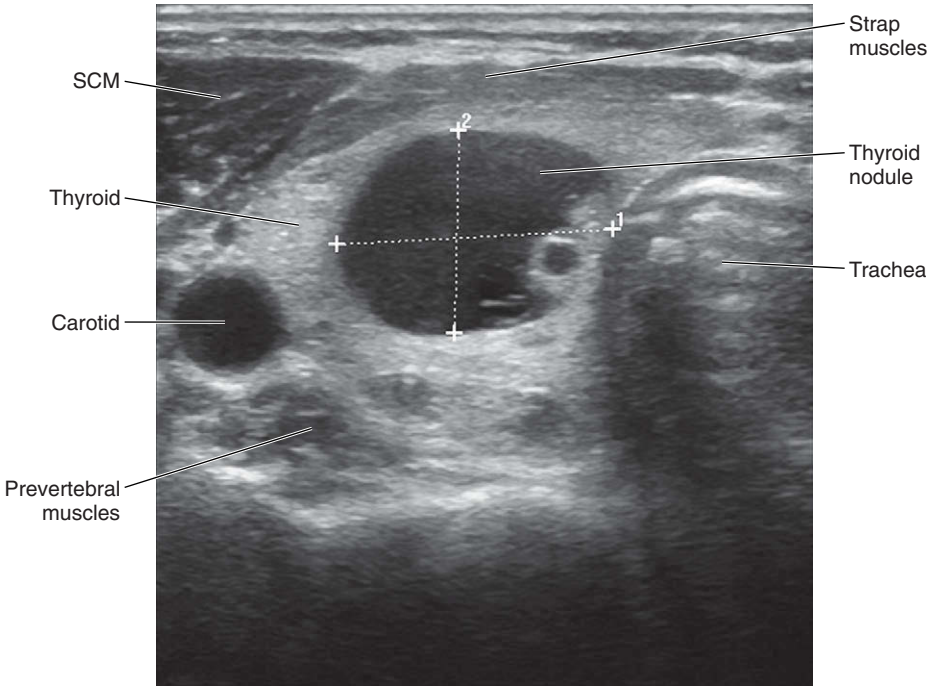

Figure 117-1. Transverse/axial image of a predominantly cystic thyroid nodule with a solid component along the medial aspect. SCM, sternocleidomastoid muscle.

usually distinguishable with currently available equipment for high-resolution ultrasonography (7 to 15 MHz). Localization of enlarged parathyroid glands (≥100 mg) requires a careful and deliberately slow transverse (axial) scanning technique. First, tilt the transducer inferiorly to examine the superior mediastinum. Then advance the transducer superiorly beyond the superior pole of the thyroid one side at a time. The initial focus is on the central neck region and expected parathyroidal orthotopic locations, but the entire anterior and lateral neck should be examined.[16,17]

Parathyroid adenomas are most often hypoechoic relative to the thyroid gland. They are rarely anechoic or cystic and occasionally nearly isoechoic relative to the thyroid. The inferior parathyroid adenomas are most often visualized just inferior to the inferior lobe of the thyroid, sometimes just posterior to the inferior lobe (Fig. 117-5). The superior parathyroid glands are almost always on the posterior aspect of the midportion of the thyroid gland, in a deeper plane than the inferior glands (Fig. 117-6). The distinction between superior and inferior parathyroid can at times be challenging, even during surgical exploration. The inferior parathyroid glands lie anterior to the plane of the recurrent laryngeal nerve, whereas the superior parathyroid glands lie posterior to this plane. Using the inferior thyroid artery or the posterior surface of the common carotid artery as a surrogate marker for the plane of the recurrent laryngeal nerve, adenomas located entirely deep to the posterior surface of the artery are most often superior parathyroid glands even if located in a somewhat more inferior location than typical (Fig. 117-7).[18]

If an enlarged parathyroid is not readily identified on either side, repeat the examination increasing the far field or overall gain in both transverse and longitudinal planes. The possibility of an ectopic location is raised. Ectopic superior parathyroid glands are located in a posterior plane from the hyoid to the posterior mediastinum, usually posterior to the carotid sheath, occasionally intrathyroid (most often posterior when "caught" by migration of the ultimobranchial body), and more commonly retropharyngeal/esophageal/tracheal. Scanning from a more lateral position will often avoid shadow artifact related to the carotid artery and trachea and reveal the hidden adenoma. Although the majority of ectopic adenomas can be localized, the posterior mediastinum cannot be visualized with US. Suspected intrathyroidal parathyroid adenomas can undergo US-guided, fine-needle biopsy with cytology to rule out thyroid malignancy and needle rinsing with 1 to 2 mL of saline for chemical identification of intact parathyroid hormone, which is better able to discriminate parathyroid from thyroid.[12] Ectopic inferior parathyroid glands are located in an anterior plane from the hyoid to the anterior mediastinum, with the majority being within or in close proximity to the thymus at the thoracic inlet or superior mediastinum. Such glands are often amenable to identification with US and resection through a cervical approach. Another common ectopic location is intrathyroidal within the posterior aspect of the inferior pole. Less commonly, the glands are within the carotid sheath.

Patients with thyroiditis often have hypoechoic reactive lymph nodes adjacent to the thyroid gland, which can be a source of false-positive localization and may be differentiated from parathyroid adenomas by their hyperechoic hilum and hilar rather than peripheral blood supply identified with color Doppler imaging. Frequently thyroid nodularity is incidentally noted and can be evaluated at the same time with US-guided, fine-needle biopsy, permitting appropriate surgical management if necessary.

Primary parathyroid hyperplasia presents a localization challenge. The glands tend to be smaller, and one gland can be predominantly larger than the others, giving the false impression of being an adenoma. In these cases, eliciting a family history of parathyroid disease can be helpful. Parathyroid hyperplasia seen in primary hyperthyroidism is more common in patients with a positive family history or multiple endocrine neoplasia (MEN) syndromes I and IIa, or both, and can often be localized with US. Sporadic primary hyperplasia should be considered in patients with negative cervical US and negative sestamibi scans because these glands, despite their collective hyperfunction, can remain too small for accurate localization. Hyperplastic parathyroid glands in secondary or tertiary hyperparathyroidism are usually easily identified on US if the hyperparathyroidism is severe enough to warrant surgical intervention.[19]

Ultrasonography of Salivary Glands

Salivary gland neoplastic disease constitutes less than 3% of the head and neck tumors, although sialadenitis is common. The clinical evaluation alone is often nonspecific. Imaging is frequently required to differentiate pathologies arising within salivary glands, as well as the ones stemming from neighboring structures. US is ideally suited for evaluation of the submandibular and parotid glands, though the

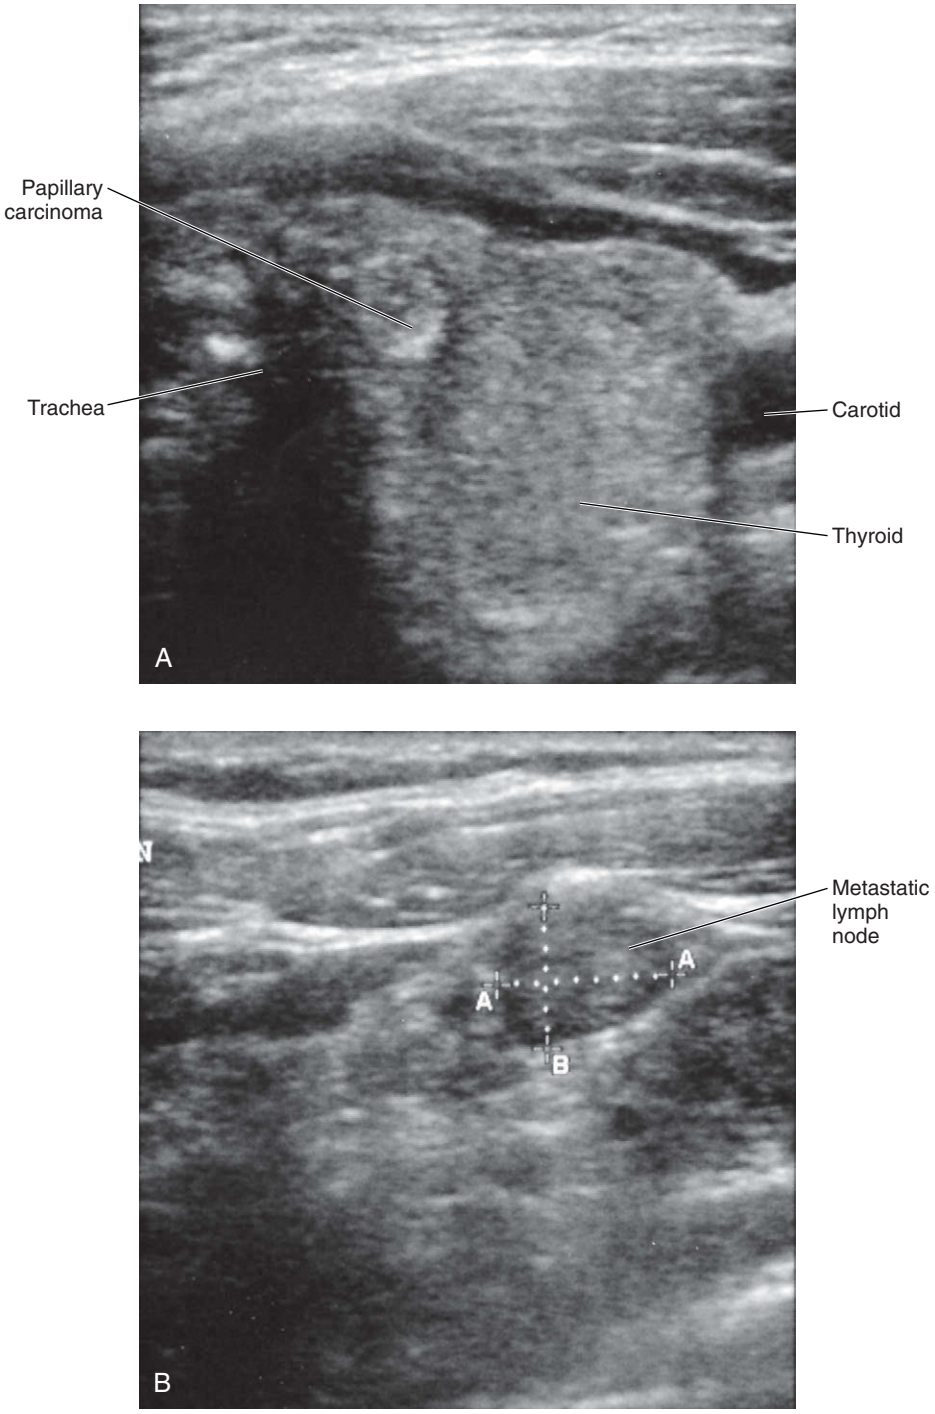

Figure 117-2. **A** and **B,** Papillary thyroid carcinoma with microcalcifications and nodal metastasis.

Marked intranodular blood flow on color Doppler

mandible precludes reliable sonographic evaluation of the deep lobe and parapharyngeal space. US can differentiate between neoplastic and inflammatory process, but without US-guided fine-needle biopsy it cannot reliably differentiate benign from malignant neoplasms. Office US is incredibly useful in discriminating among submandibular lymphadenopathy, sialadenitis, and salivary neoplasm (Fig. 117-8). It is also helpful to differentiate parotid tail neoplasm from adenopathy and superficial neoplasm from sialadenosis or sialadenitis (Fig. 117-9).

In adult patients, salivary glands have a uniform parenchymal echo appearance that is more echogenic than surrounding musculature and similar in echogenicity to the thyroid. Multiple hyperechoic linear

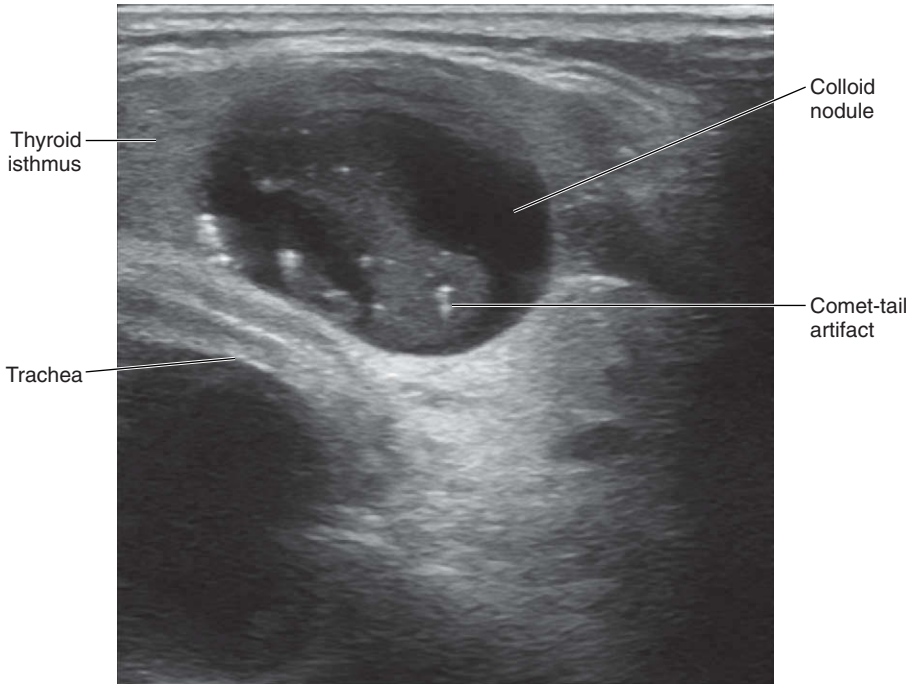

Figure 117-3. Transverse/axial image of a colloid nodule with comet-tail artifact.

streaks represent intraglandular ducts. Nondilated main ducts are usually invisible with standard probes, but dilated ducts are easily visualized in chronic sialadenitis with or without sialolithiasis. Chronic sialadenitis results in a more hypoechoic gland, similar to thyroiditis. The presence of germinal centers suggests Sjögren's syndrome.

Normal lymph nodes are usually small, ovoid hypoechoic lesions with presence of echogenic hilum and short axis equal to or less than 5 to 6 mm.[20] In the submandibular triangle, small lymph nodes are commonly seen superior and anterior to the submandibular gland. Jugulodigastric (Kuttner) lymph nodes reside just posterior to the submandibular gland. They are larger and more circular, with a prominent echogenic hilum.

The late embryogenesis (second trimester) of the parotid gland is responsible for subcapsular and intraparenchymal location of lymph nodes. These nodes may present a diagnostic challenge but can be differentiated from neoplasms by the presence of an echogenic hilum.

Intraglandular masses are often hypoechoic compared with the normal parenchyma. Solid lesions can be homogeneous or heterogeneous with or without a cystic component.[21] A solid appearance of a lesion does not predict the benign or malignant nature of the disease, but the diagnosis can be assisted by US-guided fine needle aspiration biopsy (see Fig. 117-9).

Although there are no pathognomonic features separating malignant from benign neoplasms, US can distinguish benign from malignant tumors up to 80% of the time. High-grade malignancies tend to demonstrate an irregular shape, a heterogeneous echostructure, extracapsular spread, and metastatic lymph nodes. They tend to show increased vascularity on Doppler imaging. Intraglandular metastases are usually multiple, round, and sharply demarcated. Lesions smaller than 2 cm and well-differentiated malignancies may not possess the previously mentioned features. Multiple pathologies can mimic tumors. US cannot distinguish among subtypes of malignant tumors. To make a diagnosis, cytologic assessment should be performed on all accessible lesions.

Several pathologies of salivary glands deserve specific mentioning.

Calculous lesions 2 mm and above are hyperechoic with acoustic shadowing behind a stone. Smaller calculi do not have a shadowing effect, but the obstruction can be inferred from dilated ducts (markedly hyperechoic lines). Sialogogues assist demonstration of the dilatation.

Sjögren's syndrome is a chronic autoimmune disorder associated with intense lymphocytic and plasma cell infiltration of the exocrine glands with or without connective tissue disorders. Sonographically, the gland is heterogeneous with scattered oval hypoechoic or anechoic areas or it has a reticulated appearance due to the presence of hyperechoic lines. Sonolucent areas are thought to represent dilated ductal structures and aggregates of lymphocytes, analogous to the pattern seen with the lymphocytic infiltrations found in Hashimoto's disease. It is associated with increased incidence of infections and less commonly with lymphoma. Sjögren's patients should be followed to detect changes signaling the development of lymphoma. No pathognomonic US features are associated with lymphoma, but a discrete mass lesion is worrisome. If suspicion for lymphoma has risen, US-guided core biopsy of the parotid gland is safe and accurate for diagnosis of disease.

Cystic salivary gland disease may result from salivary flow obstruction, vascular malformation, first branchial cleft cyst, Warthin's tumor, low-grade mucoepidermoid carcinoma, pleomorphic carcinoma, necrotic mass, neurogenic tumors, end-stage Sjögren's syndrome, lipoblastoma, and human immunodeficiency virus infection. Sonographically, simple cysts have anechoic content, well-defined margins, posterior acoustic enhancement, and no evidence of internal blood flow with color Doppler imaging. Any cystic lesions containing solid components dictate biopsy for final diagnosis.

Acute infections do not require imaging and can be inferred from the patient's presentation and help of serology or cultures. The sonogram is useful in cases of ductal obstruction or abscess formation, or both. In the presence of abscess, the typical clinical sign of fluctuation is absent due to lack of space between glandular parenchyma and thick fibrous capsule. Sonographically, abscess is seen as ill-defined hypoechoic avascular foci with posterior acoustic enhancement (created by increased reflection of ultrasonic waves at the fluid-solid interface). Hyperechoic air bubbles and moving debris can be visualized on careful examination.[22]

Ultrasonography in Head and Neck Cancer

Unfortunately, US cannot detect aerodigestive tract mucosal primary lesions. One of the main roles of office-based ultrasonography is detection, localization, and surveillance of cervical metastatic lymph nodes. Using well-established sonographic criteria for metastatic

lymphadenopathy, clinically occult metastatic disease can be diagnosed (tumor staging) and the extent of therapy can be determined. Sonographic features such as round shape, absence of echogenic hilum, hyper/hypoechogenicity, intranodal cystic degeneration, absence of planes and sharp borders, and adjacent soft tissue edema are highly suggestive of malignancy. Furthermore, US can detect malignancies in lymph nodes less than 1 cm not detected by CT or MRI. Reduction of the risk of occult cervical metastasis to around 10% permits expectant management of the N0 neck. With strict US follow-up of the N0 necks, the relapse and neck metastasis rates after successful early salvage surgery have been reported equivocal to prophylactic neck dissections. As a result, elective neck dissections can be avoided in a significant number of patients without negatively affecting their survival.[23] Preoperative neck US has been shown to influence surgical management of thyroid malignancy in 40% of patients.

Description of Diagnostic Ultrasound Fine-Needle Aspiration Technique

Ultrasonography renders most extracranial soft tissue masses in the head and neck region accessible to US-guided fine-needle aspiration biopsy (FNAB). US-guided FNA reduces sample error and false-negative results. It also significantly increases the diagnostic adequacy rate over palpation-guided FNA. On-site cytologic evaluation of the smears also reduces nondiagnostic aspirates but may be unnecessary with a US-guided approach.

The following technique of performing FNAB is based on personal experience that maintains a nondiagnostic aspiration rate around 7%. It is important to communicate with the cytopathologist regarding his or her preferences for specimen processing (air dried vs. fixed and glass slide vs. cell block) to optimize diagnostic utility. Detailed accurate labeling of the specimen source, as well as inclusion of relevant clinical information, is critical.

Once the lesion in question is localized, the transducer is stabilized and the mixture of local anesthetic with epinephrine is deposited subcutaneously using a 25- or 27-gauge needle. The needle is advanced in the direction of the long axis of the probe to visualize the entire shaft. The solution is deposited beneath the strap muscles and along the anticipated needle tract. The depth of the lesion and the proximity of the great vessels or airway, or both, may dictate the angle at which the needle is placed. We prefer to combine tissue acquisition via both capillary and aspiration techniques using a 22-gauge, 1½-inch needle. The capillary sampling is performed first. One should be warned that the image-acquiring surface of crystals with the transducer probe is about 1 mm (the thickness of a credit card). The FNAB needle is entered through the skin immediately next to the midportion of the long axis of the transducer at a 45-degree angle between the transducer and skin. The bevel of the needle is pointed toward the transducer to increase the echogenicity of the needle tip, which is critical to reduce sample error. On US imaging, the needle appears white (hyperechoic) (Fig. 117-10). Back-and-forth motion of a needle within the specimen during collection can be clearly visualized. With the capillary action technique, we use a free needle to shave the cells along the needle path within the lesion. Holding the needle in place for a short time is recommended to allow some time for capillary action. Microcores of the specimen can be shaved by rotating the needle within the specimen just before needle removal. With this capillary technique, the cell yield may be reduced but it tends to be less painful, the cellular architecture is better preserved, and contamination with blood is significantly less, making it ideal for glass slide smear preparation. The specimen is then deposited on a glass slide and smeared with another slide. Immediate fixation of the specimen is necessary to avoid the artifacts and cell disruption from desiccation. If submitting an air-dry smear, the cytologist needs to be notified because different stains are used. When aspirating cystic lesions, a syringe should be attached to avoid spillage of contents. The solid component of the cyst should be preferentially biopsied.The next two to three passes are performed using the suction aspiration technique. A 3-mL syringe with 1 mL of air is attached to a needle. The air will help expel the specimen into solution after aspiration into the needle hub. Once the needle is within a lesion, 2 mL of negative pressure is applied. Before changing the direction of the needle, several back-and-forth motions along the same path will shave cells and pack them into the shaft of the needle. The negative pressure should be released before withdrawal of the needle from the neck to avoid sucking the specimen into the syringe. The specimen is washed out into a container of fixative. Once a needle is irrigated with fixative, it must be discarded. A brand new needle is used for the next collection. The cells are retrieved by centrifuge, and red blood cells are lysed before specimen preparation. On completion of the procedure the patient should be instructed

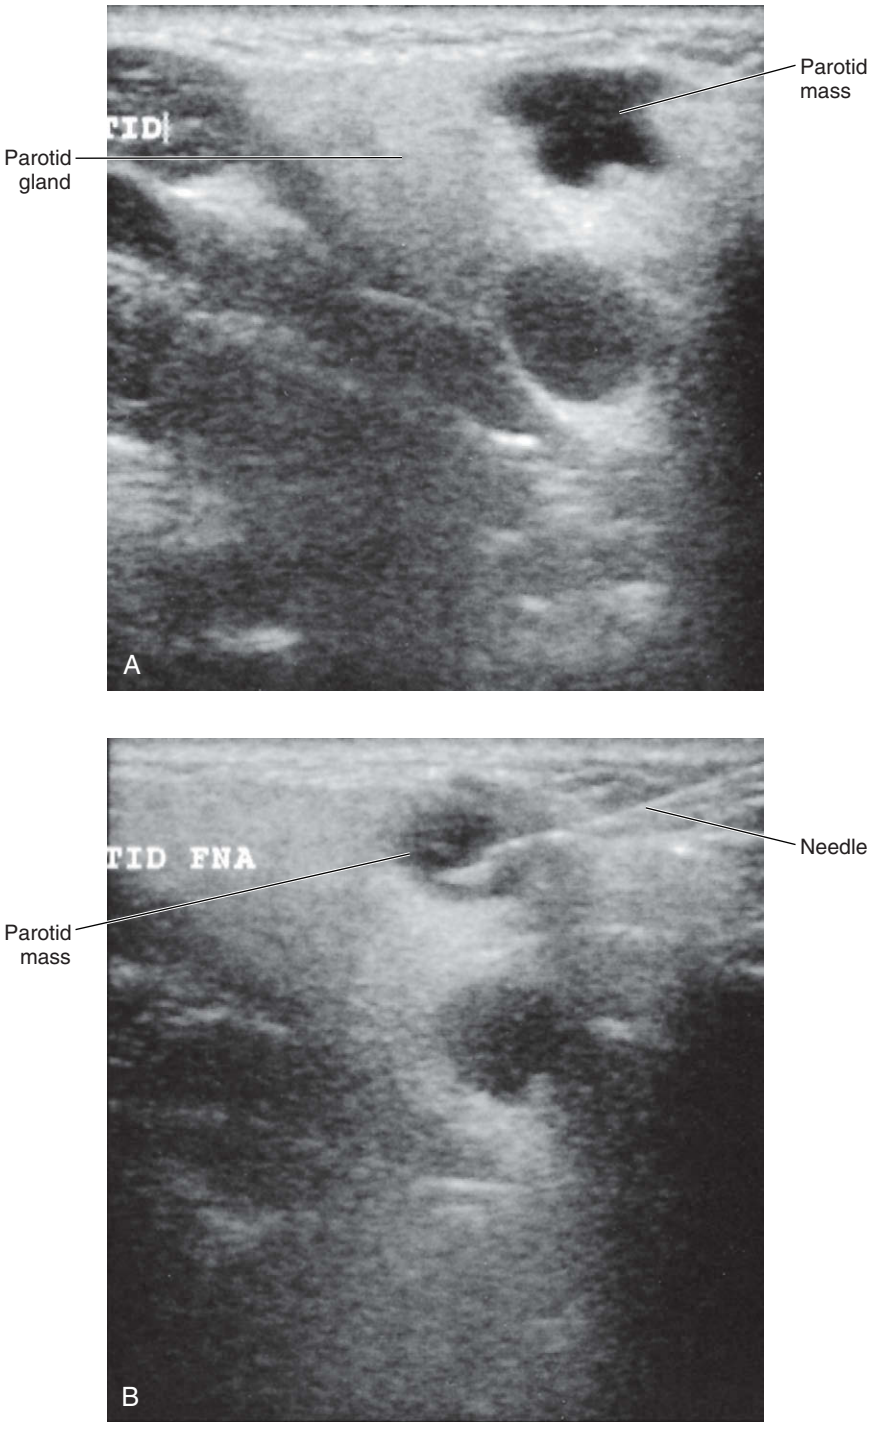

Figure 117-9. **A,** Parotid mass. **B,** Ultrasound-guided, fine-needle biopsy of parotid mass.

to use over-the-counter pain medications to control discomfort, which may last 24 to 72 hours.

To perform a biochemical analysis of metastatic or persistent/recurrent thyroid carcinoma within an abnormal lymph node, the FNAB specimen can be rinsed with 1 to 2 mL of normal saline, and the wash can be sent in a red-topped test tube to be tested for presence of high thyroglobulin level. Simultaneous serum thyroglobulin level should be obtained to avoid false-positive results due to blood contamination. If one suspects medullary carcinoma, one should request the use of calcitonin staining on the cell block and send a needle wash for calcitonin. To confirm intrathyroid parathyroid adenoma, one can submit a wash of tissue sample to test for the presence of parathyroid hormone. FNAB of lymph nodes tends to be more challenging due to the nodes' smaller size, proximity to great vessels, tendency to bounce off the needle, and lack of stability during specimen aspiration.

Conclusion

US imaging is a great tool in the armamentarium of an otolaryngologist. The sonographic images augment physical examination and, together with superior understanding of head and neck anatomy, lead to a faster and more accurate diagnosis. US imaging is a relatively inexpensive, quick, and simple-to-use technology. In some respects it is the best imaging modality that is available. As with any tool, it requires understanding of its strengths and limitations, mastering tech-

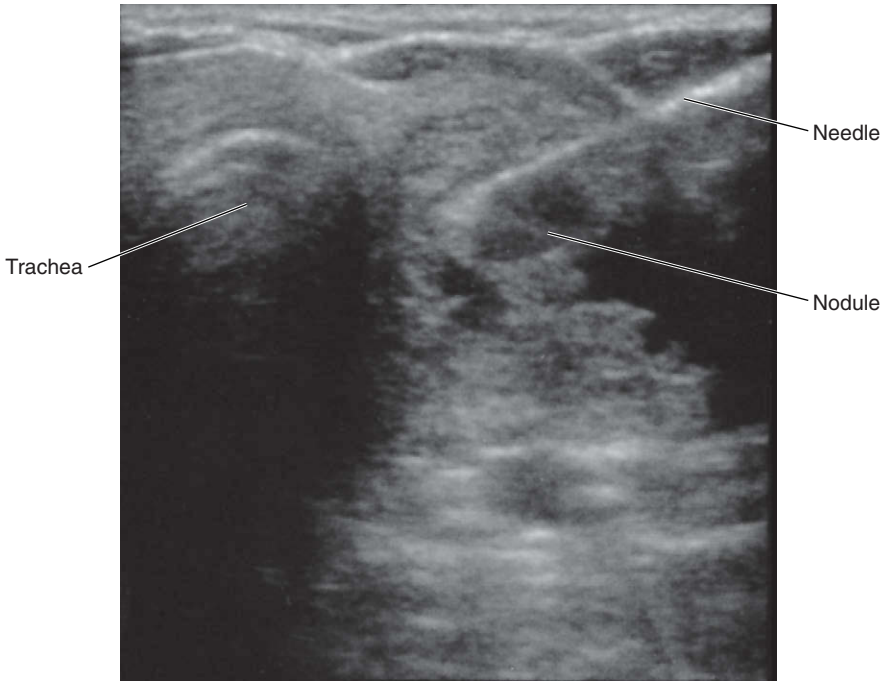

Figure 117-10. Ultrasound-guided, fine-needle biopsy of thyroid nodule.

niques, and proper application. Once a comfort level is achieved, US technology may greatly enhance patients' care and reduce health care costs.

CHAPTER ONE HUNDRED AND EIGHTEEN

Neoplasms of the Neck

Terry A. Day

Luke Buchmann

Zoran Rumboldt

John K. Joe*

Key Points

- Neck masses represent a diverse group of pathologic processes and require a broad differential diagnosis.
- Both benign and malignant lesions can present as a mass in the neck, making a careful approach to these lesions important.
- A complete history and physical examination, as well as appropriate ancillary studies, are important to arriving at the correct diagnosis.
- Appropriate use of fine-needle aspiration biopsy and endoscopy are critical for determining the presence of an upper aerodigestive tract malignancy.
- Understanding the utility of different imaging modalities such as MRI, CT scanning, PET/CT imaging, and angiography can aid greatly in the evaluation and treatment of these differing pathologies.
- Treatment depends critically on determination of a correct diagnosis and can include surgery, radiation therapy, chemotherapy or a combination of these treatment modalities.

Neoplasms of the neck include those tumors that arise from, rather than metastasize to, lymphovascular structures of the neck, as well as those tumors originating from the soft tissues of the neck. These neoplasms may be either benign or malignant, and, although they are less commonly the etiology for a mass in the neck, one should always consider these tumors in the differential diagnosis of a neck mass. This chapter is divided into benign and malignant sections and provides the reader with a comprehensive review of neoplasms that may originate in the neck.

Diagnostic Evaluation

The diagnosis of neoplasms of the neck involves the standard practice of the complete history and physical examination. Importantly, the patient should be questioned regarding prior neoplasms, family history, and systemic signs and symptoms in addition to the risk factors for primary and metastatic lesions to this area. A comprehensive head and neck examination should include the ear and temporal bone, sinonasal cavity, nasopharynx, oropharynx, hypopharynx, and larynx including a full cranial nerve examination in addition to examination of the neck. Specific information collected from the physical examination of the neck should include the character of the mass, mobility, and pulsation in addition to accurate assessment of neck level. For instance, immobility of a pulsatile mass in the craniocaudal direction may point to the presence of a carotid body tumor. If the neck mass is not pulsatile or vascular in nature, a fine-needle aspiration (FNA) should be performed. Only when the FNA is nondiagnostic or inadequate should excisional biopsy be performed, and at that time the surgeon should be prepared to proceed with appropriate neck dissection with margin analysis if necessary.

Radiologic Studies

Both computed tomography (CT) and magnetic resonance imaging (MRI) may be useful in the evaluation of soft tissue tumors of the head and neck region with particular advantages of each technique varying by type of tumor, location, regional disease, and proximity to vital structures. Although radiographic findings may provide clues to the diagnosis within the broad and, in some cases, even specific differential, accurate diagnosis cannot be ascertained without histologic evaluation. CT scanning is particularly useful in evaluating bone detail in addition to calcification within the tumor, and the addition of contrast improves the diagnostic utility of the soft tissue examination. In addition, CT-directed biopsy of difficult-to-access tumors such as the parapharyngeal space may provide diagnostic tissue. MRI has surpassed CT in evaluating soft tissue extent and relationships in the head and neck region; however, image quality may be degraded by patient motion. It is generally recommended in the majority of soft tissue tumors or tumors adjacent to vital structures of this region, primarily for nasopharyngeal, sinonasal, parotid, and possibly oral cavity lesions.

Similar to CT, MRI should be performed with contrast enhancement using gadolinium agents. Fat suppression is helpful for postcontrast and T2-weighted sequences; however, nonenhanced T1-weighted images without fat suppression should always be obtained because they frequently provide the best delineation of the normal anatomic structures and the extent of pathologic processes.[1,2] Positron emission tomography (PET) with fluorine-18 fluorodeoxyglucose (FDG),

*Deceased: A loving son, brother, husband, father, and physician who unselfishly gave himself to others every moment of his life. This chapter is dedicated to his brightest stars, Molly and Charlie.

primarily PET-CT scanning, has evolved as a well-established modality in the evaluation of the primary site, regional nodal disease, and the presence of distant tumor for staging information, particularly for squamous cell carcinoma and the detection of synchronous primary tumors such as lung and esophagus. PET-CT scans may allow for precise localization of the lesion and may decrease the number of false-positive and false-negative findings.[2,3] A controversial use of PET/CT imaging is in the clinical decision making of neck treatment following definitive chemoradiation therapy for advanced head and neck cancer. Several studies have addressed the use of PET scanning in the postirradiated neck. Porceddu and colleagues have shown that in patients with N2 and N3 neck disease a negative PET scan at 8 weeks allowed the observation of those patients with residual neck mass without compromising regional control. Of 27 patients observed by Porceddu with negative PET scans there were no failures in the neck. Yao and associates obtained similar results in a similar patient population. Optimal timing for post-therapy PET scanning appears to be at least 8 weeks, because scanning at 8 to 12 weeks significantly improved the negative predictive value over those who scanned earlier.[4-6] On the basis of these studies it may be a reasonable strategy to obtain a PET-CT scan 8 to 12 weeks following therapy to evaluate for residual disease and performing neck dissection on those with positive scans while observing those with negative scans whether a neck mass is present or not. It should be mentioned that the spatial resolution of PET (and PET-CT) allows for detection of lesions that are at least 8 mm in size.

Ultrasound imaging has become a valuable tool in the head and neck surgeons' diagnostic repertoire. It has the ability to allow the addition of imaging to the in-office examination of the neck as an adjunct to the physical examination. In addition, for the evaluation of the N0 neck it allows not only the characterization of lymph nodes in the neck but allows guided FNA biopsy of nodes of interest.[7] The ability for ultrasound to be used as a primary prognostic tool in the neck to help dictate whether elective neck dissection is necessary has been investigated but has not changed the treatment paradigm in the N0 head and neck patient.

Benign Neoplasms of the Neck

Benign neoplasms of the neck are often misdiagnosed as infectious in etiology (lymphadenitis) or congenital (branchial cleft cyst) on initial presentation. Thus, the diagnosis of all neck masses requires a vigilant approach using the history, physical examination, radiologic studies, and FNA biopsy. Because these tumors are uncommon, a review of the diagnostic approach is vital to the clinician's evaluation and management of each case. Benign primary neoplasms of the neck include vascular tumors such as paragangliomas, peripheral nerve neoplasms such as schwannomas or neurofibromas, lipomas, and salivary gland tumors. The following discussion of the more common benign neoplasms is categorized by tissue of origin.

Vascular Neoplasms

Paragangliomas comprise the most common class of benign vascular neoplasms of the neck. Paragangliomas arise from extra-adrenal paraganglionic cells derived from the neural crest.

Pathology

The paraganglion system denotes a collection of neuroectoderm-derived chromaffin cells in extra-adrenal sites. The system is vital as a source of catecholamines in fetal development, until the formation of the adrenal medulla.

Normal paraganglia contain two types of cells: type 1, chief cells or granular cells; and type 2, the supporting or sustentacular cells. Type 1 cells contain dense-core granules filled with catecholamines, a property that places them in the amine precursor and uptake decarboxylase (APUD) system. Type 2, or sustentacular cells, are elongated cells that closely resemble Schwann cells. Their function is not entirely clear. Tumors of paraganglia such as carotid body tumors contain both type 1 and 2 cells. Type 1 cells predominate and are arranged in an organized-nested pattern, known as *Zellballen,* surrounded by sustentacular cells in a fibrous stoma. These nests of Zellballen are illustrated in Figure 118-1. Type 1 chief cells tend to be polygonal shaped with abundant granular eosinophilic cytoplasm. They are peripherally surrounded by type 2 sustentacular cells that are difficult to identify by light microscopy and appear as spindle-shaped basophilic cells. Nuclear pleomorphism and cellular hyperchromatism are common in paragangliomas and should not be considered evidence of malignancy. Immunohistochemistry aids the diagnosis and differential diagnosis of these neoplasms. Type 1 cells stain positively with neuron-specific enolase, chromogranin A, and synaptophysin. Type 2 cells stain with S-100 and focally with glial fibrillary acidic protein.

Nomenclature

The controversy over the proper nomenclature of paragangliomas has been confusing. Historically they have been referred to as *glomus tumors, chemodectomas,* and *nonchromaffin tumors.* The correct terminology of paragangliomas is based on location (i.e., carotid paragangliomas, jugulotympanic paragangliomas, and vagal paragangliomas), although the terms *carotid body tumor, glomus tympanicum,* and *glomus jugulare* still persist.

Other terms such as *chemodectoma, glomus tumor,* and *nonchromaffin tumor* are less accurate terms and should be avoided. *Chemodectoma* is an inaccurate term to describe all paragangliomas of the head and neck because the carotid body is the only known paraganglia of the head and neck that behaves as a chemoreceptor. The term *glomus tumor* more accurately describes benign cutaneous tumors arising from neuromyoarterial cells surrounding arteriovenous anastomoses. Designation as nonchromaffin tumor relates to histologic staining characteristics. An early histologic staining technique employing the chromaffin reaction failed to show the presence of catecholamines; paragangliomas were therefore described as nonchromaffin tumors. Newer techniques however have detected catecholamines in small quantities.[8] The chromaffin reaction is a highly insensitive method on which to classify these tumors.[9]

Epidemiology

Approximately 90% of tumors arising from the paraganglion system are in the adrenal gland. These tumors are termed *pheochromocytoma.* The remaining 10% arise from extra-adrenal sites with 85% arising in the abdomen, 12% in the thorax, and the remaining 3% in the head and neck area.

The most common paraganglioma of the head and neck is the carotid body tumor, followed by jugulotympanic paragangliomas and vagal paragangliomas. Other sites include the larynx, nasal cavity, orbit, trachea, aortic body, lung, and mediastinum. It has been estimated that paragangliomas comprise 1 in 30,000 head and neck tumors.[10] However, the true incidence of paragangliomas may be unknown because previous reports have confused paragangliomas with neuroendocrine tumors.[11] Further complicating an accurate estimate is the multicentricity of these tumors, particularly in familial paragangliomas.

Carotid Paragangliomas

Carotid paragangliomas are the most common type of paragangliomas and serve as the template of discussion on the history, physiology, and etiologic factors relevant to paragangliomas.

History

The anatomist von Haller first described the carotid body in 1743; its function, however, was unknown at the time. Histologic studies of the carotid body revealed glandular acini, so the carotid body was renamed the *carotid gland.* Von Luschka first described a tumor of the carotid body in 1862. In 1880 Reigner performed the first resection of a carotid body tumor, but the patient did not survive. Six years later Maydl resected a carotid body tumor, and the patient survived but had postoperative hemiplegia and aphasia. In 1889 Albert was the first surgeon to resect successfully a carotid body without ligating the carotid vessels. The first successful removal of a carotid body tumor in the United States was reported by Scudder in 1903.[12] The term *paraganglion* was first used by histologist Kohn in 1903 to describe the carotid body.[13] This term was most appropriate because cells of the carotid body originate from the neural crest and migrate in close association with autonomic ganglion cells, hence the name "paraganglionic." In 1950

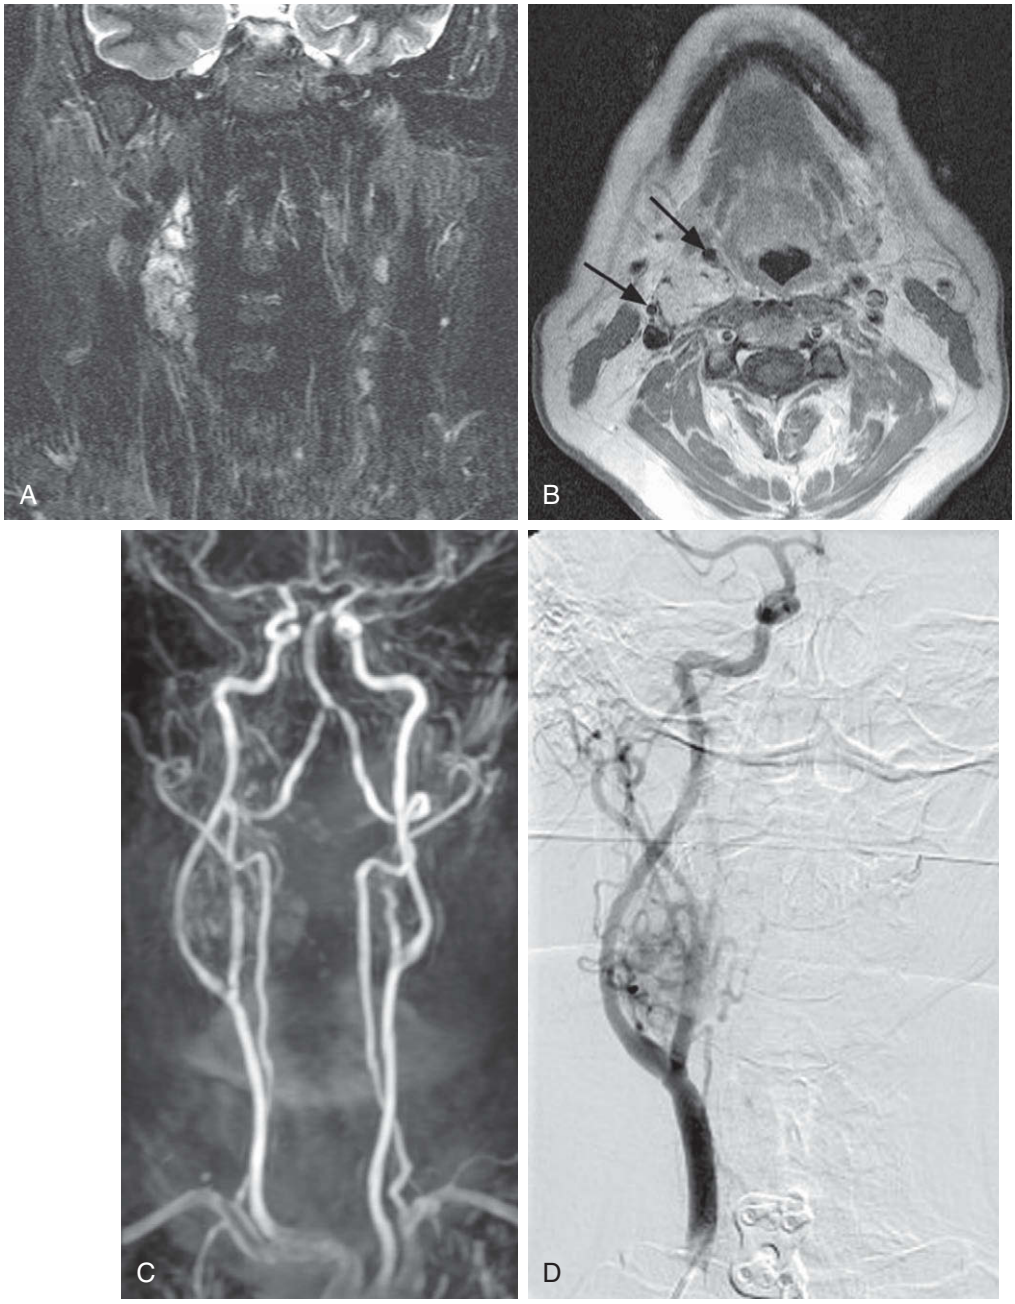

Figure 118-1. Carotid paraganglioma. **A**, Coronal T2-weighted magnetic resonance (MR) image with suppression of fat (short tau inversion recovery, STIR) shows a hyperintense mass in the right neck with prominent internal vessels (flow voids). **B**, Axial postcontrast T1-weighted MR image reveals avid enhancement of the mass, which splays apart the internal and external carotid arteries *(arrows).* Note that the internal flow voids are again visualized. **C**, Frontal projection MIP (maximum intensity projection) image from neck MR angiogram shows presence of vessels between internal and external carotid arteries on the right, which are splayed apart. **D**, DSA (digital subtraction angiogram) frontal projection image following right common carotid artery injection demonstrates the tumor vasculature to a better advantage.

Mulligan described in the dog neoplastic degeneration of the carotid body as chemodectoma because of the chemoreceptor function of the carotid body.[14]

Anatomy and Physiology

The carotid body is located in the adventitia of the posteromedial aspect of the bifurcation of the common carotid artery. The normal carotid body measures 3 to 5 mm in diameter but is often larger in persons living at higher altitudes. The average weight of the normal adult gland is 12 mg, with a wide range previously reported as 1 to 47 mg.[15] During surgical removal, the typical finding is a small, reddish-brown to tan, ovoid structure attached to the carotid vessels at the bifurcation by Mayer's ligament, through which the feeding vessels run, primarily from the external carotid artery. Blood flow and oxygen consumption of the carotid body, gram for gram, exceed those of the brain or thyroid gland.[16] Sensory innervation is from Hering's nerve, a branch of the glossopharyngeal nerve that originates approximately 1.5 cm distal to the jugular foramen.

The carotid body has a chemoreceptor role by modulating respiratory and cardiovascular function in response to fluctuations in arterial pH, oxygen, and carbon dioxide tension. Acidemia, hypoxia, or hypercapnia stimulate the carotid body to initiate an autonomic reflex, which leads to increased respiratory rate and depth, as well as increased heart rate, blood pressure, and cerebral cortical activity. It is this close association with respiratory drive and the sympathetic nervous system response that has prompted investigation of the carotid body's role in

disease processes such as obstructive sleep apnea (OSA) and sudden infant death syndrome (SIDS). Although no clear conclusions can be drawn at this time, the carotid body and its response to intermittent hypoxia appear to be related to the systemic hypertension seen in OSA. It has also been shown that some SIDS children had either small carotid bodies or a decreased ratio of mature type 1 cells to type 2 cells. It is hypothesized that this may attenuate the child's response to a hypoxic crisis.

Etiology

The etiology of paragangliomas appears to be multifactorial. Most paragangliomas are solitary. Multiple pheochromocytomas and paragangliomas are seen in familial syndromes, mainly multiple endocrine neoplasia types 2A and 2B. Other syndromes associated with paragangliomas are neurofibromatosis type 1 and von Hippel-Lindau disease, which is characterized by retinal angiomas and cerebellar hemangioblastomas. Carney's triad demonstrates the association of paraganglioma, pulmonary chondroma, and gastric leiomyosarcoma.[17]

In addition to these associations, a syndrome of familial paragangliomas characterized by multiple paragangliomas, especially in the head and neck region, has been described and occurs in at least 10% of cases. The familial nature of carotid body tumors was first suggested by Chase in 1933 in his description of two sisters with carotid body tumors.[18] Many developments have occurred recently in the characterization of the familial paraganglioma (PGL) syndromes including the genes and mutations involved and recommendations for the head and neck surgeon in managing these patients and their at-risk family members (Table 118-1). Genetic mutations responsible for the hereditary form of PGL have been identified in genes coding for succinate-dehydrogenase subunit D (SDHD), B (SDHB) and C (SDHC) genes, which map to chromosome 11, 1 and 1, respectively. Hereditary PGL syndrome has been classified genetically into four entities: PGL1, PGL2, PGL3, and PGL4. Germline mutations in SDHD, SDHB, and SDHC have been identified in PGL1, PGL4, and PGL3, respectively. The gene for PGL2 has not been identified.[19] Individuals with hereditary paraganglioma syndrome have early onset of tumors and a higher frequency of bilateral and/or multiple tumors than do those with sporadic disease. Past reports suggested familial paraganglioma to be rare, although recent literature challenges this assertion and suggests the association of paragangliomas with germline genetic mutations is likely to be significantly higher, representing 17% of sporadic patients in one study[19] and up to 28% to 40% in other studies.[20-22]

PGL1 is caused by mutations in the D subunit of the succinate dehydrogenase (SDH) gene and is the most common inherited genetic abnormality in families with a history of paragangliomas. All three syndromes follow an autosomal pattern of inheritance, but the inheritance pattern for PGL1 is autosomal dominant modified by genomic imprinting. Genomic imprinting in paragangliomas was described by van der Mey and colleagues after reviewing data from 15 large Dutch pedigrees.[23] The imprintable gene is transmitted in a mendelian manner, but the expression of the gene is determined by the sex of the transmitting parent. With paragangliomas, the gene results in the development of a tumor when it is paternally inherited. Offspring of male carriers were observed to demonstrate a 50% incidence of tumors, whereas children of female carriers never developed tumors. PGL1 is associated most commonly with head and neck tumors but also confers a risk for pheochromocytoma. It is estimated that 86% of individuals with a gene mutation will develop a tumor by age 50.[24] Gene mutations in SDHC are rare, with few families identified to date.

Of further interest is the development of a paraganglioma syndrome in head and neck patients due to the inheritance of mutations in the SDHB gene. Although the PGLs associated with mutations in SDHB are less common than their D subunit counterpart, mutations in this gene confer a higher risk for the development of extra-adrenal, catecholamine-secreting, and often malignant pheochromocytomas, making identification of these individuals crucial in management of the at-risk family members to ensure that proper screening for pheochromocytoma and other paragangliomas takes place. Several cases of renal cell carcinoma in carriers of these mutations have also been reported, and one case of papillary thyroid cancer has been documented in the literature.[24] The role of genetic counseling and testing in this population of patients cannot be overemphasized. Due to the apparent high rate of mutations in patients with a history consistent with sporadic paragangliomas, consideration of genetic counseling and testing should be given to every patient with a carotid body tumor or other paragangliomas.

Clinical Presentation and Diagnosis

The characteristic feature of carotid body tumors is slow growth rate, which is reflected clinically by the delay between the first symptoms and the diagnosis, which averages between 4 and 7 years. A carotid body tumor usually presents as a lateral cervical mass, which is mobile laterally but less mobile in the cranio-caudal direction because of its adherence to the carotid arteries. This physical finding has been called a *positive Fontaine sign.*[25] Alternatively, a carotid body tumor may present as a parapharyngeal mass. Many carotid body tumors are pulsatile by transmission from the carotid vessels or, less commonly, expand themselves, reflecting their extreme intrinsic vascularity. Sometimes a bruit may be heard by auscultation, but it can disappear with carotid compression. The consistency varies from soft and elastic to firm and these tumors are generally nontender. As they enlarge, progressive symptoms of dysphagia, odynophagia, hoarseness, and other cranial nerve (IX-XII) deficits appear. Carotid sinus syndrome syncope has been described in association with carotid body tumors.[26] The syndrome refers to a loss of consciousness accompanied with a reflex bradycardia and hypertension. Inciting stimuli include spontaneous movement of the head or following digital pressure applied to the tumor. Rarely, paraganglioma of the head and neck may present as a functional neuropeptide secreting tumor.

The capacity for catecholamine synthesis in head and neck paragangliomas, however, does not translate immediately to clinical findings. Although all paragangliomas have neurosecretory granules, only 1% to 3% are considered functional.[27] Glenner and coworkers first described a functional carotid body tumor secreting norepinephrine in 1962.[9] Patients should be asked about signs and symptoms indicating elevated catecholamines. Complaints of headaches, palpitations, flushing, and perspiration should be evaluated. In these patients a 24-hour urine collection is examined for norepinephrine and its metabolites including vanillylmandelic acid (VMA) and normetanephrine. Alternatively, plasma metanephrine may be assessed. Excess epinephrine or metanephrine should prompt suspicion of an adrenal pheochromocytoma because head and neck paraganglioma lack the enzyme to convert norepinephrine to epinephrine (phenylethanolamine-N-methyltransferase). An abdominal CT scan should be performed to rule out a concomitant adrenal pheochromocytoma. α- and β-Adrenergic blocking is undertaken if a tumor is found to be functional preopera-

tively. This decreases the risk from sudden catecholamine release that may occur with tumor manipulation in surgery. Routine screening for urinary metanephrines and VMA and serum catecholamines is only indicated for multiple or familial paragangliomas or in the presence of catecholamine-related symptoms.[28]

Multicentricity

The carotid body tumor is the most common paraganglioma in the head and neck, and the most frequent combination of multiple tumors is bilateral carotid body tumors. The overall incidence of multiple tumors is reported in the literature to be approximately 10%; some of these may be unrecognized familial genetic mutations. If a familial pattern is recognized, the incidence of multiple tumors is reported to be between 30% and 50%.

Malignancy

Cellular criteria for malignancy have not been established. Harrington and Dockerty[29] attempted to classify malignant tumors of the carotid body. Criteria for malignancy included mitoses with giant cells, nuclear pleomorphism, and capsular invasion. Using these criteria, 50% of the 20 tumors studied would be considered malignant. Batsakis[30] concurred that increased mitotic rate and capsular invasion should not be considered as determinants of malignancy. Other authors have hypothesized that all carotid body tumors demonstrate some degree of capsular invasion.[31] Malignancy is determined by metastasis, which must be proven with biopsy, because paragangliomas may exhibit multicentricity. There are no histologic criteria for malignancy. In fact, previous reports have described metastatic carotid body tumors without mitoses.[32] The diagnosis of malignancy should be made by evidence of spread to regional lymph nodes or distant sites[33,34] (most common being lung and bones).

Malignant paragangliomas have been reported in 6% of carotid body paragangliomas by Batsakis.[30] Accurate 5-year survival rates are not available because of the low malignancy rate of an uncommon tumor. Data from the National Cancer Data Base[35] suggest an overall 5-year survival rate of 60%. Distant metastases had a worse prognosis with a 5-year survival rate of 11.8%, while those with regional spread of disease fared much better with a 5-year survival rate of 78%.

Imaging Studies

Various diagnostic imaging modalities are available in the workup of carotid body tumors. Noninvasive duplex ultrasonography demonstrates a hypervascular mass and the tumor's relationship to the carotid artery. Ultrasonography may also delineate any intrinsic carotid artery disease.

Computed tomography (CT) scanning with intravenous contrast demonstrates a hypervascular mass with avid contrast enhancement, similar to normal vessels, at the carotid bifurcation, splaying the internal and external carotid arteries. CT angiography may be performed to demonstrate the relationship of the carotid vessels to the enhancing neck mass.

MRI with gadolinium may be the most useful imaging study for evaluating carotid body tumors (see Fig. 118-1A and B) because it offers superior soft tissue contrast without the need for ionizing radiation compared with CT scanning. MRI is sensitive for tumors as small as 0.8 cm.[36] Paragangliomas larger than 2 cm in diameter typically demonstrate on T2-weighted images internal flow voids, dark lines, and dots that correspond to vascular structures. This is, however, not always present with carotid paragangliomas. Carotid body tumors demonstrate a characteristic lyre sign characterized as a bowing and displacing of the internal and external carotid arteries as shown in Figure 118-1B and C. Radiographic evaluation should be sufficient to make the diagnosis of carotid body tumor.

Carotid angiography has been replaced by MRI (including MR angiography, see Fig. 118-1C), but catheter angiography remains useful when preoperative embolization is necessary (see Fig. 118-1D). The use of preoperative embolization is controversial, but many authors have recommended its use for large tumors to decrease blood loss.[37] Preoperative embolization may also be used in those rare instances where a malignant carotid body may be suspected. If preoperative embolization is planned, surgery should be performed 24 to 48 hours following in order to avoid revascularization, edema, or local inflammation. Additionally, angiography with temporary balloon occlusion using clinical and electroencephalographic monitoring, combined with brain CT perfusion scanning, can provide specificity as to the tolerance of collateral cerebral circulation across the circle of Willis in select cases.

The high density of somatostatin receptors in paragangliomas provides for newer functional nuclear medicine imaging techniques including metaiodobenzylguanidine (MIBG) scanning and octreotide scanning. MIBG scanning uses I-131 labeled tracer, which is concentrated in intracellular storage vesicles of paragangliomas.[38] Octreotide scanning uses Indium-111 labeled somatostatin analog octreotide to diagnose primary tumors of the APUD system, as well as their metastases.[39] These functional imaging studies have been recommended as a possible screening test for familial paragangliomas for patients at risk.[40] They also allow the detection of additional tumors when malignant paraganglioma is suspected.[41]

Classification

Although not universally adopted in the literature on carotid body tumors, a classification system has been previously proposed for carotid body tumors. In 1971, while a surgery resident at the Mayo Clinic, Shamblin and coworkers described a classification system used to grade the difficulty of resection in carotid body tumors.[42] Group I tumors were defined as localized, relatively small, and minimally attached to the carotid vessels. Surgical excision was described as carried out without difficulty in this group. Group II encompassed tumors adherent to or partially surrounding the vessels, with moderate arterial attachment. These tumors were described as amenable to careful surgical removal. Group III carotid body tumors completely encased the carotids. Shamblin and his colleagues recommended approaching these tumors with great care and with consideration for vessel replacement.

Management

Surgery remains the mainstay of treatment for carotid body tumors. Controversy persists in certain cases, particularly as it relates to multicentric tumors, or for patients with advanced disease or significant comorbidities.

Surgery

In a report from Memorial Sloan-Kettering Cancer Center, Lack and colleagues discussed 39 of 43 patients with carotid body tumors treated surgically; one patient received definitive radiation therapy; and 3 others were observed but not treated.[43] In this cohort of patients, 24 of 39 patients were free of disease following surgery, at an average follow-up interval of 12 years (6 months to 38 years). Local recurrence occurred in 4 of 39 patients (10%). Regional or distant metastases occurred in 4 of 39 patients (10%). All four of these patients were dead of disease within 6 years.

The incidence of permanent cranial nerve impairment as a complication of surgery has been reported in the literature to occur in approximately 20% of cases. In this report by Lack and colleagues,[43] cranial nerve sacrifice of the vagus or hypoglossal nerve was necessary in 15% (6 of 39) of patients. An additional patient developed Horner's syndrome postoperatively. Although not quantified, the superior laryngeal nerve supplying sensory innervation to the larynx and motor innervation to the cricothyroid muscle may be the most frequently injured nerve during carotid body resection. Paralysis of one superior laryngeal nerve may result in some degree of aspiration, although isolated palsy of one superior laryngeal nerve typically requires no additional rehabilitation. Furthermore, denervation of one cricothyroid muscle may result in pitch changes in singers, but changes in voice may not be perceptible. Injury to the cervical sympathetic chain will result in Horner's syndrome, with ipsilateral ptosis, miosis, and anhidrosis. Netterville and colleagues have described first bite syndrome resulting from injury to the cervical sympathetic chain, resulting in loss of sympathetic input to the parotid gland.[36] Patients with first bite syndrome complain of severe cramping in the parotid area when they take the first bite of food, particularly with the first meal of the day. The pain generally subsides over the next several bites but is more intense with strong

sialogogues such as tart or bitter foods. The physiologic mechanism behind first bite syndrome is likely due to denervation supersensitivity of the sympathetic receptors that control the myoepithelial cells in the parotid gland. With oral intake, parasympathetic neurotransmitters are released and cross-stimulation of the sympathetic receptors causes a supramaximal response of the myoepithelial cells. Treatment includes restriction to bland foods and oral carbamazepine (100 to 200 mg twice daily) for those with severe pain.

Anand and colleagues[44] reviewed 1181 published cases of carotid body tumors treated with surgical resection. Internal carotid artery injury was identified in 23% of cases (275 cases), with an overall occurrence of central nervous system (CNS) complications of 26%. This subcategory of internal carotid artery injury was further examined. In 23% of cases (62 cases), internal carotid artery repair was accomplished with simply suture or patch repair, with a CNS complication rate of 3%. The internal carotid artery was reconstructed in 45% (125 cases), with a CNS complication rate of 10% and a mortality rate of 2%. It was necessary to ligate the internal carotid artery in 32% (89 cases), resulting in a CNS complication rate of 66% and a mortality rate of 46%.

Minimizing surgical complications requires a multidisciplinary approach using head and neck surgeons familiar with cervical neurovascular anatomy for approaching the tumor and the vascular surgeon for assistance in resection and vascular repair if necessary. The keys to successful surgery are careful preoperative planning, proximal and distal control of the vasculature with vessel loops, careful identification and preservation of neural structures such as the vagus nerve and hypoglossal nerve, and dissection in the periadventitial plane with meticulous attention to hemostasis. Occasionally, ligation of the external carotid artery is necessary to resect the carotid body tumor; however, typically it can be preserved. Larger tumors may require bisection of the tumor to separate it from the internal and external carotid artery branches. The surgeon should be prepared for vascular reconstruction of the internal carotid artery if necessary, with suture repair, patch grafting, or interposition saphenous vein graft. Routine intraoperative shunting is not recommended and should be used only as needed in those rare instances where internal carotid artery resection and reconstruction is required in patients who do not tolerate preoperative balloon occlusion testing. Shunts may cause vascular complications including hemorrhage and thrombosis and are associated with a 6% incidence of CNS complications and 2% mortality rate.

Controversy over Surgery for Multicentric Tumors

In the patient with bilateral paraganglioma every effort must be made to save at least one vagus nerve and its laryngeal branches. Should a patient present with bilateral carotid body tumors, the case may be made to resect the smaller carotid body tumor first, with the intent of preserving the vagus and hypoglossal nerves on the less challenging side, before embarking on resecting the larger tumor on the other side. At a planned second stage, resection of the larger carotid body tumor may be undertaken. In the case of bilateral carotid body tumors with unilateral preexisting cranial nerve palsy, such as that affecting the vagus nerve (whether caused by surgery or the natural course of the tumor), the functional side should undergo tumor resection only if growth has been observed clinically or radiologically. In these cases, further bilateral cranial nerve damage must be prevented. In the case of an enlarging tumor, radiation therapy may be an option and some authors are advocating this therapy.

Another recently described and rarely recognized problem following bilateral carotid body excision is baroreflex failure syndrome.[36] The clinical manifestations are caused by bilateral denervation of the carotid sinus. The carotid sinus is situated in the adventitia of the carotid bulb and serves as a baroreceptor to decrease systemic blood pressure. Bilateral baroreceptor dysfunction causes unopposed sympathetic outflow, resulting in marked fluctuations in blood pressure and a sustained tachycardia postoperatively. Over time, compensation occurs, but it is variable and unpredictable. Compensation may occur by baroreceptor fibers in the aorta or through neural regrowth at the carotid sinus. Therapy consists of sodium nitroprusside in the early recovery phase to prevent excessive hypertension. Long-term control may be accomplished using oral antihypertensives such as clonidine or phenoxybenzamine. Clonidine is an α-2 agonist, resulting in decreased release of norepinephrine into synaptic clefts, and stimulation of parasympathetic outflow, slowing the heart rate. Phenoxybenzamine is an α-1 and α-2 antagonist that decreases peripheral resistance and increases cardiac output.

Radiation Therapy

Carotid body tumors were originally thought not to be radiosensitive because the effects of radiation therapy were cytostatic but not cytotoxic. Radiation therapy for paragangliomas will arrest growth but not shrink tumor size. Furthermore, potential tumor regrowth following radiation therapy remains a possibility. Risks associated with radiation therapy for paragangliomas include carotid atherosclerosis, the risk of radiation-induced malignancy, and associated morbidity including mucositis.

Radiation oncologists at the University of Florida have described effective local control of 23 carotid and vagal paragangliomas using definitive radiotherapy.[45] In their study, 15 patients with 23 carotid or vagal paragangliomas were treated with radiotherapy between 1981 and 1995. Nineteen tumors were treated with radiation therapy alone, and four were treated with surgery and postoperative radiation therapy. For benign tumors, total doses ranged from 35 to 48.5 Gy. The two malignant tumors received 64.8 and 70 Gy, respectively. Follow-up ranged from 1.5 to 10 years. Local control was achieved in 96% of tumors at 5 years. Five-year disease-specific survival was 89%, with one patient dead of locally recurrent disease 5 years after radiation therapy. This patient had been previously treated with surgery and radiation therapy before treatment by the authors. Another patient died of atherosclerotic disease 13.5 years after radiation therapy. There were no patients with regional or distant failure following treatment. Complications reported by these authors included one patient experiencing a delayed transient CNS syndrome. No other complications were reported.

Valdagni and Amichetti reported 7 patients with 13 carotid body tumors treated with radiation therapy between 1968 and 1987.[46] Treatment consisted of radiotherapy alone for 10 tumors and surgery plus radiation therapy for 3 tumors. Total doses ranged from 46 to 60 Gy at 1.8 to 2.5 Gy per fraction. Follow-up ranged from 1 to 19 years. Local control was achieved in all patients. Acute side effects were minimal. No short or long-term toxicities were reported.

Even proponents of radiation therapy for carotid body tumors concur with surgical resection as the preferred modality of treatment for most lesions.[47] Definitive radiation therapy may be reserved for patients who are poor surgical candidates due to a debilitated medical condition and for locally advanced tumors where anticipated postoperative morbidity may preclude consideration for surgical resection. Adjuvant radiation therapy may be considered following surgery for malignant carotid body tumors for locoregional control.

Observation

Using sequential radiologic imaging, Jansen and colleagues[48] have estimated the median tumor doubling time for 20 carotid body tumors to be 7.1 years including 12 cases without detectable growth. Farr has estimated a growth rate for carotid body tumors, plotting tumor size against years of symptom duration, of 2 cm in 5 years.[49] A scan-and-wait policy may be considered for those patients who are not suitable candidates for surgery or radiation therapy. This highly select group of patients includes those individuals whose medical condition is so poor that both surgery and radiation therapy are contraindicated, or those patients of such advanced age that the carotid body tumor may have minimal impact on their life expectancy or quality of life. This group may also include those patients with malignant carotid body tumors with distant metastases where locoregional treatment would be only palliative in intent.

Vagal Paragangliomas

Vagal paragangliomas are tumors derived from paraganglionic tissue associated with one of the ganglia of the vagus nerve.[50] Vagal paragangliomas most commonly arise from the inferior vagal ganglion, also referred to as the *nodose ganglion.* Tumors arising from the superior

vagal ganglion, or jugular ganglion, may be dumbbell-shaped and may extend from the neck intracranially through the jugular foramen.

Clinical Presentation and Diagnosis

Vagal paragangliomas, like carotid body tumors, may present as a palpable neck mass that is more mobile in a lateral direction than a craniocaudal orientation. Paralysis of the ipsilateral true vocal cord or Horner's syndrome, from involvement of the ipsilateral sympathetic chain, may be present as the tumor grows in size. True vocal cord paralysis may result in hoarseness with or without aspiration of liquids from glottic incompetence. Large tumors arising from the jugular ganglion may be associated with cranial neuropathies of IX, XI, and XII. Diagnostic imaging studies described previously in the chapter may demonstrate anterior displacement of the carotid artery from the tumor present in the posterior carotid sheath. Unlike carotid body tumors, the internal and external carotid arteries do not manifest a splayed configuration in vagal paragangliomas (Fig. 118-2).

Management

The treatment strategies employed for carotid paragangliomas described in the previous section apply to the management of vagal paragangliomas as well. Most are treated by surgical resection, and the discussion pertinent to preoperative embolization described earlier is germane to vagal paragangliomas as well. Patients should be counseled preoperatively as to the fact that complete resection of the vagal paraganglioma typically necessitates sacrifice of the vagus nerve. The resultant ipsilateral true vocal cord paralysis may be addressed in the postoperative period as needed on the basis of the patient's deficits. Vagal paragangliomas arising from the nodose ganglion are usually approached by a transcervical approach, whereas more superiorly located tumors of the jugular ganglion may require a combined transmastoid-transcervical approach, with possible craniotomy should there be intracranial extension. The necessity of carotid artery resection and repair is less common in vagal paragangliomas than their carotid artery counterparts. Indications for definitive radiation therapy or observation alone, which have been previously described for carotid paragangliomas, are applicable to vagal paragangliomas as well.

Arteriovenous Malformations of the Head and Neck

Arteriovenous malformations (AVMs) represent another form of benign vascular neoplasms that present in the head and neck. The most common site of head and neck AVMs are the cheek, ear, nose, forehead, and upper aerodigestive tract. These can be difficult neoplasms to manage. Both excision and interventional radiologic procedures have

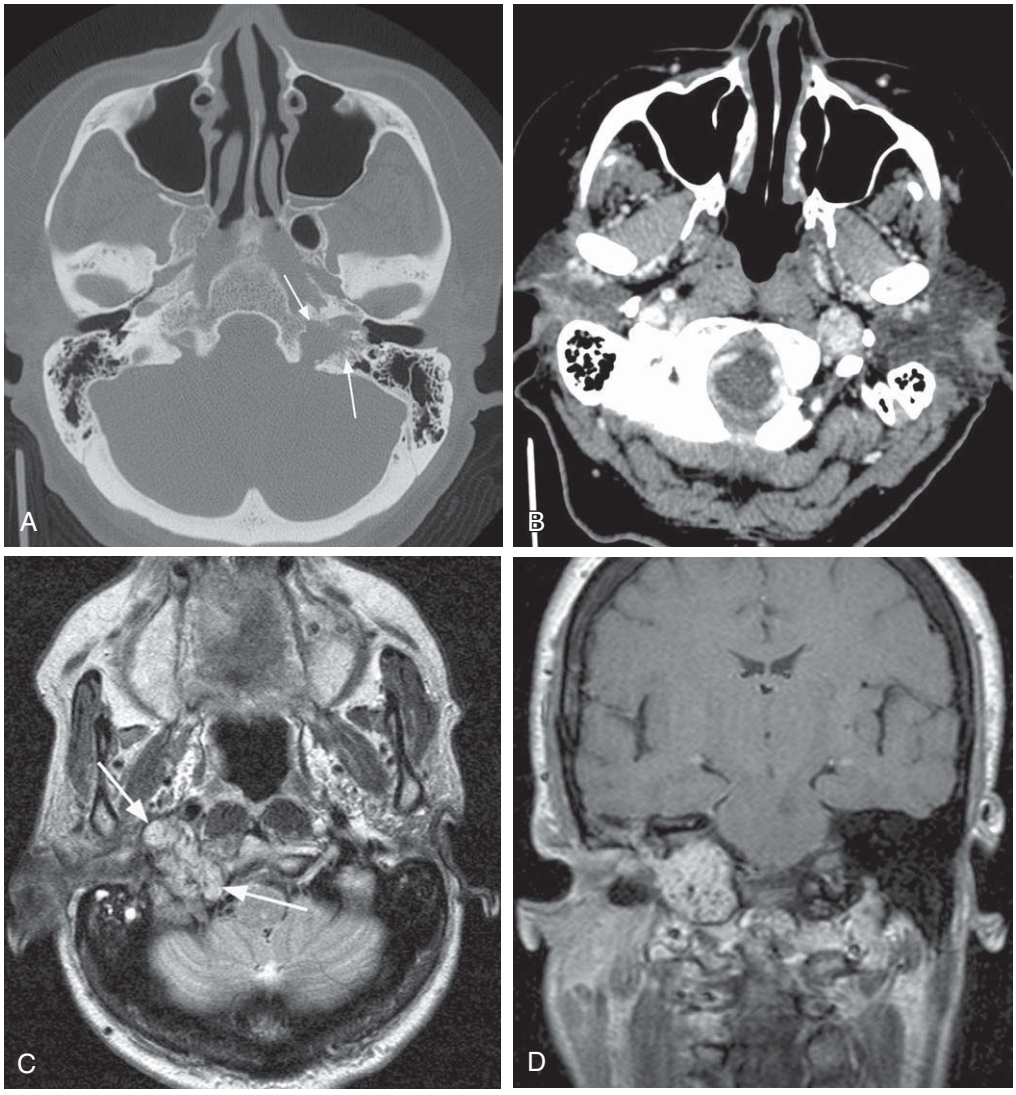

Figure 118-2. Jugular paraganglioma. **A**, Axial computed tomography (CT) image with bone algorithm and window shows subtle bony erosions and widening of the left jugular foramen *(arrows)*. **B**, Axial postcontrast CT image with soft tissue algorithm and window at a slightly lower level shows a densely enhancing mass just below the skull base on the left. **C**, Axial T2-weighted MR image in a different patient shows a hyperintense mass in the right jugular foramen *(arrows)* with internal flow voids. **D**, Coronal postcontrast T1-weighted magnetic resonance image shows enhancement of the mass with still noticeable internal vessels ("pepper").

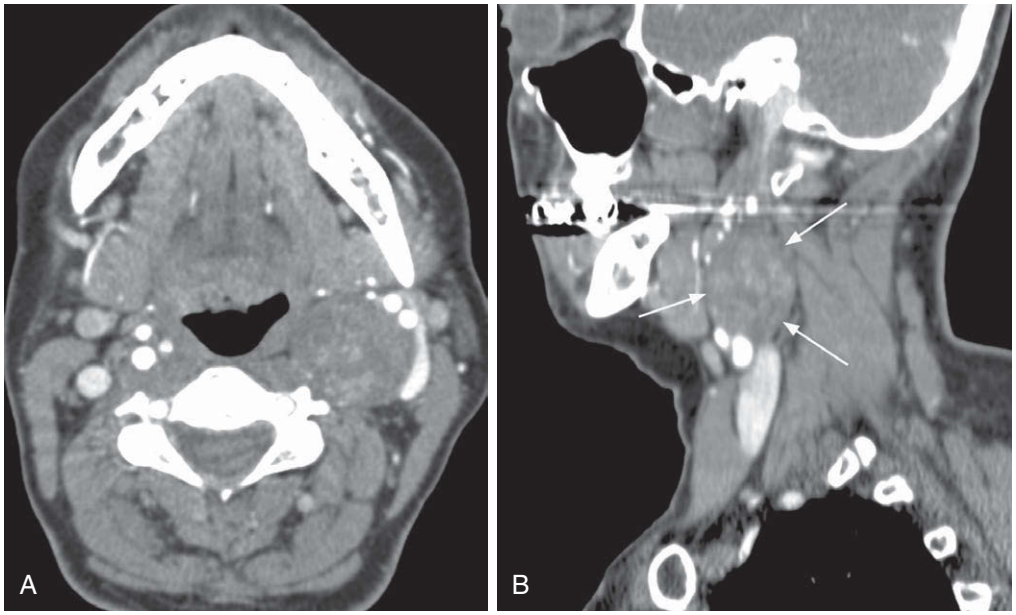

Figure 118-3. Carotid space schwannoma. **A**, Axial postcontrast computed tomography (CT) image shows a left carotid space mass with mild heterogeneous enhancement. Carotid arteries and jugular vein are displaced laterally. **B**, Reformatted sagittal postcontrast CT image demonstrates the craniocaudal extension of the tumor.

been used with some success. Kohout and colleagues[51] presented a large series of 81 patients with head and neck arteriovenous malformations in which patients were separated on the basis of the Schobinger classification and outcomes over a 20-year period were discussed. These authors found that lesions in stage I responded well to therapy and had a higher cure rate than those in stage II or III, although this did not meet statistical significance. They also found that the largest percentage of patients who did not undergo therapy were in stage I, leading to the conclusion that more potentially curable patients were left untreated. Their recommendations for intervention include early-stage lesions and rapidly progressive and painful lesions. Treatment options include both resection and embolization or a combination. Reconstructive considerations must also play a role in decision making with surgical intervention.

Peripheral Nerve Neoplasms

In addition to tumors of vascular origin, other primary tumors of the neck include those derived from peripheral nerves. Benign tumors of the head and neck arising from peripheral nerves include schwannomas and neurofibromas.

Schwannomas

Schwannomas, also called *neurilemomas,* are typically well-encapsulated, slowly growing tumors that arise from Schwann cells of peripheral nerves. These tumors are typically solitary but may occur in multiples, and up to half occur in the head and neck region.[52] Schwannomas may arise from cranial nerves such as VIII (acoustic neuromas) or X, the sympathetic chain, cervical nerve roots, or the brachial plexus. Clinically, schwannomas of the lateral neck may present as a painless neck mass. The clinical presentation of acoustic neuromas is covered elsewhere in this text (see Chapter 177). Radiologically, schwannomas typically present as a well-circumscribed mass that enhances on contrasted studies. They are usually heterogeneous and contain bright areas on T2-weighted images (Fig. 118-3A and B). Histologically, schwannomas demonstrate a characteristic cellular pattern of alternating regions containing compact spindle cells called *Antoni type A areas* and more loosely arranged, hypocellular zones called *Antoni type B areas.* Rows of nuclear palisading may be observed, and such arrangements are referred to as *Verocay bodies.* The treatment of choice of schwannomas of the neck typically involves surgical resection. Cranial neuropathies following surgical resection of head and neck schwannomas are common, and preoperative counseling of the patient as to predicted deficits is crucial in management. Preoperative speech and swallowing evaluation, as well as postoperative management, are critically important in voice and swallowing rehabilitation in these patients. Malignant transformation of schwannomas is rare.

Neurofibromas

Neurofibromas (Fig. 118-4) are benign nerve sheath tumors that may present either as a solitary neck mass or as multiple tumor nodules in association with the autosomal dominant disorder neurofibromatosis. In contrast to schwannomas, neurofibromas are unencapsulated and histologically demonstrate an interlacing bundle of spindle cells. Like schwannomas, solitary neurofibromas undergo malignant transformation uncommonly and are best treated by complete surgical resection. Neurofibromas associated with neurofibromatosis are more difficult to treat, in light of the multiple numbers of infiltrative tumors that are not well-defined. Surgery for neurofibromatosis is typically reserved for those lesions that are painful, that may cause compressive symptoms from their large size, or for lesions that are malignant. Malignant transformation of neurofibromatosis occurs more commonly than solitary neurofibromas.

Lipomas

Lipomas are benign tumors derived from adipose tissue. They are the most common soft tissue tumors of the neck and typically present as a soft, painless neck mass. Their histologic appearance is consistent with a lobular pattern of mature adipocytes. Lipomas are best treated by complete surgical resection for compressive or aesthetic reasons. The case may be made for observation of asymptomatic, small lipomas.

Benign Lesions of the Parapharyngeal Space

The parapharyngeal space is a pyramidal area bounded by the skull base superiorly, the hyoid bone inferiorly, the pterygomandibular raphe anteriorly, the vertebral fascia posteriorly, the medial pterygoid laterally, and the superior constrictor muscle medially. The space contains both the prestyloid and poststyloid compartments, and pathology in this area is based on these anatomic structures. Some tumors presented earlier in the chapter including paragangliomas and benign peripheral nerve tumors are also neoplasms of the parapharyngeal space. Salivary gland tumors are the most common tumors in the parapharyngeal

Figure 118-4. Neurofibromas in an NF-1 patient. Coronal T2-weighted magnetic resonance image with suppression of fat (short tau inversion recovery, STIR) reveals numerous bilateral masses, mostly extending along the cervical nerves.

space and are the main consideration in the differential diagnosis. A full description of both benign and malignant tumors of the salivary glands can be found elsewhere in this volume, in Chapters 87 and 88. The most common benign neoplasm of the parapharyngeal space is the pleomorphic adenoma followed by paragangliomas. Parapharyngeal space neoplasms can arise de novo or extend from surrounding structures. In the case of benign salivary gland tumors, it is hypothesized that they arise de novo from rests of salivary tissue in the parapharyngeal space. Both MRI and CT scanning are useful in assessing masses of the parapharyngeal space; however, MRI is superior in detailing the complicated neurovascular anatomy of the parapharyngeal space as illustrated in Figure 118-5A through D. Successful resection of the lesions can be accomplished by both a transparotid/transcervical approach or a strictly transcervical approach. Mandibulotomy is generally not necessary except in large tumors where wide exposure is necessary for the control of vessels. Warthin's tumors and other neurogenic tumors have been described in the parapharyngeal space but are much less common, as are salivary malignancies.[53,54]

Malignant Neoplasms of the Neck

Primary malignant neoplasms of the neck are rare entities. Few studies have elucidated the true incidence of primary malignancies of the neck because they are often described in case reports or small series or not reported at all. Thus our knowledge and data are based on these limited publications and reports on non–head- and neck-related soft tissue tumors. In the larger series of reports of these tumors of the entire head and neck region, only approximately 4 to 20 cases are listed per year.[55,56] The following discussion provides the reader with an overview of the differential diagnosis, evaluation, and management of malignant tumors of the neck.

Because malignant primary neoplasms of the neck are rare, it is imperative that consideration be given to the more common regional metastatic lesions that are often misdiagnosed before definite biopsy and treatment. Thus before addressing the "primary" tumors in this region, a brief discussion includes the unknown primary, metastatic lesions from the region and distant sites to provide the physician with the necessary foundation from which to then address primary malignancies of this complicated area.

Metastatic Lesions to the Neck

Unknown Primary

The "unknown primary" refers to a squamous cell carcinoma identified in the lymphatic structures of the neck without a known primary site. This tumor is usually identified by a mass in the neck and is typically diagnosed histologically by FNA biopsy. This diagnosis should lead the physician to repeat a thorough head and neck examination to include the entire upper aerodigestive tract, the most common site of these primary lesions. Occasionally, the unknown primary is diagnosed at the time of an excisional biopsy of a cervical lymph node. When this occurs, consideration should be given to intraoperative-directed biopsies of the most common sites harboring occult primaries (i.e., nasopharynx, base of tongue, tonsil and piriform sinus) and neck dissections. There are studies supporting both approaches (e.g., Mendenhall and Million, Robbins).

The location of the neck mass signals a clue regarding the primary site because of the well-known lymphatic drainage routes in the head and neck region and the updated classification system of neck lymph node levels. The location of the metastatic regional lymph node may direct the physician to the most common site of the primary lesion. Regional metastatic lesions from primary lesions of the oral cavity typically are found in levels 1, 2, and 3; from the oropharynx and hypopharynx, and larynx levels 2, 3, and 4; while level 5 metastases are more commonly associated with nasopharyngeal primaries. When the mass presents in the supraclavicular region, esophageal and pulmonary primary sites should be considered in addition to abdominal and pelvic locations.[57,58]

Usually, the primary site is identified during the head and neck examination or during operative endoscopy, at which time biopsies confirm the location and histology of the primary site. When the primary site cannot be identified, imaging techniques including CT, MRI, and/or PET scan have been used with varying degrees of success et al.[59,60] Fused PET/CT imaging has been helpful in determining the site of disease in unknown primary tumors of the neck. Fencl and associates found a sensitivity of 62% and a specificity of 81.9% in 190 patients with unknown primary lesions.[61] Figure 118-6 demonstrates the utility of this modality in detection of the primary site in a case of unknown primary in level 2 with detection of the primary site following PET/CT imaging. The treatment of unknown primary cancers of the neck continues to evolve, particularly related to consideration of directed biopsies, tonsillectomy, and extent of radiation therapy and neck dissection.

Metastatic Neoplasms to the Neck—Regional

Aside from the unknown primary and the far more common squamous cell carcinomas of the aerodigestive tract, it is important to not overlook the possibility of metastatic disease from other sites in the head and neck region. Common primary sites of metastatic disease include the skin of the ear, face, scalp, and neck, which often present with an enlarged lymph node in the parotid, cheek, submandibular, or cervical region. The major and minor salivary glands may present with a primary neoplasm that initially appears to be a metastatic lesion to the neck manifesting as a level 1 or level 2 neck mass. The surprising diagnosis of adenocarcinoma may lead one to an exhausting search for a primary site in the lower digestive tract only to surmise eventually that this is a primary salivary gland tumor. Another common primary site that may be diagnosed first as a primary neck neoplasm is the thyroid gland, which not uncommonly initially presents as a neck mass.[62]

Metastatic Neoplasms to the Neck—Distant

Any neck mass determined to be malignant should also be considered as originating at a distant site. Although hundreds of neoplasms have been described to metastasize to the neck, the more common distant sites include pulmonary, esophageal, renal, ovarian, cervical, and prostate.[63]

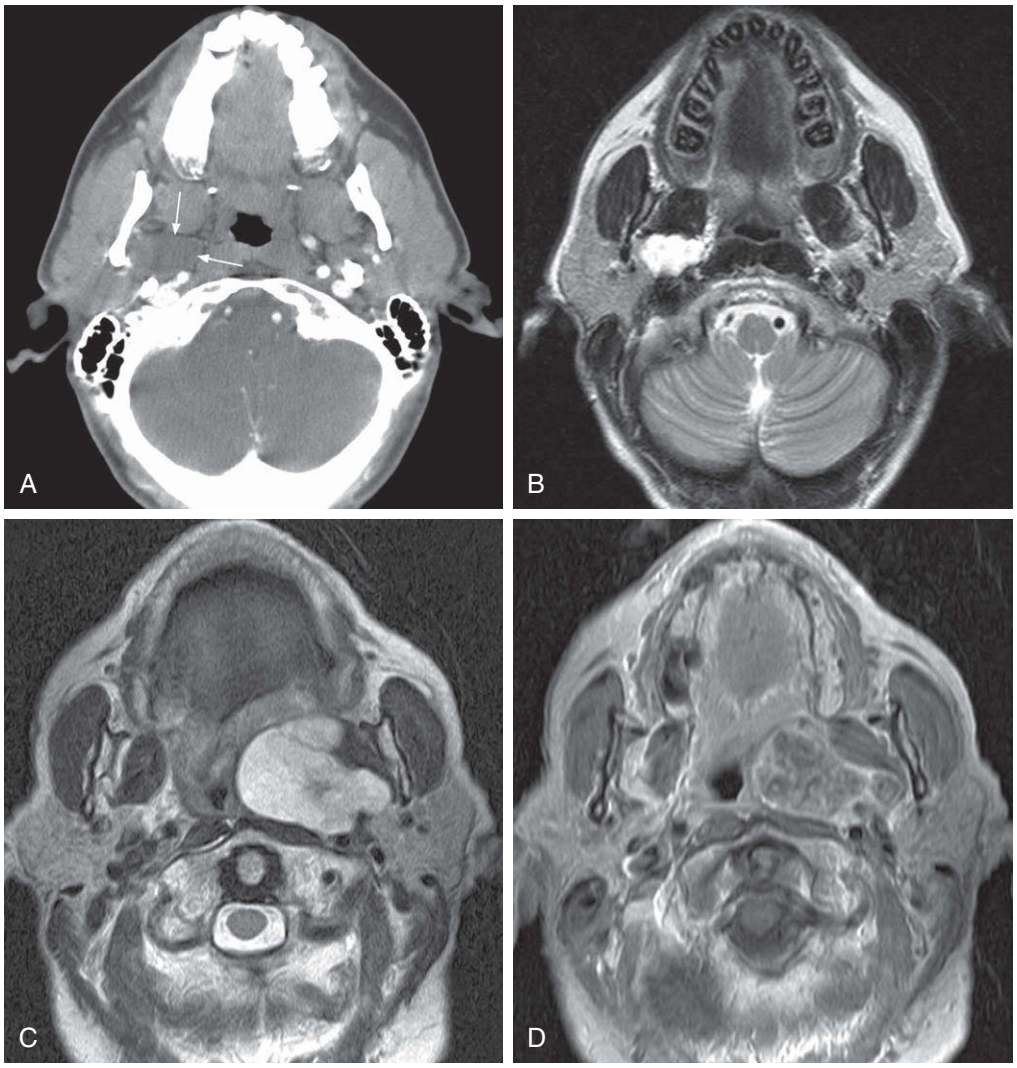

Figure 118-5. Parapharyngeal space pleomorphic adenoma. **A**, Axial postcontrast computed tomography image shows a left parapharyngeal space slightly hypodense mass *(arrows),* adjacent to the deep lobe of the parotid gland. **B**, Corresponding T2-weighted magnetic resonance (MR) image reveals characteristic brightness of the lesion comparable with the cerebrospinal fluid in the spinal canal. **C**, Axial T2-weighted MR image in a different patient shows a large well-delineated hyperintense mass in the left parapharyngeal space with prominent mass effect on the adjacent structures and displacement of the pharynx. **D**, Corresponding postcontrast T1-weighted MR image demonstrates a relatively typical heterogeneous contrast enhancement pattern of the tumor.

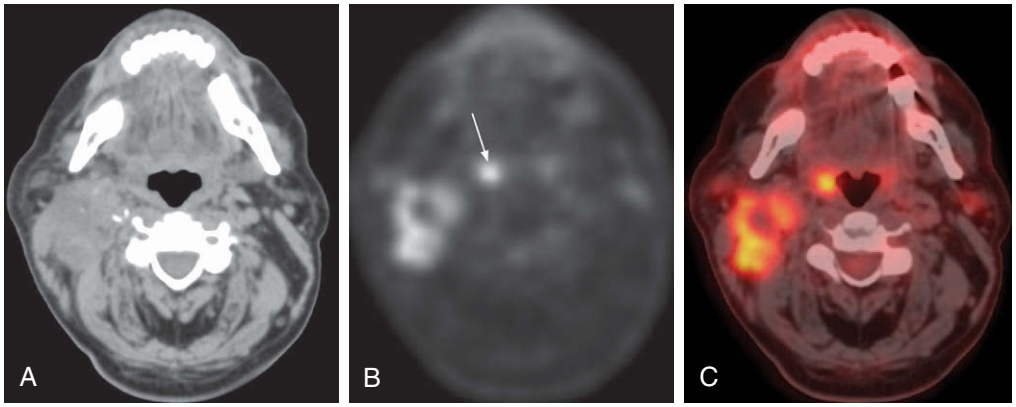

Figure 118-6. Unknown primary. **A**, Nonenhanced axial computed tomography (CT) image from positron emission tomography (PET)-CT study shows large heterogeneous level 2 lymph nodes. The palatine tonsils appear symmetric. **B**, Corresponding FDG (^{18}fluorodeoxyglucose)-PET image reveals increased metabolic activity in the nodes, as well as another focus of high FDG uptake *(arrow).* **C**, Fused PET-CT image clearly demonstrates high metabolic activity in the right palatine tonsil and metastatic nodes.

Primary Malignant Tumors of the Neck

The following discussion includes those rare malignancies that arise in the neck region without known primary sites and are considered to be isolated primary malignancies. The following neoplasms are not all inclusive but include those that most practitioners should consider in the differential diagnosis of a malignant mass in this region.

Parapharyngeal Space Neoplasms

Numerous histologic types of primary malignancies of the PPS have been reported including malignant salivary gland tumors (mucoepidermoid carcinoma, adenocarcinoma, adenoid cystic carcinoma, carcinoma ex-pleomorphic adenoma, acinic cell carcinoma); malignant neurogenic tumors; lymphoma; liposarcoma; fibrosarcoma; and malignant meningioma.[53,64-67]

Sarcomas

The neck and parotid have been described as the most common head and neck sites involved by sarcomas, although they represent less than 1% of all head and neck malignancies.[68] In the United States fewer than 5000 cases of sarcomas of all sites are reported annually with approximately 80% diagnosed in adults. Of these, only 15% to 20% are identified in the head and neck region with soft tissues of the neck and paranasal sinus region the most common sites identified. Although the etiology has not been determined, these neoplasms arise from mesenchymal cells, which may include endothelial cells, muscle, cartilage, and supporting connective tissue. More than 80% of sarcomas are derived from soft tissue, and approximately 20% arise within bone.

When all anatomic sites are considered, the most common histologic type is malignant fibrous histiocytoma. In the head and neck the most common sarcoma in children is rhabdomyosarcoma (RMS); in adults, osteosarcoma, angiosarcoma, malignant fibrous histiocytoma, and fibrosarcoma are most common. RMS is the most common sarcoma in children and is also the most common sarcoma of the head and neck region. Overall, however, malignant fibrous histiocytoma is considered the most common type of sarcoma.

Classification and Staging

Sarcomas have generally been classified and named according to the tissue of origin rather than "site" of origin. Many "soft tissue" sarcomas such as malignant fibrous histiocytoma may be diagnosed within bone, but the diagnosis depends on the histologic material for confirmation. The newer American Joint Commission for Cancer (AJCC) staging system now takes into account differing histologies and separates bone and soft tissue. The listing of types of soft tissue sarcomas is provided in Table 118-2, and the approved 2003 AJCC staging system is shown in Table 118-3 for the soft tissue histologies. The listing of bone histologies can be found in Table 118-4, and the AJCC staging system in Table 118-5.

Table 118-3

American Joint Committee on Cancer Staging System for Soft Tissue Sarcomas (2003)

Stage	Definition
Primary Tumor	
T_x	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_1	Tumor < 5 cm in greatest dimension (T_{1a}, superficial; T_{1b}, deep)
T_2	Tumor > 5 cm in greatest dimension (T_{2a}, superficial; T_{2b}, deep)
Regional Lymph Nodes	
N_x	Lymph nodes cannot be assessed
N_0	No regional lymph node metastasis
N_1*	Regional lymph node metastasis
Distant Metastases	
M_x	Distant metastasis cannot be assessed
M_0	No distant metastasis
M_1	Distant metastasis present
Histopathologic Grade	
G_x	Grade cannot be assessed
G_1	Well differentiated
G_2	Moderately differentiated
G_3	Poorly differentiated
G_4	Poorly differentiated or undifferentiated
Combined	
IA—G_{1-2}, T_{1a-b}, N_0, M_0	Low-grade, small, and superficial or deep tumor
IB—G_{1-2}, T_{2a}, N_0, M_0	Low-grade, large, and superficial tumor
IIA—G_{1-2}, T_{2b}, N_0, M_0	Low-grade, large, and deep tumor
IIB—G_{3-4}, T_{1a-b}, N_0, M_0	High-grade, small, and superficial or deep tumor
IIC—G_{3-4}, T_{2a}, N_0, M_0	High-grade, large, and superficial tumor
III—G_{3-4}, T_{2b}, N_0, M_0	High-grade, large, and deep tumor
IV—any G, any T, N_1, M_0	Any metastasis

The AJCC staging system for soft tissue sarcoma is shown in Table 118-3, although other staging systems have been described, particularly for various types of tumors. In addition, fibrosarcoma grade I (fibromatosis or desmoid tumor) and dermatofibrosarcoma are not listed under sarcoma staging. Other changes effective in 2003 include the addition of subdivisions of tumor (T) category into superficial (Ta) and deep (Tb) lesions. In general, the tumor should be described pathologically by grade as G1-G4 with tumor size less than 5 cm (T1) or greater than 5 cm (T2).

The AJCC staging system for bone sarcoma is shown in Table 118-5, although other staging systems have been described, particularly for various types of tumors. In addition, malignant lymphoma, leukemia, and multiple myeloma are not listed under bone sarcoma staging. Unlike the soft tissue sarcomas, the bone sites do not include subdivisions by depth of tumor as superficial or deep. Instead, T1 tumors are confined to within the cortex, whereas T2 tumors invade beyond the cortex.

Table 118-5

American Joint Committee on Cancer (AJCC) Staging System for Bone Sarcomas (2003)

Stage	Definition
Primary Tumor	
T_x	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_1	Tumor confined within the cortex
T_2	Tumor invades beyond the cortex
Regional Lymph Nodes	
N_x	Lymph nodes cannot be assessed
N_0	No regional lymph node metastasis
N_1	Regional lymph node metastasis
Distant Metastases	
M_x	Distant metastasis cannot be assessed
M_0	No distant metastasis
M_1	Distant metastasis present
Histopathologic Grade	
G_x	Grade cannot be assessed
G_1	Well differentiated (low grade)
G_2	Moderately differentiated (low grade)
G_3	Poorly differentiated (high grade)
G_4*	Poorly differentiated or undifferentiated (high grade)

*Ewing's sarcoma, considered G_4.

Treatment

The treatment of sarcomas involving the head and neck region involves multidisciplinary evaluation and planning in order to provide optimal chance of cure and rehabilitation. The treatment should always include consultation with a head and neck surgeon, medical oncologist, and radiation oncologist in close cooperation with a head and neck pathologist and neuroradiologist familiar with these neoplasms. Other specialists often involved in the care of these patients include dental oncologists, maxillofacial prosthodontists, speech and swallowing therapists, and rehabilitation specialists. The histology, evaluation, and treatment of each histologic type of sarcoma and site of origin will vary and thus are discussed according to the cell of origin.

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) is the most common soft tissue sarcoma in adults. Rarely, it involves the head and neck region including the soft tissues of the paranasal sinuses, neck, skull base, and parotid gland. Of 88 fibrous histiocytomas (benign and malignant) of the head and neck analyzed, the neck was the second most common site behind the sinonasal region.[69] Etiologic factors include prior radiation therapy and historical use of silica as injection material. The cell of origin has received much discussion, although consideration of fibroblastic or primitive mesenchymal cell has emerged as the leading theory.[70] Microscopically, these tumors tend to reveal histiocytes, fibroblasts, giant cells, spindle cells, and collagen with the storiform-pleomorphic form the most common. MFH is considered a high-grade sarcoma and is classified into numerous subtypes providing for a separation from the standard staging for sarcomas. There is evidence that the survival and course of the disease is related to the size and depth of these tumors.[71] The treatment is surgical with wide margins. Although elective treatment of the neck is not indicated due to the low incidence of cervical metastases, a possible exception may be the oral cavity where MFH has a higher metastatic potential to regional lymph nodes.[72,73] Local recurrence rates approach 30% with overall lymph node metastases near 10% and distant metastases approximately 35%, most of which occur within the first 2 years.[71] Recurrence seems to result in a lower surgical salvage rate for head and neck MFH than in extremities and overall survival is poorer for head and neck sites. Survival approaches 75% for patients without local recurrence following surgery and drops to 38% with local recurrence for an overall 5-year survival of approximately 51%.[74]

Rhabdomyosarcoma

RMS is a malignancy that is derived from mesenchymal cells associated with skeletal muscle differentiation. It represents the most common soft tissue sarcoma in children and accounts for 20% of sarcomas in all age groups. More than 45% of RMSs arise in the head and neck region with the highest incidence in the first decade and another peak occurring in the second and third decades. The most common sites in the head and neck from a recent series of 50 cases include the face, orbit, nasal cavity, neck, paranasal sinuses, and parameningeal sites.[75] MRI imaging provides detailed evaluation of the location and extension of disease, allowing a more precise approach to these tumors (Fig. 118-7A through D). Metastatic disease was present in 33% of cases with the most common sites being bone marrow, cerebrospinal fluid, peritoneal fluid, and lung.[75] Other reports reveal the neck soft tissue to be involved in almost 14% of adult head and neck RMSs.[76] These tumors are categorized by the Intergroup Rhabdomyosarcoma Study (IRS) into the following subtypes: embryonal, embryonal-botryoid variant, embryonal-spindle cell variant, alveolar-classic and solid variants, undifferentiated, and anaplastic. These are also commonly classified as embryonal, alveolar, pleomorphic, and mixed types. The embryonal type represents the most common RMS in both children and adults and microscopically, reveals small spindle cells with a central nucleus, although round cells often resembling lymphocytes may be seen. The botryoid variant grows in a polypoid, grapelike fashion and differs microscopically from the classic embryonal by a subepithelial condensation of tumor cells. The alveolar type occurs primarily in the teenage and young adult population and is identified histologically by an alveolar pattern of loosely arranged cells with hyperchromatic nuclei. The pleomorphic type represents approximately 17% of the adult RMS and less than 5% of pediatric cases. These lesions are found to have large, pleomorphic cells with eosinophilic cytoplasm. Immunohistochemistry has provided valuable diagnostic techniques to the histologic diagnosis of these lesions with antidesmin staining in 94%; 77% positive for desmin, 78% positive for muscle specific actin, and 30% for myoglobin.[77]

Treatment of RMS has continued to improve since the development of the IRS and now often involves combined modality treatment to include surgery, chemotherapy, and radiation therapy. Therapy has been based on the site category, which the IRS had delineated as (1) orbit, (2) parameningeal, and (3) other head and neck. Primary treatment often includes induction chemotherapy followed by radiation therapy, although concomitant therapy may be used. Surgery is typically reserved for debulking or for tumors that can be resected entirely without functional or cosmetic deformity. Neck dissection is warranted in obvious neck involvement or in clinically enlarged adenopathy. The survival rates for each of these sites were 92%, 69%, and 81%, respectively.[78-81] IRS III and IV analysis of nonorbital nonparameningeal patients does show an overall 83% five-year survival and a better prognosis in N0 patients than those with N1 disease.[82] Prognosis correlates with patient age, site of disease, histologic type, size of tumor, and

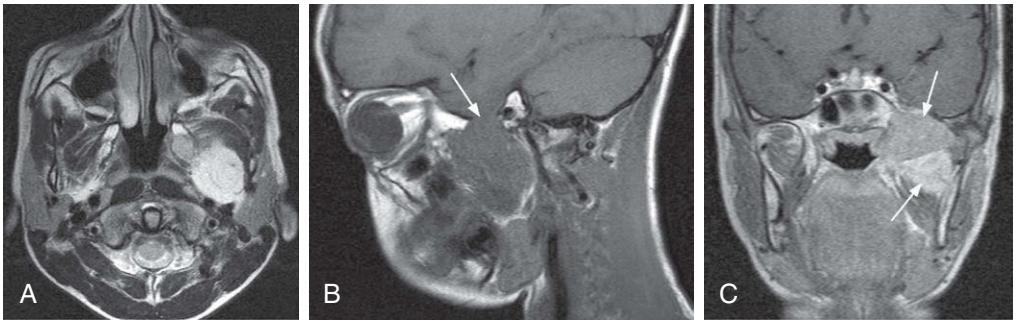

Figure 118-7. Rhabdomyosarcoma. **A**, Axial T2-weighted magnetic resonance (MR) image shows a hyperintense mass within the left masticator space. **B**, Sagittal T1-weighted MR image reveals extension of the mass through an expanded foramen ovale *(arrow)*. **C**, Coronal postcontrast T1-weighted image shows two different areas of enhancement *(arrows)* within the tumor, a relatively common finding with rhabdomyosarcomas.

metastases with botryoid and spindle associated with a better prognosis than the embryonal type, which is better than alveolar and pleomorphic.[83] Long-term follow-up has identified significant morbidity related to these treatments and long-term functional outcomes should be considered in addition to locoregional control and survival.[84] Lymphatic metastases are found to occur in 3% to 20% of RMS, although hematogenous spread may also occur.[85,86] Staging of RMS is commonly based on the IRS, which incorporates extent of disease with metastases and surgical results. It was also recommended by IRS that staging systems for this disease require ongoing analysis to confirm prognostic correlation with stage[77,85] (Table 118-6).

Osteosarcoma

Osteosarcoma of the head and neck primarily involves the mandible and maxilla with the mandible having a slightly higher incidence. The tumor rarely involves the soft tissues of the neck, although isolated regional metastases have been reported in addition to several reports involving the hyoid and larynx.[87,88] The treatment of these lesions has primarily included surgical resection with or without radiation therapy and chemotherapy. The incidence of cervical metastases is reported to be less than 10%, making routine neck dissection unwarranted.[89] The poor prognosis of soft tissue osteosarcomas of the larynx may encourage multimodality treatment for these sites in the future.

Fibrosarcoma

The neck is the second most common site of presentation of head and neck fibrosarcoma, following the paranasal sinus region. Although it can occur at any age, it is more common in adults between 40 and 70 years of age. There also exists a subset of children diagnosed before age 2. This neoplasm originates from the fibroblast and usually arises spontaneously but is known to arise in areas of prior burn scars and radiation therapy.[90,91] Histologically, they are identified by a malignant fibroblastic proliferation with variable amounts of collagen and reticulin forming a "herringbone" pattern. These lesions have a broad differential diagnosis and the well-differentiated types are commonly confused with fibromatosis and other benign processes. They typically present in the neck as a painless enlarging firm mass and have a low rate of lymphatic metastasis, thus making routine neck dissection unwarranted. There tends to be a high local recurrence rate up to 50% despite radical surgical excision with a survival of 50% to 75% and possibly higher in young children.[90,92-95] Adjuvant treatment should be based on size of the tumor, tumor grade, and status of surgical margins.[94] Review of the literature on these tumors should proceed with caution because of changes in histochemical diagnosis that may alter the inclusion of certain tumors previously classified as fibrosarcoma in earlier series.

Alveolar Soft Part Sarcoma

Alveolar soft part sarcoma is a rare tumor that is stated to involve the head and neck region in approximately 25% of cases, although it represents less than 1% of all sarcomas. The exact differentiation of this tumor remains elusive; however, muscular and neural derivations are hypothesized. Recent work has failed to recognize the cell of origin in ASPS, but identification of the unbalanced translocation der(17) t(X:17)(p11;p25) leading to the fusion gene *ASPL-TFE3* has generated two important realizations. First, the presence of this fusion protein is causative in ASPS, and second, specific immunohistochemical stain for this fusion protein has led to improved accuracy in diagnosis.[96] The common sites affected in the head and neck include the tongue and orbit with the orbit having the best prognosis. ASPS rarely involves the neck and is reported to metastasize to the neck from head and neck primary sites in less than 10% of cases making elective neck dissection unwarranted. Distant metastatic disease does occur and may not present for years or decades after the primary site was treated. Surgery remains the mainstay of treatment, although local recurrence is common. More recent reports have shown success with multimodality treatment including chemotherapy. Overall survival is approximately 65% at 5 years but drops to 50% at 10 years.[97-103]

Angiosarcoma

Angiosarcoma is another rare sarcoma representing less than 1% of all sarcomas with up to half involving the head and neck. There remains consideration that this disease involves both vascular and lymphatic vessels—hence the differentiation from lymphangiosarcoma. The etiology remains unclear, although trauma, radiation, and lymphedema have been associated with some cases.

Treatment is primarily surgical using wide margins due to the multicentric nature of these tumors and local recurrence rate nearing 50%. Postoperative adjuvant radiation therapy is also generally recommended. There is limited experience using primary or adjuvant chemotherapy in these neoplasms. Metastatic disease commonly occurs in the lung and liver, whereas regional metastatic disease is common in lesions of the scalp. Elective neck dissection is recommended for clinically and radiographically evident disease and/or primary lesion involving the scalp. The 5-year survival remains low with most reporting less than 25%.[104-110]

Epithelioid Hemangioendothelioma

This tumor is extremely rare and is described to involve the head and neck region in only approximately 10% to 15% of the cases. These lesions are found to be derived from an epithelioid or histiocytoid type of endothelial cell.[111] It does manifest a wide spectrum of biologic behavior ranging from a benign form to an extremely aggressive form of the disease, although all are vascular in nature. Aggressiveness and eventual mortality seem to be related to location of the lesion with liver lesions having a worse prognosis than other sites including the head and neck.[112] There has recently been described a more "benign" variant without distant metastases.[113] Another form has been described as *spindle cell hemangioendothelioma* but is now thought to be a benign process. This variant is referred to as *spindle cell hemangioma for solitary lesions.*[114] Variants that are more aggressive and similar to angiosarcoma most often arise in the thyroid, submandibular, and neck soft tissues, although mucosal and skin sites have been described including the paranasal sinuses, larynx, and temporal bone.[115-117] Demonstration of endothelially derived cells is important in arriving at a correct diagno-

Definitions of T, N, and M Classifications in Pretreatment Staging

Classification	Description
Tumor	
T_1	Confined to anatomic size of origin
a	<5 cm in diameter
b	≥5 cm in diameter
T_2	Extension and/or fixation to surrounding tissue
a	<5 cm in diameter
b	≥5 cm in diameter
Regional Lymph Nodes	
N_0	Regional lymph nodes not clinically involved
N_1	Regional lymph nodes clinically involved by neoplasm
N_1	Clinical status of regional lymph nodes unknown (especially with sites that preclude lymph node evaluation)
Metastasis	
M_0	No distant metastasis
M_1	Metastasis present

Survival of IRS-II and IRS-III Patients by IRSG Pretreatment Stage

	Estimated 5-Yr Survival	
Pretreatment Stage	IRS-II	IRS-III
I	91%	09%
II	73%	06%
III	52%	69%
IV	23%	30%

sis, and immunohistochemical studies for endothelial markers such as FVIII-Rag (factor VIII related antigen) and CD 34 have been found to be positive in a majority of cases.[112,118] Treatment has typically included surgical excision with possible radiation therapy. Recurrence and metastatic potential correlates with biologic aggressiveness with the more epithelioid lesions having a better prognosis, whereas the sarcomatous lesions have a higher metastatic potential and poorer prognosis.[119,120]

Chondrosarcoma

Although chondrosarcoma is typically found in the maxillary and mandibular region of the head and neck, presentation in the neck

or origin in soft tissues can occur.[121,122] Histologically, evidence of cartilage formation exists with varying degrees of differentiation and grade. These tumors are typically classified as osseous or extraosseous and may be subtyped into conventional, myxoid, and mesenchymal with mesenchymal being much more common in children and young adults. Prognosis does seem to be related to the subtype with myxoid having the worst prognosis followed by mesenchymal and conventional. There has been some controversy surrounding the histologic separation of osteoblastic chondrosarcoma from osteosarcoma. From the National Cancer Database (NCDB) report, the average age of patients with chondrosarcoma of the head and neck is 51, although more than 32% were younger than age 40. There is a slight male predominance and ethnicity reveals that non-Hispanic white constitutes more than 86% of cases. Only a small percentage of cases with regional or distant metastases at diagnosis with 5.6% and 6.7%, respectively, are found in the NCDB report.[122] Treatment includes wide surgical resection, although consideration of postoperative radiation may be entertained, particularly in high-grade tumors. Survival from the NCDB report reveals a surprisingly high survival of head and neck chondrosarcomas at 87.2% five-year and 70.6% ten-year survival, with 59.5% undergoing surgery alone and 21.0% having adjuvant radiation therapy.

Leiomyosarcoma

This is a neoplasm that generally affects older adults, although it can occur at any age. It represents 6% of all sarcomas, with 3% involving the head and neck region. The oral cavity followed by the sinonasal region and subcutaneous areas are the most common sites.[76] Although the scalp and face are the most common sites of occurrence of the subcutaneous lesions, there are reports involving the superficial and deep tissues of the cervical region.[123,124] The neoplasm develops from smooth muscle origin and histologically has a typical appearance of fascicles arranged in a perpendicular fashion with the cigar-shaped nuclei, eosinophilic cytoplasm, and paranuclear vacuoles. Most leiomyosarcomas also expresse muscle-specific actin, smooth muscle actin, and desmin.[125] These can be differentiated from fibrosarcoma by "cigar-shaped" nuclei rather than the "pointy" nuclei of fibrosarcoma. The most common presentation is a nodular dark blue or black lesion involving the dermis and epidermis, which may be tender to palpation. Those that arise in the subcutaneous tissues have a higher local recurrence, metastatic rate, and worse prognosis. Of those originating in the oral cavity, there is a high rate of local recurrence in addition to metastatic disease to the cervical nodes, lungs, and subcutaneous tissues.[76] Deep neck masses should also be considered in the differential even without skin involvement. The treatment includes wide resection with negative margins. Neck dissection may be indicated due to the potential for regional and distant metastases.[126,127] The prognosis varies greatly with site of origin and histologic variations, thus making accurate estimates of survival of each site difficult.

Liposarcoma

Although considered the most common soft tissue sarcoma of adults, constituting 12% to 18% of cases, involvement in the head and neck region is rare, occurring in an estimated 3% to 6% of cases.[76] A relationship to previous lipoma and traumatic events has been considered, yet there is insufficient evidence to confirm the relationship to the development of liposarcoma. In a review of head and neck liposarcomas, Barnes identified the larynx and hypopharynx to be the most common sites, followed closely by the neck. Others report the neck to be more commonly involved.[76,128] The prognosis appears to be dependent on site and classification with the well differentiated and myxoid having a better prognosis (75% to 100%) than the round cell and pleomorphic varieties (12% to 30%).[76,128-130] The liposarcoma is considered to occur primarily in deeper soft tissue locations than the lipoma or atypical lipoma. Although cervical metastases are rare, distant metastases have been reported primarily to the lung and liver.

Atypical Lipoma

Despite its benign behavior, the atypical lipoma or pleomorphic lipoma may be misdiagnosed as liposarcoma because of the histologic similarity. These are typically more superficial and radical treatment is not necessary if wide surgical margins are obtained. Similarly, the spindle cell lipoma has also been described and behaves in a similar fashion to the atypical lipoma. Both of these processes are more common in adult males.[131]

Malignant Hemangiopericytoma

Hemangiopericytoma (HPC) arises from the cells of Zimmerman, which occur around capillaries and postcapillary venules. The majority of HPCs of the head and neck are found in the paranasal sinuses; however, because of their cells of origin, nearly any tissue could be involved, including the neck.[132,133] The tumor primarily affects adults, although there is a subset of children from birth to 5 years of age who can be affected. The treatment is surgical because HPC has been shown to be relatively radioresistant, and the highly vascular nature of these tumors may require preoperative embolization. Adjuvant radiation therapy has been recommended for those with high-grade features and/or positive margins. Neck dissection is not necessary because lymphatic spread is rare. Varying reports of distant metastases seem to correlate HPCs with histologic pattern, mitotic figures, and proliferation indices.[134-136] The 5-year survival is near 70% and distant metastases usually portend recurrence at the primary site.

Malignant Peripheral Nerve Sheath Tumor

The malignant peripheral nerve sheath tumor (MPNST) refers to a type of neurosarcoma that represents nearly 10% of all sarcomas and behaves in an aggressive fashion with a poor prognosis. The tumor appears to have varying distribution by gender and is typically a disease of adults.[137,138] The tumor typically arises in the neck in up to half of the head and neck cases, although the sinonasal region, parapharyngeal space, parotid, and thyroid have been involved. These tumors are generally considered to occur in two settings: (1) spontaneous and (2) within the setting of a neurofibroma, particularly neurofibromatosis I (NF-1). Those arising in the latter typically occur at a younger age (fourth decade) and have a worse prognosis.[139] It is stated that for patients diagnosed with NF-1, the risk of developing an MPNST is 2%.[140] The typical presentation is of a progressive swelling with many presenting with pain in the region. Those with a history of NF-1 may describe a long history of a mass with a recent rapid enlargement. Associated neurogenic symptoms of weakness or paresthesias may be associated. Microscopically, they typically reveal atypical spindle cells similar to Schwann cells that are closely associated with a peripheral nerve. There remains significant controversy and variability in the histopathologic diagnostic criteria. The treatment includes wide resection with clear margins and postoperative radiation with margin status and tumor size correlating with survival.[139,141,142] The prognosis is poor despite aggressive treatment with more than 40% developing local recurrence. The presence of lymphatic metastases is rare.[138,141,143,144]

Synovial Sarcoma

Synovial sarcoma (SS) comprises 6% to 10% of all soft tissue sarcomas and 3% to 10% of all head and neck sarcomas. This neoplasm has been described to arise in the periarticular regions of the body, although the sites of the head and neck are not usually in these areas. This tumor typically arises in people aged 20 to 40 with the hypopharyngeal and retropharyngeal regions the most likely sites of the head and neck. It is thought to be derived from a pluripotential mesenchymal cell with both epithelioid and spindle differentiation. Microscopically, the tumor is found to have a predominant spindle cell component with cuboidal and columnar cells surrounding glandular areas and may have calcifications in up to 30% of cases.[145,146] Prognosis appears related to tumor size, mitotic indices, high grade, local recurrence, and tumor necrosis, although absence of calcifications and ploidy may also be related.[145,147] The symptoms on presentation are usually related to mass effect, although a painful mass may be identified. The treatment requires wide surgical resection. Chemotherapy may also be beneficial when used preoperatively.[148,149] Neck dissection is not necessary due to the absence of cervical metastases. The 5-year survival is 47% to 58% with up to 40% incidence of local recurrence.[76,146,150]

Malignant Giant Cell Tumor

The malignant giant cell tumor (MGCT) of the head and neck region is extremely rare and may be considered to be radiation induced after patients are treated for a benign giant cell tumor. MGCTs account for less than 10% of all GCTs. The sinonasal region and mandible are the most common sites in the head and neck.[151,152] The secondary MGCT appears more common than primary MGCTs, which arise de novo without prior evidence of a benign GCT. Overall 5-year survival of secondary MGCTs was 32%.[153] Metastatic lesions of GCT are usually identified in the lungs.[154]

Ewing's Sarcoma

Ewing's sarcoma represents a malignancy derived from primitive neuroectoderm and is the second most common bone tumor in children. Of 70 cases described at a single institution, only 5 (7.1%) occurred in the head and neck region.[155] These are separated into osseous and extraosseous types with approximately 75% occurring in the first 2 decades. Primitive neuroectodermal tumor (PNET) is a diagnosis that has many overlapping features with extraosseous Ewing's sarcoma and may be related.[89] PNET occurs in the paraspinous regions in approximately 50% of cases. The most common head and neck sites for Ewing's sarcoma include the mandible, maxilla, skull, and sinonasal region, although soft tissue sites have been described.[156] The incidence of lymphatic spread to the cervical nodes is uncommon. Treatment involves multimodality therapy including chemotherapy, whereas surgery may be necessary for complete control of the primary site and for reconstructive considerations. Radiation may be beneficial in combination with these other modalities.

Solitary Fibrous Tumor

There exists a wide range of benign and malignant fibrous tumors with varying degrees of local, regional, and metastatic growth potential. The one that deserves mention because of its frequency in the head and neck, particularly in children, is desmoid fibromatosis. These tumors have a wide range of behavior and very low mortality rate. Treatment includes wide resection because of the high local recurrence rate of 21% to 47%.[69,157,158]

Lymphoma

Lymphoma deserves mention because of the common presentation in enlarged cervical lymph nodes but is presented in detail in Chapter 119.

Melanoma

Although melanoma may arise or metastasize to the neck without a known primary site, a thorough evaluation should be undertaken to identify the primary site. A review of 300 cases of melanoma by Balm[159] revealed that 17 (5.7%) presented with a cervical lymph node without known primary. The treatment included surgery, and the 5-year disease-specific survival was 48% with a median of 36 months, which correlated with other patients with a stage II cutaneous melanoma.[159]

In a large series of head and neck melanomas, elective neck dissection and therapeutic neck dissection did not appear to improve survival over patients undergoing delayed neck dissection for regional metastases developing later than 3 months following primary treatment. There was, however, a higher incidence of distant metastatic disease in patients who did develop regional metastatic disease.[160]

Squamous Cell Carcinoma Arising in Branchial Cleft Cyst

Rarely, squamous cell carcinomas have been documented to arise within branchial cleft cysts of the neck. Cytopathologic diagnosis is difficult but should be considered in the differential diagnosis of a cystic neck mass. Final confirmation of the diagnosis should follow the criteria proposed in differentiating these tumors from cystic squamous cell carcinoma of cervical lymph nodes.[161]

Carcinoma Arising within Thyroglossal Duct Cyst

This extremely rare occurrence has been described, providing evidence for cytologic examination of thyroglossal duct cysts in suspicious cases.[162-165]

Although it is understood that many soft tissue tumors may metastasize or originate in the neck region, the most common remains squamous cell carcinoma of the head and neck aerodigestive tract. A broad differential is required when evaluating the neck mass, particularly in children, making a systematic approach essential to the diagnosis. Because of the limited number of prospective and retrospective studies of nonsquamous malignancies involving the neck, it is essential that the clinician remains updated on the optimal treatment and incorporates a multidisciplinary approach to these tumors.

Summary

Neoplasms of the neck are rare but must be considered in any neck mass allowing for optimal evaluation and management. The well-known diagnostic algorithm with FNA should be followed for any neck mass because the overwhelming majority of malignancies are regional metastases from skin and upper aerodigestive tract primaries. When atypical cells are identified on FNA biopsy or unusual findings on radiologic studies, a primary tumor of the neck region should be considered. The ultimate diagnosis often requires surgical resection, which may entail simultaneous wide resection with confirmed clear margins and neck dissection to afford the patient the best chance for cure. Review of the existing literature for rare tumors including sarcomas and consideration of clinical trials will allow for long-term improvement in locoregional response and survival.

Acknowledgment

We would like to acknowledge Anne Naumer MS, CGC for her expertise in preparing the section on familial paraganglioma syndromes and the role of genetic counseling.

CHAPTER ONE HUNDRED AND NINETEEN

Lymphomas Presenting in the Head and Neck

Nancy L. Bartlett

Key Points

- Surgery does not play a role in the curative treatment of lymphomas.
- An adequate biopsy is critical for rendering an accurate diagnosis and classification of lymphoma. An excisional or incisional biopsy is the preferred procedure for confirming a new diagnosis of lymphoma.
- Specimens should be submitted to the pathologist in saline, along with the patient's clinical history and differential diagnosis, in order to perform appropriate testing such as flow cytometry.
- Highly aggressive lymphomas such as Burkitt's or lymphoblastic lymphoma should be referred to a medical oncologist emergently.
- Limited stage Hodgkin's lymphoma and diffuse large B-cell lymphoma presenting in the head and neck are highly curable with combined modality therapy including combination chemotherapy and involved-field radiotherapy.
- Mucosa-associated lymphoid tissue lymphomas of the thyroid and salivary glands are rarely life-threatening and should be treated with low-dose involved-field radiotherapy.
- Diffuse large B-cell lymphoma of the paranasal sinuses is associated with a high risk of central nervous system relapse.
- NK/T cell lymphoma nasal type has an aggressive clinical course and frequently causes marked tissue destruction and necrosis. Wide-field radiotherapy to a dose of at least 50 Gy is the most effective therapy.

Lymphomas are malignant neoplasms of lymphocytes and their precursor cells. Historically, lymphomas were classified merely by their histologic appearance, specifically cell size (e.g., small, large, mixed) and architecture (nodular or diffuse). The current classification system is the World Health Organization (WHO) system, which defines specific subcategories of lymphoma according to the immunologic and molecular characteristics of the lymphoma cells, as well as the morphology.[1] Most subtypes of lymphoma can potentially involve the head and neck, either as the only site of disease or as one of many sites of involvement. Because an enlarged cervical or supraclavicular lymph node is a common presentation of many lymphomas, otolaryngologists are often the first physicians to evaluate and biopsy these patients, as well as the first to inform patients of their diagnosis. Understanding the pathology, clinical features, treatment, and prognosis for each of the nodal and extranodal lymphoma subtypes that can present in the head and neck will allow for a more accurate and efficient evaluation. In addition, a brief discussion of the diagnosis and prognosis by the head and neck specialist is extremely valuable to patients and their families while they are awaiting an initial appointment with a medical oncologist.

Epidemiology

It is estimated that 74,300 new cases of lymphoma will be diagnosed in the United States in 2008, including 66,100 cases of non-Hodgkin's lymphoma (NHL) and 8200 cases of Hodgkin's lymphoma (HL).[2] The incidence of NHL rose dramatically between 1970 and 1995 but has stabilized over the past 14 years. The cause of this increase is incompletely understood. The human immunodeficiency virus (HIV) epidemic and the increase in NHL after solid-organ transplants account for only a minority of the new lymphomas. The incidence of NHL is slightly higher in men than women and increases exponentially with age. The most reproducible environmental risk factor includes exposure to certain pesticides or herbicides, and inconsistent associations have been reported with hair dyes, certain occupations, smoking, consuming foods high in animal fat, and receiving blood transfusions.[3] Infectious agents including Epstein-Barr virus (EBV), HIV, human T-cell leukemia virus (HTLV)-1, *Helicobacter pylori, Chlamydia psittaci,* hepatitis C, HHV8, and *Borrelia burgdorferi* have been proposed as etiologic agents in the pathogenesis of some cases of NHL.[4] Other factors associated with a significant increased risk of NHL include autoimmune disorders, most commonly Sjögren's syndrome and rheumatoid arthritis, although it is difficult to separate the effects of immunosuppressive drugs used to treat these diseases and the underlying autoimmune disease.

HL has a bimodal age distribution in developed countries, with the first peak occurring in the third decade of life and the second peak occurring after age 50 years. Men have a slightly higher incidence than women. There is an association between HL and factors that decrease exposure to infectious agents at an early age including advanced maternal education, early birth order, decreased number of siblings, and living in a single-family residence. A history of infectious mononucleosis increases the risk of HL twofold to threefold and suggests EBV as an etiologic agent.[5] There is a slightly increased risk of HL in patients infected with HIV and other conditions associated with chronic immunosuppression. An increased incidence among first-degree relatives, a significant concordance rate among identical but not fraternal twins, and linkage with certain HLA types suggest a genetic predisposition for

Figure 119-1. Neck computed tomography scan of a 23-year-old woman with classical Hodgkin's lymphoma showing a conglomeration of bulky, right supraclavicular lymph nodes adjacent to the right thyroid lobe.

HL.[6] The incidence of HL varies significantly with geography, suggesting either an environmental or a genetic association. HL is rare in Japan, but interestingly, the incidence increases in Japanese Americans, suggesting an important environmental component.[7]

Clinical Presentation of Lymphomas of the Head and Neck

Lymphoma should be included in the differential diagnosis of any patient with adenopathy, salivary gland enlargement, or a mass in Waldeyer's ring (WR), the nasal cavity, the paranasal sinuses, or the thyroid. Approximately 75% of lymphomas presenting in the head and neck are nodal and 25% extranodal. An accurate history and physical examination can provide important clues to the diagnosis.

Classical HL occurs most commonly in young adults and usually presents as painless lymphadenopathy in the cervical and/or supraclavicular regions. In contrast to NHL, HL spreads in a contiguous pattern and rarely involves the preauricular or occipital nodes or extranodal sites of the head and neck such as the tonsil or sinus. Infraclavicular involvement in patients with bulky supraclavicular nodes is common in HL but is rarely seen in NHL. Bulky, matted nodes are not uncommon (Fig. 119-1). Although staging studies reveal mediastinal adenopathy in more than 85% of patients with HL, symptoms of cough, chest pain, dyspnea, and superior vena cava (SVC) syndrome are uncommon, even in patients with bulky mediastinal disease. Systemic symptoms or "B" symptoms including fevers (temperature > 38° C), drenching night sweats, and weight loss occur in 30% to 40% of patients with stage III or IV disease, but in less than 10% of patients with stage I or II disease. A hallmark of HL, generalized, severe pruritus, occurs in approximately 25% of patients with HL, often precedes the diagnosis by months, can be a presenting symptom of both early and advanced-stage disease, and has no known prognostic significance. Alcohol-induced pain in involved lymph nodes is a rare symptom of HL (<1%). A rare subtype of HL, nodular lymphocyte-predominant HL (LPHL), usually presents as a solitary cervical, axillary, or inguinal lymph node. In LPHL the mediastinum is generally spared, and in contrast to the contiguous pattern of lymph node involvement in classic HL, there is no consistent pattern of spread.

Presenting symptoms of NHLs vary substantially depending on the pathologic subtype of NHL and the site(s) of disease. Indolent lymphomas such as follicular (FL) or small lymphocytic (SLL) lymphomas often present with painless, peripheral adenopathy. Multiple soft, mobile, bilateral cervical nodes ranging in size from 1 to 2 cm are common presentations of both FL and SLL (Fig. 119-2). Matted peripheral lymph nodes are uncommon. Isolated head and neck involvement is unusual with these subtypes of lymphoma, and examination of axillary and inguinal regions usually reveals additional enlarged nodes. SLL can involve the tonsillar regions. Because spontaneous regressions occur in up to 20% of patients with FL, the patient may describe a history of waxing and waning adenopathy, with nodes present for years in some cases. Most patients with indolent lymphoma feel well at presentation, and B symptoms including fevers, drenching night sweats, and weight loss are unusual. Patients with SLL frequently have involvement of the peripheral blood, and a complete blood count may reveal a lymphocytosis. Peripheral blood flow cytometry may provide a diagnosis and obviate the need for a tissue biopsy. Indolent lymphomas are uncommon before age 50.

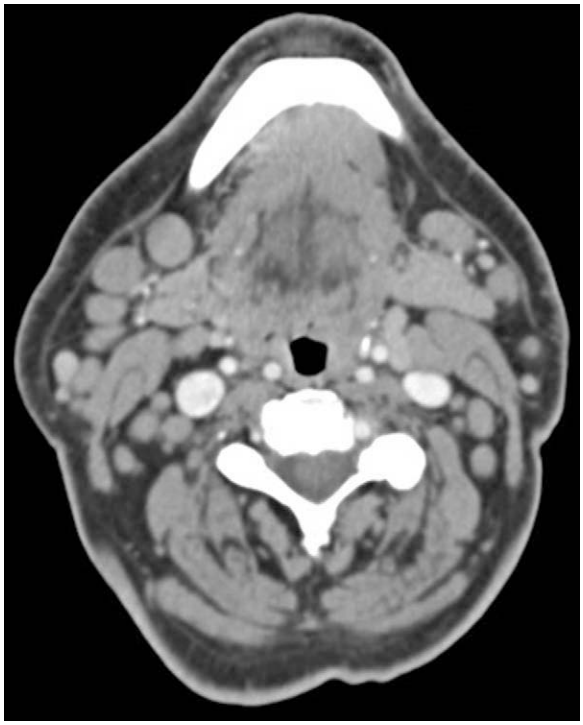

Figure 119-2. Neck computed tomography scan of an 81-year-old man with small lymphocytic lymphoma showing bilateral diffuse cervical lymphadenopathy.

Mucosa-associated lymphoid tissue (MALT) lymphomas, indolent lymphomas occurring in extranodal sites, can present as an isolated swelling in the thyroid or a salivary gland, most commonly the parotid gland. Bilateral parotid involvement can occur and occasionally a history of stable enlargement over months or years is elicited. Cases of MALT lymphoma have also been reported in the sinuses, oral cavity, and nasal cavity. MALT lymphomas of the head and neck are often associated with autoimmune disorders, such as Hashimoto's thyroiditis and Sjogren's syndrome, and occasionally precede the diagnosis of the autoimmune disorder.

Many aggressive lymphomas, the most common being diffuse large B-cell (DLBC), also often occur as painless cervical or supraclavicular adenopathy, without other associated symptoms. Fevers, night sweats, or weight loss occur in about 20% of patients with advanced-stage disease. Primary extranodal large cell lymphomas are common, accounting for 15% to 20% of all large cell lymphomas and can present in the tonsils, nasopharynx, oropharynx, thyroid, salivary glands, or sinuses. The presentation of extranodal lymphomas of the head and neck is discussed in more detail later in this chapter.

The very aggressive lymphomas, lymphoblastic and Burkitt's, are rare in the adult population, but can occur with acute symptoms and can be life threatening without rapid intervention. In adults, lymphoblastic lymphomas occur most commonly in young men, and frequently occur with acute respiratory compromise due to bulky mediastinal adenopathy, and pleural or pericardial effusions. Occasionally supraclavicular adenopathy is present and the otolaryngologist will be called upon to obtain diagnostic tissue emergently.

Biopsy Techniques and Specimen Handling

Because surgery does not play a role in the curative treatment of lymphomas, the goal of biopsy is to provide enough material for an accurate diagnosis, while minimizing the cosmetic effect of the biopsy. If the biopsy involves a nodal site, sample the largest node or any node

Table 119-1

Proposed World Health Organization Classification for NHL

- B-cell neoplasms
  - Precursor B-cell lymphoblastic leukemia/lymphoma*
  - Mature B-cell neoplasms
    - B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma
    - B-cell prolymphocytic leukemia
    - Lymphoplasmacytic lymphoma
    - Mantle-cell lymphoma
    - Follicular lymphoma†
    - Marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type
    - Nodal marginal zone lymphoma ± monocytoid B cells
    - Splenic marginal zone B-cell lymphoma
    - Hairy cell leukemia
    - Diffuse large B-cell lymphoma†
    - Subtypes: mediastinal (thymic), intravascular, primary effusion lymphoma
    - Burkitt's lymphoma
    - Plasmacytoma
    - Plasma cell myeloma
- T-cell neoplasms
  - Precursor T-cell lymphoblastic leukemia/lymphoma*
  - Mature T-cell and NK-cell neoplasms
  - T-cell prolymphocytic leukemia
  - T-cell large granular lymphocytic leukemia
  - NK-cell leukemia
  - Extranodal NK/T-cell lymphoma, nasal-type
  - Mycosis fungoides†
  - Sézary syndrome
  - Angioimmunoblastic T-cell lymphoma
  - Peripheral T-cell lymphoma (unspecified)†
  - Adult T-cell leukemia/lymphoma (HTLV1$^+$)†
  - Systemic anaplastic large-cell lymphoma (T- and null-cell types)†
  - Primary cutaneous anaplastic large-cell lymphoma†
  - Subcutaneous panniculitis-like T-cell lymphoma
  - Enteropathy-type intestinal T-cell lymphoma
  - Hepatosplenic γ/δ T-cell lymphoma

*The classification of acute lymphoid leukemias will expand on the classification of precursor B-cell and T-cell malignancies, incorporating both immunophenotypic and genetic features.
†Morphologic and/or clinical variants of these diseases are not listed, for the purpose of clarity and ease of presentation.
NHL, non-Hodgkin's lymphoma; NK, natural killer.

growing out of proportion to other nodes in order to rule out transformed lymphoma. Sampling a single site is usually adequate.

Tissue biopsy is essential in the diagnosis and management of patients with lymphomas. Recent advances in the immunology and molecular biology of lymphomas, as well as new diagnostic reagents and methods, have resulted in more precise diagnoses. The most recent WHO classification includes more than 25 subtypes of NHL, with B-cell neoplasms representing 80% to 90% of NHLs (Table 119-1). When the clinical history is suggestive of lymphoma, but initial histologic review and immunohistochemistry by flow cytometry or on paraffin-embedded tissue sections are nondiagnostic, molecular testing for T-cell receptor and immunoglobulin heavy-chain gene rearrangements should be considered. Cases in which the pathologic diagnosis seems inconsistent with the clinical history should be reviewed by an expert hematopathologist.

The proper handling of specimens for adjunctive diagnostic tests is critical whenever lymphoma is suspected. Specimens should not be transported on dry towels or surgical sponges; they should be submitted to the pathologist in saline along with the patient's clinical history and differential diagnosis. Specimens should not be held overnight or for extended periods before processing by the pathology laboratory. If there will be a delay in processing the specimen, preserve a portion of the specimen in formalin to maintain the architecture. Crushed specimens are extremely difficult to evaluate for lymphoma.

The pathologist usually reserves fresh cells or frozen tissue for immunophenotyping and molecular diagnostics as needed. Immunophenotyping is performed, either by flow cytometry or using immunohistochemical methods, on slides prepared from frozen tissue or paraffin-embedded fixed tissue, on nearly all new cases of NHL or HL. Flow cytometry requires a fresh cell suspension, but it offers the advantage of preservation of antigens. Although fewer antigens are preserved in fixed and embedded tissues, immunohistochemical staining of paraffin-embedded specimens allows analysis of archival specimens and offers the benefit of correlation with architectural and cellular details.

Application of the World Health Organization classification system requires the integration of clinical, morphologic, cytogenetic, molecular, and immunophenotypic features to accurately characterize lymphoproliferative disorders. Therefore it is essential that all available clinical and diagnostic information related to a specimen be made available to the hematopathologist including any prior diagnosis of lymphoma.

Fine-Needle Aspiration

Because of the improved diagnostic methods previously discussed, a less invasive procedure such as fine-needle aspiration (FNA) or core-needle biopsy may lead to a precise diagnosis without the need for surgery in some cases of lymphoma. Although FNA is a rapid and cost-effective method, it provides only cytologic material. Cytology alone is less useful for the initial diagnosis of lymphomas because the architectural pattern is often necessary for accurate subclassification. In addition, FNA often does not provide adequate tissue for immunophenotyping, especially when the lymphoma is associated with extensive fibrosis, limiting the ability to aspirate cells. However, if an adequate number of cells can be aspirated, many pathologists agree that FNA may be adequate in the setting of *relapsed* disease because it is often easier to confirm a previous diagnosis than to render an initial diagnosis on the basis of limited material.

Due to the lack of fibrosis and a unique cytologic appearance and immunophenotype, small lymphocytic lymphoma and lymphoblastic lymphoma can often be accurately diagnosed solely on the basis of a fine-needle biopsy. Lymphoblastic lymphoma (LL), a high-grade lymphoma, often presents with SVC syndrome or severe dyspnea and progresses extremely rapidly. The ability of pathologists to provide a preliminary diagnosis within hours on the basis of an FNA of a supraclavicular or mediastinal node may allow earlier initiation of therapy. In one report of eight children with LL, FNA was employed as the initial diagnostic procedure.[8] Immunophenotyping established the T cell derivation in all cases, and treatment was initiated only on the basis of FNA results in six cases. Two patients had subsequent surgical biopsies that confirmed the FNA diagnosis of LL. In a separate retrospective study, nine out of nine cases of lymphoblastic lymphoma were correctly identified on the basis of specimens obtained by FNA.[9]

Stewart and colleagues[10] reported that FNA of *palpable* lymph nodes correctly identified 61 of 67 (91%) malignant lymphomas, with 27% of the cases representing recurrent lymphomas. However, in a more recent study, Hehn and colleagues[11] found that a specific and complete histologic diagnosis of lymphoma was obtained in only 27 of 93 FNA attempts (29%) at initial diagnosis, and in only 9 of 22 FNA attempts (41%) done in the setting of recurrent disease. Importantly, these 115 needle aspirations were interpreted by 70 different pathologists in the community setting and only 43% had concurrent ancillary studies such as flow cytometry. Howlett and colleagues[12] reported results of an audit of 276 patients who underwent FNA and subsequent surgery for evaluation of a "neck lump" at one of five hospitals in the Sussex cancer network in the United Kingdom during 2004. Of the

276 aspirations, 105 (38%) were nondiagnostic, 54 of 104 (52%) in the neck node group, 23 of 54 (43%) in the salivary gland group, and 28 of 118 (24%) in the thyroid group. Only patients in the thyroid group had ultrasound guidance for the procedure. Interestingly, 15 of the 54 nondiagnostic FNAs in the neck node group were NHL at surgery, as well as 3 of the 23 cases in the salivary gland group and 1 of the 28 thyroid cases. Additionally, 2 of 12 neck node aspirations and 2 of 24 salivary gland aspirations diagnosed as benign revealed NHL at surgery.

An accurate diagnosis of lymphoma by FNA requires an experienced sampling team, an expert cytopathologist, and the facilities to perform and interpret appropriate ancillary tests. The continued identification of unique immunophenotypic and molecular changes associated with many subtypes of lymphoma is likely to make this procedure more promising as the sole method of diagnosis in the future.

Core-Needle Biopsy

The use of percutaneous core-needle biopsies can sometimes overcome the limitations of FNA by retaining the architecture of the tissue and providing serial sections for histochemical and immunocytochemical stains. If a core-needle biopsy is technically feasible, use the largest-gauge needle possible (12 to 16 gauge) and obtain multiple cores. In general, both the peripheral and central portion of the mass should be sampled to avoid obtaining only necrotic tissue.

Several studies evaluating core-needle biopsy for lymphoma diagnosis have been published.[13-16] In one study, 241 patients with lymphoma underwent core-needle biopsy as their initial biopsy.[13] Overall, an 82.5% success rate was observed. Several studies included both patients undergoing initial evaluation, as well as patients with suspected relapse or progressive disease.[14-16] Core-needle biopsy procedures yielded sufficient material for formulation of a treatment plan in 83% to 93% of patients. A recent report of 88 patients undergoing ultrasound-guided core-needle biopsy for head and neck masses included 16 patients with a final diagnosis of lymphoma.[17] In 3 of 16 patients inadequate tissue was obtained by core-needle biopsy, and the patients had subsequent excisional biopsies. In 12 of 13 with "adequate" tissue to make a diagnosis of lymphoma, full subclassification of the lymphoma was possible and treatment initiated on the basis of the core-needle biopsy. Importantly, these 12 patients did not have an open biopsy to confirm the results of the needle biopsy. Gong and colleagues[18] compared results of FNA and core-needle biopsy in 74 patients with lymphoma. FNA with flow cytometry was insufficient in 47% of patients and core-needle biopsy was insufficient in 28% of patients.

Open Biopsy

Despite encouraging results with limited needle biopsies, both oncologists and hematopathologists prefer an excisional or incisional biopsy as initial diagnostic tissue in nearly all cases of lymphoma. Because head and neck masses can usually be biopsied with less invasive procedures than intrathoracic or intra-abdominal lymph nodes, there should be no reason to potentially compromise the diagnosis due to limited material.

Prebiopsy Corticosteroids

Historical teaching dictates that patients with suspected lymphoma should not receive corticosteroids before biopsy because of the theoretic risk of obscured results because of rapid tumor response. In reality, except in the rare case of lymphoblastic lymphoma, steroids are unlikely to have a significant detrimental effect if tissue is obtained within 24 to 48 hours of the first dose. In one study of 86 children with mediastinal lymphoma, 23 received prebiopsy corticosteroids. In five (22%) an adverse effect on the pathologic diagnosis was observed, one patient with HL and four with probable lymphoblastic lymphoma.[19] However, the only indication for prebiopsy steroids should be severe, life-threatening airway compromise. Although patients with SVC syndrome can be quite symptomatic, these symptoms are not life threatening over the short term and steroids should not be administered until diagnostic tissue is obtained. If lymphoblastic lymphoma is suspected, every effort should be made to obtain tissue within 1 day of presentation and before administration of steroids.

Nodal Lymphomas of the Head and Neck

Hodgkin's Lymphoma

As described earlier, most patients with HL present with asymptomatic peripheral adenopathy, most commonly cervical and supraclavicular. The incidence peaks between 15 and 40 years of age. Severe, generalized pruritus is common in HL, rare in NHL, and often precedes the diagnosis by months. Systemic symptoms including fever of greater than 38° C for 3 consecutive days, drenching night sweats, or unexplained weight loss of more than 10% of body weight in the preceding 6 months occur in about 25% of patients with HL, but they are uncommon in early-stage disease.[20] Pruritus, systemic symptoms, and many of the laboratory abnormalities seen in HL are probably a result of cytokine production by Reed-Sternberg cells.

HL is a neoplastic proliferation of Reed-Sternberg (R-S) cells or R-S variants, large cells with abundant cytoplasm and multiple or multilobed nuclei. R-S cells are surrounded by host inflammatory cells including lymphocytes, plasma cells, neutrophils, and eosinophils. R-S cells are derived, in most cases, from germinal center B cells.[21] The World Health Organization classifies HL as either "classic" HL or nodular LPHL. LPHL and classic HL have different natural histories, prognoses, and treatments.[21] Immunohistochemical studies accurately distinguish LPHL from classical HL and should be performed if histology is equivocal. In classical HL, the large atypical cells generally express CD15 and CD30, whereas other T- and B-cell–associated antigens are usually negative. In contrast, the tumor cells of LPHL are $CD20^+$ (a pan-B-cell antigen), $CD45^+$ (leukocyte common antigen), $CD15^-$, and variably reactive for CD30, an immunophenotype often seen in B-cell NHL. Flow cytometry is nondiagnostic in HL.

Staging

The Ann Arbor staging system for HL and NHL is detailed in Table 119-2. The designation E applies to extranodal involvement, which is limited in extent and contiguous with lymph node disease. Extranodal involvement of HL of head and neck sites is extremely rare. Proper staging requires computed tomography (CT) scans of the chest, abdomen, and pelvis. CT scans of the neck are optional and probably add little to a thorough physical examination but may aid in designing radiotherapy portals if radiotherapy is planned. The mediastinal mass ratio (MMR), defined as the ratio of the maximal transverse diameter of the mediastinal mass to the maximal transverse intrathoracic diameter, is an important prognostic factor and should be calculated in all patients with significant mediastinal adenopathy. An MMR greater than 0.33 by chest radiograph (CXR) or 0.35 by CT portends a worse prognosis and may influence treatment recommendations. Positron emission tomography (PET)/CT upstages and potentially alters treatment in 10% to 20% of patients with HL compared with CT alone and should be considered in the initial staging of patients with early-stage disease.[22,23]

Treatment and Prognosis

The treatment of HL has been a true success story, with nearly 80% of all patients having durable remissions including 90% to 95% of patients with nonbulky stage I to II disease, 80% of patients with bulky stage I to II disease, and 70% of patients with stage III to IV disease. Current efforts are aimed at minimizing therapy for low-risk patients in an effort to avoid both short- and long-term complications and developing new therapies for the small subset of high-risk patients.

Early-stage HL is usually considered "favorable" or low risk if there are no B symptoms and no sites of bulky disease, with bulk commonly defined as an MMR greater than 0.33 or a nodal mass greater than 10 cm. Extended-field RT is no longer appropriate therapy for these patients due to long-term complications. Debate continues regarding the best approach to treatment. Several trials demonstrate equivalent survivals for chemotherapy alone versus chemotherapy followed by involved-field radiotherapy (IFRT).[24,25] In most studies, chemotherapy alone is associated with a slightly inferior event-free survival (EFS) compared with combined modality therapy (CMT). However, many investigators agree that this modest increase in relapses will be counterbalanced by a significant reduction in fatal radiation-

Table 119-2

Ann Arbor Staging System for Lymphoma*

Stage I	Involvement of a single lymph node region or lymphoid structure, or involvement of a single extralymphatic site (I_E)
Stage II	Involvement of 2 or more lymph node regions on the same side of the diaphragm, which may be accompanied by localized contiguous involvement of an extralymphatic site or organ (II_E)
Stage III	Involvement of lymph node regions on both sides of the diaphragm, which may also be accompanied by involvement of the spleen (III_S) or by localized contiguous involvement of an extralymphatic site or organ (III_E)
Stage IV	Diffuse or disseminated involvement of 1 or more extralymphatic organs or tissues, with or without lymph node involvement

*The absence or presence of fever (>38° C), unexplained weight loss (>10% body weight), or night sweats should be denoted by the suffix letters A or B, respectively.

induced complications during long-term follow-up. Both approaches are acceptable alternatives while we await mature results of randomized trials. Chemotherapy alone is particularly appealing in women aged 15 to 30 years, a subgroup particularly susceptible to second breast cancers after mediastinal and axillary radiation; smokers due to a marked increase risk of lung cancer after mediastinal RT; and patients with a strong family history of cardiovascular disease. Trials also are ongoing to determine if lower doses of radiation (20 Gy) in combination with chemotherapy are equivalent to currently prescribed doses of 35 to 40 Gy.[26] The impact of these changes on the frequency of serious long-term complications will not be realized for at least 2 decades. Another approach being studied is the use of early-restaging PET/CT scans following one or two cycles of chemotherapy. Patients with an early negative PET scan have an excellent prognosis, and eliminating RT in that subset may be reasonable. In a joint report from the Italian Intergruppo Linformi and the Danish Lymphoma Group that included 260 newly diagnosed patients with HL, the 2-year progression-free survival (PFS) for patients with a positive PET following two cycles of ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) was 12.8%, compared with 95% for patients with a negative interim PET scan.[27] Patients with clinical stage I or II disease and a bulky mediastinal mass have a worse prognosis compared with other early-stage patients. Because of high relapse rates in this subset of patients when they are treated with either chemotherapy or RT alone, CMT is recommended.

Approximately 70% of patients with advanced-stage HL can be cured with six cycles of ABVD chemotherapy, the current standard of care. The International Prognostic Factors Project on Advanced HL identified seven independent prognostic factors in patients with advanced-stage HL including serum albumin less than 4 g/dL, hemoglobin less than 10.5 g/dL, male sex, age 45 years or older, stage IV disease, leukocytosis (WBC > 15,000/mm^3), and lymphocytopenia (lymphocyte count < 600/mm^3 and/or lymphocyte count < 8% of the WBC).[28] The HL prognostic score showed that patients at the lowest risk with zero to two high-risk features had a 67% to 84% freedom from progression (FFP) at 5 years, whereas those at highest risk with four to seven adverse risk factors had a 42% to 51% FFP. The German Hodgkin's Study Group also reported encouraging results of a more intense regimen, dose-escalated BEACOPP (bleomycin, etoposide, doxorubicin [Adriamycin], cyclophosphamide, vincristine, procarbazine, and prednisone) for patients with advanced-stage HL. In a randomized trial, dose-escalated BEACOPP resulted in a 2-year FFS rate of 89% compared with 70% for standard chemotherapy.[29] Compared with ABVD, dose-escalated BEACOPP results in sterility in nearly all patients and is associated with a higher incidence of secondary acute leukemia. These added toxicities may be acceptable in the highest-risk patients if improved cure rates can be confirmed.

Complications of Treatment

Treatment advances have dramatically improved the survival of patients with HL. Unfortunately, long-term survival frequently goes hand in hand with late-term treatment complications. Consideration of latent side effects should play an integral role in the choice of treatments for this highly curable malignancy. Investigators at Stanford University performed a retrospective analysis of 2498 patients with HL treated between 1960 and 1995 to determine latent complications of therapy and causes of mortality.[30] At 15 years, risk of death from HL was 17%, with only a slight increase thereafter. Risk of death from other causes was also 17% at 15 years; however, there was a sharp increase after 15 years. Similar results have also been reported from other centers, with a consistent association between increased doses of mediastinal radiation and delayed cardiopulmonary toxicities and secondary neoplasms.

The increased incidence of second malignancies following treatment for HL has been reported in numerous studies and is thought to be due primarily to the RT.[31,32] In a large study of more than 32,000 patients pooled from 16 cancer registries, a 21.9% risk of solid tumors was observed at 25 years.[31] Frequent among these second malignancies are primary cancers of the head and neck. In patients receiving RT to the neck for HL, the relative risk (observed/expected) of thyroid cancer is 4 to 5; esophagus 2 to 2.5; tongue, mouth, and pharynx 2.8 to 3.4; and salivary gland 6.[31,32] Treatment of these second cancers is often complicated by the previous radiation. Thyroid diseases are common after neck irradiation, with an actuarial risk of 67% at 26 years after therapy.[33] In most of these patients, hypothyroidism develops, but the risk of Graves' disease is also 7 to 20 times that for normal subjects.

Diffuse Large B-Cell Non-Hodgkin's Lymphoma (DLBCL)

DLBCL is the most common subtype of NHL and frequently presents with cervical or supraclavicular adenopathy. As described later in this chapter, it is also the most common NHL to occur as a primary extranodal lymphoma in the head and neck including thyroid, sinus, WR, or a salivary gland. Additional workup after a diagnostic biopsy includes a history and physical examination with documentation of adenopathy, hepatosplenomegaly, performance status, the presence of B symptoms, laboratory evaluations, radiographic studies, and in most cases, a bone marrow biopsy. Necessary laboratory tests include a complete blood cell count, liver-function tests, calcium, creatinine, and lactate dehydrogenase. The Ann Arbor staging system, initially developed for HL, is also used to stage NHL (see Table 119-2). Alternative staging systems have been proposed but never adopted. Proper staging requires CT scans of the chest, abdomen, and pelvis, as well as bilateral bone marrow biopsies. PET and PET/CT scans have improved the accuracy of initial staging and response assessment in patients with DLBCL. As initial staging, they are most useful in patients with equivocal CT findings and in patients who appear to have localized disease at presentation, where finding additional sites of involvement could potentially alter management.

Treatment and Prognosis

Historically, the standard approach for stage I or II DLBCL was CMT. A prospective, randomized, multi-institutional study established the superiority of CMT over chemotherapy alone in this setting. Four hundred patients received either three cycles of CHOP (cyclophosphamide, doxorubicin, Oncovin, and prednisone) chemotherapy followed by IFRT or eight cycles of CHOP alone.[34] RT doses ranged from 40 to 55 Gy. Patients treated with CMT had significantly better 5-year FFP (77% vs. 64%) and overall survival (OS) (82% vs. 72%) rates compared with patients treated with chemotherapy alone. A phase II study of three cycles of rituximab (R)-CHOP chemotherapy followed by IFRT for limited-stage nonbulky large cell lymphoma showed 2-year

PFS and OS rates of 93% and 95%, respectively.[35] In contrast to previous studies, a large randomized trial published by the GELA in 2007 showed no advantage to four cycles of CHOP plus RT over four cycles of CHOP alone for the treatment of low-risk localized large cell lymphoma in patients older than 60 years.[36] Interestingly, in the subgroup of patients older than 70 years, the 5-year OS was higher in patients treated with chemotherapy alone (69% vs. 58%, $P = 0.2$). Avoiding RT in patients with head and neck sites is an appealing approach because the short- and long-term complications of dry mouth and altered taste often have a significant impact on quality of life. In patients with a negative early restaging PET scan (after one or two cycles of chemotherapy), four to six cycles of R-CHOP alone should be considered.

Patients with advanced-stage DLCBL are treated with six cycles of R-CHOP. Several randomized trials demonstrated a survival benefit when patients received R-CHOP versus CHOP as their initial therapy for large cell lymphoma.[37-39] The GELA reported 5-year OS rates of 58% and 45% and FFP rates of 54% and 30% for the R-CHOP and CHOP groups, respectively.[37] A population-based study from British Columbia confirmed the benefit of adding rituximab to standard chemotherapy.[38] Two-year PFS was 69% in the post-rituximab era and 51% in the pre-rituximab era.

Indolent Non-Hodgkin's Lymphoma

Indolent lymphomas, specifically follicular and small lymphocytic lymphoma, commonly involve the cervical and supraclavicular nodes and are often the presenting sign, even when widespread adenopathy is present. Multiple, bilateral, mobile nodes are often present and SLL may involve the tonsils. In some patients the nodes may wax and wane or remain stable over months or years, so a long history of enlarged nodes should not preclude a biopsy. Patients with FL and SLL are at risk for transformation to large cell lymphoma. Occasionally transformation is discovered at initial presentation. Signs of possible transformation include the presence of B symptoms, elevated LDH or calcium, necrosis of the node noted on CT scans, and discordant growth, with one node growing rapidly in the presence of other stable nodes. If lymphoma is suspected, an effort should be made to excise the largest node possible or any node that shows necrosis on CT scan. It is helpful to sample a non-necrotic node simultaneously because occasionally there are no viable cells for diagnosis in a necrotic node.

Treatment and Prognosis

The approach to patients with indolent lymphomas has changed significantly in the past 5 years, due to the publication of several randomized trials showing a significant improvement in remission duration and survival with the combination of rituximab (a chimeric anti-CD20 antibody specific for B lymphocytes) and chemotherapy compared with chemotherapy alone. Despite the marked improvement in outcomes, there is still no plateau in the EFS curves with the use of chemoimmunotherapy and "cures" are unlikely. The Follicular Lymphoma International Prognostic Index (FLIPI) includes five independent poor prognostic factors, age 60 years and older, stage III or IV, greater than four involved nodal areas, elevated serum LDH, and hemoglobin less than 12 gm/dL.[40] The 10-year overall survival rate for patients with three or more risk factors according to the FLIPI is 35% compared with 70% for patients with none or one high-risk feature.

Given the improved sensitivity of staging studies including CT scans, PET scans, and the use of flow cytometry to evaluate bone marrow specimens, the diagnosis of limited-stage indolent lymphoma is uncommon. Observation, IFRT, single-agent rituximab, a combination of rituximab and chemotherapy, and CMT with rituximab plus or minus chemotherapy with IFRT are all options for patients with this unusual presentation. No randomized trials have compared these approaches and treatment decisions should be based on the site and bulk of disease and patient age with the more aggressive approaches being preferred for younger patients and those with bulky stage I to II disease.

The current standard of care for patients with stage III to IV indolent lymphomas requiring therapy is a combination of rituximab and chemotherapy. Following the improvement in outcomes with chemoimmunotherapy, the role of observation or "watch and wait" has been questioned. However, despite many effective but to-date "noncurative" therapies, there has never been any objective evidence that early intervention improves overall survival in asymptomatic patients.[41] There remains a subset of patients with indolent lymphomas that have no indications for therapy more than 15 years after diagnosis. Asymptomatic, older patients with low-volume disease may still be best served by close observation until progression.

Several randomized trials show a significant improvement in EFS and overall survival with the addition of rituximab to combination chemotherapy.[42-44] Three- to five-year EFS rates range from 50% to 77% in recent series of combination therapy. There is no clear advantage of one chemotherapy regimen over another and excellent results have been reported with R-CVP (cyclophosphamide, vincristine, prednisone), R-CHOP, R-FND (fludarabine, mitoxantrone, dexamethasone) and R-Fludarabine. Currently the choice of regimen should be based on patient age and comorbid conditions. Non–anthracycline-based approaches should be considered in patients older than 65 and those with underlying cardiac disease. Fludarabine-based regimens are associated with an increased risk of opportunistic infections, particularly varicella zoster, due to a marked, prolonged decrease in the $CD4^+$ count.[45] Investigators testing R-FND in patients with newly diagnosed follicular lymphoma reported an alarming 4% incidence of myelodysplasia and acute myeloid leukemia.[46]

The question of maintenance rituximab following first-line chemoimmunotherapy is under investigation. Two large studies have shown a significant improvement in remission duration and overall survival with maintenance rituximab following chemoimmunotherapy for relapsed follicular lymphoma.[47,48] No data are available on continuing maintenance rituximab beyond 2 years. There are no known long-term effects of prolonged rituximab therapy.

An alternative approach for patients with low-volume disease, older patients, and patients with serious comorbid conditions is single-agent rituximab. Toxicities of rituximab are mild and are limited primarily to infusion-related reactions such as fevers, chills, myalgias, transient hypotension, and rarely bronchospasm. Maintenance rituximab following an initial course of four weekly doses improves remission durations but does not improve survival or increase the time to requiring chemotherapy compared with retreatment with rituximab at relapse.[49,50]

Studies of mAbs conjugated with radioisotopes are promising. Response rates of approximately 80% have been reported with both the [^{131}I]-anti-CD20 mAb, Bexxar, and the [yttrium-90]-anti-CD20 mAb, Zevalin. Side effects are modest and self-limited. The current Food and Drug Administration approval is for patients with relapsed indolent lymphomas; however, encouraging results have been reported incorporating Bexxar into front-line therapy, either as a single agent or as consolidation following chemotherapy. Kaminski and colleagues[51] reported a 95% response rate, 75% complete response rate, and 6-year PFS in 76 patients with previously untreated indolent lymphoma following a single dose of Bexxar. Press and colleagues[52] reported a 67% 5-year PFS rate for CHOP followed by Bexxar as initial therapy of follicular lymphoma. Larger series with longer follow-up are required before approaches incorporating radioimmunotherapy become the standard of care.

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) occurs most frequently in men older than age 60 and has a variable presentation ranging from adenopathy in an asymptomatic patient to a leukemic presentation with extensive blood and bone marrow involvement. Involvement of neck nodes and tonsils is not uncommon. MCL has also been reported in most extranodal sites of the head and neck.

Treatment and Prognosis

More aggressive approaches such as those used for acute leukemia and Burkitt's lymphoma have resulted in improved outcomes for patients with MCL. Although remissions and survivals are substantially longer with intensive therapy, no study has yet reported a plateau in the PFS rate with more than 5 years of follow-up. In addition, the improved results are likely biased by patient selection, with aggressive regimens

most feasible for younger patients without significant comorbidities. Historical series of standard chemotherapy regimens such as CVP or CHOP include substantial numbers of older patients. Investigators at the M. D. Anderson Cancer Center reported 3-year failure-free survival and OS rates of 64% and 82%, respectively, with R-hyperCVAD (rituximab, high-dose cyclophosphamide, vincristine, doxorubicin, dexamethasone) alternating with high-dose methotrexate and ara-C.[53] The role of consolidative autologous stem cell transplant in first remission is unproven, but this approach is widely used.

Highly Aggressive Lymphomas

Both Burkitt's lymphoma and lymphoblastic lymphoma can present with cervical or supraclavicular adenopathy. If a biopsy reveals either of these lymphoma subtypes, the surgeon should request an emergent medical oncology consult. These highly aggressive lymphomas occur most commonly in children and young adults. Lymphoblastic lymphoma is diagnosed twice as often in men than women. The majority of patients with lymphoblastic lymphoma present with a large mediastinal mass. Rapid growth of the tumor occasionally causes acute respiratory compromise because of tracheal compression and SVC syndrome and is the most likely NHL to present as a medical emergency. Pleural effusions occur in up to 70% of patients, and thoracentesis may be the quickest and least morbid diagnostic procedure. Pericardial effusions are also common.

Treatment and Prognosis

Treatment for these rare, highly aggressive lymphomas must include intensive combination chemotherapy and central nervous system (CNS) prophylaxis, similar to regimens currently used for acute leukemia. All stages of disease are approached similarly. CNS prophylaxis with intrathecal methotrexate and ara-C is an essential component of therapy. Five-year survival rates are approximately 50% for patients with advanced stage disease and 80% for the small subset of patients who present with stage I or II disease.[54,55] Tumor responses in lymphoblastic lymphoma and Burkitt's lymphoma are extremely rapid, often with complete normalization of radiographic studies within a few days. Patients are at high risk for tumor lysis syndrome and should receive their first dose of chemotherapy as an inpatient with vigorous hydration and prophylactic allopurinol or rasburicase. As discussed previously, patients suspected of having lymphoblastic lymphoma on clinical grounds should not receive corticosteroids before a diagnostic biopsy or thoracentesis.

Extranodal Lymphomas of the Head and Neck

Thyroid Lymphomas

Primary thyroid lymphomas comprise less than 5% of all thyroid malignancies and occur most commonly in middle- and older-aged women in the setting of lymphocytic thyroiditis.[56,57] Chronic thyroiditis increases the risk of primary lymphoma of the thyroid by 70- to 80-fold.[58] In one series, evidence of lymphocytic thyroiditis was present in 94% of specimens from primary thyroid lymphomas.[59] Two distinct subtypes comprise nearly all cases of primary thyroid lymphoma, diffuse large B-cell lymphoma and mucosa-associated lymphoid tissue (MALT) lymphoma, also referred to as *extranodal marginal cell* or *marginal zone lymphoma.* Approximately one third of cases are pure MALT lymphomas, one third are de novo DLBCL, and one third have features of both MALT lymphoma and DLBCL consistent with transformation of the indolent MALT lymphoma to an aggressive DLBCL.[59] The clinical presentation depends on the histology with MALT lymphoma usually presenting as a slowly enlarging thyroid mass and DLBCL presenting as a rapidly growing mass. One third of patients have symptoms of compression of surrounding structures including dyspnea, dysphagia, stridor, hoarseness, choking, and coughing.[59,60]

MALT lymphoma is difficult to diagnose on needle biopsy. Because one third of cases of primary thyroid lymphoma will have evidence of both MALT lymphoma and DLBCL, an open biopsy is still the preferred method of diagnosis. The morphologic features of MALT lymphomas include lymphoepithelial lesions, follicular colonization, and presence of plasma cells and Dutcher's bodies. The lymphoma cells resemble small lymphocytes with round or slightly irregular nuclei that center on reactive follicles with a marginal zone-type distribution. A characteristic phenotype includes the presence of the pan-B cell antigen CD20 and lack of the CD5 and CD10 antigens, which is unique among indolent lymphomas.[1]

Staging

Most cases of MALT lymphoma of the thyroid present with stage IE or IIE disease. Rarely, initial staging with CT scans of the neck, chest, abdomen, and pelvis reveals nodal involvement beyond the neck and mediastinum or involvement of another extranodal site, most commonly lung, stomach, or orbit. PET scans have a high false-negative rate in MALT lymphomas and should not be used as initial staging.[61]

In patients with DLBCL without associated MALT lymphoma, approximately half will have evidence of disseminated lymphoma at staging, raising the question of the lymphoma being primary or secondary from another involved site.[62] PET/CT scan is the most sensitive staging method for DLBCL. Serum LDH and performance status are important prognostic factors in DLBCL and should be documented before initiating therapy.

Treatment and Prognosis

Patients with DLBCL of the thyroid, with or without a component of MALT lymphoma, should receive the same therapy as patients with DLBCL of nodal sites. As described earlier, six cycles of R-CHOP chemotherapy is standard of care for stage III to IV disease.[37] CMT should be considered for most patients with stage I to IIE disease including three to six cycles of R-CHOP followed by IFRT.[35] RT is especially important in patients with a component of MALT lymphoma because this subtype is not thought to be curable with chemotherapy alone. There is no role for surgery in the treatment of DLBCL of the thyroid. The prognosis depends on the absence or presence of high-risk features including stage III to IV, age older than 60 years, abnormal LDH, performance status greater than 1, and involvement of more than one extranodal site. Patients younger than 60 with early-stage disease have approximately a 90% 4-yr PFS, whereas those with advanced-stage disease have a 55% to 80% 4-year PFS, depending on other risk factors.[63]

Stage I and IIE MALT lymphomas of the thyroid have an excellent prognosis, with PFS and OS of 95% to 100% in most series.[56,59,64] IFRT is highly effective therapy and doses of 30 Gy are often sufficient. Systemic therapy (chemotherapy and or immunotherapy) is not indicated unless advanced-stage or relapsed disease are present. Tsang and colleagues[65] reported on 85 patients with stage I to IIE MALT lymphoma treated with IFRT only. The median RT dose was 30 Gy and the local control rate with RT was 95%. None of the 13 patients with a primary MALT lymphoma of the thyroid had a recurrence. In patients where MALT lymphoma is discovered following a partial or total thyroidectomy, the need for postoperative RT is unclear. If there is disease extending to the margin of the specimen, IFRT is recommended. Following what appears to be a complete resection, IFRT or observation are both acceptable options.

Salivary Gland Lymphomas

Lymphoma of the salivary glands is uncommon, representing less than 2% of salivary malignancies, and usually presents as an enlarging mass.[66] The parotid gland is involved most frequently, followed by the submandibular, minor salivary, and sublingual glands.[66,67] The most common histologies are MALT lymphoma in 60% to 70% and diffuse large cell lymphoma in 20% to 30%. There are rare reports of nearly every other NHL subtype involving the salivary glands. Involvement of cervical nodes is uncommon with MALT lymphoma but present in more than half of patients with other histologies.[67] At least one third of patients with MALT histology have involvement of multiple salivary glands at the time of diagnosis.[67] Involvement of other nonsalivary extranodal sites such as stomach is reported, and some authors recommend upper endoscopy in addition to CT scans as initial staging.[68] At least half of patients with salivary gland MALT lymphomas have an

associated autoimmune disorder, most commonly Sjögren's syndrome. In one series, 7 of 33 (21%) patients with MALT lymphoma of the salivary gland had hepatitis C virus (HCV), a common risk factor for marginal cell lymphomas of the spleen.[69] Approximately 25% of patients have an associated monoclonal protein and cryoglobulinemia is common, especially in patients with Sjögren's or HCV.

Treatment and Prognosis

Aggressive histologies such as DLBCL presenting in the salivary glands are treated like their nodal counterpart as discussed in detail earlier. They also have a prognosis similar to nodal DLBCL with similar prognostic features. Limited-stage disease is treated with chemoimmunotherapy (R-CHOP) and IFRT, and advanced-stage disease with chemoimmunotherapy alone.

Salivary gland MALT lymphomas presenting as stage I to IIE disease are effectively treated with IFRT with RT doses of 30 Gy with 5-year OS and exhibit 5-year cause-specific survival rates of 85% and 94%.[69] In contrast to gastric and thyroid MALT lymphomas, relapses occur in at least one third of patients with salivary gland MALT lymphomas.[69,70] In one series of 32 patients with extranodal MALT lymphoma, the median time to first recurrence was 47 months with a range of 14 to 307 months.[70] The high incidence of late relapses warrants lifelong follow-up of these patients. Local relapses in a nonirradiated site can often be radiated, resulting in many cases in a second long remission. For patients with disease not amenable to IFRT, mild chemoimmunotherapy regimens such as R-CVP (cyclophosphamide, vincristine, prednisone), oral cyclophosphamide, or single-agent rituximab are effective.[69,71]

Paranasal Sinus and Nasal Cavity Lymphomas

Lymphomas of the paranasal sinuses and nasal cavity are uncommon and are pathologically and clinically heterogeneous.[72] In Asian and South American populations, nasal lymphomas are more common and are predominantly the NK/T cell subtype, whereas in Western populations the sinonasal lymphomas are usually diffuse large B-cell type.[73] These two histologic entities have distinct natural histories and prognoses and require different therapeutic approaches.

DLBCL occurs most commonly in middle-aged to older adults, has a male predilection, usually involves the sinuses without nasal involvement, is commonly associated with orbital invasion and ocular symptoms, and is rarely associated with EBV except in the case of HIV-associated lymphomas.[74] The majority of tumors confined to a paranasal sinus involve the maxillary sinus.[72] Approximately two thirds of cases present as stage I to IIE.[74]

NK/T nasal lymphoma, previously referred to as *lethal midline granuloma* or *angiocentric lymphoma,* affects young to middle-aged adults, has a male predilection in most series, and commonly presents with a nasal mass or obstruction, epistaxis, palatal destruction, and erythema and swelling of the face.[74,75] Infiltration of the tumor cells is frequently perivascular and vascular occlusion with massive necrosis of the tissue is one of the presenting features.[76] Because of tissue necrosis, it is sometimes difficult to make a diagnosis and multiple biopsies are often necessary. Virtually all cases of NK/T cell lymphoma are associated with EBV and in situ hybridization with EBER 1/2 may aid in the histologic diagnosis of nasal lymphomas.[75] Immunohistochemical stains for $CD56^+$ should also be done in any patient with a suspected diagnosis of nasal lymphoma. $CD56^+$ and EBV^+ lymphocytes are rarely observed in normal or inflammatory nasal mucosa.[76] More than 80% of patients present with stage I to IIE disease.[77]

Therapy and Prognosis

The treatment of DLBCL of the paranasal sinuses is similar to nodal or other extranodal presentations of DLBCL. Patients with stage I to IIE should receive three to six cycles of R-CHOP and IFRT.[78] Historically, poor results were reported with RT alone.[72,73] Chemotherapy alone has not been tested with modern regimens such as R-CHOP. Due to the proximity of the CNS, leptomeningeal spread and CNS relapse are more frequent than other presentations of DLBCL.[79] CNS prophylaxis is recommended and usually includes three to six doses of intrathecal methotrexate or cytarabine. Prognosis is similar to that for other presentations of DLBCL, with the majority of early-stage patients being cured.[63]

Radiotherapy is the mainstay of therapy for NK/T cell nasal lymphoma. Li and colleagues[80] reviewed 105 cases of stage I to IIE nasal NK lymphoma. Of 65 patients, 54 (83%) treated with initial RT achieved a complete response compared with only 8 of 40 (20%) of patients treated initially with chemotherapy. Five-year PFS and OS rates were similar for patients treated with RT alone and those treated with CMT. Isobe and colleagues[81] reported the importance of radiotherapeutic parameters in the outcome of patients with NK/T cell nasal lymphoma. Patients treated with greater than or equal to 50 Gy and a field that included all sites of potential contiguous spread (paranasal sinuses, palate, nasopharynx) had significantly better local control than those treated with less than 50 Gy and a field that included only macroscopic disease with wide margins. The International Prognostic Index for NHL has predictive power in NK/T cell lymphoma.[63] However, models including B symptoms, stage, LDH, regional node involvement, and local tumor invasiveness defined as bony invasion or destruction or tumor invasion of the skin improve prognostic discrimination.[82,83] In most series, 40% to 50% of patients are alive and disease free 5 years after diagnosis.

Waldeyer's Ring Lymphomas

More than half of all extranodal lymphomas of the head and neck occur in WR with the tonsil representing the most common site, followed by the nasopharynx.[84] Lymphomas of the base of tongue and soft palate are less frequent. There is controversy about whether WR should be considered nodal or extranodal.[84,85] In one series of 130 adult patients with localized lymphoma of WR, 84% were DLBCL and the remainder were equally divided among six additional histologies including both indolent and aggressive.[84] Lymph node involvement, if present, is usually regional and spleen and bone marrow involvement is uncommon.[86] In a series of 77 patients with primary WR lymphoma, no synchronous involvement of the gastrointestinal tract was found at diagnosis; however, involvement of the gastrointestinal tract at recurrence was relatively common.[86]

Treatment and Prognosis

With the use of CMT, most series show outcomes similar to those reported for stage I to II nodal lymphomas.[34,78,84,85,87] In a report of 382 patients from one center with DLBCL, 58% were nodal, 11% WR, and 31% other extranodal sites.[87] WR lymphomas showed the best 5-year OS (77%) compared with nodal (49%) and other extranodal (59%) sites. However, when the analysis was corrected for the International Prognostic Index, there was no difference according to the site of presentation. Several series show an advantage to CMT over RT or chemotherapy alone.[84,85] As previously discussed, these reports do not use current chemoimmunotherapy strategies such as R-CHOP. It is not clear whether CMT will continue to show an advantage when more effective chemotherapy regimens are used.

Summary

Lymphomas commonly present in the head and neck, either as cervical or supraclavicular adenopathy or as a primary extranodal lymphoma of the thyroid, salivary gland, paranasal sinus, nasal cavity, or WR. Most lymphomas are highly treatable and often curable with chemotherapy or radiotherapy. Otolaryngologists play a critical role in obtaining adequate tissue for accurate lymphoma classification.

CHAPTER ONE HUNDRED AND TWENTY

Radiation Therapy and Management of the Cervical Lymph Nodes and Malignant Skull Base Tumors

Vincent Grégoire

Nancy Lee

Key Points

- In the previously untreated neck, lymph node infiltration follows a predictable pattern.
- Except for nasopharyngeal carcinoma, selective irradiation can be proposed for patients with N0-N1 neck.
- Three-dimensional delineation of the node levels should be performed on thin contrast-enhanced CT sections following the consensus guidelines.
- High control rate of the node-negative neck (>90%) is achieved with a prophylactic (≈50 Gy) dose of ionizing radiation.
- For the node-positive neck, a higher dose of ionizing radiation (≈70 Gy) is required.
- After node-positive neck treatment with radiotherapy, neck dissection should be restricted to those patients who did not achieve a complete response.
- Postoperative irradiation is required for a pathologic node-positive neck (>pN1).
- Postoperative concomitant chemoradiotherapy is required for patients with extracapsular rupture.
- Proton beam irradiation can be designed to yield a uniform dose across the target and deliver virtually zero dose deep to the target, as well as lower dose proximal to the target.
- Cyberknife is a frameless robotic radiosurgical device that has been developed mainly to treat extracranial lesions.
- Intensity-modulated radiation therapy is a refinement of three-dimensional (3D) conformal radiotherapy that has the ability to treat an irregularly shaped target regardless of size while minimizing the dose delivered to the surrounding normal tissues.
- Treatment of esthesioneuroblastoma typically consists of combination therapy: either surgery followed by radiotherapy with or without chemotherapy or concurrent chemotherapy and radiation therapy followed by surgery for salvage.
- Sinonasal undifferentiated carcinoma portends a poor prognosis owing to its high rates of locoregional failures, as well as distant metastases.
- The preferred radiation technique for chordomas is proton therapy.
- High rates of locoregional control can be achieved using intensity-modulated radiation therapy for nasopharyngeal carcinoma.
- Distant failure is the predominant cause of failure in patients with nasopharyngeal carcinoma.
- The preferred treatment approach for sinonasal cancer is complete surgical resection followed by postoperative radiation therapy.

Radiation Therapy and Management of Cervical Lymph Nodes

Assessment and treatment of regional lymph nodes (LNs) in the neck are of utmost importance in the management of patients with head and neck squamous cell carcinoma (SCC). The philosophy of treatment of the neck has evolved over the past decades. Radiation oncologists and head and neck surgeons progressively realized that extensive treatments were associated with more morbidity but not always with a better oncologic outcome than less extensive procedures. Today, a comprehensive approach of the treatment of the neck needs to be multidisciplinary, taking into account the quality of life of the patients but without jeopardizing cure and survival. A better understanding of the patterns of LN metastasis promoted the use of not only selective dis-

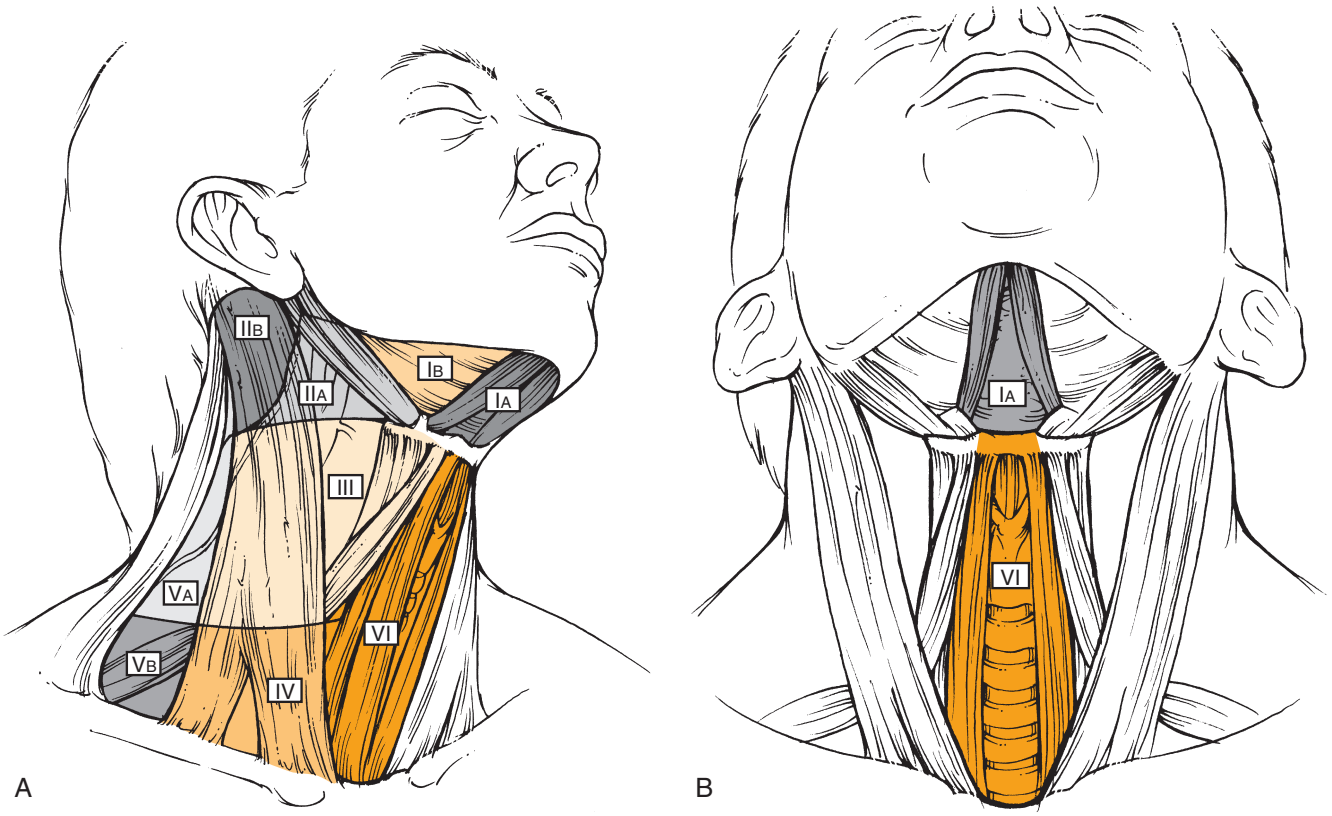

Figure 120-1. Schematic representation of the various neck node groups (**A**, lateral view; **B**, frontal view): *IA,* submental; *IB,* submandibular; *II,* upper jugular; *III,* middle jugular; *IV,* lower jugular; *V,* posterior triangle; *VI,* anterior compartment. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

section but also selective irradiation in subgroups of patients. Concepts are still evolving (e.g., with the sentinel lymph node biopsy for which the exact role is under evaluation).

In this chapter, only the management of the neck for oral cavity, oropharyngeal, hypopharyngeal, and laryngeal SCCs is discussed. The specific management of the neck for thyroid, nasal cavities, paranasal sinuses, and skin cancers is covered in the respective chapters dealing with these anatomic sites.

Lymphatic System of the Neck

The head and neck region has a rich network of lymphatic vessels draining from the base of the skull through the jugular nodes, the spinal accessory nodes, and the transverse cervical nodes to the venous jugulosubclavian confluent or the thoracic duct on the left side and the lymphatic duct on the right side.[1,2] The whole lymphatic system of the neck is contained in the celluloadipose tissue delineated by aponeurosis enveloping the muscles, vessels, and nerves. The lymphatic drainage is mainly ipsilateral, but structures like the soft palate, tonsils, base of the tongue, posterior pharyngeal wall, and especially the nasopharynx have bilateral drainage. On the other hand, sites such as the true vocal cord, paranasal sinuses, and middle ear have few or no lymphatic vessels at all.

The nomenclature of head and neck lymph nodes has been complicated by various confusing synonyms that are still in use in major textbooks and articles. More recently, several expert bodies have proposed the adoption of systematic classifications aimed at standardizing the terminology. Following the description by Rouvière, the Tumor Node Metastasis atlas proposed a terminology, dividing the head and neck lymph nodes into 12 groups.[3] In parallel to this classification, the Committee for Head and Neck Surgery and Oncology of the American Academy for Otolaryngology–Head and Neck Surgery has been working on a classification (the so-called *Robbins classification*), dividing the neck into six levels including eight node groups (Fig. 120-1).[4] This classification is based on the description of a level system, which has been used for a long time by the Head and Neck Service at the Memorial Sloan-Kettering Cancer Center.[5] Because one of the objectives of the Robbins classification was to develop a standardized system of terminology for neck dissection procedures, only the lymph node groups routinely removed during neck dissection were considered. The terminology proposed by Robbins was recommended by the Union Internationale Contre Cancer (UICC).[6] A comparison between the TNM and the Robbins terminology is shown in Table 120-1. The major advantage of the Robbins classification over the TNM terminology is the definition of the boundaries of the node levels. The delineation of these boundaries is based on anatomic structures such as major blood vessels, muscles, nerves, bones, and cartilage that are easily identifiable by the surgeon during neck dissection procedures. It is beyond the scope of this chapter to go into a detailed description of the node levels. The reader is referred to a recent review article outlining the anatomic basis of the neck node classification.[7]

Staging of Neck Node Metastasis

The sixth edition (2002) of the American Joint Committee on Cancer (AJCC) staging for neck node metastasis is presented in Table 120-2.[8] This classification does not apply to nasopharyngeal carcinoma, thyroid, or skin cancers. In comparison with the fourth (1987) or fifth (1998) edition, the only modification is the possibility to use a descriptor for nodal metastasis located below (L) or above (U) the lower border of the cricoid cartilage. The use of this descriptor will not influence the nodal staging. The classification for nodal staging does apply irrespective of the modality used for the neck assessment (i.e., clinical examination or imaging). However, the routine use of computed tomography (CT) or magnetic resonance imaging (MRI) and, in expert hands, ultrasonography, is recommended, especially to assess nodes not clini-

Table 120-1

Comparison between the Tumor Node Metastasis (TNM) Atlas and the Robbins' Classification of the Lymph Nodes of the Neck

TNM Atlas for Lymph Nodes of the Neck		Robbins' Classification	
Group Number	Terminology	Level	Terminology
1	Submental nodes	Ia	Submental group
2	Submandibular nodes	Ib	Submandibular group
3	Cranial jugular nodes	II	Upper jugular group
4	Medial jugular nodes	III	Middle jugular group
5	Caudal jugular nodes	IV	Lower jugular group
6	Dorsal cervical nodes along the spinal accessory nerve	Va	Posterior triangle group
7	Supraclavicular nodes	Vb	Posterior triangle group
8	Prelaryngeal and paratracheal nodes	VI	Anterior compartment group
9	Retropharyngeal nodes	—	—
10	Parotid nodes	—	—
11	Buccal nodes	—	—
12	Retroauricular and occipital nodes	—	—

Table 120-2

Sixth Edition (2002) of the American Joint Committee on Cancer (AJCC) Staging for Neck Node Metastasis

Stage	Definition
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral node, ≤3 cm in greatest dimension
N2a	Metastasis in a single ipsilateral node, >3 cm but ≤6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral nodes, ≤6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral nodes, ≤6 cm in greatest dimension
N3	Metastasis in a lymph node >6 cm in greatest dimension

cally identifiable (e.g., retropharyngeal, intraparotid, or superior mediastinal nodes) or in patients for whom clinical palpation of the neck is less sensitive (e.g., thick or small neck).[9] Last, it should be emphasized that the Nx classification only applies when the neck was not assessed or could not be assessed.

Incidence and Distribution of Neck Node Metastasis

Incidence and Distribution of Lymph Node Metastasis from Clinical and Radiologic Assessment

The metastatic spread of head and neck tumors into the cervical lymph nodes is rather consistent and follows predictable pathways, at least in the neck, which has not been violated by previous surgery or radiotherapy. In Figures 120-2 to 120-6, the frequency of metastatic lymph nodes is expressed as a percentage of node-positive patients.[10,11]

The frequency of neck node metastases and the distribution of clinically involved nodes depend to a major extent on the primary tumor site. Typically, hypopharyngeal tumors have the highest propensity for nodal involvement, which occurs in 70% of cases. Cranial and anterior tumors (e.g., oral cavity tumors) mainly drain into levels I, II, and III, whereas more caudally located tumors (i.e., laryngeal tumors) mainly drain into levels II and III, and to a lesser extent into levels IV and V. Contralateral nodes are rarely involved except for midline tumors or tumors in those sites where bilateral lymphatic drainage has been reported (e.g., soft palate, base of the tongue, pharyngeal wall). Even in these tumors, the incidence of contralateral involvement is much lower, reaching, for example, in base of the tongue tumors with clinically positive nodes 31% in contralateral level II compared with 73% in ipsilateral level II (data not shown). Interestingly, node distribution follows the same pattern in the contralateral neck as in the ipsilateral neck. Except for nasopharyngeal tumors, involvement of ipsilateral level V is a rather rare event, occurring in less than 1% of all oral cavity tumors, in less than 10% of all oropharyngeal and laryngeal tumors, and in about 15% of all hypopharyngeal tumors. It almost never occurs in contralateral level V. Nasopharyngeal tumors behave differently than other head and neck tumors. These highly lymphophilic tumors carry almost the same risk of nodal involvement in the ipsilateral and contralateral neck, with the preferential involvement of level V in almost one third of patients. On the other hand, the incidence of level I infiltration is much lower.

Metastatic lymph node involvement in the neck depends on the size of the primary tumor, increasing with the T stage. In the series

reported by Bataini,[10] 44% of patients with a T1 tumor had clinical lymph node involvement; this increased to 70% for patients with T4 lesions. There are, however, no data suggesting that the relative distribution of involved neck levels varies with the T stage.

Retropharyngeal lymph nodes represent a special entity inasmuch as they are usually not clinically detectable. The incidence of retropharyngeal lymph node involvement can thus only be estimated from series in which CT or MRI of the retropharynx has been systematically performed as part of the diagnostic procedure. Retropharyngeal node involvement occurs in primary tumors arising from (or invading) the mucosa of the occipital and cervical somites (e.g., of the nasopharynx, pharyngeal wall, and soft palate). Interestingly, the incidence of retropharyngeal lymph nodes is higher in patients in whom involvement of other neck node levels has also been documented. However, in clinically N0 patients with nasopharyngeal tumors, and to a lesser extent in patients with pharyngeal wall tumors, the incidence of retropharyngeal nodes is still significant (i.e., between 16% and 40%). Also, as already described for the other lymph node levels, involvement depends on the T stage and is typically lower for T1 tumors. Accurate figures are, however, not available.

Incidence and Distribution of Pathologic Lymph Node Metastasis

The distribution of pathologic lymph node metastasis in patients with primaries of the oral cavity, oropharynx, hypopharynx, and larynx can be derived from retrospective series in which a systematic radical neck node dissection was proposed as part of the initial treatment procedures.[12-15] In essence, retrospective series are biased regarding patient and treatment selection, but these series from the Head and Neck Department at Memorial Sloan-Kettering Cancer Center are the largest and most consistent data ever published on that matter. The results of these retrospective studies are shown in Table 120-3. The data are presented in terms of the number of neck dissections with positive lymph nodes over the total neck dissection procedures and expressed as a percentage. The vast majority of patients (>99% for the N0 neck patients and 95% for the N+ neck patients) only had unilateral treatment, and no distinction between the ipsilateral and contralateral neck was made.

Overall, metastatic disease was detected in 33% of the elective neck dissections and in 82% of the therapeutic neck dissections. As already observed with the pattern of clinical metastatic lymph nodes, the distribution of pathologically confirmed metastatic lymph nodes depended on the primary tumor site. Typically, in clinically N0 patients, metastatic lymph nodes were observed in levels I to III for oral cavity tumors, and in levels II to IV for oropharyngeal, hypopharyngeal, and laryngeal tumors. This pattern of node distribution is similar to that determined from the clinical palpation of the neck. It should be noted that the T-stage distribution was different in the various groups. Of patients with laryngeal tumors, 54% (42/79) had T3-T4 tumors (mainly supraglottic) compared with 27% (52/192), 25% (6/24), and 17% (8/47) in patients with oral cavity, hypopharyngeal, and oropharyngeal tumors, respectively. Such a difference in T stage presumably explains the high incidence of microscopic node metastases in the larynx group.

When considering the patients who underwent therapeutic neck dissection, the pattern of metastatic node distribution was similar to that observed in clinically N0 patients, with the difference that significant pathologic infiltration of an additional nodal level was typically observed (i.e., level IV for oral cavity tumors and levels I and V for oropharyngeal, hypopharyngeal, and to a lesser extent laryngeal tumors). Overall, this observation illustrates the gradual infiltration of node levels in the neck.

Table 120-3

Incidence of Pathologic Lymph Node Metastasis in Squamous Cell Carcinomas of the Oral Cavity, Oropharynx, Hypopharynx, and Larynx

	Distribution of Metastatic Lymph Nodes per Level (percentage of the neck dissection procedures)											
	Elective RND						Therapeutic (immediate or subsequent) RND					
Tumor Site	No. of RND	I	II	III	IV	V	No. of RND	I	II	III	IV	V
Oral cavity	192	20%	17%	9%	3%	1%	323	46%	44%	32%	16%	3%
Oropharynx	48	2%	25%	19%	8%	2%	165	15%	71%	42%	27%	9%
Hypopharynx	24	0%	12%	12%	0%	0%	104	10%	75%	72%	45%	11%

RND, radical neck dissection.

Incidence and Pattern of Node Distribution in the Contralateral Neck

Few data are available on the pattern of pathologic node distribution in the contralateral neck. Bilateral neck dissection was only performed when the surgeon considered that there was a high risk of contralateral node involvement (e.g., tumors of the oral cavity or the oropharynx reaching or extending beyond the midline, hypopharyngeal and supraglottic tumors). Obviously, in such cases bilateral radical neck dissection was never performed, so an accurate estimate of the pattern of node involvement in levels I to V of the contralateral neck is not possible. Furthermore, in almost every study, data on both sides of the neck were pooled for presentation. Kowalski presented data on 90 patients who underwent bilateral supraomohyoid neck dissection, and in whom the pattern of node distribution in each side of the neck was reported separately.[16]

The majority of these patients had SCC of the lip or oral cavity. In the ipsilateral neck, pathologic infiltration in levels I, II, and III reached 20%, 15%, and 15%, respectively. In the contralateral neck, corresponding values reached 13%, 11%, and 0%, respectively. These figures are in good agreement with data on clinical node distribution showing that both sides of the neck exhibited a similar pattern of node distribution, but with a lower incidence in the contralateral neck. Foote[17] reported the rate of contralateral neck failure in a limited series of 46 clinically N0 patients with base of the tongue tumors treated by some form of glossectomy and ipsilateral neck dissection. None of these patients received postoperative radiotherapy. Ten patients (22%) had contralateral neck recurrence, and the most common sites were in levels II, III, or IV. It appears that in two of these patients, recurrence was also observed at the primary site. The development of delayed contralateral neck metastases was not related to the clinical or pathologic extent of the base of the tongue tumor. O'Sullivan[18] reported a retrospective series of 228 patients with tonsillar carcinoma who were treated on the primary tumor and the ipsilateral neck only with radiotherapy. The vast majority of these patients had T1-T2 and N0-N1 disease. Contralateral recurrence in the neck was only observed in eight patients (2%) including five patients with local recurrence as well. No contralateral neck recurrence was observed in the 133 N0 patients. Although not significant due to the small number of events, involvement of midline structure (i.e., soft palate and base of tongue) appeared to be a prognostic factor for contralateral neck recurrence. Similar results were reported in a series of 101 node-negative tonsil carcinoma (mainly T1-T3) treated unilaterally.[19] Only two neck recurrences were observed in the contralateral neck.

Recommendations for the Selection of the Target Volumes in the Neck

The data presented in the previous sections indicate that metastatic lymph node involvement of primary SCC of the oral cavity, pharynx, and larynx typically follows a predictive pattern. Both data on clinical and pathological neck node distribution and on neck recurrence after selective dissection procedures support the concept that not all the neck node levels should be treated as part of the initial management strategy of head and neck primaries of squamous cell origin.[20,21] One should bear in mind, however, that the data on which such a concept is based have come from retrospective series, and thus may include possible bias (e.g., patient selection, series from pre-imaging area) that could limit its validity.

Tables 120-4 to 120-7 present recommendations for the selection of the target volumes in the neck for pharyngolaryngeal SCCs. These guidelines can be applied irrespective of the treatment modality (i.e., surgery or radiotherapy). The discussion of the choice between these two modalities is beyond the objective of this chapter but should be considered relative to the neck stage, the treatment option for the primary tumor, the performance status of the patient, and the institutional policy agreed on by a multidisciplinary head and neck tumor board.

For clinically N0 patients with head and neck SCC of the oral cavity, oropharynx, hypopharynx and larynx, selective treatment of the neck is appropriate.[21-23] Typically, levels I to III should be treated for oral cavity tumors, and levels II to IV for oropharyngeal, hypopharyngeal, and laryngeal tumors. Robbins has suggested that elective treatment of level IIb is probably not necessary for N0 patients with a primary tumor of the oral cavity, larynx, or hypopharynx.[24] On the other hand, Byers suggested that level IV be included in the treatment of the mobile tongue due to the high incidence (10%) of skip metastases.[25] Retropharyngeal nodes should be treated in tumors of the posterior pharyngeal wall. For subglottic tumors, tumors with subglottic or transglottic extension, or hypopharyngeal tumors with esophageal extension, level VI nodes should also be included in the treatment volume.

As proposed by Byers, similar guidelines could also be recommended for N1 patients without radiologic evidence of extracapsular infiltration.[22] However, when an involved lymph node is located at the boundary with a level, which has not been selected in the target volume, it has been recently recommended to extend the selection to include the adjacent level.[26] Typically, this will only apply for oropharyngeal tumors with a single lymph node in level II at the boundary with level Ib or for an oral cavity tumor with a N1 node in level III at the boundary with level IV.

For patients with multiple nodes (N2b), the available data suggest that adequate treatment should include levels I to V. Level I could, however, be omitted for laryngeal tumors, and level V for oral cavity tumors with neck involvement limited to levels I to III. Elective treatment of the retropharyngeal nodes should be systematically performed for oropharyngeal and hypopharyngeal tumors. As for N0 patients, level VI nodes should also be treated for subglottic tumors, tumors with

*Level IIb could be omitted for N0 patients.
AJCC, American Joint Committee on Cancer.

subglottic or transglottic extension, or hypopharyngeal tumors with esophageal extension. Recently, for patients with nodes in the upper neck (i.e., upper level II) it has been proposed to extend the upper limit of the target volume to include the retrostyloid space.[26] Similarly, the subclavicular fossae should also be included in the target volume in case of lower neck involvement (i.e., level IV or Vb nodes).[26]

No data on the distribution of pathologic metastatic neck nodes in patients presenting with a single ipsilateral large node (N2a or N3) or with bilateral or contralateral nodes (N2c) are available. For patients with a single large node, in absence of data, it appears safe not to recommend selective treatment. For N3 patients, the type of treatment of the neck is likely to be also dictated by the local extension of the node into the adjacent structures (e.g., paraspinal muscles, parotid gland, blood vessels). For N2c patients, one proposal is to consider each side of the neck separately (e.g., selective treatment in both sides for a small single node in each side, selective treatment for a small single node in one side, and more extensive treatment in the other side in the case of multiple nodes).

Elective treatment of the contralateral N0 neck is still in the gray zone and is likely to be based on clinical judgment rather than on strong scientific evidence. Typically, patients with midline tumors or tumors originating from or extending to a site that has bilateral lymphatic drainage (e.g., base of the tongue, vallecula, posterior pharyngeal wall) are thought to benefit from bilateral neck treatment, whereas well-lateralized tumors (e.g., the lateral border of the tongue, retromolar trigone, tonsillar fossa) can be spared contralateral treatment. It has also been reported in tumors of the pharynx and larynx that the risk of contralateral neck metastases increased with involvement of the ipsilateral neck.[27] Putting all these data together, one could recommend restricting the treatment to the ipsilateral neck for tumors of the lower gum (not approaching the midline); lateral floor of the mouth; lateral border of the mobile tongue; upper gum; cheek; retromolar trigone; tonsillar fossa (without extension to the base of the tongue, soft palate, or posterior pillar); and lateral wall of the piriform sinus. In the other situations, where elective contralateral neck treatment is recommended, the selection of the node levels to be treated should follow similar rules to those for the ipsilateral neck.

Because of the lymphophilicity of nasopharyngeal carcinoma tumors, bilateral treatment of levels II to V and retropharyngeal nodes is recommended even for patients with a node-negative neck (Table 120-8). For patients with node-positive necks, additional treatment of level Ib might be considered.

In principle, a similar approach should apply for the definition of the node levels to be irradiated postoperatively. However, if one agrees on the selection criteria for postoperative radiotherapy (i.e., capsular rupture, patients with a metastatic node >3 cm in diameter or with more than one metastatic node), irradiation of levels I to V are typically performed. As for primary radiotherapy, the retrostyloid space and the subclavicular fossae should be included in the target volume depending on the location of the metastatic nodes.[26] For laryngeal tumors, level I could be omitted. For oral cavity tumors, postoperative irradiation of level V could be omitted in the case of metastatic nodes located in level I and/or II only. Retropharyngeal and paratracheal nodes should be treated as mentioned earlier.

Table 120-8

Recommendations for the Selection of the Target Volume in the Neck for Nasopharyngeal Carcinoma

	Selected Levels	
Nodal Stage (AJCC 1997)	Ipsilateral Neck*	Contralateral Neck*

Neck Node Delineation and Irradiation Techniques

Delineation of the Clinical Target Volume

Since the late 1990s, several authors have proposed recommendations for the delineation of the neck node levels.[28-32] In the radiation oncology community, however, the so-called Brussels and Rotterdam guidelines have emerged as the most widely used.[28-30] A critical review of the two proposals was undertaken in 2003 in collaboration with representatives of the major European and North American clinical cooperative groups to generate an international set of guidelines for the delineation of the neck node levels in the node-negative neck.[33] The correspondence between these guidelines and neck dissection proce-

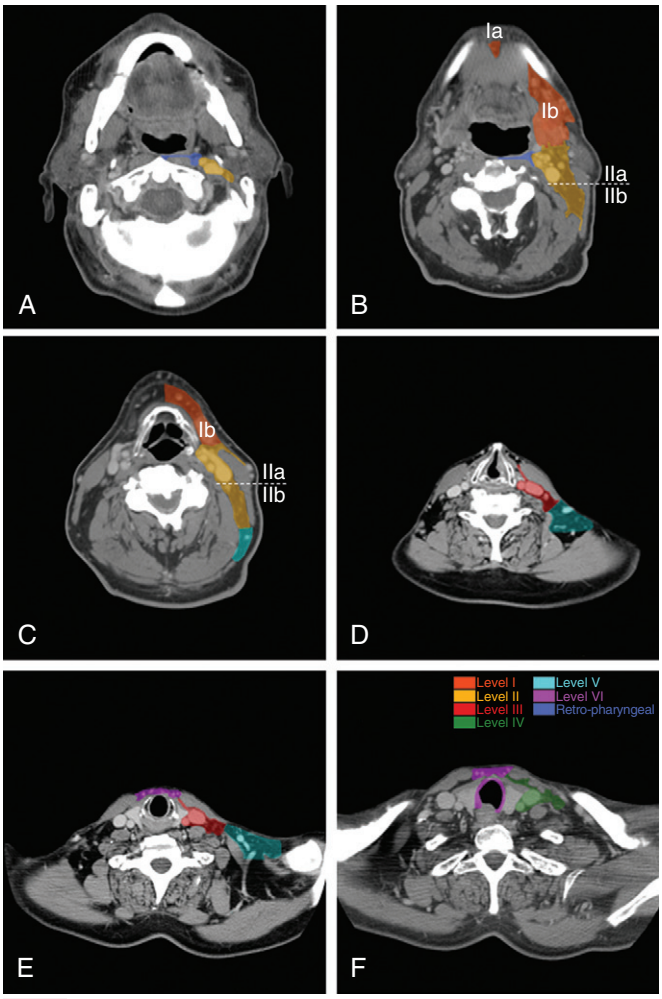

Figure 120-7. Computed tomography (CT) imaging of a patient with a T1N0M0 glottic SCC (see tumor in **D**). The examination was performed on a dual-detector spiral CT (Elscint Twin, Haifa, Israel) using a slice thickness of 2.7 mm, an interval reconstruction of 2 mm, and a pitch of 0.7. Contrast medium was injected intravenously at a rate of 2 mL/s with a total amount of 100 mL. Sections were taken at the level of the bottom edge of C1 **(A),** the upper edge of C3 **(B),** mid C4 **(C),** the bottom edge of C6 **(D),** the bottom edge of C7 **(E),** and mid D1 **(F).** Neck node levels were drawn on each CT slice using the consensus guidelines. Each node level corresponds to the clinical target volume, and thus does not include any security margin for organ motion or setup inaccuracy.

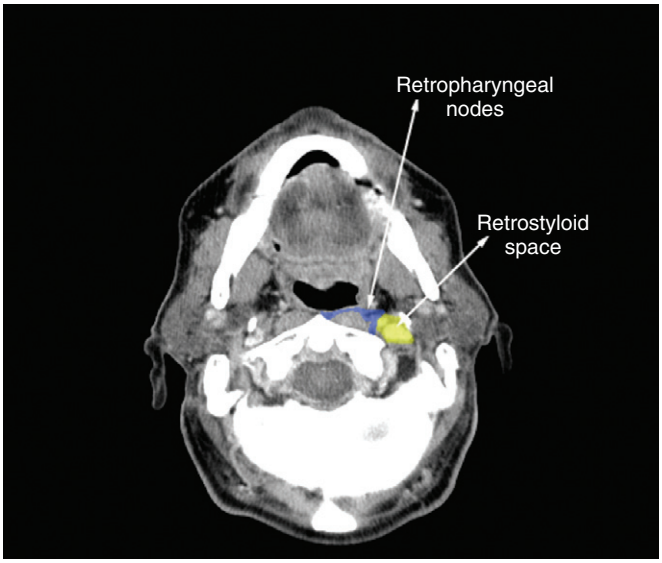

Figure 120-8. Computed tomography section at the level of the base of skull. The image was acquired as explained in Figure 120-7. The delineated areas correspond to the clinical target volume and thus do not include any security margin for organ motion or setup inaccuracy.

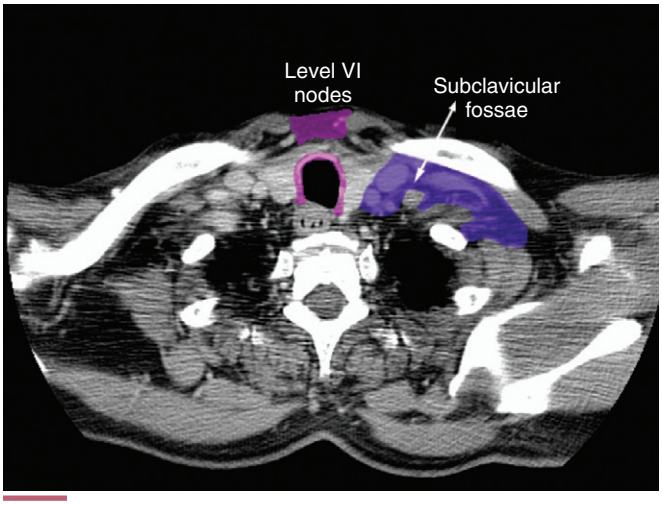

Figure 120-9. Computed tomography section at the level of the subclavicular area, 18 mm above the sterno-clavicular joint. The image was acquired as explained in Figure 120-7. The delineated areas correspond to the clinical target volume and thus do not include any security margin for organ motion or setup inaccuracy.

dures was further validated by a recent clip study.[34] Last, few amendments were recently proposed to take into account the specific situation of the node-positive and postoperative neck.[26,35] In short, this later proposal recommended the delineation of extranodal structures in case of muscular infiltration, the inclusion of the retrostyloid space in case of infiltration of level II, and the inclusion of the subclavicular fossae in case of infiltration of level IV and/or Vb.

It is beyond the scope of this chapter to present an in-depth discussion of the boundaries of the various levels. Interested readers are invited to refer to the original publications or to visit public Web sites, where atlases of neck node delineation have been posted (http://groups.eortc.be/radio/N0HEADNECKCTV.htm; http://www.rtog.org/atlases/hnatlas/main.html).[26,33] Figures 120-7 to 120-9 present several CT cuts of the neck with selected levels.

Irradiation Techniques

With the use of three-dimensional (3D) conformal radiotherapy (3D-CRT) and intensity-modulated radiation therapy (IMRT), there is no standard recipe anymore on how to set up the field sizes and borders according to bony landmarks. Instead, the irradiation technique should be selected and adapted so that the entire planning target volume (PTV) receives the prescribed dose within the adopted dose-volume constraints and in full respect of the International Commission on Radiation Units and Measurements recommendations.

The dose prescription depends on various factors (e.g., elective vs. therapeutic irradiation, the use of combined modality treatment, planned neck node dissection, postoperative irradiation), which are beyond the scope of this section for comprehensive review. Typically, for primary radiotherapy, an elective dose on the order of 50 Gy in about 2 Gy per faction over 5 weeks and a therapeutic dose on the order of 70 Gy in about 2 Gy per fraction over 7 weeks will be prescribed. For postoperative irradiation, depending on the risk factors, doses will range from 60 to 64 to 66 Gy, in 2 Gy fraction over 6 to 6.5 weeks. A typical example of neck irradiation is presented in Figure 120-10.

Control of the N0 Neck

It is generally recommended to perform elective treatment of the neck in patients with primary head and neck SCC clinically staged N0 but having 20% or greater probability of occult lymph node metastases.[36] Elective neck dissection and elective neck irradiation are equally effective in controlling the N0 neck. The choice between these two procedures thus generally depends on the treatment modality chosen for the primary tumor, which in turn mainly depends on the institutional policy. However, the basic rule that should govern the choice between surgery and radiotherapy is to favor the use of a single-modality treatment if possible and thus avoid overtreatment. For example, for a T1 or a T2-N0 supraglottic larynx, typically, a supraglottic laryngectomy with a selective neck node dissection or a primary radiotherapy on the larynx and the neck are equally effective therapeutic options. For such stage disease, the need for postoperative radiotherapy is indeed quite low. Conversely, for a T3-N0 supraglottic larynx, a conservative treatment approach with primary radiotherapy or concomitant chemoradiotherapy should be favored because of the necessity of postlaryngectomy radiotherapy and the nonsuperiority of the surgical approach.

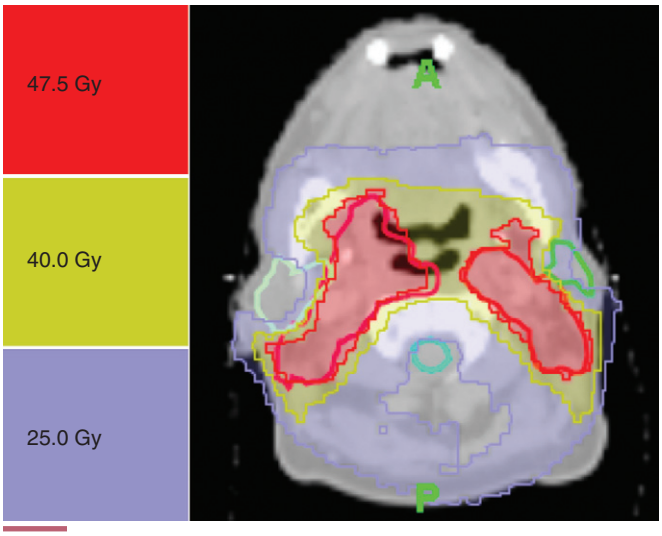

Figure 120-10. Computed tomography section at the level of C2 with dose distribution from an intensity-modulated radiation therapy plan for a hypopharyngeal T4-N0-M0 squamous cell carcinoma treated by concomitant chemoradiation. An elective dose of 50 Gy was prescribed to levels II to IV on both sides of the neck. A total dose of 70 Gy was prescribed to the right piriform sinus. Three courses of cisplatin (100 mg/m^2) were given in weeks 1, 4, and 7. The target volumes are delineated in red *(bold line).* The left parotid gland is delineated in green. The right parotid is delineated in light green. The spinal cord is delineated in blue. The color scale for the dose areas is depicted on the left. Sharp dose gradients are created between the target volumes and the normal tissues. A mean dose of 20.0 Gy was delivered to both parotids. The maximum dose to the spinal cord did not exceed 25 Gy.

Table 120-9 presents the percentage of neck recurrences in large retrospective series of pharyngolaryngeal SCC treated with conventional fractionated radiotherapy.[37-39] Some of the patients reported in those series were treated in the late 1950s, and thus the data must be interpreted with caution because of the likelihood of large uncertainties on the absolute dose calculation and dose distribution. Altogether, the neck control reached more than 92% after radiotherapy. After salvage surgery, the ultimate neck control reached a range of 94% to 100%. As expected, because of the high probability of regional control obtained with standard fractionation regimens, altered fractionation regimens or combined chemoradiotherapy do not improve the neck control.[40,41] All these studies were performed using two-dimensional (2D) irradiation techniques (i.e., with target volumes extending typically from the base of skull to the clavicles).

With the introduction of 3D-CRT and IMRT, as well as selective neck irradiation, one important issue is the potential risk of geographic miss outside of the irradiated volumes. Eisbruch reported a series of 135 patients treated bilaterally from 1994 to 2002 with 3D-CRT or IMRT for primary tumors mainly located in the oropharynx ($n = 80$) and without node metastasis on the contralateral neck.[42] On the contralateral neck, the clinical target volume (CTV) included typically level II to IV and the retropharyngeal lymph nodes. For the contralateral level II, the upper limit was set at the junction between the posterior belly of the digastric muscle and the jugular vein. The median elective dose was 50.4 Gy with a fraction of 1.8 to 2 Gy. With a median follow-up of 30 months (range: 6 to 105), 15 patients had a regional recurrence (of whom 6 also had a primary tumor recurrence), 11 on the ipsilateral side and 4 on the contralateral side. Only 1 of the 15 patients presented a retropharyngeal node recurrence marginal to the CTV. Using a similar treatment philosophy, Bussels and colleagues[43] did not report any recurrence on the ipsilateral N0 neck treated with parotid sparing 3D-CRT in a series of 72 patients with oral cavity and pharyngo-laryngeal SCC. Chao and colleagues[44] also looked at the pattern of recurrence in a series of 126 patients treated postoperatively ($n = 74$) or primarily ($n = 52$) by IMRT for head and neck SCC from 1997 to 2000. In this series the lower neck (below the thyroid notch) was treated with a "traditional" anterior field. With a median follow-up of 26 months, 17 (13%) recurrences were observed. Six of these patients recurred outside of the target volumes, of which only one was in the lower neck of a N0 patient.

Control of the N1-N3 Neck

Neck Control after Primary Radiotherapy

The lower probability of regional control of the positive neck with radiotherapy has been already documented by several retrospective series.[37,39,45] In a series of 1646 patients with SCC of the oropharynx

Table 120-9

Neck Failure after Primary Radiotherapy for Node-Negative Patients

Authors	Primary Tumor Site	Number of Patients (Study Period)	Dose/Overall Treatment Time	Control of the Neck	
				After Radiotherapy	After Salvage Surgery
Bernier[37]	Oral cavity, hypopharynx, larynx	611 (1958-1974)	45-55 Gy/4.5-5.5 wk	93%	Not stated
Johansen[39]	Oral cavity, hypopharynx, larynx	1324 (1963-1991)	57-72 Gy/6-9 wk*	92% at 10 yr	94% at 10 yr

*Including 28% of patients with a split course.

and pharyngo-larynx from the Institut Curie in Paris, the 3-year regional control probability was 98%, 90%, 88%, and 71% for N0, N1, N2, and N3 (AJCC 1976 classification), respectively.[37] The nodal size was an even more discriminating factor with nodal failure of 6%, 14%, and 39% for nodes below 3 cm, between 4 and 7 cm, and more than 7 cm, respectively.[45] In this series, 75% of the neck nodes were, however, treated by a form of concomitant boost approach with total dose in the range of 70 to 85 Gy in 5 to 6 weeks. In the series of 458 node-positive patients with SCC of the larynx and pharynx treated at Aarhus University hospital from 1963 to 1991, the 5-year neck node control reached 68%, 68%, and 56% for N1, N2, and N3 UICC 1982 stage, respectively.[39]

A key issue in the management of the positive neck by radiotherapy is whether these rather poor results are improved by hyperfractionated or accelerated regimens, or by concomitant chemoradiotherapy. In randomized studies comparing a standard fractionated regimen with an altered fractionated regimen, no improvement was observed between the two arms (Table 120-10).[46-48] In the European Organization for Research and Treatment of Cancer (EORTC) 22791 trial, only N0 or N1 neck patients were included, and because of the excellent control of the neck in the standard arm, it was not surprising that the hyperfractionated regimen did not bring any benefit.[46] In the Danish Head and Neck Cancer (DAHANCA) 6 and 7 trials, no significant regional improvement was observed with the accelerated regimen in the node-positive patients.[47] Similarly, despite a benefit in overall survival, the Toronto trial did not observe any increase in the control of the neck with an accelerated hyperfractionated regimen.[48] Contrary to results achieved with altered fractionation regimens, concomitant chemoradiotherapy regimens appear to affect the control of the neck (Table 120-11).[49,50] In the study of Calais, all neck stages were analyzed together. However, because 75% of patients were node positive, it is unlikely that the 12% improvement results only from a beneficial effect on the N0 patients. In the study of Lavertu, which included fewer patients, the improvement in node control was observed for all positive neck stages.

Indications for Postoperative Irradiation/Postoperative Chemoirradiation

The benefit of postoperative radiotherapy in head and neck SCC has progressively emerged in the 1970s and 1980s as a standard of care for patients at high risk of locoregional relapse after surgery.[51-54] Prognostic indicators for locoregional relapse after surgery have been progressively identified, including the primary disease site, surgical margins at the primary site, presence of perineural invasion, number of metastatic lymph nodes, and presence of extracapsular rupture.[55,56] On the basis of the clustering of these pathologic factors, the M. D. Anderson Cancer Center proposed to stratify the patients into three risk categories conditioning the need for postoperative irradiation (Table 120-12).[57] In the absence of any risk factor, the need for postoperative radiotherapy could not be demonstrated. Patients with extracapsular rupture or a combination of two or more risk factors were identified as being at high risk of locoregional relapse, and for those patients, a randomized study demonstrated the benefit of a radiation dose of 63 Gy (in 35 fractions) compared with 57.6 Gy (in 32 fractions). For patients with only one risk factor other than extracapsular rupture, a dose of 57.6 Gy was demonstrated as optimal. A subsequent study from the same group

further validated the use of these categories of risk factors and also individualized the time between surgery and the start of postoperative radiotherapy, as well as the total treatment time (from surgery to the end of radiotherapy) as additional risk factors.[58] In this latter study, it was also demonstrated that patients with high risk of relapse benefited from an accelerated treatment (63 Gy in 5 weeks vs. 63 Gy in 7 weeks) both in terms of locoregional control and survival.

With the need to further improve the locoregional control after surgery and postoperative radiotherapy, few trials combining postoperative concomitant chemotherapy and radiotherapy have been reported in the 1990s.[59,60] Although positive in favor of the combined approach, these studies did not really influence the pattern of care of patients primarily treated with surgery. More recently, the EORTC and the Radiation Therapy Oncology Group (RTOG) conducted similarly designed studies aiming at assessing the benefit of postoperative radiotherapy (60 to 66 Gy) combined with *cis*-platinum (100 mg/m^2) given on days 1, 22, and 43 for patients with a variety of risk factors, but slightly different between the two trials.[61,62] In the EORTC study, a highly statistically significant benefit in favor of the combined treatment was observed for both loco-regional control and overall survival (Table 120-13). In the RTOG study, the benefit in locoregional control probability did not translate into a statistically significant difference in survival. Combined modality treatment did not decrease the incidence of distant metastasis in any of these studies. In both studies, the concomitant use of chemotherapy significantly enhanced the acute local toxicity of radiotherapy and only half the patients could actually receive the full treatment as planned. A meta-analysis of these two studies was recently performed and demonstrated a statistically significant benefit of combined chemoradiotherapy, but only in patients presenting with positive surgical margins and/or extracapsular spread (i.e., patients with the highest risk of relapse after surgery).[63] For the other patients, radiotherapy alone can still be considered as a standard of care.

Two or more invaded node levels	
Invaded node(s) >3 cm in diameter	
More than 6 wk between surgery and start of radiation therapy	

Indications for Postradiotherapy Neck Node Dissection

Recent advances in (chemo)radiotherapy for advanced head and neck carcinoma have demonstrated that organ preservation is feasible without compromising disease-free survival and overall survival.[64,65] This strategy has led to controversial issues concerning the role of node dissection following radiotherapy or chemoradiation for patients with N2-N3 disease at initial diagnosis. Residual neck mass may be present in up to 30% to 50% of patients after completion of chemoradiotherapy. For those patients, irrespective of the neck stage, there seems to be a consensus in the literature favoring an immediate neck node dissection because of the low probability of achieving a neck control with salvage surgery when recurrence develops.[66] Should a neck dissection be proposed to all patients with N2-N3 disease at diagnosis or only to those with a no complete response, is still a matter of debate.[67-70] This controversy seems to be fueled by the difficulty of assessing the residual neck disease after organ-preservation protocol. In this respect, the use of FDG-PET scanning has gained some interest. In a 2004 study including 41 patients treated with definite radiotherapy (with or without concomitant chemotherapy), a negative postradiotherapy PET was highly correlated with a negative pathologic finding after neck node dissection or fine-needle aspiration, or with the absence of neck relapse (negative predictive value of 100% for a maximum standardized uptake value < 3.0).[71] In another study including 24 patients staged with FDG-PET after induction chemotherapy followed by chemoradiotherapy, the negative predictive value of PET, however, only reached 73%.[72] Further prospective studies are thus necessary to validate the use of PET to assess the need for post (chemo)radiotherapy neck node dissection. In the meantime, balancing the benefit with the increased morbidity of postchemoradiotherapy surgery, evidence suggests that neck node dissection be restricted to those patients with a noncomplete response after organ-preservation protocol.

Late Complications after Neck Irradiation

In the following section, only specific complications arising in the soft tissues of the neck are reviewed. It mainly concerns subcutaneous

fibrosis, thyroid dysfunction, and carotid artery stenosis. Typically, late-complication probability depends on the total dose, dose per faction, time interval between fractions, volume of normal tissue that received a high dose, and use of concomitant chemotherapy and/or biologic modifier.

The probability of grade 3 to 4 (RTOG late-morbidity scale) subcutaneous fibrosis in the neck is rather low after standard radiotherapy. From randomized studies performed in the 1990s, it can be estimated to be around 3%.[49,73-75] After accelerated or hyperfractionated treatments, no increase in grade 3 to 4 subcutaneous toxicity was observed, providing that enough time was left between fractions.[74] On the contrary, in an EORTC trial with only a 4-hour interfraction time, a 50% risk of fibrosis was documented at 5 years after treatment.[76] After concomitant chemoradiotherapy, randomized trials reported a substantial increase in late skin morbidity reaching figures around 10%.[49]

Clinically indolent hypothyroidism has been reported in patients irradiated on the lower neck with a frequency of up to 24%.[77,78] The majority of patients usually develop hypothyroidism within a year post treatment. Postoperative radiotherapy, especially after laryngeal surgery including partial thyroidectomy, has been shown to be a risk factor. Yearly thyroid function test (i.e., thyroid-stimulating hormone level) is advised in the follow-up of patients irradiated to the neck.

Carotid artery stenosis after neck irradiation has been reported by several authors, but few studies have investigated the incidence, disease patterns, and risk factors. Matched control Doppler ultrasound examinations have reported significant carotid stenosis in 30% to 50% of patients previously irradiated to the neck.[79] Compared with the general population, a relative risk of stroke of 5.6 has been reported in patients previously irradiated to the neck.[80] This relative risk was further increased for patients older than 60 years and with follow-up longer than 10 years. Increased attention to the clinical signs of carotid stenosis together with proper management of the other risk factors (e.g., diabetes, hypertension, hypercholesterolemia, smoking, obesity) should contribute to decrease the incidence of stroke and neurologic sequelae in this patient population.

All the published data on late complications are from the pre-IMRT area. With the use of modern radiotherapy technique, a major reduction in late complications is anticipated mainly through a reduction in the volume of normal tissue irradiated at high dose and a reduction of the "uncontrolled" hot spot within or outside of the PTV. The introduction of IMRT has, however, raised the controversial concern of an increased risk of radiation-induced secondary neoplasm because a larger volume of normal tissue might be irradiated at lower dose in comparison with standard 2D techniques. Also, the delivery of a specified dose to the isocenter from modulated fields requires a longer beam time compared with the same dose delivered with a nonmodulated field. The IMRT treatment plan then results in an increase in the number of monitor units by a factor of 2 to 3, increasing the dose outside the boundary of the primary collimator as a result of leakage and scattered radiation.[81] As a consequence, the total body dose received is substantially increased. It is estimated that an additional 0.5% of surviving patients will develop a secondary malignancy as a result of an increased volume of normal tissue receiving a small radiation dose. This number needs to be added to the 0.25% of surviving patients who subsequently develop a radiation-induced malignancy. In all, it is thus estimated that about 0.75% of surviving patients are expected to develop a secondary malignancy as a result of the switch to IMRT, which is approximately twofold greater than the incidence observed following more conventional radiotherapy.[82] Whatever the contribution of IMRT in the induction of secondary cancers may be, we should bear in mind that even if IMRT increases the probability of locoregional control and the potential for increased cause-specific survival, this group of patients will suffer from comorbidities and increased risk for a second primary associated with their lifestyle, which may decrease the relative importance of radiation-induced secondary malignancies.

Management of Recurrent Disease in the Neck

Whether treated by radiotherapy, surgery, or the combination of both, the prognosis of patients with recurrence in the neck remains abysmal. Recurrent neck disease is quite invariably associated with unfavorable prognostic factors. Extracapsular spread is almost always reported and multiple LNs levels are frequently involved.[83] Neck recurrences are often unresectable because of involvement of the wall of the common carotid artery or the internal carotid artery, the paraspinal muscles, and the cranial nerves. Even when salvage surgery is attempted, the inability to achieve a complete resection with clear margins is generally the rule.

Few studies have specifically addressed the problem of recurrent neck disease following curative treatment in head and neck SCC. Godden retrospectively reviewed the charts of 35 patients with recurrent neck disease.[83] More than 80% of patients had primary surgery and the remainder were treated with radiotherapy. Fifty percent of the patients treated with primary surgery had postoperative radiotherapy. Eighteen patients had a neck dissection at initial presentation. The recurrence was managed by neck dissection in 25 patients, and among them, 18 had postoperative radiotherapy. Ten (29%) were considered as inoperable. Of the 18 patients who had an initial neck dissection, 9 (50%) recurred in the level II, previously cleared. Neck recurrence seemed to be more related with residual disease after the first neck dissection. This surprisingly high rate of level II recurrence stresses the necessity of adequate training for surgeons performing neck dissection procedures. In this series the ultimate control of the neck was only obtained in 5 of the 35 patients and the 4-year overall survival did not exceed 20%.

The likelihood of successful salvage treatment in patients who experienced neck recurrence after primary radiotherapy is low. Bernier and colleagues[37] reviewed 116 patients with isolated nodal failure after radiotherapy alone for oropharyngeal, hypopharyngeal, and laryngeal carcinoma. Fourteen patients had salvage neck dissection and 18 were reirradiated on the neck. Only one patient (1%) was successfully salvaged. The University of Florida recently reviewed the medical records of 51 patients who experienced recurrent disease occurring in the neck only.[84] Only 18 patients (35%) underwent salvage treatment, chemotherapy alone in 4 patients, chemotherapy and neck dissection in 1 patient, neck dissection alone in 11 patients, and neck dissection with postoperative radiotherapy in 2 patients. After salvage treatment, all patients had relapse of disease (locally, regionally, or distantly). Control of the neck at 5 years was 9% for the group who underwent salvage treatment, which was similar to the rate of neck control for the whole population. For the whole group of patients, absolute and cause-specific survival reached 10% at 5 years for both end points. However, at 3 years, patients who received salvage treatment had absolute and cause-specific survival rates of 44%. In comparison, none of the 33 remaining patients was alive at 3 years. Few institutions have evaluated salvage treatment with aggressive combined modality approaches that include low-dose reirradiation (preoperation or postoperative with or without concurrent chemotherapy) combined with an attempt at gross resection plus intraoperative irradiation (IORT) with either electrons (IOERT) or high-dose-rate brachytherapy (HDR-IORT).[85] Although the series involve small numbers of patients, early results suggest potential improvements in both locoregional control and survival when compared with standard salvage approaches, and further evaluation is warranted.

In summary, the majority of patients with regional recurrence are unable to undergo salvage treatment, and when salvage treatment with standard approaches (surgical resection, external beam radiation) is attempted, control of the neck remains poor. Salvage neck dissection alone should be restricted to patients with limited recurrence in the neck.

Radiation Therapy and Malignant Skull Base Tumors

Tumors of the cranial base are rare and present with minimal symptoms. They account for less than 1% of all new cases of cancer.[86] Unless these tumors impinge on vital organs or extend from the maxillary sinus to the nasal cavity resulting subsequent epistaxis or obstruction, diagnosis is often delayed. Depending on the location and the histopathology, treatment using radiation therapy is either in the definitive, neoadjuvant, or adjuvant setting. Because multiple critical normal tissues are located within or near the skull base (e.g., optic chiasm, cranial nerves, orbits, brainstem), radiotherapy techniques are focused

on treating the tumor while minimizing toxicities and complications. In this section of the chapter, we discuss the indications of radiation and describe the different technical advances in radiotherapy and their applications in the treatment of more commonly seen skull base tumors.

The treatment of cranial base tumors presents a difficult and challenging task for the radiation oncologist. Because tumors are irregularly shaped and are near or at the cranial base, a pair of lateral-opposed fields often cannot adequately encompass the tumor without causing excessive toxicity to the surrounding normal tissues. Therefore with conventional techniques, the dose of radiation is often limited by the need to respect normal tissue tolerance to radiation. Thus multiple different methods have evolved in treating tumors of the cranial base. Stereotactic irradiation, linear accelerator (LINAC)-based or gamma knife unit, is one method used in radiation delivery. The radiation delivered has a sharp dose fall-off between the target and the surrounding tissue, thus allowing precise delivery of radiation to the tumor target while minimizing the dose of radiation delivered to the surrounding normal tissues. However, radiosurgery can be limited by the size and shape of the tumor. IMRT, an evolution of 3D-CRT, allows the delivery of radiation to larger volumes and even more irregularly shaped tumors. For this reason, IMRT has recently gained popularity in the treatment of head and neck cancer, especially in the treatment of skull base tumors. Lastly, other technical approaches such as proton beam radiotherapy (cyclotron) or the CyberKnife (photon beam), though not available in most radiotherapy clinics, are also used. Indeed, the advancement in technology allowing more precise targeting of the tumor has resulted in improved tumor control or improved palliation of tumor-related symptoms. This is especially true when these tumors are unresectable or are recurrent on presentation.[87-89]

Radiation Technical Advances

LINAC-Based and Gamma Knife Stereotactic Irradiation

Stereotactic irradiation is a procedure whereby radiation is delivered using stereotactic principles.[90] Stereotactic irradiation can be performed by using any one of the high-energy forms of radiation, whether radiographs, gamma rays, or charged-particle irradiation. This procedure requires a multidisciplinary team approach and is used to destroy or to induce a desired biologic effect in a predetermined target while minimizing radiation to the surrounding tissues without having to open the skull. The word *stereotaxis* is derived from two Greek words: stereos, which means "three-dimensional," and taxis, which means "orderly arrangement." The concept of stereotactic irradiation derived from the understanding and use of stereotactic neurosurgery. The main benefit of stereotactic irradiation is that a high dose of radiation can be delivered to a defined region, usually within a well-immobilized system that conforms closely to the 3D shape of the target volume, at the same time having a rapid dose fall-off to the surrounding normal tissues.

Stereotactic irradiation was first introduced in 1951 by Lars Leksell, who coupled a stereotactic device to an orthovoltage x-ray tube and used 280-kV x-rays to treat trigeminal neuralgia.[90,91] Dr. Leksell also used a linear accelerator using higher-megavoltage radiation beams. In 1968 Leksell began using cobalt sources for irradiation of the thalamus in two cases of intractable pain. Subsequently, 179 highly collimated cobalt-60 sources were used to treat a variety of human diseases such as cancer pain, acoustic neuromas, craniopharyngiomas, intracranial arteriovenous malformations, parkinsonism, and Cushing's disease. These multiple, small, radioactive cobalt sources produced focused gamma beams, which Leksell called *gamma knife–based radiosurgery.* During the same time period at the University of California-Berkeley Lawrence Laboratory, charged-particle beams were used to treat pituitary tumors stereotactically (i.e., with protons, helium ions, neutrons). In the 1970s and 1980s, many radiotherapy centers used the existing linear accelerator at their facilities and adapted it to produce narrow, collimated beams of high-energy photons or x-rays. This was a less expensive alternative to both the gamma knife and the heavy charged-particle units. These new techniques were all based on the concept of using stereotactic frames for lesion localization, treatment setup, and patient immobilization during treatment. It was also during this time that Lunsford at University of Pittsburgh used the first 201 cobalt-60 source gamma knife unit to treat brain lesions stereotactically in the United States. Special collimator helmets (4, 8, 14, and 18 mm) with small apertures of corresponding sizes ensure that the 201 gamma ray beams converge at the focal point. Studies have shown that the gamma unit is more successful at conforming to the highly irregular shapes of the tumor than conventional LINAC-based stereotactic irradiation. The accuracy has been on the order of plus or minus 1.2 to 1.3 mm.[92-94] With proper planning, education, and awareness, gamma knife unit can greatly increase the number of patients being treated with stereotactic irradiation and can be effective for control of skull base tumors. However, minimal complications can arise (e.g., involving the optic structures) in patients who undergo stereotactic irradiation. In general, complications can occur in less than 2% of cases when patients receive more than 8 Gy as a single dose to a short segment of the optic apparatus.[95]

Proton Beam

Proton beam radiotherapy has superior dose distribution of radiation compared with photons due to the physical characteristics of protons.[96,97] Protons can be designed to yield a uniform dose across the target and deliver virtually zero dose deep to the target, as well as lower dose proximal to the target. Another benefit of proton beam radiotherapy is that the integral dose (dose delivered to the entire body) is approximately one half that of photon beam radiotherapy. This applies to both single-field and multiple-field treatment plans. Currently, there are few available and active proton beam units in the United States (e.g., Massachusetts General Hospital, Loma Linda Medical Center, Florida Proton Therapy Institute in Jacksonville, M. D. Anderson Cancer Center), in Europe (e.g., Paul Scherrer Institute in Switzerland, Orsay in France) and in Japan (e.g., Chiba, National Cancer Center, Hyogo Ion Beam Medical Center, Proton Medical Radiation Center). Approximately 15 more units are being built or are in active planning throughout the world. Proton beam units are extremely costly (2.6 times that of photon beam units) and require a tremendous amount of physical space to implement.[98] The small but definite advantage that they offer over conventional photon radiotherapy may not justify their widespread use. However, clinical gains have been observed over conventional photon radiotherapy in the treatment of patients with uveal melanoma, chordoma, and chondrosarcoma.

CyberKnife

The CyberKnife is a frameless robotic radiosurgical device that has been developed to treat mainly extracranial lesions.[99] This is contrary to the frame-based stereotactic radiosurgery devices as seen with the gamma knife or the LINAC-based stereotactic irradiation. The advantages of the CyberKnife include the ability to deliver radiation without a frame, the feature of increased fractionation flexibility, and the ability to treat extracranial lesions. The accuracy of the first-generation CyberKnife reported by Murphy and Cox in 1996[100] is found to be comparable with that of the frame-based system, on the order of 1.6 mm. The advances in digital imaging, robotics, and high-speed computers have made the CyberKnife just as accurate as frames on the order of 1.1 mm. The robotic CyberKnife can change the target of the beam delivery instantaneously. Target coordinate can be racked with external markers or with the use of an old stereotactic technique: biplane teleradiography. This is a noninvasive alternative to conventional stereotactic techniques and also assists fractionated treatment. To correct for patient misalignment, the device provides both translational, as well as rotational, corrections. The CyberKnife depends on a co-registration of digitally reconstructed radiographs that are generated from CT images and x-ray projections that are captured during the treatment session.

Intensity-Modulated Radiation Therapy

IMRT is a refinement of 3D-CRT that relies on the modulation of radiation beams to deliver a high dose to the tumor target while significantly reducing the dose to the surrounding normal tissues.[101,102] The underlying principle of IMRT is that each broad radiation beam is divided into a number of smaller beams called *beamlets.* This is achieved with the use of an intensity-modulator (e.g., multileaf collimator) or the hardware of IMRT. The different beamlets, each with a

different intensity, are added to form a dose distribution that is tailored to the shape of the target at hand. IMRT can be divided into two broad categories: forward-planning and inverse-planning therapy. Forward planned multisegmented technique (FPMS), also called *simple IMRT* or *forward-planned IMRT* (FP-IMRT), can achieve similar dose distributions when compared with inverse-planned IMRT (IP-IMRT). The drawback with FPMS is that optimization is done using manual iteration (trial and error) by the planning dosimetrist or physicist. It is heavily dependent on the experience of the treatment planner, and it is quite time consuming. With proper placement and weighting of beam angles, the number of iterations can be significantly reduced. On the other hand, computer-optimized or IP-IMRT relies on a computer software program that has an optimization algorithm that can achieve an ideal dose distribution on the basis of thousands of iterations. Currently, different treatment software is available throughout the world. Most centers use commercially available software (e.g., Peacock, Corvus, Pinnacle). Some centers such as Memorial Sloan-Kettering Cancer Center use their own in-house computer software.

Head and neck cancers, particularly skull base tumors, are ideal tumors for IMRT application because the tumors often present in close proximity to multiple critical normal tissues such as the brainstem, optic chiasm, optic nerves, and spinal cord.[101,103] In addition, because there is a lack of organ motion in the head and neck region, daily patient setups can be reproduced appropriately, with adequate immobilization. Furthermore, because head and neck cancer often presents in a locally advanced stage, potential dose escalation to the primary tumor using IMRT may result in an improvement in local control. However, an important issue cannot be overlooked involving the use of IMRT. IMRT has a sharp dose fall-off gradient between the target and surrounding normal tissue, thus making adequate target volume delineation absolutely essential. The treatment planning system will not treat areas not drawn on the CT slices, and the algorithm will even "work hard" to spare regions that are not contoured. Precise target volume delineation is dependent on a thorough physical examination and adequate imaging studies such as MRI, especially near the skull base region. Given these factors, target volume delineation ideally should be done with a multidisciplinary team approach consisting of the involvement of a radiation oncologist, a neuroradiologist, and in the postoperative setting, a head and neck surgeon. The target volumes of each case are carefully and accurately defined jointly by the multidisciplinary team. Therefore to use this new technology properly and effectively, IMRT requires a dedicated team of physicians, physicists, dosimetrists, and therapists to work together.

Treatment of Malignant Cranial Base Tumors

The cranial base can be divided into three regions: the anterior, middle, and posterior skull base. The complex anatomy of this region requires a multidisciplinary approach to skull base neoplasms. Definitive and complete surgical resection with or without postoperative radiotherapy is in general the favored treatment approach, with the exception of nasopharyngeal cancer. At the time of initial diagnosis, there should be close communication between the surgeon and the pathologist to ensure adequate tissue for diagnosis and subsequent confirmatory studies when necessary. It is absolutely essential that the surgeon and the pathologist be in direct communication regarding sites of surgical margins of greatest concern, as well as the orientation of the resected specimens. In addition, placing surgical clips at the time of surgery in the areas of concern can also provide useful information for the treating radiation oncologist so that he or she will have a better understanding of where to focus the highest dose of radiation. The authors will discuss malignant tumors arising from the anterior and middle cranial base. Tumors of the posterior cranial base are typically benign and therefore discussed in a separate chapter.

Anterior Cranial Base

The anterior cranial base extends from the frontal bone, which contains the frontal sinus, to the anterior and superior edge of the greater wing of the sphenoid bone. The posterior wall of the frontal bone forms the anterior limit of the anterior cranial base. This anterior base is above the orbital roofs and contains the frontal poles of the brain. The roof of the ethmoid and sphenoid sinuses forms the floor of the anterior cranial base between the bilateral orbits. The olfactory nerves (cranial nerve I) exit through the foramina (cribriform plate) of the anterior skull base into the nasal cavity.[104]

Malignant tumor involvement of the anterior cranial base is the result of contiguous spread from the paranasal sinuses, nasal cavity, or nasopharynx. Tumors confined to the ethmoid sinus without any involvement of the surrounding structures and sinuses are extremely rare. Ethmoid sinus tumors with extension to the ipsilateral nasal cavity, maxillary sinus, orbit, sphenoid, anterior cranial fossa, frontal sinus, and nasopharynx are common. Tumors can also extend to the orbit via the lamina papyracea and superiorly into the anterior cranial fossa via the cribriform plate. If the dura is compressed but not involved with tumor, it does not portend a poor prognosis when compared with tumor extension with histologic involvement of the dura.

Benign lesions such as meningioma, juvenile angiofibroma, and fibroosseous lesions and malignant lesions such as esthesioneuroblastoma (ENB) and SCC can originate from the anterior skull base. For the purpose of this chapter, selected malignant tumors of the anterior skull base are discussed. The role of radiotherapy in the treatment of ENB is reviewed in this section, as is sinonasal undifferentiated carcinoma (SNUC).

Esthesioneuroblastoma

First described in 1924, ENB remains a relatively rare entity. It is also known as "olfactory neuroblastoma" and accounts for 1% to 6% of all intranasal cancers, which constitute less than 1% of all human malignancies.[105,106] The tumor arises from the olfactory mucosa at the cribriform plate and frequently invades the paranasal sinuses, orbits, and skull base. Patients present with symptoms of nasal obstruction, epistaxis, nasal discharge, sinus pain, visual changes, facial numbness, or a neck mass. Tumors are often locally advanced on presentation. Cervical nodal metastases have been reported in 17% to 27% of patients, whereas distant metastases have been on the order of 10% to 40%. Different staging systems have been used by different centers.[107] MRI in addition to CT is useful as part of the staging workup because it can better differentiate between tumor and secretions caused by sinusitis.

Prognostic factors include age, stage, sex, and grade.[108] Patients older than 50 years of age have a worse prognosis than females. Those who present with nodal disease have a lower survival than those with node-negative disease (29% vs. 64% at 5 years). Grade has also been reported to be an important prognostic factor. Hyams' grade[109] is based on defined histologic features such as lobular architecture, neurofibrillary background, rosettes, nuclear pleomorphism, mitosis, necrosis, and calcification of the tumor. Each of these features is assigned a numeric grade (the Hyams' grade). Patients who present with a high Hyams' grade did significantly worse in one series compared with those with a low Hyams' grade (36% vs. 81% 5-year overall survival).

Locoregional failure rates after definitive treatment of ENB have been reported in the range of 24% to 75%, and the 5-year overall survival rates ranged from 60% to 78% (Table 120-14). Patients treated with surgery and radiation had a 5-year local control rate of 87.4% versus 51.2% with radiation alone in one series. Patients who failed treatment locoregionally failed within the ethmoid sinus or the orbit. Patients can also fail distantly in the liver or the brain parenchyma.

There is little consensus in the literature regarding the different therapeutic approaches; however, combination therapy generally has demonstrated greater benefits than single-modality therapy. One series reported a recurrence-free rate of 92% in those who underwent surgery followed by adjuvant radiation versus 14% for surgery alone and 40% for radiation alone.[110] Radiation in addition to surgery has been shown to improve survival by as much as 20%.[107] Most authorities favor craniofacial resection followed by adjuvant radiation therapy for patients who present with Kadesh stage A (limited to tumors of the nasal fossa) and B (extension to the paranasal sinuses) disease. In those who present with stage C (extension beyond the paranasal sinuses) disease, chemotherapy such as cisplatin, cyclophosphamide, etoposide, doxorubicin, and vincristine is often added to surgery and radiation.

Table 120-14

Results of Treatment for Esthesioneuroblastoma

Author/Center	Follow-up Survival (yr)	Overall Survival (%) 5 yr	10 yr	15 yr	Disease-free (%) 5 yr	10 yr	Local Recurrence (%)

Chao[145]/Mallinckrodt, *n* = 25	8.0	66	—	—	56	—	27 (1976-1996)
Foote[108]/Mayo Clinic, *n* = 51	6.0	61	—	—	55	—	27 (1951-1990)
Eich[146]/Univ. Cologne, *n* = 17	7.2	*	—	—	60	—	24 (1981-1998)

*Median survival of 7.8 years.

Chemotherapy (cisplatin and etoposide) in conjunction with proton beam radiotherapy (equivalent to 68 Gy of photon irradiation) has been used with success in a small series of nine patients. With a short median follow-up of 20.5 months, eight of nine patients have been controlled. Longer follow-up will be required to determine the long-term success rates. Chemotherapy has also been used as a palliative modality and was found to have modest efficacy in patients who present with intracranial metastases.[111] The median survival is poor at 10.5 months.[112]

The technique of radiation used to treat ENB has evolved over time from intracavitary radium implants, cobalt-60, and orthovoltage treatment to the current use of photon or proton beam irradiation. Conventional techniques require the use of three fields, one anterior and two lateral wedged fields, to encompass the target volume. Radiation dosages range from 50 to 65 Gy given postoperatively. Due to the proximity of the tumor target to multiple critical normal tissues such as the orbital structures, there is often a limitation of dose that can be safely delivered to the tumor or the operative bed. It is likely that with IMRT and with the use of stereotactically guided conformal radiotherapy, much higher doses of radiation can be delivered safely to control the tumor target without exceeding the normal tissue tolerance (Fig. 120-11). Ultimately, this may translate into an improvement in local control, as well as survival. Whereas most centers advocated surgery followed by postoperative radiotherapy in the treatment of esthesioneuroblastoma, some centers prefer preoperative radiotherapy-chemotherapy as a complement to radical craniofacial resection attempting to reduce the tumor burden before surgery.[106] Polin and colleagues[113] reported 34 consecutive patients with biopsy-proven esthesioneuroblastoma who underwent preoperative radiation therapy with or without chemotherapy followed by surgical resection. Patients received 50 Gy along with either single-agent cyclophosphamide, vincristine, or in combination with doxorubicin hydrochloride (Adriamycin). The overall 5- and 10-year survival rates were 81% and 54.5%, respectively. The results are impressive because 23 patients had Kadesh C disease. In light of all these promising results, a recent meta-analysis of results from different centers showed that the 5-year overall and disease-free survival averaged 45% versus 41%, respectively.

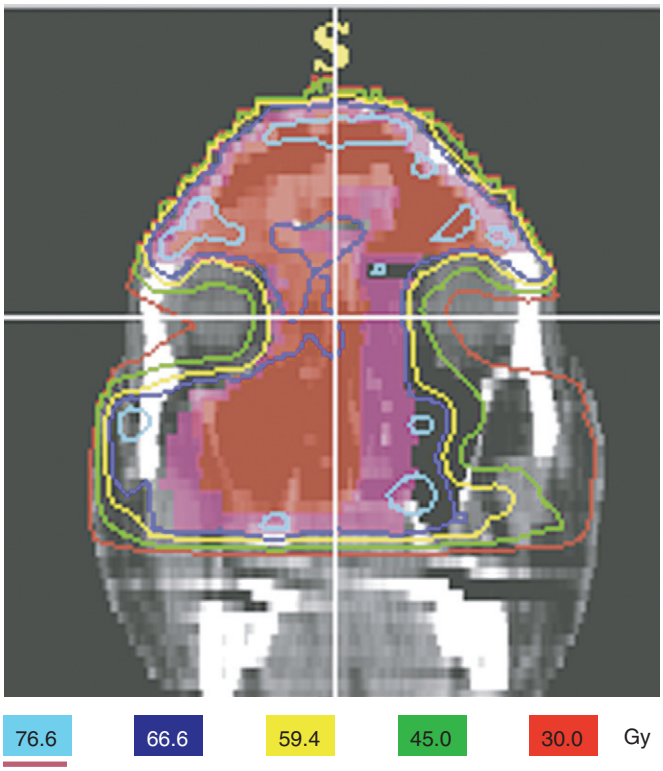

Figure 120-11. This patient presented with esthesioneuroblastoma extending intracranially and underwent complete surgical resection and postoperative intensity-modulated radiation therapy (IMRT) to the surgical bed. The red colorwash is the preoperative gross tumor volume and the magenta colorwash is the subclinical target volume. Notice that IMRT has the ability to tailor the prescription isodose lines around the target while sparing the critical surrounding orbital structures.

Sinonasal Undifferentiated Carcinoma

Primary sinonasal neuroendocrine tumors can be subdivided into four major histologic phenotypes: esthesioneuroblastoma (discussed earlier), sinonasal undifferentiated carcinoma (SNUC), neuroendocrine carcinoma, and small cell undifferentiated carcinoma.[114] SNUC portends a poor prognosis because of its high rates of locoregional failures, as well as distant metastases.[115-117] An international collaborative study reporting on the results of craniofacial resection for malignant paranasal sinus tumors reported a 5-year overall survival rates of 0% for the undifferentiated tumors.[118] Investigators have suggested that the poor outcomes were due to the lack of the use of chemotherapy and/or the inclusion of small cell histologies because recent data are more promising.[114] Recently, Rischin and colleagues[119] reported promising results with chemoradiation for SNUC patients. In their study, 10 patients, 9 of

whom had T4 disease, underwent three cycles of induction platinum and 5-fluorouracil followed by concurrent chemotherapy using platinum. With a median follow-up of 43 months (range, 8 to 101 months), the 2-year progression-free, overall survival rates were 43% and 64%, respectively. Similarly, Rosenthal and colleagues[114] also reported a 5-year overall survival rate of 64.2% for patients with SNUC histology in their cohort of sinonasal neuroendocrine tumors.

Middle Cranial Base

The intracranial portion of the middle cranial base is composed of the greater wing and body of the sphenoid body, the petrous bone that is anterior to the petrous ridge, and the squamous portion of the temporal bone. The temporal lobes of the brain occupy most of the space. The sella turcica is below the optic chiasma and located behind the posterior wall of the sphenoid sinus. The pituitary gland resides within the sella. On either side of the sella turcica is the cavernous venous sinus, which is a common site for tumor involvement in the cranial base. The cavernous sinus houses cranial nerves III, IV, V1, V2, and VI. The extracranial surface of the middle cranial base comes in contact with the temporal fossa, infratemporal fossa, pterygopalatine fossa (space between the posterior wall of the maxillary sinus and pterygoid plates), and poststyloid space. The foramen ovale, through which V3 passes, and the foramen spinosum, which transmits the middle meningeal artery, are located within the infratemporal fossa. The eustachian tube exits the skull base just medial to the spine of the sphenoid at the junction of the infratemporal fossa and the poststyloid space. The pterygopalatine fossa contains the foramen rotundum through which the second division of the trigeminal nerve exits the skull base. The fossa also contains the vidian nerve, the nerve of the pterygoid canal. The poststyloid space contains the entrance to the carotid canal and the jugular foramen. Benign lesions such as meningioma, pituitary adenoma, chordoma, and craniopharyngioma and malignant lesions such as nasopharyngeal carcinoma (NPC), SCC with paranasal sinus extension, and adenoid cystic carcinoma all can arise within the middle cranial base. The role of radiotherapy in the treatment of chordoma and NPC are discussed.

Chordoma/Chondrosarcoma

Chordoma arises from the remnants of the primitive notochord. It occurs almost exclusively along the axial skeleton with 36% of the cases involving the base of skull with a slight male predominance. The average age at diagnosis is around 38 years of age when it involves the head and neck region.[120-122] These tumors are slow growing and the development of symptoms depends on the route of spread, intracranially, or inferiorly to involve the nasopharynx, maxillary sinus, or the nasal cavity. Symptoms may include headache, visual disturbances, diplopia, nasal obstruction, otalgia, and proptosis. Radiographically, it appears as an expansile, osteolytic lesion with areas of calcifications and is associated with a soft tissue mass. Local tumor control is essential for long-term survival because salvage treatment after local recurrence is often not successful. Definitive radiotherapy alone using 2D photon beams results in recurrences in more than 80% of the cases within 5 years of treatment and can be fatal within a time period from weeks to several decades.[121]

Treatment of skull base chordoma/chondrosarcoma is challenging and fairly complex because it often requires repeated, extensive surgical resections followed by high-dose postoperative radiotherapy. Due to the nearby critical neural and vascular structures, a total surgical resection is difficult and uncommon.[123-125] With modern high-precision, 3D treatment techniques, control rates have been reported that are superior to conventional radiotherapy techniques. Local control rates given postoperatively on the order of 82% at 2 years and 50% at 5 years have been reported when using CT- or MRI-based 3D planning to a median dose of 66.6 Gy.[126] With high-dose conformal radiotherapy to the skull base, radiation-induced damage to the hypothalamus and pituitary gland can occur.[127] Patients can have hyperprolactinemia followed by hypothyroidism, hypogonadism, and finally hypoadrenalism. Heavy-particle carbon ions and protons have also been used with more success than conventional photon radiotherapy, with a control rates up to 90%.[128-130] Further research is necessary to compare high-precision radiotherapy versus particle beam radiotherapy in terms of the efficacy and toxicity of each modality.

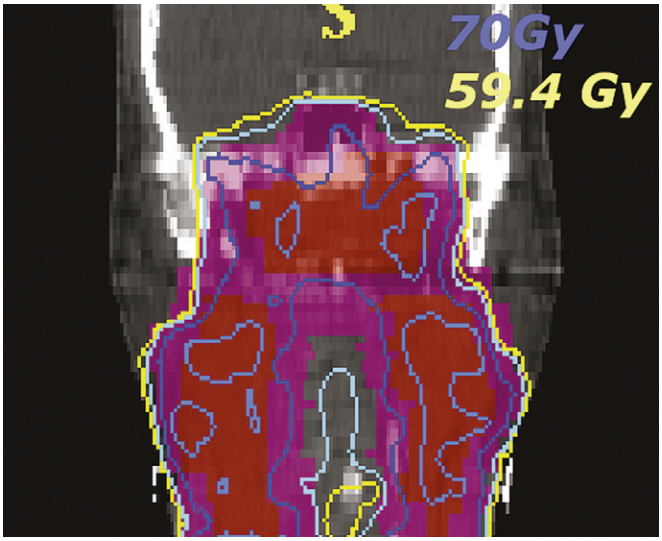

Figure 120-12. This is a patient with T4N2 nasopharyngeal carcinoma who underwent concurrent chemoradiotherapy using intensity-modulated radiation therapy: coronal view. The gross tumor volume is presented by the red colorwash, whereas the magenta colorwash depicts the subclinical region at risk for disease. The dark blue line is the 70-Gy isodose line and the light blue line is the 59.4-Gy isodose line. Notice the nice conformality of the isodose lines encompassing the respective target volumes while sparing the critical structures, specifically chiasm and brainstem. Notice that the parotid glands are outside the high dose regions with a mean dose of 28 Gy.

Nasopharyngeal Carcinoma

NPC is common among Asians, especially persons from Southern China, but it represents less than 1% of all cancers in the United States.[131] The standard treatment of patients with early-stage nasopharyngeal cancer is definitive radiotherapy, whereas those with locally advanced tumors are treated with a course of definitive chemoradiotherapy.[101] Historically, local control rates have ranged from 64% to 95% for stage T_1 and T_2 tumors, and for T_3 and T_4 diseases, the local control rate decreases to between 44% and 68%. The 5-year overall survival rate has been reported to be between 36% and 58%. IMRT has absolutely gained popularity in the treatment of head and neck cancer, especially nasopharyngeal cancer. The intensity of the radiation beams can be modulated so that a highly conformal dose of radiation can be delivered to the tumor target without causing excessive toxicity to the patient. IMRT is especially ideal in patients who present with locally advanced nasopharyngeal tumors in which it is nearly impossible to deliver a meaningful dose of radiation to the tumors without causing blindness, brainstem injury, or necrosis. Figure 120-12 is an example of a patient with locally advanced NPC treated with IMRT.

The longest experience of using IMRT in the treatment of NPC is the series from University of California–San Francisco (UCSF) Medical Center.[101] The local and locoregional progression-free rates have been 95% and 98%, respectively, for 89 patients. Approximately 60% of the patients in this series presented with T_3 and T_4 diseases. This is a marked improvement over the reported historical series. In addition, patients are complaining less of xerostomia. Because of the encouraging results, a national trial from the RTOG is currently under way to determine, at a multi-institutional level, the benefits of IMRT in the treatment of NPC. Several centers throughout the world (e.g., Hong Kong, Taiwan, China) are currently enrolling patients in their respective trials, and early results report similar encouraging results. Table 120-15 contains the local progression-free rates using IMRT in the treatment of nasopharyngeal carcinoma from different single insti-

Table 120-15

Results of Intensity-Modulated Radiation Therapy for Nasopharyngeal Carcinomas

Author	*N*	TNM Stage	Follow-up (mo)	Local-Progression Free (%)
Lee[101]	67	T1-T4	33	97
Wolden[147]	74	T1-T4	35	91
Kwong[148]	33	T1	24	100
Kam[149]	63	T1-T4	29	92

tutions. Although these results were excellent, the distant metastases rates reported in these series can be as high as 30%. Therefore the overall survival of NPC patients have not changed significantly in patients treated with IMRT versus conventional radiotherapy. Studies are under way to further decrease distant metastases rates with the incorporation of newer systemic agents.

Overexpression of vascular endothelial growth factor (VEGF) has correlated with higher recurrence and lower survival in NPC.[132] Studies have also shown that NPC patients are more likely to remain disease free when VEGF is decreased after treatment.[133] Bevacizumab, a monoclonal antibody that binds to VEGF-A, inhibits tumor neovascularization and improves chemotherapy delivery to tumors by normalizing the permeability of existing tumor vasculature.[134] Bevacizumab has shown improvement in overall survival in randomized trials when compared with standard chemotherapy, in metastatic colorectal, lung, and breast cancers. An ongoing national protocol is studying the treatment outcome in locoregionally advanced NPC patients with the addition of bevacizumab into the current standards of concurrent chemoradiotherapy followed by adjuvant chemotherapy. It is anticipated that the addition of bevacizumab, which targets VEGF expressed in NPC, will further minimize distant failures leading to improvement in patient overall survival.

Other Cranial Skull Base Tumors

It is beyond the scope of this chapter to discuss all tumors involving the cranial base. Several scattered case reports have described radiotherapy as a definitive treatment modality for tumors of the cranial base. Stereotactic irradiation has been used to treat various newly diagnosed or recurrent malignant tumors involving the skull base.[93] Tumor histologies included adenoid cystic carcinoma, basal cell carcinoma, osteogenic sarcoma, and SCC. Patients can experience symptomatic response to treatment with local control rates of 95% at 2 years and 78% at 3 years. Stereotactic irradiation can provide good local control and symptomatic relief in patients with recurrent salivary gland malignancies involving the skull base.[135]

Combination chemotherapy with high-dose radiotherapy using accelerated fractionation has also been used to manage unresectable malignant tumors of the skull base. The results are promising with a 2-year local progression-free survival of 94%, distant metastases-free survival of 57%, and overall survival of 80%. However, complications occurred in 20% and resulted in death of one patient in one series.[136] With advances in radiotherapy techniques, it is anticipated that the complications due to treatment will resolve over time. This has been supported by recent reports from centers using IMRT in the treatment of sinus cancer that involves the skull base.[137,138]

Complications after Skull Base Irradiation

For patients treated with radiation therapy for malignancies of the skull base, the high doses required to achieve local control have been historically associated with a high incidence of treatment-induced morbidity. In particular, the location of these tumors in relation to the optic structures, brainstem, spinal cord, and bony structures has raised concerns regarding the potential development of such complications as blindness, brain injury, and osteoradionecrosis. The majority of the publications on radiation-related complications have focused on patients treated using conventional nonconformal radiation techniques. Complications included radiation retinopathy, neovascular glaucoma, unilateral and bilateral blindness, and osteoradionecrosis.

Although recent studies have suggested the potential of IMRT to reduce complications, careful attention to dose constraints are necessary to minimize complications.[139-141] The UCSF series reported no patients experiencing complete loss of vision as a result of treatment with IMRT.[142] Similarly, the Memorial Sloan-Kettering Cancer Center experience did not report visual loss secondary to IMRT treatment for malignant tumors involving the skull base.[137] A longitudinal analysis of the UCSF experience showed that the incidence of grade 3 or higher late complications changed significantly for patients treated with conventional radiation therapy versus 3D-CRT and IMRT. For instance, 13% of patients treated with IMRT developed any grade 3 or higher late complication compared with 22% and 54%, respectively, of patients treated using 3D-CRT and conventional radiation therapy, respectively.[138]

CHAPTER ONE HUNDRED AND TWENTY-ONE

Neck Dissection

K. Thomas Robbins

Sandeep Samant

Ohad Ronen

Key Points

- Neck dissection is a surgical procedure that is designed to remove metastatic cancer involving the cervical lymph nodes.
- The gold standard procedure is the radical neck dissection.
- Modifications of the radical neck dissection procedure include the modified radical neck dissection, which has been designed to reduce morbidity by sparing nonlymphatic structures, and selective neck dissection, which is used for treating early nodal disease by removing only the lymph node groups at greatest risk for harboring metastases.
- The lymph nodes in the neck are grouped into six major levels (I to VI) with additional division into two sublevels (A and B) of levels I, II, and V.
- Clear anatomic, radiologic, and surgical landmarks are used to define the borders between the different levels.
- The term *therapeutic neck dissection* is used when there is clinical evidence of metastatic cervical lymphadenopathy.
- The term *elective neck dissection* is used when the procedure is performed to remove lymph node groups that have an increased risk of harboring occult disease in the neck.
- A planned neck dissection, performed whenever there is a high risk of residual cancer, is typically done 6 to 8 weeks after other treatment to the neck has been completed, such as radiotherapy or chemoradiotherapy, regardless of the clinical response to the initial treatment.
- A "salvage" neck dissection is done when there is clinical evidence of metastatic disease in the neck after previous treatment. It can further be classified as early versus late depending on whether there is persistent versus recurrent neck metastases.
- Complications of a neck dissection include air leaks, bleeding, chylous fistula, facial or cerebral edema, blindness, carotid artery rupture, and damage to nerves such as the phrenic, vagus, brachial plexus and cutaneous nerves and the mandibular branch of the facial, hypoglossal, or lingual nerves.
- A neck dissection following chemoradiation therapy poses special challenges because the indications and the extent of the procedure remain controversial.

The terms *neck dissection* and *cervical lymphadenectomy* refer to the systematic removal of lymph nodes with their surrounding fibrofatty tissue from the various compartments of the neck. This procedure is used to eradicate metastases to the regional lymph nodes of the neck. In most patients, these metastases originate from primary lesions involving mucosal sites of the upper aerodigestive tract, particularly the oral cavity, pharynx, and larynx.

The propensity for spread to the regional lymph nodes by carcinomas of the upper aerodigestive tract is variable and is associated with several factors such as histology, T classification, and location of the primary tumor. For example, if the histology shows perineural invasion or invasion of the tumor's microcirculation, the risk is higher. In general, the more advanced the T classification, the higher the likelihood of nodal spread. Certain subsites such as the oral tongue, floor of the mouth, piriform sinus, and supraglottic larynx are associated with higher rates of lymphatic metastasis as compared with such subsites as the buccal mucosa, lip, nasal cavity, paranasal sinuses, and glottic larynx. Although the anatomic distribution of the surrounding lymphatic channels may explain some of this variation, inherent differences in the biologic behavior among these cancers are likely as well. Thus the indications for cervical lymphadenectomy depend not only on the presence of palpable disease but on factors that increase the risk of occult disease such as the size and characteristics of the primary tumor. The term *therapeutic neck dissection* applies to the former condition, whereas the term *elective neck dissection* applies to the latter situation. Other factors that are important when deciding whether cervical lymphadenectomy is indicated relate to the overall treatment plan. For example, if the treatment of choice for the primary tumor is radiation rather than surgery, it may also be preferable to radiate the regional nodes when the clinical staging of the nodal disease is N_0 or N_1. If surgical transgression of the regional lymphatics is required to resect the primary tumor, cervical lymphadenectomy should also be included.

Historical Perspective

In publications that came out before the 20th century, little attention was given to the indications or techniques for treating cervical lymph node metastases. The first conceptual approach for removing nodal metastases was made by Kocher in 1880[1]; he described the removal of

the lymph nodes located within the contents of the submandibular triangle to gain surgical access to a cancer of the tongue. Later, Kocher recommended that nodal metastases should be removed more widely through a Y-shaped incision, with the long arm extending from the mastoid to the level of the omohyoid at its junction with the anterior border of the sternocleidomastoid muscle. Around the same time, Packard supported the concept of removing the surrounding lymph nodes for lingual cancer.[2] The first description of the radical neck dissection was by Jawdynski, a Polish surgeon.[3] However, the individual credited the most for developing and reporting the efficacy of this procedure is George Crile.[4] Crile believed that distant (hematogenous) metastases were uncommon in head and neck cancer and that metastases more commonly occurred in the neck through the permeation of lymphatics. The descriptions by both of these surgeons of a block resection encompassing all of the cervical nodal groups from the level of the mandible above to the clavicle below became the basis for the radical neck dissection we know today. Relevant to the modifications of radical neck dissection that were subsequently made, Crile recommended preservation of the internal jugular vein and the sternocleidomastoid muscle for patients in whom there were no palpable nodes. In addition, his technique was to remove only the regional lymph nodes that were known to drain the field of the original focus of disease when metastases could not be seen. Also, it is interesting to note that, in the accompanying illustrations of the more radical en bloc resections, the spinal accessory nerve was preserved.

This philosophy of radical en bloc resection based on Crile's descriptions remained popular with the head and neck surgeons during the first half of the 20th century, in part because of the works of Blair and Brown[5] and Martin,[6] who were strong proponents of the radical en bloc technique of neck dissection in a manner similar to the radical surgery that had evolved for breast cancer. Martin, in particular, categorically insisted that the spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle should be removed as part of all cervical lymphadenectomies. It may be useful to remember that, during this time, radiotherapy had not yet been developed as an effective adjuvant modality, and radical surgery represented the only hope for cure.

Associated with the procedure of the radical neck dissection was the presence of significant postoperative morbidity related to shoulder dysfunction; the operation also had limitations as a bilateral procedure.[7] In the 1950s Ward and Robben[8] reported that the neck dissection could be modified in some circumstances by sparing the spinal accessory nerve and thereby preventing postoperative shoulder drop. Later, Saunders, Hirata, and Jaques[9] compared the functional results of cases undergoing radical neck dissection with those in whom the spinal accessory nerve was spared; this demonstrated that shoulder symptoms were only mild or moderate in more than 80% of the patients who had the nerve preserved or cable grafted. The concept of conservation neck surgery was further popularized during the 1960s by Suarez[10] in Argentina and promoted by Bocca and Pignataro,[11] who independently described an operation that removed all of the lymph node groups while sparing the spinal accessory nerve, sternocleidomastoid muscle, and internal jugular vein. They emphasized that fascial compartments surrounding the lymphatic contents of the neck could be removed without sacrificing the nonlymphatic structures, as mentioned.

Other authors reported the sparsity of nodal disease within the posterior triangle for carcinoma of the oral cavity, pharynx, and larynx, thus setting the stage for modifications directed toward preserving lymph node groups.[12-15] These observations paved the way for another type of neck dissection modification: one in which there was selective preservation of one or more lymph node groups.[16-18] Some of the initial proponents of this concept were the surgeons at MD Anderson Cancer Center, who called the procedure "modified neck dissection."[19,20] Two of the variations of the modified neck dissection were also called "supraomohyoid" and "anterior" neck dissections.[16] However, the term *selective neck dissection* (SND) subsequently became associated with the concept of preserving lymph nodes in one or more of the neck levels through the American Academy of Otolaryngology's classification.[17,21] The lymph node groups removed are based on the pattern of metastases, which are predictable relative to the primary site of cancer.

Table 121-1

Types of Neck Dissection

Terminology	Definition
Radical	Removal of lymph node levels I to V, sternocleidomastoid muscle, spinal accessory nerve, and internal jugular vein.
Modified	Removal of lymph node levels I to V (as in radical neck dissection [ND]), but preservation of at least one of the nonlymphatic structures (sternocleidomastoid muscle, spinal accessory nerve, and internal jugular vein).
Selective	Preservation of one or more lymph node levels relative to a radical ND.
Extended	Removal of an additional lymph node level or group or a nonlymphatic structure relative to a radical ND (muscle, blood vessel, nerve). Examples of other lymph node groups are superior mediastinal, parapharyngeal, retropharyngeal, peri-parotid, postauricular, suboccipital, and buccinator. Examples of other nonlymphatic structures are external carotid artery, hypoglossal, and vagus nerves.

Terminology of Neck Dissection

The evolution of cervical lymphadenectomy procedures during the 20th century has provided the modern head and neck surgeon with a repertoire of surgical techniques for removing nodal metastases. Concurrent with this expansion has been the emergence of a multitude of terms used to describe these procedures. Originally proposed by authors without any uniformity of terminology, this lack of standardization unfortunately resulted in redundancy, misinterpretation, and even confusion among clinicians. Realizing the importance for standardizing the diverse nomenclature, the Committee for Head and Neck Surgery and Oncology of the American Academy of Otolaryngology–Head and Neck Surgery convened a special task force in 1988 to address the problems of terminology related to cervical lymphadenectomy. The specific objectives of the group were as follows: (1) to recommend terminology that adhered to more traditional terms such as "radical" and "modified radical" neck dissection, and to avoid the use of eponyms and acronyms; (2) to define which lymphatic structures and other nonlymphatic structures should be removed or preserved relative to the radical neck dissection; (3) to provide standard nomenclature for the lymph node groups and the nonlymphatic structures; (4) to define the boundaries of resection for lymph node groups; (5) to use terms for the neck dissection procedures that are basic and easy to understand; and (6) to develop a classification on the basis of the biology of the cervical metastases and the principles of oncologic surgery.[17]

Recently updated by the Committee for Neck Dissection Classification of the American Head and Neck Society (AHNS), the classification is outlined in Table 121-1).[9,22,23] The new versions included modifications of the original classification in an effort to remain contemporary and to follow the current philosophy of managing lymph node metastases.

Cervical Lymph Node Groups

The patterns of spread of cancer from various primary sites in the head and neck to the cervical lymph nodes have been documented by retrospective analyses of large series of patients undergoing neck dissection.[12,16,24] The nodal groups at risk for involvement are widespread throughout the neck, extending from the mandible and skull base

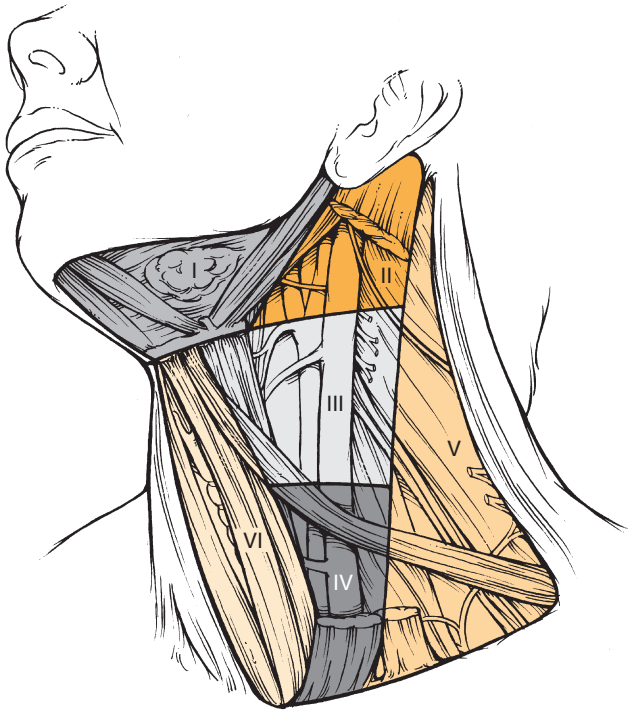

Figure 121-1. The six levels of the neck for describing the location of lymph nodes in the neck. *I,* submental and submandibular group; *II,* upper jugular group; *III,* middle jugular group; *IV,* lower jugular group; *V,* posterior triangle group; and *VI,* anterior compartment group. *(Redrawn from art provided courtesy of Douglas Denys, MD.)*

superiorly to the clavicle inferiorly and from the posterior triangle of the neck laterally to the midline viscera and to the contralateral side of the neck. It is now recommended that the lymph node groups in the neck be categorized according to the level system originally described by the Memorial Sloan-Kettering Group (Fig. 121-1).[19]

There are two important lymph node groups within level I: the submental group and the submandibular group. The submental nodes are defined as those that are contained within the boundaries of the submental triangle (i.e., the anterior belly of the digastric muscles and the hyoid bone). The submandibular lymph node group refers to the nodes lying within the boundaries of the submandibular triangle (i.e., the anterior and posterior bellies of the digastric muscle and the body of the mandible). Because many of these lymph node groups lie in close proximity to the submandibular gland, this structure is removed to ensure thorough exenteration of all of the lymph nodes within this triangle. Thus the boundaries of level I lymph nodes include the body of the mandible, the anterior belly of the contralateral digastric muscle, the posterior belly of the ipsilateral digastric muscle, and the stylohyoid muscle. It should be noted that the perifacial lymph nodes including the buccinator nodes are located outside of this triangle superior to the mandibular body. These nodes may contain metastatic disease when the primary site involved is the lip, buccal mucosa, anterior nasal cavity, or soft tissue of the cheek. Thus the neck dissection performed for nodal disease associated with primary lesions of these sites should be modified to encompass the perifacial nodes.

Level II is defined as the region containing the upper jugular lymph nodes. These are located around the upper third of the internal jugular vein and adjacent to the spinal accessory nerve, extending from the level of the carotid bifurcation (surgical landmark) or hyoid bone (clinical landmark) inferiorly to the skull base superiorly. The lateral boundary is the posterior border of the sternocleidomastoid muscle, and the medial boundary is the stylohyoid muscle. Recently, the AHNS committee recommended that the perpendicular plane defined by the posterior aspect of the submandibular gland could serve as the radiologic landmark for this boundary.

Level III contains the middle jugular lymph node group. These nodes are located around the middle third of the internal jugular vein, extending from the carotid bifurcation superiorly (surgical landmark) or the level of the inferior aspect of the body of the hyoid bone (clinical and radiologic landmark) to the junction of the omohyoid muscle with the internal jugular vein (surgical landmark) or the lower border of the cricoid arch (clinical and radiologic landmark) inferiorly. The lateral boundary is the posterior border of the sternocleidomastoid muscle, and the medial boundary is the lateral border of the sternohyoid muscle. Recently, the AHNS committee recommended that the lateral border of the common carotid artery could serve as the radiologic landmark for the medial boundary.

Level IV contains the lower jugular lymph node group. These nodes surround the lower third of the internal jugular vein, extending from the omohyoid muscle (surgical landmark) or cricoid arch (clinical landmark) superiorly to the clavicle inferiorly. The lateral boundary is the posterior border of the sternocleidomastoid muscle, and the medial or anterior boundary is the lateral border of the sternohyoid muscle. As with level II, the lateral border of the common carotid artery could serve as the radiologic landmark for the medial boundary.

Level V encompasses all lymph nodes contained within the posterior triangle, and these are collectively referred to as the posterior triangle group. The boundaries include the anterior border of the trapezius muscle laterally, the posterior border of the sternocleidomastoid muscle medially, and the clavicle inferiorly. The nodes in this triangle comprise three predominant lymphatic pathways: nodes located along the spinal accessory nerve as it traverses the posterior triangle; nodes located along the transverse cervical artery as it courses along the lower third of the triangle; and the supraclavicular nodes located immediately above the clavicle. The supraclavicular nodes also extend below the level of the upper horizontal border of the clavicle to include one particular node of importance: the sentinel—or Virchow's—node.

Level VI encompasses the lymph nodes of the anterior compartment of the neck.[19,21] This group is made up of nodes that surround the midline visceral structures of the neck, extending from the level of the hyoid bone superiorly to the suprasternal notch inferiorly. On each side, the lateral boundary is formed by the medial border of the carotid sheath. Located within this compartment are the perithyroidal lymph nodes, paratracheal lymph nodes, lymph nodes along the recurrent laryngeal nerves, and precricoid (Delphian) lymph node. These lymph nodes and their connecting lymphatic channels represent pathways of spread from primary cancers originating in the thyroid gland, apex of the piriform sinus, subglottic larynx, cervical esophagus, and cervical trachea.

The superior mediastinal lymph nodes (optionally referred to as *level VII*) are bounded superiorly by the superior edge of the manubrium, inferiorly by the superior border of the arch of the aorta, and laterally by the common carotid artery on the left side and the innominate artery on the right.

Division of Neck Levels by Sublevels

The 2001 report of the American Head and Neck Society's Neck Dissection Committee recommended the use of sublevels for defining selected lymph node groups within levels I, II, and V on the basis of the biologic significance, independent of the larger zone in which they lay.[21] These are outlined in Figure 121-2 as sublevels IA (submental nodes), IB (submandibular nodes), IIA and IIB (together composing the upper jugular nodes), VA (spinal accessory nodes), and VB (transverse cervical and supraclavicular nodes). The boundaries for each of these sublevels are defined in Table 121-2.

The risk of nodal disease in sublevel IIB is greater for tumors arising in the oropharynx as compared with the oral cavity and larynx.[25-32] Thus in the absence of clinical nodal disease in sublevel IIA, it is likely not necessary to include sublevel IIB for tumors arising in these latter sites. The dissection of the node-bearing tissue of sublevel IIB (submuscular recess) creates a risk of morbidity. Adequate exposure necessitates significant manipulation of the spinal accessory nerve and may account for trapezius muscle dysfunction observed in a significant

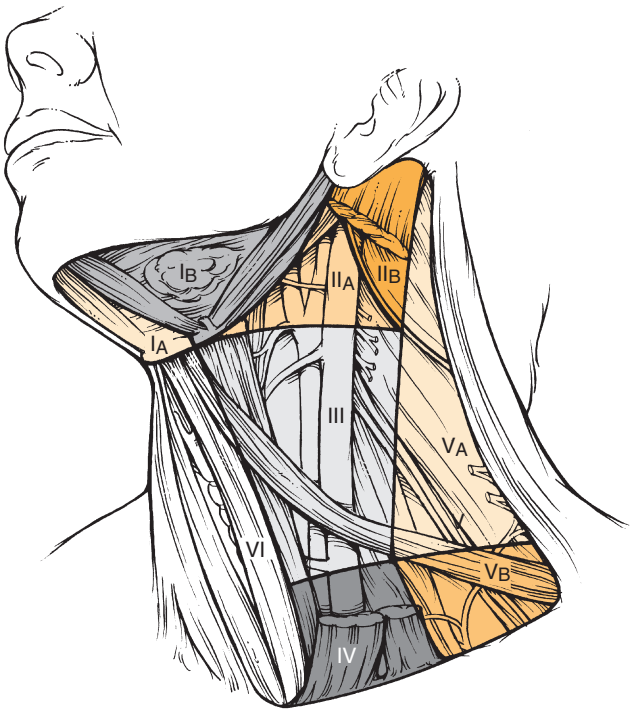

Figure 121-2. The six sublevels of the neck for describing the location of lymph nodes within levels I, II, and V. *IA,* submental group; *IB,* submandibular group; *IIA,* upper jugular nodes along the carotid sheath including the subdigastric group; *IIB,* upper jugular nodes in the submuscular recess; *VA,* spinal accessory nodes; and *VB,* the supraclavicular and transverse cervical nodes. *(Redrawn from art provided courtesy of Douglas Denys, MD.)*

minority of patients after an SND. Sublevel IA is a zone from which many surgeons do not remove lymph nodes unless the primary cancer involves the floor of the mouth, the lip, or structures of the anterior midface or there is obvious lymphadenopathy.

Level V is the third region that has been subdivided, into levels VA and VB. The superior component, level VA, primarily contains the spinal accessory lymph nodes, whereas level VB contains the transverse cervical nodes and the supraclavicular nodes, which carry a more ominous prognosis when positive in cases with upper aerodigestive tract malignancies.

Correlation of Neck Level Boundaries with Anatomic Markers Depicted Radiologically

Radiologists have now identified landmarks that more accurately identify the location of lymph nodes according to the level system (Table 121-3).[33,34] Using radiologic landmarks, level I includes all of the nodes above the level of the lower body of the hyoid bone, below the mylohyoid muscles, and anterior to a transverse line drawn on each axial image through the posterior edge of the submandibular gland. Level IA represents those nodes that lie between the medial margins of the anterior bellies of the digastric muscles, above the level of the lower body of the hyoid bone, and below the mylohyoid muscle (these were previously classified as submental nodes). Level IB represents the nodes that lie below the mylohyoid muscle, above the level of the lower body of the hyoid bone, posterior and lateral to the medial edge of the ipsilateral anterior belly of the digastric muscle, and anterior to a transverse line drawn on each axial image tangent to the posterior surface of the submandibular gland on each side of the neck (these are also referred to as *submandibular nodes*). Level II extends from the skull base at the lower level of the bony margin of the jugular fossa to the level of the lower body of the hyoid bone. Level II nodes lie anterior to a transverse line drawn on each axial image through the posterior edge of the sternocleidomastoid muscle, and they lie posterior to a transverse line drawn on each axial scan through the posterior edge of the submandibular gland. However, any nodes that lie medial to the internal carotid artery (ICA) are retropharyngeal and thus not level II.

Level III nodes lie between the level of the lower body of the hyoid bone and the level of the lower margin of the cricoid cartilage. These nodes lie anterior to a transverse line drawn on each axial image through the posterior edge of the sternocleidomastoid muscle. Level III nodes also lie lateral to the medial margin of either the common carotid artery or the ICA. On each side of the neck, the medial margin of these arteries separates level III nodes, which are lateral, from level VI nodes, which are medial.

Thus the revised classification uses the horizontal plane defined by the inferior border of the hyoid bone instead of the carotid bifurcation to delineate the boundary between levels II and III. Similarly, the revised classification uses the horizontal plane defined by the inferior border of the cricoid cartilage instead of the junction between the superior belly of the omohyoid muscle to delineate the boundary between levels III and IV. However, from a surgical perspective, it is important to note the significance of the anatomic relationship between the omohyoid muscle and the internal jugular vein because lymph nodes are usually located in this region. These nodes would be included in level III.

Neck Dissection Classification

The classification for neck dissection recommended by the American Head and Neck Society's committee is based on the following rationale: (1) that radical neck dissection is the standard basic procedure for cervical lymphadenectomy, and all other procedures represent one or more modifications of this procedures; (2) when the modification of the radical neck dissection involves the preservation of one or more nonlymphatic structures, the procedure is called *modified radical neck dissection;* (3) when the modification involves the preservation of one or more lymph node groups that are routinely removed in the radical neck dissection, the procedure is called *SND;* and (4) when the modification involves the removal of additional lymph node groups or nonlymphatic structures relative to the radical neck dissection, the procedure is called *extended radical neck dissection* (see Table 121-1).

A "planned" neck dissection is typically performed 6 to 8 weeks after the completion of radiotherapy or chemoradiotherapy when the chance of residual disease in the neck is high. Some centers use ^{18}F-fluorodeoxyglucose positron emission tomography (PET) scan to further decide whether to perform a neck dissection. Because the reliability of a PET scan is questionable before 3 months have passed following completion of radiation or chemoradiation, a "planned" neck dissection based on the results of this investigation may have to be deferred until this time.

As opposed to a planned neck dissection, a "salvage" neck dissection is performed when metastatic disease in the neck occurs after it has been treated previously. The salvage neck dissection can be further classified as "early" procedure when it is done for persistent disease after chemo/radiation or "late" when it is done for recurrent disease.

Radical Neck Dissection

DEFINITION. This procedure includes the removal of all ipsilateral cervical lymph node groups extending from the body of the mandible superiorly to the clavicle inferiorly and from the lateral border of the sternohyoid muscle, hyoid bone, and contralateral anterior belly of the digastric muscle anteriorly to the anterior border of the trapezius muscle posteriorly.[22] Included are all lymph node groups from levels I through V, the spinal accessory nerve, the internal jugular vein, and the sternocleidomastoid muscle (Fig. 121-3). It does not include the removal of the postauricular and suboccipital nodes, the periparotid nodes (except for a few nodes located in the tail of the parotid gland), the perifacial and buccinator nodes, the retropharyngeal nodes, and the paratracheal nodes.

INDICATIONS. The radical neck dissection is indicated for patients with extensive lymph node metastases with extension beyond the capsule of the node or nodes to involve the spinal accessory nerve and the internal jugular vein.

Table 121-2

Lymph Node Groups Found within the Six Neck Levels and the Six Sublevels

Lymph Node Group	Description
Submental (sublevel I_A)	Lymph nodes within the triangular boundary of the anterior belly of the digastric muscles and the hyoid bone; these nodes are at the greatest risk of harboring metastases from cancers arising from the floor of the mouth, anterior oral tongue, anterior mandibular alveolar ridge, and lower lip (see Fig. 121-2).
Submandibular (sublevel I_B)	Lymph nodes within the boundaries of the anterior belly of the digastric muscle, the stylohyoid muscle, and the body of the mandible, including the preglandular and postglandular nodes and the prevascular and postvascular nodes. The submandibular gland is included in the specimen when the lymph nodes within this triangle are removed. These nodes are at greatest risk for harboring metastases from cancers arising from the oral cavity, the anterior nasal cavity, and the soft tissue structures of the midface and the submandibular gland (see Fig. 121-3).
Upper jugular (sublevels II_A and II_B)	Lymph nodes located around the upper third of the internal jugular vein and the adjacent spinal accessory nerve, extending from the level of the skull base above to the level of the inferior border of the hyoid bone below. The anterior (medial) boundary is the stylohyoid muscle (the radiologic correlate is the vertical plane defined by the posterior surface of the submandibular gland), and the posterior (lateral) boundary is the posterior border of the sternocleidomastoid muscle. Sublevel II_A nodes are located anterior (medial) to the vertical plane defined by the spinal accessory nerve. Sublevel II_B nodes are located posterior (lateral) to the vertical plane defined by the spinal accessory nerve. The upper jugular nodes are at greatest risk for harboring metastases from cancers arising from the oral cavity, nasal cavity, nasopharynx, oropharynx, hypopharynx, larynx, and parotid gland (see Fig. 121-3).
Middle jugular (level III)	Lymph nodes located around the middle third of the internal jugular vein, extending from the inferior border of the hyoid bone above to the inferior border of the cricoid cartilage below. The anterior (medial) boundary is the lateral border of the sternohyoid muscle, and the posterior (lateral) boundary is the posterior border of the sternocleidomastoid muscle. These nodes are at greatest risk for harboring metastases from cancers arising from the oral cavity, nasopharynx, oropharynx, hypopharynx, and larynx (see Fig. 121-3).
Lower jugular (level IV)	Lymph nodes located around the lower third of the internal jugular vein, extending from the inferior border of the cricoid cartilage above to the clavicle below. The anterior (medial) boundary is the lateral border of the sternohyoid muscle, and the posterior (lateral) boundary is the posterior border of the sternocleidomastoid muscle. These nodes are at greatest risk of harboring metastases from cancers arising from the hypopharynx, thyroid, cervical esophagus, and larynx (see Fig. 121-3).
Posterior triangle (sublevels V_A and V_B)	This group is composed predominantly of the lymph nodes located along the lower half of the spinal accessory nerve and the transverse cervical artery. The supraclavicular nodes are also included in the posterior triangle group. The superior boundary is the apex formed by the convergence of the sternocleidomastoid and trapezius muscles; the inferior boundary is the clavicle, the anterior (medial) boundary is the posterior border of the sternocleidomastoid muscle, and the posterior (lateral) boundary is the anterior border of the trapezius muscle. Sublevel V_A is separated from sublevel V_B by a horizontal plane marking the inferior border of the anterior cricoid arch. Thus sublevel V_A includes the spinal accessory nodes, whereas sublevel V_B includes the nodes that follow the transverse cervical vessels and the supraclavicular nodes (with the exception of Virchow's node, which is located in level IV). The posterior triangle nodes are at greatest risk for harboring metastases from cancers arising from the nasopharynx, oropharynx, and cutaneous structures of the posterior scalp and neck (see Fig. 121-3).
Anterior compartment (level VI)	Lymph nodes in this compartment include the pretracheal and paratracheal nodes, the precricoid (Delphian) node, and the perithyroidal nodes, including the lymph nodes along the recurrent laryngeal nerves. The superior boundary is the hyoid bone, the inferior boundary is the suprasternal notch, and the lateral boundaries are the common carotid arteries. These nodes are at greatest risk for harboring metastases from cancers arising from the thyroid gland, glottic and subglottic larynx, apex of the piriform sinus, and cervical esophagus (see Fig. 121-2).
Superior mediastinum (optional—level VII)	These nodes represent an extension of the paratracheal lymph nodes chain extending inferiorly below the suprasternal notch along each side of the cervical trachea to the level of the innominate artery.

Table 121-3

Imaging-Based Classification of Location of Lymph Nodes

Level	Boundary	Clinical	Radiologic	Surgical
Level I				
Sublevel I_A (submental)	Superior	Symphysis of mandible	Geniohyoid muscle, plane tangent to inferior border of mandible	Symphysis of mandible
	Inferior	Body of hyoid	Body of hyoid	Body of hyoid
	Lateral (posterior)	N/A	Anterior belly of ipsilateral digastric muscle	Anterior belly of ipsilateral digastric muscle
	Medial	N/A	Anterior belly of contralateral digastric muscle	Anterior belly of contralateral digastric muscle
Sublevel I_B (submandibular)	Superior	Body of mandible	Mylohyoid muscle, body of mandible	Body of mandible
	Inferior	Plane through hyoid bone	Inferior edge of the hyoid bone	Digastric tendon attachment to hyoid bone
	Lateral (posterior)	Anterior border of SCM	Posterior edge of the submandibular gland	Posterior edge of the submandibular gland
	Medial	N/A	Anterior belly of digastric muscle	Anterior belly of digastric muscle
Level II (upper jugular)				
II_A	Superior	Mastoid process	Skull base, caudal edge of C1 lateral process	Skull base
	Inferior	Horizontal plane defined by the inferior border of the hyoid bone	Horizontal plane defined by the inferior border of the hyoid bone	Carotid bifurcation
	Lateral (posterior)	N/A	Posterior border of the internal jugular vein	Vertical plane defined by the spinal accessory (XI) nerve
	Medial	Anterior border of SCM	Posterior edge of the submandibular gland	Posterior edge of the submandibular gland
II_B (submuscular recess)	Superior	Mastoid process	Skull base, caudal edge of C1 lateral process	Skull base
	Inferior	Horizontal plane defined by the inferior border of the hyoid bone	Horizontal plane defined by the inferior border of the hyoid bone	Carotid bifurcation
	Lateral (posterior)	Lateral border of SCM	Lateral border of SCM	Lateral border of SCM
	Medial	N/A	Medial edge of internal carotid artery, paraspinal (levator scapulae) muscle	Vertical plane defined by the spinal accessory (XI) nerve
Level III (midjugular)				
	Superior	Horizontal plane defined by the inferior border of the hyoid bone	Horizontal plane defined by the inferior border of the hyoid bone	Carotid bifurcation
	Inferior	Horizontal plane defined by the inferior border of the cricoid cartilage	Horizontal plane defined by the inferior border of the cricoid cartilage	Omohyoid muscle
	Lateral (posterior)	Lateral border of SCM	Lateral border of SCM	Sensory branches of the cervical plexus
	Medial	Medial border of SCM	Medial aspect of the common carotid artery, paraspinal (scalenus) muscle	Sternohyoid muscle

Continued

Table 121-3

Imaging-Based Classification of Location of Lymph Nodes—cont'd

Level	Boundary	Clinical	Radiologic	Surgical
Level IV				
	Superior	Horizontal plane defined by the inferior border of the cricoid cartilage	Horizontal plane defined by the inferior border of the cricoid cartilage	Omohyoid muscle
	Inferior	Clavicle	2 cm cranial to sternoclavicular joint	Clavicle
	Lateral (posterior)	Lateral border of SCM	Lateral border of SCM	Sensory branches of the Cervical plexus
	Medial	Medial border of SCM	Medial aspect of the common carotid artery, paraspinal (scalenus) muscle	Sternohyoid muscle
Level V (posterior triangle)				
V_A	Superior	Apex of the convergence of the sternocleidomastoid and trapezius muscle	Apex of the convergence of the sternocleidomastoid and trapezius muscle	Apex of the convergence of the sternocleidomastoid and trapezius muscle
	Inferior	Horizontal plane defined by the inferior border of the cricoid cartilage	Horizontal plane defined by the inferior border of the cricoid cartilage	Horizontal plane defined by the inferior border of the cricoid cartilage
	Lateral (posterior)	Anterior border of trapezius muscle	Anterior border of trapezius muscle	Anterior border of trapezius muscle
	Medial	Lateral border of SCM	Lateral border of SCM	Sensory branches of the Cervical plexus
V_B	Superior	Horizontal plane defined by the inferior border of the cricoid cartilage	Horizontal plane defined by the inferior border of the cricoid cartilage	Horizontal plane defined by the inferior border of the cricoid cartilage
	Inferior	Clavicle	Clavicle	Clavicle
	Lateral (posterior)	Anterior border of trapezius muscle	Anterior border of trapezius muscle	Anterior border of trapezius muscle
	Medial	Lateral border of SCM	Lateral border of SCM	Sensory branches of the Cervical plexus
Level VI (anterior or central)				
	Superior	Hyoid bone	Hyoid bone	Hyoid bone
	Inferior	Superior edge of the manubrium sternum bone	Superior edge of the manubrium sternum bone	Superior edge of the manubrium sternum bone
	Lateral (posterior)	Common carotid artery	Medial aspect of the common carotid artery	Common carotid artery
	Medial	Common carotid artery	Medial aspect of the common carotid artery	Common carotid artery
Optional—Level VII (superior mediastinal)				
	Superior	Superior edge of the manubrium sternum bone	Superior edge of the manubrium sternum bone	Superior edge of the manubrium sternum bone
	Inferior	N/A	Innominate artery	Innominate artery
	Lateral (posterior)	N/A	Innominate artery and left common carotid artery	Innominate artery and left common carotid artery
	Medial	N/A	Innominate artery and left common carotid artery	Innominate artery and left common carotid artery

SCM, sternocleidomastoid.

Figure 121-3. Radical neck dissection; the boundaries of dissection are depicted by the heavy line. *(Redrawn from art provided courtesy of Douglas Denys, MD.)*

Technique

POSITIONING. The patient is positioned supine on the table with the shoulder roll placed to optimally extend the neck. The skin is prepped and draped to allow for full exposure of both sides of the neck with clear visualization of surrounding landmarks (e.g., the lower face including the mentum, both mastoid processes, earlobes) and the clavicles and suprasternal notch inferiorly. In this way the incision may be mapped in an accurate fashion, and throughout the procedure, overall orientation may be maintained.

INCISION PLANNING. The incision is planned for optimal exposure of all lymph node levels to be dissected (levels I to V) and to preserve as much blood supply as possible. The neck flaps raised should be broadly based, either superiorly or inferiorly, and preferably to avoid any trifurcations, particularly overlying the carotid sheath. Incisions that best fit these criteria are the hockey stick and boomerang patterns; the McFee incision; and, in patients undergoing bilateral neck dissection, the apron incision, which is a bilateral hockey stick incision (Fig. 121-4). Other incisions use trifurcations that overlie the carotid sheath, although modifications of the Schobinger incision include placing the trifurcation more laterally based. Although the boomerang incision may be somewhat less aesthetically pleasing, it is an excellent alternative to use in conjunction with oral cavity and oropharyngeal tumors wherein exposure of the primary site involves extending the incision through the lip for a mandibulotomy approach.

FLAP ELEVATION. The initial incision is carried through skin and platysma muscle, although the platysma is deficient in the midline and the lateral-most parts of the incision. This anatomic feature can be used to reapproximate the flaps at the time of closure because the platysmal muscle edges serve as "natural hash marks." The flap is raised in the subplatysmal plane so that the external jugular vein and the greater auricular nerves are not included in the flap (Fig. 121-5A). Although these structures will ultimately be sacrificed in the radical neck dissection, in SND procedures, they are routinely preserved. When there is gross pathologic evidence of tumor extension through the platysma muscle, with or without skin involvement, the area of disease involvement should also be removed and modifications of the skin flap may be required. Identification of the mandibular branch of the facial nerve is performed after complete elevation of the skin flaps superiorly and inferiorly to expose all of the lymph node levels of the neck. It is recommended that the anterior facial vein be ligated and retracted superiorly to protect this nerve only after the superior skin flap is raised. This allows proper assessment of the prevascular and postvascular lymph nodes in the submandibular triangle, which will need to be removed. Therefore it is best to incise the submandibular fascia at the lower border of the submandibular gland and to carefully raise this fascia off of the submandibular gland superiorly to the level of the lower border of the mandible as a separate flap. Usually the mandibular branch of the facial nerve may be seen as this fascia is raised (see Fig. 121-5B).

DISSECTION OF THE POSTERIOR TRIANGLE. The subsequent order of dissection is a matter of individual preference, although there is some oncologic rationale for dissecting from below upward rather than from above downward. Thus the next step is to expose the anterior border of the trapezius muscle from its superior aspect, where it converges with the posterior border of the sternocleidomastoid muscle, to its inferior aspect, where it approaches the clavicle (see Fig. 121-5C). The fibrofatty tissue is then incised along its anterior border beginning superiorly and working inferiorly to expose the muscular floor of the posterior triangle. In so doing, the spinal accessory nerve will be severed at the point at which it enters the trapezius muscle in the lower aspect of the posterior triangle. After this step has been completed, the floor of the posterior triangle at its inferior extent is next exposed by incising through the fibrofatty tissue immediately above the superior border of the clavicle. This requires incising through the inferior belly of the omohyoid muscle and the fibrofatty tissue overlying the brachial plexus. In this region, the transverse facial artery will be encountered immediately overlying the muscular floor of the triangle; this artery should be preserved unless there is gross disease involving the region. The fibrofatty contents of the posterior triangle are then mobilized anteriorly, lifting them away from the floor of the neck, which, in this region, is formed by the splenius capitis, levator scapulae, and scalene muscles. It is important to remain superficial to the prevertebral fascia during this step of the operation to prevent injury to the phrenic nerve and the brachial plexus. As the fibrofatty tissue is swept in a lateral-to-medial direction, the sensory branches of the cervical plexus will be encountered and divided.

ANTERIOR TRIANGLE DISSECTION. As the fibrofatty tissue is elevated medially toward the carotid sheath, it will be necessary to incise the mastoid attachment of the sternocleidomastoid muscle and the clavicular attachments (see Fig. 121-5D). The carotid sheath will be exposed, and identification of the common carotid artery and vagus nerve may be made. Attention should be given to preserving the cervical sympathetic chain, which is closely applied to the prevertebral fascia behind the carotid sheath. The plane of dissection will be carried between the vagus nerve and the carotid artery below and the internal jugular vein above. Thus the internal jugular vein may be mobilized from the skull base superiorly to its inferior aspect near the clavicle; ties may then be placed around the upper and lower ends of the internal jugular vein, thereby allowing ligation and complete mobilization. When incising the soft tissue contents of the lower medial aspect of the neck, lymphatic channels will be encountered, particularly on the left side. It is imperative to precisely identify these and ligate them immediately as they are encountered. The thoracic duct is located to the right of and behind the left common carotid artery and the vagus nerve. From here, it arches upward, forward, and laterally, passing behind the internal jugular vein and in front of the anterior scalene muscle and the phrenic nerve; it then opens into the internal jugular vein, subclavian vein, or angle formed by the junction of these two vessels. The duct is anterior to the thyrocervical trunk and the transverse cervical artery. To prevent a chyle leak, the surgeon should also remember that the thoracic duct may be multiple in its upper end and that, at the base of the neck, it usually receives the jugular trunk, a subclavian trunk, and maybe other minor lymphatic trunks that should be individually divided and ligated or clipped.

After ligation of the lower part of the internal jugular vein, the contents of the mobilized specimen are retracted superiorly and medi-

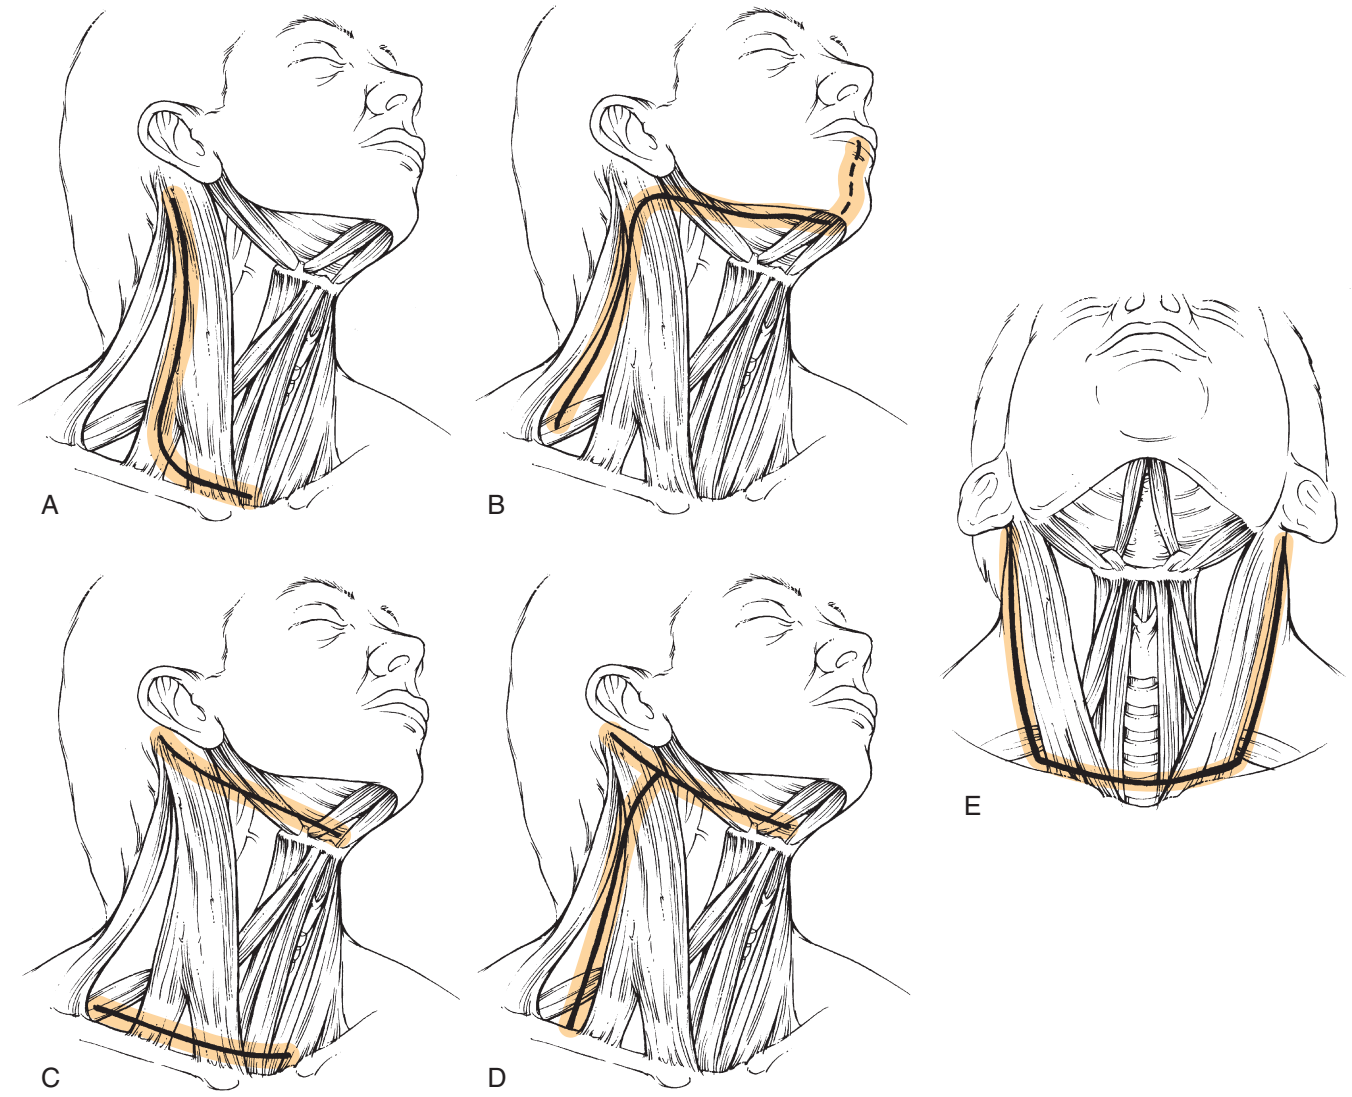

Figure 121-4. Incisions for radical and modified radical neck dissections. **A,** Hockey stick. **B,** Boomerang. **C,** McFee. **D,** Modified Schobinger. **E,** Apron or bilateral hockey stick. *(© 2008 by Johns Hopkins University, Art as Applied to Medicine.)*

ally. Dissection is carried along the common carotid artery and medially as far as the sternohyoid muscle. Further elevation of the contents exposes the carotid bifurcation. As this is done, the branches of the internal jugular vein require identification and ligation. Specifically, these are the middle and superior thyroid veins and the retromandibular vein. Further superior elevation of the fibrofatty contents away from the upper part of the carotid sheath exposes the hypoglossal nerve lying lateral to the external carotid artery and the spinal accessory nerve extending from above downward.

At this point, the posterior belly of the digastric muscle is identified, and the soft tissue attachments of the neck contents lying superior to the muscle are divided, including the sternocleidomastoid muscle as it attaches to the mastoid process, vascular channels extending into the postauricular region and parotid gland, the tail of the parotid gland that extends downward inferior to the level of the digastric muscle, and soft tissue attachments to the angle of the mandible. After completion of this part of the dissection, all of the lower contents of the neck dissection specimen should be freely mobile, and the only remaining attachments are the upper end of the internal jugular vein and the undissected contents of the submandibular triangle and the submental triangle (see Fig. 121-5E).

DISSECTION OF THE UPPER NECK COMPARTMENTS. Excision of level I lymph nodes is begun by dividing the soft tissue overlying the body of the mandible including the facial artery and vein as they emerge above the submandibular gland and extend lateral to the body of the mandible. The anterior bellies of the ipsilateral and contralateral digastric muscles are skeletonized, thereby delineating the boundaries of the submental triangle. After the fibrofatty tissue has been removed from occupying this space, the fibrofatty contents of the anterior portion of the submandibular triangle are removed from the underlying mylohyoid muscle until its lateral border may be identified. The lateral border of the muscle is then retracted anteriorly, exposing the deep contents of the submandibular triangle. This allows for visualization of the lingual nerve, submandibular duct, and hypoglossal nerve. The submandibular duct is isolated, divided, and ligated. Next, the submandibular ganglion should be divided, thus allowing the lingual nerve to retract superiorly away from the area of dissection. Care is taken to not injure the hypoglossal nerve and its venae comitantes in the deep portion of the triangle. The last attachment of the contents of the submandibular triangle is the proximal end of the facial artery as it courses deep to the submandibular gland. It is important to remember that complete excision of all contents of the submandibular triangle within its muscular boundaries—and not just the submandibular gland—is required.

Variations in the approach to the radical neck dissection should be made, depending on the location of the disease and its degree of mobility. For example, it is best to mobilize the areas that are least involved with a tumor that is difficult to remove, which will enhance

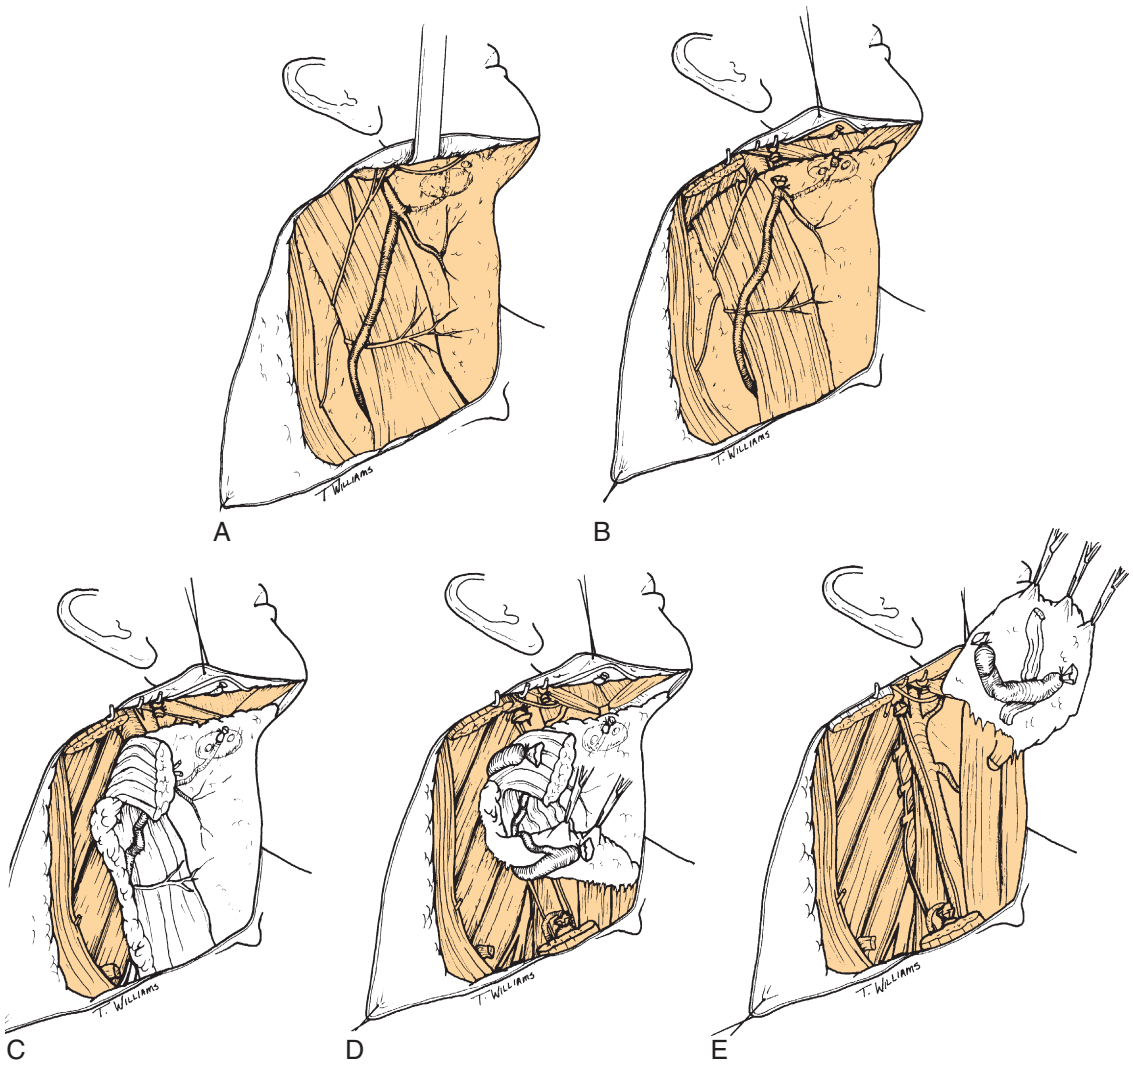

Figure 121-5. Steps of the radical neck dissection. (See text for discussion.)

the exposure of the anatomic structures that may be directly invaded by the disease itself.

Neck drains are inserted and brought through separate stab incisions through the most dependent areas of the dead space. Closure of the incisions are usually performed in two layers, including approximation of the platysma anteriorly and the subcutaneous tissue laterally and the second layer approximating the skin.

Modified Radical Neck Dissection

DEFINITION. A modified radical neck dissection is defined as the en bloc removal of lymph node–bearing tissue from one side of the neck (levels I to V). The dissection extends from the inferior border of the mandible above to the clavicle below and from the lateral border of the strap muscles medially to the anterior border of the trapezius muscle laterally. Unlike the radical neck dissection, there is preservation of one or more of the following structures in the modified radical dissection: spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle (Fig. 121-6). The major purpose of these modifications relates to the morbidity encountered when the spinal accessory nerve is removed. Although the degree of morbidity is less for removal of the sternocleidomastoid muscle and the internal jugular vein, this issue becomes far more important if bilateral neck dissections are required. Simultaneous sacrifice of both internal jugular veins may result in severe swelling of the face with increased intracranial pressure.

INDICATIONS. The major indication for a modified radical neck dissection is to remove grossly visible lymph node disease, particularly if there is involvement of several levels, that is not directly infiltrating or fixed to the nonlymphatic structures. It is difficult to justify the sacrifice of the spinal accessory nerve if it is not directly involved with disease when the hypoglossal nerve and the vagus nerve, which also lie in similar proximity to nodal disease, are spared.

TECHNIQUE. Knowledge of the surgical anatomy of the spinal accessory nerve is essential to preserve this structure. Below the jugular foramen, the spinal accessory nerve is located deep to the digastric and stylohyoid muscles and lateral or immediately posterior to the internal jugular vein; it then runs obliquely downward inferiorly and posteriorly to reach the medial surface of the sternocleidomastoid muscle near the junction of the superior and middle third. It traverses this muscle, giving off a major branch to it. The remaining part of the nerve then exits the posterior border of the sternocleidomastoid muscle near the area known as *Erb's point,* where the four superficial branches of the cervical plexus—the greater auricular, lesser occipital, transverse cervical, and supraclavicular nerves—emerge from behind the muscle. This point is located approximately at the junction of the upper and middle thirds of this muscle. From here, the spinal accessory nerve courses through the posterior triangle of the neck to enter the anterior border of the trapezius muscle at a point located approximately at the junction of the middle and lower thirds of the anterior border of this muscle.

The incisions and skin flaps are raised for modified radical neck dissection as similarly described for the radical neck dissection. The same procedure is followed to identify and protect the mandibular branch of the facial nerve in level I.

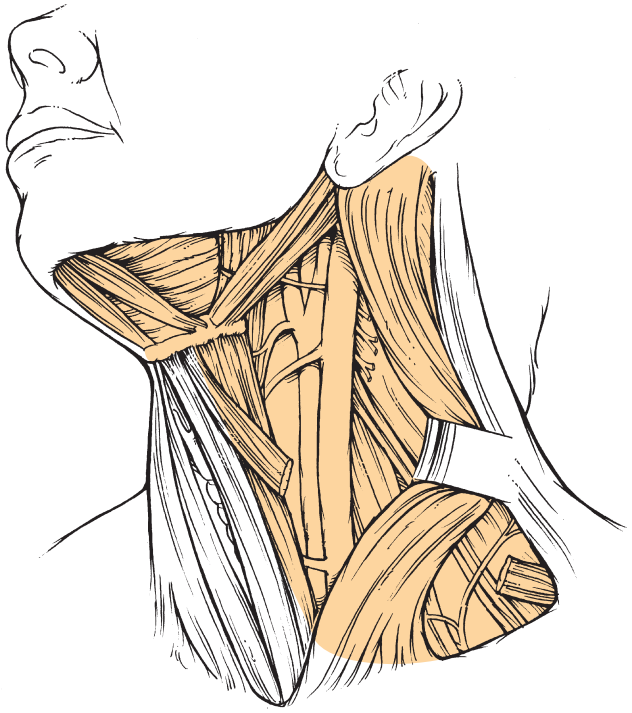

Figure 121-6. Boundaries of the modified radical neck dissection, in which there is preservation of the spinal accessory nerve, sternocleidomastoid muscle, and internal jugular vein. *(Redrawn from art provided courtesy of Douglas Denys, MD.)*

Unlike what is found in the radical neck dissection procedure, the next step is to identify the spinal accessory nerve. This is initially done in the posterior triangle from which the nerve exits at or around Erb's point (Fig. 121-7A). The nerve lies superficially in the fibrofatty contents of the posterior triangle and usually may be identified by careful spreading of the fibrofatty tissue; the use of a nerve stimulator may assist this process. Once located, the nerve is isolated and dissected away from the underlying fibrofatty contents from Erb's point medially to the point at which it enters the anterior border of the trapezius muscle laterally (see Fig. 121-7B). The nerve is next isolated in its superior third, which is done by incising the anterior border of the sternocleidomastoid muscle from its attachment superiorly at the mastoid to its lowermost attachment at the sternal head. The sternocleidomastoid muscle is retracted laterally as the fibrofatty soft tissue contents anterior to this muscle are dissected away from it, and the many arcades of small blood vessels coursing between the muscle and the soft tissue are divided. This part of the procedure mobilizes the anterior aspect of the sternocleidomastoid muscle along its full extent. As the muscle is retracted laterally in its upper portion, the spinal accessory nerve is seen entering its deep surface (see Fig. 121-7C). From this point, the nerve is traced superiorly by dividing the overlying fibrofatty contents until the posterior belly of the digastric muscle is identified. This muscle is retracted superiorly to gain exposure to the superior end of the internal jugular vein near the jugular foramen. The posterior border of the sternocleidomastoid muscle may be freed completely from the underlying fibrofatty contents all the way from its mastoid attachment above to its clavicular attachment below. Except for its course through this muscle, the spinal accessory nerve is now completely mobilized from its entry into the anterior border of the trapezius muscle below to its superior extent at the skull base above.

The fibrofatty tissue in the posterior triangle is separated from the entire anterior border of the trapezius muscle and is mobilized from a lateral to a medial direction. Tissue lying superficial to the spinal accessory nerve as it courses across the posterior triangle should be divided immediately above the spinal accessory nerve so that it may be passed along with its deep component beneath the nerve and the elevated sternocleidomastoid muscle (see Fig. 121-7D). After the fibrofatty contents have been dissected and swept over the carotid artery, vagus nerve, and internal jugular vein, the sternocleidomastoid muscle may be retracted laterally and the contents passed underneath the muscle for subsequent dissection of the anterior triangle of the neck (see Fig. 121-7E). Careful sharp dissection will allow for separation of these contents from the carotid artery and the jugular vein. This dissection is continued until the sternohyoid muscle, which is the medial boundary of anterior triangle contents in the lower neck, is reached. The branches of the internal jugular vein are usually ligated to allow a thorough clearance of the anterior triangle contents. Dissection is carried superiorly to remove the fibrofatty tissue attachments overlying the internal jugular vein at the level of the skull base. The retromandibular vein may be preserved, but the anterior facial vein needs to be ligated (see Fig. 121-7F). Subsequent dissection is then performed to remove the contents of the submandibular and submental triangles.

Sacrifice of one or two of the nonlymphatic structures of the neck (i.e., spinal accessory nerve, sternocleidomastoid muscle, and internal jugular vein) may become necessary as a result of gross involvement by cancer intraoperatively, although the operation continues to be called a modified radical neck dissection as long as at least one of these structures is preserved (Fig. 121-8).

Selective Neck Dissection (see Key Indicator Video on website)

DEFINITION. SND is performed for patients who are at risk for early lymph node metastases. The procedure consists of the en bloc removal of one or more lymph node groups that are at risk for harboring metastatic cancer, an assessment that is based on the location of the primary tumor. Thus the levels removed depend on the location of the primary lesion and its known pattern of spread.

RATIONALE. Although the concept of SND dates back to procedures used for treating lip cancer, its broader adoption to treat other cancers of the upper aerodigestive tract was popularized by surgeons at the MD Anderson Cancer Center.[20] It was based on removing lymph node groups that were at highest risk in patients with N_0 nodal disease. Studies have shown that this procedure has the same therapeutic value as more extensive neck dissections[16]; it is also intended to preserve functionally and cosmetically relevant structures as a secondary goal.

The topographic distribution of lymph node metastases appears to be predictable in patients with previously untreated squamous cell carcinoma of the head and neck, particularly in those with early disease. The basic anatomic studies of Rouviere[35] and Fisch and Sigel[36] showed that lymphatic drainage of the mucosal surfaces of the head and neck follow relatively constant and predictable routes. The clinical study by Lindberg in 1972[12] showed that the lymph node groups most frequently involved in patients with carcinoma of the oral cavity are the jugulodigastric and midjugular nodes. In addition, the nodes in the submandibular triangle are frequently involved in patients with carcinoma of the floor of the mouth, the anterior oral tongue, and the buccal mucosa. Lindberg also noted that tumors frequently metastasize to both sides of the neck and may skip the submandibular and jugulodigastric nodes, metastasizing first to the midjugular region. The Lindberg study showed that, in the absence of metastases to the first echelon nodes, tumors of the oral cavity and oropharynx rarely involve the lower jugular and posterior triangle nodes. Similar findings were reported by Skolnik in 1976,[14] who, in a study of radical neck dissection specimens, found no metastases in the nodes of the posterior triangle of the neck in radical neck dissections, regardless of the site of the primary tumor or the presence or absence of metastases in the jugular nodes. Further evidence subsequently has been provided by Shah[25] in a retrospective study of radical neck dissection specimens performed for patients with oral cavity and larynx or laryngopharyngeal metastases. Shah demonstrated that tumors of the oral cavity metastasize most frequently to neck nodes in levels I, II, and III, whereas carcinomas of the pharynx, hypopharynx, and larynx involve mainly the nodes in levels II, III, and IV. Whenever nodes were found in other areas, there was also positive disease in the areas of highest risk.

Some authorities believe that SND is, in essence, a procedure for staging the necks of patients whose tumors are amenable to treatment

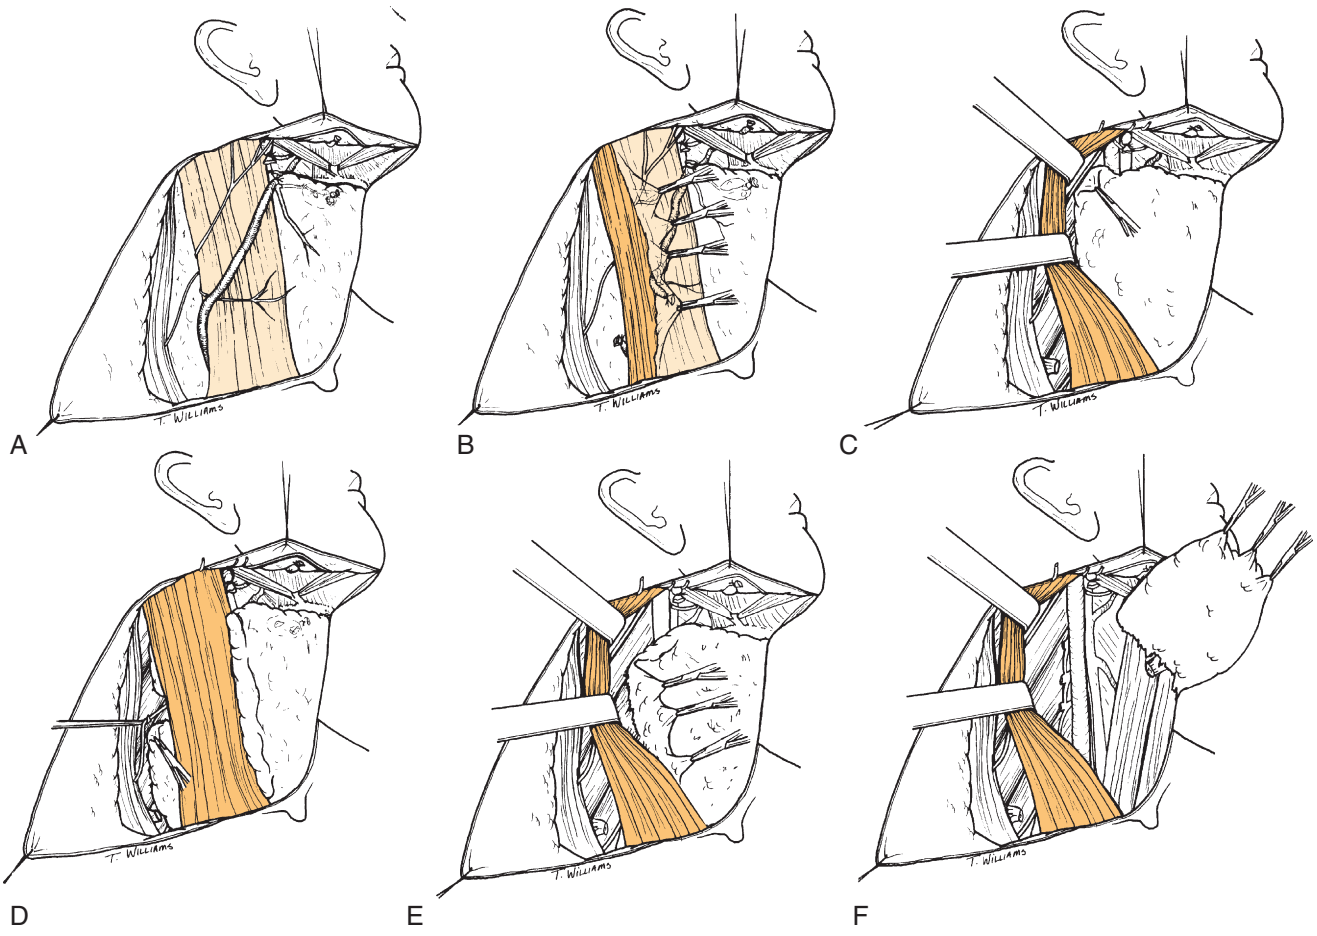

Figure 121-7. A-F, Steps of the modified radical neck dissection, in which there is preservation of the spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle.

with surgery alone. In patients who have this procedure done in conjunction with the excision of the primary tumor, further information about the status of the nodal disease is provided. If there is evidence of multiple lymph node metastases or extracapsular spread in the neck dissection contents, then postoperative radiotherapy is indicated. Byers and colleagues[37] also reported a lower rate of regional recurrence among patients with N_1 disease if postoperative radiation therapy was administered. More intensive therapy may be used for patients who have more aggressive tumors.

Selective Neck Dissection for Oral Cavity Cancer

DEFINITION AND RATIONALE. The procedure of choice is SND (levels I to III) and is often called the supraomohyoid neck dissection. The procedure involves the removal of lymph nodes contained in the submental and submandibular triangles (level I), the upper jugular lymph nodes (level II), and the midjugular lymph nodes (level III). The cutaneous branches of the cervical plexus and the posterior border of the sternocleidomastoid muscle mark the posterior limit of the dissection. The inferior limit is the junction between the superior belly of the omohyoid muscle and the internal jugular vein.

SND is recommended for patients with oral cavity cancer who are at risk of harboring occult nodal disease (Fig. 121-9). Also, SND can be performed for patients with low-volume nodal disease (N_1) located in the upper neck provided that postoperative radiation therapy is part of the treatment plan. Tumors originating in this region, particularly in the subsites of the oral tongue and the floor of the mouth, have a high propensity to metastasize early, regardless of size and differentiation. Primary echelons for nodal spread include the submental, submandibular, upper jugular, and middle jugular groups. In patients with tongue cancer, the lower jugular lymph node groups (level IV) are also at risk.[38] Even when there is no clinical evidence of nodal disease, there is at least a 20% risk for occult disease associated with these lesions. Unless the management of choice for the primary lesion is radiotherapy, elective neck dissection with removal of levels I through III (level IV for those with tongue cancer) is the minimal recommended treatment for patients with squamous cell carcinoma of the oral cavity associated with N_0 nodal disease. For patients with palpable nodal disease, it is usually necessary to perform a modified radical neck dissection, but a selective removal of levels I through IV is an appropriate alternative when the nodal disease is confined to levels I and II. With the possible exception of a solitary metastatic node without extracapsular extension, postoperative radiation therapy is usually indicated for all patients undergoing SND who have positive pathologic nodes in the specimen.[37] Elective cervical lymphadenectomy of the contralateral neck is indicated for patients with primary lesions involving the floor of the mouth or the ventral surface or with midline involvement of the tongue, in whom ipsilateral neck dissection is planned and in whom there are no definite indications for postoperative radiotherapy. Contralateral therapeutic neck dissection is indicated for patients with clinically N_{2c} disease.

TECHNIQUE. When an ipsilateral supraomohyoid neck dissection is planned, a modified apron incision is made to provide adequate exposure of levels I through III (Fig. 121-10A). If bilateral neck dissection is necessary, the horizontal component of the apron incision is carried across the midline to the other side of the neck (bilateral apron incision; see Fig. 121-10B). The ipsilateral and bilateral apron incisions are also appropriate for exposure of the primary disease when a pull-through exposure is indicated. When it is necessary to split the lip for access to the primary tumor, the medial component of the ipsilateral apron incision may be extended for this purpose. If bilateral neck dis-

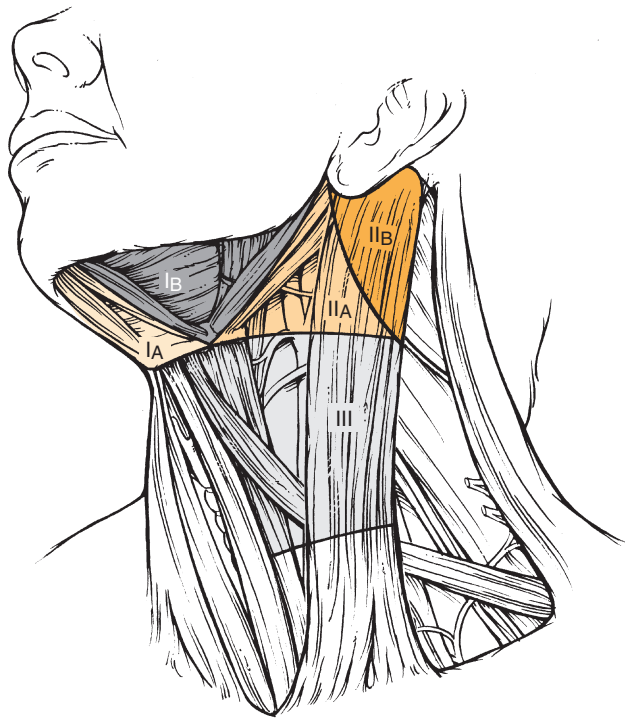

Figure 121-9. Boundaries of the selective neck dissection for oral cavity cancer, selective neck dissection (*I* to *III*) or supraomohyoid type. *(Redrawn from art provided courtesy of Douglas Denys, MD.)*

section is planned and a lip-splitting incision is also required, a bilateral boomerang incision is substituted for the bilateral apron incision (see Fig. 121-10C). This neck incision pattern is also preferred for those with more advanced nodal disease associated with oral cavity primaries in whom it is necessary to dissect all five levels of the ipsilateral neck. The boomerang incision is also preferred for patients with stage N_{2c} disease because it may be extended across the midline for exposure of all levels of the contralateral lymph nodes (see Fig. 121-10D).

For the removal of levels I through III, the modified apron skin flap is raised in the subplatysmal plane until there is exposure of the upper two thirds of the anterior border of the sternocleidomastoid muscle, mastoid process, body of the mandible, and mandibular symphysis (Fig. 121-11A and B). It is preferred not to raise the fascia off of the submandibular gland until the subplatysmal flap is first elevated to the level of the body of the mandible, which permits a more accurate assessment of the submandibular triangle for assessing tumor involvement of the superficial layer of the deep cervical fascia. After this possibility is excluded, the fascia overlying the submandibular gland is carefully raised as a separate flap to avoid injuring the mandibular branch of the facial nerve. This branch is often seen within the superficial layer of the deep cervical fascia, but, with careful dissection of this layer, the nerve may be protected and preserved.

Next, an incision is made in the investing layer of the deep fascia at the anterior border of the sternocleidomastoid muscle. Care is taken to not injure the external jugular vein and branches of the greater auricular nerve that lie lateral to the sternocleidomastoid muscle but posterior to the fascial incision being made. Because lymph nodes associated with the external jugular vein are almost never involved with aerodigestive tract carcinomas, these structures are left undisturbed. The fibrofatty contents of the anterior triangle are peeled away first from the anterior border and then from the medial aspect of the sternocleidomastoid muscle all the way from a point close to the mastoid process above down to the level of the omohyoid muscle below, stopping when the posterior border of the muscle is reached. Although the upper third of the sternocleidomastoid muscle is being separated, the spinal accessory nerve comes into view as it enters the muscle (see Fig. 121-11C). This nerve is dissected free of its surrounding fibrofatty

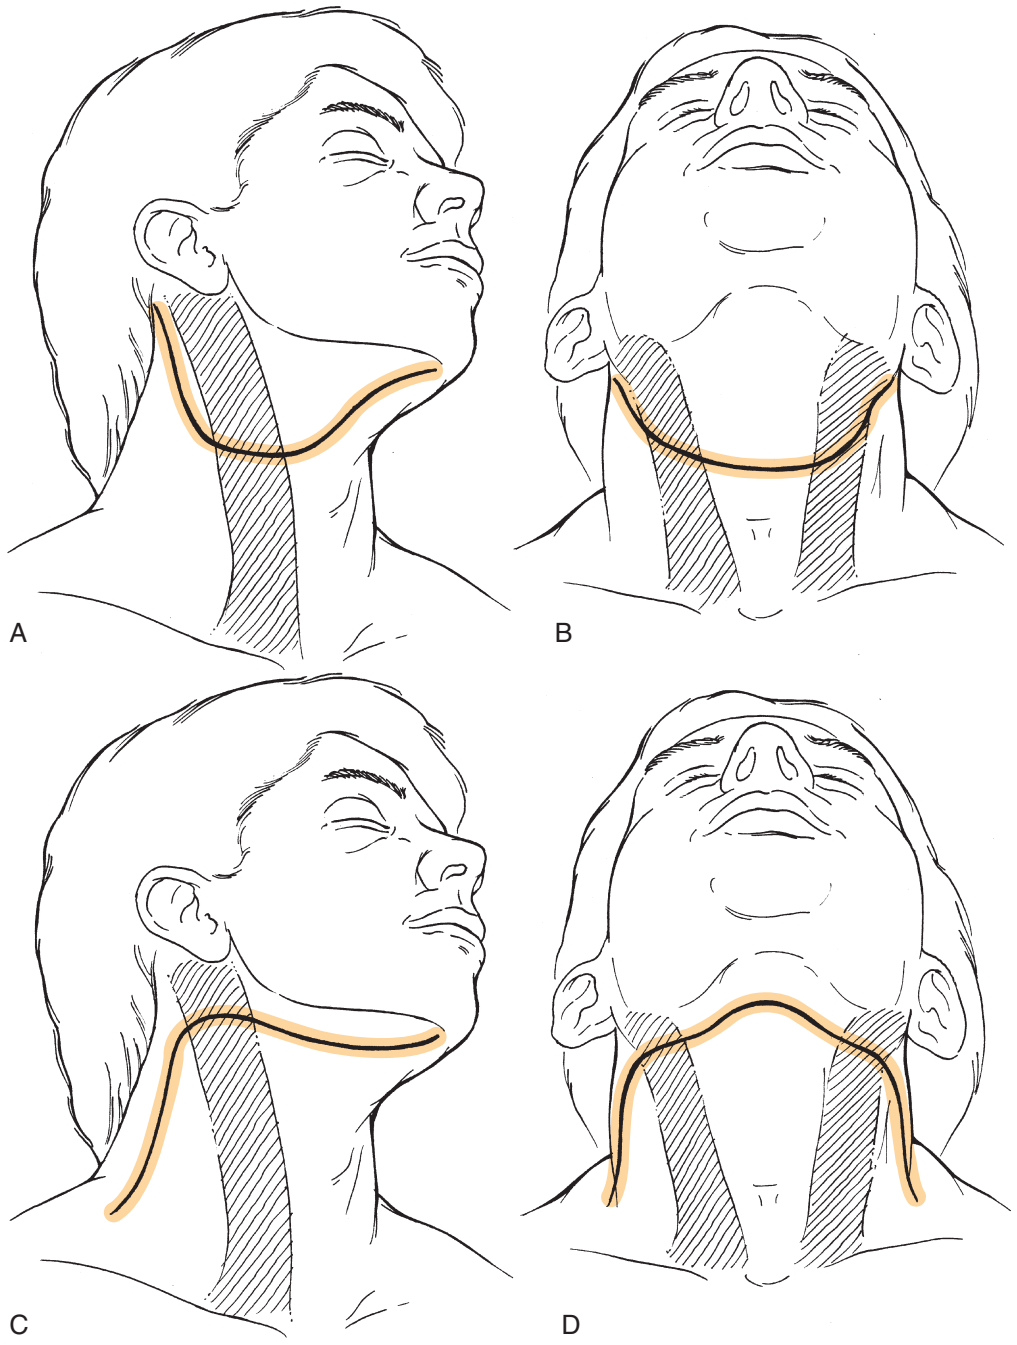

Figure 121-10. Incisions for selective neck dissection (*I* to *III*). **A,** Modified apron incision. **B,** Apron incision. **C,** Boomerang incision. **D,** Bilateral boomerang incision.

tissue from the level of the skull base adjacent to the internal jugular vein to its point of entry into the sternocleidomastoid muscle. It is necessary to dissect along the inferior border of the posterior belly of the digastric muscle and to retract it supralaterally to provide adequate exposure of the upper carotid sheath near the skull base. Fibrofatty tissue is also dissected away from the inferior border of the posterior belly of the digastric muscle as far posteriorly as the attachment of the mastoid process. This triangle formed by the digastric muscle, spinal accessory nerve, and sternocleidomastoid muscle outlines the triangular packet of tissue-bearing lymph nodes belonging to level II. It is important to separate this triangular packet from the underlying paraspinal muscles and to pass it under the spinal accessory nerve (see Fig. 121-11D). The dissection is continued inferiorly by incising along the fibrofatty tissue corresponding with the posterior border of the sternocleidomastoid muscle to the level of the omohyoid muscle. Care is taken to not cut across the sensory branches of the cervical plexus as the incision is carried down to the muscular floor. When the sensory branches of the cervical plexus are encountered, the fibrofatty tissue is dissected in a plane that is superficial to these nerves (see Fig. 121-11E). At this point in the procedure, it is important to carefully inspect and palpate the lower jugular chain and the posterior triangle for evidence of nodal disease. If found, the dissection of the lymph-node-bearing tissue would have to be extended to encompass level IV and the posterior triangle (level V), thus converting the operation to a modified radical neck dissection. For this purpose, a lower cervical flap would then be raised for adequate exposure of the clavicle and the anterior border of the trapezius.

After completion of the lateral boundary of dissection, the lymph node–bearing tissue is swept medially in a plane immediately above the fascia of the paraspinal muscles. The sensory branches of the cervical

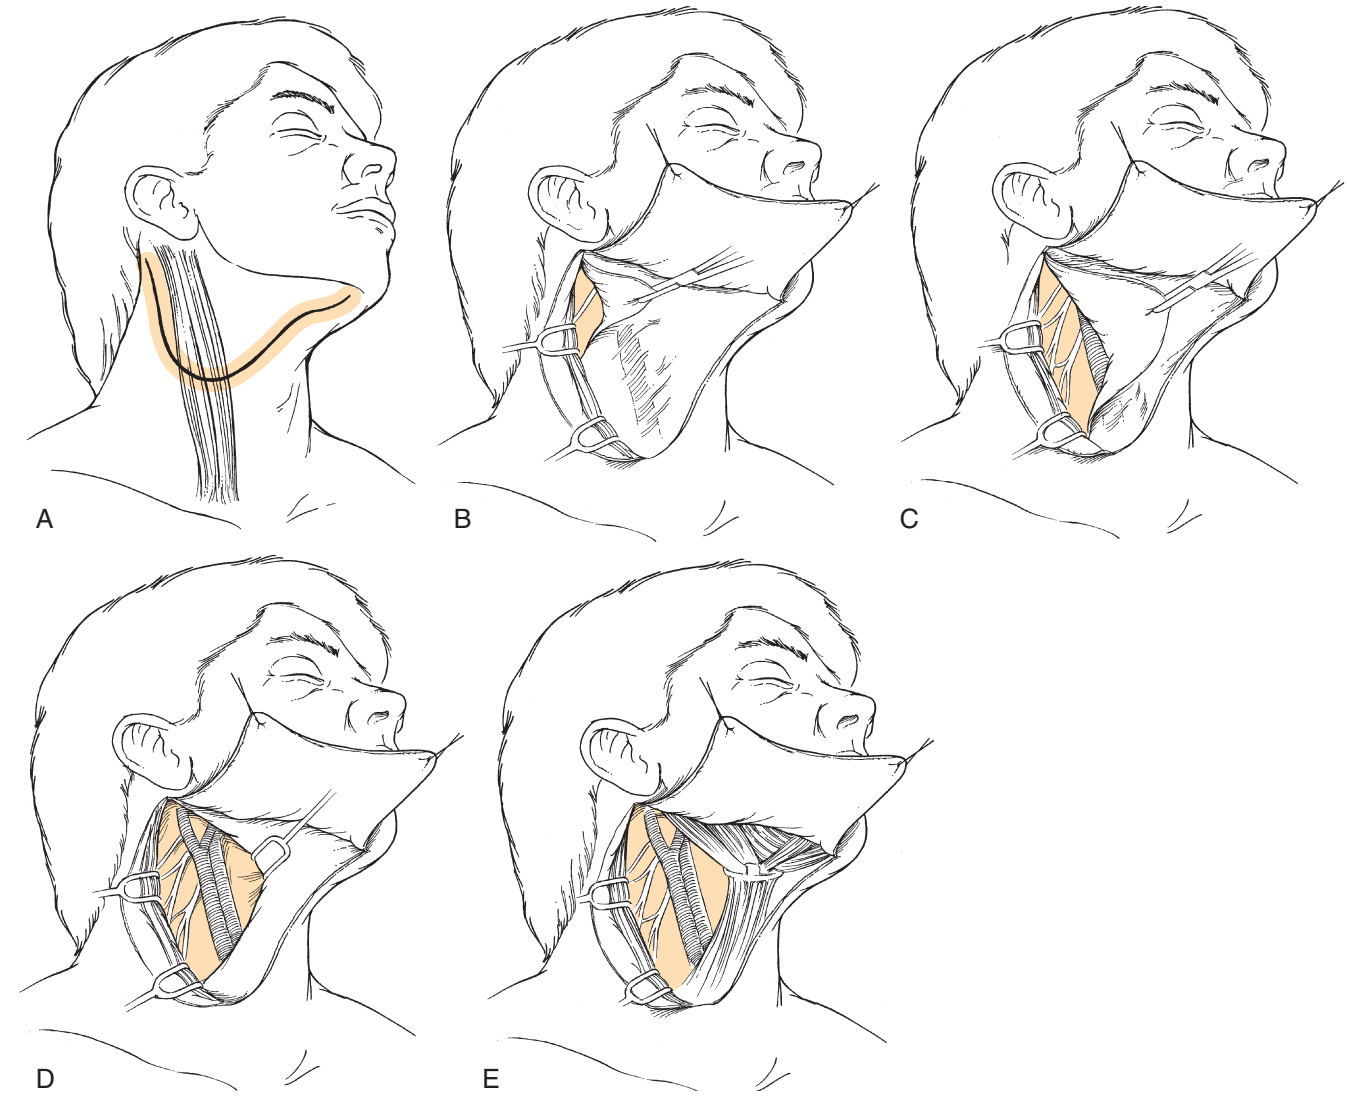

Figure 121-11. Steps of the selective neck dissection for oral cavity cancer (SND *I* to *III*). **A,** Modified apron incision. **B,** Flap raised in the subplatysmal plane to expose the upper two thirds of the carotid sheath and the submandibular and submental triangle; exposure of the upper third of the spinal accessory nerve and dissection of the submuscular recess (level IIB). **C,** Dissection of level III and preservation of the cervical plexus. **D,** Completion of the dissection of levels III and IIA. **E,** Dissection of level I.

plexus may be preserved only when level V dissection is not performed. This maneuver allows the lymph node–bearing tissue to be swept over the carotid sheath and permits exposure of its structures from the level of the clavicle or omohyoid muscle below to the skull base above. Sharp dissection is used to remove the fascia overlying the sheath, which usually includes preserving the internal jugular vein if a tissue plane can be readily identified. Next, the superior belly of the omohyoid muscle is skeletonized along its superior border to the level of the hyoid bone. The hyoid bone is also skeletonized medially, as is the anterior belly of the contralateral digastric muscle; this completes the medial boundary of dissection. The fibrofatty tissue is dissected from below at the level of the omohyoid muscle in a superior direction toward the submandibular triangle. After the lymph node–bearing tissue in the submental triangle has been cleared, the contents of the submandibular triangle are removed to complete the neck dissection (see Fig. 121-11). To ensure complete removal of all lymph nodes from this region, it is important to dissect along the fascial planes of the muscles within this triangle rather than enucleate the submandibular gland only, which includes dissecting the preglandular nodes underneath the anterior belly of the digastric muscle and the prevascular and postvascular nodes along the lower border of the body of the mandible. It is usually not necessary to remove the perifacial nodes lying lateral to the mandibular body, unless the primary cancer involves the buccal mucosa, upper gum, or upper lip. Dissection of this latter nodal group increases the risk of injury to the mandibular branch of the facial nerve. After completion of the dissection, the excised tissue is separated according to the level of the lymph node groups, each level being submitted separately for pathologic evaluation. Before closing the incisions, a single drain is placed in the surgical bed extending inferiorly from the digastric muscle above to a separate cutaneous puncture site made at the most dependent region below the skin incision. The drain is placed on continuous suction. A second drain is placed in the contralateral neck for bilateral procedures. The drain is usually removed 3 days after surgery, if the fluid collection is less than 20 mL/24 hours.

Selective Neck Dissection for Oropharyngeal, Hypopharyngeal, and Laryngeal Cancer

DEFINITION AND RATIONALE. The procedure of choice for these anatomic sites is SND (levels II to IV), and its boundaries are outlined in Figure 121-12; it is also called a *lateral neck dissection.* The procedure refers to the removal of the upper jugular lymph nodes (level II), the midjugular lymph nodes (level III), and the lower jugular lymph nodes (level IV). The superior limit of dissection is the skull base, and the inferior limit is the clavicle. The anterior (medial) limit is the lateral

border of the sternohyoid muscle and the stylohyoid muscle. The posterior (lateral) limit of the dissection is marked by the cutaneous branches of the cervical plexus and the posterior border of the sternocleidomastoid muscle. In the case of cancers involving the oropharynx and the hypopharynx, there is evidence indicating that the lateral retropharyngeal nodes are also at risk. Level IIB is at greater risk for metastases associated with oropharyngeal lesions relative to laryngeal and hypopharyngeal cancers. Thus if level IIB is excluded (as is sometimes done for N_0 laryngeal and hypopharyngeal cancers), the procedure would be designated SND (IIA, III, and IV). When the risk for lymphatic metastases is bilateral, the procedure of choice is a bilateral SND (II to IV). If the retropharyngeal lymph nodes are included, as in the case of cancers involving the pharyngeal wall, the procedure is designated SND (II to IV, retropharyngeal nodes). If the nodes in level VI are removed, as in the case of laryngeal and hypopharyngeal cancers extending below the level of the glottis, the procedure is designated SND (II to IV and VI).

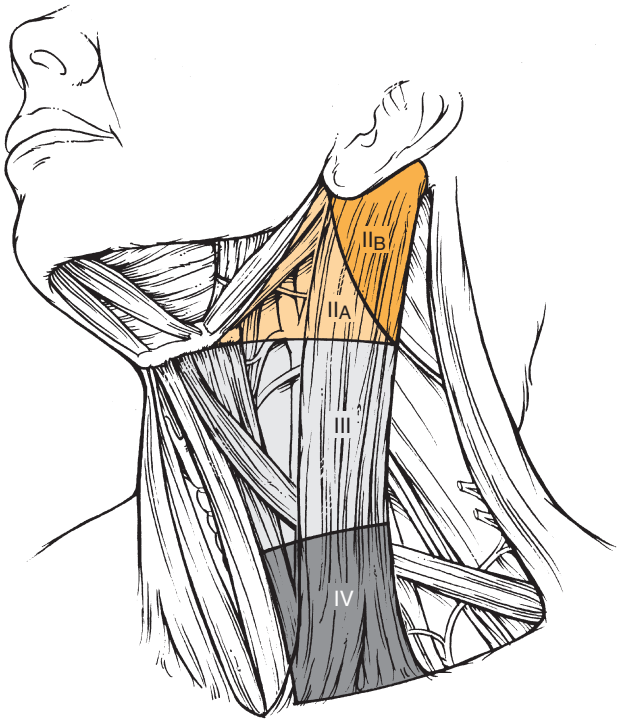

Figure 121-12. Boundaries of the selective neck dissection for oropharyngeal, laryngeal, and hypopharyngeal cancer, selective neck dissection (*II* to *IV*) or lateral type. (Redrawn from art provided courtesy of Douglas Denys, MD.)

It should be noted that there is a controversy over which selective neck dissection is indicated for an oropharyngeal cancer without known metastasis to the neck (N_0). Although the "classic" findings by Shah[25] and others[39-42] showed the pattern of lymph node to be involved is in levels II to IV, other studies have suggested that the levels at risk are I to III.[43,44] One possible explanation for this discrepancy could be the fact that it is easy to confuse nodes located posterior and deep to the submandibular gland with level IB, when in essence they are in level IIA. The same mistake could be done when dividing the specimen ex vivo into the different levels. Another possible explanation would be that an original oropharyngeal base of tongue cancer involves the oral tongue as well, thus putting level Ib at higher risk.

TECHNIQUE. The incision should allow for adequate exposure of levels II through IV and, should occult disease be found, exposure of level V as well. The hockey stick incision as described for radical and modified radical neck dissection is useful for this purpose; it may also be extended across the midline and carried along the contralateral neck as a broadly based apron flap or bilateral hockey stick incision (Fig. 121-13). After the neck flaps have been raised, the fibrofatty contents of the anterior triangle are removed en bloc, including the lymph nodes lying along the internal jugular vein from the skull base superiorly to the clavicle inferiorly. The dissection proceeds by incising along the anterior border of the sternocleidomastoid muscle and by separating it from its underlying attachments to the fibrofatty tissue. Care is taken to identify the spinal accessory nerve as it enters the anterior aspect of the sternocleidomastoid muscle. Then it is skeletonized from its entry point into the muscle inferiorly and into the skull base superiorly, wherein it lies deep to the posterior belly of the digastric muscle and lateral to the internal jugular vein. As described for the supraomohyoid neck dissection, the fibrofatty tissue deep to the sternocleidomastoid

muscle is incised and separated from the underlying splenius and levator muscles. The sensory branches of the cervical plexus may also be preserved by limiting the mobilization of fibrofatty tissue to the region superficial to these nerve branches. The contents are swept medially over the internal jugular vein, thereby exposing the full length of the vein from the skull base above to the clavicle below. At the lower end, care should be taken to meticulously identify and ligate any lymphatic channels encountered. On the left side, the thoracic duct will frequently be encountered; this structure must be carefully separated away from the fibrofatty tissue, avoiding any injury. If injury occurs, a repair must immediately be performed with fine, nonabsorbable suture material (e.g., silk, monofilament synthetic); occasionally this will necessitate ligation of the duct. After the internal jugular vein has been completely skeletonized, the remainder of the fibrofatty contents of the anterior triangle is mobilized by skeletonizing the medial border of the sternohyoid muscle and the stylohyoid muscle. The branches of the internal jugular vein in the neck may be sacrificed to assist this process, although the communicating branch to the anterior facial and retromandibular veins may be easily preserved.

Selective Neck Dissection for Cutaneous Malignancies

DEFINITION AND RATIONALE. The operation of choice depends on the location of the lesion and the adjacent lymph node groups, which are most likely to harbor metastatic disease. In the case of cancers involving the posterior scalp and upper neck, the procedure of choice is SND (II to V, postauricular, and suboccipital) (Fig. 121-14). This particular version is also called the posterolateral neck dissection; it is primarily used to eradicate nodal metastases associated with cutaneous malignancies and soft tissue sarcomas.[9]

It involves the removal of the suboccipital lymph nodes, retroauricular lymph nodes, upper jugular lymph nodes (level II), middle jugular lymph nodes (level III), lower jugular lymph nodes (level IV), and nodes of the posterior triangle of the neck (level V). The superior limit of dissection is the skull base anteriorly and the nuchal ridge posteriorly, and the inferior limit is the clavicle. The medial (anterior) limit is the lateral border of the sternohyoid muscle and the stylohyoid muscle; the lateral (posterior) limit is the anterior border of the trapezius muscle inferiorly and the midline of the neck superiorly. It is common to all sites that the lymphatic pathways for the seeding of tumor to the first and secondary echelon nodes involve the posterior auricular, occipital, posterior triangle, and jugular groups (see Fig. 121-14). Thus the dissection is designed to encompass the lymph node–bearing fibrofatty tissue of the posterior and lateral compartments of the neck. In addition, it is important to remove the intervening subdermal fat and underlying fascia between the lymph node groups and the primary disease, which ensures the removal of smaller nests of metastasizing tumor cells that are characteristic of malignancies originating in cutaneous soft tissue. For cutaneous malignancies arising on the preauricular, anterior scalp, and temporal regions, the elective neck dissection of choice is SND (parotid and facial nodes, levels IIA, IIB, III, and VA, and the external jugular nodes). For cutaneous malignancies arising on the anterior and lateral face, the elective neck dissection of choice is SND (parotid and facial nodes, levels IA, IB, II, and III). The development of techniques of lymphatic mapping may have a future role in specifically defining unpredictable lymphatic echelons of risk for cutaneous malignancies.

TECHNIQUE. The optimal incision for posterolateral neck dissection is one that allows exposure along the nuchal ridge to the occiput and the posterior triangle and exposure of the upper, middle, and lower jugular lymph node groups; this may usually be accomplished with a lazy S pattern or the combination of the hockey stick pattern with a horizontal extension from its upper aspect along the nuchal ridge. The patient should be placed in the lateral decubitus position to allow for adequate exposure of the posterior scalp and occiput. In patients with midline posterior scalp lesions, the procedure should encompass the nodal groups on both sides of the neck. In this latter situation, the patient should be placed in the prone position to allow access to both sides. The skin flaps are raised in the subplatysmal plane anteriorly and the subdermal plane posteriorly. The posterior auricular and suboccipital nodes are removed by incising the soft tissue overlying the fascia of the upper neck muscles that attach to the nuchal ridge and occiput. In addition, the upper part of the trapezius muscle that attaches to the skull base should be divided to allow for complete exposure of the suboccipital nodes; these nodes lie along the occipital artery as it courses laterally along the skull base. After completing this part of the dissection, the posterior triangle is cleared in the fashion that has already been described for the modified radical neck dissection. The spinal accessory nerve is routinely identified and preserved unless there is direct tumor

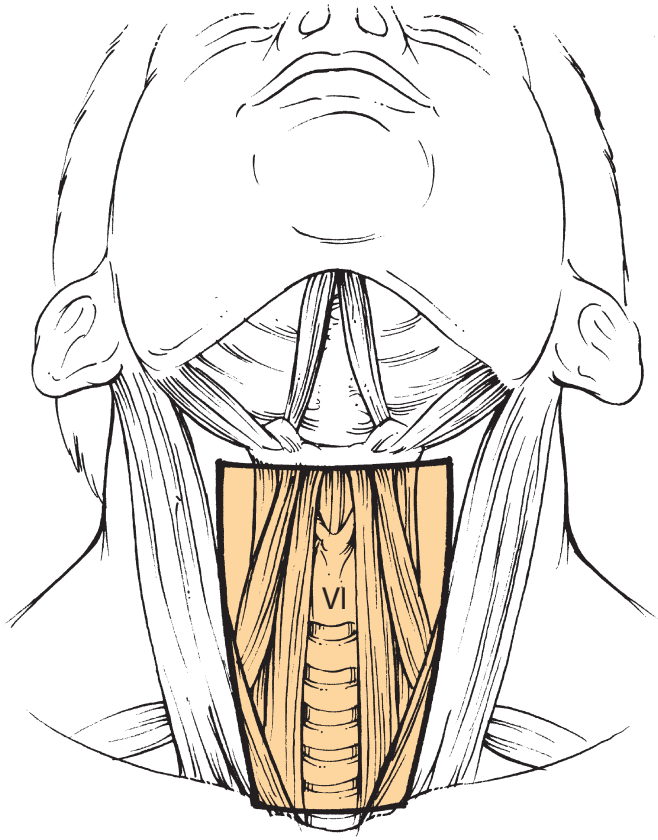

Figure 121-15. Boundaries of the selective neck dissection for thyroid cancer, selective neck dissection *(VI)* or anterior neck dissection. *(Redrawn from art provided courtesy of Douglas Denys, MD.)*

extension into the soft tissue surrounding it. The technique for locating and preserving the spinal accessory nerve has already been described. The remainder of the procedure involves mobilizing the fibrofatty contents of the anterior triangle, thereby removing the upper, middle, and lower jugular groups of lymph nodes. The technique for this procedure has already been described.

Selective Neck Dissection for Cancer of the Midline Structures of the Anterior Lower Neck

DEFINITION AND RATIONALE. The procedure of choice is SND (level VI) and is often called the *anterior neck dissection* or the *central compartment dissection* (Fig. 121-15). The procedure is most often indicated with or without dissection of other neck levels for thyroid cancer, advanced glottic and subglottic larynx cancer, advanced piriform sinus cancer, and cervical esophageal/tracheal cancer. This refers to the removal of the lymph nodes within the central compartment of the neck including the paratracheal, precricoid (Delphian), and perithyroidal nodes and the nodes located along the recurrent laryngeal nerves. The superior limit of dissection is the body of the hyoid bone, and the inferior limit is the suprasternal notch; the lateral limits are defined by the medial border of the carotid sheath (the common carotid artery). This neck dissection does not have a contralateral counterpart, and it assumes that the lymph nodes are removed on both sides of the trachea. In the case of metastases extending below the level of the suprasternal notch, dissection of the superior mediastinal nodes may be indicated, in which case the procedure is designated SND (VI, superior mediastinal nodes or the optional VII). Exposure of this latter region may require removing the manubrium and possibly one or both sternal heads of the clavicles.

In the case of thyroid cancer in which there is evidence of nodal metastases into level V, the procedure of choice would include the jugular nodes, as well as the posterior triangle nodes, and would be designated SND (II to V, VI).

In patients with unilateral laryngeal and hypopharyngeal lesions, the dissection of level VI may be confined to one side of the compartment, provided that there is no evidence of nodal metastases involving the contralateral side. In this way, the morbidity of disrupting the blood supply to the parathyroid glands or reimplanting them may be avoided.

TECHNIQUE. If there is an indication to dissect the lateral and posterior neck compartments, this procedure is done first. Then the strap muscles are either divided near the attachments at the sternum or mobilized and retracted laterally. The carotid artery is skeletonized along its medial border as far superiorly as the superior thyroid artery (Fig. 121-16A). The ipsilateral lobe of the thyroid gland is mobilized along its lateral border by dividing the fascia and its arterial and venous supply (see Fig. 121-16B). The recurrent laryngeal nerve is identified inferiorly as it courses the tracheoesophageal groove. If the larynx is to be removed, protection of the nerve is unnecessary. The fibrofatty contents of each side of the anterior compartment then may be removed by excising all of the loose areolar tissue located between the carotid artery laterally and the trachea medially (see Fig. 121-16C); the thyroid lobe also is removed as part of this en bloc resection (see Fig. 121-16D). The parathyroid glands should be identified and reimplanted into the sternocleidomastoid muscle. If it is necessary to completely remove nodal-bearing tissue from the entire anterior compartment, the procedure is completed on the contralateral side of the trachea. Thus a total thyroidectomy is performed, and all of the parathyroid glands are reimplanted. The dissection is carried superiorly as far as the hyoid bone and inferiorly as far as the suprasternal notch. If there is evidence of nodal disease at the lower end of the trachea, a more thorough cleanout of the superior mediastinum may be achieved by splitting the sternum or removing the manubrium and one or more clavicular heads.

Extended Neck Dissection

Any of the neck dissections described previously may be extended to remove either lymph node groups or vascular, neural, or muscular structures that are not routinely removed in a neck dissection. A neck dissection may be extended to remove the retropharyngeal lymph nodes on one or both sides when the primary tumor originates in the pharyngeal walls. Ballantyne[45] found a 44% incidence of retropharyngeal node involvement in a group of patients with carcinomas of the pharyngeal wall who were treated surgically. Tumors of the base of the tongue, the tonsil, the soft palate, and the retromolar trigone may also spread to these lymph nodes when they involve the lateral or posterior walls of the oropharynx. Adequate removal of a metastatic tumor in the neck may dictate the need to extend a neck dissection to resect structures such as the hypoglossal nerve, levator scapulae muscle, or carotid artery.

Controversy still exists about the advisability of resecting the common or the ICA (Fig. 121-17). Some surgeons believe that it is not justified to resect these arteries in patients with squamous cell carcinoma of the upper aerodigestive tract because of the associated morbidity and because the prognosis of patients with disease in the neck that is extensive enough to warrant such a resection is dismal.[46] For example, Moore and Baker[47] observed a mortality rate of 30% and a cerebral complication rate of 45% among patients who underwent carotid ligation; it should be noted that these figures included elective and emergency ligation. In a study of 28 patients who had tumors grossly excised by "peeling" them off of the carotid artery, Kennedy and colleagues[48] found that only 18% developed a recurrence in the neck without distant metastases; this observation led the authors to state that only this small group of patients may have benefitted from carotid resection. Goffinet and colleagues[49] reported encouraging results for patients with large cervical metastases attached to the carotid artery who were by the resection of the tumor and intraoperative iodine[125] seed suture implants over the remaining carotid artery. Tumor control was obtained in the neck in 77% of the patients, although only 15% of them were alive and free of disease after 1 year. There are surgeons who advocate resecting the common artery or the ICA when the extent of disease dictates it; they believe that current methods of assessing the adequacy of cerebral circulation on the basis of the contralateral carotid system allow for better preoperative patient selection.[50-52] These

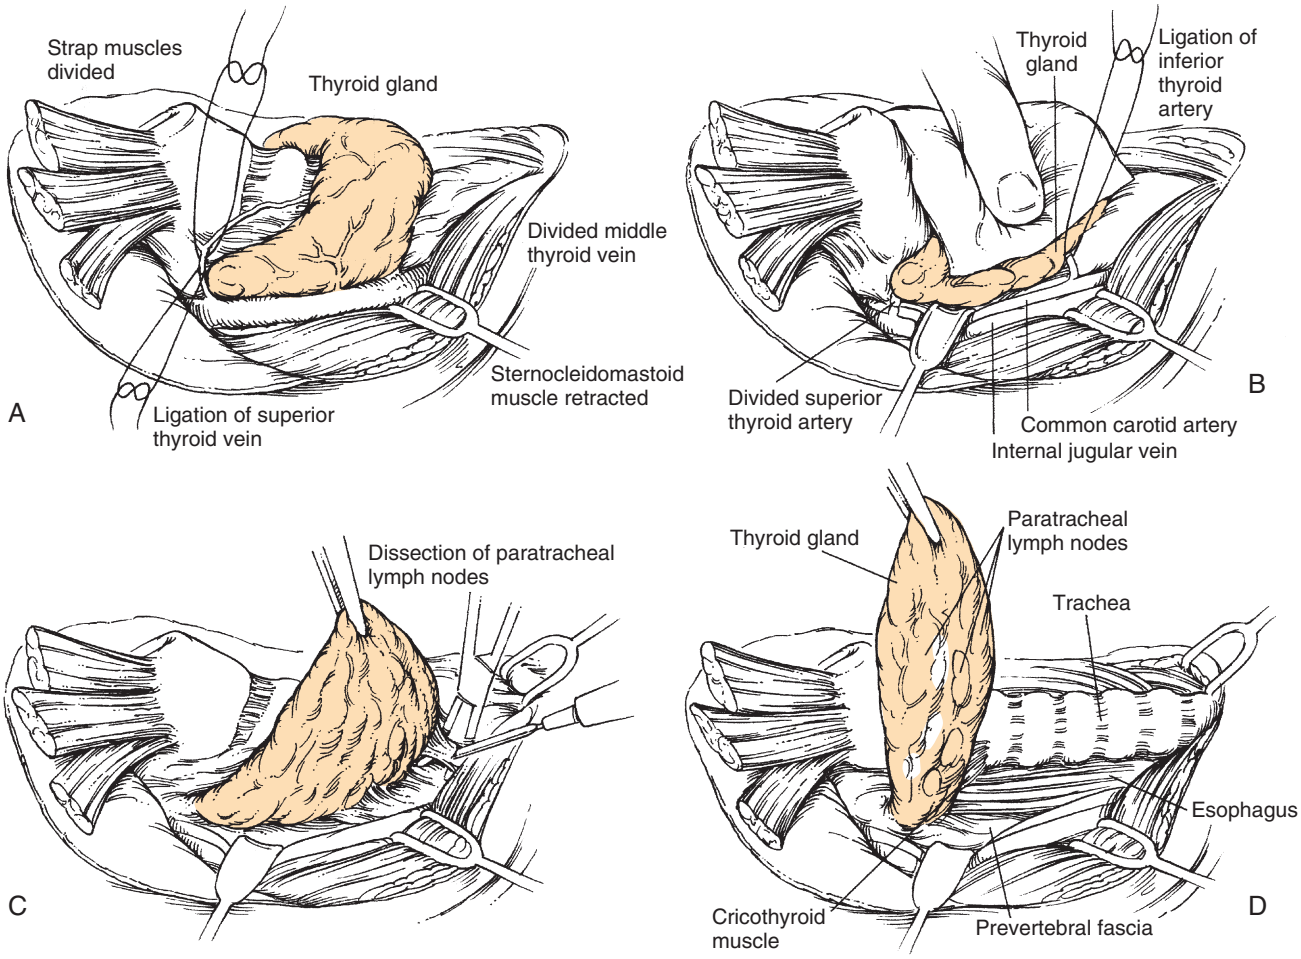

Figure 121-16. Steps of the selection neck dissection *(VI)*. See text for discussion.

Figure 121-17. Extended radical neck dissection, with resection of the common carotid artery. *(Redrawn from art provided courtesy of Douglas Denys, MD.)*

beliefs—coupled with improved techniques for vascular and soft-tissue reconstruction—have made it possible to resect the carotid artery with acceptable morbidity. McCready and colleagues[53] reported their observations in 16 patients who underwent carotid artery resection for the management of advanced carcinomas of the head and neck. Only two patients (12%) developed postoperative cerebrovascular complications, and seven patients (45%) were free of disease at 1 year. Others have reported similar results.[50,52] Patients with frank involvement of the carotid wall whose preoperative examination indicates intolerance of carotid ligation should have carotid resection and reconstruction. Saphenous vein grafts are preferred over prosthetic grafts for reconstruction, and, if the skin has been heavily radiated or a portion of the skin over the carotid is resected, a myocutaneous flap should be used to cover the graft.[54,55]

If carotid artery resection is considered preoperatively, then endovascular balloon occlusion of the ICA with physiologic assessment will strongly predict the potential for stroke and the need for revascularization.[56,57] An angiogram is performed, and an intravascular balloon placed in the ICA. The patient is heparinized, and the balloon is inflated to occlude the ICA. A second catheter in the contralateral carotid artery is used for an intracranial angiogram to assess the patency of collateral flow through the circle of Willis to the hemisphere in jeopardy. The demonstration of an excellent crossover flow through a patent anterior communicating artery, along with symmetric venous filling bilaterally, is predictive of a low probability of stroke if the ICA is sacrificed, and there is no indication for revascularization. If the angiogram is questionable, then occlusion may be maintained for 30 minutes, hypotension induced, and the patient observed clinically. Alternatively, a functional cerebral blood flow study such as intra-arterial xenon, xenon inhalation computed tomography scan, or single-photon emission computed tomography scan can be performed to

assess functional cerebral blood flow to the hemisphere in jeopardy. If studies suggest that the patient will not tolerate ICA sacrifice, then consideration should be given to surgery designed to salvage the ICA, or a revascularization procedure should be employed.

Revascularization procedures may be within the bed of the tumor resection if proximal and distal ends of the carotid artery and ICA remain. Artificial versus saphenous vein interposition grafts can be used, depending on previous or future radiation therapy and wound infection potential. ICA revascularization procedures continue to be practiced in select neurosurgical cases, particularly in those involving extracranial to intracranial bypass grafting, with good results seen at select centers.[56,57]

Patients with significant atheromatous disease pose an interesting dilemma with regard to planned cervical dissections. A history of any embolic symptoms will increase the risk of stroke with carotid vessel manipulation at surgery. If carotid salvage is planned as a part of the procedure, then preoperative stenting should be considered before cervical dissection, or endarterectomy should be performed at the time of surgery, if anatomy allows. Asymptomatic carotid bifurcation disease should be managed by careful intraoperative manipulation, with vessel preservation dictated by the surgical expectations.

Results of Neck Dissection

Radical Neck Dissection

Obviously the best results reported for patients undergoing radical neck dissection are those in whom the presence of histologically positive metastatic disease is not evident. In this scenario, 3% to 7% of patients will have disease recur in the ipsilateral neck.[58] When radical neck dissection is used as a therapeutic procedure, there is a range of regional control rates. An appropriate analysis of results should, therefore, involve the consideration of several factors related to the degree of nodal involvement and whether the primary tumor remains under control.

The presence of extracapsular spread is an important prognostic factor with regard to recurrence in the neck after neck dissection.[59,60] In addition, the degree of extracapsular involvement is also important. For example, Carter and colleagues[46] reported a 44% recurrence rate for macroscopic extracapsular spread versus a 25% rate for microscopic extracapsular spread. In addition, the number of lymph nodes involved by tumor has also been found to correlate with the rate of recurrence. Patients with four or more involved nodes had a dramatically worse 4-year survival rate than patients with only one involved node.[61] Strong also reported that the level of nodal involvement had prognostic importance, observing a recurrence rate in the neck of 36.5% in patients with positive nodes in one level versus 71% in patients with positive nodes in multiple levels.[62] Remember that the use of adjuvant radiotherapy is considered by most to improve the rate of control in the neck after neck dissection.[58,63]

Modified Radical Neck Dissection

The rate of recurrence in the neck after modified radical neck dissection depends on the amount of disease to which the procedure was applied. When used as an elective procedure for patients with clinically N_0 disease, the rate of recurrence varies between 4% and 7%. However, when this procedure is used therapeutically for patients with clinically positive disease, the recurrence rate in the dissected neck varies between 0% and 20%. In some of these reports, preoperative or postoperative radiation was also used. These results indicate that, in selected patients, modified radical neck dissection is an attractive alternative to radical neck dissection.[16,58]

Selective Neck Dissection

Data indicating the effectiveness of SND for the control of regional metastases related to upper aerodigestive tract carcinoma are available. For supraomohyoid neck dissection, Byers[16] reported a regional recurrence rate of 5.8% for 154 patients with pathologic N_0 disease, 24 of whom received postoperative radiotherapy. The rate of regional disease control for 80 patients with pathologic positive nodal disease was 15%; 62 of these patients had multiple positive nodes, and 61% had postoperative radiotherapy. In a later review of the MD Anderson experience, Medina and Byers[51] found the recurrence rate to be 5% among patients with pathologic N_0 disease, 10% when a single nodal metastases without extracapsular spread was found, and 24% when multiple positive nodes or extracapsular spread was found. Postoperative radiotherapy decreased the recurrence rate to 15% in the group with multiple nodes or extracapsular spread.

For patients undergoing lateral neck dissection, Byers[16] reported a regional recurrence rate of 3.9% among 256 patients with pathologic N_0 disease, 126 of whom received postoperative radiotherapy. Among the 41 patients with pathologic positive nodal disease, 37 of whom had postoperative radiotherapy, 7.3% had regional recurrences.

The data indicating relatively low regional recurrence rates for patients with clinical N_0 neck disease support the effectiveness of SND procedures for patients with upper aerodigestive tract carcinoma. Of greater controversy is whether the procedures are effective for patients with node-positive disease. Pelliteri and colleagues[64] found the regional recurrence rate for patients with pathologic positive nodal disease to be 11.1% among 27 patients undergoing a supraomohyoid neck dissection and 4.8% among 21 patients who had a lateral neck dissection. These results, along with those reported by Byers[16] and Medina and Byers,[51] indicate that the SND is feasible for a defined subset of patients with positive nodal disease. Postoperative radiotherapy is recommended for patients with multiple nodal disease or extracapsular spread. More recently, the efficacy of SND for clinically positive neck disease has been demonstrated by others.[65-67] In 2002 Andersen and colleagues[68] reported a 10-year, multi-institutional, retrospective review of pooled data from 106 previously untreated clinically and pathologically node-positive patients undergoing 129 SNDs and followed for a minimum of 2 years or until patient death. Overall, nine patients experienced disease recurrence in the neck, for a regional control rate of 94.3%. Six of these recurrences were in the areas of the neck that had been dissected during the SND. The authors concluded that these results support the use of SND in carefully selected patients with clinically positive nodal metastasis from head and neck squamous cell carcinoma (HNSCC). Regional control rates comparable with those achieved with the radical and modified radical neck dissections could be achieved in appropriately selected patients. The main advantages of the use of SND are that surgical time is shortened and morbidity—especially with regard to shoulder dysfunction—is decreased.

Among patients previously treated with radiotherapy or other types of neck surgery, most surgeons prefer to perform neck dissections that encompass all five neck levels when salvage surgery is feasible. However, emerging data support the use of SND as part of the planned treatment for patients with bulky neck disease whose primary tumor and regional nodes were initially treated with definitive radiation therapy or chemoradiation.[69,70] Nigauri and colleagues[71] failed to find evidence of skip metastases outside of levels II and III among 217 patients with squamous cell carcinoma of the oropharynx who were treated with radiation therapy. These authors recommended SND for patients with N_1 disease, whereas modified radical neck dissection or radical neck dissection was recommended for patients with N_2 or N_3 disease. Boyd and colleagues[72] analyzed 25 patients with squamous cell carcinoma of the oropharynx, nasopharynx, hypopharynx, and supraglottic larynx who had been treated with radiation therapy. Among the 28 necks dissected (all but one patient had N_2 or N_3 disease), only one had a tumor outside of levels II through IV. On the basis of this, SND was recommended for patients with disease in all pharyngeal sites who required salvage or planned neck surgery after radiation therapy. Efficacy of targeted chemoradiation and planned SND to control bulk nodal disease in advanced neck cancer has been reported by Robbins and colleagues.[73] In addition, Clayman and colleagues[74] have used SND after chemoradiotherapy for oropharyngeal cancer in patients with advanced nodal disease. Thus it may be that, in the future, SND will play a more definitive role in the overall management of patients with initial bulky neck node disease with head and neck cancer that has been treated with nonsurgical modalities; however, further evidence is necessary.

Lymphoscintigraphy-Directed Neck Dissection

A potentially powerful adjunct to surgical treatment of the neck is lymphoscintigraphy and sentinel lymph node biopsy. This technique,

which was pioneered by Morton and colleagues[7] for use in detecting the lymphatic spread of cutaneous melanoma, capitalizes on the ability of nuclear radiography to identify primary, secondary, and tertiary echelons of lymphatic drainage basins and to identify the index or "sentinel" lymph node associated with primary regions within the head and neck. It is minimally invasive, and it possesses the capacity to accurately stage the clinically occult neck in a number of different neoplasms.[75] Linking this diagnostic and staging modality to lymphadenectomy or other elective treatment of the neck in mucosal carcinomas represents an attractive concept that has recently been explored by Pitman and colleagues[76] at the University of Pittsburgh. These investigators examined the feasibility of identifying the sentinel lymph node in primary echelons of drainage from known primary neoplasms through lymphoscintigraphy and sentinel lymph node biopsy, thus enabling one to stage the N_0 neck in a minimally invasive manner and to direct elective neck therapy accordingly. On the basis of findings with both N_0 and N_+ patients, the investigators thought that lymphoscintigraphy and lymphatic mapping would offer the ability to stage neck disease and provide information about the presence of atypical basins of lymphatic flow from upper aerodigestive tract primary sites that would not typically be addressed by the more classic anatomic regions outlined for SND. Accordingly, patients undergoing this procedure would have lymphatic flow patterns uniquely defined according to neck anatomy and the effects of previous treatment. In addition, findings from the study suggested that lymphoscintigraphy in the N_+ or previously treated neck demonstrated the potential for defining unpredictable cervical nodal levels at risk for metastasis. Studies such as this indicate that the use of lymphatic mapping for the treatment of HNSCC may ultimately provide the surgeon with the ability to adequately stage the N_0 neck and direct elective therapy or assess the neck with recurrence in a minimally invasive manner to determine the extent of salvage required. The place of lymphatic mapping for avoiding a neck dissection remains inadequately defined at this time in terms of therapeutic efficacy, practical application, and health-related quality of life. Lymphatic mapping in HNSCC is probably best considered an investigational technique; as such, it has not yet achieved the status of "standard of care" for the treatment of head and neck carcinoma patients.[77]

Sequelae of Neck Dissection

The most notable sequela observed in patients who have undergone a radical neck dissection is related to the removal of the spinal accessory nerve. The resulting denervation of the trapezius muscle, which is one of the most important shoulder abductors, causes destabilization of the scapula, with progressive flaring of this bone at the vertebral border (drooping of the scapula and lateral and anterior rotation of it). The loss of the trapezius function decreases the patient's ability to abduct the shoulder above 30 degrees at the shoulder. These physical changes result in the recognized shoulder syndrome of pain, weakness, and deformity of the shoulder girdle that is commonly associated with radical neck dissection.

For the past few years, it has been debated in the literature whether there is a major difference in postoperative shoulder dysfunction after a radical neck dissection that preserves the spinal accessory nerve. Using patient questionnaires, Schuller and colleagues[78] compared symptomatology and the ability to return to preoperative employment of patients who underwent either a radical neck dissection or a modified radical neck dissection. Although they found no statistically significant difference between the two groups, Sterns and Shaheen[79] and others using similar methods found that the majority of patients who had a nerve-sparing procedure did not have postoperative pain or shoulder dysfunction.[80,81]

Only recently have objective data about shoulder dysfunction after neck dissection been gathered prospectively. Leipzig and colleagues[82] studied 109 patients who had undergone various types of neck dissections using preoperative and postoperative observations of shoulder movement made by the surgeons who rated the degree of shoulder dysfunction. The researchers concluded that any type of neck dissection may result in an impairment of function of the shoulder. They also noted that dysfunction occurred more frequently among those patients in whom the spinal accessory nerve was extensively dissected or resected.

In 1985 Sobol and colleagues[55] performed a prospective study in which preoperative and postoperative measures of shoulder range of motion were compared. In addition, postoperative electromyograms (EMGs) were obtained in some patients. Shoulder range of motion was better in patients who underwent a nerve-sparing procedure than in patients who had a radical neck dissection. In addition, the type of nerve-sparing procedure was found to have an influence on the degree of shoulder disability. Patients who had undergone a modified radical neck dissection, in which the entire length of the nerve was dissected, had no dramatic difference in shoulder range of motion as compared with those patients who had a radical neck dissection 16 weeks after surgery. Patients who underwent a supraomohyoid neck dissection, in which there was less-extensive dissection of the spinal accessory nerve, performed significantly better ($P > .05$) than either of the other groups in terms of shoulder range of motion and EMG findings for the trapezius muscle. Interestingly, 16 weeks after surgery, moderate to severe EMG abnormalities were noted in up to 65% of the patients in whom the spinal accessory nerve was dissected along its entire length (i.e., modified radical neck dissection). Although no severe abnormalities were noted in the group undergoing supraomohyoid neck dissection, 22% of these patients showed moderate abnormalities. Several patients from each group had repeat studies at approximately 1 year after surgery. Unlike patients who had a radical neck dissection, patients in whom the nerve was spared showed evidence of improvement in all parameters studied.

A prospective study by Remmler and colleagues[83] revealed that patients who had a nerve-sparing procedure had a serious but temporary spinal accessory nerve dysfunction. In this study, preoperative strength, range-of-motion measures, and EMG of the trapezius muscle were compared with postoperative measures obtained at 1, 3, 6, and 12 months. The groups studied consisted of patients undergoing nerve-sparing procedures and those who had the nerve resected. Most of the patients in the nerve-sparing group had supraomohyoid neck dissections. Patients who underwent radical neck dissections had a major decrease in trapezius muscle strength on EMG at 1 month; these parameters did not improve with time. Interestingly, patients in the nerve-sparing group had a small but significant reduction in trapezius muscle strength and evidence of trapezius muscle denervation at 1 and 3 months, which improved by 12 months. More recently, Kuntz and Weymuller[84] reported reduced quality-of-life scores among patients after neck dissection, with the worst scores being associated with radical neck dissection and the best scores with SND.

Hence the evidence indicates that even procedures involving minimal dissection of the spinal accessory nerve may result in shoulder dysfunction.[84] It is only appropriate, therefore, to make every effort to avoid undue stretch or trauma to the nerve when a nerve-sparing procedure is performed. In addition, it is imperative that every patient who undergoes a neck dissection be questioned about the function of the shoulder and be examined by a physical therapist early during the postoperative period. If any deficit is detected, the patient should be properly counseled and coached to ensure proper rehabilitation of the shoulder.

Complications of Neck Dissection

In addition to the various medical complications that may occur after any surgical procedure in the head and neck region, a number of surgical complications may be related solely or in part to the neck dissection. If the course of a patient who has undergone a neck dissection as part of the surgical treatment of cancer of the head and neck region is followed, several complications may arise. When a neck dissection is done after radiotherapy of more than 70 Gy, there might be a higher risk of complications.[48] However, adding chemotherapy to radiotherapy may not increase the complication rate.[17]

Air Leaks

Circulation of air through a wound drain is a common complication that is usually encountered 1 day after surgery. The point of entrance of air may be located somewhere along the skin incision, although, if

the drains are connected to suction in the operating room near the completion of the wound closure, such an air leak usually becomes apparent then and may be corrected. Other points of entrance may not become apparent until after surgery, when the position of the neck changes or when the patient begins to move. A typical example of this situation is the improperly secured suction drain that gets displaced, thereby exposing one or more of the drain vents. A similar situation occurs frequently when a lateral trapezius flap is used in conjunction with a neck dissection. The slightest movement of the shoulder may produce an air leak into the neck wound through the extensive donor defect, even after meticulous tacking of the skin edges to the underlying tissues and painstaking suturing of a skin graft. This problem may be prevented by using an adhesive vinyl drape applied over the defect and surrounding skin to seal any possible air leak instead of using the bolster of gauze that is traditionally used to immobilize the skin graft.

Air leaks with potentially more serious consequences are those that occur through a communication of the neck wound with the tracheostomy site or through a mucosal suture line. In these patients, it is likely that, in addition to air, contaminated secretions are circulated through the wound. Thus early identification of the site of leakage is desirable, although it may not be a simple task, and correcting it may require revision of the wound closure in the operating room.

Bleeding

Postoperative hemorrhage usually occurs immediately after surgery. External bleeding through the incision, without distortion of the skin flaps, often originates in a subcutaneous blood vessel. In most patients, this may be readily controlled by ligation or infiltration of the surrounding tissues with an anesthetic solution containing epinephrine. Pronounced swelling or ballooning of the skin flaps immediately after surgery, with or without external bleeding, should be attributed to a hematoma in the wound. If a hematoma is detected early, "milking" the drains occasionally may result in evacuation of the accumulated blood and the problem will resolve. If this is not accomplished immediately or if blood reaccumulates quickly, it is best to return the patient to the operating room, explore the wound under sterile conditions, evacuate the hematoma, and control the bleeding. Attempting to do this in the recovery room or at the bedside is ill advised because lighting and surgical equipment may be inadequate and sterile conditions may be precarious. Failure to recognize or manage a postoperative hematoma properly may predispose the patient to the development of a wound infection. Although bulky pressure dressings may be useful for curtailing postoperative edema and they do not prevent hematomas, they may delay their recognition as well.

Chylous Fistula

In a 1990 review of 823 neck dissections performed by the surgeons at Memorial Hospital in New York City that included the removal of the lymph nodes in level IV, Spiro and colleagues[63] found that 14 patients (1.9%) developed a chyle fistula. In this and other studies,[85] a chylous leakage was identified and apparently controlled intraoperatively in the majority of patients who developed the complication. These observations remind the surgeon to not only avoid injury to the thoracic duct proper but also to ligate or clip any visualized or potential lymphatic tributaries in the area of the thoracic duct. This may be accomplished with relative ease if the operative field is kept bloodless when dissecting in this area of the neck. In addition, as soon as the dissection of this area is completed and again before closing the wound, the area should be observed for 20 or 30 seconds while the anesthesiologist increases the intrathoracic pressure; even the smallest leak of chylous material should be pursued until it is arrested. Indiscriminate clamping and ligating may be difficult and sometimes counterproductive because of the fragility of the lymphatic vessels and the surrounding fatty tissue. Hemoclips are ideal to control a source of leakage that is clearly visualized; otherwise it is preferable to use suture ligatures with pliable material, such as no. 5-0 silk, which are tied over a piece of hemostatic sponge to avoid tearing.

Despite the surgeon's best efforts to avoid it, a postoperative chylous fistula occurs after 1% to 2% of neck dissections. Management of this complication depends on the time of onset of the leak, the amount of chyle drainage in a 24-hour period, and the physician's ability to prevent accumulation of chyle under the skin flaps. When the daily output of chyle exceeds 600 mL (especially when the chyle fistula becomes apparent immediately after surgery), conservative closed wound management is not likely to succeed. In such patients, early surgical exploration is preferred, before the tissues exposed to the chyle become markedly inflamed and before the fibrinous material that coats these tissues becomes adherent, thus obscuring and jeopardizing important structures such as the phrenic and vagus nerves.

Chylous fistulas that become apparent only after enteral feedings are resumed and, particularly those that drain less than 600 mL of chyle per day, are initially managed conservatively with closed wound drainage, pressure dressings, and low-fat nutritional support. Parenteral alimentation through a central line can further reduce chylous output and may be considered for high-output or intractable fistulas.

Facial/Cerebral Edema

Synchronous bilateral radical neck dissections, in which both internal jugular veins are ligated, may result in the development of facial edema, cerebral edema, or both. The facial edema, which sometimes may be dramatically severe, appears to be caused by an inadequacy of venous drainage, which usually resolves to a variable extent with time as collateral circulation is established. Facial edema appears to be more common and more severe in patients who had previous radiation to the head and neck and in those patients in whom the resection includes large segments of the lateral and posterior pharyngeal walls. Massive facial edema may be prevented by preserving at least one external jugular vein whenever a bilateral radical neck dissection is anticipated. The external jugular is usually separated from the tumor in the neck by the sternocleidomastoid muscle and may be dissected free between the tail of the parotid and subclavian veins.

The development of cerebral edema may be at the root of the impaired neurologic function and even coma that may occur after bilateral radical neck dissection. Ligation of the internal jugular veins leads to increased intracranial pressure.[86,87] It has been shown experimentally that the increased cerebral venous pressure that occurs as a result of ligating both internal jugular veins in dogs is associated with inappropriate secretion of antidiuretic hormone.[88] It may then be speculated that the resulting expansion of extracellular fluids and dilutional hyponatremia aggravate the cerebral edema and create a vicious cycle. In practice, these observations behoove the surgeon and the anesthesiologist to curtail the administration of fluids during and after bilateral radical neck dissections.[89] In addition, perioperative management of fluid and electrolytes in these patients should not be guided solely by their urine output but rather by the monitoring of central venous pressure, cardiac output, and serum and urine osmolarity.

Blindness

Visual loss after bilateral neck dissection is a rare but catastrophic complication. To date, there have been five cases reported in the literature.[90] In one report, histologic examination revealed intraorbital optic nerve infarction, which suggests intraoperative hypotension and severe venous distension as possible etiologic factors.[61]

Carotid Artery Rupture

The most feared and the most commonly lethal complication after surgery of the neck is the exposure and rupture of the carotid artery; therefore every effort should be made to prevent it. If the skin incisions have been designed properly, seldom does the carotid artery become exposed in the absence of a salivary fistula. Fistula formation and flap breakdown are more likely to occur in the presence of malnutrition, diabetes, infection, and previous radiotherapy, which impair healing capacity and compromise vascular supply. Faced with any of these risk factors, the surgeon should use flawless surgical techniques in the closure of oral and pharyngeal defects. The use of free and pedicled vascularized flaps (which provide skin for the closure of mucosal defects) has rendered nearly obsolete the use of "protective" measures such as dermal grafts, levator scapulae muscle flaps, and controlled pharyngostomies.

Management of the exposed carotid artery depends on the likelihood of rupture based on the length of the exposed segment, condition

of the surrounding tissues, and size of the oropharyngocutaneous fistula. Large cutaneous defects or large, high-output fistulas in previously irradiated patients are not likely to heal by secondary intention in a timely manner. The likelihood of rupture of the carotid artery in these patients is extremely high. Therefore an attempt should be made to repair the defect and to cover the carotid using well-vascularized tissue before the vessel has been irreversibly damaged. Whenever the carotid is exposed, it is advisable to take "carotid precautions," which include warning and instructing nursing personnel and house staff about the possibility of a carotid rupture, the site of potential rupture, and the steps to be taken in the event of bleeding, having compatible blood available, and keeping appropriate surgical instruments at the bedside.

When a carotid artery rupture occurs, it is usually possible to stop the bleeding with manual pressure while blood and fluids are administered to restore and maintain the patient's blood pressure; only then is the patient taken to surgery. Attempts to repair the area of rupture are futile. Introduction of Fogarty catheters through the area of rupture is helpful for controlling the bleeding temporarily while the artery is exposed and ligated proximally and distally to the area of rupture.

Neck Dissection after Treatment with Chemoradiation

One of the treatment options for advanced local or regional squamous cell carcinoma of the head and neck is chemoradiation. This method of treatment may allow for preservation of one or more upper aerodigestive organs with comparable or even better local and regional control rates compared with radiation alone.[91-93] The neck following treatment with chemoradiation is hard to evaluate both clinically and with the use of imaging techniques. As newer, more effective chemotherapy agents are developed, further innovations in the way radiotherapy is administered, and as diagnostic tool are improved, constant assessment of the recommended approaches to evaluate and treat the neck post chemoradiation therapy is necessary. The current assessment approach relies on the initial tumor stage and the clinical and imaging assessment before and after treatment.

When there is a disease failure at the primary site without evidence of nodal disease, following chemoradiation, a neck dissection should be considered if the primary site is to be salvaged surgically. A salvage neck dissection is necessary in a situation where there is an evidence of nodal disease after chemoradiation treatment to the neck. The salvage neck dissection can be further divided into an "early" procedure when there is persistent disease following chemoradiation. A "late" salvage neck dissection is done for recurrent disease. Recurrent disease in the neck following chemoradiation has a worse prognosis than a neck dissection done for persistant disease.[94] The assessment of the regional response to chemoradiation treatment is done 6 to 8 weeks after completion of treatment and is based on clinical examination and imaging (a computer tomography/magnetic resonance imaging [CT/MRI] and or PET scans).[73,95-98]

For patients with nodal disease of stage N_0 or N_1 who have a complete response after radiation alone or chemoradiation, a neck dissection is indicated only if there is evidence of persistance regional disease.[73,96,98-101] It is controversial to perform a neck dissection for patients with stage N_2 and N_3 nodal disease who achieve complete response after chemoradiation on the basis of clinical examination and imaging. Some support performing a planned radical or modified neck dissection 6 to 8 weeks after completion of chemoradiation therapy,[72,95,100,102,103] whereas others have found that this can be avoided in certain cases[49,73,98,104,105] or, if done, a selective neck dissection can be appropriate.[72-74,98,106,107]

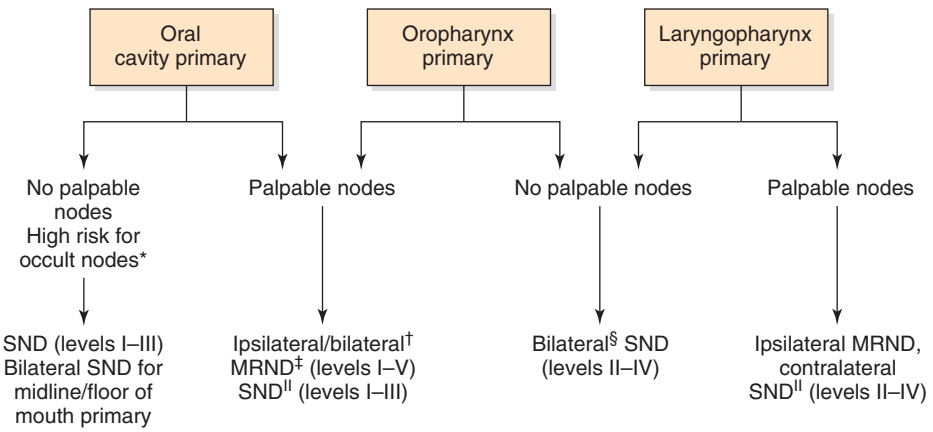
Differences in approaches might be related to different chemoradiation protocols used and different treatment response assessment methods.[108]

The major advantage of avoiding a neck neck dissection under such conditions is the avoidance of the potential morbidity.[84,109,110]

When a neck dissection is considered, it should be done when wound healing is optimal, PET-CT scans false-positive rates are minimal, and patients have recovered from the toxicities associated from the chemotherapy and radiotherapy. The typical timing is 6 to 8 weeks following radiation therapy, but it may be as long as 12 weeks.[111-114] The delay is based on reported inaccuracy of FDG PET scans for detecting residual neck disease in the early postchemoradiation therapy setting.[115]

Summary

Neck dissection is an operative procedure that is designed to remove metastases involving the regional cervical lymph nodes. The gold standard procedure is the radical neck dissection, which, for most patients, is too extensive and results in excessive morbidity. Modifications of the radical neck dissection procedure, which have been designed to reduce morbidity by sparing nonlymphatic structures (modified radical neck dissection) and to treat early nodal disease by removing only the lymph node groups at greatest risk for harboring metastases (SND), have now evolved. To help the reader determine which type of neck dissection is most appropriate for the management of nodal disease associated with the three major sites of the upper aerodigestive tract, an algorithm is provided (Fig. 121-18).



*T_1–T_4 oral tongue; $T_{2–4}$ other sites; perineural/lymphatic invasion.
†Bilateral neck dissection for N_{2c} disease.
‡RND if gross tumor invasion of nonlymphatic structures.
§Ipsilateral neck dissection for oropharyngeal primaries if postoperative radiotherapy is planned.
II SND for nodes confined to one level.

CHAPTER ONE HUNDRED AND TWENTY-TWO

Complications of Neck Surgery

Frederick C. Roediger

David W. Eisele

Key Points

- Complications of neck surgery have evolved over time with the introduction of new procedures and philosophies in the management of patients with head and neck cancer.
- Comprehensive neck dissection provides the best framework for describing the four major categories of neck complications: wound, vascular, nerve, and chyle/chest.
- Components of these four categories can be applied selectively to other, less extensive neck surgical procedures.
- Awareness, early recognition, and prompt and effective management of complications can have a significant impact on outcomes.

Complications of neck surgery affect every surgeon regardless of experience and technical skill. Despite our best intentions, complications arise due to the intricate anatomy of the neck and complexities of the diseases and patients treated. Factors such as medical comorbidities (hypertension, hepatitis, etc.), substance abuse, prior radiation therapy, aerodigestive tract entry, prolonged anesthesia times, the volume of intraoperative fluid administered, and the need for microvascular free flap reconstruction have been associated with head and neck surgical complications in various studies.[1-4] Prevention and management of complications that occur both intraoperatively and postoperatively are essential to proper head and neck surgical care.

The history of neck dissection reveals a continuing quest to reduce complications and their sequelae.[5] The results of a systematic approach to cervical lymphadenectomy for the treatment of a series of patients with head and neck cancer was first reported by George Crile, MD, in 1906.[6] In that era, radical neck dissection (RND), with removal of the sternocleidomastoid muscle (SCM), the internal jugular vein (IJV), and the spinal accessory nerve (SAN), was considered the standard of care for patients with neck metastasis but resulted in significant functional and cosmetic morbidities.[7] Introduction of the modified radical neck dissection (MRND) and proof that it was oncologically sound led to improved functional outcomes without sacrifice of oncologic effectiveness.[8-11] Further technique refinements that established selective neck dissections (SND) were based on predictable patterns of spread from specific primary tumor locations.[12,13] This approach is highly effective for management of the clinically negative neck and may have applications in clinically positive necks as long as postoperative radiation therapy is administered.[14-17] In addition, SND may be the preferred approach for planned neck dissection after concurrent chemoradiation for advanced head and neck cancer because these patients have a low incidence of recurrence in the neck.[18] As head and neck surgical techniques have evolved, so have the type and frequency of complications. Shoulder disability from spinal accessory nerve injury was an expected sequela of RND but is now considered a potential complication of MRND. Internal jugular vein thrombosis and hemorrhage may occur more frequently in the modern era because this structure is more commonly preserved with MRND and SND.[19]

In this chapter, complications of neck dissection are considered primarily and are grouped into four major categories: wound, vascular, nerve, and chyle/chest. This framework provides structure for the informed consent process and individual components can be applied selectively to any neck surgery depending on the location and extent of a given procedure.

Wound Complications

Incision Planning

Carefully designed neck incisions must take into account the location and extent of the primary tumor; adequate exposure for the type of neck dissection planned; carotid artery coverage; excision of previously violated skin, when applicable; and cosmesis. Preferred incisions combine limbs that meet at right angles to create skin flaps that preserve the blood supply to neck skin, which includes branches of the facial and occipital arteries superiorly and branches of the transverse cervical and suprascapular arteries inferiorly.[20] Subplatysmal flap elevation should be used in all approaches to preserve the skin flap blood supply.

Numerous neck incisions for neck dissection have been described. Early designs such as the Crile single-Y and the Martin double-Y provided excellent exposure but placed a trifurcation over the carotid artery. Furthermore, they created tenuous posterior skin flaps and anterior skin flaps that relied partially on blood flow from branches of the contralateral external carotid artery. The Conley-modified Schobinger approach was an improvement, maintaining excellent exposure for comprehensive neck dissection with creation of a large, robust anterior flap and placement of the trifurcation posterior to the carotid artery.[20] MacFee introduced the use of two transverse incisions that appear to transect the dominant blood supply, but studies have shown that the central, bipedicled skin flap is resistant to ischemia and may be the preferred approach in the previously irradiated patient.[21,22] Certain incisions are well-suited to accompany the extirpation of specific primary tumors such as the apron flap for neck dissection with laryngectomy and the Attie incision for neck dissection with thyroidectomy.[23]

Figure 122-1. Seroma formation after modified radical neck dissection following prior radiation therapy. Fluid collection under the anterior skin flap has resulted in loss of the expected postoperative scaphoid appearance of the neck.

The principles of adequate exposure and protection of critical structures cannot be overemphasized and are equally important for comprehensive neck dissection as they are for less extensive procedures. For example, care should always be taken to place submandibular incisions, whether for supraomohyoid neck dissection, submandibular gland resection, or mandibular fracture repair, sufficiently below the lower border of the body of the mandible to avoid injury to the marginal mandibular branch of the facial nerve. Cosmesis must often be considered secondary to successful tumor extirpation and safety (e.g., when a small incision for lymph node biopsy of a posterior triangle node is desired but a slightly larger wound may improve surgical exposure and assist preservation of the spinal accessory nerve).

Wound Dehiscence and Flap Necrosis

Flap survival depends on incision design, surgical technique, and factors intrinsic to the patient. A study of 184 neck dissections using triradiate, modified MacFee, or apron incisions showed a wound dehiscence rate of 11%, 8%, and 0%, respectively, for each approach.[24] The same study showed a statistically significant increase in the overall rate of wound dehiscence in previously irradiated necks, particularly for the triradiate group, leading the authors to recommend the apron flap for neck dissection in patients who have received prior radiation therapy.[24] Whether or not preoperative radiation therapy increases the complication rate of neck dissection continues to be debated, but several reports indicate that higher total radiation doses are associated with a higher rate of wound complications.[25,26] Skin loss from involvement with tumor or excision of violated skin may lead to increased tension on the closure. Poor microvasculature, secondary to malnutrition, active tobacco use, or uncontrolled diabetes mellitus, contributes to the lack of tissue tolerance for surgical manipulation and a higher rate of wound dehiscence or flap necrosis.

Seroma

Division of lymphatic and adipose tissue during neck dissection allows for formation of seroma, the collection of serous fluid in the potential space between cervical skin flaps and underlying structures. Seromas present as enlarging masses under the skin, with or without overlying induration or erythema. Loss of the expected postoperative scaphoid appearance of the neck following neck dissection is cause for suspicion (Fig. 122-1). If left untreated, a seroma may lead to flap necrosis or infection. Many case series report seroma and hematoma formation together, with rates ranging from 3% to 10% with RND to as high as 20% with functional neck dissection.[27-29] These differences may be explained by the increased amount of native tissue preserved in MRND or SND compared with RND that can weep serous fluid into the wound bed. Causes of seroma include incorrect drain placement, drain failure, or early drain removal. Prevention consists primarily of proper management of closed suction drains that are left in place until the total output per drain falls below 25 mL in a 24-hour period. Some authors also advocate the routine use of fibrin glue, which has been shown in animal models to prevent seroma formation.[30] Some small seromas can be observed with anticipation of gradual resorption. In most cases, however, management of seroma includes needle aspiration and, in select patients, drain replacement. Pressure dressings do not appear to prevent fluid reaccumulation.

Wound Infection

Wound infection may manifest as a cellulitis with erythema, warmth, or induration of the cervical skin flaps, abscess formation from an infected seroma or hematoma, or fistula. Occasionally, purulent fluid will be seen in a closed suction drain. Early recognition and proper drainage or diversion of fluid away from the carotid artery and internal jugular vein are critical to prevention of spread of the infection and vascular rupture.

Aerodigestive tract entry is the single most important factor that contributes to the risk of wound infection. Neck dissection without exposure to oral flora is considered a clean procedure. In a study of 438 patients undergoing parotidectomy, thyroidectomy, or submandibular gland excision, three (0.7%) patients developed a wound infection, one of whom had received perioperative erythromycin.[31] Administration of prophylactic antibiotics for clean neck dissections is controversial. One study showed a 10% rate (9/92) of infection for those not receiving antibiotics compared with 3.3% (3/93) of patients receiving first-generation cephalosporins, clindamycin, or pencillin.[32] Although the difference did not reach statistical significance, the trend may justify its use.[32] Antibiotic prophylaxis in this setting has been shown to be cost-effective.[33] In terms of duration, no difference in the rate of infection was seen with 1-day versus 4- or 5-day antibiotic regimens for clean procedures.[34,35] Interestingly, significantly higher infection rates for RND compared with other clean surgical procedures have been documented, for reasons that remain unclear.[35]

The risk of wound infection increases significantly with entry into the oral cavity, pharynx, or larynx, ranging from 15% to 87%.[36,37] Factors associated with wound infection include the performance of bilateral neck dissections, total laryngectomy, advanced-stage tumors, and in some studies, a history of prior tracheotomy.[35] The benefit of antibiotic prophylaxis in surgery that required aerodigestive tract entry was demonstrated convincingly in a well-designed prospective clinical trial in which 20/23 (87%) patients who received a placebo developed an infection compared with 12/32 (38%) in a cefazolin-treated group.[36] In another prospective, randomized clinical trial of four antibiotic regimens, statistically significant reductions in the infection rate were seen with gentamicin-clindamycin (4% to 7%) compared with cefazolin (20% to 33%), demonstrating the importance of broad-spectrum coverage that includes gram-negative and anaerobic organisms.[37] A trend toward fewer infections with a 5-day course compared with 1 day of antibiotics was found.[37] Cefazolin-metronidazole prophylaxis is a suitable alternative regimen to gentamicin-clindamycin and avoids the potential ototoxicity associated with gentamicin.[38]

Once a wound infection is detected, action must be taken to minimize sequelae. Collections must be completely aspirated or incised and drained, wounds cultured, and antibiotics that target the potential or confirmed pathogens initiated. Ensuring that the infection does not spread to the major blood vessels is of utmost importance.

Salivary Fistula

Saliva may enter the wound from either aerodigestive tract communication or parotid leak (Fig. 122-2). With associated infection, an inflammatory response in adjacent tissue rapidly occurs. Erythema, edema, and induration of skin flaps, as well as a change in the character of drain output to that of saliva or purulent discharge, are common signs.

The risk of pharyngocutaneous fistula formation with aerodigestive tract entry during surgery varies from 10% to 30%.[39,40] Prevention consists of water-tight, inverted, and tension-free closure during the

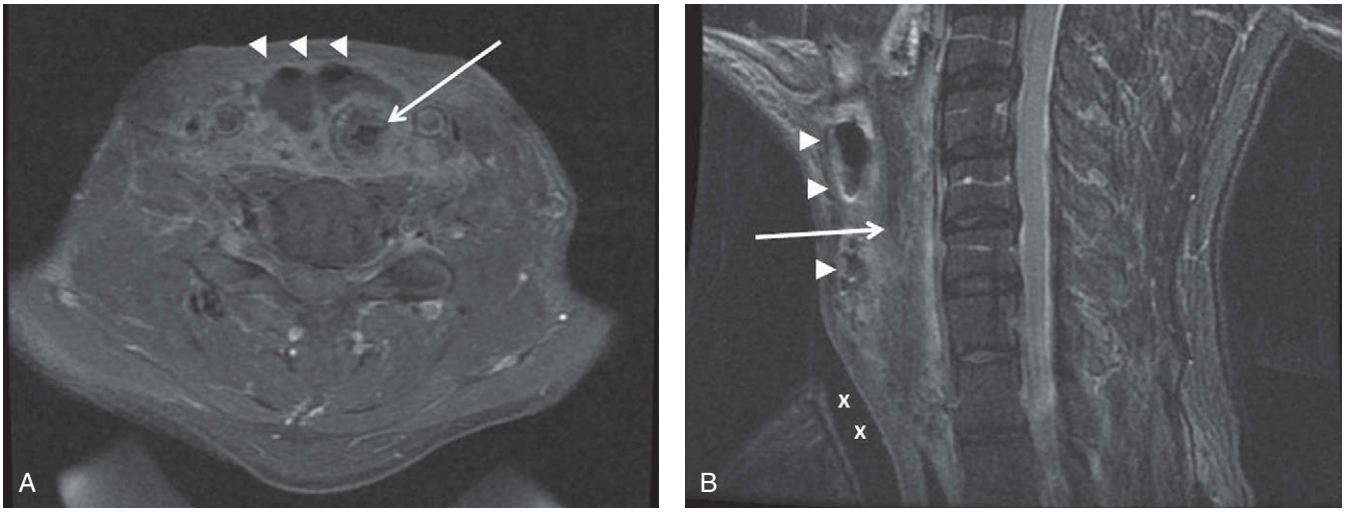

Figure 122-2. Magnetic resonance imaging of a pharyngocutaneous fistula after total laryngopharyngectomy, cervical esophagectomy, and tubed radial forearm free flap reconstruction for hypopharyngeal cancer. **A,** Axial T1-weighted gadolinium-enhanced image with fat saturation showing fluid and air *(arrowheads)* anterior to the proximal, pharyngeal anastomosis *(arrow)*. **B,** Midline sagittal T2-weighted image with fat saturation demonstrating the same fluid and air collection *(arrowheads)* anterior to the free flap *(arrow)* with no direct communication to the tracheostoma *(X)*.

primary surgical procedure and consideration of vascularized tissue coverage if the closure appears tenuous. Conservative management with broad-spectrum antibiotics and continued closed drainage is usually successful, although one should have a low threshold for opening a suture line to divert drainage away from the major blood vessels and gently packing the wound.[19] Nutritional status and glucose control should be optimized and thyroid-stimulating hormone levels checked, particularly in previously irradiated patients. Fistulae refractory to conservative measures require closure with vascularized tissue, either local-regional flaps or free flaps.

Postparotidectomy fistula does not carry a risk of major blood vessel rupture but can be annoying to patients. Most are small-volume leaks that exit the divided inferior cervical portion of the parotid gland. These normally respond well to conservative management.[41] Although numerous treatment modalities for persistent leaks have been proposed, injection of the parotid gland with botulinum toxin is usually effective.[42,43]

Scar Formation

Cosmetic principles that apply to neck surgery include placement of incisions in natural skin creases or relaxed skin tension lines, using gently curved vertical limbs to avoid linear scar contracture, and performance of a tension-free, everted skin closure.[44] Lapses in meticulous technique or postoperative wound infection may lead to the development of a hypertrophic scar (Fig. 122-3A). Formation of a keloid—scar tissue that exceeds the boundaries of the original incision—usually occurs in patients with a personal or family history of exuberant scar formation. Web formation along linear vertical limbs in the lateral neck may also occur (see Fig. 122-3B). Unilateral deep plane neck lift and midline platysmaplasty can be considered for rehabilitation of post–neck dissection asymmetry.[45]

Vascular Complications

Carotid Artery Hemorrhage

Complications involving the common carotid artery are the most feared sequelae of neck surgery. Intraoperative injuries to the common carotid artery generally require primary vascular repair. Vascular surgery consultation is highly recommended.

Acute postoperative carotid artery rupture, or "blowout," occurs in 3% to 4% of RNDs and is associated with a mortality rate of approximately 50%.[46-48] Factors associated with carotid artery hemorrhage include wound breakdown, necrosis, and infection; pharyngocutaneous fistula; prior radiation therapy; tumor involvement of the arterial wall; and rough handling of the adventitia during dissection.[47,48] Close surveillance of dehiscent or infected wounds for lack of improvement and signs of impending carotid rupture such as carotid exposure or a sentinel bleed is critical to postoperative management of the at-risk patient. This is because the mortality of elective carotid artery ligation is significantly lower than for emergency ligation,[49] rising from 14% to 64%, respectively, in one series.[50]

Emergent treatment consists of control of hemorrhage with application of direct pressure to the area of rupture and expeditious return of the patient to the operating room for definitive control. Fluid resuscitation with blood products and crystalloid is performed. Separate incisions are made inferior and superior to the region of infected or necrotic tissue, and proximal and distal vessel control is obtained.[51] Vessel ligation away from the contaminated wound is preferred in order to prevent rebleeding. The central wound is left packed or is covered with vascularized tissue. Endovascular techniques including angiography with selective embolization and temporary stent grafts for patients at high risk for stroke have been described.[52,53]

Internal Jugular Vein Complications

The theoretic benefits of preserving the internal jugular vein (IJV) during unilateral MRND or SND include decreased incidence of edema and less morbidity if a contralateral RND becomes necessary in the future,[54] although this practice has not been evaluated by any outcome studies. Preservation of at least one IJV during bilateral neck dissection is clearly beneficial to avoid facial or laryngeal edema, intracranial pressure elevations, stroke, and blindness (Fig. 122-4).[55] Techniques for reconstruction of the IJV from either the external jugular vein or a greater saphenous vein graft have been described[56] but are not used routinely. The widespread use of MRND and SND with IJV preservation has made possible other complications including IJV thrombosis and hemorrhage.

The IJV remains patent in approximately 86% of patients after MRND in studies using preoperative and postoperative imaging with CT or MRI.[54,57] Factors that predispose to immediate IJV thrombosis include damage to the adventitia, desiccation, and improper ligation of IJV branches intraoperatively, as well as the presence of central venous catheters.[19,58] One study of patients undergoing MRND examined with retrograde venography within 1 month postoperatively demonstrated IJV occlusion in 8/27 (29.6%) of operated necks.[59] Five of these patients had postoperative courses complicated by wound infection or salivary fistula, indicating that wound complications may lead to a high rate of IJV thrombosis.[59] Furthermore, postoperative radiation therapy may contribute to IJV thrombosis. An ultrasound study of patients

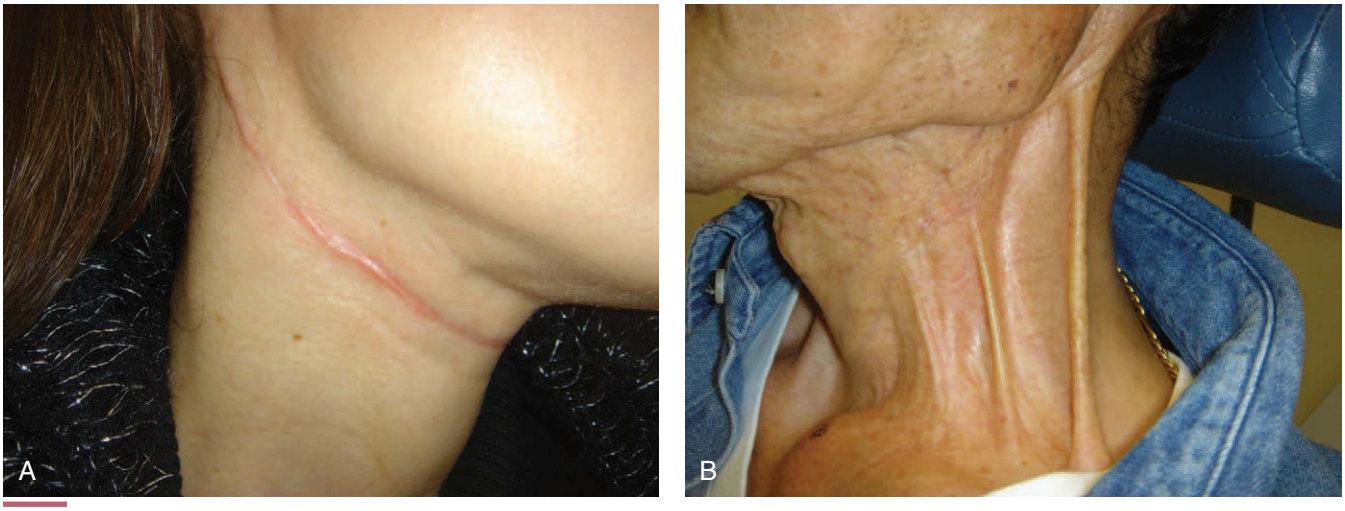

Figure 122-3. Scar complications. **A,** Hypertrophic scar after selective neck dissection. **B,** Web formation in the lateral neck after radical neck dissection.

Figure 122-4. Facial edema after left radical neck dissection. The patient had a right, peripherally inserted central venous catheter that impaired flow of the right internal jugular vein.

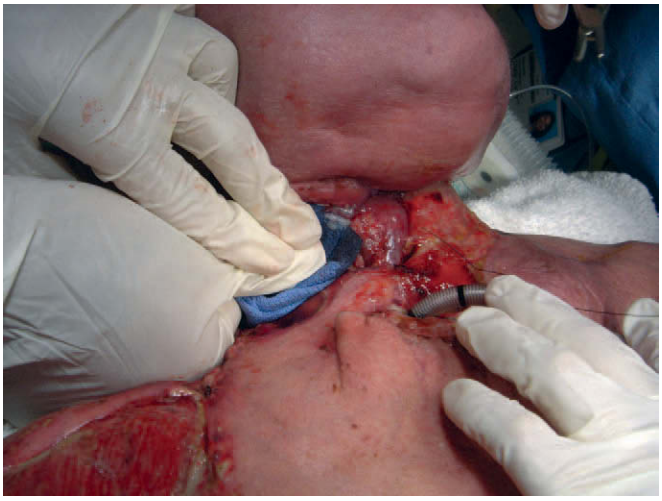

Figure 122-5. Internal jugular vein hemorrhage in the setting of pharyngocutaneous fistula. Direct pressure is being applied to the site of hemorrhage while the patient is transported emergently to the operating room for surgical control of the bleeding.

undergoing MRND alone, radiation therapy alone, or MRND plus postoperative radiation therapy showed a normal-appearing vein when compared with the contralateral, untreated IJV in 88%, 57%, and 18% of patients, respectively.[60] In the long term, the rate of IJV thrombosis may be significantly lower, only 5.8% in one ultrasound study, indicating that many thrombosed veins will recanalize with reestablishment of patency.[61]

Internal jugular vein hemorrhage is rare, occurring in less than 1.3% of MRND with concurrent laryngectomy or pharyngectomy.[62] Although often less severe than arterial bleeding, this event can be just as life-threatening (Fig. 122-5). Similar to carotid artery bleeding, the major risk factors for this complication include salivary fistula, significant tobacco use, and poor nutritional status.[63] Careful handling of the IJV and avoidance of circumferential dissection in cases involving aerodigestive tract entry may help in its prevention.[63]

Blindness, an exceedingly rare complication of neck dissection, may occur following unilateral or, more commonly, bilateral RND.[64,65] Prolonged intraoperative hypotension, increased cerebrospinal fluid pressure, and venous pressure on the optic nerve may be causative factors.[66]

Hematoma

Hematoma occurs in approximately 1% of neck dissections and 4% of major head and neck surgeries.[67,68] Hematoma can usually be differentiated from seroma by the presence of skin ecchymosis, firmness to palpation, or clotted drain output, although both complications can cause elevation of skin flaps and loss of the expected scaphoid contour of a dissected neck. Failure to recognize and properly treat a neck wound hematoma results in increased wound complications.[67] Even a small venous bleed or hematoma in an undesirable location, for example, in proximity of the vascular pedicle of a free flap reconstruction, can have serious consequences. Prevention consists of preoperative avoidance of anticoagulants and antiplatelet agents and meticulous intraoperative hemostasis. Treatment should include prompt evacuation of clotted blood, at the bedside if necessary, to prevent upper airway edema, and return of the patient to the operating room for wound exploration and control of any bleeding vessels.

Nerve Complications

Motor Nerves

Facial Nerve

The classic RND includes removal of a portion of the tail of the parotid gland. Surgical entry of the parenchyma of the parotid gland theoreti-

cally places the main trunk of the facial nerve at risk; however, during a standard neck dissection usually only the cervical and marginal mandibular branches of the facial nerve are encountered.

The cervical branch of the facial nerve innervates the platysma muscle, which lies in the superficial fascia of the neck and blends with depressors of the lower lip.[69] Sacrifice of the cervical branch does not usually produce clinically significant deficits, although loss of neck skin tone and some degree of decreased lip depressor function may occur due to either transection of the cervical branch of the facial nerve or division of the platysma muscle.

The marginal mandibular nerve is encountered during the approach to level I of the neck as it descends along the inferior border of the mandible and lateral to the submandibular gland before coursing superiorly to innervate the orbicularis oris, depressor anguli oris, mentalis, and depressor labii inferioris muscles.[69] The nerve is typically a single branch, but double branches can occur and its position with respect to the body of the mandible is highly variable. Injury to this nerve results in asymmetry of the lower lip at rest with inability to depress the lip during facial expression. A recently reported series of 258 submandibular gland excisions demonstrated a low rate of transient paresis of the marginal mandibular branch of the facial nerve (9%) and only one case of permanent paralysis (<1%).[70] Another study of 107 patients undergoing excision of submandibular gland neoplasms showed a transient paresis rate of 10% and a permanent paralysis rate of 1% for benign tumors, and rates of 8% and 6%, respectively, for malignant lesions; selective neck dissection was performed in 43% of cases overall.[71] In a large European series of patients with laryngeal or hypopharyngeal cancer and no prior radiation therapy, injury to the marginal mandibular branch of the facial nerve occurred in 9/714 (1.26%) of neck dissections.[72] The Hayes Martin maneuver for preventing marginal mandibular nerve injury involves ligation and superior retraction of the facial vein and submandibular fascia to carefully retract the nerve superiorly. With or without the aid of a nerve stimulator, identification of the marginal mandibular nerve is recommended before elevation of underlying tissue to avoid nerve injury.

Vagus Nerve

The main trunk of the vagus nerve exits the skull base at the jugular foramen and descends through the neck in the carotid sheath, initially medial to the internal jugular vein and carotid artery, then posterior to these structures lower in the neck.[69] Injury to the main trunk of the vagus nerve is rare but is known to occur during carotid endarterectomy, particularly during revision surgery in which the incidence of this complication approaches 2%.[73] During neck dissection, injury to the main trunk of the vagus nerve may occur during posterolateral to anteromedial clearance of level III and IV lymph nodes and ligation of the internal jugular vein in the inferior neck or at the skull base. An obscured operative field due to hemorrhage may contribute to this complication. High vagus nerve injuries result in significant dysphonia from vocal fold paralysis and dysphagia with pooling of secretions from loss of pharyngeal muscle function and sensory loss. The superior laryngeal nerve (SLN) arises from the nodose ganglion of the vagus nerve and divides into a larger internal branch, which carries sensation from the supraglottic larynx and an external branch that supplies the cricothyroid muscle. The recurrent laryngeal nerve (RLN) arises from the vagus nerve, looping under the subclavian artery on the right and the aorta on the left, and passes through the neck in the tracheoesophageal groove. SLN and RLN injuries are best discussed in the context of thyroid surgery (see Chapter 124).

Spinal Accessory Nerve

In the neck the spinal accessory nerve (SAN) consists entirely of motor fibers to the sternocleidomastoid muscle (SCM) and trapezius muscle.[69] As the SAN travels medial to lateral, it passes anterior to, posterior to, or through the internal jugular vein in 70%, 27%, and 3% of cases.[69] Branches to the undersurface of the SCM arise approximately 4 cm below the insertion of the muscle at the mastoid tip. The main portion of the SAN then either pierces the muscle (82% of cases) or passes posterior to it (18% of cases) before running obliquely through the posterior triangle to the trapezius muscle.[69] Usually at least one contribution from the cervical plexus (fibers from C2, C3, or both) occurs in the posterior triangle.[74] These contributions are thought to be primarily proprioceptive rather than motor nerve fibers.

Several landmarks for identifying the SAN during neck dissection exist. In SND, when dissecting the medial border of the SCM, the SAN lies in the same plane as the vessels that perforate the muscle. Secondly, the nerve commonly enters the posterior triangle 2 cm above Erb's point, where the greater auricular nerve emerges along the posterior border of the SCM.[74] Also, the nerve passes under and pierces the trapezius approximately 2 to 4 cm above the clavicle.[74]

The impetus for the development of the MRND was largely to avoid the morbidity of SAN sacrifice during RND. "Eleventh nerve syndrome" consists of shoulder drooping, aberrant scapular rotation, inability to fully abduct the shoulder, and a constant, dull ache secondary to atrophy of the trapezius muscle and adhesive capsulitis of the glenohumeral joint.[75] A temporary, reversible period of shoulder dysfunction can be seen with nerve dissection in MRND, whereas a profound and unrecoverable loss can occur in patients with sacrifice of the SAN,[76] although not universally.[77] Early studies comparing RND, MRND sparing only the SAN, and MRND with preservation of the SCM, IJV, and SAN showed SAN dysfunction in 60%, 50%, and 30% of patients, respectively.[78] Contemporary studies of SND have demonstrated a 5% rate of shoulder droop after dissection of levels II to IV compared with 30% when levels II to V were dissected.[79] In one large series of patients undergoing MRND, SAN transection occurred in 12 of 714 (1.68%) nerves at risk; less severe forms of dysfunction were not reported.[72] Shoulder function–specific quality of life (QOL) instruments have shown no significant change from pretreatment scores after SND.[80] MRND patients reported worse QOL at 6 months but improved to SND levels by 1 year, while those undergoing RND had persistent disability.[80] It is important to distinguish nerve damage from direct muscle injury; for example, stiffness and atrophy of the SCM may occur after division of perforating vessels or vigorous retraction and might be mistaken for spinal accessory nerve injury. In addition, adhesive capsulitis of the glenohumeral joint may occur due to lack of proper postoperative shoulder rehabilitation and cause ongoing shoulder disability despite recovery of SAN function.

Prevention of injury is achieved by proper identification of the SAN using the previously named landmarks and meticulous handling of the nerve once identified.[81] Intraoperative electrophysiologic monitoring of the SAN has been described,[82,83] although the benefit of this technique in reducing SAN injury is unclear and the use of handheld nerve stimulators with visualization of trapezius or SCM muscle contraction usually provides sufficient confirmation of the identity and integrity of the SAN. Local anesthesia should be avoided during posterior triangle lymph node biopsy to assist identification and protection of the SAN, and thin skin flaps should be raised because the nerve is most superficial in the midposterior triangle.

Unintentional spinal accessory nerve division is best treated with primary neurorrhaphy (Fig. 122-6). If a tension-free anastomosis cannot be achieved or if a long segment of the nerve must be sacrificed for oncologic purposes, cable grafting using the greater auricular nerve can be performed.[84] Cable grafting yields favorable results in terms of subjective shoulder function, strength testing, and electromyography findings compared with patients in whom the spinal accessory nerve was sacrificed, but it does not fully restore shoulder function to a level equivalent to patients with an anatomically intact nerve.

Hypoglossal Nerve

The hypoglossal nerve exits the skull base at the hypoglossal canal. As it passes lateral to the internal and external carotid arteries, it gives off the superior root of the ansa cervicalis (composed entirely of cervical nerve fibers) and then courses medial to the posterior belly of the digastric muscle and the stylohyoid muscle. Distally, under the sublingual gland, the hypoglossal nerve branches to innervate the ipsilateral intrinsic muscles of the tongue.[69] Hypoglossal nerve injury is a rare complication of neck dissection, occurring in 3 of 714 (0.42%) nerves at risk in one large study.[72] The nerve is susceptible to injury during dissection of levels I and II, near the greater cornu of the hyoid bone, and adjacent to the carotid artery. The rich venous plexus near the nerve

Normal shoulder function returned.

Figure 122-7. Phrenic nerve paresis. Postoperative chest radiograph showing right hemidiaphragm elevation after right radical neck dissection.

must be carefully controlled to prevent inadvertent injury. The deficits from hypoglossal injury include ipsilateral tongue weakness, deviation of the tongue to the affected side with protrusion, and difficulty with speech and swallowing. Management of nerve transection includes primary neurorrhaphy or cable grafting. Following nerve repair, residual tongue motion impairment occurs because of synkinesis but tongue atrophy is usually avoided.

Phrenic Nerve

The phrenic nerve arises from C3, C4, and C5 and is encountered in the base of the neck where it courses between the anterior scalene muscle and its overlying fascia.[69] The nerve then passes from the neck posterior to the subclavian vein to enter the thorax, innervate the ipsilateral diaphragm, and supply portions of the pericardium, mediastinum, pleura, and peritoneum.[19] Phrenic nerve paralysis is considered a rare complication of neck dissection, although phrenic nerve injury occurred in 14 of 176 (8%) consecutive neck dissections in one series.[85] Injury to the phrenic nerve leads to ipsilateral hemidiaphragm elevation with or without mediastinal shift on chest radiograph and symptoms such as cough, chest pain, or abdominal discomfort mediated by the somatic afferents (Fig. 122-7). The paresis is generally transient and without sequelae[86]; however, bilateral phrenic nerve injury with resultant respiratory failure has been reported.[87] Factors associated with phrenic nerve damage include a fibrosed or edematous anterior scalene muscle, tumor infiltration, or diffuse bleeding.[85] Preserving the fascial layer over the nerve and anterior scalene muscle is the primary method for prevention of injury.

Sensory Nerves

Lingual Nerve

The lingual nerve is primarily a branch of the mandibular division of the trigeminal nerve that carries general sensation from the anterior two thirds of the tongue. It also receives the chorda tympani nerve from the facial nerve, which carries taste from the same region of the tongue, as well as preganglionic parasympathetic fibers that enter the submandibular ganglion. The lingual nerve is encountered during level I lymph node dissection or other surgical procedures of the submandibular triangle. It is susceptible to injury because it is tethered inferiorly by its connections with the submandibular ganglion. Clinically, injury results in loss of taste from the ipsilateral anterior two thirds of the tongue. This complication occurs in up to 3% of patients undergoing submandibular gland excision[88] and may occur in neck dissections that include level I, although the exact rate of injury for the latter procedure has not been shown.

Greater Auricular Nerve

The greater auricular nerve (GAN) originates from the cervical plexus (C2, C3) and supplies sensation to most of the auricle and a small area of adjacent neck skin.[69] As mentioned previously, this nerve emerges from under the posterior border of the SCM in the top half of level V of the neck and travels across the lateral surface of the SCM toward the auricle. Sacrifice of this nerve during parotidectomy or neck dissection leads to a sensory deficit of the auricle that usually diminishes with time. Ear lobule numbness, however, tends to persist. Amputation neuroma of the divided GAN can occur. Recent reports with new modifications of technique indicate that preservation of at least the posterior branches of the GAN may be possible in approximately 70% of cases of parotidectomy with occasional transient sensory deficits.[89,90]

Cervical Sensory Nerves

Sensory branches of the cervical roots provide sensation to skin of the neck and shoulder. Sacrifice of these branches is often intentionally performed during RND or MRND and results in diffuse sensory loss across the entire neck. Some sensory deficit still occurs after SND with preservation of cervical rootlets, but the region of numbness is reduced significantly.[91]

Branches of the cervical plexus can also form amputation neuromas, which present as firm, painful masses in the lateral neck that are exquisitely

tender to palpation. Neuromas can be treated with excision, ligation, or implantation of the nerve stump into adjacent muscle or soft tissue.

Sympathetic Nerves

The cervical sympathetic chain consists of two to four ganglia with a connecting neural trunk running parallel and posteromedial to the carotid sheath.[69] Injury can occur during retraction of the carotid sheath to clear tumor or adjacent lymph nodes and may be temporary, related to traction, or permanent due to transection. Full loss of sympathetic innervation results in a classic Horner's syndrome (ptosis, miosis, and anhidrosis); the manifestations of partial losses vary depending on the location of the injury in relation to the ganglia (Fig. 122-8). Horner's syndrome occurred in 4 of 714 (0.56%) neck dissections in a recent case series.[72]

Figure 122-8. Right Horner's syndrome with ptosis and miosis after right neck dissection.

Sympathetic chain interruption is also thought to be the cause of first bite syndrome, the development of parotid region pain after the first bite of each meal associated with parapharyngeal space surgery.[92,93] The syndrome was first described in a series of patients undergoing vagal paraganglioma excision in which 9 of 46 (20%) patients experienced this complication.[92] Division of the sympathetic trunk does not always produce first bite syndrome—two patients in this series had known intraoperative transection of the sympathetic trunk but did not develop parotid pain.[92] Also, a recent study of surgical management of cervical sympathetic chain schwannomas showed that only 2 of 4 (50%) patients developed first bite syndrome.[94] The rate of this complication after neck dissection is unknown but low.

Chyle/Chest Complications

Chylous Fistula

A chyle leak is a complication of radical neck dissection in 1% to 2% of cases.[95,96] The majority of chyle leaks occur on the left side, where the thoracic duct enters the base of the neck and travels anterolaterally to empty into the left subclavian vein, usually at or within 1 cm of the junction with the internal jugular vein (Fig. 122-9A).[97] Up to 25% of

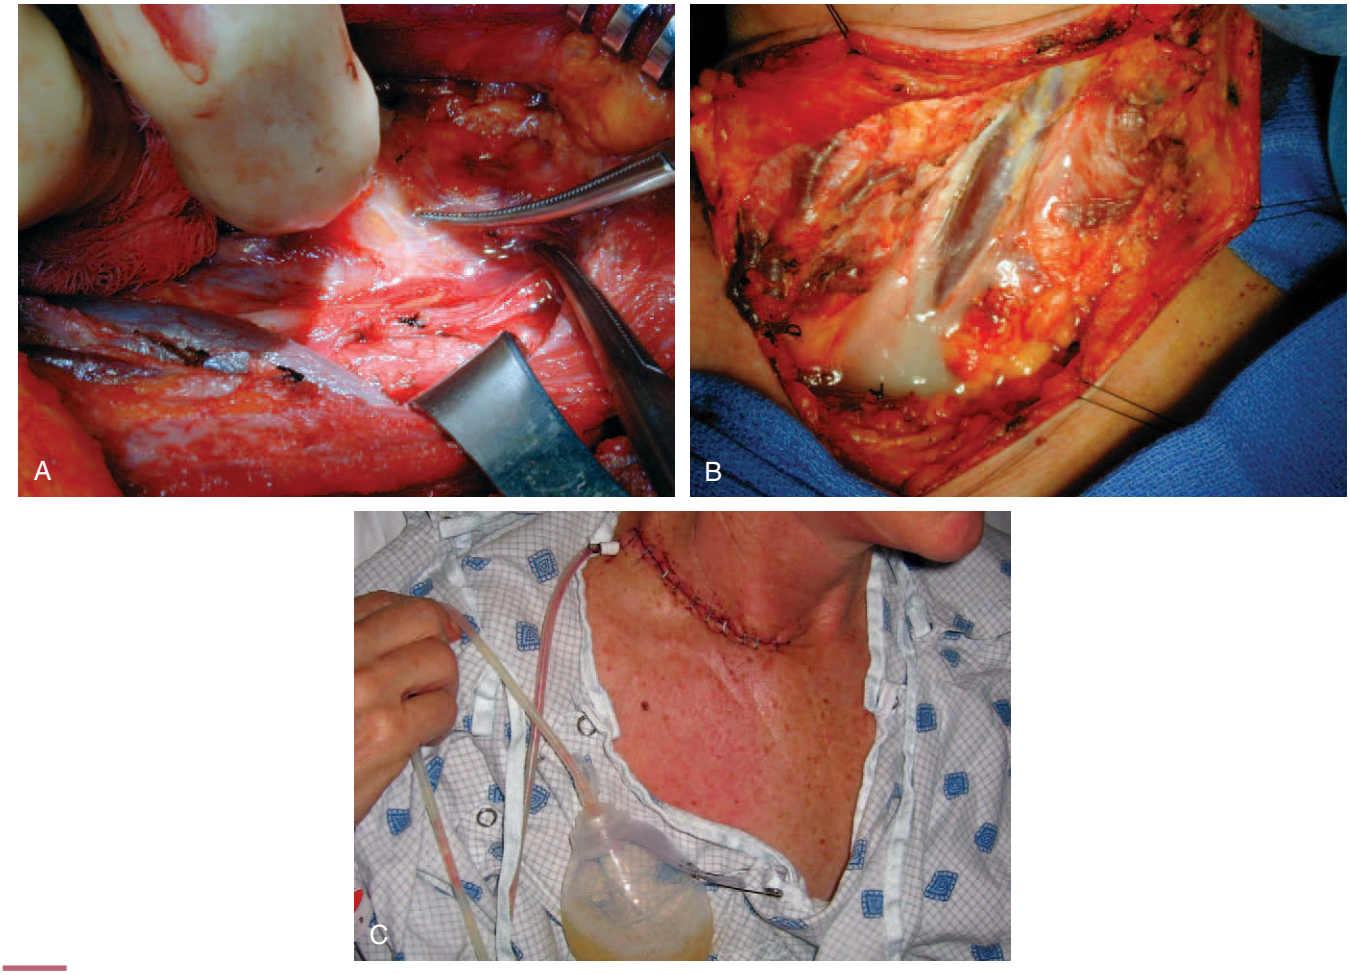

Figure 122-9. Thoracic duct and chylous fistula. **A,** An intact thoracic duct encountered during dissection of the inferior aspect of the neck. **B,** Intraoperative chyle leak noted during left neck dissection. **C,** Postoperative chyle leak presenting with typical milky drain output following resumption of oral diet.

chyle leaks, however, occur on the right side because of interruption of the right lymphatic duct on its path to the right subclavian vein.[98] The duct may be more accurately described as a plexus of tributaries and terminal ducts, each of which can create a chylous fistula if transected or incompletely ligated.[19]

Intraoperative suspicion of chyle leak during any lower neck dissection should be investigated by asking the anesthesiologist to administer positive ventilatory pressure. Pooling of milky fluid or visualization of discrete lymph vessels may occur (see Fig. 122-9B). Gentle exploration and meticulous ligation of the duct and identifiable branches with nonabsorbable sutures is recommended.[99] Adjunctive measures including use of the operating microscope, fat grafting, and application of Surgicel or a sclerosing agent to the region have been described.[100,101]

Postoperative leaks are usually discovered with the resumption of feedings. Most are easily diagnosed clinically by observing a change in the character of drain output from serosanguineous to milky (see Fig. 122-9C). Drain output fluid analysis may be helpful in diagnosis because the triglyceride (TG) level of normal neck dissection fluid is typically less than 100 mg/dL; a drain TG level greater than 100 mg/dL and greater than the serum TG level is diagnostic of chyle leak.[102] A chest radiograph is important to rule out concurrent chylothorax.

Several treatment algorithms for postoperative leaks have been proposed.[103] Conservative management with a medium chain triglyceride diet (which is absorbed directly into the portal circulation and circumvents the lymphatic system), closed drainage to promote adherence of skin flaps, and/or pressure dressings may be sufficient to promote spontaneous closure of most fistulae.[104] A potentially beneficial adjunctive measure is the use of a long-acting analog of the hormone somatostatin (octreotide 100 mcg subcutaneously three times a day), which reduces splanchnic blood flow and, therefore, decreases gastrointestinal chyle production.[105]

Conservative management is warranted for most chyle leaks, but high output leaks require operative intervention, regardless of the exact cutoff used (>500, >600, or >1000 mL per 24-hour period according to various studies).[96,98,103] Chylomas refractory to needle aspiration and pressure dressings may also require wound exploration for control.

Chylothorax

Chylothorax is a rare complication of neck dissection, but case reports continue to emerge.[106,107] Possible mechanisms include retrograde pressure formation from cervical thoracic duct ligation leading to extravasation or mediastinal propagation of a leak originating in the neck. Successful management includes dietary modifications and thoracentesis or thoracostomy tube drainage. Somatostatin analog injection may also be beneficial.[108] Rarely, operative intervention via thoracoscopic or open thoracotomy approaches are necessary to identify the leak and ligate the thoracic duct in the chest.

Pneumothorax

Extensive dissection at the base of either side of the neck can also threaten the cupula of the lung, with a risk of pleural transection leading to pneumothorax.[19] Early recognition of changes in ventilatory status, detection of decreased breath sounds on chest auscultation, and urgent treatment with needle decompression and/or thoracostomy tube placement are required. Air leak can also cause subcutaneous emphysema, which is rare during isolated neck dissection but may occur when concurrent tracheotomy is performed and the tracheotomy wound is closed too tightly.[19] The mechanism of postoperative pneumothorax may be extension of subcutaneous emphysema into the mediastinum and eventual rupture of the pleura.[109] Overall, pneumothorax is more common with tracheotomy, which carries a 1% to 2% risk of this complication.[109,110] The available evidence, however, does not support routine chest radiography after tracheotomy.[111,112] Chest radiographs after neck dissection are considered on a case-by-case basis.

Conclusion

Complications in neck surgery may occur despite the best efforts to prevent them. It is imperative that all head and neck surgeons be intimately aware of the risks associated with any given surgical neck procedure. Proper preoperative planning, early recognition of perioperative complications, and prompt, effective management can minimize the impact of complications that may occur.

CHAPTER ONE HUNDRED AND TWENTY-THREE

Disorders of the Thyroid Gland

Phillip K. Pellitteri

Steven Ing

Brian Jameson

Key Points

- Thyroxine (T_4) and triiodothyronine (T_3), produced by the thyroid gland, are iodinated derivatives of tyrosine.
- Most circulating thyroid hormones are bound to one of several plasma proteins, the most important of which is thyroxine-binding globulin (TBG), which accounts for 70% of circulating hormone.
- Circulating T_3 accounts for most of the physiologic activity of thyroid hormone.
- The primary internal regulation of thyroid activity is through the anterior pituitary gland by way of thyrotropin-releasing hormone (TRH) released by the hypothalamus.
- The most effective biochemical study for assessing thyrometabolic status is through measurement of thyrotropin (thyroid-stimulating hormone [TSH]).
- The greatest clinical value of thyroglobulin measurement (TBG) is in the management of patients with differentiated thyroid cancer.
- Circulating thyroid antibodies, antimicrosomal and antithyroglobulin, are usually present in patients with autoimmune thyroid disease.
- The principal usefulness of the radioactive iodine uptake study is to differentiate hyperthyroidism into high-uptake and low-uptake states.
- A palpable, hypofunctional nodule in the presence of Graves' disease should be regarded as highly suspicious for harboring malignancy.
- A patient with Graves' disease, manifesting thyroid ophthalmopathy, should be treated with surgery and not radioactive iodine ablation to avoid complicating the ocular problems attributable to the disease.
- Acute or subacute thyroiditis may be treated with salicylates or nonsteroidal anti-inflammatory drugs. If the thyroiditis is resistant to these medications, a trial of prednisone may be considered.
- Acute suppurative thyroiditis is most commonly caused by staphylococcal and streptococcal species of bacteria.
- Toxic thyroid adenoma may be effectively treated by surgical resection, leaving a normally functioning thyroid remnant.
- Medical treatment for acute life-threatening thyrotoxicosis (thyroid storm) is antithyroid medication, propranolol to reduce peripheral effects of T_3, and glucocorticoid administration to combat cortisol degradation.
- Myxedema coma, a late manifestation of hypothyroidism, is managed with administration of large doses of intravenous T_4 and hydrocortisone.

Thyroid diseases are common. They occur in the form of abnormalities in the size and shape of the thyroid gland (goiter) and of abnormalities of thyroid secretion. Nonthyroidal illness can be accompanied by any alteration in thyroid physiology that can complicate the evaluation of thyroid status.

The scope of problems relating to thyroid disease can be so complex and encompassing as to create a major challenge to the diagnostic capabilities of the clinician. The patient may have such a variety of seemingly unrelated signs and symptoms as to lull the practitioner into a suspicion of hypochondriasis. This is especially true in our current "cost-effective" frame of mind, in which screening batteries of diagnostic tests are no longer in vogue, and time is of the essence. The patient's symptoms can be confusing and bizarre, leading the physician sometimes to nonspecific diagnoses, such as psychological problems with depression or anxiety, chronic fatigue syndrome, cardiac failure, fibromyalgia, and a host of other nonspecific entities. The dilemma is more than simply one of hyperfunction versus hypofunction or nodular versus diffuse or benign versus malignant. The examination should not merely comprise placing the thumb on the lower neck while the patient swallows a few sips of water and answers a couple of quick questions about heat intolerance, weight changes, and gastrointestinal function.

The thyroid gland controls body metabolism and has a profound effect on all bodily functions. In addition, the peculiarities of development and the strategic location of the thyroid gland may produce symptom complexes that divert the physician's attention away from the thyroid gland and toward the symptoms itself. To be proficient in the management of thyroid disease, the physician must be knowledgeable about all phases of the embryology, anatomy, endocrine function, genetic implications, and environmental issues that may affect the

thyroid, and he or she must be keenly suspicious of all the patient's signs and symptoms.

The patient's history and review of symptoms should be comprehensive. Generalized symptoms relating to hypothyroidism include weakness and fatigue with cold intolerance; weight gain; hair loss; edema of the hands and face; thick, dry skin and hair; and a decreased tendency to sweat. Otolaryngologic symptoms include hearing loss, dizziness, tinnitus, voice aberrations, middle ear effusion, and slurred speech with an enlarged tongue. Gastrointestinal symptoms include constipation, anorexia, intermittent nausea and vomiting, and dysphagia and bloating. Dysphagia is especially common if there is external compression on the esophagus by a circumferential or enlarged thyroid gland. Genitourinary symptoms include menstrual disorders and a tendency toward polyuria. Cardiovascular symptoms include bradycardia, some elevation of the blood pressure, intermittent angina, pericardial effusion sometimes, and peripheral edema. Central nervous system symptoms include daytime somnolence but insomnia at night, headaches and dizziness, mental and physical slowness, delayed reflexes, and psychological symptoms suggestive of depression or anxiety. Pulmonary symptoms include shortness of breath if there is tracheal compression or pleural effusion. Musculoskeletal symptoms include arthritis and stiffness of the joints with muscle cramps and weakness.

The general symptoms of hyperthyroidism commonly include a rapid heartbeat or perceptible palpitations, irritability, anxiety, easy fatigue, increased number of bowel movements with weight loss, and heat intolerance. Physical findings include tachycardia with or without arrhythmia; moist, warm skin; a fine tremor of the fingers; and often an enlarged thyroid. Eye signs may be present, including lid lag, eyelid retraction, and exophthalmos.

The thyroid gland is strategically located in the lower anterior neck in close relationship to the larynx, the trachea, the esophagus, the carotid sheath structures, the sympathetic chain, the recurrent laryngeal nerve, and the mediastinal structures. Diffuse or nodular enlargement, whether benign or malignant, may cause compression or invasion of these adjacent structures. Resulting symptoms include dysphagia, dyspnea, voice aberration, vocal cord paralysis, Horner's syndrome, superior vena cava syndrome, and sometimes pericardial or pleural effusions.

The medical history may disclose a history of thyroid agenesis; prior thyroidectomy; therapeutic irradiation with iodine-131 (^{131}I); external radiation therapy; Hashimoto's thyroiditis; history of laryngeal cancer or laryngectomy; history of cancer elsewhere with possible metastasis to the thyroid; and a history of other recent head and neck infections, which may have resulted in an inflammatory process within the thyroid gland.

Physical Examination

Facility with the examination of the thyroid and surrounding structures is essential for accurate diagnosis and appropriate management of malignant and benign thyroid disease. The patient is initially observed anteriorly. Some findings may be obvious, whereas others may be subtle. A clinical patient with hypothyroidism usually seems more lethargic, is perhaps overweight, and is slower in response. Skin and hair may appear dry and coarse. Conversely, a hyperthyroid patient may seem more anxious, is thinner, and is more apprehensive, with moist, warm skin and perhaps a visible tremor noted in the fingers. Eye signs, including exophthalmos, lid lag, or lid retraction, may or may not be present.

In either a hypothyroid or a hyperthyroid patient, a diffuse or nodular goiter commonly may be visible in the neck on simple inspection. The patient may have some aberration of the voice. The patient with hypothyroidism with myxedematous infiltration of the vocal cords has a husky, raspy tone of voice. A patient whose recurrent laryngeal nerve is compromised by pressure or tumor infiltration has the voice of a paralyzed vocal cord, which is breathy, barely audible, and inefficient as far as air use is concerned. In other circumstances, the voice may have a guttural quality signifying obstruction of the aerodigestive passage, usually at the level of the tongue base. This would suggest a lingual thyroid that has failed to descend along normal developmental pathways.

Horner's syndrome may be present with either benign or malignant thyroid disease. The patient may seem to have a hearing deficit in normal conversational situations. This may be the result of middle ear effusions, which can be drained and reversed. Inner ear myxedematous changes involving the cochlear or vestibular structures may contribute to a sensorineural type of hearing loss accompanied by tinnitus and vertigo. Facial swelling or plethora and the distention of the jugular veins may signify obstruction of the superior vena cava from benign or malignant substernal thyroid disease. Pemberton's sign should be elicited in patients with large goiters. Pemberton's sign is elicited by having the patient extend both arms above the head and observing for facial erythema, swelling, or distention of the jugular veins indicating cervicothoracic inlet obstruction.

After careful observation of the patient's general appearance, the neck is examined. The thyroid should be examined from behind the patient. The thyroid is palpated initially for gross pathology. The patient is then asked to swallow several sips of water. This moves the thyroid cephalad and makes the lower portion of the thyroid more easily approached. If the patient extends the neck less fully, the more inferior aspects of the thyroid (especially in patients with substernal goiter or kyphosis) may be easily and accurately examined. Moderate pressure in the tracheal groove on one side facilitates more accurate palpation of the contralateral lobe. The examiner notes the size relative to a normal thyroid gland. Similarly, the size and locations of nodules should be accurately recorded. A pyramidal lobe of the thyroid sometimes can be palpated in patients, especially patients with Graves' or Hashimoto's disease. A thyroid nodule with recent hemorrhage may be moderately tender, whereas an acute, suppurative, or subacute viral thyroiditis is usually exquisitely tender to palpation. Commonly, the pain from the thyroid radiates to the ipsilateral ear.

The texture of the thyroid may suggest the etiology of the disease. Autoimmune thyroid disease often is seen as a firm, bosselated (cobblestone-like) gland. This, in conjunction with a low or elevated serum thyroid-stimulating hormone (TSH) level, should strongly suggest Graves' disease (low TSH) or Hashimoto's thyroiditis (elevated TSH). Smooth nodularity of the thyroid usually represents colloid goiter. Although firm nodules may represent thyroid cancer, this clinical characteristic is not diagnostic.

Attention is next turned to the areas of lymphatic drainage of the thyroid. The superior pole and the lateral lobes drain superiorly and laterally toward the jugular lymph nodes, whereas the isthmus and lower poles of the thyroid drain inferiorly along the tracheoesophageal groove and into the mediastinum. Each side of the neck should be examined methodically from the mandible to the supraclavicular notch.

After observation of the external surfaces and examination of the external neck, attention is turned to the internal examination of the aerodigestive system. Intraorally, the tongue in a myxedematous patient may be enlarged and thickened. The base of the tongue should be examined carefully to rule out a lingual thyroid gland. If present, this would indicate a developmental anomaly. The lingual thyroid can enlarge during periods of increased hormonal demand, such as puberty and pregnancy. When this enlargement occurs, the guttural qualities of the voice may be even more profound. In addition, bleeding may occur from the lingual thyroid; finally, enlargement of the lingual thyroid may continue to the point of dysphagia and airway obstruction that may precipitate a semiemergent condition. Most commonly, hormonal treatment reduces the size of the mass on the back of the tongue. Occasionally, surgical intervention is required to ensure a safe airway. This area of the oropharynx and tongue base is usually readily examined with the aid of a tongue blade and a laryngeal mirror. In patients with an extremely active gag reflex, however, a better examination is usually obtained with a fiberoptic nasopharyngolaryngoscope.

The etiology of the patient's hoarseness is determined with a dynamic examination of the hypopharynx and larynx using the fiberoptic nasopharyngolaryngoscope. In the hypothyroid patient, the vocal cords are mobile. The vocal cords may exhibit myxedematous changes, however, causing them to be thickened and sometimes even polypoid along the edges of the vocal folds. The voice in these instances is quite harsh and raspy. The airway may become partially compromised by the

thickened myxedematous polypoid tissue, and sometimes it is necessary to trim this back surgically to ensure an adequate airway.

When one vocal cord is paralyzed, the airway initially becomes incompetent. The patient may cough or choke on liquids or secretions unless careful swallowing is followed. The larynx is inefficient and produces only two or three words per each breath of air. The voice is of an exaggerated, forced, whispered quality. As time passes, the larynx compensates by having the mobile vocal cord cross the midline to close the deficit in the airway partially. This compensation improves speech and swallowing almost to normal levels. It is important that preoperative laryngeal examination be done before thyroid surgery to establish the mobility of the vocal cords. Because it is possible to have a nearly normal sounding voice with one cord paralyzed, it is important for the operating surgeon to know that there is a paralyzed cord, as injury to the opposite cord would precipitate the more emergent situation of bilateral vocal cord paralysis, and the probable need for subsequent tracheostomy or thyroplasty or both. Paralysis of the vocal cords usually implies compromise of the recurrent laryngeal nerve on the ipsilateral side. This compromise may be secondary to pressure on the nerve, but more likely is caused by infiltration of the nerve by malignancy.

External compression on the trachea or esophagus or both by thyroid masses can lead to severe dyspnea or dysphagia or both. It is important to know whether the airway and esophageal involvement is secondary to external compression alone, or whether there is an element of tumor infiltration within these organs. Internal examination with a bronchoscope and an esophagoscope is necessary to determine the status of these organs. Radiographic studies sometimes are necessary to complement the examinations and to aid in surgical planning. Under such circumstances, barium swallow of the esophagus may outline the areas of obstruction. Elucidating the various etiologies of thyroid disease is often accomplished by considering the aggregate data obtained from the patient's history, clinical examination, chemical and imaging studies, and specific diagnostic examinations.

Physiology of the Thyroid Gland

The thyroid gland produces two hormones, 3,5,3′-triiodothyronine (T_3) and 3,5,3′,5′-tetraiodothyronine or thyroxine (T_4). Both are iodinated derivatives of tyrosine. Hormone production depends on an external iodine supply and on intrathyroidal mechanisms for concentrating ingested iodide and then incorporating it into the tissue-specific protein, thyroglobulin. The thyroid gland is unique within the endocrine system in having a large extracellular space, the follicular lumen, which is used for storage of the hormones and their precursors. As hormone is needed by the organism, thyroglobulin is retrieved by the cell, where the biologically active hormones are released from thyroglobulin before being passed into circulation (Fig. 123-1).

Iodide Transport

A daily dietary intake of at least 100 µg of iodine per day is required in humans to ensure adequate production of thyroid hormone. In North America, the average daily intake is higher than this, largely because of the use of iodine as a food additive.[1] In many parts of the world, however, consumption is significantly below the minimum level, and iodine deficiency is the leading cause of thyroid-related disorders.

The thyroid normally concentrates iodide 20-fold to 40-fold over the extracellular space and against an electrical gradient of approximately 40 mV. Key to this trapping action is a protein located in the basal membrane of the thyroid cell known as the sodium/iodide symporter (NIS).[2] NIS couples with the influx of Na^+ down its electrochemical gradient with the simultaneous influx of I^- up its electrochemical gradient. An Na^+,K^+-ATPase acts to maintain the Na^+ gradient. Iodide travels down its electrochemical gradient to the apical surface of the thyrocyte, where it is incorporated into thyroglobulin. More recent evidence suggests an apical membrane protein, pendrin, aids in releasing iodide into the follicular lumen.[3] Mutations in the gene and coding for this protein are responsible for the common hereditary disorder Pendred's syndrome, which is associated with mild hypothyroidism, goiter, and hearing loss.[3] Mutations in the gene coding for NIS have been identified in patients with iodide trapping defects, a rare cause of congenital hypothyroidism.[2]

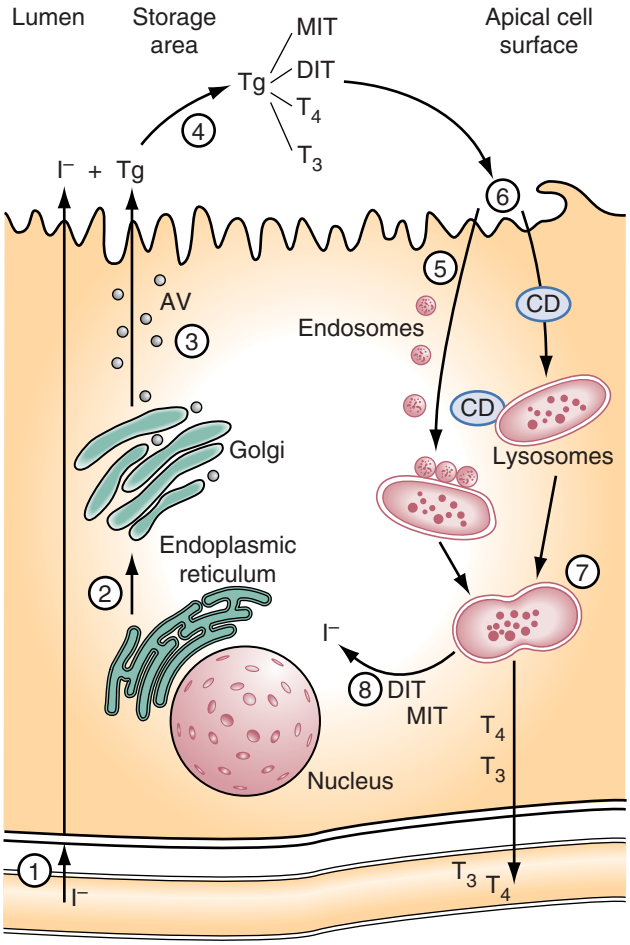

Figure 123-1. Synthesis and release of thyroid hormone. (1) Iodide transported into the thyrocyte at the basal cell membrane by the symporter (NIS) travels down its electrochemical gradient to the apical surface. (2) Polypeptide chain of thyroglobulin (Tg) is synthesized on the surface of the endoplasmic reticulum, then translocated into its lumen. Synthesis of carbohydrate units begins, and conformational changes transform the polypeptide chains into stable dimers. Tg enters the Golgi where carbohydrate units are completed. (3) Uniodinated Tg travels to the apical surface in small vesicles (AV). (4) Tg is iodinated, and iodotyrosyls are coupled to form T_4 and T_3 by thyroperoxidase in the presence of H_2O_2. (5) Tg, retrieved by micropinocytosis, enters the endosome-lysosomal pathway, where proteolysis and hormone release occurs. (6) Alternatively, Tg, retrieved by macropinocytosis, travels to lysosomes in colloid droplets (CD). (7) Thyroid hormones and precursors leave the lysosomes, and T_4 and T_3 enter the bloodstream. (8) MIT and DIT are deiodinated, and released iodide is recirculated. *(From Dunn AD. Thyroid physiology. In: Pellitteri PK, ed. Endocrine Surgery of the Head and Neck. New York: Delmar Publishing; 2003:50.)*

Thyroglobulin

Thyroglobulin is essential to thyroid physiology. It is a tissue-specific protein that serves as a matrix for the synthesis of hormone and as a vehicle for its storage.[4] The human thyroglobulin gene has been cloned and is located on the long arm of chromosome 8Q24. Thyroglobulin is a large dimeric glycoprotein of approximately 660 kD, consisting in humans of two identical polypeptide chains each of 2750 amino acids. About 10% of its weight is carbohydrate, and about 0.1% to 1% is iodine. Synthesis and maturation of thyroglobulin follow a pathway typical of proteins destined for secretion. The polypeptide chain is synthesized on the surface of the rough endoplasmic reticulum. As that passes through a series of intracellular compartments, it undergoes important post-translational modifications before reaching the

follicular lumen.[5] Carbohydrate units are added to the polypeptide chain as it is translocated into the lumen of the rough endoplasmic reticulum. Folding and dimerization of the polypeptide chain occurs within this compartment, aided by folding enzymes and a group of proteins known as molecular chaperones. Perturbations of this process result in block of protein transport beyond this point and cause congenital hypothyroidism.[5] Under normal circumstances, the properly folded thyroglobulin dimers migrate to the Golgi complex, where processing of the carbohydrate units are completed. Mature but as of yet uniodinated thyroglobulin is transferred from the Golgi complex to the apical cell surface in small vesicles.

Iodination and Thyroperoxidase

Newly formed thyroglobulin and iodide meet at the apical cell surface, where hormone synthesis occurs. This process includes (1) the oxidation of iodide; (2) its subsequent transfer to thyrosyl residues on thyroglobulin, producing monoiodotyrosine (MIT) and di-iodotyrosine (DIT); and (3) coupling of two iodotyrosine molecules, either one each of MIT and DIT to form T_3 or two of DIT to form T_4. Thyroperoxidase (TPO), an enzyme present in the apical cell membrane, is responsible for each of these steps.[6] Hydrogen peroxide (H_2O_2), required in the iodinating and coupling reactions, is generated at the apical membrane by a reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase.[7] Mutations in the TPO gene have been found in patients with congenital hypothyroidism caused by defective organification. Abnormalities in H_2O_2 generation seem to be more rare.

Under normal circumstances, iodide, when trapped, is rapidly incorporated into thyroglobulin so that little free iodide exists within the thyroid gland at any given time. The extent to which thyroglobulin is iodinated depends on the thyroid's iodide supply. At a level of 0.5% iodine, the thyroglobulin dimer in humans contains on average 5 residues of MIT, 5 of DIT, 2.5 of T_4, and 0.7 of T_3 of a total of 132 residues of tyrosine.[4]

Hormone formation involves the coupling of two residues of iodotyrosine within the thyroglobulin polypeptide chain. At the hormonogenic site, the "acceptor" DIT receives the iodinated phenol ring of the "donor" iodothyrosyl (either MIT or DIT) located at some distal site on the polypeptide chain. In the process, the alanine side chain of the donor remains behind, now presumably in the form of hydroalanine. Iodination in vitro of low iodine human thyroglobulin indicates that certain thyrocele sites are favored for early iodination, and that three or four major sites exist for hormone formation. The most important hormonogenic site is located five residues from the amino terminal thyroglobulin, whereas a second major site is located three residues from the carboxy terminal. The locations of donor thyrosyls are incomplete. To date, only one has been identified in human thyroglobulin, and this resides in the amino terminal region of the molecule.[4]

Storage and Release of Hormone

Most mature iodinated thyroglobulin is stored in the colloid as soluble dimers, although some (approximately 10%) highly iodinated molecules associate as tetramers. The colloidal nature of the follicular lumen is caused by its high concentration of protein. This intracellular space contains a large supply of iodine and hormone available to the organism, which protects it against times of iodine deprivation.

Hormone release is initiated by the retrieval of thyroglobulin from the follicular lumen. Under stimulatory conditions in some species, this process may occur by macropinocytosis. Pseudopods form at the thyrocytes' apical surface and engulf thyroglobulin as large colloid droplets. Under physiologic conditions in most species, however, including humans, thyroglobulin is retrieved by micropinocytosis into small vesicles. It is then passed through the endosome-lysosomal system, where the combined action of several acid proteases, including cathepsins B, D, and L, and lysosomal dipeptidase 1, releases the hormones and their iodotyrosine precursors from the polypeptide backbone.[4] Evidence suggests the iodo-amino acids may be preferentially cleaved first, but ultimately thyroglobulin is broken down into amino acids or small peptides within the lysosomes.

When released from thyroglobulin, the thyroid hormones and their precursors enter the cytosol; there MIT and DIT are deiodinated by an iodotyrosine-specific deiodinase, and the released iodide re-enters the iodine pool. Some T_4 is deiodinated to T_3 before it is released into the circulation by 5′-iodothyronine deiodinase similar to that found in peripheral tissue.[8] The mechanism by which T_4 and T_3 are released from the thyrocyte is unknown, but more recent evidence suggests a carrier protein may be involved.[9]

Circulating Thyroid Hormones

Less than 1% of circulating thyroid hormones exist as free iodo-amino acids. The remainder are bound in reversible, noncovalent linkage to one of several plasma proteins.[10] In humans, the most important of these is thyroxine-binding protein (TBG), accounting for approximately 70% of circulating hormone. The TBG molecule has one hormone-binding site with a very high affinity for T_4 and lower affinity for T_3. A second plasma protein transthyretin accounts for approximately 10% of circulating T_4 and T_3. Each transthyretin molecule has two hormone-binding sites, but the affinity of the first is lower than that of TBG, and that of the second site is very low for both hormones. Albumin also serves as a thyroid hormone transport protein. Although it has low affinity, its abundance allows it to account for 10% to 20% of bound circulating hormone.

The bound hormones are in equilibrium with the minute fraction of free circulating hormone that is available for use in peripheral tissue. Under euthyroid conditions, approximately 0.2% of T_4 and about 0.3% of T_3 in circulation is unbound. The larger free-to-bound ratio of T_3 to T_4 is caused by the lower affinity of TBG for T_3.[11] To date, no change in thyroid state has been attributed to abnormalities in these hormone-binding proteins, despite their apparent role in thyroid function homeostasis.

Metabolism of Thyroid Hormones

T_4 must first be deiodinated to T_3 to exert most of its biologic actions. Because little T_3 is directly synthesized on thyroglobulin, this transformation becomes an important step in hormonogenesis. Three iodothyronine deiodinases are present in mammals.[8] These are membrane-bound enzymes that are closely related structurally and are distinguished by the presence of selenocysteine at their active sites. Each has distinctive substrate preferences, activity characteristics, inhibitor sensitivities, and relative tissue specificity. Type I and II deiodinases, through their combined action, are responsible for generating approximately 80% of the total T_3 production.

Type I deiodinase is the primary source of circulating T_3 and is found in liver, kidney, and thyroid (where it is activated by TSH) tissues, and to a lesser extent in other tissues. Type I deiodinase is positively regulated by thyroid hormones and is greatly reduced under pathophysiologic states, such as starvation and nonthyroidal illnesses. It is inhibited by the antithyroid drug propylthiouracil. Type II deiodinase is present primarily in the central nervous system, the pituitary, the placenta, and the skin, and has more recently been found in the thyroid.[12] Its major role is thought to be in the local production of T_3, but it may also contribute to circulating T_3. In contrast to type I deiodinase, the type II enzyme is negatively regulated by thyroid hormone and is unaffected by propylthiouracil. Type III deiodinase inactivates T_4 and T_3 by inner ring deiodination in the five position, forming reversed T_3. The enzyme is present in the adult brain, skin, and placenta, and is present in high levels in fetal tissues, where it is thought to be important in protecting developing tissue from excess levels of thyroid hormone.[13]

Control of Thyroid Function

The anterior pituitary is the primary internal regulator of thyroid function, influencing virtually all phases of thyroid metabolism.[14] It secretes TSH, also known as thyrotropin, which is a 28- to 30-kD lipoprotein consisting of two subunits, α and luteinizing hormone. The α subunit is common to the pituitary hormones follicle-stimulating hormone and luteinizing hormone and to chorionic gonadotropin. The α subunit is unique to TSH, however, and is responsible for the binding of the hormone to its receptor in the basal membrane of the thyroid cell. On interaction with TSH, the receptor, a member of a family of G protein–coupled receptors, undergoes conformational changes that activate one

or two regulatory pathways. Most TSH effects are mediated by the activation of the cyclic adenosine monophosphate (cAMP) pathway; others involve the Ca^{2+}/phosphatidylinositol cascade. The pathway used to elicit a given effect may vary among species. TSH stimulates the efflux of iodide into the follicle and the resorption of colloid into the cell within minutes. Later effects include increased expression of the NIS, thyroglobulin, and TPO genes; stimulation of H_2O_2 production; promotion of glycosylation; and increased production of T_3 relative to T_4.

Circulating levels of TSH are controlled by the opposing influences of thyroid hormone and of thyrotropin-releasing hormone (TRH) from the hypothalamus.[15] The latter is a modified tripeptide secreted to the anterior pituitary by way of the hypothalamohypophyseal portal system. TRH binds to the plasma membrane of the thyrotrope and stimulates the release of TSH and the expression of its gene. Levels of circulating TSH are under strict control by the thyroid in a classic negative feedback system. As levels of thyroid hormone increase in response to TSH stimulation, T_4 and T_3 block the TRH-stimulated release of TSH in the thyrotrope. The thyroid hormones also act indirectly by inhibiting TRH gene expression in the hypothalamus.

Iodine supply is the major external factor influencing the thyroid state. Autoregulatory mechanisms present in the thyroid help to compensate for variations in iodide intake. In response to increasing doses of iodine, the thyroid initially increases hormone synthesis, but then reverses this process as intrathyroidal levels of iodide reach a critical level, and further organification is inhibited.

Withdrawal of iodide from the diet leads to a rapid decrease in serum T_4 and an increase in serum TSH. Serum T_3 levels initially are unaffected, but eventually decline with prolonged withdrawal. In response to TSH stimulation, the thyroid increases iodide uptake and organification, alters the distribution of iodo-amino acids within thyroglobulin by increasing the ratios of MIT to DIT and T_3 to T_4, and increases the intrathyroidal conversion of T_4 to T_3 by type I and II deiodinases.[8] With prolonged iodine deficiency, TSH-stimulated cell proliferation eventually leads to goiter.

Antithyroid Agents

Antithyroid drugs can inhibit thyroid hormone synthesis secretion or metabolism.[16] Common agents and their major actions are summarized in Table 123-1. Numerous agents used in the treatment of nonthyroidal illnesses may have profound effects on thyroid hormone production. Notable among these are the iodinated radiocontrast agents that are potent inhibitors of thyroid hormone deiodination, and can interfere with hepatic uptake of T_4 and binding of T_3 to nuclear receptors.[17] The antiarrhythmic agent amiodarone, which is also heavily iodinated, elicits similar alterations in thyroid hormone metabolism and action. Lithium, used in the treatment of bipolar illness, is a potent inhibitor of thyroid hormone release and acts by blocking thyroglobulin endocytosis.[18]

Table 123-1

Drugs Used in Hyperthyroidism

Drug	Usual Starting Dose
Propylthiouracil	200 mg PO tid
Methimazole	20 mg PO bid
Propranolol	10-40 mg PO qid
Saturated solution of potassium iodide (SSKI)	1-2 drops PO qd-tid
Compound solution of iodine (Lugol's solution)	2-5 drops PO qd-tid
Dexamethasone	2 mg PO qid
Prednisone	40-60 mg po qd
Ipodate	1 g PO qd
Lithium	300-450 mg PO tid
Perchlorate	1 g PO qd
Cholestyramine	2-4 g PO bid-qid
Colestipol	5 g PO one to five times a day
Octreotide	50-100 μg SC bid-tid
Diltiazem	120 mg PO tid

Thyroid Hormone Mechanism of Action

The thyroid has multiple effects on development, growth, and metabolism. The effects on development are widespread phylogenetically and can be dramatically observed during the course of amphibian metamorphosis. The appropriate levels of thyroid hormone during fetal and neonatal stages in humans are crucial for the normal maturation of the central nervous system, muscle, bone, and lung. In severe cases of thyroid hormone deficiency during this period, the syndrome of cretinism results with its associated mental retardation, deafness, mutism, and stunted growth.[19] Similarly, an excess of thyroid hormone during these critical developmental periods can result in neurologic abnormalities. The metabolic effects of thyroid hormone seem to be confined to birds and mammals, presumably evolving in response to the increased metabolic pressures of thermogenesis. Oxygen consumption and the metabolism of proteins, carbohydrates, and fats all are under thyroid hormone control.

Most effects of thyroid hormone are now believed to be exerted by interactions with specific nuclear thyroid hormone receptors, resulting in the altered expression of specific genes.[20] T_4 has little affinity for the nuclear receptors and first must be converted to T_3 to be effective. The receptors themselves belong to a large superfamily of nuclear receptors, which includes the steroid hormones, retinoic acid, and vitamin D. The thyroid hormone receptors are closely related isoforms, despite being encoded by two different genes (α and β).

The thyroid hormones may have some nongenomic actions, including plasma and mitochondrial membrane transport, familiarization of actin in astrocytes, and modulation of the activities of several enzymes including type II deiodinase. Such nongenomic effects tend to occur rapidly and, in contrast to nuclear events, T_4 may be as effective as, or more so than, T_3.

Thyroid Function Studies

Thyroid function may be assessed by measuring circulating thyroid hormone levels, serum TSH concentrations, and thyroidal ^{123}I uptake.

Circulating Thyroid Hormone Measurement

Radioimmunoassay remains the standard method for measuring serum total T_4, although isotopic methods may also be used. Previous methods, none of which are used today, include the protein-bound iodine test, the butanol extraction iodine test, and T_4 measurement by column or by competitive protein binding. Although the serum total T_4 measurement generally reflects the functional status of the thyroid gland, many factors may alter total T_4 levels without changing the individual's thyrometabolic status. The most common of these, in an ambulatory individual, is a change in concentration of TBG. High or low TBG states, with their respective increases and decreases in total T_4 concentrations, do not affect metabolic status.

Elevated total T_4 levels may also occur when there is production of endogenous antibodies to T_4, especially in patients with Hashimoto's thyroiditis or other autoimmune disorders, and occasionally in patients with Waldenström's macroglobulinemia associated with a benign monoclonal gammopathy.[21] Another condition of elevated total T_4 level is peripheral resistance to thyroid hormone. Individuals with this

condition may have goiter, and they may be hyperactive.[22] Patients with this disorder are euthyroid. Although rarely found, this disorder has led to inappropriate treatment for hyperthyroidism.

The most widely used measurement of thyrometabolic status is measurement of serum free T_4 by equilibrium dialysis.[23] When measured by the dialysis method, free T_4 is not affected by changes in binding protein concentrations or by nonthyroidal illness. This method is cumbersome and expensive, and it is not routinely performed. Commercial free T_4 levels are most commonly measured by immunoassay techniques, but their reliability is suboptimal because they may be affected by illness or significant changes in binding proteins.[24] The clinical usefulness of free T_4 measurements by any method may be limited.[25]

Although the thyrometabolic status is best reflected by the free T_4 level, from a clinical standpoint, an index or estimate of free T_4 is generally adequate. The free T_4 index is obtained by multiplying the serum total T_4 and an indirect assessment of thyroglobulin. Serum thyroglobulin is generally estimated by one of two methods—the thyroid uptake test and the T_3 uptake test.[25] The thyroid uptake test is directly proportional to thyroglobulin levels in serum, whereas the T_3 uptake test is inversely proportional to thyroglobulin levels.[26] The result, by use of either method, is that variances in serum thyroglobulin levels are largely eliminated, and the calculated free T_4 index accurately reflects actual free T_4 status. Extreme changes in thyroglobulin levels, or the presence of the severe nonthyroidal illness, may result in poor correlation between calculated and measured free T_4 levels.

T_3 is measured in serum by radioimmunoassay. Similar to T_4, T_3 is bound to thyroglobulin, although less avidly. Alterations in thyroglobulin levels result in changes in total T_3 (but not free T_3) concentrations. As with serum T_4, an estimate or index of free T_3 may be obtained by using the same formula employed in calculating the free T_4 index. Because most T_3 is derived from peripheral metabolism of T_4, clinical states or pharmacologic agents that impair normal T_4 metabolism result in lower T_3 levels.

The principles used for obtaining the serum T_3 are to determine the severity of hyperthyroidism and to confirm the diagnosis of suspected thyrotoxicosis in cases in which serum T_4 levels are normal or equivocal. In addition, the serum T_3 may be indicated in evaluating patients with autonomously functioning thyroid adenomas, in whom so-called T_3 toxicosis may be present. Such patients may have normal or borderline elevated serum T_4 levels along with suppressed serum TSH levels.[27]

Serum Thyrotropin Measurement

Until approximately 10 years ago, virtually all clinical TSH assays were performed by radioimmunoassay. By the mid-1980s, many commercial laboratories began using more sensitive immunometric TSH methods with either monoclonal or polyclonal antibodies. Functional sensitivity of these assays represented a 10-fold improvement in sensitivity over radioimmunoassay methods. More recently, nonisotopic immunometric TSH assays have been developed with a chemiluminescent label. These newer assays have a 10-fold greater sensitivity than the early immunometric TSH assays and are 100 times more sensitive than radioimmunoassay methods. These latest TSH assays, with a sensitivity of 0.01 mU/L, are currently termed third-generation TSH assays and represent the most sensitive method for detecting TSH level.[28]

The clinical application of TSH detection may be summarized as follows:

1. *The diagnosis of primary hypothyroidism*. The presence of an elevated TSH is confirmation of primary hypothyroidism. The degree of hypothyroidism may be determined by obtaining a serum T_4 level. TSH levels are also elevated in patients with subclinical hypothyroidism, in which total serum T_4 is normal or borderline low.

2. *Guidance of thyroid hormone replacement therapy*. The goal of treatment of primary hypothyroidism with levothyroxine is normalization of serum T_4 and TSH levels. Current TSH assays may detect over-replacement with levothyroxine because TSH concentrations would be low. Chronic over-replacement with levothyroxine may be associated with cardiac abnormalities, including ventricular arrhythmias and ventricular septal hypertrophy, and bone demineralization, especially in postmenopausal women.[29-31]

3. *Determination of TSH suppression in treating thyroid cancer*. Thyroid-suppressive therapy is part of the routine management of some patients with well-differentiated thyroid carcinoma because growth of these tumors may be TSH responsive. Treatment with levothyroxine is titrated to suppress TSH, while attempting to avoid clinical hyperthyroidism. With few exceptions, suppressed TSH levels, when measured in third-generation assays, correlate with absent TSH response.[32]

4. *Determination of suppressive therapy for nodular goiter*. TSH measurements are useful for following patients with either solitary or multinodular goiter, in whom suppressive thyroid hormone therapy may be used. Although the efficacy of levothyroxine suppression for benign goiter is not uniformly agreed on, it is still frequently used.

5. *Diagnosis of subclinical hyperthyroidism*. Patients with few or equivocal symptoms and signs of hyperthyroidism, with normal or borderline elevated total T_4 and total T_3 levels, and with suppressed serum TSH levels have subclinical hyperthyroidism.[33] Before the development of more sensitive TSH assays, these individuals usually went undiagnosed.

The fact that serum TSH is abnormal in hypothyroidism and hyperthyroidism would seem to make it ideally suited as a screen of thyroid status because, with rare exceptions, a normal TSH level would suggest normal thyroid hormone homeostasis. Experience in ambulatory individuals suggests that a normal TSH virtually excludes the possibility of thyroid dysfunction.[34] In addition, the serum TSH level is more sensitive than the serum T_4 level as a test for thyroid dysfunction because TSH can detect subclinical thyroid disorders in which serum total T_4 (and T_3) is usually normal. As a result of advances in TSH methodology, measurement of circulating thyroid hormones may become assigned to a second line of assessment of suspected thyroid dysfunction. Many investigators believe that the serum TSH is preferable as a screening method for thyrometabolic status.[11,29] Figure 123-2 is an algorithm for the use of TSH level in the evaluation of thyroid function.

Serum Thyroglobulin Measurement

Thyroglobulin is elevated in the serum of patients with nearly all types of thyroid disorders, limiting its usefulness as a diagnostic test. Its greatest clinical value is in managing patients with well-differentiated thyroid carcinoma. An elevated or increasing thyroglobulin level (after initial surgical and ablation therapy) suggests persistence or recurrence of tumor.[35] Thyroglobulin is measured by either radioimmunoassay or immunometric technique. Although antithyroid antibodies may cause interference with accurate thyroglobulin measurement in 10% of individuals, in these patients measurements of thyroglobulin and antithyroglobulin antibodies may be used concurrently to provide information regarding the tumor status.[35]

Thyroid Antibody Status

Circulating antithyroid antibodies, specifically antimicrosomal (AMA) and antithyroglobulin (ATA) antibodies, are usually present in patients with autoimmune thyroid disease.[36] Since the introduction of immunoassay techniques, the term antithyroperoxidase (anti-TPO) has become interchangeable with AMA. AMAs are detectable in more than 90% of patients with chronic autoimmune thyroid disease; nearly 100% of patients with Hashimoto's thyroiditis and more than 80% of patients with Graves' disease have positive titers.[37] Although ATAs are more specific than AMAs, they are less sensitive, and they are not as useful in the detection of autoimmune thyroid disease.[38] Elevated levels of AMA are also frequently positive in various other organ-specific autoimmune diseases, such as lupus, rheumatoid arthritis, autoimmune anemia, Sjögren's syndrome, type 1 diabetes mellitus, and Addison's disease.[39]

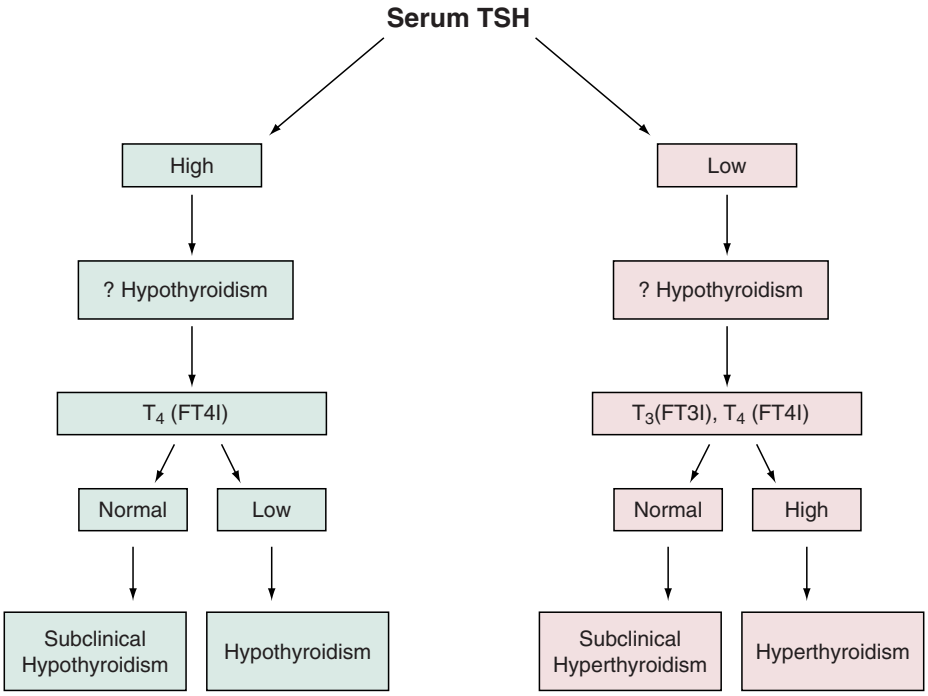

Figure 123-2. Algorithm for using the thyroid-stimulating hormone (TSH) level in the evaluation of thyroid function.

Approximately 15% of adults (especially women) in the United States have elevated AMA titers.[31] Prevalence of positive AMA titers increases with age, as does the incidence of primary hypothyroidism. The presence of a positive AMA titer should alert one to the possibility of hypothyroidism. Individuals with positive AMA and elevated TSH levels, even with normal serum total T_4 levels (subclinical hypothyroidism), had a 3% to 5% per year likelihood of clinical hypothyroidism developing.[40] In this manner, determination of AMA levels may be useful in the diagnosis of individuals with suspected autoimmune thyroid disease and in providing prognostic information when used in conjunction with TSH levels.

Thyroid-Stimulating Antibody Measurement

The immunopathogenesis of Graves' disease was first suspected in the mid-1950s, when it was observed that injecting sera of patients with Graves' disease into rats produced a prolonged uptake of radioactive iodine in the rat thyroid glands. The term long-acting thyroid stimulator (LATS) was coined.[41] Later, LATS was characterized as a 7S immunoglobulin, and in recent years several assays have been developed for the detection of LATS, or thyroid-stimulating antibodies. Two methods are commonly used; one depends on generation of cAMP, and the other is a radioreceptor method that relies on the TSH binding inhibitory properties of the immunoglobulin. The cAMP-generating assay is termed thyroid-stimulating immunoglobulin, and it is detectable in 90% to 95% of hyperthyroid patients with Graves' disease. The other assay detects stimulating and blocking antibodies termed TBII; it is detected in 85% of patients with hyperthyroid Graves' disease.[42] Thyroid-stimulating antibody measurements are not indicated for the routine diagnostic evaluation of suspected Graves' disease, but they may be useful when the diagnosis of Graves' disease is not evident.

Radioactive Iodine Uptake Test

The thyroidal radioactive iodine uptake test is performed by administering an isotope of iodine (usually ^{123}I) orally and measuring the percentage of the ^{123}I trapped by the thyroid gland. The test is usually performed 24 hours after administration of the isotope, although this may be done earlier. Before the development of sensitive and specific assays for thyroid hormones, the radioactive iodine uptake test was used as an adjunct to differentiate hyperthyroid from hypothyroid states, with elevated and low radioactive iodine uptake values implying hyperthyroidism and hypothyroidism. Today, the principal usefulness of this test is in differentiating hyperthyroidism into high-uptake or low-uptake states. Radioactive iodine uptake generally provides an accurate estimate of the thyroid gland's functional activity, provided that the iodide pool has not been expanded by iodine-containing drugs or radiocontrast materials.

Thyrotoxicosis

Thyrotoxicosis is a clinicopathologic and biochemical syndrome that results from exposure to excessive concentrations of thyroid hormones. The syndrome is usually categorized as overt or subclinical. Overt thyrotoxicosis is defined as high serum T_4 and T_3 concentrations and low serum TSH concentrations, whereby most patients have symptoms and signs of this entity. Subclinical thyrotoxicosis is defined as normal serum T_4 and T_3 concentrations and low serum TSH concentrations; most patients in this category have no symptoms or signs of this disorder. Thyrotoxicosis may develop suddenly or gradually, it may be transient or persistent, and it may be of little importance or life-threatening. The diagnosis may be obvious and may be confirmed easily by a few simple laboratory studies, or, conversely, it may be exceedingly difficult, requiring repeated serial investigations or prolonged clinical observation.

Thyrotoxicosis is a common disorder. The overall prevalence rates of overt and subclinical thyrotoxicosis gleaned from clinical surveys in the United States and Europe show an incidence of approximately 0.5 to 1 (United States) and 10 to 40 (Europe) per 1000 people.[43-46] Within these ranges, the rates are generally higher in older individuals, especially women, and seem to be lower in community-based screening programs.

Thyrotoxicosis is about 10 times more common in women than in men, especially with regard to overt thyrotoxicosis. The etiology is Graves' disease in 60% to 85% of patients, toxic nodular goiter in 10% to 30%, and toxic thyroid adenoma in 2% to 20%, with the remainder being represented by some type of thyroiditis.[47,48] The frequency of toxic multinodular goiter and toxic adenoma varies the most, being higher in areas of lower iodine intake.[48] Most individuals with Graves' disease are 30 to 60 years old, whereas individuals with toxic multinodular goiter or toxic thyroid adenoma are 40 to 70 years old.[49]

Pathophysiology

Thyrotoxicosis results from the unregulated release of T_4 and T_3 from the thyroid gland or the ingestion of excessive amounts of T_4, T_3, or both. It may be due to increased T_4 and T_3 synthesis and release because of intrinsic thyroid disease, excessive TSH, or, theoretically, excessive TRH secretion, or the production of other thyroid-stimulating hormones, such as TSH receptor stimulating autoantibody and chorionic gonadotropin. It also may be caused by the destruction of thyroid tissue with the subsequent release of stored T_3 and T_4.

Most patients with thyrotoxicosis have increased production of T_4 and T_3 and increased serum T_4 and T_3 concentrations. The increases in the production rate of T_3 and serum T_3 concentrations are characteristically greater than the increases found in T_4. Some patients with thyrotoxicosis have high serum T_3 concentrations, but normal serum T_4 concentrations. This is called T_3 thyrotoxicosis; in these patients, T_3 production is increased relative to that of T_4, even more than is the case in the usual patient with thyrotoxicosis. There are, however, no characteristic clinical manifestations of T_3. It is most common in patients whose thyrotoxicosis is due to a toxic thyroid adenoma or recurrent Graves' disease, but it may be due to hyperthyroidism of any cause. It is more common in regions where iodine intake is limited, and is rare in the United States. The abnormality responsible is probably relative intrathyroidal iodide deficiency.

Table 123-2 lists the causes of thyrotoxicosis. The cause of thyrotoxicosis can usually be identified with reasonable certainty by history and physical examination. The most important findings to elicit concern are the duration of symptoms, the degree and pattern of thyroid enlargement, and the presence or absence of thyroid pain and tenderness.

Graves' Disease

Graves' disease is the most common cause of thyrotoxicosis. It most commonly occurs in women 30 to 60 years old, but may occur in children and in men and women of any age. It is fundamentally an autoimmune disorder consisting of one or more of the following: hyperthyroidism (with thyrotoxicosis), diffuse thyroid enlargement, infiltrative ophthalmopathy (exophthalmos), localized myxedema (dermopathy), and thyroid acropachy. Toxic goiter may appear alone or may be seen before, during, or after ophthalmopathy develops. Ocular signs range from mild periorbital puffiness to severe extraocular muscle dysfunction with proptosis, corneal ulceration, and optic neuritis and blindness. The extrathyroidal manifestations of Graves' disease can occur in the absence of thyroid disease.

Table 123-2

Etiology of Thyrotoxicosis

- Graves' disease
- Thyroiditis
  - Subacute thyroiditis
  - Painless (silent) thyroiditis
  - Postpartum thyroiditis
  - Radiation-induced thyroiditis
- Exogenous thyrotoxicosis
  - Thyroid hormone–induced thyrotoxicosis
  - Iodine-induced thyrotoxicosis
  - Drug-induced and cytokine-induced thyrotoxicosis
- Toxic uninodular goiter (toxic thyroid adenoma)
- Toxic multinodular goiter
- Autosomal-dominant and sporadic thyrotoxicosis
  - McCune-Albright syndrome
- Ectopic thyrotoxicosis (struma ovarii)
- Thyroid carcinoma
- Thyrotropin-dependent thyrotoxicosis
- Pregnancy-related thyrotoxicosis
  - Gestational thyrotoxicosis
  - Trophoblastic tumors

The major gross anatomic abnormality in patients with Graves' thyrotoxicosis is diffuse thyroid enlargement. Microscopic examination reveals hypertrophy and hyperplasia of the thyroid follicular cells.

The natural history of Graves' thyrotoxicosis varies considerably among different patients. Some patients have a single episode of thyrotoxicosis (and Graves' disease) that subsides spontaneously in a few months or years. Other patients have lifelong thyrotoxicosis, and still others have repeated remissions and relapses. In patients who are treated with an antithyroid drug, the occurrence of a remission of Graves' disease means that prolonged therapy is not required. Although the disease potentially undergoes spontaneous remission, prolonged antithyroid medication, ^{131}I ablation, or surgery is usually necessary to control the thyrotoxicosis.

Well-differentiated thyroid cancer is approximately two times more prevalent in patients with Graves' disease than the general population.[50] Well-differentiated thyroid cancers may contain TSH receptors that can be stimulated by the thyroid-stimulating immunoglobulins. These tumors associated with Graves' disease tend to be larger and more aggressive and have more local invasion with more regional lymph node metastases than cancers occurring without Graves' disease.[51] When a palpable, hypofunctional thyroid nodule is found in a patient with Graves' disease, it has about 45% probability of being a thyroid malignancy.[51] A palpable hypofunctional nodule in a diffuse toxic goiter of Graves' disease should be regarded with great suspicion and, if proven to be malignant, should be managed aggressively.[50]

An antithyroid drug and ^{131}I are the two best treatments for patients with Graves' thyrotoxicosis. Both methods are effective, safe, and relatively inexpensive. They represent treatments for hyperthyroidism, rather than for the autoimmune process itself, although some antithyroid drugs may also have an immunosuppressive effect. The antithyroid drugs used in the United States are methimazole and propylthiouracil (PTU). These drugs inhibit thyroid hormone biosynthesis by inhibiting the oxidation and organification of iodine and the coupling of iodotyrosines, reactions that are catalyzed by thyroid peroxidase.[52] PTU also inhibits the thyroidal and extrathyroidal conversion of T_4 to T_3.[53] Both medications are concentrated in the thyroid, and intrathyroidal concentrations, especially of methimazole, remain high for considerably longer than do serum concentrations.[54]

Methimazole and PTU have immunosuppressive actions that may contribute to the occurrence of remissions of Graves' disease. Both drugs reduce the number of intrathyroidal T cells and inhibit lymphocyte function, including thyroid autoantibody production in vitro, although the latter actions require very high concentrations.[55]

The initial goal of antithyroid drug therapy is to inhibit thyroidal T_4 and T_3 synthesis almost completely. Neither drug has an effect on the release of thyroid hormones stored in the thyroid gland, and their onset of action is relatively slow, depending on the severity of disease, size of the goiter, drug dosage, and timing. Release of intrathyroidal hormone stores, which may be substantial, continues until they are depleted.

Adverse reactions to antithyroid drugs are uncommon and probably occur with equal frequency with either methimazole or PTU. Pruritus, urticaria or other rashes, arthralgia or myalgia, and fever occur in approximately 5% of patients taking either drug.[16] Both drugs may result in dysgeusia. The most dangerous adverse effect is agranulocytosis, which occurs in 0.2% or less of patients taking these medications.[46] Rare adverse effects include aplastic anemia, thrombocytopenia, hepatocellular hepatitis (with PTU), cholestatic hepatitis (with methimazole), and a lupus-like vasculitis (with PTU).[56,57]

Inorganic iodine inhibits thyroid hormone secretion, primarily by inhibiting thyroglobulin proteolysis, and inhibits thyroidal iodine transport, oxidation, and organification.[52] These actions require only a few milligrams of iodine daily, which may be administered in dosages of 5 to 10 drops of a saturated solution of potassium iodide (Lugol's solution) several times daily. This compound is often given in preparation for thyroidectomy, for its antithyroid action and because it reduces thyroid blood flow, theoretically reducing hemorrhage at the time of surgery. Lithium carbonate shows antithyroid action similar to that of inorganic iodine and has proved effective in doses of 300 mg three or four times daily.[58] Cholestyramine, when added to thionamides and

β-blockers, leads to a more rapid decrease in thyroid hormone levels, especially in the first few weeks.[53]

β-Blockers are valuable in the management of hyperthyroidism. Independent of alteration of thyroid function, these drugs minimize many of the sympathetic overdrive symptoms found in hyperthyroidism, such as tachycardia, excessive sweating, nervousness, tremors, and hyperdynamic cardiac activity. They are contraindicated in patients with severe thyrotoxic cardiomyopathy and heart failure, but may benefit patients with atrial fibrillation and heart failure.[59] β-Blockers are useful for reducing symptoms of thyrotoxicosis before and for several weeks after ^{131}I therapy, before subtotal thyroidectomy, in thyroiditis, and in thyroid storm.

In the United States, radioactive iodine is the preferred management for most adults, and for children in cases where thionamides fail or where the patient does not respond well to these medications. The goal of ^{131}I therapy is to reduce the amount of functioning thyroid tissue, and its efficacy is independent of whether a remission of Graves' disease occurs. A major advantage of ^{131}I therapy for patients with Graves' thyrotoxicosis are that usually only a single dose is necessary, it reduces thyroid size to normal in most patients, and it is safe.[60] Thionamides should be stopped for about 3 days before and after radioactive iodine therapy, which is usually effective in 2 to 4 months.

Radioactive iodine usually causes a transient exacerbation of thyrotoxicosis and rarely precipitates thyroid storm. This occurs within 1 to 2 weeks and is caused by radiation-induced thyroiditis; it is a major problem in seriously thyrotoxic or elderly patients. Thyrotoxicosis may also be exacerbated by stopping thionamides before radioactive iodine therapy. Hypothyroidism is not so much a complication of ^{131}I treatment as an almost inevitable consequence of it. Early hypothyroidism, defined as occurring within 1 year after treatment, is caused by the acute destructive effects of ^{131}I. Its frequency ranges from 40% to 80% in patients treated with higher doses of radioactive iodine.[61] Lower doses result in early hypothyroidism less often and persistent thyrotoxicosis more often.

Some physicians have been reluctant to treat young adults and especially adolescents and children with ^{131}I. The reasons are that it might cause thyroidal or other tumors or gonadal damage, or the patient may be pregnant, which is an absolute contraindication to the treatment. ^{131}I crosses the placenta and can destroy the fetal thyroid, and care must be taken to ensure that any woman about to be treated with ^{131}I is not pregnant.

Surgical therapy for thyrotoxic Graves' disease is effective and expeditious. The classic operation for surgical treatment of Graves' disease is subtotal thyroidectomy. Performing this operation either unilaterally or bilaterally, a narrow margin of thyroid tissue in the superolateral aspect of the thyroid where the recurrent laryngeal nerve enters the larynx is preserved by dividing across thyroid tissue at that location.[62] This operation provides the additional benefit of preserving the blood supply to the superior parathyroid gland on one or both sides. The intended goal of subtotal thyroidectomy is to leave 3 to 6 g of thyroid tissue, providing the benefit that patients become euthyroid without hormone replacement therapy.[32] The amount of thyroid tissue remnant preserved directly affects the recurrence rate of hyperthyroidism and the development of long-term hypothyroidism.[63] For patients who have larger remnants preserved, an increased incidence of recurrent hyperthyroidism is noted that can often be treated efficiently with radioactive iodine ablation because of the preserved small amount of residual thyroid tissue.[64] Patients in whom more complete thyroid removal is performed are generally guaranteed to have resolution of their hyperthyroidism; however, long-term hypothyroidism would be the outcome of therapy.[65]

Authors favoring more complete surgical resection of thyroid tissue in the form of near-total thyroidectomy for Graves' disease point out that long-term hypothyroidism may be easily remedied by appropriate hormone replacement therapy, whereas recurrent hyperthyroidism, as a result of leaving behind a larger than intended thyroid remnant, carries with it the need for further treatment.[66] Arguments have been raised in favor of subtotal thyroidectomy as a means by which complications such as permanent hypoparathyroidism and recurrent laryngeal nerve injury may be avoided.[66] The rate of permanent recurrent laryngeal nerve injury approaches zero, however, as does the rate of long-term hypocalcemia, in patients operated by experienced surgeons.[67] The general recommendation for the surgical approach in patients with indications for thyroidectomy is a near-total thyroidectomy, completely eliminating the potential for recurrent or persistent hyperthyroidism.[68,69]

The absolute indications for surgical treatment for Graves' disease are in patients who have significant adverse reactions to thionamide drugs and cannot be appropriately blocked before radioactive iodine administration.[70] Included in this category are patients with very severe skin reactions, hepatic damage, or agranulocytosis. Other indications for surgery in patients with Graves' disease include very large thyroid glands in excess of 75 g and neoplasia either suspected or proven within the setting of diffuse toxic nodular goiter.

Surgical therapy is relatively indicated in young women of childbearing age, who wish to attempt achieving pregnancy or who are in the process of lactating and want to continue to do so. An additional relative indication for surgery as opposed to radioactive iodine is moderate or severe ocular symptoms related to Graves' ophthalmopathy. Ophthalmopathy may be worsened with radioactive iodine administration secondary to the development of tissue edema and worsening of the ocular symptoms.[71]

Patients undergoing surgery for Graves' thyrotoxicosis require preoperative preparation so as not to induce thyrotoxicosis on induction of general anesthesia and subsequent manipulation of the thyroid intraoperatively. This is accomplished by administering antithyroid drug treatment 4 to 6 weeks and inorganic iodine treatment for 7 to 10 days preoperatively. Treatment with a β-adrenergic antagonist drug for several weeks, with or without concomitant inorganic iodide for 10 to 14 days, also has proved to be safe and effective preoperative therapy.[72]

Postoperative problems after thyroidectomy include wound hematoma, transient or permanent hypocalcemia, vocal paresis or paralysis, recurrent thyrotoxicosis, and transient or permanent hypothyroidism. The frequency of nonthyroid complications is low, especially in experienced surgical hands. Transient hypocalcemia may occur secondary to temporary hypoparathyroidism or the healing of thyrotoxic osteopenia. The incidence of wound hematoma is less than 1%, as is the incidence of permanent hypoparathyroidism. In addition, the risk of permanent injury to the recurrent laryngeal nerves in the setting of initial surgery is a fraction of 1%.[74]

Thyroiditis

The thyrotoxicosis that occurs in all forms of thyroiditis is caused by T_4 and T_3 release from thyroglobulin as a result of thyroid inflammation and disruption of thyroid follicles. Because the stores of thyroglobulin are limited, and the new T_4 and T_3 synthesis ceases, thyrotoxicosis is generally transient. Approximately half of patients with subacute or granulomatous thyroiditis have clinical manifestations of thyrotoxicosis, and a significant proportion of the remainder have high serum T_4 and T_3 concentrations.[75] This illness is dominated by nonspecific systemic manifestations of inflammation, including fever, malaise, and myalgias. In addition, local symptoms of thyroid pain and tenderness are also noted that may be severe. Approximately 50% of the patients have a history of a recent upper respiratory tract infection preceding the illness. Any manifestations of thyrotoxicosis together with thyroid pain and tenderness are usually short-lived, lasting approximately 4 to 6 weeks or less. This inflammatory and thyrotoxic phase may be followed by transient hypothyroidism, but permanent hypothyroidism is rare. The thyroid gland is usually firm in consistency and may be quite hard. Cervical lymphadenopathy is uncommon. If pursued, thyroid radionuclide uptake scanning is generally low, and ultrasonography reveals thyroid hypoechogenicity.[76]

Indirect evidence suggests that subacute thyroiditis may be a viral illness, but conclusive proof is lacking. The disorder has been associated with mumps, influenza, adenovirus, and other viral infections, and small epidemics of subacute thyroiditis have been reported.[77]

The inflammatory and the thyrotoxic components of subacute thyroiditis may be so mild and transient that no therapy is required. More often, thyroid pain and tenderness result in sufficient discomfort

to warrant anti-inflammatory therapy. Salicylates in dosages of 2.4 to 3.6 g daily or high doses of other nonsteroidal anti-inflammatory drugs usually provide effective relief. Patients with severe thyroid pain and tenderness and patients who do not improve readily and quickly with one of these medications should be treated with prednisone in a dosage of approximately 40 mg daily for 3 to 4 weeks, after which the dose should be gradually reduced and then discontinued to minimize the likelihood of recurrence. Anti-inflammatory therapy promptly relieves not only the symptoms of subacute thyroiditis, but also probably reduces thyroid hormone release, accelerating recovery from thyrotoxicosis. Thyrotoxicosis itself usually requires no therapy, but in patients in whom thyrotoxic symptoms may become a problem, a β-adrenergic drug may be administered for approximately 1 to 2 weeks.

Thyrotoxicosis, which is caused by thyroid inflammation in the absence of thyroid pain and tenderness, is known as painless or silent thyroiditis and has also been termed subacute lymphocytic thyroiditis. It is an uncommon cause of thyrotoxicosis. In contrast to Graves' disease, it occurs in almost equal proportions of men and women. The thyroid gland is not painful or tender and does not appear enlarged, or perhaps only slightly enlarged. In contrast to subacute thyroiditis, there is generally no history of antecedent upper respiratory tract infection. Generally, no extrathyroidal manifestations of Graves' disease are present in this disorder. When present, the thyrotoxicosis associated with painless thyroiditis lasts 2 to 6 weeks and is followed by either recovery or transient hypothyroidism that lasts an additional 2 to 8 weeks. Approximately half of the patients later had goitrous autoimmune thyroiditis, hypothyroidism, or both. Painless thyroiditis with thyrotoxicosis likely may represent a variant form of chronic autoimmune thyroiditis.

Radiation-induced thyroid follicular necrosis and inflammation occur regularly after ^{131}I therapy and occasionally are sufficiently intense to cause exacerbations of thyrotoxicosis, with or without thyroid pain and tenderness. These complications of ^{131}I therapy are most likely to occur 1 to 2 weeks after treatment, last 1 to 2 weeks, and then subside spontaneously.

Acute suppurative thyroiditis is most commonly caused by *Staphylococcus aureus,* hemolytic streptococcus, or *Streptococcus pneumoniae,* but occasionally is caused by other organisms, such as *Fusobacterium* and *Haemophilus*.[78] This bacterial infection of the thyroid gland may be the result of trauma, hematologic seeding from a distant infected site, or direct extension from a deep cervical infection. The infection is usually localized to a single lobe, and most commonly develops an abscess cavity that may rupture through the glans capsule, extending into the mediastinum or the deep neck spaces along fascial planes. This disorder is especially common in children, in whom a prodrome of malaise is followed by the acute onset of fever, neck pain and tenderness, severe systemic symptoms, and marked leukocytosis. Referred pain to the homolateral mandible and ear may be present, and typically the child fixes the head and neck in a single position similar to torticollis. Localized tenderness over the gland and pain on head movement is commonly noted. This disorder may be difficult to distinguish from subacute nonsuppurative thyroiditis, but the pain is generally more severe, the thyroid hormone levels are generally normal, the erythrocyte sedimentation rate is normal, and the leukocyte count is high. Although the diagnosis is generally made on clinical grounds, needle aspiration of the abscess cavity establishes the bacterial organism causing the infection.

The initial therapy is the administration of high-dose antibiotics, usually penicillinase-resistant penicillin together with a cephalosporin, although antibiotics that cover anaerobic organisms should be considered. Antibiotic therapy that is started before the cavitary phase of the infection may be successful in limiting the progression of infection. When an abscess has been shown on needle aspiration, however, surgical drainage is usually required. Drainage may involve a partial thyroidectomy to remove all evidence of abscess and necrotic tissue and to prevent recrudescence. The neck should be drained externally until purulence ceases, and antibiotics should be continued for at least 2 weeks after the surgical procedure. Thyrotoxicosis during the course of infection and post-treatment hypothyroidism rarely develop in this entity in contrast to other types of inflammatory thyroiditis.

Exogenous Thyrotoxicosis

Thyrotoxicosis may occur as a result of either intentional or accidental administration of inappropriately high doses of thyroid hormone initiated by caregivers or patients themselves. Important clues to the presence of exogenous thyrotoxicosis are the absence of thyroid enlargement or the failure of thyroid enlargement to regress much if the treatment was given for this purpose. This occurs together with normal or low serum T_4 concentrations if the patient is taking T_3 or preparations containing T_3. These patients also show low thyroid radioactive iodine uptake values and low serum thyroglobulin concentrations. Despite the ability of iodine supplementation to decrease the size of goiter and to improve thyroid function in patients living in regions of endemic goiter, it has the potential to induce thyrotoxicosis in these same patients. This usually occurs as a result of a preexisting thyroid abnormality that results in autonomous thyroid secretion—Graves' disease or, more commonly, a nodular goiter—but insufficient iodine intake to permit excessive production of T_4 and T_3. Iodine-induced thyrotoxicosis may also occur in nonendemic goiter regions.[79] Most of these patients have autonomously functioning thyroid tissue, such as a multinodular goiter or a thyroid adenoma, that transports iodide poorly.

Amiodarone, because it contains iodine, can cause iodine-induced thyrotoxicosis in patients with nodular goiter.[80] It may also cause painless thyroiditis that is sufficiently severe to cause thyrotoxicosis, apparently because of a direct toxic effect of the drug or one of its metabolites.

Approximately 2% of patients who are treated with interferon-α have thyrotoxicosis develop, caused mostly by painless thyroiditis, but sometimes by overt Graves' disease.[81] This thyrotoxicosis is generally more subclinical than overt.

Toxic Thyroid Adenoma

Toxic uninodular goiters or toxic thyroid adenoma are autonomously functioning thyroid neoplasms.[82] Among patients with these adenomas, about 20% have overt and 20% have subclinical thyrotoxicosis at the time of diagnosis.[83] Although these neoplasms occur in adults of all ages and occasionally in children, most patients having thyrotoxicosis are in older age groups. Hemorrhagic infarction of a nontoxic thyroid adenoma may result in a transient thyrotoxicosis.[84]

The characteristic finding in patients with toxic thyroid adenoma is a solitary thyroid nodule, which is usually 3 cm or more in diameter. Radionuclide uptake imaging of the thyroid shows intense nuclear uptake in the location of the palpable nodule and nearly complete absence of uptake in the remainder of the thyroid gland.

Management of the toxic adenoma is required unless spontaneous infarction occurs because the resultant thyrotoxicosis is usually permanent. Definitive treatment may be obtained by either surgical resection of the adenoma through thyroid lobectomy or ^{131}I ablative therapy. Definitive ^{131}I therapy carries a slight to moderate risk of either transient or permanent hypothyroidism after completion of therapy, although with appropriate dosing of ^{131}I, this risk may be minimized. Surgical resection may be carried out after 4 to 6 weeks of antithyroid drug administration and a 7- to 10-day course of inorganic iodine therapy in the form of Lugol's solution. Complications after lobectomy are generally exceedingly rare, and the surgical resection is usually definitive, resulting in no evidence of recrudescent thyrotoxicosis or evidence of hypothyroidism.[85]

An alternative approach that is performed more commonly in Europe than in the United States is the percutaneous administration of ethanol directly into the adenoma by use of ultrasound needle guidance. Although there may be some discomfort associated with the injections, long-term complications are rare, and it seems to be a safe procedure done in appropriately experienced hands. The shortcoming of this technique is that it may require multiple treatment sessions. This approach may be desirable in patients who are poor candidates for surgical resection and who wish to avoid exposure to radioactive iodine.

Toxic Multinodular Goiter

Thyrotoxicosis may occur late in the natural history of multinodular goiter, usually in women 50 years old or older. The characteristic

patient with this disorder has a long history of thyroid enlargement with insidious development of subclinical and then subsequently overt thyrotoxicosis. These patients generally do not have ophthalmopathy or localized myxedema and do not undergo spontaneous remissions; thyrotoxicosis generally persists until the autonomous thyroid tissue is destroyed.

^{131}I is generally the treatment of choice for patients with thyrotoxicosis caused by a multinodular goiter, primarily because spontaneous remission does not occur, and because surgical resection generally requires removal of most of the thyroid gland. Patients who are not candidates for radioactive iodine therapy or who refuse this modality may undergo surgery after preparation with an antithyroid medication and inorganic iodine therapy, similar to patients being treated for Graves' disease surgically. The usual operation is either bilateral subtotal thyroidectomy or near-total thyroidectomy with preservation of a 3- to 6-g remnant of thyroid tissue. Surgery is more effective in rapidly reducing the effects of thyrotoxicosis than is ^{131}I, and is attractive in terms of volume reduction of goiter size. Surgery may be more likely to result in long-term or permanent hypothyroidism.[86]

Ectopic Thyrotoxicosis

The only recognized etiologies of thyrotoxicosis secondary to excessive ectopic thyroid hormone secretion are dermoid tumors and teratomas of the ovary. Most of the uncommon patients with substantial amounts of thyroid tissue in their tumors (struma ovarii) who have thyrotoxicosis also have Graves' disease or a multinodular goiter.[87] They have one of the common causes of thyrotoxicosis, affecting the thyroid gland and the ectopic thyroid tissue within the ovarian tumor. In the absence of a functional thyroid gland because of surgical removal or radioactive iodine ablation, the ovarian tumor may be the only source of excessive thyroid hormone in these patients when it contains a toxic thyroid adenoma.[88]

Special Situations in Thyrotoxicosis

Subclinical Thyrotoxicosis

Subclinical thyrotoxicosis is characterized chemically by a normal serum T_4 and T_3 with low TSH concentrations. Most patients with subclinical thyrotoxicosis are asymptomatic, but a few may have nonspecific symptoms or physical signs compatible with overt thyrotoxicosis. The course of this disorder generally varies, with some patients showing resolution within weeks to years, others maintaining a state of subclinical thyrotoxicosis, and a smaller percentage (approximately 10%) showing the development of overt thyrotoxicosis.[89] There seems to be some increased risk of progression to overt thyrotoxicosis in patients who also have thyroid adenomas, multinodular goiters, or history of Graves' disease.[90,91]

If the disorder is due to overt administration of exogenous thyroid hormone, the treatment of choice is to reduce the dosage of thyroid hormone supplementation. If the disorder is secondary to native thyroid disease, treatment is rarely required, primarily because the disorder generally remains asymptomatic. If the disorder is associated with a solitary thyroid adenoma, surgical resection of the adenoma or ^{131}I therapy may be a treatment option. In the setting of multinodular goiter or Graves' disease, patients may be treated with ^{131}I or antithyroid medication or both.

Thyroid Storm

Severe, life-threatening thyrotoxicosis is referred to as thyroid storm. This disorder usually occurs abruptly in a thyrotoxic patient who has had an acute infection or other medical illness, an injury, or a major operation. It may also occur after ^{131}I therapy, discontinuation of an antithyroid medication, or spontaneously.

The index clinical findings in patients with thyroid storm are fever greater than 38.5°C, tachycardia, and generally some type of central nervous system dysfunction. Central nervous system abnormalities include anxiety; agitation and delirium; possibly acute psychosis or seizures; and, as a terminal event, coma. Severe cardiovascular effects, such as congestive heart failure or atrial fibrillation, may also be present.[92]

Determinative laboratory abnormalities in patients with thyroid storm are generally not found. Serum T_4 and T_3 concentrations may be high, but no more so than in ordinary thyrotoxicosis. Serum free T_4 and T_3 concentrations may be more elevated than in less ill patients with thyrotoxicosis.[93]

The treatment of thyroid storm should be directed toward decreasing production of T_4 and T_3, peripheral production of T_3, and the peripheral actions of thyroid hormone, and administering supportive treatment to maintain adequate cardiovascular and central nervous system function. Antithyroid medications should be given in large doses, if necessary by nasogastric tube or rectally. Propranolol given orally or intravenously is the most immediately effective treatment for tachycardia and neuromuscular dysfunction of thyroid storm. Glucocorticoids are usually given in large doses, such as 50 mg of hydrocortisone or 2 mg of dexamethasone intravenously every 8 hours. The rationale for glucocorticoid therapy is that adrenocorticotropic hormone and cortisol secretion may not increase sufficiently to meet cortisol requirements in patients who are quite ill and in whom cortisol degradation is increased. Inorganic iodine should be given orally or by nasogastric tube in a dose of 50 to 100 mg four times daily to inhibit the thyroidal release of T_4 and T_3 after administration of the antithyroid medication. Additional supportive systemic therapy should include treatment to reduce hyperpyrexia and appropriate parenteral fluid and electrolyte support.

Hypothyroidism

Prevalence

Hypothyroidism affects women fourfold to sixfold more often than men and increases with advancing age. The National Health and Nutrition Examination Survey (NHANES III), a sample of 17,353 individuals 12 years old and older representing the geographic and ethnic distribution of the U.S. population from 1988 to 1994, reported a prevalence of clinical hypothyroidism at 0.3% and subclinical hypothyroidism at 4.3%.[94] Thyroid peroxidase antibodies were elevated in 11.3%, and thyroglobulin antibodies were elevated in 10.4%. Thyroid peroxidase antibody positivity was associated with hypothyroidism (and hyperthyroidism), but thyroglobulin antibodies were not.

Etiology

Hypothyroidism can be classified (in order of decreasing frequency) as thyroid (primary), pituitary (secondary), or hypothalamic (tertiary) failure and thyroid hormone receptor resistance. Causes of primary hypothyroidism are listed in Box 123-1. Worldwide, the most common cause of hypothyroidism is iodine deficiency. In iodine-sufficient areas, such as the United States, the most common cause is chronic autoimmune (Hashimoto's) thyroiditis. With current administered doses of ^{131}I for patients with Graves' disease, approximately 90% become hypothyroid by the first year.[95] External neck irradiation in a cohort of 1677 patients with Hodgkin's disease followed for a mean of 9.9 years was associated with a cumulative incidence of hypothyroidism of 30.6%, highlighting the importance of continued clinical and biochemical evaluation.[96]

Clinical Features

The severity of clinical features depends on the severity of thyroid hormone deficiency, rather than etiology. Individuals with mild hypothyroidism with elevated TSH but normal free T_4 (subclinical hypothyroidism) may have few or no symptoms. At the opposite extreme, individuals with severe hypothyroidism may have myxedema coma. Even in individuals with overt biochemical hypothyroidism, severity of symptoms varies. Generally, patients are more symptomatic if hypothyroidism develops rapidly. Elderly patients have fewer symptoms than younger patients.[4] Common symptoms of hypothyroidism, such as fatigue, constipation, dry skin, and cold intolerance, may be mistakenly misinterpreted as part of the normal aging process.

Hypothyroidism should be suspected in individuals with goiter and risk factors (Box 123-2). With the widespread use of the serum TSH assay, hypothyroidism is frequently detected at an earlier stage.

Box 123-1

Causes of Primary (Thyroidal) Hypothyroidism

- Thyroid agenesis
- Destruction of thyroid tissue
  - Surgical removal
  - Therapeutic irradiation (^{131}I or external radiation)
  - Autoimmune (Hashimoto's) thyroiditis
  - Replacement by cancer and infiltrative diseases (amyloidosis, scleroderma)
  - Post-thyroiditis (acute or subacute)
  - Postlaryngectomy alone or with external irradiation
- Inhibition of thyroid hormone synthesis or release or both
  - Iodine deficiency
  - Iodine administration in individuals with underlying autoimmune thyroiditis (amiodarone, iodine-containing expectorants, kelp, SSKI, Lugol's solution, povidone-iodine, iodine-containing radiocontrast agents)
  - Other medications with antithyroid action (methimazole, propylthiouracil, lithium, interferon-α, interferon-β, interleukin-2)
  - Inherited enzyme defects
- Transient
  - After surgery or ^{131}I therapy
  - Postpartum
  - Recovery from thyroiditis
  - Autoimmune (Hashimoto's) thyroiditis
  - After withdrawal of thyroid hormone in euthyroid patients

Modified from Braverman LE, Utiger RD. Introduction to hypothyroidism. In: Braverman LE, Utiger RD, eds. *Werner and Ingbar's the Thyroid: A Fundamental and Clinical Text*. 7th ed. Philadelphia: Lippincott-Raven; 1996:736.

Box 123-2

Risk Factors for Hypothyroidism

- Older age
- Female gender
- Graves' disease
- Hashimoto's disease
- Other autoimmune disease (e.g., type 1 diabetes, adrenal insufficiency, vitiligo)
- Post-thyroidectomy
- Goiter
- Prior neck irradiation
- Laryngectomy alone or with external irradiation
- Drugs: lithium, amiodarone, iodine-containing compounds

Box 123-3

Symptoms and Signs of Hypothyroidism

- General
  - Fatigue, weakness, lethargy
  - Weight gain
  - Cold intolerance
- Eye, ear, nose, throat
  - Macroglossia
  - Hearing loss, vertigo, tinnitus
  - Hoarseness of voice
  - Middle ear effusion
  - Blurred vision
- Central nervous system
  - Slowed speech, movement, and mentation
  - Delayed relaxation phase of deep tendon reflexes
- Gastrointestinal
  - Constipation
  - Anorexia, nausea, vomiting
  - Dysphagia
  - Ascites
- Cardiovascular
  - Bradycardia
  - Diastolic hypertension
  - Pericardial effusion
- Integumentary
  - Dry, rough, thick skin
  - Coarse hair
  - Nonpitting edema (myxedema)
  - Periorbital edema
  - Loss of lateral eyebrows
  - Decreased perspiration
  - Carotenemia
- Musculoskeletal
  - Arthralgia
  - Carpal tunnel syndrome
- Pulmonary
  - Pleural effusion
  - Dyspnea on exertion
- Genitourinary
- Menstrual irregularity (oligomenorrhea, menorrhagia)

Modified from Watanakunakorn, et al. *Arch Intern Med*. 1965;16:183.

The classic symptoms and signs of hypothyroidism are now less frequently found (Box 123-3).

Otolaryngologic Manifestations

Hearing Loss

Hearing loss may be conductive, mixed, or sensorineural in origin. It occurs more frequently and with greater severity in congenital than in adult hypothyroidism.[97] Progressive mixed hearing loss is reported in one half to nearly all children with endemic cretinism,[98] but only approximately 30% to 40% of adults with myxedema have bilateral sensorineural hearing loss. Substantial deafness persists after T_4 therapy in 10% of children with congenital hypothyroidism.[99] Although it mainly occurs in primary hypothyroidism, deafness has been reported with panhypopituitarism.[100]

Children with cretinism may have anomalous ossicles involving any bone in the middle ear, and may have atrophy of the organ of Corti.[101] The tectorial membrane is the first structure to change, followed by degeneration of hair cells at the basal turn of the cochlea, with prolongation of wave I; outer hair cells remain intact.[102] Patients with acquired hypothyroidism who have hearing loss may display similar abnormalities. Only a few adults and almost no children with a well-established hearing loss improve with thyroid hormone therapy.

Some adults with severe myxedema have bilaterally symmetric and progressive sensorineural hearing loss that worsens as the severity of hypothyroidism increases. Conductive losses also may occur as a result of edema of the eustachian tube mucosa.

Vertigo

Vertigo is experienced in two thirds of patients with hypothyroidism. Attacks are usually mild and brief, and are not associated with electronystagmography changes or concurrent hearing loss.[103]

Hoarseness

Gradual and progressive hoarseness occurs in hypothyroidism as a result of mucopolysaccharide infiltration of the vocal cords and possibly tissue edema in the ambiguous nucleus or the cricothyroid muscles.[104] Finding bilaterally edematous, mobile vocal cords should raise the suspicion of hypothyroidism. Hoarseness almost invariably dissipates with thyroid hormone replacement alone.

Goitrous Hypothyroidism

The most common cause of goitrous hypothyroidism in adults in the United States is autoimmune thyroiditis (Hashimoto's disease).[105] Other less common causes are drugs (lithium, amiodarone, sulfisoxazole, large doses of iodides, aminosalicylic acid, interferon, and antithyroid drugs), infiltration of the gland with tumor or inflammatory processes, and familial defects in thyroid hormonogenesis.

Transient Hypothyroidism

Hypothyroidism resulting from Hashimoto's thyroiditis is transient in approximately 10% of cases. Spontaneous remission is associated with the presence of a larger goiter, a high initial TSH level, and a family history of thyroid disease.[106] Autoimmune thyroid dysfunction may become apparent after surgery for Cushing's disease.[107] Smoking increases the metabolic effects of overt and subclinical hypothyroidism in a dose-dependent way.[108]

Excessive Iodine Intake

In iodine-sufficient areas of the world such as the United States, excess iodine intake can cause hypothyroidism in individuals with autoimmune thyroiditis, ^{131}I-treated or surgically treated Graves' disease patients, and patients treated with hemithyroidectomy for thyroid nodules.[46] Hypothyroidism may develop in individuals taking amiodarone, especially individuals with an underlying thyroid abnormality. Thyroid autoantibodies are risk factors for the development of hypothyroidism.[109]

Endemic Goiter

Endemic goiter is uncommon in the United States, but TSH levels are elevated in more than 50% of patients with this disorder, many of whom have no clinical features of thyroid failure.[110]

Familial Hypothyroidism

Kindreds with hypothyroidism usually have inherited defects in hormonogenesis, but rarely may have generalized thyroid hormone resistance.[111]

Nongoitrous Hypothyroidism

Nongoitrous hypothyroidism is most often caused by thyroid disease—most commonly autoimmune diffuse thyroid atrophy and management of Graves' disease with ^{131}I, thionamides, or thyroidectomy—but may be caused by pituitary and hypothalamic disorders.[112,113]

Hypothyroidism after Laryngectomy and Radiotherapy

Hypothyroidism may start within 4 months of surgery, but may not become clinically apparent for 1 year.[114] In a multivariate analysis of 221 patients, risk factors for hypothyroidism were high radiation dose, combination of radiotherapy and cervical surgery, time from therapy, and no shielding of the midline neck. Patients receiving irradiation to the neck—particularly patients undergoing neck dissections or total laryngectomy—should have routine thyroid function studies performed every 3 to 6 months the first year after management and annually thereafter.

Pituitary and Hypothalamic Hypothyroidism

Pituitary and hypothalamic hypothyroidism is uncommon and includes large pituitary tumors and pituitary apoplexy. Hypothalamic causes include lymphocytic hypophysitis, tumors, infarctions, trauma, and infiltrative diseases.

Subclinical Hypothyroidism

Diagnosis

The diagnosis of subclinical hypothyroidism is made by an elevated TSH with normal free T_4 or a free T_4 index. Clinically, there are no or a few mild symptoms of hypothyroidism. Some patients may have goiter, especially when antithyroid antibodies are positive.

Prevalence

In population-based studies, the prevalence of subclinical hypothyroidism is approximately 8% in women and 3% in men, higher in whites (versus blacks), and in individuals older than 75 years (versus 55 to 64 years).[115,116] NHANES III reported that in the 16,533 participants who reported no known thyroid disease, goiter, or thyroid hormone use, 4.3% had subclinical hypothyroidism.[94]

Natural History

Progression from subclinical to overt hypothyroidism is not inevitable in all individuals. In a large population study in Great Britain followed for more than 20 years, women with an elevated TSH and elevated antithyroid antibody titers progressed to overt hypothyroidism at a rate of 4.3% per year, greater than women with elevated TSH alone (2.6% per year) or antithyroid antibodies alone (2.1% per year).[46] In this study, there was no increase in all-cause or cardiac mortality in participants with subclinical hypothyroidism at baseline. In a natural history study of 26 elderly subjects with subclinical hypothyroidism, one third had overt biochemical hypothyroidism develop within 4 years of follow-up. Progression to overt hypothyroidism occurred in subjects with an initial TSH greater than 20 μIU/mL and in 80% with high-titer AMAs greater than 1:1600.[78] In a more recent prospective study of 82 women with subclinical hypothyroidism, the cumulative incidence of overt hypothyroidism was 43% of women with TSH 6 to 12 μIU/mL and 77% with TSH greater than 12 μIU/mL, and no women with TSH less than 6 μIU/mL followed for 10 years. TPO antibody positivity was associated with development to overt hypothyroidism.[117]

Effects on Lipids, Hypothyroid Symptoms, and Mood

Treatment of subclinical hypothyroidism prevents progression to overt hypothyroidism. Other potential benefits of therapy include improvement in hypothyroid symptoms and mood, improvement in lipid profile, and decrease in thyroid volume by 20%.

The relationship between subclinical hypothyroidism and effects of lipid profile are inconsistent. Some studies show that individuals with subclinical hypothyroidism have an atherogenic lipid profile (higher total cholesterol, low-density lipoprotein [LDL] cholesterol, lipoprotein (a), and apolipoprotein B, and lower high-density lipoprotein [HDL] cholesterol) than euthyroid individuals,[118-120] but other studies show no difference.[121-123] In the largest cross-sectional study of 25,862 subjects in the United States, subjects with subclinical hypothyroidism had a higher total cholesterol than the euthyroid group (223 mg/dL versus 216 mg/dL; $P < .003$), and had higher LDL cholesterol than the euthyroid group (144 mg/dL versus 140 mg/dL; $P < .003$).[43] In small studies, T_4 therapy of patients with subclinical hypothyroidism leads to an increase in HDL cholesterol[124] and decrease in total and LDL cholesterol.[119,121,125] Meta-analysis of T_4 therapy in subclinical hypothyroidism shows a 10 mg/dL decrease in LDL cholesterol and 7.9 mg/dL decrease in total cholesterol concentration.[126] Greater improvement was seen in subjects with baseline total cholesterol levels 240 mg/dL or greater versus subjects with total cholesterol less than 240 mg/dL.

T_4 therapy leads to significantly increased cardiac output, increased mean arterial pressure, and decreased systemic vascular resistance.[127] In a survey of postmenopausal women, subclinical hypothyroidism is associated with an increased risk of myocardial infarction (odds ratio 2.3) and aortic atherosclerosis (odds ratio 1.7), but no subsequent risk of myocardial infarction at 4.6 years of follow-up.[128] It is unclear whether

thyroid hormone therapy in subclinical hypothyroidism improves cardiac mortality.

Subclinical hypothyroidism is associated with depression in some,[129] but not in all, studies.[130] Similarly, some randomized placebo-controlled trials in subjects with subclinical hypothyroidism show improvement in symptoms of hypothyroidism,[131,132] but one reported no difference.[133] Depressed patients with subclinical hypothyroidism have a poorer response to antidepressant therapy than depressed patients who are euthyroid.[134] Individuals with subclinical hypothyroidism show impairment in neurobehavioral scores, such as memory, which improve with T_4 therapy. Treatment of subclinical hypothyroidism is reasonable in pregnant women to avoid impairment of intellectual potential of the fetus,[135] and in women who have ovulatory dysfunction with infertility.[131]

Treatment

Patients with subclinical hypothyroidism and positive TPO antibodies, with TSH greater than 10 μIU/mL, are prone to have overt hypothyroidism develop and should receive thyroid hormone replacement. Risk of overt disease may depend on the etiology of subclinical hypothyroidism. Individuals receiving radioactive iodine therapy or high-dose external radiation are likely to progress to overt hypothyroidism and should probably be treated with thyroid hormone. Others who may benefit include patients with goiter, individuals with elevated total or LDL cholesterol, pregnant women, and women with ovulatory dysfunction with infertility.[131] Small doses are usually needed (e.g., 50 to 75 μg daily), with monitoring of TSH and dose titration in 4 to 6 weeks until TSH is normalized. Patients with coronary artery disease should begin at a lower dose of 25 μg daily.

Nonthyroidal Illness

TSH elevation may occur in conditions other than hypothyroidism, including recovery from nonthyroidal illness, also known as sick euthyroid syndrome. Hospitalized and critically ill patients may have a decreased free T_4 index or free T_4 concentration by radioimmunoassay. When measured by equilibrium dialysis, however, free T_4 is normal or elevated. In one report, serum total T_4 levels less than 3 μg/dL were associated with mortality in 84% of critically ill patients.[136] In a randomized prospective study, T_4 treatment in an intensive care unit did not alter mortality.[137]

Laboratory Diagnosis

There is a set-point for optimal serum free T_4 concentration in a given individual. Because of the log-linear relationship between serum TSH and T_4 concentrations, small changes in free T_4 from this set-point lead to relatively large changes in TSH by negative feedback. The most sensitive test for hypothyroidism is an elevated serum TSH. In subclinical hypothyroidism, TSH is elevated, whereas free T_4 remains normal. If the disorder progresses to overt hypothyroidism, free T_4 is decreased (see Table 123-3 for thyroid function tests in hypothyroidism and other low T_4 syndromes). Radioactive iodine uptake is not indicated for the diagnosis of hypothyroidism because low, normal, or high values can occur, depending on the cause.

Central hypothyroidism caused by pituitary or hypothalamic disorder shows a low free T_4 and TSH that is low, inappropriately normal, or mildly elevated. TRH stimulation testing of TSH has traditionally been used to distinguish between these two entities, but is unreliable.[138,139]

Management

Oral synthetic levothyroxine (T_4) is the therapy of choice to correct hypothyroidism. Gastrointestinal absorption is 81%.[140] Because the plasma half-life of T_4 is long (6.7 days),[141] once-daily administration leads to stable T_4 and T_3 concentrations. Numerous brand name (Euthyrox, Levothroid, Levoxyl, Synthroid, Unithroid) and generic preparations of T_4 are available, each in varying doses with different color-coded tablets to allow dose titration at precise increments. In one study, comparison of two brand-name and two generic preparations in the United States showed bioequivalency.[142] Equivalent doses of different formulations of T_4 are generally interchangeable.

Table 123-3

Thyroid Function Tests in Hypothyroidism and Other Low Thyroxine Syndromes

	Free	T_4T_3	TSH
Hypothyroid hypothyroidism			
Primary hypothyroidism			
Overt	Low	NL/low	High
Subclinical	NL	NL	High
Pituitary (secondary)	Low	Low/NL	NL/low/slightly high
Hypothalamic (tertiary)	Low	Low/NL	NL/low/slightly high
Euthyroid hypothyroidism			
Low TBG	NL	Low	NL
Nonthyroidal illness			
Mild	NL	Low	NL
Severe	Low	Low	NL

NL, normal; T_4T_3, thyroxine and triiodothyronine; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone.

One should repeat the TSH level 4 to 6 weeks after switching, however.[140,143]

In young, otherwise healthy adults, a full replacement dose can be prescribed at 1.6 μg/kg/day for nonmalignant conditions. In patients with known coronary disease, patients with multiple coronary risk factors, and elderly patients who may have previously silent coronary disease, conservative therapy with an initial dose of 25 μg/day is advisable. One should repeat TSH measurements with dose adjustment every 4 to 6 weeks (four to six half-lives of T_4) until serum TSH normalizes or cardiac symptoms arise that may limit therapy to less than a full replacement dose. In individuals without residual thyroid tissue, such as a patient with thyroid cancer who has undergone thyroidectomy, the mean T_4 dose required to achieve euthyroidism is generally higher (2.1 μg/kg/day).[144]

In patients with primary hypothyroidism, the goal of therapy is to normalize the serum TSH level. After initiation or change in dose of T_4, TSH should be repeated in 4 to 6 weeks. Ultimately, TSH measurements are needed annually, or sooner depending on clinical status. In individuals with central hypothyroidism, free T_4 alone should be normalized, also with repeat measurements free in 4 to 6 weeks. The use of the patient's symptoms to judge the adequacy of T_4 dosing is frequently inaccurate. When subjective symptoms were used to determine T_4 dosing, patients chose a dose that produced mild hyperthyroidism.[145]

Potential adverse effects of overtreatment with an excessive dose of T_4 include bone loss in postmenopausal, but not premenopausal, women,[146,147] and in elderly patients, cardiac complications, including cardiac arrhythmias, heart failure, angina, and myocardial infarction.[88] Occasionally, patients have manic behavior develop with T_4 replacement. Severe behavioral manifestations of T_4 therapy for juvenile hypothyroidism are uncommon, but mild behavioral symptoms and poorer school achievement may occur in approximately 25% of patients, who represent the most severe cases at the time of diagnosis.[148]

Poor patient compliance with taking thyroid hormone leads to therapeutic failure. Alternatives to a daily regimen include twice-weekly[149] or once-weekly regimens.[150] These probably should not be used in patients with coronary artery disease. Numerous medications may bind to and interfere with intestinal absorption of T_4, including aluminum hydroxide,[151] ferrous sulfate,[152] sucralfate,[153] cholestyramine,[94] and calcium carbonate.[139] Thyroid hormone administration should be separated in time from these medications by a few hours.

Thyroid hormone preparations that contain T_3 alone (e.g., Cytomel), combinations of T_4 and T_3 (e.g., Thyrolar), and desiccated thyroid extract (Armour Thyroid) should not be used for the treatment of hypothyroidism. Serum T_3 levels fluctuate widely because of the short half-life of T_3. Temporary T_3 therapy is indicated in patients with thyroid cancer who have undergone thyroidectomy and await thyroid remnant ablation to shorten the period of hypothyroidism. T_3 can be discontinued 2 weeks before ^{131}I.[154] In addition, temporary switching from T_4 to T_3 therapy in individuals undergoing thyroid hormone withdrawal whole-body scanning also reduces the period of hypothyroidism.

Thyroid hormone requirements are increased during pregnancy by an average of 45%[151] because of an estrogen-mediated increase in TBG, fetal T_4 transfer, and increased T_4 clearance. Serum TSH should be obtained at each trimester of pregnancy. If the T_4 dose requires adjustment, TSH should be remeasured in 4 weeks with further dose adjustment as necessary. After delivery, the prepregnancy T_4 dose should be resumed.[155] A hypothyroid woman starting oral estrogen therapy such as with hormone replacement therapy may also require a higher thyroid hormone dose,[156] and TSH should be obtained 3 months after initiation of estrogen to determine whether a dose increase is needed. Increases in dose may be necessary in patients who start medications that increase T_4 catabolism (e.g., phenytoin, carbamazepine, phenobarbital, rifampin), have gastrointestinal malabsorption, or have nephrotic syndrome develop.[157] A decreased thyroid hormone dose requirement may be seen in elderly patients[158] and in women with breast cancer treated with androgens.[159]

Myxedema Coma

Myxedema coma, a thyroid emergency, is a late manifestation of hypothyroidism, and is characterized by coma or precoma with severe clinical manifestations of myxedema. An underlying infection or other precipitating cause of the myxedema coma is usually present. Patients characteristically have extreme hypothermia, bradycardia, pleural and pericardial effusions, hyponatremia, hypoventilation, respiratory acidosis, and hypoxia. Focal or generalized seizures typically precede the coma.

Management is with large doses of intravenous T_4 and hydrocortisone. Although management is usually instituted without laboratory confirmation, the clinical diagnoses should be certain before large doses of intravenous T_4 are given. Supportive care includes intubation and assisted ventilation, cautious warming, support of blood pressure, and management of infection. Mortality rates are approximately 50% and depend on the severity of superimposed illnesses and underlying coronary heart disease.

Surgery

With mild to moderate hypothyroidism, postoperative complications are frequent, but are rarely serious or lasting, and necessary surgery should not be postponed simply to replete thyroid hormone.[160] This is not true for patients with severe myxedema, who should be given preoperative thyroid hormone except in the most urgent surgical emergencies or uncontrolled ischemic heart disease.

In euthyroid patients, total T_4 tends to decrease in the first postoperative day, then spontaneously normalizes in 7 days; the same occurs in hypothyroid patients, but T_4 levels do not normalize until thyroid supplementation is given.[161] It is usually unnecessary to increase the postoperative dose of T_4, however, and almost never necessary to use parenteral T_4, unless the patient cannot take medication by mouth for several weeks. If parenteral T_4 therapy is necessary, half of the patient's usual daily T_4 dose is ordinarily given, and attention is given to the patient's cardiac status because this therapy may precipitate cardiac arrhythmias, angina, and heart failure.

Cardiac and pulmonary problems are prevalent in elderly patients with hypothyroidism. The prevalence of coronary artery disease is high, but the diagnosis is easily overlooked because patients often have few symptoms because of their low metabolic activity or because they fail to communicate their symptoms clearly.[103] Pericardial effusions are often apparent and rarely cause tamponade. Patients with severe hypothyroidism also respond poorly to stress by having hypothermia and hypotension develop, and they do not have tachycardia develop in response to infection or hypotension. Shock responds poorly to vasoconstrictors.

Patients with severe hypothyroidism often display upper airway obstruction caused by oropharyngeal muscle dysfunction and tissue infiltration with mucopolysaccharide.[162] They may have central sleep apnea, insensitivity to hypoxia and hypercarbia,[163] and respiratory muscle weakness,[164] changes that often lead to severe postoperative hypoxia and difficulty in weaning from a ventilator. These defects are reversible with T_4 replacement therapy, but obstructive sleep apnea may be more closely related to obesity and male gender than hypothyroidism.[165]

A von Willebrand's disease–like defect is common in hypothyroidism, which may lead to bleeding.[166,167] It resolves promptly with infusion of desmopressin, suggesting that it acts through the β-adrenergic receptor.[89] This can be helpful in the acute management of bleeding. It resolves permanently with T_4 therapy.[168,169]

CHAPTER ONE HUNDRED AND TWENTY-FOUR

Management of Thyroid Neoplasms

Stephen Y. Lai

Susan J. Mandel

Randal S. Weber

Key Points

- The incidence of thyroid cancer is increasing, although this increase may be mostly attributable to improved detection, rather than a true increase in incidence. Women are three times more likely than men to develop differentiated thyroid cancers, and two times more likely to have anaplastic thyroid cancer.
- Exposure to ionizing radiation remains the only well-established environmental risk factor for thyroid cancer.
- The molecular mechanism underlying thyroid carcinoma is incompletely understood, but seems to involve rearrangements of RET or activation of BRAF in papillary thyroid carcinoma, and is associated with RAS mutations in follicular thyroid carcinoma. RET mutations are frequently identified in medullary thyroid carcinoma, and specific point mutations are linked to the aggressiveness of the disease.
- A rational and systematic approach to the management of a thyroid nodule is necessary to classify benign versus malignant disease appropriately.
- Fine-needle aspiration cytology (FNAC) has become the procedure of choice in the evaluation of thyroid nodules. Increasingly, FNAC is being performed with ultrasound guidance to improve diagnostic accuracy and yield.
- The role of ultrasonography is evolving in the management of thyroid carcinoma. Ultrasonography may improve the detection of early, clinically occult cervical lymph node metastasis and alter surgical management. Additionally, ultrasonography is useful in the evaluation of the thyroid bed and neck in patients with a history of thyroid cancer who present with new neck masses or increasing thyroglobulin levels.
- Intraoperative ultrasound may be useful for the resection of radiographically identified, nonpalpable lesions within the thyroid bed or nodal basins.
- Central compartment (level VI) neck dissection should be considered in patients with papillary thyroid carcinoma and suspected Hürthle cell carcinoma. Elective neck dissection is not recommended.
- Bilateral central compartment neck dissection should be performed in patients with medullary thyroid carcinoma. Lateral neck dissection should be considered depending on the disease burden.
- In patients with well-differentiated thyroid carcinoma and cervical metastases, a comprehensive neck dissection should be performed, rather than selective cervical lymph node excision or "berry-picking."
- New surgical approaches provide improved cosmesis and decreased postoperative discomfort. These minimally invasive techniques use endoscopic instruments to provide surgeons with improved visualization of critical anatomic structures, such as the superior and recurrent laryngeal nerves.
- Patients with thyroid carcinomas require long-term follow-up and monitoring. The extent of this workup depends on the risk classification of each individual patient.

Thyroid neoplasms represent almost 95% of all endocrine tumors, although they are relatively uncommon, accounting for approximately 2.5% of all malignancies. In 2008, the estimated annual incidence of thyroid cancer in the United States was 37,340 cases, and approximately 1590 patients (4.3%) were expected to die from thyroid cancer.[1] The incidence of thyroid cancer has been steadily increasing over the past 2 decades, and thyroid cancer has the fastest increasing incidence of all major cancers in the United States (approximately 4% increase annually).[2] Mortality rates have remained stable, and evidence suggests that improved detection has primarily contributed to the increased incidence.

Although thyroid cancer is rare, the incidence of thyroid nodules is significantly greater, affecting approximately 4% to 7% of the U.S. population.[3] Although most of these nodules are benign, the challenge

is to identify the approximately 5% of patients with a malignant lesion. A subset of thyroid cancers is particularly aggressive with a potential for devastating morbidity. No reliable indicators are currently available to determine which patients will develop aggressive or recurrent disease, although risk categories based on clinical and pathologic criteria yield important prognostic information.

Most thyroid carcinomas are well-differentiated tumors of follicular cell origin.[4,5] These lesions are histologically defined as papillary carcinoma, follicular carcinoma, and Hürthle cell carcinoma. A survey of 53,856 patients described the overall incidence of thyroid cancer in the United States.[5] In this report, approximately 79% of cases were papillary carcinoma, 13% were follicular carcinoma, and approximately 3% were Hürthle cell carcinoma. A small proportion (6%) of patients with these lesions have a family history of thyroid cancer. Medullary thyroid carcinoma (MTC), which arises from parafollicular C cells, accounts for about 4% of thyroid carcinomas. Approximately 30% of patients with these lesions have a strong genetic contribution. Anaplastic carcinomas, lymphoma, and metastatic disease constitute a small portion of thyroid malignancies.

The most common presentation of a thyroid cancer is the development of a thyroid mass or nodule. Assessment of the lesion requires a careful history, physical examination, fine-needle aspiration cytology (FNAC), and perhaps imaging studies. With correct diagnosis and management, most patients with well-differentiated thyroid carcinomas have an excellent prognosis. The 10-year disease-specific mortality rate is less than 7% for papillary thyroid cancer and less than 15% for follicular thyroid cancer.[5-8] Controversy regarding the treatment of thyroid carcinomas and the extent of thyroidectomy to be performed arises because of the indolent course of most thyroid cancers. Interventions for thyroid cancer have been difficult to evaluate because of the long follow-up and the large number of patients needed to determine differences in survival. The morbidity that may accompany any aggressive intervention needs to be balanced with the generally good prognosis of patients with thyroid cancer.

In this chapter, we begin with a review of the surgical anatomy and embryology of the thyroid gland. After a brief overview of the present understanding of pathogenetic mechanisms leading to thyroid cancer, we review risk factors and staging of thyroid carcinomas. We describe an algorithm for the evaluation of a thyroid nodule, and assess available diagnostic tools, including the increasing role of ultrasound examination in the evaluation of the thyroid and neck. A review of the different forms of thyroid cancer, ranging from well-differentiated carcinomas to anaplastic and other, less common malignancies, is followed by a discussion of surgical management and postoperative adjuvant treatment.

Surgical Anatomy and Embryology

The thyroid medial anlage derives from the ventral diverticulum of the endoderm from the first and second pharyngeal pouches at the foramen cecum.[9,10] The diverticulum descends from the base of the tongue to its adult pretracheal position through a midline anterior path with the primitive heart and great vessels during weeks 4 to 7 of gestation. The proximal portion of this structure retracts and degenerates into a solid, fibrous stalk; persistence of this tract can lead to the development of a thyroglossal duct cyst with variable amounts of associated thyroid tissue. The lateral thyroid primordia arise from the fourth and fifth pharyngeal pouches and descend to join the central component. Parafollicular C cells arise from the neural crest of the fourth pharyngeal pouch as ultimobranchial bodies and infiltrate the upper portion of the thyroid lobes.[11] Because of the predictable fusion of the ultimobranchial bodies to the medial thyroid anlage, C cells are restricted to a zone deep within the middle to upper third of the lateral lobes.[12]

The thyroid gland is composed of two lateral lobes connected by a central isthmus, weighing 15 to 25 g in adults. A thyroid lobe usually measures about 4 cm in height, 1.5 cm in width, and 2 cm in depth. The superior pole lies posterior to the sternothyroid muscle and lateral to the inferior constrictor muscle and the posterior thyroid lamina. The inferior pole can extend to the level of the sixth tracheal ring. Approximately 40% of patients have a pyramidal lobe that arises from either lobe or the midline isthmus and extends superiorly (Fig. 124-1).

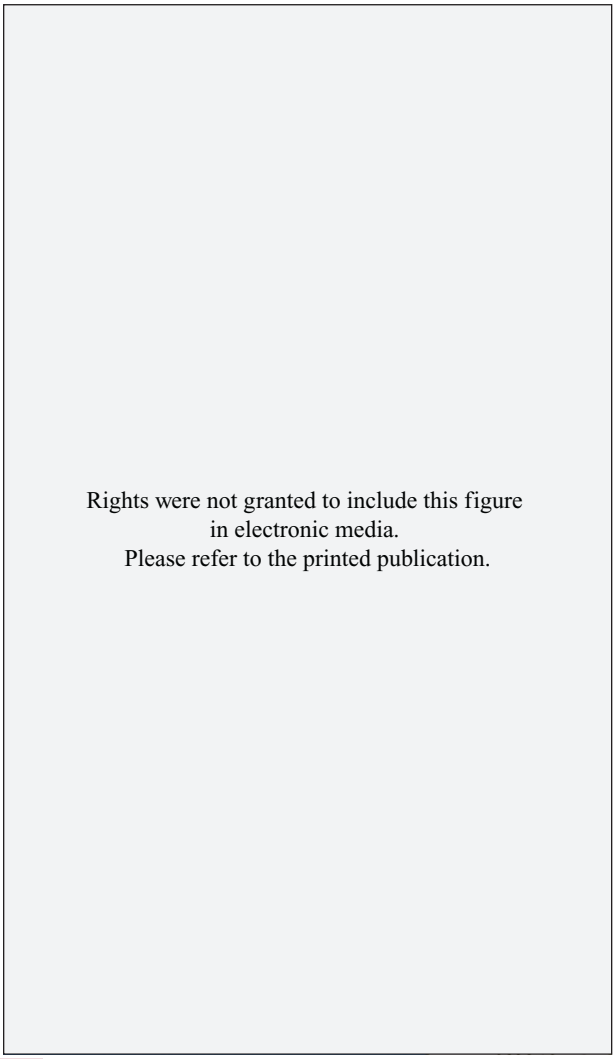

Figure 124-1. A and **B,** A pyramidal lobe of the thyroid gland may occasionally arise from the isthmus. This portion of the thyroid gland can be quite variable in size and should be carefully identified and removed with the surgical specimen. (***B,*** *From Lai SY, Weber RS. Thyroid cancer. In Ensley JF, Gutkind JS, Jacobs JR, et al, eds.* Head and Neck Cancer: Emerging Perspectives. *San Diego: Academic Press; 2002:419.*)

The thyroid is enclosed between layers of the deep cervical fascia in the anterior neck. The true thyroid capsule is tightly adherent to the thyroid gland, and continues into the parenchyma to form fibrous septa separating the parenchyma into lobules. The surgical capsule is a thin, filmlike layer of tissue lying on the true thyroid capsule. Posteriorly, the middle layer of the deep cervical fascia condenses to form the posterior suspensory ligament, or Berry's ligament, connecting the lobes of the thyroid to the cricoid cartilage and the first two tracheal rings.

Blood supply to and from the thyroid gland involves two pairs of arteries, three pairs of veins, and a dense system of connecting vessels within the thyroid capsule. The inferior thyroid artery arises as a branch of the thyrocervical trunk (Fig. 124-2). This vessel extends along the anterior scalene muscle, crossing beneath the long axis of the common carotid artery to enter the inferior portion of the thyroid lobe. Although variable in its relationship, the inferior thyroid artery lies anterior to the recurrent laryngeal nerve (RLN) in approximately 70% of patients.[13] The inferior thyroid artery is also the primary blood supply for the parathyroid glands.

The superior thyroid artery is a branch of the external carotid artery and courses along the inferior constrictor muscle with the superior thyroid vein to supply the superior pole of the thyroid. This vessel

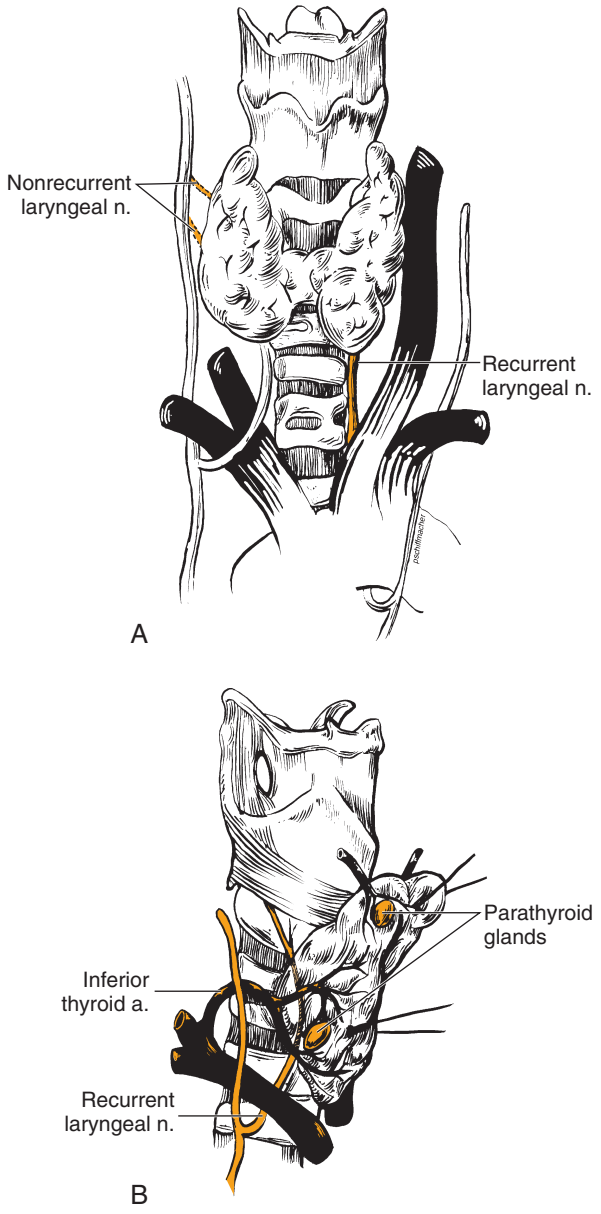

Figure 124-2. **A** and **B,** The thyroid gland is intimately associated with several important adjacent structures. In the lateral view, the gland has been mobilized medially to show the recurrent laryngeal nerve and its close relationship to the inferior thyroid artery. This relationship can vary between sides within a patient. See the text for details. The potential courses of the nonrecurrent laryngeal nerve have been indicated *(dashed lines)*. *(From Lai SY, Weber RS. Thyroid cancer. In Ensley JF, Gutkind JS, Jacobs JR, et al, eds.* Head and Neck Cancer: Emerging Perspectives. *San Diego: Academic Press; 2002:420.)*

lies posterolateral to the external branch of the superior laryngeal nerve (SLN) as the nerve courses through the fascia overlying the cricothyroid muscle. Care should be taken to ligate this vessel without damaging the SLN. Occasionally, arteria thyroidea ima may arise from the innominate artery, carotid artery, or aortic arch, and supply the thyroid gland near the midline.[13] Many veins within the thyroid capsule drain into the superior, middle, and inferior thyroid veins, leading to the internal jugular or innominate veins. The middle thyroid vein travels without an arterial complement, and division of this vessel permits adequate rotation of the thyroid lobe to identify the RLN and parathyroid glands.

The RLN provides motor supply to the larynx and some sensory function to the upper trachea and subglottic area. Careful management of thyroid carcinomas requires a thorough knowledge of the course of the RLN (see Fig. 124-2). During development, the RLN is dragged caudally by the lowest persisting aortic arches. On the right side, the nerve recurs around the fourth arch (subclavian artery), and on the left side, the nerve recurs around the sixth arch (ligamentum arteriosum).

The right RLN leaves the vagus nerve at the base of the neck, loops around the right subclavian artery, and returns deep to the innominate artery back into the thyroid bed approximately 2 cm lateral to the trachea. The nerve enters the larynx between the arch of the cricoid cartilage and the inferior cornu of the thyroid cartilage. The left RLN leaves the vagus at the level of the aortic arch, and loops around the arch lateral to the obliterated ductus arteriosus. The nerve returns to the neck posterior to the carotid sheath and travels near the tracheoesophageal groove along a more medial course than the right RLN. The nerve crosses deep to the inferior thyroid artery approximately 70% of the time and often branches above the level of the inferior thyroid artery before entry into the larynx.[14] The RLN travels underneath the inferior fibers of the inferior constrictor (i.e., the cricopharyngeus muscle) and behind the cricothyroid articulation to enter the larynx. A "nonrecurrent" laryngeal nerve may rarely occur on the right side and enters from a more lateral course (see Figs. 124-2 and 124-4C).[15] Typically, an aberrant retroesophageal subclavian artery (arteria lusoria) or other congenital malformation of the vascular rings is present.

The SLN arises beneath the nodose ganglion of the upper vagus and descends medial to the carotid sheath, dividing into an internal and external branch about 2 cm above the superior pole of the thyroid.[16] The internal branch travels medially and enters through the posterior thyrohyoid membrane to supply sensation to the supraglottis. The external branch extends medially along the inferior constrictor muscle to enter the cricothyroid muscle. Along its course, the nerve travels with the superior thyroid artery and vein. The nerve typically diverges from the superior thyroid vascular pedicle about 1 cm from the thyroid superior pole.

Proper management of the parathyroid glands during thyroid surgery is crucial to avoid hypoparathyroidism. The superior parathyroid glands are derived from the fourth pharyngeal pouch, whereas the inferior counterparts originate from the third pharyngeal pouch. The parathyroid glands are caramel-colored glands weighing 30 to 70 mg. The subtle distinction of tan and yellow coloration permits differentiation from adjacent fatty tissue, although with trauma, the glands can become mahogany in color. Four parathyroid glands exist in 80% of patients, and at least 10% of patients have more than four glands.[17] The glands are situated on the undersurface of the thyroid gland in predictable locations. The superior glands are located at the level of the cricoid cartilage, usually medial to the intersection of the RLN and the inferior thyroid artery.[17] The inferior glands are more variable in location than their superior counterparts. These glands may be on the lateral or posterior surface of the lower pole. In many patients, the position of the parathyroid glands on one side is similar to the other side and should be a useful guide.

Molecular Basis for Thyroid Neoplasms

Numerous genetic and molecular abnormalities have been described in thyroid neoplasms. Similar to other head and neck cancers, an accumulation of genetic alterations seems to be required for progression to a thyroid carcinoma. The specific molecular events and their order continue to be defined.

Alterations noted in the development of thyroid carcinomas include changes in total cellular DNA content. The loss of chromosomes, or aneuploidy, has been noted in 10% of all papillary carcinomas, but is present in 25% to 50% of all patients who die as a result of these lesions.[18] Similarly, the development of follicular adenomas is associated with a loss of the short arm of chromosome 11 (11p), and transition to a follicular carcinoma seems to involve deletions of 3p, 7q, and 22q.[19,20] Loss of heterozygosity involving multiple chromosomal regions is much more prevalent in follicular adenomas and carcinomas than in papillary carcinomas.[21]

Several oncogenes, altered genes that contribute to tumor development, have been identified in early thyroid tumor progression. Mutations in the thyroid-stimulating hormone (TSH) receptor and G-protein

mutations are found in hyperfunctioning thyroid adenomas.[22] These changes can lead to the constitutive activation of cell-signaling pathways, such as the adenylate cyclase–protein kinase A system. Point mutations of the G-protein Ras found in thyroid adenomas and multinodular goiters are believed to be an early mutation in tumor progression.[23] Somatic Ras mutations are associated with follicular adenomas, and to a lesser extent with follicular carcinomas. The resultant activation of the phosphatidylinositol 3′-kinase (PI3K) signal transduction pathway and AKT, a PI3K-related serine/threonine kinase, also seems to be specific to follicular thyroid carcinoma.[24]

Other genetic changes have also been associated with certain types of thyroid carcinoma. Mutations within the mitogen-activated protein kinase (MAPK) pathway are involved in malignant transformation to papillary thyroid cancer. Additionally, rearrangements or activation of RET or BRAF proto-oncogenes, which can also activate MAPK, are often found in papillary thyroid cancer.[25] Gene rearrangements involving tropomycin-receptor-kinase A, also known as neurotropic tyrosine receptor kinase type 1, a receptor for nerve growth factor, are associated with papillary carcinomas. Mutations in MET/hepatic growth factor have been linked to papillary and poorly differentiated thyroid carcinomas. Other growth factors, such as fibroblast growth factors, epidermal growth factor, and vascular endothelial growth factor, and their cognate receptors may have increased expression in thyroid tumors and contribute to tumor progression.

Different types of galectin, a carbohydrate-binding protein, seem to be differentially expressed in papillary and anaplastic carcinomas, and may be useful in distinguishing benign from malignant thyroid lesions.[26,27] In Cowden's disease (familial goiter and skin hamartomas), inactivating mutations of the phosphatase and tensin homolog (PTEN) gene have been identified.[28] PTEN may inhibit phosphorylation and kinase activity of AKT1, leading to the development of follicular adenomas and carcinomas.[24] The PAX8/PPARγγ1 (peroxisome proliferator-activated receptor) rearrangement seems to be unique to follicular thyroid carcinoma.[29] PAX8 is expressed at high levels during thyroid development, and the PAX/PPARγγ1 gene product seems to function as a dominant negative, blocking the activation of wild-type PPARγγ1. Mutations in the tumor-suppressor gene *p53,* a transcriptional regulator, seem to be involved in insular thyroid carcinomas and the progression from papillary to anaplastic carcinoma.[30,31]

The role of mutations of the RET oncogene in the development of papillary carcinoma and MTC has been extensively studied.[32] Located on chromosome 10, RET codes for a transmembrane tyrosine kinase receptor that binds glial cell line–derived neurotrophic factor. During embryogenesis, RET protein is normally expressed in the nervous and excretory systems. Abnormalities in RET expression result in developmental defects, including the disruption of the enteric nervous system (Hirschsprung's disease). Presumably, RET gene mutations result in the activation of the Ras/JNK/ERK1/2 signaling pathways, resulting in further genomic instability and prevention of entry into the apoptotic pathway.[33]

MTC and pheochromocytoma arise from neural crest cells containing RET point mutations. These point mutations have been well documented in patients with familial MTC, multiple endocrine neoplasia (MEN) type IIA, and MEN IIB.[34,35] The aggressiveness of the MTC that develops is linked to the specific RET mutation identified.[36] Somatic mutations of RET are also found in approximately 25% of sporadic MTCs. Many of these are identical to the codon 918 mutation found as a germline mutation in MEN IIB, although other codons are more infrequently involved.[37]

Rearrangements of the RET gene by fusion with other genes also create transforming oncogenes. Although more than 10 rearrangements have been described, three oncogene proteins—RET/PTC1, RET/PTC2, and RET/PTC3—account for most of the rearrangements found in papillary thyroid cancers, and are more frequently associated with childhood thyroid carcinomas.[38] Not all patients with papillary carcinomas express a RET/PTC gene however.[39] There are marked geographic differences, and the gene rearrangement is strongly associated with radiation exposure. After the Chernobyl nuclear disaster, 66% of the papillary thyroid cancers removed from affected patients had RET/PTC1 or RET/PTC3 rearrangements.[40] The RET/PTC3 rearrangement is most commonly associated with a "solid" follicular variant of papillary thyroid carcinoma, whereas RET/PTC1 is associated more often with the classic or diffuse sclerosing variants of papillary thyroid cancer.[41,42]

Risk Factors and Etiology

Although the specific molecular events related to the development of thyroid carcinomas remain incompletely defined, several patient and environmental factors have been closely examined. Women are three times more likely than men to develop differentiated thyroid cancer, and two times more likely to have anaplastic thyroid cancer. The median age at diagnosis is 47 years, with a peak in women at 45 to 49 years and in men at 65 to 69 years.[2] Epidemiologic studies have not shown a clear association between dietary iodine and thyroid carcinomas.[43] Also, there does not seem to be a simple relationship between benign goiter and well-differentiated thyroid carcinomas. Although papillary thyroid carcinomas are not associated with goiter, follicular and anaplastic thyroid carcinomas occur more commonly in areas of endemic goiter. Additionally, two particularly important risk factors, exposure to radiation and a family history of thyroid cancer, have been studied extensively.

Exposure to ionizing radiation increases patient risk for the development of thyroid carcinoma.[44,45] Ionizing radiation exposure is the only established environmental risk factor for thyroid cancer.[46] Low-dose ionizing radiation treatments (<2000 cGy) were used in the treatment of "enlarged thymus" to prevent "sudden crib death," enlarged tonsils and adenoids, acne vulgaris, hemangioma, ringworm, scrofula, and other conditions. The risk increases linearly from 6.5 to 2000 cGy, and typically has a latency period lasting 10 to 30 years. Although higher doses of ionizing radiation typically lead to the destruction of thyroid tissue, patients with Hodgkin's disease who receive 4000 cGy also have a higher incidence of thyroid cancer. Palpable thyroid nodularity may be present in 17% to 30% of patients exposed to ionizing radiation.[47] A patient with a history of radiation exposure who presents with a thyroid nodule has a 50% chance of having a malignancy.[48] Of these patients with thyroid cancer, 60% have cancer within the nodule, and the remaining 40% have cancer located in another area of the thyroid. The thyroid carcinoma tends to be papillary and frequently multifocal. There is also a higher risk of cervical metastases.

Similarly, patients exposed to radiation from nuclear weapons and accidents have a higher incidence of thyroid cancer. Children near the Chernobyl nuclear power facility had a 60-fold increase in thyroid carcinoma after the nuclear accident in 1986.[49] Most of these children were infants at the time of the accident, and many of these cases developed without the typical latency period. The thyroid gland seems to be particularly vulnerable to ionizing radiation in children and yet relatively insensitive in adults. In the life span study of atomic bomb survivors in Hiroshima and Nagasaki, the risk of thyroid cancer was associated with patient age at the time of the bombings.[50] The risk was greatest for individuals younger than 10 years, and no increased incidence of thyroid cancer was seen in individuals older than 20 years at the time of exposure.

Finally, familial and genetic contributions need to be fully evaluated. A patient with a family history of thyroid carcinoma may require specific diagnostic testing. Approximately 6% of patients with papillary thyroid cancer have familial disease. Papillary thyroid cancer occurs with increased frequency in certain families with breast, ovarian, renal, or central nervous system malignancies.[51] Gardner's syndrome (familial colonic polyposis) and Cowden's disease are associated with well-differentiated thyroid carcinomas. Patients with a family history of MTC, MEN IIA, or MEN IIB warrant evaluation for the RET point mutation.

Tumor Staging and Classification

Numerous staging and classification systems have been devised to stratify patients with thyroid carcinomas. These classifications have identified key patient-specific and tumor-specific characteristics that predict patient outcome. Risk-grouping has been used to focus aggressive treatment for high-risk patients and to avoid excessive treatment and its potential complications in patients with a lower risk for tumor recurrence or tumor-related death.

TNM Classification

The American Joint Commission on Cancer (AJCC) and the Union Internationale Contre le Cancer (UICC) adopted a tumor-node-metastasis (TNM) classification system (Table 124-1). In this system, patient age at presentation influences the clinical staging of a thyroid carcinoma. Of patients with stage I disease, 82% had a 20-year survival of nearly 100%, whereas the 5% of patients with stage IV disease experienced a 5-year survival of only 25%.[52]

AMES

In the AMES system, patient *a*ge, the presence of *m*etastases, *e*xtent of tumor invasion, and tumor *s*ize were used to stratify patients into low-risk and high-risk groups (Table 124-2). Low-risk patients were young (men, <41 years old; women, <51 years old) without distant metastases and all older patients without extrathyroidal papillary carcinoma, without major invasion of the tumor capsule by follicular carcinoma or with a primary tumor less than 5 cm in diameter. In a review of 310 patients from 1961-1980, low-risk patients (89%) had a mortality of 1.8% compared with a mortality rate of 46% in high-risk patients (11%). Recurrence in low-risk patients was 5%, and in high-risk patients was 55%.[53] In DAMES, nuclear DNA content was added to the AMES system to improve risk-stratification for papillary thyroid carcinoma.[54]

AGES and MACIS

In the original AGES system, age at diagnosis, histologic tumor grade, extent of disease at presentation, and tumor size were used to calculate a prognostic score.[55] Because of the infrequent practice of tumor grading, a more recent modification of the system eliminated histologic tumor grade and incorporated metastasis and extent of resection. The MACIS system accounts for *m*etastasis, *a*ge at diagnosis, *c*ompleteness of surgical resection, extrathyroidal *i*nvasion, and tumor *s*ize.[56] The MACIS score is calculated as follows:

$$3.1\,(\text{patient age} < 40\text{ years}) \text{ or } 0.08 \times \text{age (patient age} \geq 40\text{ years)} + 0.3 \times \text{tumor size (in cm)} + 1\,(\text{if extrathyroidal extension}) + 1\,(\text{if incomplete resection}) + 3\,(\text{if distant metastases})$$

Patients were stratified by their prognostic scores into four groups with statistically significant differences in 20-year disease-specific mortality.

Other risk-classification systems with similar diagnostic criteria have been described.[57-59] Although numerous multivariable prognostic scoring systems have been developed, none is universally accepted. Additionally, none of these classifications has shown clear superiority, and application of these systems to a single population has shown incompatible findings compared with the original studies.[59,60] These systems do not apply to patients with poorly differentiated and more aggressive thyroid carcinomas.

Nevertheless, some general conclusions can be drawn from these studies regarding the prognosis of patients with well-differentiated thyroid carcinomas. Low risk for tumor recurrence and disease-specific mortality is noted in patients who are younger at diagnosis, have smaller primary tumors that lack extrathyroidal extension or regional/distant metastases, and have complete gross resection of disease at the initial surgery. Delay in treatment negatively affects prognosis. The most significant overall indicator of a poor prognosis is distant metastases, however, especially to bone.[6] Although a single risk-classification strategy is unavailable, these criteria should guide physicians to use therapeutic strategies that are directed toward the particular disease and risk for an individual patient, rather than applying a general treatment strategy for all patients with a particular form of thyroid carcinoma. More recent management guidelines from the American Thyroid Association (ATA) have recommended use of the AJCC/UICC staging system for all patients with differentiated thyroid cancer.

Evaluation of a Thyroid Nodule

The incidence of thyroid nodular disease is quite high, spontaneously occurring at a rate of 0.08% per year starting in early life and extending into the eighth decade.[47] Although thyroid nodules represent a wide spectrum of disease, most are colloid nodules, adenomas, cysts, and focal thyroiditis, with only a few (5%) being carcinoma. With a lifetime incidence of 4% to 7%, the annual incidence of thyroid nodules in the United States is about 0.1%, which is approximately 300,000 new nodules each year.[61,62] Most of these nodules are benign and do not require removal. With approximately 37,000 new thyroid cancers each year, about 1 in 20 new thyroid nodules contains carcinoma, however, and approximately 1 in 200 nodules is lethal. The challenge in treating patients with thyroid nodules is to identify the patients with malignant lesions and to balance the potential morbidity of treatment with the aggressiveness of their disease.

Clinical Assessment: History and Physical Examination

Numerous findings should raise suspicion of malignancy in a patient presenting with a thyroid nodule. Younger and older patients are more likely to have a malignant thyroid nodule. Patients younger than 20 years have an approximately 20% to 50% incidence of malignancy when presenting with a solitary thyroid nodule.[63] Nodular disease is more common in older patients, usually men older than 40 years and women older than 50 years. Although children may present with more advanced disease and even cervical metastases, malignancy in older patients has a considerably worse prognosis. Men often have more aggressive malignancies than women, but the overall incidence of thyroid nodules and malignancy is higher in women.

A family history of thyroid carcinoma should be carefully evaluated. Similarly, any history of medullary carcinoma, pheochromocytoma, or hyperparathyroidism should raise suspicion for the MEN syndromes. Gardner's syndrome (polyposis coli) and Cowden's disease also have been associated with well-differentiated thyroid carcinomas. As described previously, a history of previous head and neck radiation exposure significantly increases the risk of malignancy in patients with a thyroid nodule.

When evaluating the patient, rapid growth of a preexisting or new thyroid nodule is concerning, although the change may represent hemorrhage into a cyst. Throat or neck pain is rarely associated with carcinoma, but frequently occurs with hemorrhage into a benign nodule. Patients should be carefully questioned regarding any compressive or invasive symptoms, such as voice change, hoarseness, dysphagia, or dyspnea. The clinician should not rely on these findings alone, however, because unilateral vocal cord paralysis can be present without voice change or swallowing difficulties. Although most patients with thyroid cancer are euthyroid at presentation, symptoms of hyperthyroidism and hypothyroidism should be explored. Patients with large carcinomas that have replaced a significant portion of the normal thyroid gland may be hypothyroid, and patients with Hashimoto's thyroiditis may develop lymphoma. Although the history alone cannot determine the presence of thyroid cancer, important historic features are associated with thyroid carcinoma, and should not be discounted even if diagnostic tests indicated a benign lesion.

The physical examination of a patient with a thyroid nodule begins with careful palpation of the thyroid to assess the lesion. One should determine whether the lesion is solitary or the dominant nodule in a multinodular gland, although the risk of carcinoma in either setting is the same.[3,48] Having the patient swallow assists in the examination because nonthyroid pathology does not typically elevate with the thyroid during swallowing. Palpable nodules are typically 1 cm or larger. Smaller nodules can be found incidentally on radiographic studies for other reasons and may be monitored. Lesions greater than 1 cm in size warrant a complete workup. The firmness of the nodule may be associated with an increased risk of carcinoma by twofold to threefold.[64] Nodules greater than 2 cm in diameter and solid lesions have an increased incidence of harboring carcinoma. The evaluation of larger lesions also requires more caution because the rate of false-negative results during FNAC also increases.[65]

Potential substernal extension can be estimated by the relationship of the inferior aspect of the mass to the clavicle. Potential thoracic inlet obstruction owing to a substernal goiter can be assessed with Pemburton's maneuver. The patient raises his or her arms over the head, and positive findings of obstruction include subjective respiratory discomfort or venous engorgement, resulting in facial suffusion.

Table 124-1

TNM Staging for Thyroid Cancer

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor = 2 cm in greatest dimension, limited to thyroid
T2	Tumor >2 cm and = 4 cm in greatest dimension, limited to thyroid
T3	Tumor >4 cm in greatest dimension, limited to the thyroid *or* Any tumor with minimal extrathyroid extension (e.g., extension to sternothyroid muscle or perithyroid soft tissues)
T4a	Tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve
T4b	Tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels
All Anaplastic Carcinomas Are Considered T4 Tumors	
T4a	Intrathyroidal anaplastic carcinoma—surgically resectable
T4b	Extrathyroidal anaplastic carcinoma—surgically unresectable
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)
N1b	Metastasis to unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Vascular invasion
Lymph node metastasis
Distant metastasis
Histologic type
- Tall-cell variant of papillary carcinoma
- Follicular carcinoma
- Hürthle cell carcinoma

*At initial presentation.

Radiographic studies are more definitive in determining substernal involvement.

Further assessment of the patient may reveal the extent of involvement of a thyroid lesion. Palpable cervical nodes adjacent to the thyroid nodule increase the suspicion for malignancy, and may be the only presenting sign of a thyroid carcinoma. Adenopathy may be present, however, in a patient affected by Hashimoto's thyroiditis, Graves' disease, or infection.[66,67] Large lesions can potentially shift the larynx and trachea within the neck. The mobility of the nodule relative to the laryngotracheal complex and adjacent neck structures should be evaluated. Malignant lesions are more likely to be fixed to the trachea, esophagus, or strap muscles.

All patients with a thyroid lesion should have a complete vocal cord examination. Extension into the thyroid cartilage and larynx may result in a complete vocal cord paralysis that is clinically silent. Laryngoscopy should be performed to assess vocal cord motion.

Despite the importance of the initial clinical assessment, the history and physical examination are unreliable in predicting carcinoma. Many of the clinical signs of malignancy are manifest late in the course of disease. Additionally, many of these same findings may be caused by events associated with benign disease (e.g., hemorrhage into a benign nodule). The clinical assessment should provide a justification and a context for the interpretation of diagnostic studies, such as FNAC. Of particular note would be any patient and thyroid nodule features that might be concerning for aggressive carcinoma behavior (Table 124-3).

Diagnostic Studies

Laboratory Studies

Most patients who present with a thyroid nodule are euthyroid. The finding of hypothyroidism or hyperthyroidism tends to shift the workup away from thyroid carcinoma to a functional disorder of the thyroid gland, such as Hashimoto's thyroiditis or a toxic nodule.[68] Although many thyroid hormone tests are available, few are needed in the initial patient evaluation. TSH measurement serves as an excellent screening test. Full thyroid function tests can be performed if the TSH level is abnormal.

Measurement of thyroglobulin is generally not performed initially because thyroglobulin is secreted by normal and malignant thyroid tissue, and it is not recommended in the 2006 ATA guidelines.[69] Levels of thyroglobulin cannot differentiate between benign and malignant processes, unless levels are extremely high, as in metastatic thyroid cancer. Antithyroglobulin antibodies can also interfere with the assay. Thyroglobulin levels may be useful in studying patients who have undergone total thyroidectomy for well-differentiated thyroid cancer.

Serum calcitonin levels are not a typical initial test for patients with a thyroid nodule, unless the patient has a family history of MTC or MEN II. If FNAC shows or is suspicious for MTC, however, calcitonin levels should be obtained. In addition, if the patient has RET oncogene mutations, the possibility of a coexisting pheochromocytoma should be evaluated with abdominal magnetic resonance imaging (MRI) and a 24-hour urine collection to measure metanephrines and catecholamines (total and fractionated). The serum calcium level should be measured to exclude hyperparathyroidism.

Fine-Needle Aspiration Cytology

FNAC has become the procedure of choice in the evaluation of thyroid nodules.[69] The findings are highly sensitive and specific, although the accuracy of FNAC is related to the skill of the aspirator and the experience of the cytopathologist.[70] The procedure is minimally invasive and may be performed quickly with little patient discomfort. In contrast to large-bore needle biopsies such as the Tru-cut or Vim-Silverman needle, there are fewer complications. With the advent of this technique, the number of patients requiring surgery has decreased by 35% to 75%, and the cost in managing patients with thyroid nodules has been substantially reduced.[71-73] Also, the yield of malignancies has almost tripled in patients who have had thyroid surgery after FNAC.[73,74] The accuracy of FNAC diagnosis of papillary carcinoma is 99% with a false-positive rate of less than 1%.[75]

FNAC should be one of the initial steps in the surgical evaluation of a thyroid nodule. Approximately 15% of all aspirates are inadequate or nondiagnostic, largely because of the sampling from cystic, hemorrhagic, hypervascular, or hypocellular colloid nodules. Repeat aspiration of such a nodule is crucial because a nondiagnostic finding should never be interpreted as a negative finding for carcinoma. Surgical diagnoses after repeated nondiagnostic aspirations revealed malignant nodules in 4% of women and 29% of men.[76] Nodules that are difficult to localize and nodules that have yielded nondiagnostic aspirates on previous attempts may benefit from ultrasound-guided aspiration. FNAC is increasingly being performed with ultrasound guidance to improve diagnostic accuracy and yield. Cystic nodules with multiple nondiagnostic FNAC studies require close observation or surgical excision. Also, surgery should be more strongly considered for a solid nodule that is cytologically nondiagnostic.[69]

Successful FNAC categorizes a nodule into the following groups: benign, malignant, or suspicious. In 60% to 90% of nodules, FNAC reveals a benign or "negative" diagnosis. The likelihood of malignancy (false-negative rate) is 1% to 6%.[71,77] The diagnosis of malignancy, particularly papillary (including follicular variant), medullary, and anaplastic carcinomas and lymphomas, can be determined in about 5% of nodules. The likelihood of a false-positive finding is less than 5%.[71,77] Frequently, false-positive results occur because of difficulties in interpreting cytology in patients with Hashimoto's thyroiditis, Graves' disease, or toxic nodules. A benign cytology is a macrofollicular lesion or a colloid adenomatous nodule. The remaining "suspicious" samples are composed of lesions that contain abnormal follicular epithelium with varying degrees of atypia. This finding needs to be evaluated in the context of patient history and physical findings that may be suggestive of malignancy. A complete report of the FNAC detailing specimen adequacy and pathologic findings is crucial, and efforts have been made to standardize this information.[78,79]

Follicular neoplasms cannot be classified by FNAC alone. The presence of hypercellular, microfollicular arrays with minimal colloid increases the concern for carcinoma. The differentiation between follicular adenoma and follicular carcinoma depends on the histologic finding of capsular or vascular invasion, which requires evaluation of the entire thyroid nodule. Occasionally, patients with a diagnosis of follicular neoplasm on FNAC have an iodine-123 (^{123}I) thyroid scan. If the suspicious nodule is "cold," surgery is indicated. If the nodule is hyperfunctioning compared with the surrounding thyroid, surgery can be avoided. Overall, 20% of nodules diagnosed as follicular neoplasms by FNAC contain thyroid carcinomas.[80]

Similarly, Hürthle cell (oxyphilic) neoplasms can be difficult to evaluate. The presence of Hürthle cells in an aspirate may indicate an underlying Hürthle cell adenoma or carcinoma, but these cells can also be present in thyroid disorders, such as multinodular goiter and Hashimoto's thyroiditis. Carcinomas can be found in 20% of nodules identified as follicular and oxyphilic neoplasms.[81] Because of the risk of underlying carcinoma in these cases, surgery is recommended.

Imaging

Ultrasonography is tremendously useful and sensitive. These studies detect nonpalpable nodules and differentiate between cystic and solid nodules. Ultrasound detection of subcentimeter nodules is valuable because most are nonpalpable and not detected by other imaging modalities, even though they may harbor malignant disease. In patients with a neck that is difficult to examine (e.g., a patient with a history of head and neck irradiation), ultrasonography can also clarify findings. These studies provide key baseline information regarding nodule size and architecture. Ultrasonography is also a noninvasive and inexpensive method for following changes in the size of benign nodules. Ultrasonography can identify hemiagenesis and contralateral lobe hypertrophy, which may be misdiagnosed as a thyroid nodule. The utility of ultrasound studies has expanded from detection of thyroid nodules to examination of nodal basins for locoregional staging, intraoperative localization of nonpalpable lesions, and routine follow-up examination of the neck after thyroidectomy. Ultrasound examinations are being performed in the office by appropriately trained surgeons. Additionally, ultrasound guidance of FNAC has become integral to the initial workup, resulting in improved target selection and diagnostic yield.

A systematic ultrasound examination can be extremely valuable in the assessment of a patient with thyroid cancer, including color and power Doppler examination of the thyroid, specific nodules, and lymph nodes.[82,83] Examination of the nodal basins should be bilateral and include the jugular, submandibular, supraclavicular, paratracheal, and suprasternal regions. These studies may detect cervical nodes that may contain early clinically occult metastatic disease that would not otherwise have been included in a surgical dissection.[69,84] Characteristics of lymph nodes suspicious for metastatic deposits include loss of the fatty hilum, increased vascularity, rounded node configuration, hypoechogenicity of a solid nodule, and microcalcifications.[83,85,86] Ultrasonography is also useful in the evaluation of cervical lymph nodes in patients with a history of thyroid cancer who present with adenopathy or increasing thyroglobulin levels. These studies are not useful, however, in the evaluation of substernal extent of disease or the involvement of adjacent structures.

In a patient with multiple thyroid nodules, FNAC should be performed in conjunction with a diagnostic ultrasound study. Aspiration of the largest or "dominant" nodule alone may miss a thyroid malignancy. In the presence of two or more thyroid nodules larger than 1 to 1.5 cm, nodules with a suspicious ultrasound appearance should be aspirated preferentially. If none of the nodules has suspicious ultrasound characteristics, and multiple sonographically similar coalescent nodules are present, aspiration of the largest nodule only is reasonable.[69]

Currently, there is no role for ultrasonography in screening asymptomatic patients for thyroid nodules. Preoperative ultrasound evaluation of the lateral cervical lymph nodes is recommended for all patients with papillary and Hürthle cell thyroid cancer before initial thyroidectomy because operative management may be altered in 20% of patients.[87] In addition, intraoperative ultrasound examination may be useful in the localization of nonpalpable lesions in the thyroid bed or nodal metastases.

Computed tomography (CT) and MRI scans are usually unnecessary in the evaluation of thyroid tumors except for fixed or substernal lesions. Although these studies are not as effective as ultrasonography in the evaluation of thyroid nodules, they are more reliable in evaluating the relationship of the thyroid lesion to adjacent neck structures, such as the trachea and esophagus. These studies are useful in determining substernal extension, identifying cervical and mediastinal adenopathy, and evaluating possible tracheal invasion.[88] Anatomic imaging should be obtained when visceral compartment invasion is suspected and for localization in patients with nodal disease. Also, CT or MRI can supplement ultrasound imaging, which cannot visualize the regions behind the sternum, trachea, and esophagus. Caution must be exercised in the use of iodine-containing contrast material in patients with multinodular goiter if a hyperthyroid state is suspected, and in patients with well-differentiated thyroid cancer. In the latter group, iodinated contrast media preclude the use of postoperative radioactive iodine therapy for 2 to 3 months. Finally, MRI is more accurate than a CT scan in distinguishing recurrent or persistent thyroid tumor from postoperative fibrosis.

Thyroid Isotope Scanning

Radionuclide scanning with ^{123}I or technetium 99m (^{99m}Tc) sestamibi assesses the functional activity of a thyroid nodule and the thyroid gland. Nodules that retain less radioactivity than the surrounding thyroid tissue are termed "cold," nonfunctioning, or hypofunctional. These cold nodules are thought to have lost functions of fully differentiated thyroid tissue and to be at increased risk of containing carcinoma. In a meta-analysis of patients with scanned nodules that were surgically removed, 95% of all nodules were cold.[66,67] The incidence of malignancy in cold nodules was 10% to 15% compared with only 4% in hot nodules.

^{99m}Tc scanning tests iodine transport only, but can be performed in 1 day and involves less radiation exposure than ^{123}I. Cold nodules identified with this test are also cold with iodine scanning. Any "hot" nodules require ^{123}I scanning for confirmation, however. ^{123}I scanning tests transport and organification of iodine. This test is more expensive

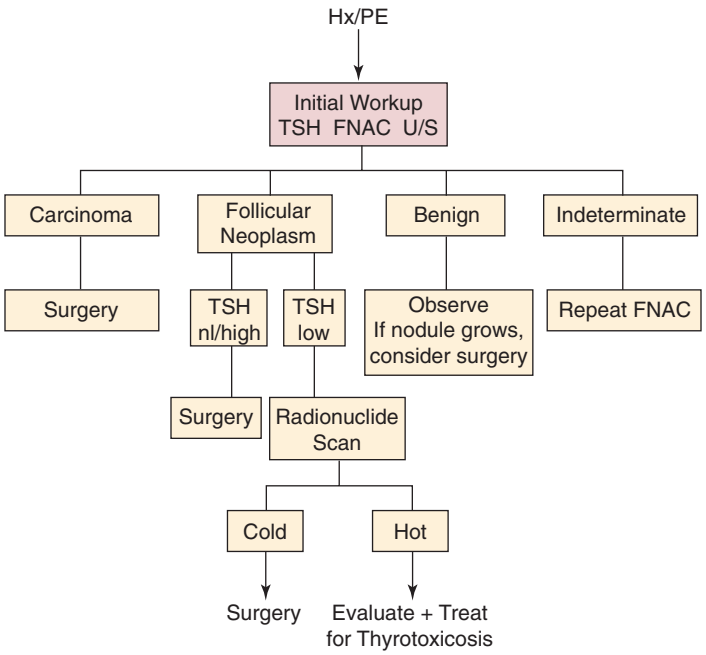

Figure 124-3. Algorithm for a rational approach to the evaluation and management of a thyroid nodule. Surgery is indicated for well-differentiated thyroid carcinoma. Anaplastic carcinoma and lymphoma require additional workup and assessment to determine treatment. Ultrasound guidance should be considered for repeat FNAC after an indeterminate result. FNAC, fine-needle aspiration cytology; Hx/PE, history/physical examination; TSH, thyroid-stimulating hormone; U/S ultrasonography.

and requires 2 days to complete. Cold lesions can be more difficult to visualize because of overlying thyroid tissue and glandular asymmetry, although oblique views during scanning can improve detection. In addition, ^{99m}Tc does not penetrate the sternum, and is not useful in confirming substernal extension.

With the evolution of FNAC, radionuclide scanning is not routinely performed in the evaluation of a thyroid nodule. More frequently, "cold" nodules are detected in patients during evaluation for hyperthyroid disorders. Patients who present initially with a thyroid nodule, however, and are found to be hyperthyroid on preliminary thyroid function testing should have radionuclide scanning to differentiate between a toxic nodule and Graves' disease and a nonfunctioning nodule. Also, after indeterminate FNAC, ^{123}I thyroid scan should be considered. Surgical treatment should be contemplated if a concordant autonomously functioning nodule is not seen.[69]

Rational Approach to Management of a Thyroid Nodule

Numerous diagnostic algorithms have been proposed for the evaluation of a thyroid nodule (Fig. 124-3).[70,89] Evaluation generally begins with a thorough history and physical examination to identify significant risk factors. Surgery may be deemed appropriate based solely on high-risk factors, such as age, sex, history of radiation exposure, rapid nodule growth, upper aerodigestive tract symptoms, and fixation.

Baseline TSH screening determines the diagnostic course. Patients with hyperthyroidism (suppressed serum TSH level) should receive radionuclide scanning to determine the presence of a toxic "hot" nodule, or Marine-Lenhart syndrome, or Graves' disease with a concomitant "cold" nodule.[90] A patient with hypothyroidism (elevated serum TSH level) should be appropriately treated by an endocrinologist, and then FNAC should be performed. Most patients are euthyroid (normal serum TSH level), and FNAC should be performed. Ultrasound examination can provide valuable diagnostic information, especially in the selection of a nodule for biopsy in a patient with multiple nodules, and may facilitate FNAC. In a patient with a thyroid malignancy, evaluation of the nodal basins may detect early clinically occult disease and alter surgical management. Patients with cytologic findings that are diagnostic or strongly suggestive of malignancy should be referred to a surgeon for removal of the lesion.

A diagnosis of follicular neoplasm by FNAC requires surgery to determine the presence of follicular adenoma or follicular carcinoma. FNAC suspicious for medullary carcinoma may be subject to immunohistochemical techniques to detect calcitonin. Before surgical intervention, a patient with FNAC suggestive of medullary carcinoma requires genetic studies and additional testing (discussed later in the section on MTC). Suspicious findings on FNAC must be assessed in the context of patient risk factors in determining the need for surgery. If a nonsurgical approach is taken, the nodule must be closely monitored, usually with ultrasonography. Benign lesions are usually observed and require surgical removal only in cases of cosmetic or symptomatic concerns. These nodules must be aspirated again to confirm the diagnosis if growth is detected.

Review of Thyroid Neoplasms

Thyroid Adenoma

Clinical Presentation

A thyroid adenoma is a true benign neoplasm derived from follicular cells. These follicular lesions are occasionally multiple and may arise in the setting of a normal thyroid, nodular goiter, toxic goiter, or thyroiditis. They occur most commonly in women older than 30 years. Patients usually present with a solitary, mobile thyroid nodule. The thyroid mass is often found incidentally on a routine physical examination and is frequently not associated with any other signs or symptoms. Sudden hemorrhage into the adenoma may cause a sudden increase in size and associated pain.

Pathology

The revised histologic classification of thyroid tumors divides epithelial tumors into the categories of follicular adenoma and other rare tumors (Table 124-4). Follicular adenomas are the most common benign thyroid lesions. Atypical follicular adenomas may show atypical microscopic features, including excess cellularity, increased mitotic figures, and necrotic foci. Although most of these lesions are benign, they may metastasize even in the absence of microinvasion.[91]

Table 124-4

World Health Organization Revised Histologic Classification of Thyroid Tumors

I. Epithelial tumors
  A. Benign
    1. Follicular adenoma
      a. Architectural patterns
        i. Normofollicular (simple)
        ii. Macrofollicular (colloid)
        iii. Microfollicular (fetal)
        iv. Trabecular and solid (embryonal)
        v. Atypical
      b. Cytologic patterns
        i. Oxyphilic cell type
        ii. Clear cell type
        iii. Mucin-producing cell type
        iv. Signet-ring cell type
        v. Atypical
    2. Others
      a. Salivary gland–type tumors
      b. Adenolipomas
      c. Hyalinizing trabecular tumors
  B. Malignant
    1. Follicular carcinoma
      a. Degree of invasiveness
        i. Minimally invasive (encapsulated)
        ii. Widely invasive
      b. Variants
        i. Oxyphilic (Hürthle) cell type
        ii. Clear cell type
    2. Papillary carcinoma
      a. Variants
        i. Papillary microcarcinoma
        ii. Encapsulated variant
        iii. Follicular variant
        iv. Diffuse sclerosing variant
        v. Oxyphilic (Hürthle) cell type
    3. Medullary thyroid cancer
      a. Variant
        i. Mixed medullary-follicular carcinoma
    4. Undifferentiated (anaplastic) carcinoma
    5. Other carcinomas
      a. Mucinous carcinoma
      b. Squamous cell carcinoma
      c. Mucoepidermoid carcinoma
II. Nonepithelial tumors
III. Malignant tumors
IV. Miscellaneous tumors
  A. Parathyroid tumors
  B. Paragangliomas
  C. Spindle cell tumors with mucous cysts
  D. Teratomas
V. Secondary tumors
VI. Unclassified tumors
VII. Tumor-like lesions
  A. Hyperplastic goiters
  B. Thyroid cysts
  C. Solid cell nests
  D. Ectopic thyroid tissue
  E. Chronic thyroiditis
  F. Riedel's thyroiditis
  G. Amyloid goiter

From Hedinger C, ed. *Histological Typing of Thyroid Tumours*. 2nd ed. Berlin: Springer-Verlag; 1988.

On gross examination, thyroid nodules and adenomas are well circumscribed and demarcated from adjacent normal thyroid tissue. The classic adenoma is fleshy and pale, although areas of necrosis, hemorrhage, and cystic change may be readily apparent. Microscopic findings include large and small follicles with abundant colloid. Cells may be flat, cuboidal, or columnar. The nuclei are small and round with an even chromatin pattern. Mixed populations of macrophages and lymphocytes, and fibrosis, hemosiderin, and calcification may be visible. Cystic areas may be present near areas of abundant papillae formation. Adenomas that exhibit pseudopapillary structures need to be distinguished from papillary carcinoma. Oxyphilic (Hürthle) cell adenoma contains mitochondria-rich eosinophilic cells. Thyroglobulin immunohistochemical staining can distinguish a clear cell adenoma from a parathyroid adenoma and metastasis from a renal carcinoma. This adenoma also needs to be differentiated from the clear cell variant of follicular carcinoma.

Nodules within a nodular goiter occasionally may be hyperfunctional or "hot." These lesions are termed *autonomously hyperfunctioning thyroid adenomas,* and may or may not cause thyrotoxicosis. These lesions often occur in women, and nodules associated with thyrotoxicosis are frequently in patients older than 40 years.

Management and Prognosis

Thyroid nodules that are determined to be benign require follow-up because of a low false-negative rate (approximately 5%) with FNAC.[92,93] Nodule growth alone is not an indication of malignancy, but growth is an indication for repeat biopsy. The 2006 ATA guidelines recommend serial clinical examination for easily palpable benign nodules at 6- to 18-month intervals.[69] All other benign nodules should be followed with serial ultrasound examinations 6 to 18 months after initial FNAC. Patients with nodules that remain stable in size may have subsequent examinations at longer time intervals. Patients with evidence of nodule growth should have repeat FNAC, preferably with ultrasound guidance.

The surgical evaluation of a thyroid nodule begins with FNAC that shows follicular neoplasm. Distinguishing follicular or Hürthle cell adenoma from carcinoma depends on histopathologic analysis after surgical excision. Concern for a potential malignancy increases with highly cellular findings or pseudopapillary structures on FNAC. The lack of tumor capsule and vascular invasion is characteristic of a follicular adenoma.

Surgical excision involves a thyroid lobectomy. A unilateral partial thyroid lobectomy is no longer an acceptable standard of care. Patients with a history of radiation to the head and neck, other head and neck cancers, potential high-risk factors, and comorbidities may benefit from a total thyroidectomy. Risk of surgical morbidity at the initial surgery must be balanced with the potential risks of reoperation. In most patients, thyroid hormone administration is unnecessary when the patient has undergone resection of a single thyroid lobe for a thyroid adenoma.

Autonomously hyperfunctioning thyroid adenomas are usually anatomically and functionally stable. Although most patients do not develop thyrotoxicosis, 20% of patients with lesions greater than 3 cm may develop thyrotoxicosis. Surgery and radioiodine therapy can be used to manage these lesions, although many physicians prefer surgery for patients younger than 40 years. These patients may require preoperative medications to control thyrotoxic symptoms. The lesions are typically removed with a unilateral thyroid lobectomy. The remaining thyroid tissue typically returns to normal function after several months. Ethanol injection has become increasingly common, especially in Europe, to manage these lesions.[94]

Thyroid Cyst

Clinical Presentation

Although a thyroid cyst is not a specific diagnosis, this entity is frequently encountered in clinical practice. Approximately 15% to 25% of all thyroid nodules are cystic or have a cystic component.[47] The presence of a cyst does not signify a benign lesion because papillary carcinomas and parathyroid tumors may manifest with cystic masses.

Papillary carcinoma may be present in 14% to 32% of all cystic nodules, although most of these lesions are benign adenomas or colloid nodules.[95,96]

Pathology

A thyroid cyst can result from congenital, developmental, or neoplastic causes.[95] Many cysts result from intranodular ischemia causing tissue necrosis and liquefaction. True epithelial-lined cysts are rare. Occasionally, parathyroid or thyroglossal duct cysts can be mistaken for thyroid nodules. A parathyroid cyst contains high parathyroid hormone levels within the clear fluid, and a thyroglossal duct cyst contains columnar epithelium. These lesions may also be differentiated by ultrasound imaging.

Management and Prognosis

When encountered during FNAC, a thyroid cyst should be drained completely. This procedure may prove curative in most simple cysts, although one or two additional drainage procedures may be required. If a cyst persists after three drainage attempts or reaccumulates quickly, the suspicion for carcinoma should increase. Brown fluid withdrawn from a cyst may represent old hemorrhage into an adenoma, but red fluid is more suspicious for carcinoma.[64] Clear, colorless fluid may be withdrawn from a parathyroid cyst and can be assessed for parathyroid hormone.[97] In suspicious cases, the surgeon and patient should consider ultrasound-guided FNAC to sample a solid component of the lesion or a unilateral thyroid lobectomy to obtain a definitive diagnosis. Because of the potential for thyroid carcinoma in cystic lesions, surgical excision for diagnosis is preferable to the injection of sclerosing agents.

Papillary Carcinoma

Clinical Presentation

Papillary carcinoma is the most common form of thyroid malignancy, accounting for 60% to 70% of all thyroid cancer.[58,98] This lesion typically occurs in patients 30 to 40 years old, and is more common in women, with a female-to-male ratio of 2:1. This ratio has decreased steadily over the past 40 years as the incidence in men has increased.[99] Papillary carcinomas are the predominant thyroid malignancy in children (75%). Although children more commonly present with advanced disease, including cervical and distant metastases, their prognosis remains quite favorable.

Most cases of papillary carcinoma occur spontaneously. Patients with a history of low-dose radiation exposure tend to develop papillary carcinomas (85% to 90%).[100] These lesions also are more common in patients with Cowden's syndrome (familial goiter and skin hamartomas), Gardner's syndrome (familial colonic polyposis), and familial polyposis. Only 6% of papillary carcinomas are associated with familial disease.

Papillary carcinoma can be classified into three categories based on size and extent of the primary lesion.[101,102] Minimal carcinoma or occult carcinoma/microcarcinoma tumors are 1.5 cm or smaller in size, and show no evidence of invasiveness through the thyroid capsule or to cervical lymph nodes. These lesions are typically nonpalpable and are usually incidental findings during operative or autopsy examination. Intrathyroid tumors are greater than 1.5 cm in diameter, but are confined to the thyroid gland with no evidence of extrathyroid invasion. Extrathyroid tumors extend through the thyroid capsule to involve the surrounding viscera. This latter form of papillary carcinoma is associated with substantial morbidity and decreased survival.[7,101]

Most patients present with a slow-growing, painless mass in the neck and are often euthyroid. Often, the primary lesion is confined to the thyroid gland, although 30% of patients may have clinically evident cervical nodal disease.[103,104] Histologic studies have shown the strong lymphotropic nature of papillary carcinoma, leading to multifocal disease within the thyroid and regional lymphatics. Microscopic disease has been identified in the cervical nodes of 50% to 80% of patients and in the contralateral lobe in 80% of patients with papillary carcinoma at the time of surgery.[105] The significance of this microscopic disease is unclear, however, because clinical recurrences in the neck and in the contralateral lobe occur in less than 10% of patients.[106] More likely, the prevalence of microscopic disease suggests that most papillary carcinomas have an indolent course that only occasionally becomes clinically evident. Definite predictors of the clinical course for papillary carcinoma are not well defined, however.

Advanced disease may be associated with symptoms of local invasion, including dysphagia, dyspnea, and hoarseness. Occasionally, cervical nodal involvement may be more apparent than the thyroid nodule. Distant metastases, especially to the lungs, are more commonly encountered in children, although 10% of all patients may ultimately develop distant disease.[81]

Thyroid cancer is often suspected in these patients after a thorough history and physical examination. The diagnosis is usually established by FNAC. Thyroid function tests are done routinely in the preoperative assessment. Radiographic imaging (CT or MRI) is selectively performed to define extensive local or substernal disease and to evaluate possible lymph node involvement.

Pathology

On gross examination, papillary carcinoma is firm, white, and not encapsulated. The lesion tends to remain flat on sectioning, rather than bulging the way normal thyroid tissue or benign nodular lesions do. Macroscopic calcifications, necrosis, or cystic changes may be readily apparent.[107]

Histologically, these lesions arise from thyroid follicular cells and contain papillary structures that consist of a neoplastic epithelium overlying a true fibrovascular stalk.[14] Cells are cuboidal with a pale, abundant cytoplasm. Large, crowded nuclei with folded and grooved nuclear margins may have intranuclear cytoplasmic inclusions. Prominent nucleoli account for the "Orphan Annie eye" appearance. Laminated calcium densities, psammoma bodies, are likely the remnants of necrotic calcified neoplastic cells and are present in 40% of cases.

Although a follicular component may predominate, lesions with any papillary features behave clinically as papillary carcinomas. The designation of "papillary carcinoma" includes mixed papillary follicular carcinoma and the follicular variant of papillary carcinoma. A more unfavorable prognosis is associated with certain histologic forms of papillary carcinoma, including diffuse sclerosing and tall-cell variants.[14,108] The tall-cell variant is characterized by well-formed papillae covered by cells that are twice as tall as they are wide. The rarer columnar cell variant is characterized by the presence of prominent nuclear stratification.[109]

Papillary carcinomas have a strong tendency for lymphatic spread within the thyroid and to local lymph nodes in the paratracheal and cervical regions. The tendency for intraglandular spread may lead to the multifocal disease often present in patients. Discrete lesions may be due to de novo formation, however, especially in patients previously exposed to ionizing radiation.[110]

Local invasion occurs in 10% to 20% of these tumors, leading to involvement of the overlying strap muscles, laryngeal and tracheal framework, RLNs, pharynx, and esophagus. This extension may evolve from the primary lesion or from extracapsular extension of metastatic nodes. Angioinvasion is a clear harbinger of increased risk for recurrence and worse prognosis.[58] A coexisting lymphocytic thyroiditis has been correlated with decreased recurrence and better overall prognosis.

Management and Prognosis

Most patients with papillary carcinoma do well regardless of treatment. Prolonged survival, even with recurrent disease, has led to controversy regarding the extent of thyroidectomy for patients with well-differentiated thyroid carcinomas (see section on extent of surgery under surgical management and technique). A balance must be achieved between an effective surgical treatment for these malignancies and the potential morbidity of this surgery. Numerous studies have attempted to categorize patients by their risk factors and to justify more aggressive surgical intervention for high-risk patients (see section on tumor staging and classification). The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology provides specific recommendations for evaluation and management of well-differentiated thyroid carcinomas.[111]

Incidental micropapillary thyroid carcinoma is usually identified in a thyroid specimen removed for other reasons. Unilateral thyroid lobectomy and isthmectomy is usually sufficient surgical treatment, unless there is angioinvasion or tumor at the margins of resection. These patients can be treated with thyroid hormone to suppress TSH and closely followed up with ultrasonography. In patients with a small, encapsulated papillary thyroid carcinoma (<1 cm in diameter), a total lobectomy is sufficient.

When patients present with biopsy-proven disease or indications of disease in both lobes, total or near-total thyroidectomy is the procedure of choice. Additionally, patients stratified into high-risk categories in any of the classification schemes previously described (see section on tumor staging and classification) would probably benefit from a more extensive surgical procedure that includes paratracheal lymph node dissection. This procedure would permit possible thyroid hormone suppression therapy and radioiodine ablation of remaining disease.

Multifocal disease is present in 80% of patients in some reports.[104,108] This percentage may represent de novo multicentric tumor formation or intraglandular metastasis. The prevalence of multifocal disease lends credence to the argument for more complete surgical removal of the thyroid gland in patients with papillary thyroid cancer. Patients with partial thyroidectomy had higher local recurrence rates and increased pulmonary and cervical metastases.[33,112] Controversy remains, however, because this increased local recurrence did not compromise disease survival in some studies.[53,113]

Generally, invasive tumors are associated with a compromise in survival. Woolner and colleagues[107] reviewed 1181 thyroid cancer patients and found that no patient died of papillary cancer when the lesion was less than 1.5 cm in size. Only 3% of patients died when the lesion was larger but remained intrathyroid. Mortality increased to 16% of patients when extrathyroid disease was present.

After total thyroidectomy, patients may be monitored by following thyroglobulin levels, which should remain undetectable, and by neck ultrasonography to evaluate the central and lateral cervical compartments. Any increase in thyroglobulin levels is suspicious for disease recurrence and requires appropriate screening. Approximately 12% of patients with papillary carcinoma are not cured by initial treatment, leading to a prolonged clinical course.[114] Recurrent disease may occur after many years, involving the thyroid bed (5% to 6%), regional lymphatics (8% to 9%), or distant sites (4% to 11%).[115] Successful treatment of recurrence varies by site of involvement and the patient's initial risk classification.

Local recurrence is a serious complication and is associated with a disease-related mortality of 33% to 50%.[115] Typically, patients with nodal recurrence fare better than patients with tumor recurrence in the thyroid bed or distant sites. Studies have been inconsistent regarding the impact of cervical metastases on survival. Patients older than 40 years may have clinically evident nodal disease in 36% to 75% of cases and overall increased mortality.[6,99] Some studies suggest prognosis is better with more cervical node involvement.[56,116] Although the role of cervical metastasis in survival may be controversial, there is an association with an increased recurrence rate, especially in elderly patients.[114,116,117] Generally, lymph node metastases do not seem to have an impact on overall survival in most patients with low-risk and intermediate-risk disease.[101,118] Cervical recurrences occur in 20% of patients with low-risk disease, however, and 59% of patients with high-risk disease.[53,119] The continuing debate regarding extent of lymphadenectomy at the time of thyroidectomy reflects a shift in focus from overall survival to recurrence-free survival.

Because of these findings and the overall prevalence of microscopic cervical disease with uncertain prognostic implications, management of cervical metastasis tends to be conservative. There is no role for elective neck dissection in the clinically disease-free neck, especially considering the effectiveness of radioiodine therapy in ablating microscopic disease.[106] The central compartment from hyoid bone to mediastinum between the internal jugular veins (levels VI and VII) should be carefully inspected and palpated. The 2006 ATA management guidelines recommend considering routine central compartment (level VI) neck dissection for patients with papillary thyroid carcinoma and suspected Hürthle cell carcinoma, although postoperative radioiodine therapy may provide an alternative approach.[69]

Elective dissection of the pretracheal and ipsilateral paratracheal nodes may be reasonable, especially in patients with high-risk factors. Additionally, elective removal may potentially decrease nodal recurrence in this region and the need for reoperation. In patients with palpable or visible neck disease, a comprehensive neck dissection (levels II-V) should be performed, as opposed to selective cervical lymph node excision or "berry-picking." Although level I is seldom involved, metastatic disease is frequently noted on histologic examination of nodal levels II through V.[120] In addition, because the incidence of contralateral subclinical metastasis is less than 20%, elective treatment of the contralateral neck is not advocated.

The presence of distant metastasis is associated with a worse prognosis. Approximately 10% of patients with papillary thyroid carcinoma develop distant metastasis at some point during their disease course.[81] Most commonly, the lungs are involved, although bone sites and the central nervous system may also be affected.

In nearly every study, patient age at the time of diagnosis is an important prognostic variable.[6,116,121] Older patients (especially >40 years old) with papillary carcinoma have a worse prognosis. Extrathyroidal invasion seems to be more common in older patients. The prognosis for men younger than 40 years is comparable to women of the same age. Overall survival is worse for men, however, and the risk of death from papillary thyroid carcinoma may be twice as great.[53,116] In the last 40 years, the increase in incidence of papillary thyroid carcinoma in men has decreased the gender ratio of men to women with the disease from 1:4 to 1:2.[99]

Children fare better with this disease. Among patients younger than 15 years, 90% show cervical metastasis at some time during their disease course.[122] Twenty percent of children may present with pulmonary metastases.[123] Neither cervical nor pulmonary metastases seem to have any impact on survival, however. Perhaps these differences may be related to biologic differences in the disease process or between age groups.

Finally, the tall-cell variant of papillary thyroid carcinoma is different from other forms of this disease. A review of patients with tall-cell variant papillary carcinoma showed a more aggressive natural history in all age groups and a worse prognosis.[124]

Follicular Carcinoma

Clinical Presentation

Follicular carcinomas represent 10% of thyroid malignancies. The mean age of presentation is 50 years compared with 35 years mean age of patients with papillary carcinoma. Women more commonly have this lesion, with a female-to-male ratio of 3:1.[125] These lesions occur more frequently in iodine-deficient areas, especially areas of endemic goiter. Follicular carcinomas have been correlated with pregnancy and with certain HLA subtypes (DR1, DRw, and DR7). Also, a rare form of familial follicular carcinoma is reported in patients with dyshormonogenesis. The overall incidence of follicular carcinoma in decreasing in the United States.

Patients usually present with a solitary thyroid nodule, although some patients may have a history of long-standing goiter and recent rapid increase in size. These lesions are typically painless, although hemorrhage into the nodule may cause pain. Cervical lymphadenopathy is uncommon at initial presentation, although distant metastases are more frequently encountered than with papillary carcinomas. In rare cases (1%), the follicular carcinoma may be hyperfunctioning, and the patient presents with signs and symptoms of thyrotoxicosis.

Other than characterization of a follicular neoplasm, a definitive preoperative diagnosis is usually impossible by FNAC. Differentiation between follicular adenoma and follicular carcinoma requires an evaluation of the thyroid capsule for invasion or identification of vascular invasion. Typically, about 20% of thyroid nodules showing follicular neoplasm cytology contain carcinoma.

In contrast to papillary carcinoma, follicular thyroid carcinomas are less likely to metastasize via lymphatic pathways (found in <10% of patients).[88] More commonly, follicular carcinomas spread through

local extension and hematogenous spread. Often, the presence of cervical lymph node disease indicates significant local disease and visceral invasion.[99,126] Distant metastasis is also more common in follicular cancers than papillary cancers, especially at presentation.[127,128] A pathologic bone fracture may be the initial presentation of follicular carcinoma. Other common sites include liver, lung, and brain.

Pathology

Follicular thyroid carcinoma tends to manifest as solitary, encapsulated lesions. Cytologic analysis of follicular neoplasms reveals small follicular arrays or solid sheets of cells.[14] The follicular structures have lumens that do not contain colloid, and the overall architectural pattern depends on the degree of tumor differentiation. Increased cellularity may increase the suspicion for carcinoma, but cytology alone is insufficient to distinguish between a follicular adenoma and carcinoma.

Histologic findings are necessary to distinguish benign and malignant lesions. Malignant lesions are differentiated by the identification of capsular invasion and potential microvascular invasion of vessels along the tumor capsule.[91,129] Complete capsular evaluation must be performed. Frozen-section analysis is often inadequate, and definitive diagnosis requires complete assessment of permanent sections.

The degree of capsular invasion is important for patient prognosis. Follicular carcinomas can be divided into two broad categories. Minimally invasive tumors show evidence of invasion into, but not through, the tumor capsule at one or more sites. These lesions do not exhibit small-vessel invasion. Frankly invasive tumors show invasion through the tumor and often exhibit vascular invasion.[130] Tumor infiltration and invasion may be apparent at surgery, with tumor present in the middle thyroid or jugular veins.

Many other factors have been investigated as means to differentiate between adenomas and carcinomas. To date, no molecular markers have been clinically useful. DNA ploidy varies in adenomas and carcinomas with considerable overlap.[131] Aneuploid follicular carcinomas are noted to behave in a more aggressive manner.

Management and Prognosis

Patients diagnosed with a follicular lesion by FNAC should have a thyroid lobectomy with isthmectomy performed. The pyramidal lobe, if present, should be included in the resection. As described previously, cytologic findings alone cannot determine the presence of adenoma or carcinoma. Intraoperative frozen-section analysis is not helpful because of the incomplete assessment of the tumor capsule. Frozen sections should be analyzed, however, to confirm gross evidence of adjacent cervical lymphadenopathy. A total thyroidectomy is recommended if carcinoma is identified. In patients with a clinical suspicion for follicular carcinoma, the tendency is to perform a more complete resection. Total thyroidectomy is performed in older patients with a nodule greater than 4 cm in size diagnosed by FNAC as follicular neoplasm. In these patients, the risk of carcinoma is approximately 50%.[112] Additional factors that may favor a total thyroidectomy as the initial surgical procedure include a family history of thyroid carcinoma, history of radiation exposure, and patient preference.[69]

A diagnosis of follicular carcinoma after a thyroid lobectomy usually necessitates a completion thyroidectomy. Patients with minimally invasive follicular cancer have a very good prognosis, and the initial thyroid lobectomy may be sufficient treatment. Invasiveness of follicular carcinoma correlates directly with decreased survival, however. In patients with invasive follicular carcinomas, many surgeons tend toward completion and total thyroidectomy to permit radioiodine scanning for detection and ablation of metastatic disease. More aggressive surgical intervention does not improve survival because invasiveness already indicates the increased likelihood of distant metastasis. Neck dissection is performed if cervical lymphadenopathy is present. When cervical disease is present, consultation with the pathologist is warranted because the patient may have a follicular variant of papillary thyroid carcinoma. Elective neck dissections are unwarranted because nodal involvement is unlikely.[10]

The recurrence rate after initial management is approximately 30%.[132] Recurrence is related to the degree of invasiveness of the initial lesion, not the extent of initial thyroid surgery. Minimally invasive disease behaves similarly to follicular adenoma and is typically cured with conservative surgical procedures (thyroid lobectomy).[133] Recurrence of minimally invasive follicular carcinoma is approximately 1%. About 15% of patients with recurrent or metastatic disease can be cured. The prognosis of these patients relates to the site of recurrence and the patient's initial risk stratification. Survival outcomes are significantly poorer in patients with capsular invasion and angioinvasion.[134] Patients with cervical node recurrence have a 50% cure rate, whereas patients with distant metastases have a cure rate of about 9%.[115,132]

Overall, 5-year survival is 70% and decreases to 40% at 10 years for patients with follicular carcinoma. The presence of distant metastasis diminishes 5-year survival to 20%.[135] Factors that worsen prognosis include age older than 50 years at presentation, tumors greater than 4 cm in size, higher tumor grade, marked vascular invasion, extrathyroidal invasion, and distant metastasis at the time of diagnosis.[10] Extrathyroidal invasion beyond the capsule and into the thyroid parenchyma and local structures is the key factor decreasing patient survival. Risk stratification shows marked differences in patient survival. In one study, the low-risk group had a 5-year survival rate of 99% and a 20-year survival rate of 86%. In the high-risk group, the 5-year survival rate was only 47%, and this decreased to a 20-year survival rate of 8%.[125]

The prognosis for patients with follicular carcinoma has typically been reported to be worse than for patients with papillary carcinoma. Some reports that matched age, sex, and stage at time of diagnosis suggest that patients with papillary and follicular carcinomas have similar survival patterns.[6,8] The poor prognosis of patients with follicular carcinoma may be related to the increased number of patients who present at an older age and a more advanced disease stage. Also, in contrast to papillary carcinoma, mortality is directly related to recurrence in patients with follicular carcinoma.[99]

Hürthle Cell Tumor

Clinical Presentation

According to World Health Organization classification, Hürthle cell tumor is a subtype of follicular cell neoplasm. Hürthle cell tumor nodules can be found in patients with Hashimoto's thyroiditis or Graves' disease or within a nodular goiter. These tumors are derived from oxyphilic cells of the thyroid gland. Although the precise function of these cells is unknown, Hürthle cells express TSH receptors and produce thyroglobulin.

Hürthle cell neoplasms are typically diagnosed by FNAC. Approximately 20% of these lesions are malignant. Similar to follicular lesions, histologic criteria are required to diagnose carcinomas. Hürthle cell carcinomas represent approximately 3% of all thyroid malignancies. The mean age of presentation for patients with Hürthle cell carcinoma may be older than for follicular carcinoma.[80,136] Hürthle cell carcinomas are more aggressive than follicular carcinomas. They are often multifocal and bilateral at presentation. These malignancies also are more likely to metastasize to cervical nodes and distant sites.[137]

Pathology

FNAC of Hürthle cell tumor typically shows hypercellularity and the presence of eosinophilic cells. These neoplasms are characterized by sheets of eosinophilic cells packed with mitochondria. Cytologic differentiation between adenoma and malignant tumor by FNAC is extremely difficult. Histologic findings of capsular or vascular invasion confirm the presence of Hürthle cell carcinoma.

Management and Prognosis

The clinical approach to Hürthle cell tumors is similar to that for follicular neoplasms. With Hürthle cell adenoma, resection of the affected lobe and isthmus is sufficient. Invasive findings for Hürthle neoplasms on formal pathology warrant a total or completion thyroidectomy. Hürthle cell carcinomas tend to be more aggressive than other follicular carcinomas, and they are less amenable to radioiodine therapy because of their decreased tendency to uptake radiolabeled iodine. Because locoregional nodal metastases may occur, careful examination for local disease extension or adjacent cervical lymphadenopathy should

be performed. The paratracheal region should be carefully palpated and examined. The paratracheal nodes should be removed if disease is obvious during inspection. Also, a comprehensive neck dissection should be undertaken if lateral neck nodes are palpable.

Postoperative management should include TSH suppression and thyroglobulin monitoring, and periodic ultrasound evaluation of the central and lateral cervical compartments. A ^{99m}Tc scan may be useful for detecting persistent local or metastatic disease. A ^{123}I scan and ablation can be performed to remove any residual normal thyroid tissue to allow for better surveillance. This therapy is unlikely to be effective in tumor ablation, however, because few (approximately 10%) Hürthle cell carcinomas uptake radioiodine.[138]

Overall, survival rates for Hürthle cell carcinoma are significantly worse than for follicular thyroid cancer. The number of patients who die of Hürthle cell carcinoma is greater than the number who die of papillary or follicular carcinoma.[139] Additionally, Hürthle cell carcinoma is associated with the highest incidence of distant metastases among the well-differentiated thyroid carcinomas.[140]

Medullary Thyroid Carcinoma

Clinical Presentation

MTCs are a distinct category of disease and represent approximately 5% of all thyroid carcinomas. These malignancies arise from parafollicular C cells and may secrete calcitonin, carcinoembryonic antigen (CEA), histaminidases, prostaglandins, and serotonin. Measurement of secreted calcitonin is useful for the diagnosis of MTC and for postsurgical surveillance for residual and recurrent disease.

MTC shows an intermediate behavior between well-differentiated thyroid cancers and anaplastic carcinomas. Women and men are equally affected by MTCs.[141] Patients usually present with a neck mass associated with palpable cervical lymphadenopathy (≤20%).[142] Local pain is more common in these patients, indicating the presence of local invasion, and may be associated with dysphagia, dyspnea, or dysphonia. MTC may manifest along with papillary thyroid carcinoma because related mutations in RET are present in both diseases. Although MTC spreads initially to cervical nodes, distant metastases may be found in the mediastinum, liver, lung, and bone, and are present in 50% of patients at diagnosis.[143]

Most (70%) MTCs are spontaneous unifocal lesions in patients 50 to 60 years old without an associated endocrinopathy.[142] The remaining 30% of cases affecting younger patients are familial. These hereditary MTCs are inherited as autosomal dominant traits with nearly 100% penetrance. MTC in these patients is preceded by multifocal C-cell hyperplasia and leads to disease that is multicentric and bilateral in 90% of cases.[144,145] Familial MTC is not associated with any other endocrine pathology. Two forms of MEN syndrome are associated with MTC. Patients with MEN IIA exhibit MTC, pheochromocytoma, and hyperparathyroidism.[144,146] Patients with MEN IIB have a marfanoid body habitus and may have MTC, pheochromocytoma, or mucosal neuromas. Although penetrance for MTC approaches 100% in these patients, expression of other features varies.[145,147]

FNAC diagnosis of MTC is confirmed by elevated serum calcitonin. These patients also should have testing for mutation of the RET proto-oncogene. Genetic screening has replaced provocative pentagastrin-stimulation testing. Careful screening for hereditary diseases is also necessary when a patient is diagnosed with MTC. Hyperparathyroidism can be assessed by serum calcium levels and appropriate imaging studies. Patients should also be screened for the presence of a pheochromocytoma with 24-hour urinary levels for catecholamines and metanephrines, and should undergo abdominal MRI. An undiagnosed pheochromocytoma could lead to an intraoperative hypertensive crisis and death. Additionally, the detection of any hereditary form of MTC in a patient should lead to family screening. Affected family members can often be identified and treated at earlier stages of disease with improved survival.[148,149]

Pathology

MTC originates from parafollicular C cells of neuroectodermal origin.[150] The cells descend to join the thyroid gland proper and are concentrated mainly in the lateral portions of the superior poles. Most MTC lesions are located in the middle and upper thyroid poles. In patients with hereditary forms of MTC, the disease is often multifocal. Grossly, the tumor is solid and firm, and has a gray cut surface. The lesion is nonencapsulated, but well circumscribed.

These lesions are composed of sheets of infiltrating neoplastic cells that are heterogeneous in shape and size. The cells are separated by collagen, amyloid, and dense irregular calcification. The amyloid deposits are likely polymerized calcitonin and are virtually pathognomonic for MTC, although not all MTCs contain amyloid.[151] More aggressive tumors typically have increased mitotic figures, nuclear pleomorphism, and areas of necrosis. Immunohistochemistry for calcitonin and CEA are useful diagnostic studies.

Management and Prognosis

Specific guidelines were recently published by the American Thysoid Association regarding the management of MTC.[151a]

Preoperative workup includes measurement of calcitonin and serum CEA. Patients with germline RET mutations should be screened for pheochromocytoma (MEN IIA/IIB) and hyperparathyroidism (MEN IIA). CT scan of the chest and mediastinum and ultrasound examination of the neck are recommended.

Total thyroidectomy is the treatment of choice in patients with MTC because the lesions have a high incidence of multicentricity and an aggressive disease course. Patients with familial MTC or MEN II should have the entire gland removed, even in the absence of a palpable mass.

Because of the frequent involvement of cervical nodes, initial surgical management should include bilateral central compartment neck dissection. When central compartment nodes are involved, or when palpable lateral cervical nodes are present, treatment including an ipsilateral or bilateral comprehensive neck dissection (levels II-V) should be considered. When the primary lesion is greater than 1 cm (>0.5 cm for MEN IIB patients), or when central compartment lymph node metastases are present, elective ipsilateral comprehensive neck dissection should be considered because nodal metastases may be present in more than 60% of these patients.[111,152,153] The superior mediastinal lymph nodes (level VII) should be routinely removed as well.

Potentially associated conditions, such as hyperparathyroidism and pheochromocytoma, must be carefully evaluated and, if necessary, treated before thyroidectomy. A pheochromocytoma may need to be removed before treatment of the thyroid lesion. Alternatively, preoperative treatment with α-adrenergic blockade (phenoxybenzamine) or α-methyltyrosine is necessary to avoid a hypertensive crisis during surgery. In the presence of hypercalcemia, the parathyroid glands need to be identified during thyroidectomy. If the parathyroid glands are abnormal, they should be removed. Otherwise, they should be adequately marked to facilitate future identification, especially in patients with MEN IIA.

Children with any of the genetic disorders leading to MTC need to be treated aggressively. Typically, a total thyroidectomy should be performed by the time the patient is 2 to 3 years old, or before C-cell hyperplasia occurs. Removal of the thyroid gland should prevent development of MTC in these patients and improve survival. MTC has been diagnosed in MEN IIB patients 7 months old, however.[154]

After surgery, patients require close follow-up and monitoring of serum calcitonin and CEA levels. Calcitonin is more sensitive for detecting persistent or recurrent disease, but CEA levels seem to be predictive for survival.[153] Increasing or persistent calcitonin levels should increase suspicion for residual or recurrent disease. Localization studies should be performed to identify potential sites of disease involvement. Tumor debulking for metastatic disease or local recurrence can decrease symptoms of flushing and diarrhea, and may reduce the risk of death resulting from recurrent central neck disease.[143,155] MTCs do not respond to radioiodine therapy or TSH suppression therapy, however, because of their parafollicular C-cell origin.[149] External-beam radiation therapy (EBRT) has been controversial for patients with positive tumor margins or unresectable tumor, and there is no effective chemotherapy regimen.

Prognosis for patients with MTC is directly related to disease stage. The overall 10-year survival rate is 61% to 75%, but decreases to 45% if cervical nodes are involved.[149,156] The best outcome is for patients with familial MTC, then MEN IIA, sporadic disease, and MEN IIB.

Anaplastic Carcinoma

Clinical Presentation

Anaplastic thyroid carcinomas are one of the most aggressive malignancies, with few patients surviving 6 months beyond initial presentation.[62,157] These lesions represent less than 5% of all thyroid carcinomas.[158] These tumors affect patients 60 to 70 years old; presentation before age 50 years is extremely rare. Women are more commonly affected than men, with a ratio of 3:2. Of these malignancies, 80% may occur with a coexisting carcinoma and may represent transformation of a well-differentiated thyroid cancer.[157,159]

Typically, patients have a long-standing neck mass that enlarges rapidly. This sudden change is often accompanied by pain, dysphonia, dysphagia, and dyspnea. Often the mass is quite large and fixed to the tracheolaryngeal framework, resulting in vocal cord paralysis and tracheal compression. More than 80% have jugular lymph node involvement at the time of presentation, and greater than 50% have systemic metastases.[160] Most patients die of superior vena cava syndrome, asphyxiation, or exsanguination.

Pathology

In the case of anaplastic thyroid carcinoma, the gross specimen shows areas of necrosis and macroscopic invasion of surrounding tissues, often with lymph node involvement. Microscopically, sheets of cells with marked heterogeneity are present. Spindle, polygonal, and giant, multinucleated cells are present with occasional foci of differentiated cells. These cells do not produce thyroglobulin, do not transport iodine, and do not express thyroid hormone receptors.[157] These findings can often be established on FNAC, although a formal biopsy is occasionally necessary to exclude a diagnosis of lymphoma.

Management and Prognosis

Management of anaplastic carcinoma is extremely difficult, requiring a multidisciplinary approach and close consultation with the patient and family. Surgical debulking may be performed for palliation. Initial therapy should ensure airway protection with a tracheostomy and nutritional support. All treatment forms are disappointing, and median survival is 2 to 6 months.[158,161] One current treatment protocol involves doxorubicin, hyperfractionated radiation therapy, and potential surgical debulking.[162,163] Although survival beyond 2 years is only 12%, this is one of the only regimens currently available for these patients.

Retrospective evaluation of various treatment strategies identified a subset of patients who have had long-term survival.[5,86,164] Independent prognostic variables include resectability of local disease, absence of distant metastasis at diagnosis, and adjuvant treatment with radiation therapy. Additionally, many long-term survivors had small areas of anaplastic foci within well-differentiated carcinoma.

Other Forms of Thyroid Cancer

Insular Thyroid Carcinoma

Insular carcinoma was named for the clusters of cells that contain small follicles resembling pancreatic islet cells.[165] These tumors are very rare and manifest as an independent lesion or concomitantly with papillary or follicular thyroid carcinomas. These cells stain with thyroglobulin antibodies, but not for calcitonin. Typically, capsular and vascular invasion is present at the time of diagnosis.

These lesions are very aggressive when compared with follicular and papillary carcinoma, and seem to have an increased recurrence and mortality rate when present as an independent process.[166] Insular carcinoma located within follicular or papillary thyroid cancer does not seem to affect the clinical course adversely, however. Many insular thyroid carcinomas are able to concentrate radioiodine.

Lymphoma

Primary thyroid lymphoma is unusual and represents less than 5% of all thyroid malignancies.[167] Women are more commonly affected at a ratio of 3:1, and lymphoma typically manifests in patients older than 50 years. Patients may present with symptoms similar to anaplastic carcinoma, although the rapidly enlarging mass is often painless. Symptoms may also include regional adenopathy, dysphagia, and vocal cord paralysis caused by RLN invasion. Many affected patients are clinically hypothyroid or already receiving thyroid replacement therapy for conditions such as Hashimoto's disease.[168] Non-Hodgkin B-cell type lymphoma is most common, although Hodgkin's disease and plasmacytomas occur.[169] Thyroid lymphoma can arise as part of a generalized lymphomatous condition because many of these patients have Hashimoto's disease. A current hypothesis as to why this occurs is chronic antigenic lymphocyte stimulation that results in lymphocyte transformation.

A definite diagnosis needs to be made and frequently can be established by FNAC. Occasionally, a needle-core or open cervical lymph node biopsy may be necessary. Because of the rare incidence of primary thyroid lymphoma, a comprehensive survey must be done to exclude the presence of lymphoma at other sites.

Patients typically respond rapidly to chemotherapy, especially CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone).[170,171] Combined radiation and chemotherapy regimens have also been developed and have been promising. Thyroidectomy and nodal resection may be considered to alleviate symptoms of airway obstruction in patients who do not respond rapidly to treatment, but surgical options are not primary treatment modalities.

The prognosis depends on the histologic grade of the tumor and the presence of extrathyroidal disease. Overall, 5-year survival is about 50%. Intrathyroid disease survival is 85% and decreases to 40% for patients with extrathyroid disease.

Metastatic Carcinoma

The thyroid is a rare site for metastases from other cancers. Metastasis can occur, however, from primary lesions in the kidney, breast, lung, and skin (i.e., melanoma). The most common metastatic tumor to the thyroid is from a hypernephroma. Also, approximately 3% of bronchogenic carcinomas metastasize to the thyroid, but account for 20% of all metastases to the thyroid.[172]

Typically, the history and physical examination identify the source of the metastasis. FNAC is performed for definitive diagnosis. Thyroidectomy may be considered for palliation, especially when the primary lesion is very slow growing (e.g., renal cell carcinoma).[173]

Squamous Cell Carcinoma

Squamous cell carcinoma of the thyroid is very rare, representing less than 1% of thyroid cancers.[174] Older patients are most commonly affected, and the disease can progress rapidly with local invasion and metastasis. During the workup, metastasis from another site within the upper aerodigestive tract needs to be excluded. Early detection and aggressive surgical treatment seems to represent the best option for palliation and cure. As with other squamous cell carcinomas of the head and neck, radiation therapy is probably important, although not well characterized.[175]

Surgical Management and Technique

Approach to the Thyroid Gland

Before any thyroid surgery, any voice changes or previous neck surgery should prompt assessment of vocal cord mobility by indirect laryngoscopy. Although many patients with thyroid carcinomas are euthyroid, necessary medical therapy should be instituted for patients with thyrotoxicosis or hypothyroidism to avoid intraoperative metabolic derangements, such as hypertensive crisis. Details of this management are beyond the scope of this chapter, but management should include consultation with an endocrinologist.

The patient should be positioned supine on the operating table with an inflatable pillow or shoulder roll and adequate head support to permit full neck extension for optimal exposure. A symmetric, trans-

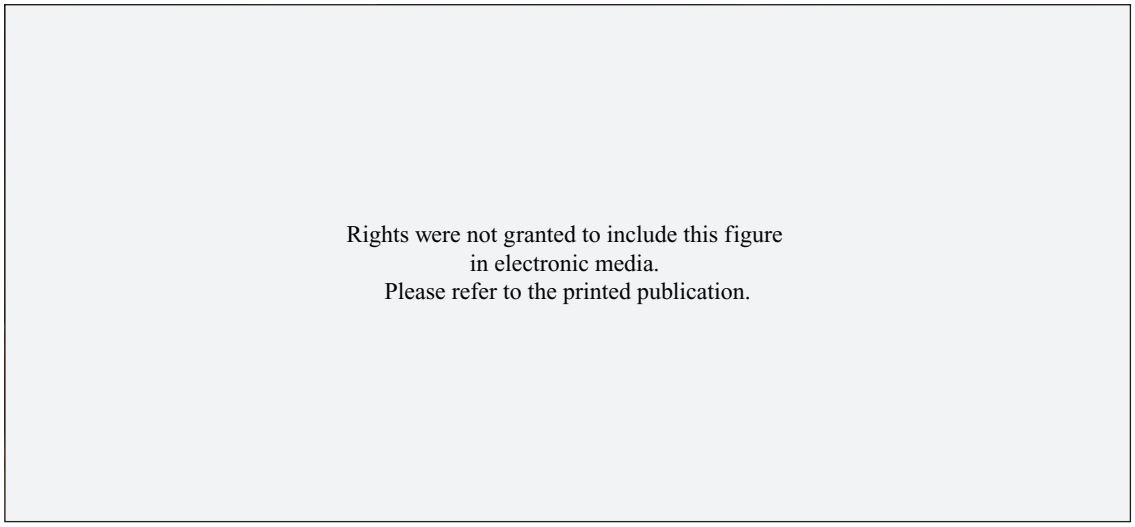

Figure 124-4. **A,** Careful dissection along the lateral portion of the thyroid lobe permits mobilization of the gland medially. The middle thyroid vein(s) should be carefully identified and ligated. **B,** The course of the recurrent laryngeal nerve along the tracheoesophageal groove is shown intraoperatively. **C,** The lateral course of a nonrecurrent laryngeal nerve has been revealed intraoperatively.

verse incision along a skin crease approximately 1 cm below the cricoid cartilage is made through the platysma. The length of the incision depends on the size of the thyroid gland. Larger incisions are necessary for patients with short, thick necks, difficulty with neck extension, or a low-lying thyroid gland. Subplatysmal skin flaps are raised superiorly to the level of the thyroid cartilage notch and inferiorly to the clavicle.

Exposure of the thyroid gland is obtained through a midline, vertical incision through the superficial layer of the deep cervical fascia between the sternohyoid and sternothyroid muscles. The strap muscles are bluntly separated, and dissection proceeds laterally along the thyroid capsule until the ansa cervicalis is noted at the lateral edge of the sternohyoid muscle/medial aspect of the internal jugular vein. Rarely, the strap muscles must be divided to gain access to a large thyroid lobe or tumor. This division should be done high on the muscle to preserve innervation from the ansa hypoglossal nerve. The strap muscles should be reapproximated before skin closure. Any evidence of frank invasion of thyroid carcinoma into the strap muscles should result in the en bloc resection of the section of the affected muscle with the thyroid lobe.

Through blunt dissection, the thyroid lobe is swept anteromedially to the tracheolaryngeal framework (Fig. 124-4A). The middle thyroid vein should be identified; division of this vessel improves lateral exposure. The cricoid and trachea should be identified in the midline, and continued mobilization is achieved by sweeping dorsally all tissue along the posterolateral border of the thyroid lobe. Meticulous hemostasis should be maintained to facilitate identification of the SLN, RLN, and parathyroid glands.

The pedicle along the superior thyroid pole is identified early by retracting the thyroid inferomedially. Dissection should be carried out close to the thyroid capsule to avoid possible injury to the external branch of the SLN. Occasionally, the external branch of the SLN that supplies the cricothyroid muscle can be visualized. The superior pole vessels should be individually identified and isolated for ligation close to the thyroid lobe. At this point, the tissues posterolateral to the superior pole can be swept away from the lobe in a posteromedial direction.

Identification of the RLN is best achieved through an inferior approach in a space defined by Lore and colleagues[176] as the RLN triangle. The triangle is bounded by the trachea medially, the carotid sheath laterally, and the undersurface of the retracted inferior thyroid pole superiorly. Careful dissection in this area parallel to the course of the RLN should safely identify the nerve (see Fig. 124-4B). A thyroid goiter or unusually large thyroid mass can potentially displace the nerve. The RLN, in these cases, can become fixed to and splay across the undersurface of the enlarged thyroid lobe. Great care needs to be taken in these situations, and identification of the nerve may require a superior approach, identifying the RLN at its entry into the larynx.

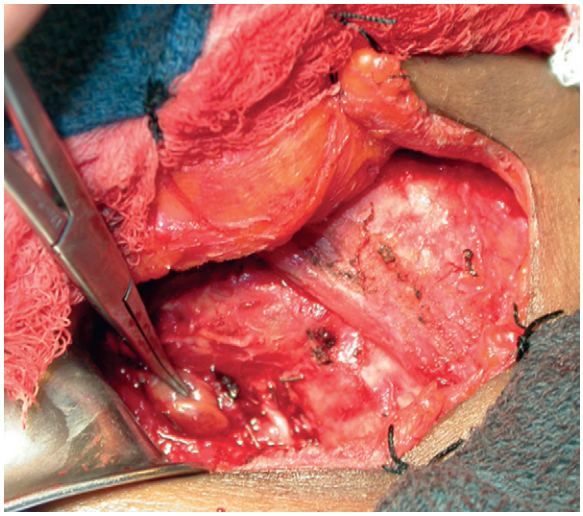

Figure 124-5. A parathyroid gland is shown in close proximity to the recurrent laryngeal nerve. Close dissection and ligation of vessels along the thyroid capsule ensure that the vascular supply to the parathyroid glands remains intact.

When identified, the RLN should be followed to its laryngeal entry at the level of the cricoid cartilage, passing under or through Berry's ligament and entering the larynx deep to the inferior constrictor muscle. The nerve may divide into multiple branches before entering the larynx.[177] The most difficult portion of the operation is typically in dealing with the dissection where the recurrent nerve passes through Berry's ligament. The RLN is in close proximity to the thyroid, tethered down by the ligament. Bleeding can occur at this site and should be controlled by gentle pressure before identification of the nerve to avoid injury. Use of electrocautery in this region should be strictly avoided. A small portion of thyroid tissue may be embedded with the ligament, accounting for a remnant of thyroid tissue left after total thyroidectomy. Although controversy exists regarding routine use of intraoperative RLN monitoring, it may be useful if nerve identification or handling or both are anticipated to be more difficult.[178-180] Examples of such situations include large tumors or goiters, paratracheal node disease or dissection, and reoperative cases in the thyroid bed or central compartment.

All vessels are ligated and divided on the capsule to reduce the risk of parathyroid devascularization (Fig. 124-5). Ischemic parathyroids and parathyroids situated anteriorly on the thyroid gland or removed with the thyroid lobe should be examined. Biopsy specimens should be obtained and confirmed by frozen-section examination. The parathyroid glands can be minced into pieces of 1 mm^3 and reimplanted in the ipsilateral sternohyoid muscle or sternocleidomastoid muscle with a silk suture or clip to mark the reimplantation site.

When the lobe is mobilized and key structures are identified, the isthmus can be transected close to the contralateral side. The edge of the isthmus is oversewn, and a careful search is made for a pyramidal lobe that should be removed in continuity with the thyroid lobe and isthmus, when present.

For a total thyroidectomy, the same procedure is repeated on the contralateral side. The decision to proceed to excision of the opposite thyroid lobe should depend on the course of the initial thyroid lobectomy. After removal of the thyroid specimen, hemostasis is verified, and a Jackson-Pratt suction drain is placed in the thyroid lobe bed. Divided strap muscles are reapproximated with absorbable sutures and closed along the midline to prevent tracheal adhesion to the skin. The platysma is reapproximated with absorbable sutures, and the skin is closed with a running subcuticular suture.

Special Surgical Situations

Management of Regional Lymphatics

Management of the neck in patients with well-differentiated thyroid carcinomas is typically conservative. Cervical node disease is rare in follicular carcinomas, but more common in papillary carcinomas. There is currently no role for elective neck dissection in cases of follicular carcinoma. Current ATA guidelines recommend consideration of central compartment (level VI) neck dissection for patients with papillary thyroid carcinoma and suspected Hürthle cell carcinoma.[69] If disease is present by palpation or visible inspection, patients with papillary or Hürthle cell thyroid carcinoma have a concurrent central compartment lymph node dissection with total thyroidectomy or the completion thyroid lobectomy.

Because of the higher frequency of microscopic tumor spread in MTCs and their lack of radioiodine uptake, elective central compartment lymph node dissection is commonly performed. When these patients present with palpable anterior lymph node disease, bilateral central compartment dissection is performed with the total thyroidectomy, and the lateral cervical nodes are carefully inspected. Central compartment dissection should include the Delphian, paratracheal lymphatic, and lymph nodes of the upper mediastinum. The RLN, inferior thyroid artery, and parathyroid glands should be clearly identified, and the lymphatics should be removed en bloc from the level of the cricoid to the innominate artery.

When performing bilateral central compartment dissection, preservation of the parathyroid glands can be difficult. Attempts should be made in the dissection, especially contralateral to the thyroid lesion, to identify and preserve the ascending branch of the inferior thyroid artery that supplies the superior parathyroid gland. If the vascular supply to the parathyroid gland is compromised, a biopsy specimen of the gland should be obtained to confirm the presence of parathyroid tissue and placed into a pocket in the sternocleidomastoid muscle. The gland should be minced into 1-mm pieces, and the implantation site should be marked with vascular clips.

When palpable lateral cervical nodes are present, and metastatic disease is confirmed by FNAC, a selective neck dissection, including levels II through V, should be performed. The submandibular and submental nodes (level I) are rarely involved and should be dissected only when there is clinically positive disease in this region.[105,181] Cervical involvement is frequently ipsilateral to the primary thyroid lesion.[182] Extension of the collar incision superior to the mastoid tip provides adequate exposure of the lateral neck if palpable disease is present. Careful inspection and dissection should be performed along the spinal accessory nerve because this is a frequent site of metastatic thyroid disease.[10] A more extensive modified radical neck dissection may be necessary to remove gross disease. Radioiodine ablation is an important adjunctive therapy for the management of cervical disease in these patients.

In patients with MTC, lymph node metastasis can occur in 81% of cases.[183] Retrospective analysis revealed a 10-year survival rate of 67% for patients with MTC treated with neck dissection versus 43% for patients who were not treated with neck dissection.[152] Palpable cervical disease necessitates central compartment and comprehensive neck dissection. In patients with clinically negative neck disease, surgical treatment should include total thyroidectomy, central compartment dissection, and elective, ipsilateral comprehensive neck dissection. Dissection of the contralateral neck in all patients should be considered, especially when the primary thyroid lesion is 2 cm or greater in size because bilateral neck dissection may be necessary to maximize regional control.[183]

Intrathoracic Goiter

Less than 1% of patients may have a thyroid gland that is partially or completely intrathoracic.[184,185] In most of these patients, the intrathoracic goiter can be removed via a collar incision in the neck without resorting to a sternotomy. The vascular supply, typically originating in the neck, is identified, ligated, and divided. Division of the isthmus may facilitate mobilization of the substernal goiter from beneath the sternum. Large sutures can be placed deeply into the goiter to facilitate traction and blunt dissection to permit delivery of the thyroid through the neck.

Patients with substernal goiters who have had previous thyroid operations, some patients with invasive malignant tumors, and patients with no thyroid tissue in the neck may require a median sternotomy. Occasionally, the substernal goiter may simply be too large to deliver through a cervical incision. In these cases, the thyroidectomy is usually performed in collaboration with a thoracic surgeon.

Recurrent Laryngeal Nerve Invasion

Surgical situations necessitating the sacrifice of the RLN are uncommon. If preoperative vocal cord paralysis is present, and carcinoma invasion is seen intraoperatively, the nerve may be sacrificed. More commonly, the RLN should be dissected free of gross disease. Among patients with well-differentiated thyroid carcinomas, there is no survival difference between patients with RLN sacrifice and patients treated postoperatively with radioiodine for gross disease left on the nerve.[171] Because of the lack of response by MTC to postoperative radioiodine treatment, RLN sacrifice must be considered to achieve complete removal of gross disease.

Sacrifice of the RLN requires the exclusion of nerve infiltration by benign disease processes. Graves' disease, Hashimoto's thyroiditis, and Reidel's thyroiditis can involve the RLN with or without vocal cord paralysis. Benign processes can cause stretch injuries to the RLN that resolve with surgical removal of the mass. Finally, lymphomas can involve the RLN, but treatment is rarely surgical and should not involve excision of the nerve.

Extended Surgical Resection

Surgical treatment of thyroid carcinomas should remove all gross disease, especially in patients with MTC. Fixation to the thyroid cartilage or trachea may require partial-thickness to full-thickness removal of those structures (Fig. 124-6). A thyroid cartilage lamina can be removed without major morbidity if the internal thyroid perichondrium is left intact. The trachea can be partially resected and repaired to permit en bloc tumor removal. Primary anastomosis can be performed for resections involving up to four tracheal rings.[186] Additionally, tracheal shaving can be performed, leaving the internal mucosa intact. Isolated full-thickness defects can be repaired with composite mucosal-cartilage grafts from the nasal septum. In patients with more extensive skeletal involvement, a partial laryngectomy may be required and has shown improvements in survival.[187,188] Total laryngectomy should be performed in only the most extreme cases of extensive intraluminal invasion, substantial cricoid involvement, or bilateral RLN dysfunction. Typically, this procedure would be done after the failure of radioiodine treatment, EBRT, or both. Pharyngeal and esophageal local invasion typically requires resection of the immediate area and primary closure (Fig. 124-7).

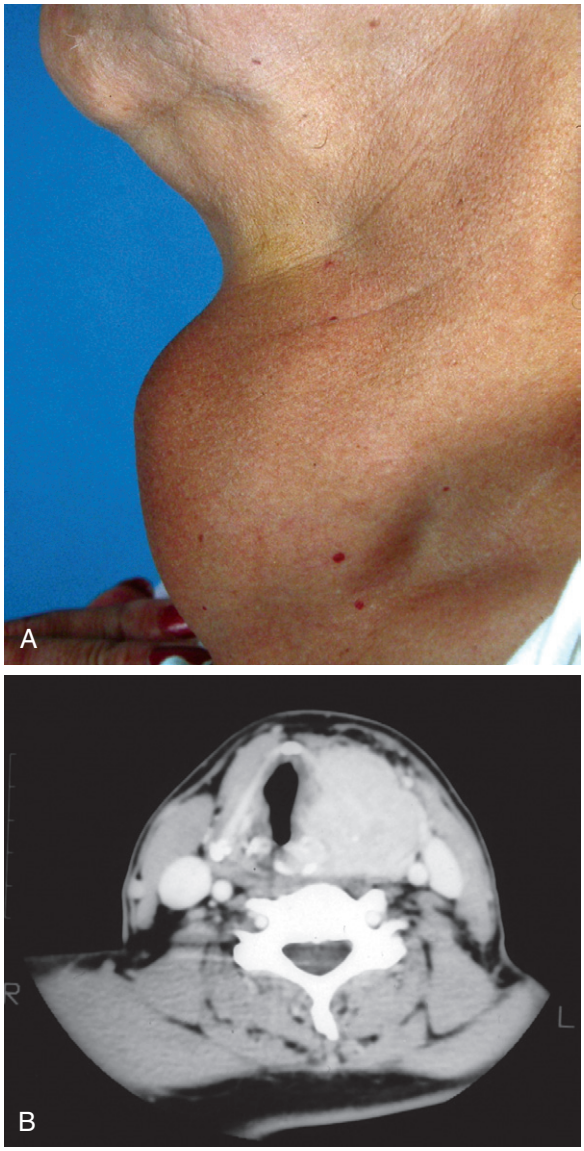

Figure 124-6. **A,** Lateral view of the neck shows a large, compressive thyroid mass. **B,** Axial CT scan reveals extensive local invasion by the thyroid lesion involving the thyroid cartilage, larynx, and esophagus.

Reoperative Thyroid Surgery

Reoperative thyroid surgery may be required in various clinical situations. A patient may have had a previous thyroid lobectomy and require a completion thyroidectomy. Recurrence of disease may require re-exploration of the thyroid bed or dissection of the cervical lymph nodes, including the central compartment (level VI). In addition, previous neck surgery, such as a parathyroidectomy, may have involved the thyroid bed.

Reoperative surgery has been associated with a higher incidence of complications than initial thyroid surgery. Scarring and fibrosis from prior surgery may cause difficulty in identifying tissue planes, resulting in an increased risk of injury to the RLN. Potential injury or devascularization of the parathyroid glands on one side of the neck creates increased concern for preservation of the glands on the contralateral side. Older series reported a high incidence of complications in reoperative surgery.[106,189] More recent reports indicate, however, that the risk of permanent hypoparathyroidism or RLN injury is less than 2%.[190-193]

Although reoperative thyroid surgery cannot be completely avoided, steps may be taken to minimize the need for reoperation. Before the initial surgery, preoperative preparation should include a thorough evaluation for thyroid mass fixation or RLN palsy or paralysis. In these patients, preoperative imaging and potential coordination with other surgeons help to prevent unexpected intraoperative findings.

The minimum adequate surgical treatment for a thyroid nodule is a thyroid lobectomy and isthmectomy. A unilateral subtotal thyroidectomy may encompass a suspected thyroid nodule, but leave residual disease behind. En bloc resection of the thyroid lobe can be performed safely, and often eliminates the need to return to the original surgical bed for re-exploration.

The effectiveness of FNAC has also directed surgeons to perform the appropriate surgery for a particular disease. The presence of a follicular or Hürthle cell adenoma should direct a surgeon to perform a unilateral thyroid lobectomy, avoiding exploration of the contralateral lobe. In cases of carcinoma, reoperation is safer because the contralateral lobe has been left undisturbed. When a patient has significant comorbidities that may preclude reoperation, the contralateral side can be addressed at the initial surgery by performing a total or near-total thyroidectomy. FNAC that shows papillary carcinoma prepares a surgeon for total thyroidectomy or more comprehensive surgery for MTC. Although intraoperative frozen-section analysis is controversial, frozen-section analysis in conjunction with cytologic examination can be valuable for cases diagnosed on preoperative FNAC as suspicious for papillary thyroid carcinoma.[194,195] Finally, ultrasound evaluation of the thyroid bed and lateral neck provides improved preoperative assessment of the extent of disease and facilitates surgical planning. Even in patients with palpable lymph node recurrences, ultrasound evaluation of the lateral and central compartments may change the extent of the surgical procedure in 40% of patients undergoing reoperative surgery.[87]

Typically, reoperation should be performed within 3 to 4 days of the initial operation, if definitive pathology is available, or after 3 months. Healing and inflammation during the early and late time points are typically manageable for reoperation. No control studies to date have addressed the issue of the degree of inflammation in the neck encountered during repeat surgery.

Before reoperation, the vocal cords should be visualized to identify any potential RLN injury. Imaging studies can be useful in cases of disease recurrence to identify local invasion or cervical disease and potential involvement of the RLN or parathyroid glands. During surgery, the RLN should be followed from a previously undissected area into the surgical bed. The surgeon should be familiar with numerous techniques to identify the RLN. A lateral approach from the medial border of the sternocleidomastoid, a low anterior neck approach, and a medial approach to the superior pole of the thyroid have been described.[192] Intraoperative monitoring of the RLN can be helpful, and an electrophysiologic nerve stimulator can facilitate and confirm nerve identification. Visualization of the RLN is crucial, and the use of loop magnification may be helpful to identify the RLN and parathyroid glands.

Because of the difficulties associated with permanent hypoparathyroidism, preservation of the parathyroid glands is crucial in reoperative surgery. As described for initial thyroid surgery, extracapsular thyroid dissection and close vessel ligation aid in preserving parathyroid gland vascular supply. Prior surgery may have disrupted the normal anatomic locations of the gland or created scarring that makes gland localization difficult. In these cases, all perithyroidal fat should be carefully mobilized and preserved. When reoperation includes central compartment dissection, the parathyroid glands may be removed en bloc with the disease.

The surgical specimen needs to be inspected carefully, and biopsy specimens of potential parathyroid tissue should be obtained. Identified parathyroid tissue should be reimplanted into the sternocleidomastoid muscle. All parathyroid tissue should be preserved when possible. The combination of parathyroid preservation in situ and autotransplantation of devascularized parathyroid tissue significantly reduces the risk of permanent hypoparathyroidism.[196] Parathyroid tissue that has been reimplanted functions even when other parathyroid glands have been left intact and in the absence of hypocalcemia.[197]

Intraoperative ultrasound may be useful for the resection of radiographically identified, nonpalpable lesions within the thyroid bed or nodal basins. The technique may be particularly helpful in patients who

The esophagus was closed primarily. **D,** Postoperative barium swallow study showed that the esophagus was intact, and the patient was able to tolerate a regular diet. *(From Lai SY, Weber RS. Thyroid cancer. In Ensley JF, Gutkind JS, Jacobs JR, et al, eds.* Head and Neck Cancer: Emerging Perspectives. *San Diego: Academic Press; 2002:424.)*

have had EBRT or for lesions that are smaller than 2 cm, locally invasive, or adherent to the airway. Ultrasound can be performed through the strap muscles in an open wound, and a needle can be placed in the target lesion as a guide.

Extent of Surgery

Surgery is the primary modality for treatment of thyroid carcinomas. Although well-differentiated thyroid cancers can be extremely aggressive and lethal, most patients have prolonged survival even with residual or recurrent disease. Controversy exists regarding the extent of surgery to be performed in patients with well-differentiated carcinomas. The primary goals of surgical treatment should be to eradicate primary disease, to reduce the incidence of local or distant recurrence, and to facilitate the treatment of metastases. These oncologic goals should be achieved with minimal morbidity.

The large body of literature regarding thyroid carcinoma and its treatment has created a wide variety of terms for describing the extent of thyroid tissue removal. Most surgeons agree that a subtotal excision of a thyroid nodule is unacceptable, and that the minimum amount of thyroid removed should be a lobectomy and isthmectomy. Some surgeons have advocated in the past a near-total thyroidectomy that preserves the posterior portion of the gland on one side to avoid injury to the RLN and at least one parathyroid gland. A total thyroidectomy involves the complete removal of both thyroid lobes, although ^{123}I scans may reveal 2% to 5% residual tissue.[198]

Proponents of a more conservative surgical approach suggest that thyroid lobectomy and isthmectomy is sufficient treatment for most patients (>80%). These patients would be categorized as low-risk in the different classification schemes (see section on tumor staging and classification). Thyroid lobectomy and isthmectomy are simpler to perform and less time-consuming than a total thyroidectomy. The overall risk of morbidity from RLN, SLN, and parathyroid gland injury is less. Finally, compared with total thyroidectomy, this conservative approach does not adversely affect prognosis and survival.

Numerous studies support the conservative approach. In the AGES classification, low-risk patients with papillary carcinoma had the same 2% 25-year mortality rate regardless of whether they were treated with thyroid lobectomy or total thyroidectomy.[55] A study by Shah and associates[58] based risk classifications on the AJCC staging system. There was no difference in 20-year survival based on surgical treatment for patients with intrathyroidal tumors of less than 4 cm. Patients treated with total thyroidectomy had an increased risk of complications, however.

Although survival differences are not found, several studies report an increased incidence of local recurrence in patients treated with only a thyroid lobectomy.[199,200] Some controversy exists regarding the relationship of local recurrence to disease survival, especially with papillary carcinomas.[121,193] Finally, patients categorized as high-risk in these classification systems are treated with near-total or total thyroidectomy and radioiodine ablation therapy.

A more aggressive surgical approach favors total thyroidectomy in most cases and lobectomy for small, single lesions. Proponents of this approach favor total thyroidectomy as a better oncologic operation. Removal of the entire thyroid gland encompasses potential extracapsular extension and multicentric lesions. Morbidity of this procedure is low with good technique and an experienced surgeon.[191] Several studies showed improved survival and decreased local or distant recurrence.[101,114,201] Cautionary studies also show the risk of aggressive disease even in patients determined to be low-risk in the various classification schemes.[202,203]

Postoperative thyroglobulin levels are more valid with removal of all normal thyroid tissue. Total thyroidectomy also facilitates the use of postoperative diagnostic scans to evaluate for metastases and recurrence. Diagnostic radioiodine uptake should ideally be 3% or less after

total thyroidectomy. Subsequent radioiodine treatment does not need to be used to ablate excess normal tissue and can be concentrated on the removal of residual carcinoma and distant metastases. Finally, although rare, removal of the entire thyroid reduces the risk of transformation from a well-differentiated thyroid carcinoma to an anaplastic carcinoma.

Controversy surrounding the extent of surgery will continue to persist because no uniform set of characteristics can be used to classify the aggressiveness of well-differentiated thyroid carcinomas. Results of treatment will also continue to differ among institutions and surgeons. Nevertheless, initial surgery should address gross disease in the thyroid and neck nodes. The extent of the surgery should be guided by the patient's risk factors, operative findings, and intraoperative progress. Ultimately, the primary goal of thyroid surgery should remain the effective eradication of thyroid cancer with minimal morbidity.

Minimally Invasive Thyroidectomy

Over the past decade, surgical approaches have been developed to permit thyroid surgery through smaller incisions.[204,205] Some of these approaches advance to the thyroid bed from remote incisions in the axilla or chest.[206,207] In addition to improved cosmesis and decreased postoperative discomfort, these approaches have afforded surgeons superior visualization of critical structures such as the SLN through the use of endoscopic instruments (Fig. 124-8). In the transcervical approach, a surgical drain is often not required, and many patients are discharged after adequate same-day postoperative observation and instruction.[208] Implementation of these approaches has been careful with an emphasis on providing equal or improved operative outcomes relative to traditional open approaches.[209,210]

Special Treatment Situations

Children

In children, nodular thyroid disease is uncommon, with an incidence of 0.2% to 1.8%.[211] Most neck masses occurring in children are due to congenital or inflammatory causes. Malignant neck masses may be due to lymphoproliferative disorders, sarcomas, or thyroid carcinomas. Less than 6% of pediatric neck tumors are thyroid malignancies.[212] Approximately 10% of all thyroid carcinomas occur in patients younger than 21 years.[213]

Most children with thyroid neoplasms present with an asymptomatic mass within either the thyroid or the lateral neck. The lesions are often asymptomatic and frequently noted by a parent or pediatrician during a routine physical examination. A complete history should include special attention to family history and radiation exposure. The physical examination should carefully evaluate potential fixation of the thyroid gland to surrounding neck structures. Vocal cord mobility should be documented by indirect fiberoptic nasolaryngoscopy. The central compartment and lateral necks also should be carefully palpated. Lymph node metastases are present in more than 50% of children with differentiated thyroid cancer.[214] Local extension was reported in 18%. In addition, 15% of patients have distant metastasis, frequently identified with postoperative radioiodine.[215,216] A chest radiograph may be normal or may show a fine interstitial reticular pattern, potentially mistaken for miliary tuberculosis. Children with extensive pulmonary involvement may present with dyspnea on exertion.

The diagnostic workup in children should include FNAC and ultrasonography. An uncooperative child may require sedation and ultrasound guidance for FNAC. Because an advanced stage of disease is common in children at initial presentation, ultrasonography provides valuable information regarding the size and consistency of the thyroid mass. Ultrasound examination also can identify potential regional involvement of the paratracheal or cervical lymphatics.

Although the most common cause of a solitary thyroid nodule in children is a follicular adenoma (68.9%), malignancies are found in 16% to 25% of the nodules.[217,218] The most common malignant histologic type is papillary carcinoma, present in more than 80% of these cases. In contrast to thyroid carcinoma in adults, papillary carcinomas are usually follicular in pattern, and tall-cell and columnar-cell variants do not occur in children.[219,220] Hürthle cell carcinomas may manifest with multiple lesions and a papillary architecture as a familial syndrome.[221] MTCs constitute about 10% of pediatric thyroid carcinomas, and all family members need to be carefully evaluated for possible familial MTC or MEN syndromes.

Management of a child with thyroid carcinoma must balance the potential morbidity associated with treatment against the low probabil-

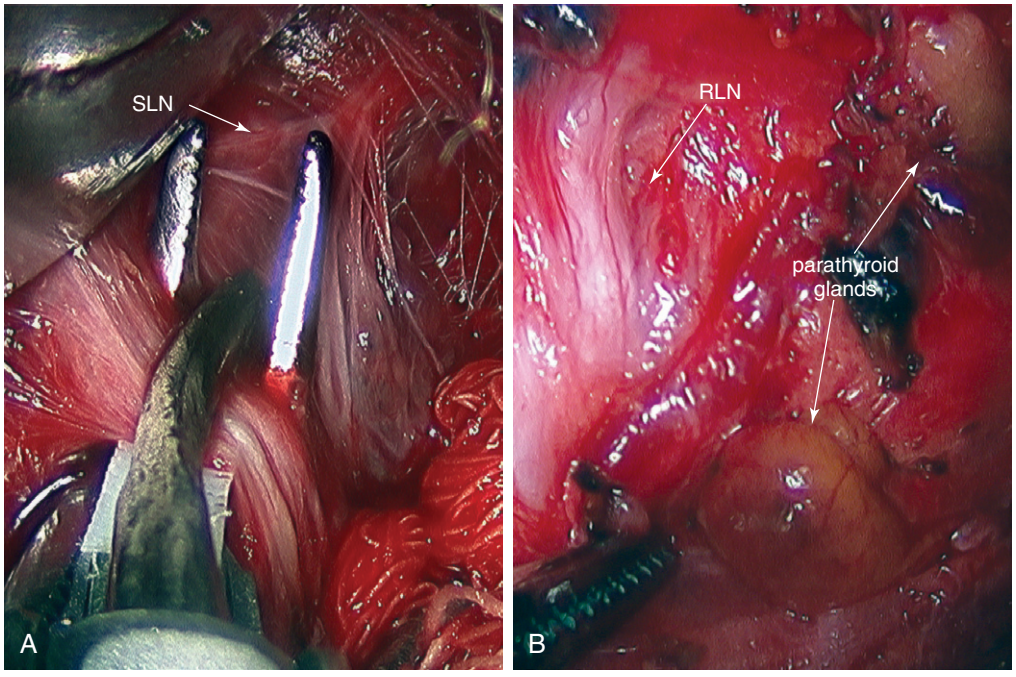

Figure 124-8. A and **B,** The magnification provided through a 5-mm 30-degree endoscope provides excellent intraoperative visualization of the superior laryngeal nerve (SLN) **(A)** and the recurrent laryngeal nerve and parathyroid glands (RLN) **(B)**. *(From Lai SY, Walvekar RR, Ferris RL. ity that the patient will die of this disease. The primary goal of surgery is to remove gross disease completely at the primary and regional metastatic sites. A total or near-total thyroidectomy is recommended.[213,214,222,223] Multifocal disease is present in 10% to 30% of patients. In addition, a total or near-total thyroidectomy allows the use of serum thyroglobulin to monitor disease recurrence, and facilitates the use of radioiodine to identify and treat distant metastases. More recent studies have shown a low incidence of permanent hypoparathyroidism and RLN injury after total thyroidectomy. The recurrence rate is lower for patients undergoing total thyroidectomy than for patients undergoing lesser procedures.[224]

Children often present with cervical nodal metastases requiring therapeutic lymphadenectomy. In patients with nodal disease, the paratracheal and pretracheal lymph nodes are involved in 90% of cases.[32] The metastatic deposits are frequently compressive rather than infiltrative with respect to adjacent neck structures. Radical neck dissection is rarely necessary. Patients should have central compartment dissections when cervical disease is present, rather than simple node plucking. Care should be taken to identify and preserve the blood supply to the parathyroid glands. Also, lateral neck disease requires a comprehensive lateral neck dissection (levels II-V).

Although children and adolescents commonly present with more advanced disease than adults, their prognosis remains excellent. In several series, young patients have a 10-year survival near 100% and a 2- to 5-year survival rate near 90%.[225] Relapse is most common in the cervical lymphatics, and is more common in children than in adults. Recurrence seems to be more common in younger patients and patients with papillary histology.[226] Cervical disease can be surgically excised, and pulmonary recurrence is responsive to radioiodine therapy.[227]

Pregnancy

Because thyroid neoplasms occur more commonly in women and often during their childbearing years, physicians occasionally need to manage this disease in pregnant women. The incidence of thyroid nodules during pregnancy has been reported as 2% to 10%.[228,229] Management of these patients must protect the well-being of the mother and fetus, and minimize the risks of preterm labor or abortion. A crucial difference in thyroid nodule management during pregnancy and breastfeeding is the absolute contraindication for the use of radioactive iodine.[230]

During pregnancy, the thyroid gland physiology is markedly altered. The gland can increase significantly in size because of a relative iodine insufficiency and hormonal changes.[231,232] These physiologic and hormonal changes may increase the incidence of thyroid nodules or cause the enlargement of existing thyroid nodules.

The presence of any discrete thyroid nodule should be evaluated by FNAC.[233] Some authors argue that a pregnant patient beyond 20 weeks of gestation should have FNAC deferred until after the pregnancy to reduce patient anxiety.[229,234] These authors argue that treatment would likely occur after surgery, and they advocate FNAC only when the nodule shows continued growth or other suspicious features. Other authors advocate immediate FNAC at any stage of pregnancy.[230]

Ultrasonography may be used for initial assessment and continued monitoring. Ultrasound evaluation is effective for the evaluation of thyroid and cervical involvement. CT scans during pregnancy are not recommended, although MRI, if necessary, may be performed safely.

When FNAC is benign, the patient should be reassured, and ultrasonography can monitor the nodule for possible growth during pregnancy. A follicular neoplasm may be monitored closely or surgically explored. If FNAC is suspicious or shows thyroid carcinoma, surgery is recommended at the safest time possible.[228] Thyroid carcinomas identified late in pregnancy should be treated in the immediate postpartum period. Carcinomas diagnosed during the first and early second trimesters may be surgically treated during the 22nd through 26th gestational weeks, when the risk to fetal development and for preterm labor is lowest. The patient can be reassured that thyroidectomy and even cervical lymphadenectomy at midtrimester do not carry significant risks for the fetus. Maternal complications are similar to nonpregnant patients. A more recent study suggests, however, no difference in the natural history and prognosis of pregnant patients with a thyroid carcinoma diagnosed early in gestation who defer surgery until after labor.[235] Most patients would likely experience too much stress and anxiety to have an untreated cancer present throughout gestation.

Aggressive thyroid carcinomas that grow rapidly or invade adjacent cervical structures may demand immediate surgical attention. Additionally, a diagnosis of medullary or undifferentiated carcinoma in pregnant patients requires prompt treatment. These tumors are rare and often affect older women. Before starting treatment in these cases, the pregnancy should be terminated.

Complications

Among head and neck surgical procedures, thyroid surgery is very safe. Mortality rates are extremely low, and morbidity is relatively low. Generally, serious complications occur in less than 2% of all thyroid cases.[10] Complications can typically be divided into nonmetabolic and metabolic complications. Of particular concern are injuries to the RLN and the parathyroid glands.

Perioperative complications are unusual in thyroid surgery. Postoperative infections are very unusual because of the abundant blood supply in the thyroid bed. The prevention of scar widening or hypertrophy depends on proper placement of the incision. The incision can often be hidden within existing skin creases. The incision should not be placed too low in the neck to avoid the increased skin tension over the sternal notch. Pneumothorax is very rare and often associated with extended procedures that involve subclavicular dissection. Chylous fistulas may occur more often on the left side, but are usually self-limiting when wound drainage is adequate.

Bleeding Complications

Hemorrhage is uncommon when surgery is performed with meticulous hemostasis. Bleeding may occur, however, because of an undetected coagulopathy or a technical mishap. Significant hemorrhage in the immediate postoperative period can lead to life-threatening airway compression. A rapidly expanding hematoma requires immediate opening of the surgical incision and evacuation of blood. Airway control can be established, and the patient can be returned to the operating room for complete exploration to identify bleeding sites. A wound seroma may occur, especially after the removal of a large goiter. If a fluid collection is present, simple needle aspiration should manage the problem and prevent the risk of infection.

Superior Laryngeal Nerve Injury

Injury to the external branch of the SLN is believed to be rare, but the exact frequency is unknown. Often disturbance of SLN function is temporary and unrecognized by the patient and the surgeon.[236] Injury to the SLN alters function of the cricothyroid muscle. Patients may have difficulty shouting, and singers find difficulty with pitch variation, especially in the higher frequencies. The external branch of the SLN is not often visualized and lies near the superior pole vessels. Adequate exposure of the superior thyroid pole and close ligation of the individual vessels on the thyroid capsule may prevent SLN injury. Voice therapy may help patients to compensate in cases of SLN injury.

Recurrent Laryngeal Nerve Injury

Injury to the RLN has a much greater impact and is more noticeable than SLN injury. The incidence of permanent RLN paralysis is approximately 1% to 1.5% for total thyroidectomy and less for near-total procedures.[101,237,238] Temporary dysfunction because of nerve traction occurs in 2.5% to 5% of patients.[176] Incidence increases with second and third procedures. RLN injury is also more common in thyroidectomy with neck dissection, although this may reflect more advanced disease states.[239] Disease-specific risk factors for permanent nerve damage include recurrent thyroid carcinoma, substernal goiter, and various thyroiditis conditions. Vocal cord function should be evaluated and documented by indirect laryngoscopy, especially in patients who have had previous surgery.

Unilateral RLN injury leads to a vocal cord in the paramedian position, and the voice may be breathy and lack volume. Concurrent injury of the SLN results in a more laterally positioned vocal cord and worsens voice quality and glottic competence.[240] Occasionally, patients may have difficulty with aspiration and pneumonia.[239]

Bilateral RLN injury may manifest very dramatically. Immediate postoperative stridor and dyspnea may require immediate reintubation and a possible tracheostomy. Occasionally, bilateral RLN injury may not be immediately noticeable, and patients may adapt to the reduced airway. Over time, the vocal cords move to the midline compromising the airway.

Identification and careful dissection along the course of the RLN decreases the incidence of permanent injury. The surgeon should also be aware of the possibility of a nonrecurrent nerve, most commonly on the right side. If the nerve is transected during surgery, microsurgical repair of the nerve is recommended. Although the repair is unlikely to restore normal function, reanastomosis of the RLN may decrease the extent of vocal cord atrophy.[241] Some surgeons advocate anastomosis of the ansa hypoglossal nerve to the distal end of the severed RLN to prevent laryngeal synkinesis and possible vocal cord hyperadduction.[242,243]

Comprehensive management of vocal cord injury is beyond the scope of this chapter. In most cases, RLN injury is detected postoperatively. Management is supportive, although some surgeons favor reexploration when vocal cord paralysis is noted in the immediate postoperative period. Return of normal vocal cord function occurs 6 to 12 months after temporary RLN injury occurs. Speech therapy can be valuable. Serial examinations should document a potential return of function or compensation by the contralateral vocal cord. In patients with continued vocal incompetence or aspiration, treatment directed toward vocal cord medialization may consist of vocal cord injection, thyroplasty, or arytenoid medialization. In cases of bilateral RLN injury, management is directed at improving the airway, while not completely sacrificing airway quality, and may involve arytenoidectomy or transverse cordotomy.

Hypocalcemia

Transient symptomatic hypocalcemia after total thyroidectomy occurs in approximately 7% to 25% of cases, but permanent hypocalcemia is less common (0.4% to 13.8%).[244,245] The risk of hypoparathyroidism is related to the size and degree of invasion of the tumor, pathology, and extent of procedure and surgeon experience.[55,246] Changes in serum calcium levels are often transient and may not always be related to parathyroid gland trauma or vascular compromise.

Parathyroid autotransplantation may be considered when the risk of postoperative hypocalcemia is increased.[247,248] These situations may include thyroid carcinoma requiring total thyroidectomy with central neck dissection, en bloc resections that require removal of the parathyroid glands, and reoperation after previous thyroid or parathyroid surgery. Autotransplantation is commonly performed in the sternocleidomastoid muscle, although various locations, including the brachioradialis muscle of the nondominant forearm, have been used.[249]

Transient hypocalcemia is often related to variations in serum protein binding caused by perioperative alterations in acid-base status, hemodilution, and albumin concentration. These changes do not produce hypocalcemic symptoms. Sudden changes in levels of ionized serum calcium can result in perioral and distal extremity paresthesias, however. As calcium levels continue to decline, patients may experience tetany, bronchospasm, mental status changes, seizures, laryngospasm, and cardiac arrhythmias. Chvostek's sign and Trousseau's sign may develop with increased neuromuscular irritability as serum calcium levels decrease to less than 8 mg/dL.

Typically, serum calcium levels are measured in the immediate postoperative period and the next morning for patients with a total or completion thyroidectomy. Patients should have a stable or increasing serum calcium level. Patients undergoing a thyroid lobectomy do not usually require serum calcium monitoring. Findings that should be worrisome for hypoparathyroidism include hypocalcemia, hyperphosphatemia, and metabolic alkalosis. PTH levels may also be measured to predict potential hypocalcemia.[250]

Treatment for hypocalcemia is typically initiated if the patient is symptomatic or serum calcium levels decrease to less than 7 mg/dL. In these patients, cardiac monitoring is warranted. Patients should receive 10 mL of 10% calcium gluconate and 5% dextrose in water intravenously, titrated to symptom resolution and subsequent serum calcium level tests. Oral calcium supplementation should begin with 2 to 3 g of calcium carbonate per day. Calcitriol (1,25-dihydroxycholecalciferol) also should be initiated. Adjustments in supplemental calcium and vitamin D should be done in consultation with an endocrinologist.

Postoperative Management and Special Considerations

Thyroid Hormone Replacement

After total or completion thyroidectomy, exogenous supplementation of thyroid hormone is necessary to prevent symptomatic hypothyroidism.[6,77] To counteract potential trophic effects of TSH that could facilitate recurrence or progression of well-differentiated thyroid carcinomas, long-term supplementation with levothyroxine is monitored to suppress TSH to below-normal levels (<0.1 mU/L in high-risk patients and 0.1 to 0.5 mU/L in low-risk patients).[67] Patients receiving suppressive therapy have a lower recurrence rate and improved survival.[251,252]

In the immediate postoperative period, patients are frequently given liothyronine sodium (Cytomel). Liothyronine sodium has a shorter half-life than levothyroxine, decreasing the waiting period before radioiodine body scanning and possibly enabling ablative therapy to be performed.

Radioactive Iodine Treatment

Radiolabeled iodine has been used for more than 40 years to ablate normal thyroid tissue and to treat residual tumor and metastases.[253] The ^{131}I isotope emits β particles that penetrate and destroy tissue within a 2-mm zone. Patients classified as high risk with papillary thyroid carcinoma and most patients with follicular carcinoma are considered for treatment.[127] When administered as part of the initial therapy, postoperative ^{131}I treatment contributes to decreased recurrence and disease-specific mortality.[254-256] Despite poor radioiodine uptake in Hürthle cell and medullary carcinomas, these patients are often treated to provide any possible benefit.

Elevated TSH levels are necessary to enhance uptake of iodine by thyroid cancer cells. A TSH greater than 30 mU/L is associated with increased radioiodine uptake in tumors.[257] Patients are taken off thyroid hormone suppression therapy for 2 to 4 weeks before scanning and placed on a low-iodine diet.[69] Additionally, the administration of exogenous recombinant human TSH has proved safe and effective for stimulating radioiodine uptake and for detecting serum thyroglobulin in patients undergoing evaluation for thyroid cancer persistence and recurrence.[258,259]

Whole-body diagnotic scans stage the patient and determine the need and potential benefit of radioiodine therapy. The phenomenon termed *stunning* may occur, however, when scanning doses of ^{131}I induce follicular cell damage. Poor uptake by thyroid remnant and metastases of subsequent therapeutic ^{131}I doses reduces the potential benefits of this therapy.[260] Pretreatment scans are now performed with small doses of ^{131}I (2 to 3 mCi) or ^{123}I. The physical properties of ^{123}I permit better image quality and decrease possible stunning of functioning thyroid cells by the β particle emission of ^{131}I[261]; this permits the maximal benefit of ^{131}I in ablation after the diagnostic procedure.[262]

After the diagnostic scan, therapeutic ablative doses of ^{131}I can be given. Typically, 100 mCi of ^{131}I is given for uncomplicated cases with only thyroid bed uptake. Although a lower dose of 30 mCi has commonly been used, studies have shown this is not as effective. Current guidelines recommend employing the minimum activity necessary to achieve successful thyroid remnant ablation, particularly for low-risk patients.[69] Patients with uptake in cervical nodes, distant metastases, or more aggressive tumor histology (e.g., tall-cell, insular, columnar-cell carcinoma) receive 100 to 200 mCi.[263,264] Doses greater than 200 mCi have not been shown to be more effective in most cases.

No clear evidence exists regarding the superiority of ^{131}I delivery by empiric fixed amounts, quantitative tumor dosimetry, or blood/body dosimetry.[265] In addition, there are not enough outcome data currently to recommend recombinant human TSH–mediated ^{131}I therapy for patients with metastatic disease. Such use of recombinant

human TSH may be indicated, however, in patients with underlying comorbidities who would be at risk because of iatrogenic hypothyroidism. Post-treatment scans are typically performed approximately 1 week after radioactive iodine therapy to visualize potential metastases.

Diverse alternatives and protocols exist regarding the use of radioiodine therapy. Surgeons who favor total thyroidectomy for most thyroid carcinomas argue that removal of normal tissue enhances radioiodine ablation therapy. Proponents of more conservative treatment suggest that radioiodine therapy can be used to remove even a remaining thyroid lobe before whole-body scanning for residual tumor or metastases. The 2006 ATA guidelines recommend against the use of radioactive iodine ablation instead of completion thyroidectomy.[69] Continued work in this area is aimed at improving patient outcomes and decreasing disease recurrence.

External-Beam Radiotherapy and Chemotherapy

Because of the effectiveness of surgery and radioiodine treatment for most thyroid carcinomas, experience with EBRT and chemotherapy is more limited. EBRT seems to improve local control of well-differentiated carcinomas, especially when used in combination with doxorubicin.[182,216,266] The effect of EBRT on survival is uncertain, however.[266,267] Palliation of patients with distant metastasis of well-differentiated carcinomas, especially to the bone, seems to be improved with EBRT.[182] Current recommendations support consideration of EBRT for patients older than 45 years with grossly visible extrathyroidal extension at the time of surgery and a high likelihood of microscopic residual disease.[69] EBRT also may be employed for patients with gross residual tumor unlikely to respond to further surgery or radioactive iodine.

Limited success with EBRT in combination with doxorubicin/cisplatin has been noted with anaplastic carcinoma.[86,268] This disease remains uniformly fatal, however, and palliation through local control and airway protection are the only realistic goals. Patients with metastatic medullary carcinoma may benefit from EBRT and chemotherapy to decrease local recurrence.[269,270] Typically, patients with regional nodal metastases recognized during surgery receive postoperative EBRT. Generally, the poorer outcomes for patients with medullary and anaplastic carcinomas have not been significantly altered by EBRT and chemotherapy. Overall, there is no role for the routine adjunctive use of chemotherapy with differentiated thyroid cancer.[69] Based on improved understanding of the biologic basis for thyroid cancer development and progression, numerous novel targeted-therapy agents, including kinase and angiogenesis inhibitors, are currently in clinical trials.[271] A more recent phase II clinical trial showed some promising results with the BRAF inhibitor sorafenib in patients with iodine-refractory metastatic disease.[272]

Follow-up Management

Patients treated for thyroid carcinomas require long-term follow-up and monitoring. Approximately 30% of patients with differentiated thyroid carcinomas have tumor recurrences within several decades, and 66% of these recurrences occur within the first decade after initial treatment.[6] Various staging systems for thyroid cancer, including the AJCC/IUCC system, were developed to predict risk for death, not recurrence.[69,273,274] After initial surgery and remnant ablation, low-risk patients have no local or distant metastases, complete resection of all macroscopic tumor, no locoregional tumor invasion, no aggressive histology, no vascular invasion, and no ^{131}I uptake outside the thyroid bed in the first post-treatment whole-body radioiodine scan. Intermediate-risk patients have microscopic invasion of tumor into the perithyroidal soft tissues at initial surgery, aggressive histology, or vascular invasion. High-risk patients have macroscopic tumor invasion, incomplete tumor resection, distant metastases, or radioiodine uptake beyond the thyroid bed on the post-treatment scan done after thyroid remnant ablation.

In addition to regular physical examination, thyroid hormone and TSH levels are monitored to ensure adequate suppression. Thyroglobulin levels should be closely monitored, and diagnostic radioiodine scanning should be performed. These tests should be performed annually for the first 2 years and then every 5 years for 20 years.[275] Typically, thyroglobulin levels should be less than 2 ng/mL after total thyroidectomy and radioiodine ablation therapy (<3 ng/mL if the patient is off thyroid replacement therapy). Increasing serum thyroglobulin levels are highly sensitive (97%) and specific (100%) for thyroid cancer recurrence.[276] Elevation of thyroglobulin levels warrants repeat radioiodine scanning and therapy. More recent studies have shown the sensitivity of serum thyroglobulin measurements for predicting thyroid cancer recurrence after a patient has received two injections of recombinant human TSH.[277] Depending on risk classification, additional follow-up procedures vary. The 2006 ATA guidelines recommend measurement of serum thyroglobulin and a cervical ultrasound examination in low-risk patients approximately 12 months after initial treatment with surgery and radioiodine ablation, but not additional whole-body radioiodine scans.[69] In intermediate-risk and high-risk patients, cervical ultrasound examination and diagnostic whole-body radioiodine scans are recommended every 6 to 12 months.

Patients with MTCs require serial measurements of calcitonin and CEA. Suspected recurrences may also be detected with pentagastrin-stimulation test. See the section on medullary thyroid carcinoma for further details.

Summary

A great deal of literature addresses the treatment of thyroid carcinomas. Questions remain unresolved regarding the extent of thyroidectomy to perform in patients with well-differentiated carcinomas and the effect on patient survival. Because most patients with well-differentiated thyroid carcinomas do well, failures to resolve issues such as this are tolerated. Also, studies to address these issues require very large cohorts with long-term follow-up of 20 to 30 years.

Nevertheless, surgeons need to remain wary of the devastating progression of disease in MTCs and anaplastic thyroid carcinomas. Despite clinical classification schemes, even well-differentiated carcinomas can have unpredictably aggressive clinical manifestations. As understanding of the molecular and genetic mechanisms of thyroid carcinomas improves, better diagnostic tests should improve our ability to treat these cancers. Targeted therapies based on understanding of the biologic basis of thyroid cancer development and progression are currently in clinical trials, and may provide patients with additional treatment options.

CHAPTER ONE HUNDRED AND TWENTY-FIVE

Management of Parathyroid Disorders

Phillip K. Pellitteri

Robert A. Sofferman

Gregory W. Randolph

Key Points

- Early reports of hyperparathyroidism involved symptomatic disease, including disorders of bone and kidney. In contrast, most current patients with hyperparathyroidism are minimally symptomatic at presentation.
- Genetic mutational events seem to trigger mechanisms of propagation, resulting in clonal expansion of cells as an etiology for parathyroid adenoma. These mutational events have been characterized as altering the *PRAD1* proto-oncogene together with loss of tumor suppressor gene function.
- Calcium homeostasis is modulated by the complex interrelationship of parathyroid hormone (PTH), vitamin D, and calcitonin.
- The intact (1-84) PTH molecule is the major circulating form of biologically active PTH, and possesses a very short half-life (approximately 3 to 5 minutes).
- PTH release is regulated predominantly by serum ionized calcium levels, the physiologically active component of total serum calcium.
- The major target end organs for PTH are the kidneys, skeletal system, and intestine.
- The parathyroid glands are derived from pharyngeal endodermal pouches—superior glands from the fourth pouch and inferior glands from the third pouch.
- The embryonic descent of the parathyroid glands into the neck account for their normal and potential ectopic locations.
- Superior glands are generally located within 1 to 2 cm of the cricothyroid muscle–recurrent laryngeal nerve junction.
- Inferior glands may be more difficult to locate because of the longer migratory descent during development.
- A cervical approach may be used to remove 95% of parathyroid adenomas.
- The major functional parenchymal cells of the parathyroid glands are chief cells.
- Oxyphil cells, the second most common parenchymal cell, concentrate sestamibi because of the high concentration of mitochondria.
- Solitary glandular enlargement (adenoma) accounts for 80% to 85% of primary hyperparathyroidism.
- Diffuse glandular enlargement (hyperplasia) is the etiology for most of the remaining patients with primary hyperparathyroidism and patients with renal failure–induced disease.
- The hallmark of parathyroid carcinoma is invasion of the soft tissue components of the central neck.
- The diagnosis of primary hyperparathyroidism is confirmed by the biochemical findings of hypercalcemia, elevated serum PTH, and elevated or normal levels of calcium in the urine.
- Hypocalciuria associated with hypercalcemia and elevated levels of PTH may indicate a nonsurgical genetic disorder known as familial hypocalciuric hypercalcemia.
- Vitamin D deficiency may cause falsely elevated levels of PTH, mimicking hyperparathyroidism, in a setting of high normal serum calcium levels.
- Localization of abnormal hyperfunctional parathyroid glands may be accomplished using nuclear uptake studies or anatomic imaging with ultrasound or computed tomography.
- Directed exploration for hyperparathyroidism exploits the ability to localize preoperatively abnormal parathyroid tissue together with the capability to confirm biochemically removal of all hyperfunctional parathyroid tissue using rapid measurement of PTH intraoperatively.
- Conventional bilateral neck exploration represents the gold standard by which all other, less extensive exploration procedures are measured.
- The ability to perform less extensive operations for hyperparathyroidism is not a substitute for a thorough knowledge of the embryoanatomic detail of the central neck, and the ability to conduct a comprehensive and meticulous four-gland exploration.

The recorded history of hyperparathyroidism in modern medicine is relatively recent. Owen, a renowned British anatomist and curator, is generally acknowledged as being the first to describe the existence of the parathyroid glands in 1852.[1] The discovery occurred subsequent to the death of the Zoological Society of London's Indian rhinoceros, the postmortem of which was conducted by Owen and subsequently reported to the Zoological Society. In 1877, the Swedish histologist Sandstrom reported the existence of distinct glandular tissue adjacent to the thyroid in a dog.[2] Over the subsequent 2 years, similar findings in other small mammals led to the search for, and ultimate discovery of, a similar organ in humans (glandulae parathyroideae), which Sandstrom reported on in 1880.

The earliest reports of clinical hyperparathyroidism involved bone disease, or *osteitis fibrosa cystica,* as termed by von Recklinghausen.[3] These reports did not associate the characteristic changes in bone from hyperparathyroidism with parathyroid gland abnormalities, however. In 1903, Askanazy[4] reported on an autopsy performed on a patient with osteomalacia and nonfusing long bone fractures in whom a large (>4 cm) tumor was seen adjacent to the thyroid gland, noting that it might represent a parathyroid tumor.

When Erdheim,[5] a Viennese pathologist, discovered parathyroid gland morphologic and histologic abnormalities in patients with bone disease, an association between osteomalacia and parathyroid gland function was suspected. Erdheim studied the parathyroid glands by autopsy on all patients who died with bone disease, and noted that many patients with osteomalacia and osteofibrosis cystica showed enlarged parathyroid glands. He postulated that these glandular enlargements were secondary to compensatory hyperplasia, and that the bone disease was the primary initiating factor. Following up on initial experiments performed in rats by Gley, a French physiologist, Erdheim showed that cautery destruction of the parathyroid glands in rats produced not only tetany, as shown by Gley, but also the typical dental changes consistent with calcium not being laid down.[5]

Numerous reports of large parathyroid glands and bone disease followed until Schlagenhaufer[6] suggested, at a meeting in Vienna in 1915, that if only a single parathyroid gland was thought to be enlarged, it should be excised. The event that followed this suggestion years later would usher in the future treatment of parathyroid disease. von Eiselberg,[7] a pupil of Billroth, is noted as having performed the first parathyroid transplant. After performing total thyroidectomy in cats, von Eiselberg autografted the thyroid gland and a parathyroid gland into the animal's abdominal wall. Postoperatively, the animals showed no sign of tetany, and, when subjected to histologic examination, these grafts showed evidence of neovascularization.[7]

Halsted's experience with chronic hypocalcemia in thyroidectomy prompted him to study parathyroid transplantation experimentally in dogs.[8] He showed that even very small portions of surviving parathyroid tissue autograft could be lifesaving in these animals, and tetany and death would result after removal. In addition, Halsted used intravenous calcium gluconate solution to treat animals after experimental thyroidectomy. These experiments and others sparked his ever-present mandate to perform thyroidectomy carefully and meticulously avoiding injury to the parathyroid glands and their blood supply. Halsted worked with Evans, a medical student at Johns Hopkins, to define the blood supply to the parathyroid glands using vascular casting technique, and emphasized that tetany after thyroidectomy was caused more by interruption of the vascular supply to the parathyroid glands than by their inadvertent removal.[8]

From a clinical standpoint, the treatment of parathyroid disease was to change significantly with the work of Mandle.[9] Albert Gahne, a tram conductor, lived in Vienna after a bout with tuberculosis, which he acquired while serving in the Army during the years 1914-1918. He subsequently developed bone pain and muscle fatigue in 1921 from which he became disabled. In 1924, after a fall that resulted in a fractured femur, he came under the treatment of Mandle, who recognized these events as being consistent with parathyroid abnormality. Believing that this case might represent compensatory parathyroid hyperplasia as postulated by Erdheim, Mandle administered fresh parathyroid extract to Gahne without improvement. Subsequently, Mandle transplanted fresh parathyroid glands obtained from the victim of a street accident into Gahne, which again did not result in any resolution of symptoms. Recalling Schlagenhaufer's suggestion of nearly 10 years earlier, Mandel explored the neck of the now severely crippled tram conductor and removed a parathyroid tumor.[9] Gahne experienced a remarkable and immediate improvement in bone pain, and nearly 4 years later was walking with a cane free of pain. The disease recurred, and the patient was subsequently re-explored, but died after the procedure.[10] This experience illustrated several important issues that would come to influence future work with surgical parathyroid disease, including clinical use of parathyroid transplantation in humans and the treatment of recurrent disease by re-exploration.

In 1924, Hanson developed a potent extract of the parathyroid glands, which when injected into animals led to increased serum calcium, decreased phosphate, and elevated output of calcium in the urine. When used chronically, this extract would produce osteoporosis in the animals.[11]

The association of elevated blood calcium levels and parathyroid dysfunction was well acknowledged when Charles Martell, a sea captain, was evaluated at the Massachusetts General Hospital in 1927, and found to have hypercalcemia and generalized demineralization of the skeleton believed to be caused by hyperparathyroidism. The first two of a total of six operations performed on Martell were done by Richardson, the Chief of Surgery at Massachusetts General Hospital. These first two neck explorations yielded only a single normal parathyroid gland on each side without identification of abnormal tissue.[12] A third neck exploration was performed in New York in 1929 by Patterson without success. As renal function began to deteriorate with increasing symptoms of parathyroidism, Martell returned to Massachusetts General Hospital under the care of Albright and Cope. Cope had experience in several parathyroid explorations under the supervision of Churchill, and began cadaver dissection in preparation for re-exploration of Martell, which he did on three occasions in 1932 without success. At the urging of Martell, who had read extensively about his own disease and the potential locations of ectopic parathyroid tissue, Churchill planned a mediastinal exploration, the seventh surgical procedure on Martell. With Cope assisting, Churchill identified and removed most of a 3-cm tumor from the mediastinum, leaving an attached remnant portion with its vascular pedicle intact to avoid profound hypocalcemia. Despite these measures, tetany developed postoperatively, which required treatment with calcium supplementation. Several weeks after surgery, Martell experienced renal colic from an impacted ureteral stone, which required surgery. Martell died from laryngospasm after an operation to relieve obstruction from the impacted stone.

Although the series of procedures performed on Martell predated it and received more notoriety, the first successful parathyroidectomy performed in the United States was performed by Olsch in 1928 at Barnes Hospital of Washington University. In this instance, a large adenoma was removed precipitating a profound decline in serum calcium, which required massive doses of parathyroid extract and intravenous calcium to save the patient.[12,13]

The Nobel work of Berson and Yalow in 1963 paved the way for accurate identification of parathyroid hormone (PTH) levels in serum, and heralded a new era in the presentation of patients with parathyroidism. In addition, multichannel autoanalyzing systems rapidly assessed blood chemical components including calcium in a routine fashion, changing the manner in which patients with hyperparathyroidism present for treatment. Instead of renal stones and bone abnormalities, patients now present in an asymptomatic fashion without significant subjective complaints and very few (if any) clinical signs. In most instances, the only abnormality facing the surgeon is an elevated serum calcium and PTH level. It is on these findings, and the assessment of risk of developing end organ damage that modern-day surgeons treating parathyroid disorders must base their management decisions.

Etiology and Pathogenesis of Hyperparathyroidism

Parathyroid adenomas apparently are monoclonal or oligoclonal neoplasms, whereby the mechanism of propagation is believed to be clonal

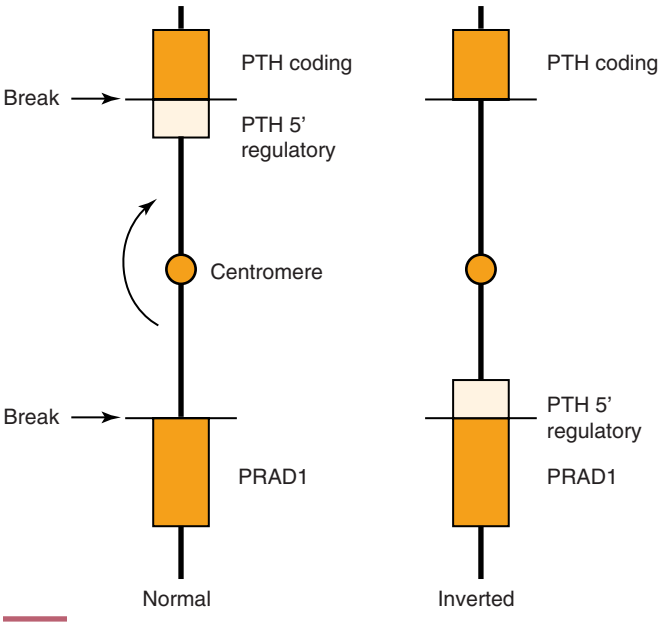

Figure 125-1. Genetic rearrangement of the parathyroid hormone (PTH) gene in primary hyperparathyroidism. Pericentromeric inversion of chromosome 11 illustrating *PRAD1* and PTH gene rearrangement. *(From Arnold A. Genetic basis of endocrine disease 5: molecular genetics of parathyroid gland neoplasia.* J Clin Endocrinol Metab. *1993;77:1108-1112. The Endocrine Society; reprinted with permission.)*

expansion of cells that have an altered sensitivity to calcium.[14] The work of Arnold and colleagues[14] indicates that the molecular events that seem to trigger clonal propagation are heterogeneous. The genetic mutational events that occur in hyperparathyroidism have been characterized in a few tumors. Among the events identified are genetic rearrangements of *PRAD1,* or parathyroid adenomatosis 1 oncogene, which is also known as cyclin D1. This proto-oncogene is located in the vicinity of the regulatory region of the gene for PTH production (Fig. 125-1).[15,16] Subsequent realignment of DNA in this event now combines a growth promoter (*PRAD1*) with a regulatory region that would ordinarily control only PTH synthesis. This genetic realignment has not been uniformly shown in most parathyroid adenomas, with only a few having been shown to manifest rearrangement.

A more common molecular event, postulated to occur in parathyroid neoplasia, is alteration in tumor suppressor gene expression (Fig. 125-2). For this gene to be inactivated and product deficient, both alleles on the gene must be affected by the mutational event. Tumorigenesis occurs as a sequential event by inactivation of both copies of the suppressor gene.[17] The most well known of these is the *MEN1* tumor suppressor gene, which shows somatic mutations in both gene copies in 20% of patients with primary hyperparathyroidism.[18] This gene was initially recognized in patients with multiple endocrine neoplasia type I (MEN-I) syndrome.[19] Evidence of loss of suppressor gene function on chromosome 1p has been postulated as being an even more common event in the development of sporadic parathyroid adenomas. It has been suggested that patients with this chromosomal abnormality may be subject to developing the same constellation of endocrine changes found in MEN-I syndrome and perhaps at an earlier age.[17] Suspected loss of tumor suppressor gene function has been identified in other chromosomal loci in patients with parathyroid adenomas including sites 15q, 9p, 6q, and 1q.[17]

Point mutations in the calcium-sensing receptor gene that reduced the activity of this gene have been elucidated as the basis for familial hypocalciuric hypercalcemia and neonatal severe hyperparathyroidism.[20] This gene seems to represent a likely candidate for molecular rearrangement and altered calcium sensing function in patients with hyperparathyroidism. To date, however, a calcium-sensing receptor gene mutation or allelic inactivation has not been shown in these patients. It has been postulated that alterations in the calcium-sensing function in primary hyperparathyroidism may represent postgenomic events related to reduced RNA transcript or the actual protein receptor in the parathyroid cell clone.[21] Whether these events may represent the primary cause for, or secondary effect of, hypercalcemia remains to be determined. Abnormalities in the parathyroid cells vitamin D receptor similarly may represent changes occurring secondary to hypercalcemia and not a primary genetic event. An inactivating mutation in the gene coding for this receptor has been postulated in primary hyperparathyroidism, but results from these investigations are conflicting.[22]

Firm evidence supports the theory that ionizing radiation can represent the etiologic factor in several solid and humoral human cancers. Tisell and colleagues[23] observed that there seems to be an association between exposure to ionizing radiation to the head and neck at an early age and the late development of hyperparathyroidism. This finding is supported by other independent observations where hyperparathyroidism has developed, presumably as a late complication of radiation therapy to the head and neck, similar to the finding noted with differentiated thyroid cancer.

Calcium Homeostasis and Parathyroid Hormone Secretion and Regulation

Calcium homeostasis is maintained by the complex interrelationship of PTH, vitamin D and its derivatives, and calcitonin. The polypeptide PTH contains 84 amino acids. When secreted by the parathyroid glands, PTH undergoes immediate degradation into the amino- and carboxyl-terminal fragments. The amino-terminal fragment is biologically active, but is rapidly cleared from the circulation, whereas the carboxyl-terminal fragment is biologically inert, is predominately cleared from the circulation by the kidney, and persists for a longer time particularly in patients with renal failure.[24,25] The intact 1-84 molecule is the major circulating form of biologically active PTH; assays that measure the intact hormone more clearly reflect dynamic changes in PTH metabolism compared with the previous polyvalent assays, which measured a predominately inactive section of the PTH molecule.[26]

The release of PTH is regulated predominately by serum ionized calcium levels. PTH is secreted in response to a decrease in serum-ionized calcium, and is inhibited by an increase of serum-ionized calcium. Ionized calcium is considered to be the physiologically active component of total serum calcium.

The major target end organs for PTH action are the kidneys, skeletal system, and intestine.[27] PTH functions by binding to receptor sites in bone and kidney, which results in stimulation of the production of cyclic adenosine monophosphate (cAMP), which acts to carry out the cellular response of that specific target tissue to PTH.

The primary response to PTH by the kidney is to increase the tubular resorption of calcium and decrease the tubular resorption of phosphorus.[28,29] The action of PTH on bone to regulate serum calcium is through the remodeling effect of osteoclast and osteoblast activity. The osteoblasts and their precursor cells in bone have a PTH receptor site, and binding to this site results in the production of cAMP. The osteoclasts do not have a PTH receptor site, but are stimulated indirectly through the cAMP response in the osteoblasts.[30] The last important function of PTH occurs indirectly by increasing the rate of conversion in the kidney of 25-hydroxyvitamin D_3 (calcifediol) to 1,25-dihydroxyvitamin D_3 (calcitriol).[31] The coordinated actions of PTH on bone, kidney, and intestine increase the flow of calcium into the extracellular fluid and as a consequence increase the serum calcium levels.

PTH is the primary regulator of rapid changes of extracellular calcium levels. The action of vitamin D affects delayed changes in calcium balance as opposed to the more immediate direct action of PTH.[27] Calcitonin plays a much smaller role in calcium homeostasis. Calcitonin is secreted by the parafollicular cells of the thyroid gland and inhibits bone resorption. Calcitonin tends to be decreased in postmenopausal women, and may be increased by estrogen administration in these patients. Extremely high levels of calcitonin found in medullary carcinoma of the thyroid gland do not result in hypocalcemia.[32]

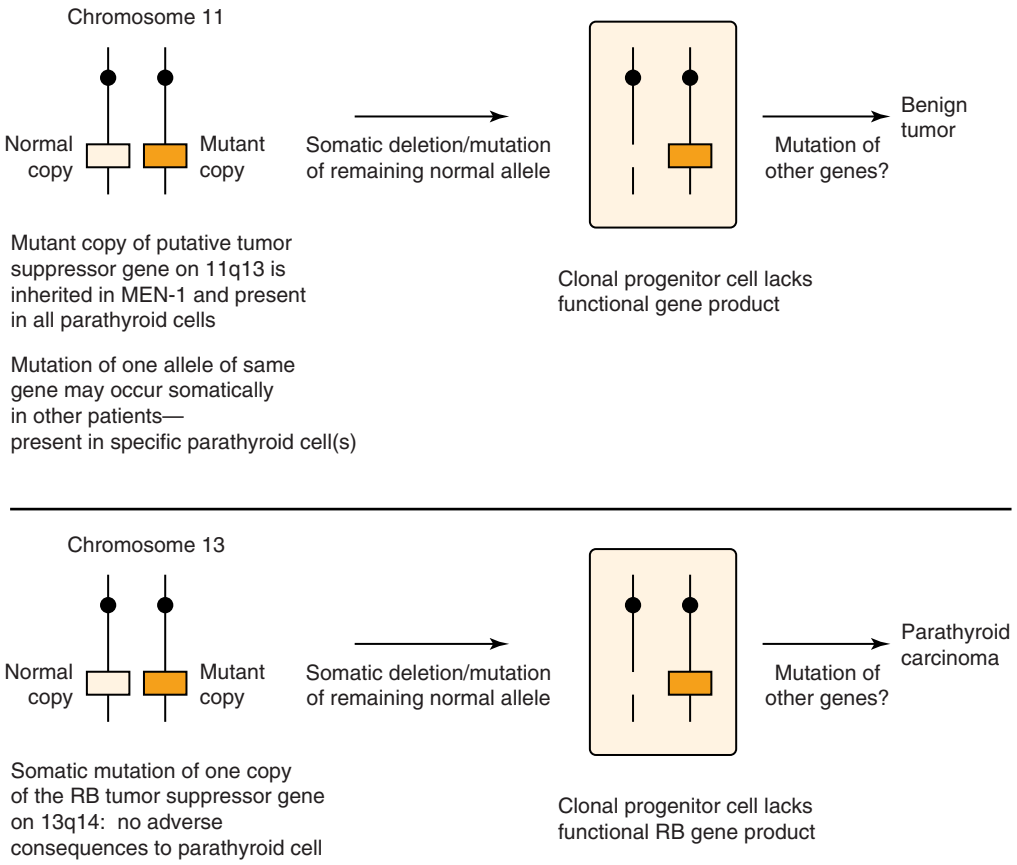

Figure 125-2. Hypothesized roles of inactivated tumor suppressor genes in the development of parathyroid neoplasia. *(From Arnold A. Genetic basis of endocrine disease 5: molecular genetics of parathyroid gland neoplasia.* J Clin Endocrinol Metab. *1993;77:1108-1112. The Endocrine Society; reprinted with permission.)*

Several endogenous substances, including peptides, steroid hormones, and amines, have been found to influence PTH release.[33,34] Calcium represents the most potent regulator of PTH secretion, however. Minor alterations within the physiologic calcium concentration range can induce considerable secretory responses—reduction of ionized plasma calcium by 0.04 mmol/L may elevate serum PTH by 100% or more. The rapid effect of extracellular calcium on PTH release suggests that calcium directly interferes with the release process, but the nature of this interference has been only partly clarified. It has been shown that external calcium mainly regulates secretion of newly synthesized hormone, which may bypass the few secretory granules in the parathyroid's chief cells.[35] Intracellular degradation with release of carboxy terminal PTH fragments occurs especially at high extracellular calcium concentrations; this attenuates the biologic activity of the secretory product because the calcium-regulating properties of PTH reside predominantly in its amino terminal portion.

Messenger RNA (mRNA) levels for PTH are increased within hours by low extracellular calcium, consistent with the effects of calcium on PTH secretion.[36,37] Calcitriol (1,25-dihydroxyvitamin D_3) reduces PTH mRNA levels and inhibits PTH secretion.[38]

Abnormalities in calcium-controlled PTH release represent a fundamental characteristic of the pathologic parathyroid tissue from hypercalcemic patients with parathyroid adenoma and hyperplasia of varying etiologies.[39,40] The representative disturbance is characterized by variable calcium insensitivity of PTH secretion. The calcium insensitivity of ionized calcium and PTH release correlate to each other and to the degree of hypercalcemia in the patient.[39]

Intact PTH 1-84 is rapidly cleared from the human circulation and has a half-life of only a few minutes.[41] Evidence does not exist to support dynamic regulation of peripheral PTH metabolism. PTH clearance mainly depends on high capacity uptake of Kupffer's cells in the liver and on glomerular filtration. A small amount of PTH appears in the urine, however, because of tubular resorption and proteolysis. Circulating PTH is heterogeneous and contains various carboxy-terminal peptide sequences arising by cleavage, mainly at residues 33 to 43. Although approximately 15% of intact PTH 1-84 is metabolized to such circulating fragments, they make up at least half, and sometimes substantially more, of the immunoactive PTH in the circulation.[42] The metabolism of such fragments depends virtually only on an intact renal function; consequently, they are accumulated to considerable degrees in renal insufficiency. In contrast, very few amino terminal PTH fragments exist in the circulation of euparathyroid individuals, although these fragments may become appreciable in primary and secondary hyperparathyroidism.

The diagnosis of primary hyperparathyroidism and evaluation of the extent or severity of secondary hyperparathyroidism have been facilitated by the development of immunometric "sandwich" assays. These assays use a pair of antibodies that recognize different regions of the PTH protein sequence.[43-45] Because of cooperative effort of the antibodies, such a sandwich assay is more sensitive than either of the antibodies alone in displacement radioimmunoassays. With careful selection of antibodies, the immunometric assays are specific and sensitive for intact PTH, which allows identification of insufficient PTH secretion of hypoparathyroidism and a wide range of PTH levels without sample dilution. The immunometric analyzing process is swifter than the radioimmunoassays. With a reduction in the incubation times, the analysis may be accomplished in 15 to 30 minutes and, consequently, may be applicable intraoperatively.[46,47]

Clinical analysis with immunometric PTH assays usually discriminates hypercalcemic patients with hyperparathyroidism from patients with other causes of hypercalcemia. This discrimination is particularly evident with regard to malignancies of nonparathyroid origin, although approximately 5% to 10% of these patients show intact serum PTH in the low-normal range. Nonparathyroid tumors

that produce intact PTH are exceptionally rare. These include ovarian and small cell carcinomas and thymoma.[48-50]

Parathyroid Anatomy and Histopathology

Normal Parathyroid Gland

The usual weight, size, and fat content of a normal parathyroid gland vary. The weight of a normal gland has been recorded to be as low as 40 mg, and a limit of 50 to 60 mg has been suggested.[51] One study showed that the weights of normal parathyroid glands have a skewed distribution.[51] The mean total weight in the study was 29.5 ± 17.8 mg, with an upper limit of 65 mg. The actual value for the 98th percentile was 75 mg, and this correlates with the operative findings typically noted in primary hyperparathyroidism.

Chronic illness, race, and other individual variations may affect the weights of normal parathyroid glands. In patients with chronic illness, total glandular weights are lower; in male and black patients, total glandular weights are higher. Glands that are removed from the patient may show wide variations in weight. One gland may be much smaller than another, and sometimes two glands may be small.

The dimensions of normal glands are rarely mentioned in the literature. Normal dimensions of 3 to 6 mm in length, 2 to 4 mm in width, and 0.5 to 2 mm in thickness, and an average of three dimensions of 5 mm × 3 mm × 1 mm have been proposed.[52] Normal glands measuring 12 mm and greater have been reported.[53]

Glandular weight, rather than glandular dimension, is accepted as a better measure of size. For the surgeon, knowing the normal dimensions of parathyroid glands is crucial. In most operative situations, enlargement of parathyroid glands is determined by the surgeon in the operating room through a judgment of size, rather than assessment of weight. The determination of weight or density requires the removal of the glands, which may not be indicated in all circumstances.

The stromal fat content of parathyroid glands is the hallmark in the evaluation of their functional status. Detailed studies of normal glands have shown wide variations in fat content.[54,55] The accepted percentage of normal fat content is approximately 50%. One study indicated that more than 75% of normal parathyroid glands had less than 30% stromal fat, 50% had less than 10%, and only a few had 40%.[54] The variability of fat content reported by different studies suggests that measurement of stromal fat within parathyroid glands has become nearly useless as an indicator of function.[54,55] In children and adolescents, parathyroid glands contain very sparse amounts of fat. After adolescence, stromal fat progressively increases until 25 to 30 years of age; subsequently fat content is largely determined by constitutional factors. Women seem to have a tendency to have higher glandular fat content, which may be related to total body fat concentrations.[56]

The characteristic cellular content of the normal gland is dominated by chief cells with rare water clear cells. Oxyphil cell concentrations tend to increase with age and are noted to be rare in young individuals. Oxyphil cell concentrations seem to be more common in adults older than 40 years.

Four parathyroid glands is the usual number found in humans. In dissection studies of 428 human subjects by Gilmour,[57] four parathyroid glands were found in 87% of all patients, and three glands were found in 6.3%. Akerstrom and coworkers[58] reported comparable rates in an autopsy study of 503 individuals. In this study, four parathyroid glands were found in 84% of patients, and three parathyroid glands were found in 3%. The presence of supernumerary parathyroid glands is rare, and may have important clinical consequences, especially with respect to patients with hyperparathyroidism resulting from multiple-gland disease.

In a series of 2015 patients who were operated on for primary hyperparathyroidism, a hyperfunctioning supernumerary fifth parathyroid gland was the source of hypercalcemia in 15 patients (0.7%).[59] Nine of these patients required reoperation to remove the supernumerary gland representing the parathyroid tumor. Most of these fifth gland tumors were located in the mediastinum, either in the thymus (seven tumors) or related to the aortic arch (three tumors). Edis and Levitt[60] reported a rate of persistent hyperparathyroidism of 10% resulting from an enlarged supernumerary parathyroid gland in patients with secondary hyperparathyroidism. In a series of 762 patients with primary hyperparathyroidism, Wang and colleagues[61] documented 6 patients with persistent hyperparathyroidism caused by hyperfunctional supernumerary glands (0.6%), all of which were located in or in close association with the thymus.

In the previously mentioned study by Gilmour,[57] supernumerary parathyroid glands were observed in 29 of 428 specimens (6.7%). Five parathyroid glands were observed in 25 specimens (5.8%), 6 parathyroids were observed in 2 specimens (0.05%), 8 parathyroids were observed in 1 specimen, and 12 parathyroids were observed in 1 other specimen. From the studies by Gilmour[57] and Akerstrom and coworkers,[58] it is evident that supernumerary parathyroids are most commonly found within the thymus or in relation to the thyrothymic tract.

Parathyroid Gland Location

The location of parathyroid glands may vary, as a consequence of the variation in degree of migratory descent during development. Additional influences on these variable locations involves displacement of enlarged parathyroid glands during the development of hyperparathyroidism. Enlarged parathyroid glands tend to migrate in a fibroareolar plane, which offers little resistance as a result of gravity and the action of swallowing and variations in intrathoracic pressure.[62]

Eighty percent of the superior parathyroid glands are found at the cricothyroid junction approximately 1 cm cranial to the juxtaposition of the recurrent laryngeal nerve and the inferior thyroid artery.[58] The superior parathyroids, which are intimately associated with the posterior capsule of the superior thyroid pole, are usually covered by an extension of the pretracheal fascia that envelopes the thyroid gland and connects it to the hypopharynx and esophagus and the carotid sheath. The relationship of these superior parathyroid glands with the pretracheal fascia is such that the glands themselves are allowed freedom of movement under this "pseudocapsule." This feature discriminates parathyroid glands from thyroid nodules, which cannot move freely because they are enveloped by the true capsule of the thyroid gland.

Normal superior parathyroid glands may be found in the retroesophageal or paraesophageal space in approximately 1% of all instances.[63] These spaces represent sites where enlarged superior parathyroid glands potentially descend to the superior and posterior mediastinum.

The inferior parathyroid glands tend to have a more variable location. Greater than 50% of the inferior parathyroid glands are situated neighboring the lower pole of the thyroid gland. Twenty-eight percent of the inferior parathyroids are found within the thyrothymic ligament or within the anterior superior mediastinal thymic gland. The migratory pattern of inferior parathyroid glands tends to follow a pathway into the anterior superior mediastinum, where one third of all missed parathyroid tumors may be found.

The incidence of intrathyroidal parathyroid glands is controversial. Akerstrom noted true superior intrathyroidal parathyroid glands in 3 instances (0.2%) among 503 autopsy specimens.[58] Wang[64] considered the superior parathyroid gland the most likely to be intrathyroidal primarily because of the close embryologic relationship of the primordium of the superior parathyroid gland with the lateral complex of the thyroid. In a series by Wheeler[64a] in which 8 intrathyroidal parathyroid tumors were noted in 7 of 200 patients (3.5%) undergoing neck exploration, 7 of these intrathyroidal glands were considered to originate from the inferior position. The overall incidence of intrathyroidal parathyroid glands ranges from approximately 0.5% to 3% as reported in the literature.[65-68]

Morphologic Characteristics of Parathyroid Glands

The visible discrimination between normal and abnormal hyperfunctioning parathyroid glands is essential to successful parathyroid surgery. The appearance of normal and abnormally functioning parathyroid glands varies and depends on the anatomic position and relationship to the thyroid capsule. Parathyroid glands that are located in loose connective tissue generally are more characteristically oval-shaped, bean-shaped, or teardrop-shaped. When parathyroid glands are closely

juxtaposed to the thyroid capsule compressed by the pretracheal fascia, their appearance tends to be more conforming resulting in a flat shape with well-defined edges. The color of normal parathyroid glands ranges from yellowish brown to reddish brown. Generally, the color may depend on the amount of stromal fat, oxyphil cell concentration, and degree of vascularity.[69] Normal glands tend to be more reddish brown or rust-colored in younger patients, whereas older individuals have parathyroid glands of a more yellow-brown or tobacco color. Enlarged hyperfunctional parathyroid glands have a color variation from dark brown to light yellow. Enlarged glands occurring in either secondary or tertiary hyperparathyroidism may have a lighter gray tone to the coloration. Parathyroid carcinoma can also show a mottled gray-to-white surface appearance.

Vascular Anatomy of the Parathyroid Glands

Normal parathyroid glands most commonly are supplied by a single dominant artery (80%).[70] The length of the dominant artery supplying the parathyroid gland may vary from 1 to 40 mm. In most instances, the superior and inferior parathyroid glands derive their dominant arterial blood supply from the inferior thyroid artery. Ligation of the inferior thyroid artery during thyroid surgery may not always compromise the blood supply to the superior parathyroid gland, however. Abundant arterial anastomoses exist between the parathyroid glands and include anastomoses with thyroid arteries and dominant arteries of the larynx, pharynx, esophagus, and trachea. Of the superior parathyroid glands, 20% or more may be vascularized solely by the superior thyroid artery. In an autopsy study by Delattre and associates,[70] 10% of the inferior parathyroid glands derived their dominant arterial supply from a branch of the superior thyroid artery. In most of these instances, the inferior thyroid artery was noted to be absent. Primary mediastinal parathyroid glands have shown an arterial supply that represents a thymic branch of the internal mammary artery.[71]

The venous drainage distribution of the parathyroid glands generally runs parallel to the arterial vessels and drains via the neighboring thyroid venous tributaries into the internal jugular system. Similarly, lymphatics from the parathyroid glands drain with the lymphatics of the thyroid gland into the paratracheal and deep cervical lymphatic basins.

Histopathology of the Parathyroid Glands

The parathyroid glands are enveloped in their own thin collagenous connective tissue capsule. This capsule extends septa into the gland, which separate the parenchyma into elongated chords or clusters of functional secretory cells. Blood vessels, lymphatics, and nerves travel along the septa to reach the interior of the gland.[72]

The major functional parenchymal cells of the parathyroid glands are the chief cells, which are slightly eosinophilic staining and measure 5 to 8 millimicrons in diameter. The chief cells contain many cytoplasmic granules (200 to 400 nm in diameter), which arise from the Golgi complex and represent the secretory granules.[72] These granules contain PTH, which is synthesized from a precursor of prepro-PTH. With increasing age, the secretory cells of the parathyroid glands may be replaced by adipose cells, which may make up 50% to 60% of the gland in older individuals.

The second cell type making up parathyroid glandular parenchyma is the oxyphil cell. Although their function is unknown, it is believed that oxyphil cells and a third cell type, sometimes described as intermediate cells, may represent inactive phases of a single cell type.[73] Oxyphil cells are less numerous, are larger (6 to 10 millimicrons in diameter), and stain more deeply with eosin than chief cells. Oxyphil cells tend to be more mitochondrial-rich, which may explain the increased ability of abnormal parathyroid glands with high oxyphil cell concentrations to concentrate technetium 99m (Tc 99m) sestamibi.[74]

By electron microscopy, chief cells show Golgi apparatus among dispersed granular endoplasmic reticulum and few secretory granules. The resting chief cells contain abundant lipid and glycogen, whereas during active phase the chief cells are smaller in size and contain decreased amounts of glycogen and lipid.[75] The oxyphil cells are characterized by their large size and numerous cytoplasmic mitochondria.[75]

Single Glandular Enlargement or Parathyroid Adenoma

Single glandular enlargement, or adenoma, is the most common cause of hyperparathyroidism. Because of the variation in pathologic interpretation and patient population, however, the reported incidence of parathyroid adenoma ranges from 30% to 90%.[76-80] In larger series of patients, where more uniformly accepted pathologic criteria were followed, approximately 80% to 85% of patients with primary hyperparathyroidism were found to have solitary parathyroid adenoma.[76-78] Parathyroid adenoma may occur in any of the four parathyroid glands, but tends to involve inferior glands more commonly than superior glands.[74]

The gross appearance of parathyroid adenomas varies, but adenomas generally are oval-shaped or bean-shaped, red-brown in color, and soft in consistency.[81,82] Adenomas may be bilobed or multilobulated in conformation. In 70% of adenomas, a rim of normal parathyroid tissue may be found around the hypercellular portion of the replaced normal gland. The absence of this characteristic does not exclude the presence of a parathyroid adenoma, however. The incised surface of an adenoma may appear smooth or nodular, or may show obvious areas of cystic change. Under light microscopy, adenomas appear similar to normal parathyroid glands, exhibiting a thin fibrous capsule with a cellular framework arranged in nests and cords invested by a rich capillary network. Other growth patterns include follicular, pseudopapillary, and acinar patterns.

Chief cells are the dominant cell types in most parathyroid adenomas. Oxyphil cells and transitional oxyphil cells are usually seen in varying proportions interspersed between the collections of chief cells.[80-82] The chief cells in adenomas may be larger than found in normal glands, and may exhibit a greater degree of nuclear pleomorphism and giant cell formation.[83,84] Nuclear atypia is of limited value, however, in distinguishing between parathyroid adenoma and carcinoma. Mitotic figures are uncommon in adenomas; however, they may be seen in a small percentage of cases.[85]

Variations in single glandular enlargement representative of parathyroid adenoma may occur and include the following subtypes: oncocytic adenoma, lipoadenoma, large clear cell adenoma, water clear cell adenoma, and atypical adenoma. Oncocytic adenoma is a rare subtype of parathyroid adenoma (4.4% to 8.4% of adenomas) that is composed predominantly (>80% to 90%) or exclusively of oxyphil cells.[86,87] Previously, adenomas of the oncocytic variety were believed to be nonfunctional; however, oxyphil adenomas associated with hyperparathyroidism have been reported.[88-90] Similar to typical adenomas, oncocytic tumors occur more frequently in women and are found most often in the sixth or seventh decade.[89,90] Grossly, the tumors tend to be large, reported to range in size from 0.2 to 61 g; they are soft, spherical, ellipsoid, lobulated, or nodular, and range in color from light tan to dark orange-brown or mahogany.[89,91] Microscopically, adenomas are composed predominantly of polygonal cells with abundant brightly eosinophilic granular cytoplasm and small round central hyperchromatic nuclei. Fat stain shows reduce cytoplasmic fat as per typical adenomas. Numerous mitochondria are densely packed throughout the cytoplasm on ultrastructural examination.

Lipoadenoma is another rare subtype of adenoma that was first described in 1958 as a parathyroid hamartoma.[92] The initial description was that of a nonfunctioning mass; subsequent reports documented that these lesions can be responsible for hyperparathyroidism.[93-95] The tumor comprises a lobulated yellow-tan mass composed of nests, acini, and cords of chief cells and occasional oxyphil and clear cells, intimately associated with large areas of adipose tissue or myxoid stroma or both. A rim of normal parathyroid tissue may be present at the periphery.

Water clear cell adenomas have been described, although their existence was initially doubted.[96] In contrast to the large clear cell adenomas that accumulate glycogen, true water clear cell adenomas show a glycogen-free cytoplasm that is filled with membrane bound vesicles.[97]

Atypical adenoma is the term used to describe parathyroid adenomas that exhibit atypical cytologic features without definite evidence of malignancy (i.e., vascular or soft tissue invasion or both or metastases).[98] It is important to distinguish these benign lesions from parathyroid carcinoma. The malignant potential of atypical adenomas in

terms of recurrent or metastatic behavior is uncertain. These lesions may exhibit conspicuous mitoses, adherence to surrounding tissues, trabecular cellular arrangements, capsular invasion, or broad fibrous bands.[99] One such lesion described consisted of a multifocal spindle cell proliferation that was mitotically active, averaging eight mitoses per 10 high-power fields within an otherwise typical parathyroid adenoma.[100]

Multiple Enlarged Glands or Parathyroid Gland Hyperplasia

Primary parathyroid hyperplasia is defined as proliferation of the parenchymal cells leading to increase in gland weight in multiple parathyroid glands in the absence of a known stimulus for PTH secretion. Two types of parathyroid hyperplasia are seen: the common chief cell hyperplasia and the rare water cell or clear cell hyperplasia.[76,77]

Chief Cell Hyperplasia

In 1958, Cope and associates[101] first showed chief cell hyperplasia as a cause of primary hyperparathyroidism. It accounts for approximately 15% of hyperparathyroidism in reported series; however, some reports have indicated that about half of primary hyperparathyroidism may be produced by hyperplasia. A variation in this reporting is generally attributable to discrepancies in pathologic interpretation of abnormal parathyroid glands. The stimulus for this disorder is unknown; some studies have indicated a role of a possible circulating factor that can induce proliferation of parathyroid cells in culture. Approximately 30% of patients with chief cell hyperplasia have some type of familial hyperparathyroidism or one of the MEN syndromes.[76,77,102,103] Molecular studies have shown that hyperplasias are monoclonal proliferations.[15,16]

Grossly, there is enlargement of all four glands. The glands may be of variable size, or they may be uniformly enlarged. By light microscopy, the dominant cell types are chief cells; however, one may also observe intermixed oxyphil cells and transitional oxyphil cells. The cellular proliferations may also give rise to nodular formation, and this can cause asymmetric gland enlargement.[76,77]

The amount of cytoplasmic fat in the chief cells is either reduced or absent.[76,77] The chief cell in the nodular areas may be totally devoid of any fat, whereas the cells between the nodules may contain fat. Abnormal nuclei or mitoses are distinctly rare.[77]

Water Clear Cell Hyperplasia

Water clear cell hyperplasia is rare and is characterized by a proliferation of vacuolated water clear cells in multiple parathyroid glands. It shows a female predilection and leads to pronounced hypercalcemia and severe clinical disease. This represents the only parathyroid disorder in which the superior glands are larger than the inferior parathyroid glands. The glands affected by water clear cell hyperplasia tend to be larger and more irregular in shape with lobular extensions to surrounding soft tissue. By light microscopy, the glands show diffuse proliferations of clear cells characterized by clear cytoplasm and small dense nuclei. On high-power magnification, the cytoplasm is shown to be filled with small vacuoles. Cytoplasmic lipid is generally not present; however, moderate amounts of glycogen may be identified. The histologic appearance of water clear cell hyperplasia bears a resemblance to that of renal cell carcinoma.[104]

Secondary parathyroid hyperplasia as a consequence of renal failure cannot be distinguished from primary hyperplasia with the exception that early in the disorder there seems to be a greater tendency for the glands to be more uniform in size.[105] As the disease progresses, asymmetry becomes more evident in renal failure–induced disease. The degree of glandular enlargement tends to reflect the severity of the underlying renal disorder.[106] The largest glands are noted in patients whose renal disease began in childhood.[107]

Parathyroid Carcinoma

Parathyroid carcinoma is a rare malignant neoplasm derived from the parenchymal cells of the parathyroid glands. It has been reported to be responsible for 0.1% to 5% of cases of primary hyperparathyroidism.[108-112] It is uncertain whether parathyroid carcinoma actually begins within preexisting benign parathyroid lesions.[112,113] Carcinoma has been postulated to arise in the setting of primary parathyroid hyperplasia, notably familial hyperplasia.[114-116] Only rare patients with parathyroid carcinoma have a history of prior neck irradiation.[110,112]

Morphologic features diagnostic of parathyroid malignancy are difficult in terms of definition and practical application during surgery. In one series of 40 patients with metastatic parathyroid cancer, 50% were thought to have benign disease by the operating surgeon and consulting pathologist during the time of initial exploration.[117] Metastases are the only certain sign of malignancy. Metastatic behavior at the time of presentation is distinctly rare, however.[108]

Parathyroid carcinomas are characteristically large tumors, with 30% to 50% being palpable at the time of presentation.[108,109] The tumors may measure 6 cm in diameter with a mean of approximately 3 cm.[108] Although the average weights of carcinomas are reported to be greater than those of adenomas, there seems to be great overlap, indicating that weight alone may not be a major distinguishing characteristic between benign and malignant lesions. Carcinomas generally arise in the usual parathyroid locations, although they have been described in ectopic supernumerary glands within the mediastinum.[118] Most parathyroid carcinomas are firm or hard in consistency and have a gray-to-white surface color as opposed to adenomas, which tend to be soft and tan in appearance. Adherence of the lesion to surrounding tissues is common, and these glands may be noted to extend to involve the soft tissues around the thyroid gland or the thyroid parenchyma itself. This may not prove to be a valuable differentiating feature because previous hemorrhage into a benign adenoma may be associated with fibrosis and adherence to adjacent structures in benign disease.[112]

Metastases at the time of presentation are unusual, but may rarely be found in regional lymph node basins.[117] As opposed to regional metastases, parathyroid carcinoma is more often associated with widespread local infiltration, with invasion into contiguous structures, such as thyroid gland, strap muscles, trachea, and recurrent laryngeal nerve. Advanced metastases may occur and may be found in the lungs, bone, cervical and mediastinal lymph nodes, liver, occasionally kidney, and adrenal glands.[117,119] Pulmonary metastases are the most common distant metastasis noted.[117]

Microscopic diagnosis of parathyroid carcinoma is a difficult task. The entire gland is traversed by broad fibrous bands that seem to originate from the capsule and extend into the substance of tumor leading to a lobulated appearance. The cells may be clear or rarely oxyphilic, and are arranged in nests and trabeculae.[120] The cell may be uniformly bland or may show metaplasia, but the cases with minimal atypical findings may be difficult to distinguish from an adenoma.[121-123]

Mitosis can be seen in most instances and has been suggested as a primary factor in diagnosing parathyroid carcinoma.[124] Mitotic figures may also be seen in parathyroid adenoma and hyperplasia, however, and their absence does not rule out a diagnosis of carcinoma.[125,126] It is generally acknowledged that mitoses in parathyroid lesions should be of concern, especially because the follow-up in reported benign cases of parathyroid tumor exhibiting mitoses has been limited. Increased mitotic activity in unequivocal parathyroid carcinoma is an indicator of poor prognosis.[127]

The only reliable indicators of malignancy in parathyroid carcinoma are invasion of the surrounding structures, metastases, or both.[127] Features such as desmoplastic reaction, mitotic activity, nuclear atypia, and necrosis may be more common in carcinoma than in benign lesions, but do not constitute criteria sufficient for a diagnosis of malignancy.[127] In the absence of an infiltrative growth pattern, the parathyroid lesion showing some other feature of malignancy including mitoses may be designated as *atypical adenoma*.[128] Nonfunctioning parathyroid carcinomas have been rarely described, tending to be large and consisting of clear or oxyphil cells.[129,130]

Parathyroid carcinoma usually grows slowly and can be an indolent tumor. Multiple recurrences after surgical resection are common and may occur over a 15- to 20-year period.[121,122] Patients with parathyroid carcinoma often die as a result of the effects of excessive PTH secretion and uncontrolled hypercalcemia, rather than growth of the tumor mass. Surgical excision of recurrence or metastases may provide excellent palliation by reducing tumor burden and consequently hormone production.[131,132]

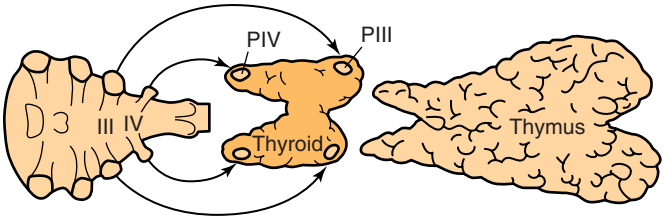

Figure 125-3. Embryologic derivation and subsequent descent of the parathyroid glands with associated structures.

Surgical Embryo-Anatomic Relationships in the Central Neck

Parathyroid tissue originates from primordial pharyngeal endoderm formed in the third and fourth pharyngeal pouches during the fifth week of embryologic development (Fig. 125-3). The epithelial lining of the dorsal wing of the third pharyngeal pouch differentiates into primordial parathyroid glandular tissue, whereas the ventral portion of the pouch differentiates into the thymus. As the thymus migrates medially and inferiorly, it pulls the inferior parathyroid gland (parathymus) with it into the thymic tail. Eventually, the main portion of the thymus migrates to its final position in the upper thoracic region, and its tail involutes, leaving the developing parathyroid gland to come to its position on the dorsal surface of the inferior pole of the thyroid gland. This glandular tissue eventually forms the inferior parathyroid gland. Simultaneously, the epithelium of the dorsal wing of the fourth pharyngeal pouch begins to differentiate into parathyroid glandular tissue. After separation from the regressing pouch, it becomes associated with the lateral portion of the caudally migrating thyroid, and is carried a short distance medially and inferiorly until it resides posterior to the superior pole of the thyroid gland. This tissue eventually develops into the superior parathyroid gland.

This embryologic pattern of development has significant implications for the identification of ectopic or normal glandular variance during the course of parathyroidectomy. The longer embryologic migration results in an extensive area of potential dispersal for the normal inferior parathyroid gland. In 61% of cases, the glands are situated at the level of the inferior poles of the thyroid lobes on the posterior, lateral, or anterior aspects. In 26% of cases, they are situated in the thyrothymic ligament or on the upper, cervical portion of the thymus. More rarely, in 7% of cases, they are situated higher up, at the level of the middle third of the posterior aspect of the thyroid lobes, and may then be confused with the superior parathyroid gland. Because the embryonic descent of the thymus extends from the angle of the mandible to the pericardium, anomalies of migration of the parathymus, whether excessive or insufficient, are responsible for high or low ectopic locations of the inferior parathyroid gland. The incidence of higher ectopia along the carotid sheath, from the angle of the mandible to the lower pole of the thyroid, does not seem to exceed 1% to 2%.[133-135] Alternatively, if the separation from the thymus is delayed, the inferior parathyroid gland may be pulled inferiorly into the anterior mediastinum to a varying degree. In this circumstance, they are usually within the thymus, at the posterior aspect of its capsule, or still in contact with the great vessels of the mediastinum. Lower ectopic regions such as these are noted in 3.9% to 5% of instances.[134,136]

The superior parathyroid glands follow the thyroid migration of the ultimobranchial bodies, which travel toward the lateral part of the main medial thyroid rudiment. In contradistinction to the inferior glands, the superior parathyroids have a limited descent within the neck. They remain in contact with the posterior part of the middle third of the thyroid lobes. This limited course of embryonic migration explains why they remain stable in their regional distribution when not pathologic. In most instances, they are grouped at the posterior aspect of the thyroid lobes, in an area 2 cm in diameter, whose center is situated about 1 cm above the crossing of the inferior thyroid artery and the recurrent laryngeal nerve.[134,137] Because of the more extensive descent of the inferior parathyroid gland, the descent of the parathymus result in the inferior and superior glands crossing during development. This embryonic crossing of the glands explains why their grouping at the level of the inferior thyroid artery, at the junction of the middle and inferior thirds of thyroid lobe, is in many respects quite close, depending on the degree of migration of the inferior parathyroid gland.

Because of the short migratory descent of the superior parathyroid gland, the area of dispersal of these glands is limited, and congenital ectopic positions of the superior gland are unusual. In 13% of instances, the glands are on the posterior aspect of the superior pole of the thyroid lobe in a laterocricoid, lateropharyngeal, or intercricothyroid position, and, exceptionally, in less than 1% of instances, they are above the upper pole of the lobe. In 1% to 4% of instances, they are clearly posteriorly based behind the pharynx or esophagus. Parathyroid glands that are found in the posterior superior mediastinum are usually neoplastic superior parathyroid glands that have migrated as a consequence of gravity and changes in intrathoracic pressure.[137]

Clinical Features of Primary Hyperparathyroidism

Incidence

The incidence of hyperparathyroidism has changed dramatically over the past 3 decades. In the early 1970s, before the widespread use of multichannel autoanalysis of blood chemistry, Heath and colleagues[138] reported an annual incidence of 7.8 cases/100,000 in Rochester, Minnesota. After the introduction of routine serum calcium assessment later in the 1970s, the incidence rate increased to 51 cases/100,000/year. After the most prevalent or clinically significant cases were managed, the incidence declined to 27 cases/100,000 annually, and more recent reports indicate that within the population associated with this area of Minnesota, a steady decline in the incidence of hyperparathyroidism has been noted since the late 1970s. This decline cannot be explained by the more limited routine use of multichannel autoanalyzing of blood, which has become part of cost-saving measures since the late 1990s; also, this declining incidence has not been similarly experienced in other populations nationally or internationally.

A higher rate of incidence was noted in the Stockholm study, which examined more than 15,000 subjects over a 2-year period (1971-1973) with a follow-up at 10 years. The early rate was assessed at 6 cases/1000, which at the 10-year follow-up was verified to be 4.4 cases/1000. This rate has not changed appreciably over a 20-year period, in contrast to the Rochester experience.[139] One may postulate that the Rochester experience is unique in that after obtaining a very high incidence rate promulgated by routine calcium screening, higher prevalence cases were eliminated to reveal a lower base incidence rate in a population that receives its treatment at a single major center, explaining the steady decline in this fixed population base.

There seems to be a distinct predilection for a higher incidence of hyperparathyroidism in women, especially women beyond menopause. The highest prevalence rate among women in the Stockholm experience confirmed at the 10-year follow-up was approximately 13/1000, which represented a female-to-male ratio of about 4:1. This experience is similar to that of other published reports.[138,140-143] Several of these studies based on serum calcium screening have shown that the prevalence of primary hyperparathyroidism in the general population is 0.1% to 0.3%, and in women older than 60 years, the prevalence is more than 1%.[138,139,144] The clear female preponderance points to the fact that every woman has a 1% risk of experiencing primary hyperparathyroidism during her lifetime. It has been estimated, however, that about 90% of individuals with primary hyperparathyroidism remain undiagnosed.[145] The screening of serum calcium has been a particularly important factor leading to the detection of patients with mild symptoms or no symptoms, especially among postmenopausal women.

Presentation

The concept of clinical features associated with primary hyperparathyroidism has changed during recent years. So-called classic, specific

symptoms (i.e., bone disease, renal stones, and hypercalcemic crisis) represent obvious manifestations of the disease. The relative proportion of patients with osteitis fibrosis cystica, nephrolithiasis, and hypercalcemic crisis has continuously decreased in clinical series because of the increase in the number of patients with nonspecific or nonapparent symptoms. Currently, osteitis fibrosis occurs in about 1% of patients, and only 10% to 20% of patients have renal stones.[146-148] Nonspecific symptoms include malaise, fatigue, depression and other psychiatric symptoms, sleep disturbance, weight loss, abdominal pains, constipation, vague musculoskeletal pains in the extremities, and muscular weakness.

The term *asymptomatic hyperparathyroidism* has been commonly applied when the disorder is detected during health screenings and population studies, or coincidentally during medical examinations. The usual presenting abnormality in these patients is an abnormally elevated serum calcium detected on routine blood chemistry screening. Despite the lack of obvious abnormalities noted at the time of diagnosis, caution should be exercised before declaring that a patient is asymptomatic. Many seemingly asymptomatic patients may manifest subtle or even "silent" sequelae of hyperparathyroidism at the time of presentation, and these patients may be more appropriately described as minimally symptomatic because nonspecific symptoms and unidentified complications of hyperparathyroidism would be eliminated by parathyroidectomy.[149] Some of these nonspecific sequelae include emotional complaints, muscular fatigue, constipation, bone and joint pain, and silent objective findings such as asymptomatic renal calculi and decreased bone mineral density. In most patients with asymptomatic or minimally symptomatic hyperparathyroidism, these symptoms are subtle and may be so common in the general population that they preclude establishment of a causal relationship to primary hyperparathyroidism.

Among patients in whom symptoms are present or evolving at the time of diagnosis, two populations may be identified. In the first group, the disease progresses insidiously over several years and eventually manifests as renal colic. The second group manifest symptoms over a considerably shorter time with marked elevations in serum calcium leading to weight loss, acute gastrointestinal symptoms, anorexia, bone pain, and occasionally pathologic fracture. Traditionally, clinical manifestations are described according to the organ system affected.

Kidney and Urinary Tract

Historically, greater than 50% of patients with hyperparathyroidism develop renal symptoms manifested by nephrolithiasis and nephrocalcinosis. This percentage decreased significantly to approximately 4% after the widespread use of screening tests for serum calcium levels.[150] Most stones are composed of calcium oxalate; however, calcium phosphate stones may also occur. The symptoms associated with urolithiasis include renal colic, hematuria, and pyuria. Metabolic acidosis may also be a part of the clinical syndrome.

Skeletal System

Abnormalities of the skeletal system in the form of osteitis fibrosis cystica, previously a common malady in patients with primary hyperparathyroidism, are now rarely encountered (<10%). These changes include subperiosteal erosion of the distal phalanges, bone wasting and softening, and chondrocalcinosis as a result of bone demineralization. Bone disease may manifest as bone pain, pathologic fracture, cystic bone changes, or focal areas of bone swelling (epulis of the jaw or "brown tumors") representing accumulations of osteoclasts, osteoblasts, and fibrous matrix. Symptoms attributable to joint pathology include gout and pseudogout.

Bone loss in hyperparathyroidism occurs at cortical bone sites generally sparing trabecular bone.[151] Because of this finding, the role of hyperparathyroidism in osteoporosis is unclear, especially for patients in whom symptoms are minimal or absent, and in whom the disease is mild. Postmenopausal women with primary hyperparathyroidism exhibiting early signs of osteoporosis seem to be at significant risk for developing more severe bone disease and resultant sequelae (i.e., vertebral and hip fractures). The benefit of parathyroidectomy is most apparent in these patients.[152]

Neuromuscular System

Muscle weakness, particularly in the proximal extremity muscle groups, together with progressive fatigue and malaise, may occur in symptomatic primary hyperparathyroidism. Electromyography changes may be seen in these patients together with atrophy of the skeletal muscle on biopsy specimens.[153-155] Although the severe symptoms are rarely encountered, some signs of muscle fatigue and weakness may be present in 40% of patients with mild primary hyperparathyroidism.[156] Usually these subtle symptoms are manifested as muscle aches and fatigue on rising from a chair or climbing stairs. Progression of the disease may ultimately result in weakness that limits activity and ambulation over weeks to months. This neuromuscular syndrome is noted to improve after parathyroidectomy in 80% to 90% of the patients affected.[157,158]

Neurologic System

Neurologic manifestations of primary hyperparathyroidism are represented by a spectrum of symptoms ranging from anxiety and mild emotional disturbance to frank psychosis. Depression, nervousness, and cognitive dysfunction may commonly occur to varying degrees in primary hyperparathyroidism. Cerebral dysfunction characterized by organic brain syndrome is more common in elderly patients with an underlying mild cognitive abnormality exposed to hypercalcemia. Other neurologic changes occasionally seen in patients with hyperparathyroidism include deafness, dysphagia, dysosmia, and dysesthesia.[159] Many of the psychiatric symptoms in patients with primary hyperparathyroidism are improved after parathyroidectomy.[158,160] Fifty percent of patients with depression or anxiety, or both, improve after surgery. A favorable effect has also been shown in about 50% of patients with organic brain syndrome and dementia. Some older patients experience dramatic improvement; however, it is impossible to predict whether any specific patient will improve after surgery.[160]

Gastrointestinal System

Gastrointestinal disorders that may occur in hyperparathyroidism include acid peptic disease, pancreatitis, and cholelithiasis. Peptic ulceration occurs with increased frequency in these patients secondary to increased serum gastrin and gastric acid secretion stimulated by hypercalcemia. Hyperparathyroidism may be the heralding manifestation of endocrine disease in patients with MEN-I syndrome. Patients with Zollinger-Ellison syndrome show the highest incidence of peptic ulceration. The lower gut also may be affected by hyperparathyroidism. Frequently, patients with "asymptomatic disease" complain of sluggish bowels or constipation, which improves after surgery and achievement of normocalcemia.

Cardiovascular System

Hypertension may occur in 50% of patients with hyperparathyroidism.[161] Convincing evidence of a pathogenic mechanism does not exist, however, and parathyroidectomy results in a reduction in blood pressure in a few of these patients.[162] Swedish investigators reported an association with myocardial ischemia and left ventricular dysfunction in patients with hyperparathyroidism and various symptoms, which exhibited reversibility after parathyroidectomy.[163]

Hypercalcemic Abnormalities

Hypercalcemic syndrome occurring as a result of hyperparathyroidism includes polydipsia and polyuria, anorexia, vomiting, constipation, muscle weakness and fatigue, mental status changes, and skin abnormalities. Patients developing markedly elevated serum calcium levels approaching 15 mg/dL may present with severe mental status changes or coma, a so-called hypercalcemic crisis. If untreated, this condition may progress to acute renal failure and the onset of dysrhythmias, which may precipitate sudden death.[164] Other abnormalities include metastatic calcifications at the corneal-scleral junction (so-called band keratopathy), shortened Q-T interval on electrocardiogram, ectopic calcium deposits in various organs, and pruritus. Some patients also may present with a nonspecific debility manifested by anorexia, fatigue, anemia, weight loss, and advancing osteitis, all of which are reversible after parathyroidectomy.

Clinical Course of Untreated Hyperparathyroidism

Several 8- to 10-year prospective studies have shown a benign course of untreated mild hyperparathyroidism in most patients, with no significant progression of symptoms, hypercalcemia, bone marrow density loss, or renal function impairment. No pathologic fractures or kidney stones developed during these observation periods.[165,166] There was evidence, however, of disease progression in 27% of patients, including marked hypercalcemia, hypercalciuria, or loss of bone mineral density in 10%.[167]

The clinical manifestations of hyperparathyroidism tend to relate to the level of hypercalcemia, even if this is not always evident because of slowed disease progression, individual susceptibility, and sex-dependent and age-dependent symptoms. Younger men are particularly prone to have renal stones, sometimes even with only mild hypercalcemia. For renal stones, the individual susceptibility is more than the level of hypercalcemia, and the risk of this particular symptom is probably more efficiently revealed by the patient history. In postmenopausal women, renal stones occur infrequently (generally <5%) and are often clinically silent.

Osteitis fibrosis cystica is currently uncommon in patients with primary hyperparathyroidism, and is most often seen in patients with severe hypercalcemia. Bone density measurements have shown an average reduction in cortical bone of 17% among current patients with primary hyperparathyroidism, however, and the bone loss tends to be the most pronounced in postmenopausal women.[167-169] Total and trabecular bone mass is often significantly but less markedly reduced.[170] No bone loss has been detected in postmenopausal women with borderline hypercalcemia, but losses were significant when the serum calcium level was greater than 2.74 mmol/L.[168]

Clinically evident renal failure is currently an unusual complication of primary hyperparathyroidism. Reduction of creatinine clearance and urinary concentrating capacity occur in more than one third of patients with mild hypercalcemia, however, indicating that impairment of glomerular and tubular function may occur silently.[168] Serum creatinine measurements are crude estimates, and increase only after creatinine clearance is substantially reduced. Serum creatinine levels also decrease with declining muscle mass of aging.[168]

Rare patients with initially mild hypercalcemia but rapidly advancing disease may have parathyroid carcinoma.[171] In addition, stepwise "clinical progression" may occur during observation in patients with primary hyperparathyroidism, possibly representing development of secondary mutations that cause accelerated growth of the tumor. Bleeding in parathyroid tumor may also cause an abrupt increase in serum calcium levels. A history of mild primary hyperparathyroidism has been reported in one third of patients with hypercalcemic crisis. Because it is impossible to predict whether progressive disease will occur in any patient, extended follow-up is crucial if surgery is deferred in primary hyperparathyroidism.[172-174] Younger patients seem to be at greater risk for progressive disease. Medical surveillance is inappropriate in younger patients and in patients with more marked hypercalcemia. The indications for surgical intervention and the alternative of medical surveillance are discussed later.

Diagnosis of Hyperparathyroidism

Evaluation of Hypercalcemia

Hypercalcemia has been reported to occur in 1% to 3.9% of the general adult population and 0.2% to 2.9% of hospitalized patients.[175] These patients present with widely variable clinical symptoms, depending on the severity of the elevated serum calcium. In most situations, mild hypercalcemia is asymptomatic, but severe hypercalcemia may become life-threatening, especially when the serum calcium is greater than 14 mg/dL.

The definition of hypercalcemia depends on the range of normal serum calcium—this is generally reported as 8.5 to 10.5 mg/dL. Variations in this normal range as reported by various laboratories depend largely on differences in assay procedures. Of circulating serum calcium, 47% binds to proteins, and approximately 10% binds primarily to albumin or complexes to circulating anions such as bicarbonate, phosphate, citrate, or sulfate. The remaining 43% is found as the free ionized form. Only the free ionized form of serum calcium exerts physiologic effects. Serum ionized calcium is the major regulator of PTH secretion.

Table 125-1

Causes of Parathyroid Hormone–Mediated Hypercalcemia

Primary hyperparathyroidism
Parathyroid adenoma
Parathyroid lipoadenoma
Parathyroid hyperplasia
Parathyroid carcinoma
Neck or mediastinal parathyroid cyst
Secondary hyperparathyroidism
Tertiary hyperparathyroidism

Several factors may influence measured serum total or ionized calcium. Alterations in serum albumin level increase or decrease serum total calcium without affecting the ionized calcium level. Of the circulating calcium that is bound to protein, 70% is albumin bound, having 12 calcium binding regions per molecule. Under normal circumstances, only about 20% of these specific calcium binding sites are actually occupied by serum calcium. Decreases in serum albumin less than 4 g/dL decrease total calcium by 0.8 mg/dL for each 1-g/dL decrease in serum albumin. Increases in serum albumin greater than 4 g/dL increase serum total calcium by 0.8 mg/dL for each 1-g/dL increase in serum albumin. Dehydration may increase total serum total calcium because of the resulting hemoconcentration. Acidosis increases serum ionized calcium by decreasing binding of calcium to albumin, and alkalosis decreases ionized calcium by increasing binding of calcium to albumin, without affecting serum total calcium. Under most clinical circumstances, it is adequate and appropriate to measure serum total calcium, but serum ionized calcium should be measured in clinical situations that may be associated with changes in albumin concentration or serum pH.[176,177]

Serum calcium reflects the balance between calcium influx into and calcium efflux out of extracellular fluid. Calcium influx into extracellular fluid is derived from intestinal absorption, skeletal resorption, and renal reabsorption, and calcium efflux out of extracellular fluid is determined by intestinal secretion, skeletal uptake, and renal excretion. Hypercalcemia usually results when the rate of calcium influx into the extracellular fluid exceeds the rate of calcium efflux out of the extracellular fluid.

The differential diagnosis of hypercalcemia is varied and extensive. The most common etiology of hypercalcemia in nonhospitalized patients is primary hyperparathyroidism, and the most common cause of hypercalcemia in hospitalized patients is malignancy. In most circumstances, the differential diagnosis of hypercalcemia may be categorically divided into causes that are mediated by PTH and causes that are not (Tables 125-1, 125-2 and 125-3). Hypercalcemia that is mediated by PTH is most frequently caused by primary hyperparathyroidism (see Table 125-1). Additionally, physiologic secondary hyperparathyroidism, which is defined as hyperparathyroidism caused by a physiologic source without associated renal insufficiency, or pathologic secondary hyperparathyroidism with associated renal failure may result in PTH-mediated hypercalcemia.

Secondary hyperparathyroidism from a nonrenal physiologic source may occur in patients with insufficient calcium intake, decreased intestinal calcium absorption, insufficient vitamin D intake or malabsorption, or renal hypercalciuria, and represents the homeostatic attempt to maintain a normal serum calcium level by any means necessary. It is important to distinguish physiologic secondary hyperparathyroidism from primary hyperparathyroidism before embarking on surgical correction of presumed primary hyperparathyroid disease.

Table 125-2

Causes of Hypercalcemia of Malignancy

Parathyroid hormone–related protein secretion by lung, esophagus, head and neck, renal cell, ovary, bladder, and pancreatic cancers; thymic carcinoma; islet cell carcinoma; carcinoid; sclerosing hepatic carcinoma
Ectopic parathyroid hormone secretion by small cell lung cancer, small cell ovarian carcinoma, squamous cell lung carcinoma, ovarian adenocarcinoma, thymoma, papillary thyroid carcinoma, hepatocellular carcinoma, undifferentiated neuroendocrine tumor
Ectopic 1,25-dihydroxyvitamin D production by B-cell lymphoma, Hodgkin's disease, lymphomatoid granulomatosis
Lytic bone metastases caused by multiple myeloma, lymphomas, breast cancer, invasive sarcoma
Tumor production of other cytokines by T-cell lymphomas/leukemias, non-Hodgkin's lymphoma, other hematologic malignancies

Pathologic secondary hyperparathyroidism and tertiary hyperparathyroidism occur as a result of renal insufficiency or renal failure. Hyperparathyroidism associated with these conditions results from subtle ionized hypocalcemia persisting over months to years, resulting in chronic stimulation of the parathyroid glands. Parathyroid glands may become autonomous after long-standing renal disease, and consequently no longer respond to regulation by serum ionized calcium in the course of developing tertiary hyperparathyroidism.

An important entity that must be considered in the differential diagnosis of hypercalcemia is familial hypocalciuric hypercalcemia.[178,179] This disorder has the ability to mimic the serum biochemical appearance of primary hyperparathyroidism, but is not treated surgically. Familial hypocalciuric hypercalcemia is an autosomal dominant disorder that is linked to chromosomes 3q, 19p, and 19q, and is largely caused by inactivating mutations in the parathyroid cell calcium-sensing receptor.[180] Patients with familial hypocalciuric hypercalcemia have low 24-hour urinary calcium excretion relative to their hypercalcemia. Presently, the most useful study to distinguish familial hypocalciuric hypercalcemia from primary hyperparathyroidism is the 24-hour urinary calcium-to-creatinine clearance ratio.[178] Patients with familial hypocalciuric hypercalcemia typically have ratios of less than 0.01, whereas patients with primary hyperparathyroidism have ratios greater than 0.01.

The second most common etiology of hypercalcemia is malignancy (see Table 125-2). Humoral hypercalcemia of malignancy, which is caused by excessive PTH-related protein secretion by tumors of various types, represents the most common source of malignancy-associated hypercalcemia.[181] Numerous solid tumors have been reported to secrete excessive PTH-related protein, including cancers of the lung, esophagus, head and neck, kidney, ovary, bladder, breast, and pancreas. Other tumors that have been variably noted to secrete PTH-related protein include thymic carcinoma, islet cell carcinoma, malignant carcinoid, and hepatic carcinomas. Patients with adult T-cell leukemia or lymphoma or B-cell lymphoma have also been variably shown to produce excess PTH-related protein.[182,183]

Ectopic PTH secretion has been shown in small cell lung cancer, small cell ovarian carcinoma, squamous cell lung carcinoma, ovarian adenocarcinoma, thymoma, papillary thyroid carcinoma, hepatocellular carcinoma, and undifferentiated neuroendocrine tumor.[184,185] Ectopic 1,25-dihydroxyvitamin D has been found to be secreted by B-cell lymphomas, Hodgkin's disease, and lymphomatoid granulomatosis.[186-190] Excessive cytokine production that may result in hypercalcemia has been associated with T-cell lymphomas and leukemias, non-Hodgkin's lymphomas, and other hematologic malignancies.

Table 125-3

Causes of Non–Parathyroid Hormone–Mediated, Nonmalignant Hypercalcemia

Benign Tumors
Parathyroid hormone–resecreting ovarian dermoid cyst or uterine fibroid
Endocrine Disease
Thyrotoxicosis
Pheochromocytoma
Addison's disease
Islet cell pancreatic tumors
VIPoma
Granulomatous Disorders
Sarcoidosis
Wegener's granulomatosis
Berylliosis
Silicone-induced and paraffin-induced granulomatosis
Eosinophilic granuloma
Tuberculosis (focal, disseminated, *Mycobacterium avium* complex in AIDS)
Histoplasmosis
Coccidioidomycosis
Candidiasis
Leprosy
Cat-scratch disease
Drugs
Vitamin D excess (oral or topical)
Vitamin A excess
Thiazide diuretics
Lithium
Estrogens and antiestrogens
Androgens
Aminophylline, theophylline
Ganciclovir
Recombinant growth hormone treatment of AIDS patients
Foscarnet
8-Chloro-cyclic adenosine monophosphate
Miscellaneous
Familial hypocalciuric hypercalcemia
Immobilization with or without Paget's disease of bone
End-stage liver failure
Total parenteral nutrition
Milk-alkali syndrome
Hypophosphatasia
Systemic lupus erythematosus
Juvenile rheumatoid arthritis
Recent hepatitis B vaccination
Gaucher's disease with acute pneumonia
Aluminum intoxication (long-term hemodialysis)
Manganese intoxication
Primary oxalosis

AIDS, acquired immunodeficiency syndrome; VIPoma, vasoactive intestinal polypeptide–secreting tumor.

Another source of hypercalcemia resulting from malignancy is that of calcium released by extensive lytic bone metastasis as a consequence of multiple myeloma, lymphomas, breast cancer, or invasive sarcomas.[191]

Table 125-3 is an extensive list of causes of non–PTH-mediated hypercalcemia. Nine tumors, including ovarian dermoid cysts or

uterine fibroids, may occasionally secrete PTH-related protein or other bone-resorbing cytokines.[192] Endocrine disorders, including thyrotoxicosis (resulting from increased bone resorption), pheochromocytoma (caused by coexisting primary hyperparathyroidism in MEN syndrome), adrenal insufficiency or crisis (caused by volume depletion or hemoconcentration), and VIPomas (resulting from excess secretion of vasoactive intestinal peptide causing dehydration and metabolic acidosis), may also cause non–PTH-mediated hypercalcemia.[193-197] Granulomatous disease in the absence of malignancy or endocrine disorder may be a source of hypercalcemia, especially in younger and middle-aged patients, and may manifest with elevated serum calcium levels. The source of this hypercalcemia is generally increased production of 1,25-dihydroxyvitamin D, and has been shown in patients with sarcoidosis, Wegener's granulomatosis, berylliosis, silicone-induced or paraffin-induced granulomatosis, eosinophilic granuloma, focal or disseminated tuberculosis, histoplasmosis, coccidioidomycosis, candidiasis, leprosy, and cat-scratch disease.[198-210]

Medications may cause hypercalcemia via various mechanisms. Excessive vitamin D intake, or hypervitaminosis D, may stimulate intestinal calcium absorption, and thiazide diuretics may directly inhibit renal calcium excretion.[211,212] Lithium compounds may interfere with the ability of calcium to interact with parathyroid and renal calcium-sensing receptors, increasing PTH secretion by the parathyroid glands.[213] Numerous other agents, including estrogens, antiestrogens, androgens, aminophylline, theophylline, ganciclovir, and recombinant growth hormone in acquired immunodeficiency syndrome (AIDS) patients, and hypervitaminosis A may affect other physiologic mechanisms resulting in hypercalcemia.[214-220] Miscellaneous disorders that can also be associated with hypercalcemia are listed in Table 125-3.

Diagnosis of Primary Hyperparathyroidism

The diagnosis of primary hyperparathyroidism is usually straightforward, and is based on minimal criteria involving the serum total calcium and measurement of intact PTH levels. Generally, patients present with increased serum total calcium with overtly increased or inappropriately high-normal PTH levels. Some patient with surgically proven primary hyperparathyroidism present with high-normal serum total calcium, and inappropriately high-normal or increased PTH levels. Patients with primary hyperparathyroidism almost always have documented increased serum total or ionized calcium sometime during the course of their disease, recognizing that serum calcium exhibits some variation over time.

It may be difficult to establish a diagnosis of primary hyperparathyroidism in patients in whom serum calcium documentations are noted to be in the middle to lower normal range over time, even if they are found to have increased intact PTH levels. This difficulty is due to the possibility that these patients may have physiologic secondary hyperparathyroidism (see earlier). Patients with serum calcium levels in the middle to lower normal range associated with increased intact PTH levels should be evaluated further to ensure that they do not have low calcium or vitamin D intake, calcium or vitamin D malabsorption, inability to convert 25-hydroxyvitamin D to biologically active 1,25-dihydroxyvitamin D, or significant hypercalciuria. These entities could explain why PTH levels are increased in the setting of serum calcium determinations in the middle to lower normal range.

Patients with primary hyperparathyroidism usually have serum phosphate levels in the low-normal to mildly decreased range. Patients with simultaneously high-normal or increased serum calcium and high-normal or increased serum phosphate should be investigated further for intestinal hyperabsorptive states or hypervitaminosis D.

Intact PTH, determined by current immunoradiometric or immunochemiluminometric assays, is mildly increased or inappropriately high normal for the level of simultaneously measured serum calcium in patients with primarily hyperparathyroidism. The use of current assays prevents any cross-reactivity between PTH and PTH-related protein, making the distinction between primary hyperparathyroidism and PTH-related protein–mediated hypercalcemia of malignancy certain. Patients with primary hyperparathyroidism almost always have suppressed PTH-related protein levels when checked, and patients with PTH-related protein–mediated hypercalcemia of malignancy almost always have suppressed intact PTH levels. Patients who are receiving thiazide diuretics or lithium compounds may have mild hypercalcemia and increased intact PTH levels without coexisting primary hyperparathyroidism, and so it is important to remove these medications for at least 1 month before assessing levels of serum total calcium and intact PTH to make the correct diagnosis. Hypercalcemic patients who are being treated with thiazides or lithium therapy and who have coexisting primary hyperparathyroidism have persistent hypercalcemia and increased intact PTH levels after discontinuation of the medication.

Accurate diagnosis of primary hyperparathyroidism is essential before surgical exploration and attempted parathyroidectomy. Careful attention to the biochemical parameters as described with special notice of the serum total calcium, phosphate, and intact PTH levels is essential in making the correct diagnosis. A 24-hour total urinary calcium level is also important in eliminating the possibility of familial hypocalciuric hypercalcemia from the differential diagnosis.

Localization Studies and Their Application

Although a comprehensive bilateral exploration of all appropriate cardinal parathyroid locations in the surgical management of hyperparathyroidism remains the gold standard, and must be fundamental to the armamentarium of all parathyroid surgeons, the development of more effective imaging methods or parathyroid localization has permitted surgeons to employ more limited procedures in neck exploration, while achieving the same, or improved, surgical outcomes as achieved by four-gland exploration.[74,221] Aside from the application of these imaging techniques for parathyroid localization in more limited, focused explorations of the neck for primary hyperparathyroidism, the use of localization studies before re-exploration for persistent or recurrent hyperparathyroidism has been universally accepted.[222-224] Localization methods may be operationally classified as preoperative (invasive or noninvasive) and intraoperative (Table 125-4).

Noninvasive Preoperative Localization

Pertechnetate (Technetium 99m) Thallous Chloride (Thallium 201) Imaging

Thallium uptake by parathyroid adenomas was initially reported by Fukunaga and others.[225-232] Subsequently, Ferlin and Young and their colleagues[226,227] performed the clinical application using Tc 99m together with thallium 201 (Tl 201). Subtraction of the resulting two

Table 125-4

Localization Studies in Hyperparathyroidism

Noninvasive Preoperative Methods
Ultrasonography
Radioiodine or technetium thyroid scan
Thallium-technetium scintigraphy
Technetium 99m sestamibi scintigraphy
Computed tomography scan
Magnetic resonance imaging
Invasive Preoperative Methods
Fine-needle aspiration
Selective arteriography or digital subtraction angiography
Selective venous sampling for parathyroid hormone assay
Arterial injection of selenium-ethionine
Intraoperative Methods
Intraoperative ultrasonography
Toluidine blue or methylene blue
Urinary adenosine monophosphate
Quick parathyroid hormone intraoperative

images helped to locate the abnormal parathyroid gland or glands. This technique required prolonged patient immobilization for obtaining images as the patient remained in the same position for both radionuclide administrations. Results of this localization technology have been variable, with sensitivity rates ranging from 27% to 82% reported.[228,229] Sensitivity has been reported to be improved by the application of single-photon emission computed tomography (SPECT) techniques with three-dimensional images.[230] The previously noted advantages of this imaging technique are widespread availability, minimal irradiation, and low risk. False-positive results, attributable to patient motion during the examination or as a result of concurrent thyroid abnormalities, have resulted in poor acceptance of this technique as a reliable preoperative localization method for limited parathyroid exploration.

Technetium 99m Sestamibi Scintigraphy

In 1989, Coakley and colleagues[231] reported using Tc 99m sestamibi for cardiac function studies. Chiu and coworkers[232] showed the incorporation of Tc 99m into the cytoplasm and mitochondria of mouse fibroblasts in response to certain stimuli. Parathyroid cells have large numbers of mitochondria that enable sestamibi to enter parathyroid tissue more intensely than into the neighboring thyroid parenchyma.[233] O'Doherty and associates[234] compared radionuclide uptake in parathyroid tissue, and noted a greater uptake per gram for sestamibi than for Tl 201.

In 1992, Taillefor and colleagues[235] proposed a dual-phase scan using Tc 99m sestamibi and cervicothoracic planar parathyroid scintigraphy. In this method, the patient is intravenously injected with 20 to 25 mCi of Tc 99m sestamibi. Subsequent images are obtained at 10 to 15 minutes and then at 2 to 3 hours after the injection. Late phase is usually preferable for detecting parathyroid adenomas because the thyroid and thyroid nodules clear of uptake faster than do parathyroid neoplasms. Jofre and associates[236] showed that 70% of delayed images are best seen at 2 hours, and only 15% are best seen at 4 hours. In certain circumstances, oblique or lateral images can be obtained to attempt to add a third dimension to the study. The advantages of the technique include the ability to use this imaging method without patient immobilization between images.

The sensitivity reported for solitary adenomas is 100%, with a specificity of approximately 90%.[237-239] Few false-positive results have been reported using this imaging technique, and are predominantly due to solid thyroid nodules, predominantly adenomas.[240] Hürthle cell carcinoma and malignant thyroid lymph node metastases have also been noted to result in false-positive sestamibi imaging results; however, cystic lesions of the thyroid gland have not.[74,241]

False-negative results may be attributable to smaller parathyroid adenoma size or suboptimal dosing of Tc 99m sestamibi.[74] Intrathyroid, mediastinal, and deep cervical parathyroid glands have been located with Tc 99m sestamibi; location seems to be independent of its efficiency (representing an advantage over technetium/thallium subtraction scanning). This technique has shown the presence of multiple-gland disease in the form of double parathyroid adenomas (Fig. 125-4).[74] Sestamibi, similar to Tl 201, is inaccurate in patients with diffuse four-gland parathyroid hyperplasia.

Tc 99m sestamibi has been combined with iodine 123 and recorded simultaneously in nonoverlapping windows and subtraction. In a series by Hindie and colleagues,[242] 25 of 27 solitary adenomas were identified with a sensitivity of 94%. In the same population, examination with Tc 99m sestamibi as the sole radionuclide identified 22 of these 27 patients correctly for a sensitivity of 79%. Neumann and associates[243] used Tc 99m sestamibi/iodine 123 subtraction and SPECT in patients with secondary hyperparathyroidism with a sensitivity of 77%. In this series of 13 patients with recurrent secondary hyperparathyroidism, all hyperplastic parathyroids were predicted and subsequently correctly identified at surgery.

Technetium 99m Sestamibi with Single-Photon Emission Computed Tomography

The application of SPECT uses a camera collimator that rotates 360 degrees around the patient in the axial plane, and in essence portrays a three-dimensional image as the sequence progresses from mandible through the thorax. Some investigators have shown a superior sensitivity and localization in the early phase compared with cervicothoracic planar images, whereas the delayed images are approximately equivalent.[244] The images appear to have a higher resolution and have two definite recognized advantages over planar sestamibi images: (1) anatomic localization in ectopic adenomas within the carotid sheath, and (2) localization of mediastinal lesions to the anterior or posterior compartment, allowing planning of surgery by lateral thoracotomy versus median sternotomy.[245]

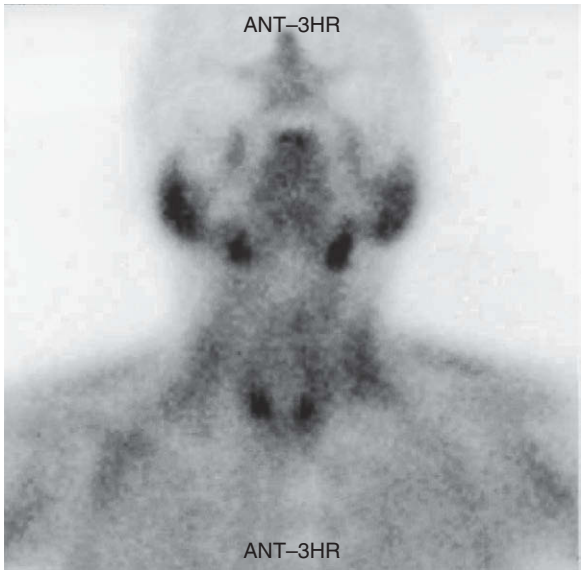

Figure 125-4. Two-hour delayed Tc 99m sestamibi nuclear scan in a patient with hyperparathyroidism secondary to double parathyroid adenomas. Nuclear uptake is shown bilaterally on the image, indicating the location of both adenomas confirmed at surgery.

Computed Tomography–Sestamibi Fusion

Although the regional anatomic localization provided by MIBI-SPECT imaging has been shown to be superior over that of planar imaging, the anatomic relationship of imaged parathyroid tissue with other cervical structures (bony, vascular, visceral) is not clearly defined by these physiologic imaging techniques. Computed tomography (CT)–sestamibi fusion is a combined imaging modality whereby anatomic and physiologic images are combined (fused) to create a single image providing concise anatomic localization of physiologically hyperactive parathyroid tissue (Fig. 125-5). Images are created after the acquisition of contrast-enhanced CT scans of the neck and mediastinum and a standard Tc 99m sestamibi scan with planar and SPECT imaging. The delayed (3-hour) SPECT image is "fused" with the CT scan using specialized software, which provides an automated alignment using a matrix of coordinates. The radiopharmaceutical uptake resolution within the fused image is fine-tuned manually by the radiologist to produce the final localized region. Images are depicted in three dimensions (axial, coronal, and sagittal) in 3-mm slices to provide precise anatomic localization and correlation with other central neck structures in each plane of orientation.

One of the authors (P.K.P.) has accrued experience with this technique in more than 300 patients; the analysis of this experience has yielded specific clinical settings for which this modality has shown clear superiority over planar and SPECT imaging. These settings include refining the directed "minimally" invasive approach (Fig. 125-6); the accurate localization of ectopic glands (i.e., thymic, retroesophageal, mediastinal, intrathyroid) (Figs. 125-7, 125-8, and 125-9); and for patients in whom re-exploration is being carried out in a previously operated region with significant fibrovascular change (Figs. 125-10 and 125-11), to focus the approach and limit dissection in hopes of minimizing the risk of complications. In contrast, early experience suggests that CT-MIBI fusion has limited advantage in distinctly localizing

solitary parathyroid glands that are tightly juxtaposed to the thyroid capsule, especially inferior glands. Although CT-MIBI fusion has shown superiority over conventional sestamibi imaging, selection criteria for routine implementation have not been defined and require further investigation.

Ultrasonography

High-resolution ultrasonography (10 or 12 MHz) was introduced by Edis and Evans in 1979.[246] High-resolution ultrasonography provides for sonographic exploration of the thyroid, carotid, and jugular areas and the cervical area between the thyroid cartilage and the sternal margin. The advantages of this technique are that it is easy to perform, it is well tolerated by the patient, it does not require the injection of a radiotracer, and it can be performed rapidly and at low cost. Disadvantages include localization of enlarged parathyroid glands in the retroesophageal, retrotracheal, retrosternal, and deep cervicothoracic inlet regions. Intrathyroid parathyroid adenomas have reportedly been localized more efficiently with ultrasonography than with other techniques, although they may be confused with cystic thyroid lesions.[247] The sensitivity of ultrasonography in identifying abnormal parathyroid glands varies according to the ultrasonographer's experience, the frequency of the transducer, the resolution of the image, and parathyroid gland size.[248]

Gray-scale ultrasound with high-resolution linear array transducers is the ideal modality for parathyroid study. Transverse and longitudinal scans are required. Transverse scans are useful in identifying adenomas, whereas longitudinal scans better show the relationship of the adenoma to the thyroid and its internal architecture and vascularity. A parathyroid adenoma typically appears as a hypoechoic mass posterior or inferior to the thyroid gland in its usual extracapsular location. Retrothyroid lesions tend to be oval or flat, whereas infrathyroid lesions are usually spherical. Some parathyroid adenomas may show cystic portions within, but calcification is rare. Given that the most common false-positive image with a Tc 99m sestamibi image is that caused by a thyroid adenoma (Fig. 125-12), this particular entity may be reconciled with adjunctive ultrasonography. A discrete blood supply to the mass within the thyroid parenchyma identified by color Doppler suggests a diagnosis of intrathyroidal parathyroid adenoma, rather than a lesion of the thyroid itself (Fig. 125-13).

False-positive ultrasound studies have resulted from thyroid nodules, adenopathy, and esophageal lesions.[248] The presence of surgical clips can also make interpretation more difficult. The overall false-positive rare has been reported to be approximately 15% to 20%.[247,249,250]

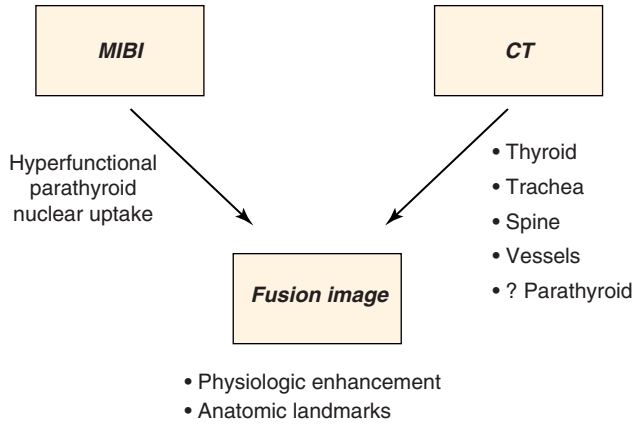

Figure 125-5. Schematic depicting combination imaging for parathyroid localization exploiting the characteristics of nuclear uptake with Tc 99m sestamibi and CT.

Computed Tomography

CT is a less sensitive method than magnetic resonance imaging (MRI). It is relatively expensive, exposes the patient to radiation, and

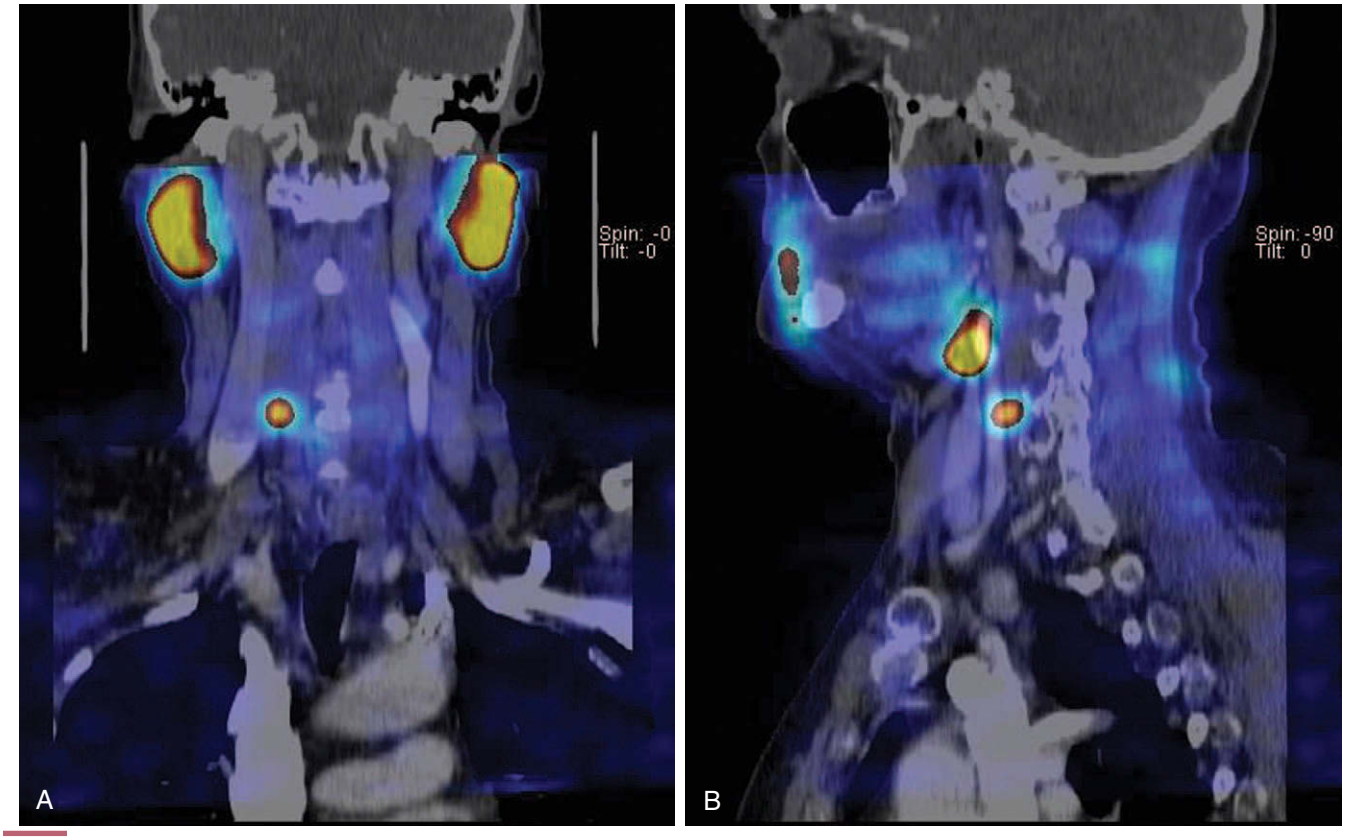

Figure 125-6. **A** and **B,** CT-MIBI fusion image in coronal and sagittal planes showing ectopic superior parathyroid adenoma located superior to the thyroid lobe.

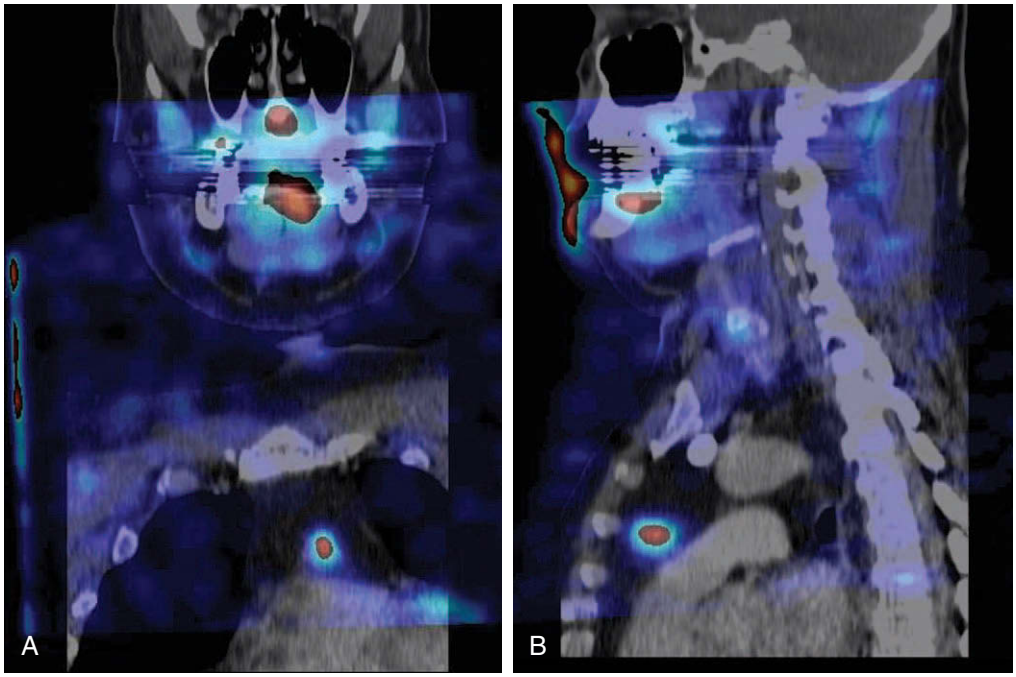

Figure 125-7. **A** and **B,** CT-MIBI fusion image showing ectopic parathyroid adenoma within anterior mediastinal compartment in coronal and sagittal planes.

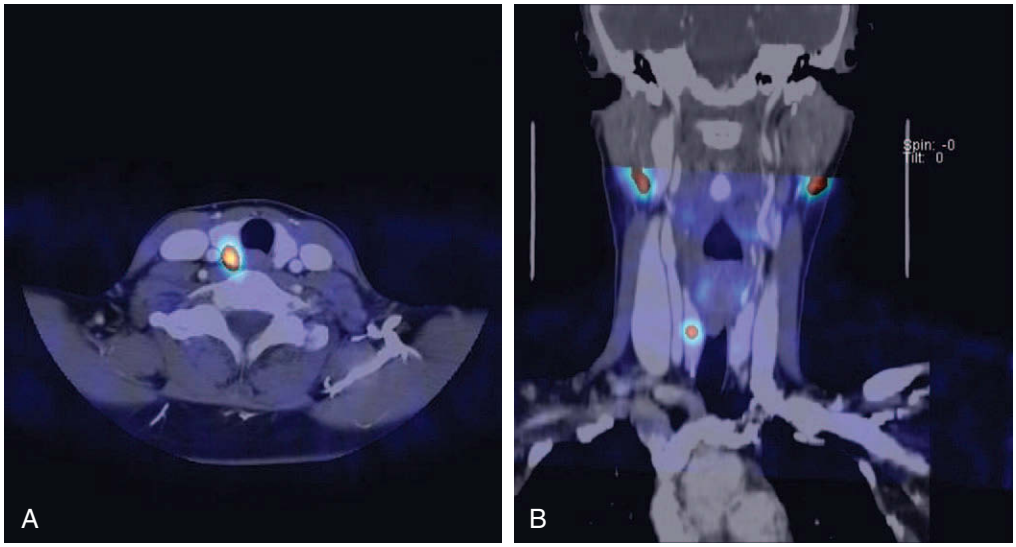

Figure 125-8. **A** and **B,** CT-MIBI fusion image (axial and coronal planes) showing ectopic hyperplastic supernumerary parathyroid gland within the thyroid lobe in a patient with multiple endocrine neoplasia syndrome type I.

requires the administration of contrast material to obtain optimal imaging. It may be useful for ectopic parathyroid glands (retrotracheal, retroesophageal, and mediastinal), but is less effective for parathyroid adenomas that reside in a normal anatomic location. Metal clips distort the image of CT. Perithyroidal lymph nodes and ectopic vasculature may make identification of adenoma difficult.[251] This technique does not selectively image endocrine tissue, and is not physiologically based, supplying only anatomic information. False-positive results are usually more frequent than with other techniques and may be 50%, making this technique impractical for most clinical situations.[252,253]

Magnetic Resonance Imaging

MRI is generally believed to be superior to CT because it does not require the administration of radioiodinated contrast material, and there is no interference from surgical clips left in the neck after initial exploration. A parathyroid neoplasm usually has a low signal intensity in T1-weighted imaging (similar to muscle or thyroid) and a high signal intensity (more than or the same as fat) in T2-weighted imaging (Fig. 125-14).[254]

MRI may be more useful for identifying ectopic parathyroid tissue. In an investigation evaluating patients undergoing reoperation for recalcitrant hyperparathyroidism, Jeelos and colleagues[255] noted that MRI localized 79% of ectopic glands and only 59% of enlarged glands situated in a normal position. Parathyroid adenomas located in a superior position have been noted to be difficult to locate posterior to the thyroid at the level of the cricoid cartilage.[256]

The sensitivity for MRI has been reported to be superior than that for CT, ranging from 50% to 80%.[252,255] MRI, similar to Tl 201 scanning, shows false-positive findings as a consequence of enlarged lymph

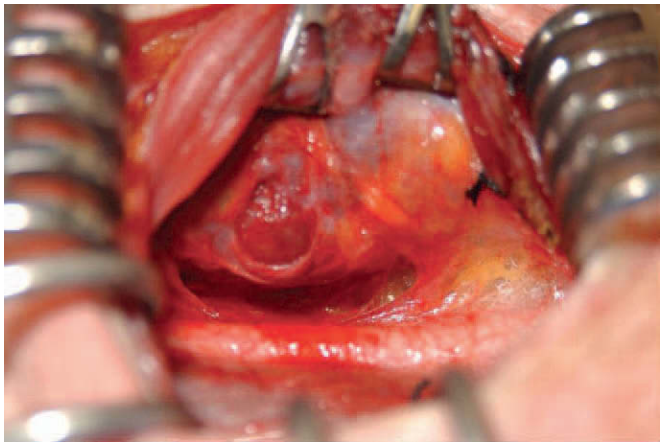

Figure 125-9. Intraoperative photograph showing thyroid lobotomy to expose intrathyroid parathyroid gland in the patient from Figure 125-8.

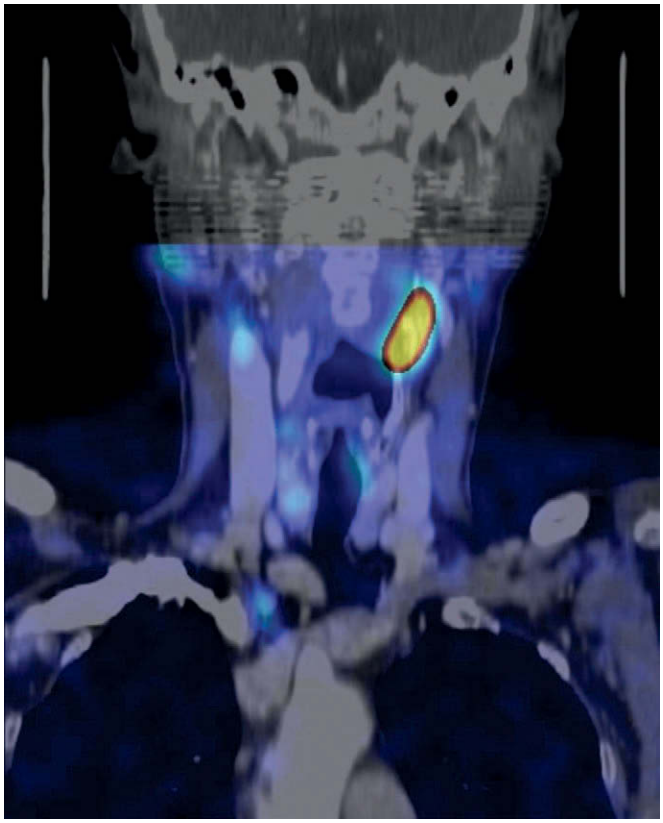

Figure 125-10. Sagittal CT-MIBI fusion image showing intense focus of nuclear activity in left superior position in a patient with hyperparathyroidism who previously underwent total thyroidectomy and neck dissection for thyroid cancer.

nodes.[257] Thyroid adenomas may also lead to false-positive results with MRI.

MRI and CT offer limited application in preoperative localization; however, the relative cost of these procedures and their inconsistent results generally preclude their universal use before initial exploration. MRI and CT are important modalities to be used in patients who have recalcitrant hyperparathyroidism and require re-exploration.

Invasive Preoperative Localization

Invasive localization studies are indicated when the combined results of noninvasive tests are negative, equivocal, or conflicting. These studies

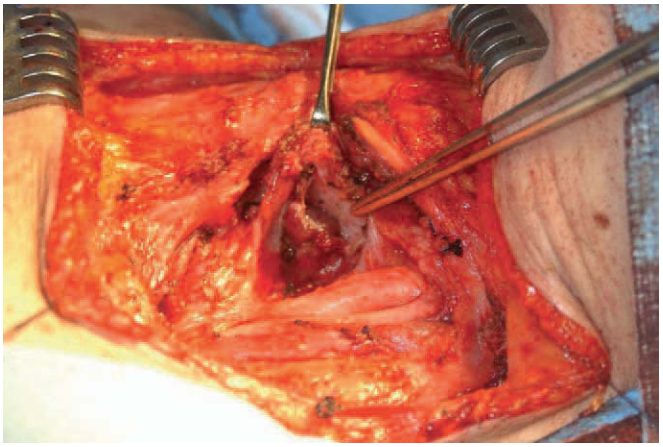

Figure 125-11. Intraoperative photograph showing large parathyroid adenoma in previously operated central neck compartment in the patient from Figure 125-10.

Figure 125-12. Tc 99m sestamibi nuclear scan in a patient with hyperparathyroidism and nodular thyroid disease. Nuclear uptake in right lower cervical region on delayed image represents uptake by a thyroid adenoma.

are generally indicated in the setting of recalcitrant hyperparathyroidism before re-exploration.

Parathyroid Arteriography

Appropriate parathyroid arteriography includes examination of both thyrocervical trunks (search for glands in the superior mediastinum, tracheoesophageal sulcus, or intrathyroid or juxtathyroid glands), the internal mammary arteries (glands in the thymus and the anterior mediastinum) and carotids (juxtathyroid or undescended glands), and sometimes the selected catheterization of the superior thyroid artery. Parathyroid adenomas appear highly vascularized and oval or round in shape. Conventional arteriography has a reported sensitivity of about 60%, although the results obtained with digital subtraction arteriography are slightly better.[258-260]

Selective Venous Sampling for Parathyroid Hormone

Angiography is performed primarily to outline the venous drainage, facilitating sampling for PTH assay. This investigation is expensive and technically difficult. Sampling must be obtained as selectively as possible from the smallest venous branch to document the exact location of the parathyroid tumor.[261] Published reports suggest, however, that

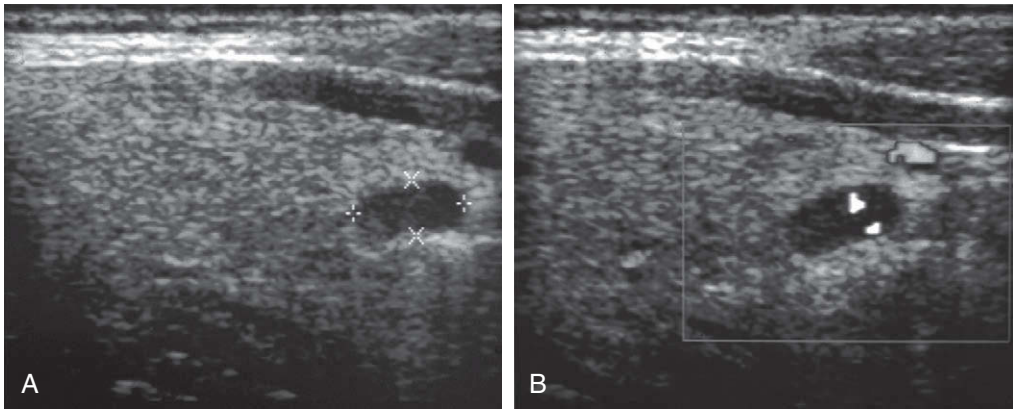

Figure 125-13. **A,** A small but hyperfunctioning parathyroid adenoma is shown on sagittal ultrasonography to be completely within the thyroid gland. **B,** Doppler ultrasonography shows a discrete blood supply that differs from the more diffuse perinodular vascular support for a thyroid adenoma from its surrounding parent gland.

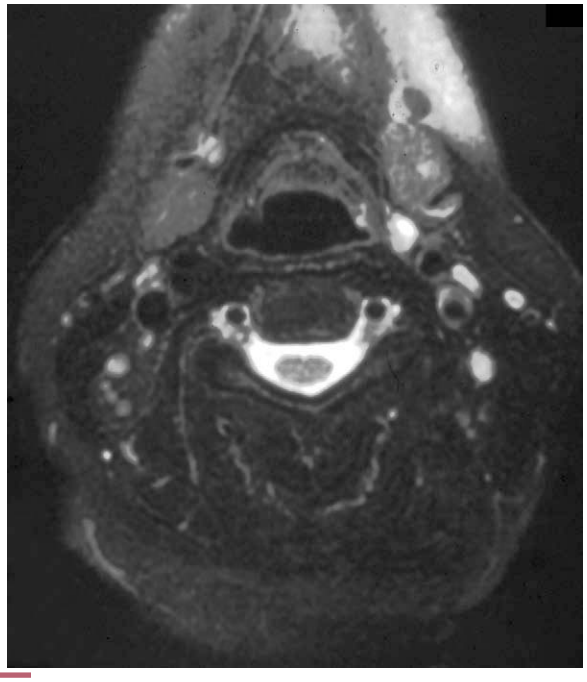

Figure 125-14. MR image showing a mass in the left submandibular triangle consistent with an undescended superior parathyroid adenoma.

sampling from large veins such as the internal jugular vein, innominate vein, and superior vena cava may yield optimal results.[262] A twofold gradient between the PTH concentration in peripheral blood and that in the selectively sampled venous tributary establishes the site of the venous drainage from the tumor.

This technique is generally believed to be the most sensitive, lateralizing about 80% of the parathyroid tumors.[255,259,263,264] It seems to be just as effective in localizing mediastinal glands as it is for cervical glands, and depends on physiologic properties of the parathyroid gland rather than size. It may be helpful in multiple-gland disease, and has the ability to reconcile an equivocal noninvasive study so that localization may be achieved.

Ultrasound-Guided Fine-Needle Aspiration

Fine-needle aspiration of a parathyroid tumor performed under ultrasound guidance may offer an improvement over the results obtained with ultrasound. Fine-needle aspiration may provide for direct cytologic examination, or it may facilitate the use of a bioassay of the aspirate to determine PTH level. When the aspirate is positive for PTH, it confirms the presence of parathyroid tissue within the enlarged gland.[265] PTH determination is generally more helpful than cytology examination for diagnosing parathyroid lesions because of the difficulty in differentiating between parathyroid and thyroid tissue in such a limited sample.[266] In one study reported by Tikkakosky and associates,[267] 100% of abnormal parathyroid glands were diagnosed by bioassay, but only 60% were diagnosed by cytologic examination.

Intraoperative Localization Methods

High-resolution intraoperative ultrasonography may be useful in many operative settings, including primarily re-exploration for hyperparathyroidism in a neck that shows significant surgical fibrosis. The injection of methylene blue or toluidine blue is of little value because the pathologic gland has to be identified.[268] Methylene blue has been used in the setting of reoperation within 1 to 2 days after initial parathyroidectomy for persistent hyperparathyroidism. Because postoperative edema and seroma fluid makes re-exploration difficult in this circumstance, the blue color may be helpful in identifying parathyroid tissue.

Norman and colleagues[269,270] have advocated radiation-guided parathyroid gland identification and removal. Hand-held gamma probes developed for operating room use are used to detect the gland concentrating Tc 99m sestamibi, which is injected on the day of operation usually within approximately 2 hours of the operation. The initial scan provides information regarding localization of putative adenomas and the presence of delayed uptake of nuclear material within the thyroid gland. If excessive delayed activity is present in the thyroid, the patient is subjected to thyroid suppression for 6 to 8 weeks before operation to reduce background radiation in the thyroid bed, and to increase the accuracy of the probe. This is the usual circumstance in reoperative settings. After identification and removal of the abnormal gland or glands, the final abnormal gland removed is checked for the degree of radioactivity ex vivo against background tissues in the surgical bed. Based on previous reported data, excised glandular tissue emitting radiation greater than 20% of that found in tissues in the surgical bed was confirmed as the hyperfunctional parathyroid tissue implicated in disease.[269]

Surgical Management

Indications for Exploration

The decision to perform surgical exploration in a medically stable patient with primary hyperparathyroidism is predicated on the potential for development of complications from prolonged exposure to hypercalcemia and the long-term benefit of surgery. Generally, patients should be assessed for the risk of developing complications on the basis of disease severity at the time of diagnosis; patients who have received a previous diagnosis in whom complications have arisen over a short interval since the diagnosis are at significant risk of developing further problems.

Patient age should not represent an exclusive determinate of candidacy for surgery; general medical condition and the potential for pursuing an active lifestyle should play a more prominent role in determining the recommendation for treatment. Generally, younger patients, who potentially will have longer exposure to hypercalcemia, are at a substantially greater risk for developing complications.

The severity of hypercalcemia represents a consideration in the decision to perform surgery. Although no absolute level of serum calcium provides stringent criteria for surgery, most endocrine surgeons consider a serum calcium level of 11.5 mg/dL or greater as an absolute indication for surgery. Surgery in postmenopausal women should be given special consideration independent of the severity of hypercalcemia or absence of symptoms. Women in this population are at greater risk for development of long term skeletal complications from generalized demineralization and osteopenia (i.e., hip and vertebral fractures).[271]

A major factor to be considered in determining the need for surgery is the potential for long-term benefits and prospects for cure. In 85% to 90% of patients, hyperparathyroidism occurs as a result of a single adenoma. Exploration and removal of the adenoma is curative in greater than 95% of patients, and the long-term benefit and potential for cure is high. Primary hyperplasia occurs in approximately 10% to 12% of patients with hyperparathyroidism. Surgery in these patients involves subtotal parathyroidectomy, with the amount of tissue left ultimately determining the long-term benefit of the surgery. Because of the variable amount of parathyroid tissue left in the neck, and potential for variable activity, the prospect for cure is less reliable than for patients with adenoma. These patients have cure rates significantly reduced compared with patients in whom an adenoma is removed.[272]

Because of the considerations mentioned previously, the decision to perform surgery on patients who seem asymptomatic and who have no obvious metabolic complications is problematic. Although early surgical intervention seems to be favored, stringent criteria as to whether or not these patients should undergo surgery have not been clearly defined. About 50% of asymptomatic patients go on to develop metabolic complications from hyperparathyroidism within 5 to 7 years of the onset of hypercalcemia.[273]

Because of the uncertainties about the indications for surgery in asymptomatic patients, a consensus conference held by the National Institutes of Health in 1990 addressed the question of management in this clinical situation.[274] Recommendations for surgical management or surveillance or both for patients with primary hyperparathyroidism derived from that conference predated much of what has evolved over the course of the last decade with respect to clinical experience with asymptomatic primary hyperparathyroidism, the evolution of contemporary surgical technique, and the development of newer technologies in preoperative localization. This conference was reconvened in early 2002 in an effort to re-evaluate the original recommendations from the 1990 symposium and contemporize recommendations on the management of asymptomatic primary hyperparathyroidism.[275] The indications for surgery as suggested by the conference are as follows:

1. Serum calcium is greater than 1 mg/dL above the upper limit of normal.
2. Creatinine clearance is reduced more than 30% for age in the absence of another cause.
3. Measurement of 24-hour urinary calcium is greater than 400 mg/dL.
4. Patients are younger than 50 years of age.
5. Bone mineral density measurement at the lumbar spine, hip, or distal radius is reduced more than 2½ standard deviations (by T-score).
6. Patients request surgery, or patients are unsuitable for long-term surveillance.

These recommended indications are conservative; they provide a framework for surgical decision making, but are not absolute or universal. The decision to perform surgery on a patient with primary hyperparathyroidism and metabolic complications is straightforward. The decision is less clear in asymptomatic patients and must be guided by the potential benefits of surgery, the patient's risk of developing complications from disease, the wishes of the patient, and, importantly, the experience of the surgeon. The success rate of surgery and the incidence of complications after parathyroidectomy have been documented to vary greatly depending on the surgeon's experience. In one study, experienced Swedish surgeons achieved normal calcium in greater than 90% of patients with recurrent laryngeal nerve complications in less than 1%. Surgeons who perform fewer than 10 parathyroidectomies per year had a success rate of 70%, but with 15% of patients remaining hypercalcemic and 14% becoming permanently hypocalcemic.[276] In weighing potential benefits of surgery against risks for patients with asymptomatic hyperparathyroidism, the experience of the surgeon should be a primary consideration.

Although patients with mild to moderate hypercalcemia seldom experience rapid elevation in serum calcium level, hypercalcemia and the risk of developing occult symptoms and risks for potential end organ damage increase with time. As a result, patients with untreated primary hyperparathyroidism are at risk for major morbidity and mortality from cardiovascular disease.[277,278] The benefits derived from parathyroidectomy in patients with occult or minimally symptomatic disease were discussed earlier in the section on clinical manifestations of hyperparathyroidism. In addition, parathyroidectomy seems to offer a distinct and measurable advantage in patients with mild asymptomatic primary hyperparathyroidism, as indicated by the results of a randomized trial in which patients were subjectively surveyed using a standardized health survey instrument.[279] In this investigation, patients with mild symptomatic hyperparathyroidism were randomly assigned to surgery or observation, and assessed every 6 months after randomization for 2 years using the SF-36 Health Survey, an instrument that measures wellness.[280] Significantly improved function was noted in patients after parathyroidectomy compared with patients who were observed.

Technique of Parathyroidectomy

(see Key Indicator Video on website)

Anesthesia and Preparation

Exploration of the neck in patients with hyperparathyroidism is generally performed under general anesthesia with endotracheal intubation. In patients who are medically unfit for general anesthesia, parathyroid exploration for removal of a solitary adenoma localized preoperatively may be performed under local anesthesia supplemented by intravenous sedation.[281,282]

Positioning of the patient on the operating table is very important. The patient's neck should be hyperextended dorsally to provide optimal access to the neck, particularly in patients with a short wide neck, and access to the cervicothoracic junction. The arms of the patient should lie along aside the body to allow the surgeon and the assistant to stand on both sides of the neck comfortably. Long ventilation tubes are helpful in facilitating placement of the ventilator at some distance from the operating table, which allows for rotation of the operating table away from the anesthesia personnel. Patients in whom exploration is being performed in a directed or minimally invasive fashion should have an accessible intravascular site, intravenous or intra-arterial, from which a peripheral sample of blood may be drawn to assess PTH levels intraoperatively. After complete positioning and preparation of the patient on the operating table, the table may be adjusted in the reverse Trendelenburg position to decrease venous congestion around the thyroid bed and central neck.

Exploration of the Neck

A low transverse cervical incision (Kocher) is designed two fingerbreadths above the suprasternal notch, usually over a natural skin crease, and is carried down through the platysma. The incision may be tailored according to the surgeon's preference with respect to the type of exploration being carried out. More directed, focused procedures

Figure 125-15. Exposure achieved through anteromedial rotation of the thyroid gland with demonstration of superior and inferior parathyroid gland positions.

require a shorter incision than a traditional bilateral four-gland exploration. In any event, the incision should not extend beyond the sternocleidomastoid muscles. After incising the platysma, the cranial skin-platysma flap is dissected upward to the notch of the thyroid cartilage, and the caudal-platysma flap is dissected inferiorly to the suprasternal notch. A self-retaining retractor is useful in spreading the cranial and caudal flaps to expose the midline strap muscles in the region of the thyroid bed and central neck structures. The midline raphe of the strap muscles is identified and separated from the thyroid notch to the suprasternal notch, allowing the sternohyoid muscles to be retracted laterally. It is usually unnecessary to divide the sternohyoid muscles. The sternothyroid muscle is separated over the thyroid lobe on the side of the neck to be explored first, carefully elevating the muscle away from the thyroid capsule.

In contrast to the plane between the strap muscles, which is predominantly avascular, the plane separating the sternothyroid muscle from the true thyroid capsule may be quite vascular, and particular attention to hemostasis is important in carrying out this maneuver. Hemostasis during parathyroid exploration cannot be overemphasized because blood-stained tissues hinder the ability of the surgeon to identify abnormal and normal parathyroid glands within the fatty tissue of the central neck.

The thyroid lobe on the side being explored is retracted anteromedially to access the potential space posterior to the thyroid lobe. This is facilitated by exposing the dominant middle thyroid venous tributaries, dividing and ligating them to access this region. Ligation of the superior or inferior thyroid artery is unnecessary for adequate rotation of the thyroid anteromedially during this maneuver.

After this region has been accessed, blunt dissection of fibroareolar tissue facilitates evaluation of the area where normal and abnormal parathyroid glands generally reside. This dissection permits visualization or palpation, or both, of enlarged parathyroid tissue with minimal dissection to prevent staining of tissues with blood. It is essential to maintain anteromedial retraction of the thyroid gland to expose the angle of visualization and subsequent exploration (Fig. 125-15); this is facilitated further by opening the fascial sheath (pretracheal fascia) connecting the carotid sheath and the thyroid gland. This maneuver provides access to the paraesophageal and retroesophageal spaces. Although identification of the recurrent laryngeal nerve is not generally mandatory, dissection in either the retroesophageal or paraesophageal space requires visualization of the nerve to prevent injury.

A systematic approach to the surgical identification of the parathyroid glands is essential to ensure a high success rate, and to avoid missing abnormal glands. It is important to develop a methodical and disciplined sequence of exploration to minimize the potential for missing either normal or abnormal glands. The ability to palpate abnormal glands cannot be overemphasized. Often glands within the paraesophageal space just dorsal to the juxtaposition of the recurrent laryngeal nerve and the inferior thyroid artery may be palpated before they are seen. Palpation in this area generally directs the surgeon to this region so that focal areas of meticulous dissection may be carried out, minimizing the potential for significant tissue staining by blood and inadvertent devascularization of normal parathyroid glands. Initial palpation along the posterior aspect of the thyroid capsule, especially adjacent to the superior pole above the inferior thyroid artery entrance to the gland, sometimes reveals the presence of an enlarged superior parathyroid gland closely situated against the true thyroid capsule underneath a covering of pretracheal fascia.

Depending on surgical preference, the usual trend is to identify the inferior glands initially. They tend to be larger and more anterior; however, their location may also be less predictable and constant. Typically, they are found adjacent to the inferior pole of the thyroid gland or within a tongue of thymic tissue inferior to the thyroid, the so-called thyrothymic ligament. Commonly, the inferior glands may be located anterior and slightly medial to the juxtaposition of the inferior thyroid artery and recurrent laryngeal nerve. The superior parathyroid glands are most commonly found along the posterior capsule of the thyroid gland at a point slightly lateral and posterior to the juxtaposition between recurrent nerve and inferior thyroid artery. Blunt dissection along the posterior capsule often reveals the superior gland to be suspended in a teardrop fashion within 1 cm of the entrance of the recurrent laryngeal nerve under the cricothyroid muscle. A helpful maneuver in exposing this superior location is to divide the sternothyroid muscle close to the superior thyroid pole to provide maximal medial mobilization without devascularizing the superior pole of the thyroid gland.

Parathyroid glands are often (partially) surrounded by fat. Any lobule of fat that is noted at sites that may harbor parathyroid glands should be carefully inspected. This inspection is facilitated by opening the thin fascia that covers the fat lobule and applying pressure allowing the parathyroid gland to extrude or "blossom" out of the fat. Most normal parathyroid glands have a light brown or tobacco color. This color is important in differentiating parathyroid glands from fat, which is generally more yellow, versus thyroid nodules, which are more rust-red in color.

Parathyroid glands also have a degree of freedom of mobility along the true thyroid capsule in relationship to the thyroid gland. It is helpful to dissect bluntly along the thyroid capsule with a Kitner (peanut) dissector to visualize moving structures within fat and adjacent to the true thyroid capsule. The close relationship of the pretracheal fascia overlying these pseudosubcapsular parathyroid glands allows this freedom of movement on blunt dissection. In contradistinction, a thyroid nodule mimicking a parathyroid gland does not enjoy this freedom of movement, and is more firmly attached to the central thyroid lobe without a plane of cleavage between it and the thyroid gland, and without a vascular pedicle.

Perithyroidal lymph nodes, particularly those within the thyrothymic ligament, may be confused with parathyroid glands. The consistency of lymph nodes is more firm, however, than that of parathyroid glands, and lymph nodes are noted to be more of a translucent white-gray than are parathyroid glands.

During the exploration for normal and abnormal parathyroid glands, the vascular anatomy of these glands should be observed. Dissection of the superior parathyroid glands should be initiated at the outermost tip of this gland to prevent injury to the parathyroid vessels, which usually ascend from arterial anastomoses originating from the inferior thyroid artery. The dissection of the inferior parathyroid gland should begin at the caudal end of the parathyroid because the vascular pedicle generally enters on the upper or cranial side of the inferior parathyroid gland. Suspected devitalization of a normal parathyroid gland during dissection generally requires that it be autotransplanted within cervical muscle. This procedure involves sharply fragmenting the gland into cubic millimeter pieces and implanting them in a hemostatic fashion within the sternocleidomastoid muscle of the same side.

After it is identified, the abnormal gland is removed and sent for pathologic analysis. A thorough search is conducted to locate the second gland on the same side; if found, it too is removed and sent for pathologic determination. If the enlarged gland is reported as hypercellular, and the second gland is normal or suppressed, the operation proceeds by accessing the viscerovertebral angle of the opposite side. Surgical

preference and the type of procedure advocated (directed unilateral versus traditional bilateral) determine the extent of exploration at this point. If the biopsy specimen of the second gland on the side explored first is found to be abnormal, or if it appears enlarged, all four glands should be identified and histologically examined. In this instance, the presumptive diagnosis is hyperplasia, which requires subtotal (3½ gland) parathyroidectomy. The distinction between adenoma and hyperplastic parathyroid tissue is difficult or impossible on frozen section analysis; the surgeon cannot rely on histologic analysis of a single gland for definitive therapy.

The appearance of normal and diseased parathyroid tissue is generally readily recognizable, provided that the fibroareolar tissues remain free of excessive blood staining. In contrast to normal parathyroid tissue, parathyroid adenomas appear rust-red or beefy red in situ. They may be mottled or variegated in their coloring, and usually lighten on resection. In contrast, hyperplastic glands generally appear darker than adenoma, usually a dark rust, brown, or chocolate color resembling more the color of thyroid tissue.

Failure to identify a missing gland suspected to be an adenoma or, in the case of hyperplasia, failure to locate all glands mandates a thorough dissection in an effort to locate abnormally located or ectopic parathyroid tissue. A systematic approach is undertaken to examine all areas potentially harboring an ectopic gland. It is imperative that the surgeon know which gland is missing with the understanding that a search is predicated on the likely variable or ectopic sites. Surgical dissection should address all areas accessible through a cervical approach, including the removal of thymic tissue within the superior mediastinum, examination of the retroesophageal space and carotid sheath to the hyoid, and thyroid lobectomy (lobotomy), if necessary. Approximately 90% of all parathyroid adenomas are resectable through a transcervical approach, and a missing gland is usually harbored in an ectopic location accessible to the surgeon at initial operation.

Closure of the Incision

After completion of the surgical exploration, the operative field is irrigated with warm saline solution and inspected for adequate hemostasis. Particular attention to any normal parathyroid glands that were isolated and dissected is important to document apparent viability. Parathyroid glands judged to be poorly vascularized or of compromised viability should be autotransplanted as discussed previously. Depending on the extent of exploration, the body habitus of the patient with respect to depth of dissection within the cervicothoracic junction, and degree of bleeding encountered, a drain may or may not be used. In most cases, drainage of the wound is not required because most dissections are limited and hemostatic. Depending on surgical preference, the skin may be closed in either a cuticular or a subcuticular fashion after reapproximation of the strap muscles in the midline and closure of the platysma. An occlusive dressing is placed to prevent fluid collection under the incision.

Postoperative Care

Successful parathyroid exploration with removal of a solitary adenoma results in a decrease in total serum calcium level, which usually reaches a nadir at approximately 48 hours after the operation. Postoperative hypocalcemia may be seen in patients with severe skeletal depletion of calcium, resulting in "bone hunger." In some patients, symptoms of hypocalcemia or tetany may develop while the serum calcium level is normal. This phenomenon may be due to a rapid decrease in serum calcium after removal of the parathyroid tumor, causing an increased neural excitability, but may also persist after calcium replacement because of accompanying hypomagnesemia.[283]

Depending on surgeon preference, postoperative total serum calcium levels should be measured at least once within the first 24 hours after operation either in the hospital or in an outpatient facility. Normocalcemia at 6 months postoperatively is the usual standard assessment for surgical success, and total serum calcium level and intact PTH level should be assessed at 1 month and 6 months postoperatively.

Surgical Strategy and Approach to Exploration

The optimal surgical approach in managing primary hyperparathyroidism is one in which normocalcemia is achieved, while minimizing potential surgical morbidity, including recurrent laryngeal nerve injury, postexploration hypocalcemia, and persistent or recurrent hyperparathyroidism requiring reoperation. Additionally, the approach selected should be individualized to the patient and disease entity (suspected single-gland versus multiple-gland disease), and should be time and cost efficient. The development of a surgical strategy in managing patients with primary hyperparathyroidism has evolved in recent years from the routine performance of bilateral cervical exploration to a more directed unilateral approach. In theory, because most patients with primary hyperparathyroidism have a single hyperfunctioning adenoma as the offending lesion, it follows that the ideal surgical approach would involve directed removal of the solitary abnormal gland in the least invasive and potentially traumatic manner. Incorporating this theoretical ideal into a practical and reliable surgical approach had previously been limited by two constraints. The first of these was accurate preoperative localization of the abnormal gland, and the second was an inability to confirm intraoperatively removal of all hyperfunctioning parathyroid tissue without performing a bilateral cervical exploration and examining all four parathyroid glands.

Traditionally, the argument for a bilateral cervical exploration in patients with suspected adenoma has been the high success rate in achieving normocalcemia with a conventional bilateral approach in experienced hands (>95% cure), the inability to predict accurately which side to explore selectively, and the potential risk of missing unsuspected multiple-gland disease such as double adenoma or unsuspected hyperplasia.[284-289] More recent technologic advances have helped address these areas of concern, and there is now growing consensus for a less extensive, directed exploration in the approach to primary hyperparathyroidism. The first impetus to this shift in surgical philosophy was provided by improvements in preoperative imaging for the accurate localization of hyperfunctioning solitary adenomas through the use of Tc 99m sestamibi imaging (see section on noninvasive preoperative localization). The second major advance involved the quest for a more precise and timely means of judging surgical success, which led to the development of assays to measure the intact PTH molecule. With the ability to confirm biochemically removal of all hyperfunctioning parathyroid tissue intraoperatively, the theoretical advantages of a directed unilateral cervical approach have increasingly become reality.[290-292]

Single-Gland Disease

Directed Unilateral Cervical Exploration

Directed unilateral cervical exploration employs preoperative localization with Tc 99m sestamibi and the implementation of intraoperative assay for PTH determination for the surgical management of primary hyperparathyroidism secondary to anticipated parathyroid adenoma. In the initial preoperative evaluation, all patients with disease entities exhibiting multiple-gland hyperplasia, such as patients with familial hyperparathyroidism and MEN-I or MEN-IIA, are determined to be candidates for standard bilateral cervical exploration and do not have localizing studies performed before initial operation. A preoperative Tc 99m sestamibi scan is obtained on all other patients with primary hyperparathyroidism and, depending on surgical preference, may be combined with high-resolution ultrasound evaluation of the thyroid bed and central neck.

If the scan is inconclusive or equivocal, as judged by the surgeon and nuclear medicine specialist, a standard bilateral cervical exploration is planned and carried out, whether or not an enlarged gland is found on the side explored first. Failure to localize with an optimally performed Tc 99m sestamibi scan, in the absence of significant thyroid disease, is strongly suggestive of sporadic diffuse hyperplasia.[293,294] If the nuclear scan identifies a discrete nuclear focus on delayed imaging, suggestive of adenoma, a directed exploration to the side localized is performed, and biochemical confirmation of removal of all hyperfunctioning parathyroid tissue is obtained through the use of intraoperative assay for PTH determination.

It has been previously shown that the most precipitous decrease in PTH levels occurs 5 minutes after removal of all hyperfunctioning parathyroid tissue.[295] The short half-life of PTH (roughly 2 to 5 minutes) allows peripheral blood samples to be obtained intraopera-

tively for rapid PTH testing 7 to 10 minutes after excision of all suspected hyperfunctioning parathyroid tissue.[293] A peripheral blood sample for rapid PTH assays is drawn at the time of abnormal gland identification (baseline) and subsequently at 10 minutes after removal of all suspected hyperfunctioning parathyroid tissue. A degradation in the serum PTH level exceeding 50%, noted in the postexcision PTH level compared with the pre-excision level, provides biochemical confirmation of removal of all hyperfunctioning parathyroid tissue, allowing the procedure to be concluded without identification or biopsy of any other parathyroid glands. If the postexcision PTH level is greater than 50% of the baseline pre-excision level, suggesting the presence of residual hyperfunctioning parathyroid tissue, a standard bilateral cervical exploration is performed.

Intraoperative PTH determination may be carried out by many methodologies. One method uses a radioimmunoassay developed through a simple, previously described modification of an intact PTH overnight assay method.[294] The intact PTH assay is a two-antibody sandwich system. One antibody (the capture antibody) is fixed to a plastic bead; the second is conjugated with a measurable marker. The amount of intact PTH present in a plasma sample can be determined by measuring the amount of the marker material remaining after all unbound solutions have been removed. Results of this rapid PTH assay are generally available within 8 to 10 minutes after submission to the radioimmunoassay laboratory.

To overcome problems associated with sensitivity of the rapid immunoradiometric assay, researchers began conjugating the labeling antibody with chemiluminescent tracers to avoid the handling issues of their radioactive predecessors.[291,292,295] Since the introduction of the immunochemiluminometric assay in 1993, researchers have experimented with several different variations on this theme, and some manufacturers now offer so-called quick kits. Experience with this assay is consistent among the investigators in that a decrease of 50% or greater between the postexcision and baseline pre-excision PTH values is indicative of removal of all hyperfunctioning parathyroid tissue.[293-301] The major drawback of these kits is their high cost. Because the assay negates the need for frozen section analysis in most cases, however, the overall cost is only slightly more expensive than the traditional unilateral approach.[291] These modifications can provide a cost-effective alternative to preformed kits, especially when weighed against the potential costs of a missed ectopic adenoma.[74]

The kinetics of postadenoma resection are important to understand if logical management strategies are based on these objective data. Libuttis[302] showed that the half-life of PTH varies within a brief window—0.42 to 3.81 minutes. Randolph[303] showed that the lowest values occur within 1 to 3 days. In 38% of patients with successful resection of a single parathyroid adenoma and return to normocalcemia, intact PTH levels may remain elevated at 1 month. Suggested mechanisms are cortical bone remineralization, increase in calcium receptor set-point, and a relative secondary hyperparathyroidism.

In situations where localization studies are inconclusive or equivocal (lacking mutual agreement by the surgeon and radiologist), or where clinical circumstances suggest multiple-gland disease (e.g., MEN, familial hyperparathyroidism), a traditional bilateral cervical exploration is recommended. Specifically, both sides of the neck are explored in an attempt to identify at least four parathyroid glands, independent of whether or not the first side explored yields an enlarged gland. Routine biopsy of all normal-appearing glands is not recommended. Instead, incisional biopsy of glands is performed selectively. Intraoperative PTH determination remains an important adjunct in the bilateral approach because this modality serves to confirm biochemically removal of all hyperfunctioning parathyroid tissue, and reduce the chance of missing ectopic multiglandular disease, whether as a result of "double adenoma" or ectopic supernumerary glands.

Minimally Invasive Techniques

Surgical techniques that derive from the basic cervical exploration described previously have been termed *minimally invasive* techniques primarily because of modifications resulting from advances in technology. Scanned directed surgery under local or regional anesthesia has been advocated by many investigators reporting excellent surgical results.[302,303] These techniques capitalize on the ability to administer effective regional anesthesia to an awake, sedated patient to perform directed unilateral focused exploration with removal of a localized solitary parathyroid adenoma. The technique employs preoperative scanning with Tc 99m sestamibi using planar and SPECT imaging and intraoperative PTH assay for biochemical confirmation of removal of all hyperfunctioning parathyroid tissue.

Advantages of this technique have been reported as improved patient comfort postoperatively, the performance of ambulatory procedures, and reduced cost.[302] Disadvantages of the technique include the potential for conversion to a comprehensive bilateral dissection if the adenoma is not found in the area indicated by the scan (necessitating general anesthesia), and the potential for patient anxiety or discomfort or both requiring conversion to general anesthesia.

The ability to localize solitary parathyroid adenomas accurately using Tc 99m sestamibi has allowed numerous investigators to pursue intraoperative nuclear mapping to isolate and recover the enlarged parathyroid gland representing the adenoma. This procedure has been termed *radioguided parathyroidectomy,* using preoperative administration of Tc 99m sestamibi immediately before operation combined with intraoperative use of the hand-held gamma detection device (gamma probe).[269,304,305] In this technique, the patient is administered approximately 18 to 20 mCi of Tc 99m sestamibi approximately 2 hours before surgery. The timing of the preoperative injection may be modified by the visualized washout sequence shown by the solitary parathyroid gland on review of delayed images.

After appropriate positioning of the patient on the operating table, intravenous sedation is administered. The gamma probe is applied to the anterior surface of the neck to measure the radioactivity of the thyroid isthmus, which is used to determine the background radioactive count. The threshold of the gamma probe is set to filter out background radioactivity. Radioactive counts are measured in each quadrant of the neck, and a marking pen is used to mark the area of maximal radioactivity, the location of which should correspond to the location of the adenoma on the sestamibi scan. The size of the incision may be considerably smaller than that used for conventional four-gland bilateral parathyroid exploration. The area to be incised is anesthetized with a local anesthetic, and a small 2- to 3-cm incision is made directly over the area of maximal radioactivity. A gamma probe is used to guide the surgical dissection by repeatedly placing it into the operative field allowing a precise surgical dissection.

When the adenoma is found, it is carefully dissected close to its capsule; its pedicle is identified, clipped, and divided insuring first that the recurrent laryngeal nerve is not within the dissected field. Radioactivity of the removed parathyroid adenoma (ex vivo) and the operative basin is measured, the sum of which should roughly equal the radioactivity in the corresponding quadrant of the neck before making the incision. In most cases, frozen section analysis is unnecessary, but a permanent histopathologic assessment on the specimen is performed. As experience with this procedure has increased, the technique has been applied more selectively to exclude the following clinical situations: deep retroesophageal lesions, ectopic glands, superior adenomas in men, and persistent or recurrent hyperparathyroidism.[305]

Endoscopic Parathyroid Exploration

Parathyroid exploration performed in humans was first described by Gagner in 1996.[306] With the advent of improved technology and video-assisted endoscopic technology, several pioneering investigators have evaluated this technique in the management of hyperparathyroidism.[307-310] This procedure is generally done under general anesthesia on patients who have shown focal areas of nuclear uptake on delayed imaging using Tc 99m sestamibi scanning for parathyroid localization. The instrumentation allows for minimal access surgery through several very small incisions placed in the cervical region, the upper chest wall, or the axilla.[308-310] Miccoli and colleagues[310] reported a larger series of video-assisted parathyroidectomy with limited use of insufflation in 137 patients.

Potential advantages of the endoscopic approach to parathyroid removal include excellent cosmesis, negligible discomfort, and minimal problems with cervical motion. Investigators advocating this technique

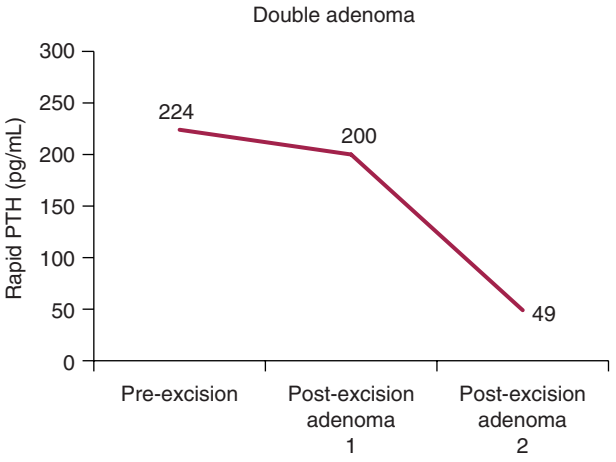

Figure 125-16. Sequential serum parathyroid hormone (PTH) levels assessed by intraoperative rapid PTH immunoassay after removal of the first and then second parathyroid adenoma in a patient with hyperparathyroidism and double adenomas.

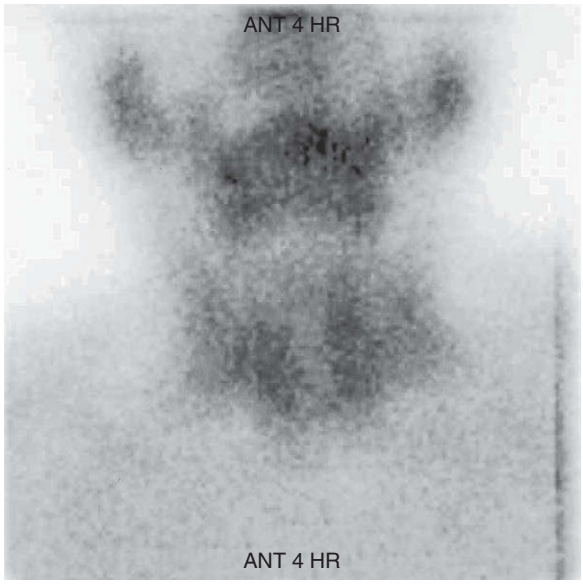

Figure 125-17. Delayed Tc 99m sestamibi nuclear scan performed on a patient with hyperparathyroidism secondary to diffuse four-gland hyperplasia. Note the absence of any focus of nuclear uptake on the image.

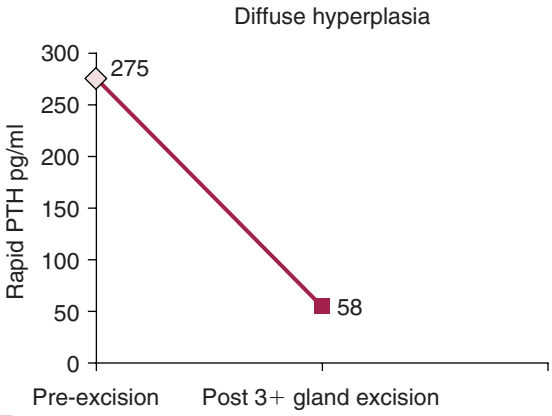

Figure 125-18. Sequential serum parathyroid hormone (PTH) levels as assessed by intraoperative rapid PTH immunoassay comparing hormone level obtained before and 10 minutes after a 3½-gland subtotal parathyroidectomy in a patient with diffuse 4-gland hyperplasia.

have indicated that the selection process in determining which patients are candidates for the procedure is a crucial aspect with regard to surgical success. Generally, the criteria for consideration of the procedure include initial explorations, single-gland disease, and the absence of significant thyroid enlargement or multinodularity. All patients must have a preoperative localization study performed with unequivocal focus of nuclear uptake on delayed imaging. In addition, all patients should have PTH levels assessed intraoperatively using the intraoperative PTH assay to confirm biochemically removal of the suspected hyperfunctional parathyroid gland. Although endoscopic cervical exploration for parathyroid disease represents the least invasive and most focused of the minimally invasive surgical techniques, the time required to perform this procedure may be extensive, and in some ways counterproductive to limiting anesthesia time and cost.[311] At this point, although this procedure shows promise, the role of endoscopic parathyroid exploration remains undefined.

Multiple-Gland Disease

True Double Adenoma

The incidence of double parathyroid adenomas seems to increase with age. Synchronous double adenomas have been variably reported at rates ranging from 1% to 2% to 10% in patients older than 60 years of age.[312,313] Approximately 50% of true double adenomas image accurately to each of the two locations (see Fig. 125-4). Bilateral exploration is required despite high suspicion on localization because of the possibility of asymmetric hyperplasia. Intraoperative PTH assay provides biochemical confirmation that all hyperfunctional parathyroid tissue has been removed: a sequential decrease in PTH levels is noted after successive excision of the first and then second enlarged gland (Fig. 125-16). At least one other normal gland should be identified, but surgical biopsy and histologic analysis of additional glands is unnecessary, provided that the final postexcision PTH level ultimately decreases beyond 50% of the pre-excision level intraoperatively to within a normal range.

Sporadic Hyperplasia

Multiglandular disease secondary to diffuse hyperplasia of the parathyroid glands may occur in 10% to 15% of patients with sporadic primary hyperparathyroidism. The approach to these patients includes performance of a nuclear imaging study using Tc 99m sestamibi preoperatively unless the patient is known to have a MEN syndrome.

A scan that does not indicate an unequivocal area of nuclear uptake on delayed images raises the surgeon's suspicion of diffuse hyperplasia. In a series performed by one of the authors (P.K.P.), 40% of equivocal scans were associated with the ultimate finding of multiglandular hyperplasia at exploration (Fig. 125-17). An equivocal scan showing the absence of a distinct focus of delayed uptake of nuclear material mandates the performance of a bilateral exploration with histologic identification of at least one abnormal and one normal gland, and the assurance that no additional grossly enlarged glands exist on either side. After removal of all enlarged glands (either single or multiple), and the demonstration of a histologically normal gland (in the event of less than four gland disease), rapid PTH assessment (Fig. 125-18) is performed to confirm the removal of all hyperfunctional parathyroid tissue, per the same protocol used in the directed exploration strategy. Failure to achieve this degree of PTH degradation mandates further exploration, for either an ectopically located gland or, uncommonly, a supernumerary gland.

When all hyperplastic glands have been located in situ, the three largest glands are removed and histologically confirmed. Subtotal excision of the remaining gland follows, leaving at least one third to one half of the gland as a viable vascularized remnant. Titration of PTH levels is helpful using rapid PTH assay. If the postexcision level

declines to less than 10 pg/mL, consideration should be given to cryopreservation of parathyroid tissue excised from the fourth gland. Although this is rarely necessary, this approach is favored over routine forearm autotransplantation of parathyroid tissue because additional surgery is avoided, and because a measurable PTH level detected intraoperatively is generally predictive of euparathyroid function and normocalcemia.[74,314]

Familial Hyperparathyroidism

Familial hyperparathyroidism accounts for less than 5% of all cases of hyperparathyroidism.[315] Familial hyperparathyroidism comprises a spectrum of autosomal dominant inherited diseases that include MEN-I, MEN-IIA, non-MEN, and familial neonatal hyperparathyroidism. In contrast to sporadic hyperparathyroidism, patients with familial hyperparathyroidism are younger and more likely to have multiglandular disease, and persistent or recurrent hyperparathyroidism after parathyroidectomy. Subtotal or total parathyroidectomy in combination with bilateral transcervical thymectomy is more frequently necessary for definitive treatment, rather than simple excision of an adenoma, which is all that is required for approximately 80% of patients with sporadic primary hyperparathyroidism. It is imperative that long-term follow-up of patients with familial hyperparathyroidism be performed for early detection and treatment of other endocrine neoplasms associated with these disorders, and for the diagnosis of recurrent hyperparathyroidism. In addition, screening of family members represents an important aspect of the overall management of familial hyperparathyroidism. As a result of the identification of causative genetic components in these disorders, genetic screening of family members to allow for a global treatment plan for members identified as gene carriers is now possible.

Multiple Endocrine Neoplasia Type I

MEN-I is an autosomal dominant inherited syndrome characterized by the presence of neoplastic lesions involving the parathyroid glands, the anterior pituitary, the pancreas, and the duodenum. Patients may also have carcinoid tumors of the bronchus or thymus; tumors of the ovaries, thyroid gland, or adrenal glands; or multiple lipomas. MEN-I is an uncommon disorder, with an incidence of 2 to 20/100,000.[316] Not all patients with MEN-I present with the complete syndrome indicating a variable degree of penetrance. Primary hyperparathyroidism is the most common manifestation of MEN-I, occurring in greater than 95% of patients, usually before age 30 and as the initial manifestation of the syndrome.[317-319] Pancreatic endocrine tumors are most often multiple and are distributed throughout the pancreas. Nonfunctioning tumors, gastroma, and insulinoma are the islet cell tumors that are most often associated with MEN-I. A pituitary tumor is diagnosed in 30% to 40% of patients and is most commonly a prolactinoma.

The syndrome of hyperparathyroidism may occur 10 years before the onset of other endocrine disorders, and MEN-I should be considered in any patient diagnosed with primary hyperparathyroidism at an early age or with multiglandular disease.[318] The hyperparathyroidism in MEN-I is due to diffuse four-gland parathyroid hyperplasia.[318-323]

Generally, the clinical manifestations of primary hyperparathyroidism in patients with MEN-I are similar to manifestations found in patients with sporadic primary hyperparathyroidism. Some of the symptoms in primary hyperparathyroidism associated with MEN-I may be masked by Zollinger-Ellison syndrome or insulinoma.[318] Alternatively, the symptoms associated with hyperparathyroidism may also aggravate the clinical manifestations of Zollinger-Ellison syndrome as a result of calcium stimulation of gastrin secretion.[318]

Biochemical findings (serum calcium and PTH levels) in MEN-I patients are similar to findings in patients with sporadic primary hyperparathyroidism, and the diagnosis is made by documenting hypercalcemia associated with an inappropriately elevated PTH level.[324] If a patient with hyperparathyroidism has a family history of the same disorder or other endocrinopathies, further screening for tumors of the pituitary gland and pancreas is warranted.[319] This screening should consist of serum prolactin levels, glucose, basal serum gastrin, and pancreatic polypeptide levels.

Werner[325] noted that 50% of the offspring of individuals with MEN-I inherited the disorder (without gender differentiation), and that this inheritance did not skip generations. This pattern of inheritance is characteristic of an autosomal dominant trait with a high degree of penetrance.[319,326]

The *MEN1* locus has been mapped to a section of chromosome 11[327]; this was further shown to involve a mutation at the 11q13 locus.[327] Subsequently, the *MEN1* gene has been identified as a tumor suppressor gene that encodes the protein menin.[328] Greater than 90% of MEN-I patients have germline menin gene mutations, and most MEN-I families have their own unique mutation.[329] The predisposition to MEN-I is a heterozygotic mutation.[324]

The finding of multiple abnormal parathyroid glands and, commonly, supernumerary glands in patients with MEN-I represents a formidable management dilemma in these patients. The inability to recognize a supernumerary gland at the time of initial exploration for this disorder is a well-documented cause of persistent disease.[318,330-332]

The surgical approach should consist of a routine bilateral neck exploration with identification of all four parathyroid glands. The extensiveness of surgical resection of the parathyroid glands, after they have been identified, is controversial with advocates of subtotal and total parathyroidectomy. Numerous authors have reported their experience with subtotal parathyroidectomy in patients with MEN-I and hyperparathyroidism with differing degrees of surgical success.[318,320,321,330] Edis and colleagues[331] reported that 82% of patients with chief cell hyperplasia had normal parathyroid function at least 1 year after subtotal parathyroidectomy. Of these, only 6 of 55 had hyperparathyroidism secondary to MEN-I syndrome, however. In 12 patients undergoing subtotal parathyroidectomy for hyperparathyroidism of MEN-I as reported by Prinz and colleagues,[330] only 5 ultimately achieved normocalcemia.

It has been postulated that the difference in success rates between hyperparathyroidism attributable to sporadic four-gland hyperplasia and hyperparathyroidism associated with MEN-I may be due to persistent exposure of a trophic factor. A potential parathyroid mitogenic humoral factor was identified by Brandi and coworkers[333] in 1986 from the serum of patients with familial MEN-I syndrome. The mitogenic activity of this humoral factor persisted in the patient's plasma for 4 years after total parathyroidectomy.[333] As a consequence, any parathyroid remnant remaining after subtotal parathyroidectomy would be exposed to this humeral factor, potentially increasing the chance of recurrence. This theory was supported by a finding by Prinz and colleagues,[330] who reported a patient with persistent hypoparathyroidism requiring calcium supplementation for 10 years after subtotal parathyroidectomy before development of recurrent disease. The re-exploration of this patient showed that remnant parathyroid hyperplasia was the etiology of recurrence.

Total parathyroidectomy with autotransplantation of fragmented parathyroid tissue has been advocated by other investigators as the procedure of choice for the initial operation for patients with primary parathyroid hyperplasia caused by MEN-I syndrome.[334,335] In this procedure, four glands are identified and removed with sectioning of the most morphologically normal-appearing gland into cubic centimeter fragments. These fragments are implanted into the brachioradialis muscle of the nondominant forearm. Sections from this gland may also be cryopreserved and successfully autotransplanted if the primary autograft does not function. Wells and associates[335] pioneered this approach, and reported that 30% of their patients developed recurrent, graft-dependent hyperparathyroidism. Autotransplantation of cryopreserved parathyroid autografts has been successful in only 50% of patients resulting in permanent hypoparathyroidism.[336]

The concept that a humoral factor may be initiating growth in the remnant parathyroid tissue is supported further by the finding of Mallete and colleagues,[322] who reported a higher incidence of graft-dependent recurrence in MEN-I patients treated with total parathyroidectomy with autotransplantation than in patients with sporadic hyperplasia undergoing the same operation. Independent of a humoral stimulating factor for parathyroid cell proliferation is the finding that MEN-I–associated hyperparathyroidism is associated with the finding of supernumerary parathyroid glands. This factor contributes to the

potential for missed glands at the time of initial operation, increasing the risk of recurrence. The implementation of intraoperative assay for PTH determination has been helpful in reconciling this problem in patients with hyperparathyroidism associated with MEN-I.[74]

Primary surgical explorations in patients with MEN-I and hyperparathyroidism may result in cure rates greater than 90%. The requisite for identifying all four parathyroid glands in these patients is emphasized in a report by O'Riordan and colleagues.[320] In this series, immediate cure was noted in 94% of patients; however, hypercalcemia was noted to be persistent in 19% of patients in whom fewer than four glands were visualized at initial operation compared with 3% of patients in whom four glands or more were noted at initial surgery. Generally, persistent and recurrent disease rates are higher in patients who have less than total parathyroidectomy performed and in whom fewer than four glands are found at the time of initial operation.[319,320]

Multiple Endocrine Neoplasia Type IIA

MEN-IIA is a syndrome characterized by medullary thyroid carcinoma, pheochromocytoma, hyperparathyroidism, lichen planus amyloidosis, and Hirschsprung's disease. In 1932, Eisenberg and Wallerstein[337] first reported a pheochromocytoma and concurrent thyroid carcinoma in a patient at autopsy. In 1961, Sipple[338] estimated that the incidence of thyroid cancer in patients with pheochromocytoma was 14 times higher than that of the normal population; Cushman[339] subsequently reported a family with hereditary thyroid carcinoma and pheochromocytoma in which one affected member had a parathyroid tumor. These reports resulted in the description and characterization of the syndrome, formerly known as Sipple's syndrome, now known as MEN-IIA.[340]

The penetrance of the independent entities for patients with MEN-IIA syndrome is variable, with the exception of medullary thyroid carcinoma, which is seen in essentially all affected individuals. Pheochromocytoma and hyperparathyroidism show variable penetrance with pheochromocytoma occurring in 70% of individuals affected, and hyperparathyroidism reported least commonly in approximately 20% to 35% of affected patients.[341-345]

Hyperparathyroidism is usually diagnosed as a result of screening patients or family members with MEN-IIA, or incidentally during thyroidectomy for C cell hyperplasia or medullary thyroid carcinoma.[346] In a review of 67 patients with hyperparathyroidism associated with MEN-IIA syndrome, Raue and coworkers[345] noted that 75% were diagnosed at the time of thyroidectomy for either C cell hyperplasia or medullary thyroid carcinoma. These patients had normal serum calcium and PTH levels preoperatively, and the diagnosis was based on intraoperative morphology or histology. Uncommonly, a diagnosis of hyperparathyroidism is made because of the development of clinical symptoms that are similar to those encountered in sporadic primary hyperparathyroidism.[344]

MEN-IIA–associated hyperparathyroidism usually develops after the third decade of life in the form of mild hypercalcemia with rare hypercalcemic crises.[343,345] It is generally acknowledged that the hyperparathyroidism associated with MEN-IIA is less aggressive than its counterpart noted for MEN-I or non-MEN syndromes.[320,344] Patients with MEN-IIA generally have lower serum calcium levels, fewer symptoms or complications of hypercalcemia, less frequent multiple-gland involvement, and a lower incidence of persistent or recurrent disease after surgical treatment than patients with MEN-I or non-MEN hyperparathyroidism. A circulating humeral factor that stimulates parathyroid cell proliferation has not been postulated to exist in association with the hyperparathyroidism associated with MEN-IIA.

Similar to MEN-I, MEN-IIA is a genetic disease that is transmitted in an autosomal dominant fashion with a high degree of penetrance but with variable expression. In the late 1980s, the inherited defect of the MEN-II syndrome was mapped to the pericentromeric region of chromosome 10.[347,348] Subsequent work identified the ret proto-oncogene as a segment on chromosome 10 that encodes for a specific cell surface receptor complex, the exact function of which is poorly characterized. Mutations in the segment of the ret proto-oncogene coding for the extracellular domain of the tyrosine kinase receptor protein are responsible for producing the MEN-IIA phenotype.[349] Although the mutation has been well characterized for its association with medullary thyroid carcinoma, the exact relationship to parathyroid disease is unknown.

If parathyroid exploration for hyperparathyroidism associated with MEN-IIA syndrome is required, the presence of a pheochromocytoma must be excluded in patients before surgery. Surgery on a patient with an unrecognized pheochromocytoma may result in a hypertensive crisis intraoperatively with potential catastrophic sequelae. These patients should be screened for the presence of a catecholamine-producing neoplasm of the adrenal, and a plasma collection for catecholamines, metanephrine, and nonmetanephrine levels should be performed before parathyroid exploration. When this is ensured, the surgical approach in these patients is generally more conservative than in patients with MEN-I–associated hyperparathyroidism.

A bilateral neck exploration is performed with identification of all four parathyroid glands. Although the hyperparathyroidism associated with MEN-IIA–affected patients shows a higher incidence of multiglandular disease than in patients with sporadic primary hyperparathyroidism, it is not as high as found in patients with MEN-I syndrome. Subtotal parathyroidectomy with removal of only the obviously morphologically enlarged parathyroid glands is the approach of choice in patients with MEN-II–associated hyperparathyroidism. Transcervical thymectomy is generally unnecessary because supernumerary gland involvement is uncommon in these patients. If all four glands are involved, transcervical thymectomy may be performed concurrent with subtotal parathyroidectomy. In surgery for medullary thyroid carcinoma, normal parathyroid glands in the superior position are generally preserved with resection of the inferior parathyroid and subsequent autotransplantation so that lymph nodes in the central neck compartment and the anterior mediastinum are not missed.

Surgical exploration for patients with MEN-IIA–associated hyperparathyroidism is generally quite effective. Cance and Wells[341] reported a 100% surgical success rate and 3% recurrence rate treating patients with primary hyperparathyroidism associated with MEN-IIA. In contrast to MEN-I, in which the extensiveness of parathyroid gland resection is important in defining operative success, the degree of parathyroid gland resection does not seem to influence the success rate significantly in patients operated for hyperparathyroidism associated with MEN-IIA. O'Riordan and colleagues[320] reported a 100% cure rate with no recurrences whether total parathyroidectomy, subtotal parathyroidectomy, or excision of enlarged glands independently was performed.

Non–Multiple Endocrine Neoplasia Familial Hyperparathyroidism

Non-MEN familial hyperparathyroidism, also known as familial isolated hyperparathyroidism, refers to hyperparathyroidism occurring in the absence of other endocrinopathies in patients with at least one first-degree relative with surgically proven hyperparathyroidism and no personal or family history of MEN. Familial hyperparathyroidism occurs in young patients with a mean age at diagnosis of approximately 36 years. Some of these patients experience this disorder as children, although it is rare before age 10 years.[350] In contradistinction, patients with sporadic primary hyperparathyroidism typically present during the fifth or sixth decades of life.[315] Familial hyperparathyroidism seems to be more aggressive than sporadic or MEN-related hyperparathyroidism; frequently, patients with this disorder manifest profound hypercalcemia and more frequently present with hypercalcemic crisis.[350,351] Renal lithiasis occurs in one third to one half of patients reported with familial hyperparathyroidism; patients commonly also present with other nonspecific signs and symptoms, such as fatigue, weakness, hypertension, and peptic ulcer disease.[350] It has been postulated that familial hyperparathyroidism may be associated with an increased risk for the development of parathyroid cancer.[350,352,353]

A high incidence of persistent or recurrent disease after treatment seems to be a characteristic feature of the clinical profile of non-MEN–related familial hyperparathyroidism. Of the 97 patients reported in the literature, persistent or recurrent disease has been noted to occur at a rate of 33%. This degree of recalcitrant disease contrasts markedly with the very low rate of recurrent disease after treatment in patients with sporadic hyperparathyroidism undergoing parathyroidectomy.

This characteristic bears strong consideration in planning the appropriate operative strategy in patients with non-MEN–related familial hyperparathyroidism.

Before initiating treatment for this disorder, it is important to exclude all other familial sources for hyperparathyroidism, and the entity known as benign familial hypercalciuric hypercalcemia. When these other entities have been excluded, patients with non-MEN–related familial hyperparathyroidism should be considered for parathyroid exploration because of the aggressive biologic behavior of this disorder. There is a high incidence of multiglandular and supernumerary gland disease accounting for the high rate of recalcitrance after initial surgery. Similar to the other familial hyperparathyroidism disorders, a bilateral neck exploration with identification of all four parathyroid glands is performed.

Either subtotal or total parathyroidectomy together with bilateral cervical thymectomy is generally performed with autotransplantation of parathyroid tissue as necessary depending on the extent of parathyroid gland resection. If only one or two parathyroid glands are morphologically abnormal and enlarged, the goal of therapy is to resect all abnormal parathyroid tissue from one side of the neck, and leave existing remnant parathyroid tissue in only one side.[350] Intraoperative PTH determination is helpful in determining the degree of hyperfunctional parathyroid tissue remaining after subtotal parathyroidectomy in these patients, and may serve as an indicator of remnant parathyroid function after abnormally enlarged glands have been removed. The visualization and subsequent removal of abnormally enlarged glands and the intraoperative PTH findings guide the extensiveness of surgery in patients who manifest this disorder and have fewer than four glands appearing abnormal. It is important that these patients be followed long-term to recognize if and when recalcitrant disease occurs.

Familial Neonatal Hyperparathyroidism

Neonatal hyperparathyroidism is a rare condition characterized by severe hypercalcemia occurring in association with severe hypotonia, poor feeding, constipation, failure to thrive, and respiratory distress. The clinical manifestations of this disorder become evident during the first week of life; however, the disorder may not become manifest until age 3 months or older.[350] Most patients with familial neonatal hyperparathyroidism have been part of families with a known history of benign familial hypercalciuric hypercalcemia. The disease locus for familial hypercalciuric hypercalcemia has been identified on the long arm of chromosome 3, and patients with familial hypercalciuric hypercalcemia are heterozygous for the mutation, with one affected allele.[354,355] The occurrence of two defective alleles is believed to cause severe neonatal hyperparathyroidism.[356] Most patients with this disorder require urgent parathyroid exploration and resection of all four glands. Total parathyroidectomy is advocated together with parathyroid autotransplantation, bilateral transcervical thymectomy, and cryopreservation of parathyroid tissue because of the high recalcitrance rate for this disorder.

Renal Failure–Induced Hyperparathyroidism

The indications for parathyroid exploration in patients with renal failure–induced hyperparathyroidism may be characterized as those manifested before and after renal transplantation. Surgery is generally indicated when medical therapy fails to control progressive secondary hyperparathyroidism.[357-359] The clinical manifestations occurring in this disorder include persistent or worsening skeletal symptoms, intractable pruritus, and soft tissue calcifications.[360] Additional indications for a parathyroidectomy include the presence of biopsy-proven, high-turnover bone disease, calciphylaxis, or both in a patient with chronic renal failure and secondary hyperparathyroidism.[361-363] Parathyroidectomy may be indicated in some patients after successful renal transplantation because of the development of clinical manifestations similar to the manifestations of primary hyperparathyroidism, including hypercalcemia with nephrolithiasis, pancreatitis, central nervous system manifestations, and overt bone demineralization.[364] The presence of mild hypercalcemia in and of itself does not seem to be a serious threat to a patient after renal transplantation, but impaired kidney function in the presence of high PTH levels and hypercalcemia represents an indication for parathyroidectomy, as is the association of kidney stones and long-standing hypercalcemia.[365-368]

Generally, preoperative localization studies are not recommended before initial exploration for renal failure–induced hyperparathyroidism. This is principally due to the need to perform bilateral exploration with visualization of all four parathyroid glands, and the finding that nuclear imaging with Tc 99m sestamibi is not as effective for localization as it is for single-gland disease. In contrast to the directed exploration protocols for minimally invasive operations performed for solitary adenoma, the operation of choice for patients with renal failure–induced hyperparathyroidism at initial surgery is traditional four-gland bilateral exploration. The surgical principal of "not removing anything before seeing everything" is aptly applied to this situation.

The two most widely used initial surgical procedures for the management of renal failure–induced hyperparathyroidism are subtotal parathyroidectomy and total parathyroidectomy with parathyroid autotransplantation with or without cryopreservation of parathyroid tissue. If subtotal parathyroidectomy is the procedure of choice, the smallest, most normal-appearing parathyroid gland is selected to represent the remnant gland left in situ. The pole opposite the vascular pedicle is excised leaving approximately one third to one half of the entire gland as a vascularized remnant. All parathyroid glands need to be in situ when this excision is accomplished so that if the remnant proves to be nonviable after its sectioning, the next most normal-appearing gland is selected for the remnant, and the initial remnant is completely removed. It is generally easier to leave a superior remnant with a viable pedicle than an inferior remnant because of the proximity of the vascular pedicle to the normal position of the gland. The remnant is marked with a nonresorbable suture or metal surgical clip.

If only three parathyroid glands are found after a comprehensive exploration, all three are removed. This circumstance has been noted to result in approximately 30% of patients with persistent hyperparathyroidism.[369] If total parathyroidectomy and autotransplantation with or without cryopreservation is planned, all four glands are removed after discovery with the most normal-appearing gland selected as the autograft.[370] Because hemorrhage into the implant beds may result in poor "take" of the grafts, 10 to 15 cubic millimeter fragments of the selected autotransplant gland are placed into intramuscular pockets in the brachioradialis muscle of the nondominant forearm in a hemostatic fashion.[335] Cryopreservation of the remaining portion of this autotransplant gland should be performed if sufficient parathyroid function does not develop after revascularization of the implants.

Numerous reports supporting one procedure versus the other are noted in the literature, but objective controlled trials dealing specifically with renal failure–induced hyperparathyroidism are rare. Of the few trials conducted, the only prospective randomized series was reported by Rothmund and colleagues,[371] who found that parathyroidectomy with autotransplantation was superior to subtotal thyroidectomy in controlling symptoms in a group of 40 patients with renal failure–induced hyperparathyroidism. In this series where follow-up was noted over a mean of 4 years, four patients who were randomly assigned to the subtotal parathyroidectomy cohort experienced recurrent disease. The elimination of bone pain was significantly improved proportionally in patients who underwent total parathyroidectomy with autotransplantation. Three independent reports compared both techniques in a retrospective analysis and found that both procedures resulted in similar outcomes.[372-374] In assessing the merit of each technique, one should keep in mind that most surgeons find the procedure they routinely use and have more experience with to be the most applicable and appropriate in dealing with patients with this disorder.

The success of subtotal parathyroidectomy depends mainly on the size and viability of the remnant parathyroid gland left in situ. Remnants that are nodular are more likely to grow and result in recurrent hyperparathyroidism. This procedure has a theoretical advantage of producing less postoperative hypocalcemia because the remnant continues to function. The main disadvantage is that if these remnants become hyperfunctional, the reoperations often are tedious, are difficult technically, and carry increased risk of complications such as injury to the recurrent laryngeal nerve. Generally, successful subtotal parathyroidectomy alleviates bone pain to a lesser degree than total parathy-

roidectomies with autotransplantation, but carries less risk of postoperative low-turnover bone disease.[375]

The success of total parathyroidectomy with autotransplantation depends mainly on the nodularity of the gland from which the graft is obtained, and number and weight of the fragments that are implanted. As in recurrent disease within a nodular remnant after subtotal parathyroidectomy, graft-dependent recurrence is three times higher when implanting a nodular gland instead of a diffusely hyperplastic one.[376] The advantage of autotransplantation is that if hyperparathyroidism recurs in the graft remnant, this may be partially resected under local anesthesia with minimal potential complications. Several studies show a 5% to 38% rate of postoperative hypercalcemia attributable to a hyperfunctional graft with a 2% to 6% chance of recurrence requiring graft resection, and a 5% to 30% chance of hypocalcemia lasting more than 12 months secondary to poor graft viability and function.[377-385]

Re-exploration for Recalcitrant Hyperparathyroidism

The distinction between *persistent* (hypercalcemia persisting or recurring within 6 months after initial operation) and *recurrent* (hypercalcemia recurring after 6 months of normocalcemia following the initial surgery) hyperparathyroidism after a prior cervical or mediastinal exploration for hypercalcemia has been applied loosely, but poses an equitable management dilemma and technical challenge to the surgeon. It has been estimated that 2% to 10% of surgical failures may be attributed to an incorrect diagnosis.[386,387] The first requirement for success in reoperative parathyroid surgery is proper diagnosis. By definition, hyperparathyroidism (primary or secondary) must be proven by elevation of serum calcium levels associated with high or inappropriately elevated PTH levels. Elevated serum chloride and decreased serum phosphate levels are frequently noted. In addition, urinary calcium should be appropriately elevated to exclude a diagnosis of familial hypocalciuric hypercalcemia. If all these parameters are not present, other causes of hypercalcemia must be considered because a repeat surgical procedure is almost guaranteed to be unsuccessful.[388] The diagnosis of hyperparathyroidism is currently more straightforward with immunoradiometric and immunochemiluminescent assays of PTH levels. Diagnostic errors in hyperparathyroidism can result from medications (calcium, vitamin D, furosemide, thiazide diuretics, calcitonin, lithium), familial hypocalciuric hypercalcemia, malignancy (bone metastasis or humoral hypercalcemia), granulomatous disease, acute renal failure, bone disease (Paget's disease, immobilization), hyperthyroidism, or adrenal insufficiency.

The indications for surgical intervention in secondary cases must be solid because the morbidity and technical difficulty are increased. Generally, the guidelines for surgery in primary hyperparathyroidism, as outlined in the National Institutes of Health 2002 Consensus Conference, serve as a framework for surgical decision making in patients requiring further treatment after initial failed exploration.

Causes of Failed Exploration

The most common finding on parathyroid re-exploration by an experienced parathyroid surgeon is a missed single adenoma. Akerstrom and colleagues[389] reported on 84 parathyroid re-explorations in 69 patients with primary hyperparathyroidism. Of these patients, 37 had missed adenomas; 4 of these patients had double "adenomas" with only one adenoma being resected on the initial exploration. Most of the remaining patients had persistent hyperparathyroidism secondary to inadequate resection of parathyroid hyperplasia, with only four patients showing recurrent "single" adenomas. Rotstein and colleagues[390] analyzed their series of 28 reoperations for primary hyperparathyroidism. They identified solitary adenomas in 24 patients, with 2 patients each having hyperplasia and carcinoma. Norman and Denham[391] have used the technique of minimally invasive radiation-guided parathyroidectomy for reoperative disease and resected 23 solitary adenomas from 24 patients. Jaskowiak and associates[392] reviewed their experience at the National Institutes of Health with 288 patients with persistent or recurrent hyperparathyroidism. Of these patients, 222 (77%) were ultimately shown to have solitary adenomas.

In patients with secondary hyperparathyroidism, hyperplasia is the expected histopathology. Cattan and colleagues[393] explored 89 patients for persistent or recurrent secondary hyperparathyroidism; 53 of these patients had undergone subtotal parathyroidectomy, whereas 36 had prior total parathyroidectomy with autotransplantation. They identified hypertrophy of the remnant as the principal cause of recurrence in the subtotal group. In the group receiving total parathyroidectomy, recurrence was located in the autotransplant in half; hyperplastic disease was identified in the neck or mediastinum in the other half.

Equally as important is the finding that the cause of recalcitrant hyperparathyroidism is a solitary adenoma in most patients, through the observation that in most of these cases the adenoma is in a "standard" location. In the report by Akerstrom and colleagues,[389] only eight patients required sternotomy for ectopic adenomas identified in the mediastinum, despite 17 sternotomies being performed. In 5 of the 17 patients who had sternotomy, the offending lesion was ultimately identified in a normal location in the neck. Of the more unusual ectopic locations, one was ventral to the left atrium, one was ventral to the aortic root, and one was in the aortopulmonary window. Only one gland was truly intrathyroid, despite 19 thyroid lobectomies performed as part of the re-exploration.

In the series by Norman and Denham,[391] only one gland was in the mediastinum (just anterior to the right atrium), whereas two were intrathyroid. Jaskowiak and associates[392] identified adenomas in the posterior superior mediastinum, specifically in the tracheoesophageal groove in 27% of their patients (59 of 215). This was the most common location of the adenoma in the failed first exploration. This site is easily explored transcervically, and should be considered as an inferior extension of the normal superior gland position. The authors point out that these adenomas were almost always in direct apposition to the recurrent laryngeal nerve, perhaps suggesting that inadequate dissection around the nerve initially contributed to the failure. Another 24.3% of patients had their adenomas in the normal positions adjacent to the thyroid gland.[394]

In the National Institutes of Health series, the most common ectopic site was within the thymus or mediastinum, accounting for 16.7%.[394] This value is lower than other reports of 22% intrathymic tumors at the initial operation and 38% for reoperation.[393] An intrathyroidal lesion was noted in 10% (22 patients) of their study population. A similar percentage of patients had undescended parathyroid glands. These so-called parathymus lesions are located at the bifurcation of the carotid artery, high in the neck, and represent an inferior gland that is arrested in the descent from the third branchial pouch. Other "typical" ectopic locations included lesions within the carotid sheath and the retroesophageal space. Unusual ectopic locations include the aortopulmonary window in two patients, the hypopharynx at the base of the tongue in one patient, the wall of the nasopharynx near the nasal septum in one patient, and within the vagus nerve high in the neck at the level of C1-C2 vertebrae. Three patients had lesions "seeded" within the strap muscles, most likely because of the first exploration.[394]

Preoperative Assessment

Because a missed single adenoma located in a "standard" position accounts for most patients who fail initial procedures, accessing the records from the original exploration, including the operative note and the pathology report, is essential. Notes from the original operation may describe in detail the thoroughness of the exploration—which parathyroid glands remain in situ, whether the recurrent laryngeal nerve was identified and thoroughly skeletonized, and whether any "atypical" but regional areas were explored. Pathology reports should document what histologic items were identified (i.e., whether all normal parathyroid glands were biopsy proven). Ideally, all four glands should be identified before calling an initial exploration negative.

No matter what the original surgical and pathologic reports state, endocrine surgeons universally agree that preoperative imaging studies are an essential component of reoperative parathyroid surgery. Various invasive and noninvasive techniques are available to image or localize abnormal parathyroid glands, and these have been discussed previously.

Operative Risk in Re-exploration

When a decision has been made to pursue re-exploration for persistent or recurrent hyperparathyroidism, the patient and surgeon must review

and mutually understand the inherent risks of such surgery. The risk of injury to the recurrent laryngeal nerve, a potentially very problematic complication, is greater in re-explored necks than the risk for initial exploration. In two large studies, the incidence of vocal paralysis exceeded 6% after parathyroid re-exploration, in sharp contrast to the exceedingly low rate (<1%) after initial bilateral exploration.[395] Although more limited approaches to parathyroid re-exploration (e.g., targeted exploration, minimally invasive radiation-guided surgery) are likely to result in a reduced incidence of nerve injury after reoperation, surgical treatment of the operated neck will always be associated with increased risk. In addition to an incidence of recurrent nerve injury, re-exploration carries with it a greater likelihood for postoperative temporary and permanent hypocalcemia.[396] Finally, although the success rate for reoperative parathyroid surgery may exceed 90% in experienced hands, this remains substantially less than the near-perfect success rate for initial surgery. In addition to reconfirmation of the diagnosis and careful patient preparation, it is important that the risks associated with reoperation be discussed candidly with the patient.

Operative Strategy

After the decision to proceed with re-exploration has been made, and a review of the initial operative procedure and localization studies have been performed, the surgeon considers the operative approach. Ideally, the objective is to remove a single gland without extensive dissection, which may result in injury to the surrounding structures (i.e., recurrent laryngeal nerve or devascularization of remaining parathyroid tissue). The likelihood of accomplishing this objective depends on two factors: the experience of the initial operating surgeon and the demonstration of an enlarged parathyroid gland on correlative localization studies. In most cases, reoperation after initial surgery by an experienced surgeon is difficult and tedious because the initial dissection will have been comprehensive, and the surgical bed will have significant fibrosis. In contradistinction, the extensiveness of initial exploration and resulting degree of fibrosis may be significantly less in patients having had the original surgery performed by a relatively inexperienced surgeon. In both of these circumstances, the localizing studies are of prime importance in targeting the putative hyperfunctional gland and limiting the reoperative dissection.

The best of all scenarios, and the most common, is unequivocal localization to a cervical site, which may also include the anterior superior mediastinum. The previous neck incision is generally used for access, in some cases by excising the old scar completely. The usual superior and inferior flaps are raised, and access is gained to the side of the neck indicated by the localization studies. A lateral to medial approach to dissection is undertaken to avoid the dense scarification and fibrosis in the region of the tracheoesophageal groove where the recurrent laryngeal nerve resides. In this manner, dissection proceeds medially from the sternomastoid muscle superficial to the great vessels and then directly to the region overlying the cervical spine.

This approach exploits the concept of the visceroverterbral angle as described by Tenta and Keyes.[397] This potential anatomic space is defined as the area bordered laterally by the carotid sheath structures, medially by the trachea and esophagus, anteriorly by the thyroid, and posteriorly by the cervical spine (Fig. 125-19). In accessing this region, the surgeon may take advantage of a tissue plane with relatively little vascularity and fibrosis. This area allows the surgeon to examine the superior mediastinum inferiorly, the retroesophageal compartment medially, and as far superiorly as the hyoid bone, all within planes of dissection that separate with relative freedom. Although unnecessary in most cases, the recurrent laryngeal nerve may be identified and isolated for protection by following this approach because dense fibrosis is infrequently encountered over the prevertebral space, even after a thorough initial exploration.

If a gland is suspected in the superior retrothyroidal area, the nerve should be identified because it may be lateral to a medially displaced superior gland. Most missed adenomas, which are accessible through a cervical incision, may be approached using this technique, which also allows for thyroid lobectomy if an intrathyroidal gland is suspected. A situation whereby localization studies indicate a mediastinal location usually mandates a thoracic approach, either by median sternotomy or by lateral thoracotomy, depending on the involved area within the mediastinum. An enlarged gland identified within the anterior mediastinum is usually associated with the thymus and may be accessed by median sternotomy. These glands are usually found at the level of the innominate vein within thymic tissue, but may also be found adjacent to the aortic arch or between the thymus and pleura.

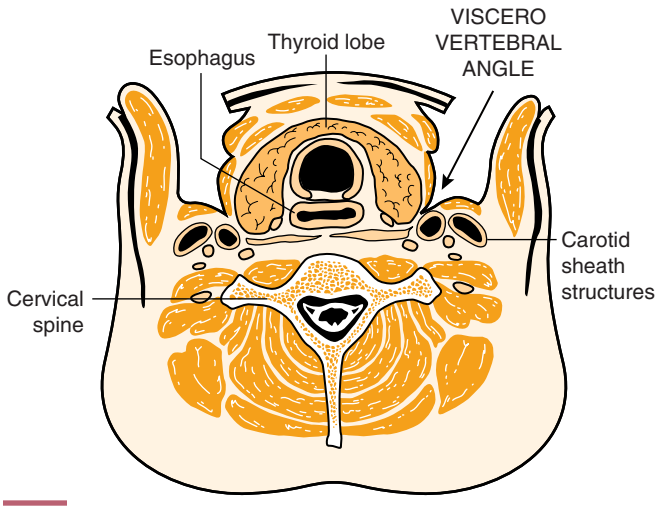

Figure 125-19. Viscerovertebral angle approach relative to parathyroid exploration.

If the localizing studies show a posterior-based mediastinal gland, a lateral or posterolateral thoracotomy should be strongly considered to avoid attempts at dissection through critical structures in the anterior mediastinum. These posterior glands may reside in the aortopulmonary window or the retroesophageal region. The recurrent laryngeal nerve may be injured when approaching the posterior mediastinum through a left lateral thoracotomy. Despite what may be interpreted as compelling localization results, the surgeon should be prepared to perform concurrent cervical exploration if initial intraoperative PTH levels do not confirm removal of all hyperfunctional parathyroid tissue.

The most problematic preoperative scenario to confront is that in which localization fails to identify any suspicious site. In this situation, reoperative surgery for hyperparathyroidism is potentially the least successful and the most morbid. Failure to localize usually mandates a bilateral cervical exploration that comprehensively and methodically addresses all potential sites that may harbor a missing gland or glands. A properly constructed initial operative note that accurately documents remaining histologically identified parathyroid glands and regions explored is crucial and of potential value for the reoperating surgeon. An orderly systematic approach to re-exploration is required in these circumstances to locate the missing gland or glands and limit morbidity.

The order in which regions are approached may vary according to the surgeon; however, it is important that all potential areas be accessed to increase the chance of success and avoid a failed re-exploration. The preferred approach is to explore each side through the visceroverterbral angle via a lateral-to-medial orientation. Regions of dissection are addressed in the following manner: The anterior superior mediastinum is dissected first, with careful attention to the thyrothymic ligament and tracheoesophageal groove region adjacent to the recurrent nerve (Fig. 125-20). Cervical thymectomy, if not performed during initial surgery, is completed at this time (Fig. 125-21). Dissection then turns to the retropharyngeal, retroesophageal region where blunt dissection within the prevertebral space allows for digital exploration superiorly above the cricoid larynx and inferiorly into the posterior mediastinum. Enlarged glands in this anatomic plane may often be felt before they are seen using these techniques. Next, the thyroid lobe is mobilized, possibly truncating the superior vascular pedicle to rotate the gland anteromedially so that the posterior thyroid capsule may be closely examined for a folded, lobulated parathyroid gland under the capsular fascia (Fig. 125-22). Using this maneuver, the thyroid lobe is

Figure 125-20. A gloved finger inserted beneath the pretracheal fascia overlying the cervical spine shows the "pseudo" ectopic location of a descended superior parathyroid adenoma in the tracheoesophageal groove.

palpated for any nodular densities that may be suspicious for an intrathyroidal parathyroid gland. The carotid sheath is opened from the superior mediastinum to the hyoid bone, inspecting and palpating for nodular structures within the sheath (Fig. 125-23).

Failing identification on the side explored first, the dissection proceeds contralaterally in the same manner with orderly inspection of all of the above-noted regions. If a bilateral exploration fails to identify the offending gland, thyroid lobectomy or lobotomy is usually performed on the side suspected to harbor the missing gland. During these maneuvers, it is important to document carefully all normal parathyroid tissue found, or if glands are not identified, the putative missing parathyroid gland by position.

If all maneuvers previously described are unsuccessful in identifying the missing gland, the procedure is terminated, and further measures are undertaken to identify the gland's position by imaging and possibly angioinvasive studies. Mediastinal exploration should not be performed in this setting, predominantly because of the lack of localization and element of time involved with the unsuccessful bilateral cervical exploration just completed.

Special Circumstances

Parathyroid Hormone Level Considerations

The utility of intraoperative PTH is only as valuable as the appropriateness of its application. As patients with primary hyperparathyroidism

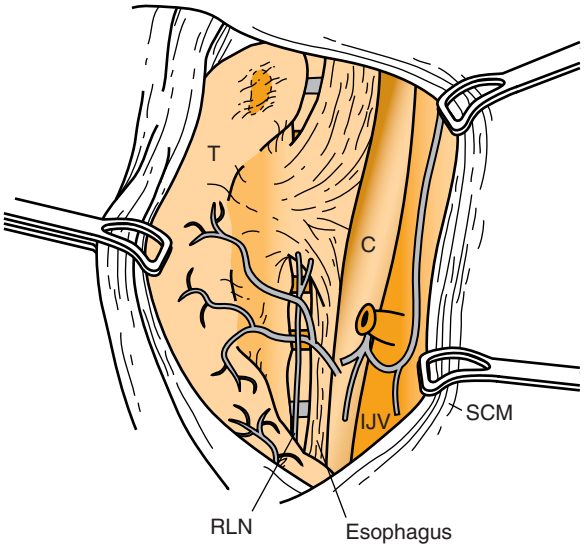

Figure 125-22. Superior parathyroid adenoma located under the pretracheal fascia over the posterior aspect of the thyroid gland, a "pseudo" subcapsular parathyroid gland. C, carotid sheath; IJV, internal jugular vein; RLN, recurrent laryngeal nerve; SCM, sternomastoid muscle; T, thyroid gland.

are diagnosed and evaluated for surgery earlier in the course of their disease, the potential exists for variations in the baseline levels of PTH to influence PTH degradation profiles and the accuracy of the test.

The interpretation of intraoperative PTH levels may be confounded by unrecognized PTH "spikes," whereby pre-excision values may variably exceed baseline or preincision levels. These acute differences in PTH levels have been postulated to occur from various etiologies, including technical problems with the assay performance, acute changes in renal status, pharmacologic influences, and pre-excision gland manipulation. In most instances, when technical assay problems are excluded, manipulation of the hyperfunctional gland before resection would seem to present the most plausible explanation for these "spikes." Riss and colleagues[398] noted that a substantial delay in PTH degradation beyond 10 minutes post resection in patients shows PTH

"spikes" thought to be due to gland manipulation before excision. This study and the authors' own experience acknowledge the importance of recognizing PTH "spikes" and reacting to them by delaying postexcision PTH measurements 20 to 25 minutes. A subthreshold decline (<50%) beyond this interval should prompt further exploration. PTH "spikes" may best be recognized by comparing the pre-excision value with the baseline obtained before surgery, provided that the same laboratory was used for both determinations.

A finding that may result in considerable frustration and anxiety is an elevated PTH level in a normocalcemic patient after curative parathyroid surgery. Approximately 20% (and perhaps more) of patients achieving normocalcemia after parathyroid surgery, during which intraoperative PTH determination predicted curative resection, have persistently elevated PTH levels postoperatively. This phenomenon has been postulated to occur as a result of the development of secondary hyperparathyroidism in response to a rapidly changing serum calcium level, variably explained by vitamin D deficiency, changes in renal function, or peripheral resistance to PTH.[399,400] In a setting of normocalcemia after curative parathyroid surgery, PTH levels obtained postoperatively do not seem to improve on the predictive value of intraoperative PTH levels. Further elevations in PTH levels in these patients postoperatively do not indicate operative failure in most patients in whom intraoperative PTH levels predicted curative resection.[399]

A growing body of evidence suggests that a disparity exists in the predictive value of intraoperative PTH between patients with low and high baseline levels of PTH determined before treatment. This evidence indicates that patients with lower baseline levels of PTH may not experience a predictable decline in hormone levels after what is thought to be curative surgery, suggesting that this cohort of patients may be at risk for unrecognized multiple-gland disease.

The concept that time-indexed PTH decay curve kinetics held potential for discriminating between single-gland and multiple-gland disease, and that this may be influenced by baseline PTH levels, was investigated by Miller and associates.[401] Two groups of patients were investigated: patients noted to have indexed PTH levels greater than (high baseline) and less than (low baseline) 100 pg/mL. Using PTH decay curve slope analysis and two time points for each group individually and combined, data were generated and correlated with pathologic findings (i.e., single-gland versus multiple-gland disease), and then compared with the standard (50% rule) arithmetic results. This study yielded two important findings with reference to the patients with low baseline (<100 pg/mL) hormone levels: (1) 50% degradation was less valid in confirming single-gland disease, and (2) multiple-gland disease was more prevalent in low baseline patients.

One of the authors (P.K.P.) has examined a series of 304 patients surgically treated for primary hyperparathyroidism and categorized them into a high baseline (>100 pg/mL) and low baseline (<100 pg/mL) PTH group based on levels obtained before initiating treatment. Twenty percent of the low baseline group ($n = 146$) was noted to have multiple-gland disease compared with 8% of the high baseline ($n = 158$) group. A significant (>50%) decline in PTH was not realized in 15% of the low baseline group, whereas only 6% of the high baseline group experienced a suboptimal decline. More importantly, optimal decline in the intraoperative PTH level did not consistently signal solitary gland disease in the low baseline group, in which 21 patients were noted to have multiple-gland disease despite intraoperative PTH degradation greater than 50%. It would seem from these investigations that the variability in baseline levels of PTH can influence the predictive value of intraoperative hormone determination. Patients with low baseline levels of PTH seem to be at greater risk for harboring multiple-gland disease, and do not consistently show intraoperative PTH degradation kinetics that are predictive of surgical care.

Unsuccessful Localization

In most situations, failure to localize to a discrete area of the neck after sestamibi imaging occurs as a result of unrecognized multinodular thyroid disease (Fig. 125-24). In the absence of a nodular thyroid gland, one must suspect diffuse hyperplasia or, less likely, an ectopically located cervical or mediastinal gland. One must be careful that an appropriately dosed (minimum 23 to 26 mCi) and correctly conducted nuclear scan has been carried out in all studies. SPECT Tc 99m sestamibi imaging may be helpful in reconciling equivocal planar images.[402,403] A failure to localize on delayed nuclear imaging mandates the performance of a standard bilateral exploration.

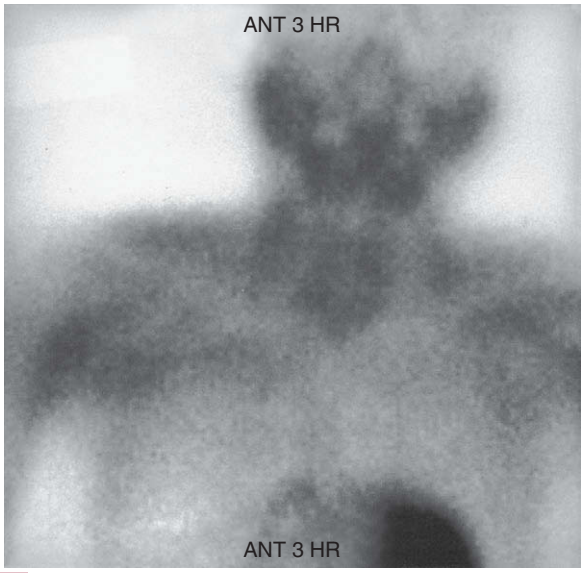

Figure 125-24. Tc 99m sestamibi nuclear scan in a patient with hyperparathyroidism and nodular thyroid disease.

A false-positive sestamibi scan (i.e., discrete areas of delayed nuclear uptake representing false-positive localizations shown at surgery) may occur. Almost without exception, this false-positive scan occurs as a result of unsuspected nodular thyroid disease. In a series examined by one of the authors (P.K.P.), nodular thyroid abnormalities accounting for false-positive scans were exclusively solid in consistency. In contrast, none of the cystic lesions concurrently noted during exploration for hyperparathyroidism were associated with a false-positive localization study.

This finding suggests the importance of performing high-resolution ultrasound evaluation in patients with nodular thyroid disease because the finding of a cystic nodule would decrease suspicion that the localization result is a false-positive result. Even in the presence of solid nodular thyroid disease, subcapsular and intrathyroidal abnormal parathyroid glands have been encountered that have imaged correctly. This finding emphasizes the importance of evaluating all nodularity within or associated with the thyroid gland in the event that these abnormal parathyroid glands be located in a "hidden" region either between thyroid nodules or tightly held under the pretracheal fascia representing the "pseudocapsule" over the thyroid gland (Fig. 125-25). More likely, however, is that solid thyroid nodularity with a false-positive sestamibi image is consistent with an adenomatous thyroid nodule, mandating bilateral cervical exploration.

Mediastinal Exploration

Initial exploration or re-exploration for parathyroid disease may require exploration of the mediastinum. Ectopic parathyroid glands located within the mediastinum and below the level of the thymus account for a small percentage (0.2%) of all abnormally located glands.[404] In contrast, Wang[405] and Norton[406] have shown that a more substantial proportion, 18% (Wang[405]) and 20% (Norton[406]), of ectopically located adenomas reside in the mediastinum accessible only through a mediastinal approach. These inferior parathyroid glands are associated in almost all circumstances with the thymus with which they descend during embryonic development, having arisen with the thymus as a third pharyngeal pouch derivative.

Several approaches to the mediastinum are available for exploration. The choice of approach depends on the location of the putative adenoma. Localization studies that, in combination, corroborate

and specify the mediastinal location are required before undertaking exploration. In the experience of most investigators Tc 99m sestamibi imaging together with MRI represents the optimal combination of physiologic and anatomic imaging for localization (Fig. 125-26).

The techniques available for approaching the mediastinum include transcervical substernal with thymectomy using anterior retraction of the sternum for superior mediastinal glands; median sternotomy with direct approach to the anterior middle and caudal mediastinal compartments; posterolateral thoracotomy for selective, posteriorly based glands in the lower mediastinal compartment; and endoscopic, minimally invasive mediastinal dissection for selectively focused exploration.[407] Most glands are approached via a median sternotomy, owing to this technique's capability to address safely numerous areas within the mediastinum and the lower cervical region immediately posterior to the clavicular heads and manubrium. This technique also allows uninterrupted visualization of both recurrent laryngeal nerves, preventing inadvertent injury to these structures within the mediastinum. Surgical adjuncts that may aid in the intraoperative localization of adenomas, and that may be employed after median sternotomy include intraoperative ultrasound and gamma probe after preoperative sestamibi injection.

Gamma Radiation Detection Device

Minimally invasive surgical exploration using a gamma radiation detection device has been developed and advocated by Norman and Chheda[269] to assist actively and expedite initial surgery for parathyroid adenoma (see the section on intraoperative localization).[404] This methodology exploits the nuclear uptake characteristics of parathyroid adenoma with respect to Tc 99m sestamibi, and the ability of the gamma probe to localize these glands in the neck intraoperatively after preoperative sestamibi injection.
